<td>MCO external hydrogen explosion (cont.)</td>
<td>PWC system safety-class components</td>
<td>X Provide isolation valves for pressure boundary connection and fail-closed PWC isolation valves with IA line filters for MCO isolation pressure boundary Provide process piping and flex hoses for pressure boundary connection and isolation of the PWC from MCO</td>
<td>Process water piping connects to the MCO long process tube port and contains process water isolation valves. The isolation function is required when the SCHe is actuated. Flex hoses and piping connect to the isolation valves and become an extended pressure boundary for the MCO such that the SCHe can function.</td>
<td>LCO 3 2 1</td>
</tr>
<tr>
<td>Process bay local exhaust HVAC and process vent system (HVACC/PV system)</td>
<td>X Maintain local exhaust flow sufficient to dilute potentially hydrogen-rich process gas discharges into exhaust duct to preclude flammable mixtures Reestablishes local exhaust flow sufficient to dilute potentially hydrogen-rich process gas discharges into exhaust duct to preclude flammable mixtures within 1 minute after HVACC/PV system loss of flow accident (with standby power interface) Provides hood isolation dampers Provides process hood low flow alarm to control room Mitigates gas cloud release in process bay as a result of a hydrogen explosion discharging into the process bay through HEPA filtration before discharge to outside of the facility With standby power interface, maintain a sufficient process bay DP when the HVACC system is not operable Provides cask venting connection with flow restricting orifice along with shut-off valve interlocked to local exhaust low flow switch</td>
<td>Exhaust flow of 1 000 ft³/min required for cask venting. Low flow alarm set above 1 070 ft³/min. Flow is also maintained during standby operation. SCHe design pressures provide for at least a 1-minute delay prior to discharging into the local exhaust, which must be running to dilute purge flow from MCO The restart function actuates dampers to reopen. The system is required to verify adequate dilution flow is available prior to cask venting. Some airborne contamination, if discharged within a bay as a result of an internal hydrogen explosion, will be swept into the local exhaust system, which includes HEPA filters and collects air from the process bays. The local exhaust in restart mode provides confinement in conjunction with the facility structure by maintaining a negative building pressure without the general exhaust or automatic temperature control operating. The flow restricting orifice is required to keep concentrations below the flammable limit even with 1 000 ft³/min flow in ductwork. Because flammable concentrations would be generated almost instantaneously during cask venting into a stagnant local exhaust duct, interlock of flow alarm to cask venting valve is required.</td>
<td>LCO 3 4 2</td>
<td></td>

<td>Pressure control valve and rupture disk in each tank protect MCO from helium overpressurization from the He bottles.</td>
<td>The SCHe system provides two redundant paths for passively purging and pressurizing the MCO. Each purge system contains helium supplies at high pressure. Pressure control valves are provided along with SC rupture disks on each line from each bottle to ensure bottle pressure cannot be applied to the MCO. Bottle pressure of ~2,500 lb/in² gauge would exceed the 150 lb/in² gauge design pressure of the MCO and breach the confinement boundary. This is prescriptive a SC function to protect the MCO pressure boundary.</td>

*Safety function identifies safety-significant or safety-class function required to prevent or mitigate the specific accident. Safety-class components often perform safety-significant functions.

Summary system description provides overall system discussion. Table B4-2 text provides specific discussions of safety components.

*General-service structure designed and built to performance category 3 criteria provides safety-significant confinement function in conjunction with HEPA filtered exhaust systems.

CVDF = Cold Vacuum Drying Facility
DP = differential pressure
FHIA = fire hazards analysis
GUV = gas operating valve
GS = general service
HEPA = high-efficiency particulate air (filter)
HVAC = heating, ventilation, and air conditioning.
HVACB = process bay recirculation heating, ventilation, and air conditioning.
HVAC/PV = process bay heating, ventilation, and air conditioning and process vent.
HVACD = process general supply heating, ventilation, and air conditioning.
IA = instrument air
LCO = Limiting Condition of Operation.
MCO = mult-carrier overpack.
PLC = programmable logic controller
FWC = process water conditioning.
SC = safety class
SCHE = safety-class helium.
SCIC = safety-class instrumentation and control
SS = safety significant.
TSR = technical safety requirement.
TW = tempered water (auxiliary) system.
VPS = vacuum purge system.

Note: Safety classification of structures systems or components is listed as the highest designation for the specific design basis accident.

1. General service structure designed and built to performance category 3 criteria provides safety significant confinement function in conjunction with HEPA filtered exhaust system.
2. Designed to important to safety Category A for natural phenomena important to safety Category B for confinement functions and important to safety Category C for weather protection and operating environment control.
3. General service structure designed and built to performance category 2 criteria provides safety significant confinement function in conjunction with HEPA filtered exhaust system.
4. Designated as important to safety to prevent inadvertent criticality even though criticality events would not result in public health and safety consequences (e.g., offsite doses) that exceed guideline values.

GS = general service  
HEPA = high-efficiency particulate air (filter)  
HVAC = heating, ventilation, and air conditioning  
MCO = multi-canister overpack  
NRC = U.S. Nuclear Regulatory Commission  
SC = safety class  
SCIC = safety-class instrumentation and control  
SS = safety significant  
VPS = vacuum purge system

Important to safety categories:
- **Category A** Critical to Safe Operation  
  SSCs in this category include those whose failure or malfunction could directly result in a condition adverse to public health and safety.
- **Category B** Major Impact on Safety  
  SSCs in this category include those whose failure or malfunction could indirectly result in a condition adversely affecting collocated worker health and safety. The failure of a Category B item, in conjunction with the failure of an additional item, could result in an unsafe condition. (Note: From the definition of Category C Category B is understood to include events that could significantly damage an MCO without severe impact to collocated worker health and safety.
- **Category C** Minor Impact of Safety  
  SSCs whose failure or malfunction would not significantly reduce MCO effectiveness and would not be likely to create a situation adversely affecting public or collocated worker health and safety.
B4 2 REQUIREMENTS

This section identifies design codes, standards, regulations, and U.S. Department of Energy (DOE) orders that are required for establishing the facility safety basis. The intent is to provide only the requirements that are specific to this chapter and pertinent to the safety basis. Specific codes, standards, and requirements applicable to the CVDF are defined in HNF-SD-SNF-RD-001, *Spent Nuclear Fuel Project Standards/Requirements Identification Document*. Table B4-3 provides a summary table of general standards imposed at the CVDF for safety SSCs. Letter 99-SFD-134, *Approval of Spent Nuclear Fuel (SNF) Project Regulatory Requirement* (Loscoe 1999) provides justification for using ASME B31.3, *Process Piping Code*, with augmented quality requirements, for safety-class process piping and valves rather than using ASME *Boiler and Pressure Vessel Code*, Section III (ASME 1995).

The following DOE orders are applicable to the safety basis for the facility:

- DOE Order 6430 1A, *General Design Criteria*. This order provides general criteria and guidance for facility and system design. Division 1300-3, "Safety-Class Criteria," provides design, fabrication, and testing standards for safety-class items. Compliance with this order is documented in compliance matrices (SNF-4547), which provides a requirement-byrequirement evaluation of the compliance of the CVDF design to DOE Order 6430 1A. The contractor will maintain the design configuration, including compliance to DOE Order 6430 1A, throughout facility operation.

- DOE Order 5480 23, *Nuclear Safety Analysis Reports*. This order sets the requirements for preparing safety analysis reports, and Attachment 1 to the order includes guidance to meet the requirements. DOE-STD-3009-94 supplements DOE Order 5480 23.

- DOE Order 5480 28, *Natural Phenomena Hazards Mitigation*. This order establishes mitigation requirements for natural phenomena hazards and target probabilistic performance goals based on the facility performance category. Additional discussion of the natural phenomena hazard performance criteria is provided in Section B1.5. DOE Order 5480 28 is implemented via WHC-SD-SNF-DB-010, *Cold Vacuum Drying System Natural Phenomena Hazards*.

- DOE Order 5480 22, *Technical Safety Requirements*. This order sets the requirements for the development and preparation of a TSR document, which is prepared separately.

*The Spent Nuclear Fuel Project has justified the use of ASME B31 3 Process Piping Code with augmented quality assurance requirements for the Cold Vacuum Drying Facility safety-class piping and valves (Loscoe 1999)

HVAC = heating ventilation and air conditioning
HEPA = high-efficiency particulate air (filter)
PC = performance category
SS = safety significant
SC = safety class
SSC = structure system or component
UBC = Uniform Building Code
DOE-STD-1020-94 *Natural Phenomena Hazards Design and Evaluation Criteria for Department of Energy Facilities* This standard provides the methodology for design of the CVDF for natural phenomena hazard events and is implemented via WHC-SD-SNF-DB-010

In Letter 95-SFD-167, *Implementation of K Basins Spent Nuclear Fuel Project (SNFP) Regulatory Policy* (Sellers 1995), DOE established the requirement that new SNF Project facilities such as the CVDF achieve "nuclear safety equivalency" to comparable U S Nuclear Regulatory Commission (NRC)-licensed facilities. The SNF Project identified the NRC requirements that were needed in addition to existing and applicable DOE requirements to establish nuclear safety equivalency. These NRC requirements and the process used to identify them are documented in HNF-SD-SNF-DB-003

Applying NRC equivalency requires that SSCs important to safety be identified and a graded approach applied using the definitions in HNF-SD-SNF-DB-003. Important to safety is subdivided into the categories defined in HNF-SD-SNF-DB-003

- **Category A — Critical to Safe Operation**

  SSCs in this category include those whose failure or malfunction could directly result in a condition adverse to public health and safety. Important-to-safety SSCs in this category are classified as safety class, as defined in DOE Order 6430 1A, with the additional requirements therein.

- **Category B — Major Impact on Safety**

  SSCs in this category include those whose failure or malfunction could result in a condition adversely affecting collocated worker health and safety. Note that from the definition of Category C, Category B is understood to include events that could significantly damage the MCO without severe impact to public health and safety. SSCs in this category are classified as safety significant as defined in DOE-STD-3009-94.

- **Category C — Minor Impact on Safety**

  SSCs whose failure or malfunction would not significantly reduce containment and would not be likely to create a situation adversely affecting public or collocated worker health and safety. SSCs in this category are classified as general service (safety-class 3 [nonsafety] in DOE Order 6430 1A).

Additional discussion of the NRC criteria for mitigation of natural phenomena is provided in Section B.12.
Specific natural phenomena hazards design requirements implementing NRC equivalency requirements have been established for the CVDF in WHC-SD-SNF-DB-010

B4.3 SAFETY-CLASS SYSTEMS, STRUCTURES, AND COMPONENTS

Safety-class items are SSCs, including portions of process systems, whose failure could adversely affect the environment or the safety and health of the public. Safety-class SSCs also include the items defined in DOE Order 6430 1A, Division 1300-3. Detailed definitions of safety-class SSCs are provided in Section 3.4.1 of the SNF Project FSAR.

DOE Order 6430 1A identifies several aspects of safety-class SSCs that must be addressed in an enhanced manner. A summary discussion of the requirement and the methodology implemented by the project to impose these requirements in the design is provided below.

- Requirement

Safety-class items shall be subject to appropriately higher quality design, fabrication, and industrial test standards and codes to increase the reliability of the item and to allow credit to be taken for its capabilities in a safety analysis. Safety-class items shall be designed to the ASME Boiler and Pressure Vessel Code, Section III, Class I (ASME 1995), or to other comparable safety-related codes and standards that are appropriate for the system being designed.

- Implementation

HNF-SD-SNF-DRD-002, Cold Vacuum Drying Facility Design Requirements, identifies specific and additional requirements and reference standards and guides to be imposed on the design of safety-class SSCs. These are identified in Tables 5-2 and 6-2 of HNF-SD-SNF-DRD-002 and are listed in Table B4-3. Safety-class items were procured or fabricated to ASME NQA-1, Quality Assurance Program Requirements for Nuclear Facilities, requirements of the SNF Project quality assurance program plan (HNF-SD-SNF-QAPP-004). Safety-class piping was designed and fabricated in accordance with ASME B31.3 with augmented quality assurance requirements. An evaluation was performed to demonstrate that this is a comparable and appropriate code with the enhanced quality requirements (Loscoe 1999).

Single-Failure Criterion and Redundancy

- Requirement

The design shall ensure that a single failure (as defined in DOE Order 6430 1A) does not result in the loss of capability of a safety-class system to accomplish its required...
safety functions. To protect against single failures, the design shall include appropriate redundancy and shall consider diversity to minimize the possibility of concurrent common-mode failures of redundant items.

- Implementation

Safety-class systems have been designed to ensure that a single failure does not result in loss of capability to accomplish its safety function. Analysis to demonstrate final design compliance with IEEE 603-1991, *Criteria for Safety Systems for Nuclear Power Generating Stations*, single-failure criteria was required by HNF-SD-SNF-DRD-002. Single-failure analysis was conducted for all safety-class systems and component functions. This is documented in SNF-4290 *Analysis of Failure Modes and Their Effects on Safety-Class Systems and Components of the Cold Vacuum Drying Facility*. Safety-class SSCs meet the single-failure criterion of DOE Order 6430 1A, as shown in SNF-4290.

**Equipment Environment Considerations**

- Requirement

Safety-class items shall be designed to withstand the effects of, and be compatible with, the environmental conditions associated with operation, maintenance, shutdown, testing, and accidents. The environmental capability of equipment shall be demonstrated by appropriate testing, analysis, and operating experience, or other methods that can be supported by auditable documentation or by a combination of these methods. Equipment qualification shall provide assurance that safety-class items will be capable of performing required safety functions under DBA conditions. The qualification shall demonstrate that the equipment can at least perform for the period of time that its safety functions are required. Environmental temperature, pressure, and humidity shall be based on the most severe postulated accident affecting the particular item.

- Implementation

All safety components were designed to function under worst-case internal and external environmental conditions. These conditions are composed of design basis events and process upset conditions identified in Section 3.5.2 of HNF-SD-SNF-DRD-002, and the associated internal and external environmental conditions listed. Safety detection or protection are provided where the design could not guard against these impacts. The design mitigates conditions that represent a potential common-mode failure, as demonstrated in single-failure analyses.
The CVDF SSCs and their safety function and design criteria, codes and standards, and quality assurance requirements that are required to establish the safety basis of the SSCs are provided in HNF-SD-SNF-SEL-002, *Spent Nuclear Fuel Project Cold Vacuum Drying Facility Safety Equipment List* Environmental qualification of equipment is an important aspect of the safety equipment list. It is important to note that two ranges of environmental conditions have been identified for procurement and performance of the SSCs as follows.

**Condition A**  
60°F at 40% relative humidity (RH), 75°F at 25% RH

**Condition B**  
40°F at 60% RH, 115°F at 22% RH

(Note: The CVDF is a mild environment as defined in IEEE-323-1983 similar to condition A above)

Safety-class SSCs meet the more harsh requirements of condition B. In addition, the process bay temperature sensor is a control to prevent continued processing of the MCO in an environment that could exceed safety-class component temperature limits. If the temperature exceeds the parameter limit of 95°F, the bay monitoring system is designed to trip the safety-class instrumentation and control (SCIC) system relay that isolates the MCO and activates the safety-class helium (SCHe) system.

Seismic qualification criteria for the SSCs is also provided in HNF-SD-SNF-SEL-002, as follows:

**Condition A**  
Maintain critical function during and after a seismic event  
(certification to DOE-STD-1020-94, IEEE 344-1987, or equivalent)

**Condition B**  
Maintain pressure boundary before and after a seismic event  
(certification to DOE-STD-1020-94, IEEE 344-1987, or equivalent)

**Condition C**  
Maintain critical function before, during, and after a seismic event  
(certification to DOE-STD-1020-94, IEEE 344-1987, or equivalent)

**Condition 3/1**  
A general-service, safety-significant, or safety-class component cannot impact a safety-class component during a seismic event  
(certification to WHC-SD-GN-DGS-30006)

Safety-class SSCs cover the full range of seismic conditions depending on the requirements for specific components and equipment. Qualification of the safety-class and safety-significant equipment and components for the CVDF has been accomplished by vendor certification and/or testing. Shaker-table testing has been used to qualify equipment required to maintain operability after a seismic event has occurred.
Bay temperature alarm/interlock and seismic shutdown ensure that SCIC components can perform their safety functions for the period of time required.

- Requirement

Equipment operability qualification testing or a combination of testing and analysis shall be the preferred method of demonstrating the operability of fluid system components, mechanical equipment, instrumentation, and electrical equipment that are required to operate during and following a design basis earthquake (DBE).

- Implementation

The CVDF SCIC performance specification contains prescriptive testing and analysis requirements to demonstrate the operability of the SCIC system and all safety-class components that are required to operate during and after a DBE. These safety-class components are designated as performance category 3 in HNF-SD-SNF-SEL-002. An independent review of the seismic adequacy and testing of the performance category 3 components (safety-class components that are relied upon during and after an earthquake) has been performed by qualified personnel.

Maintenance

- Requirement

The design shall consider the maintainability factors unique to the specific equipment to be used in the facility. Facility design shall provide for routine maintenance, repair, or replacement of equipment subject to failure.

- Implementation

The maintenance philosophy for the CVDF with its short operating life is that if any equipment does fail, it will be replaced rather than repaired. Containment glove-bags will be used for breaking potentially contaminated lines to accomplish confinement of radioactive materials during maintenance. No contaminated maintenance or repair capability is required or provided at the CVDF.

- Requirement

Safety-class items shall be designed to allow inspection, maintenance, and testing to ensure their continued function, readiness for operation, and accuracy.
Implementation

The designs of safety-class systems provide for inspection, testing, and maintenance. Safety-class valves, which include local position indication, are of three-piece construction that provides ease of maintenance and allows for in-place pressure testing at system pressures. Safety-class instrumentation is designed with redundancy test functions, and provisions for calibration. A critical point in the maintenance is that the facility has an anticipated life of two to five years and few failures will occur during that period of operation.

Requirement

The design of all process equipment shall include features to minimize self-contamination of the equipment, piping, and confinement areas. The design of process equipment also shall include features to minimize the spread of contamination out of local areas.

Implementation

The MCO HEPA filter will minimize contamination of the vacuum purge system (VPS) piping, process vent piping, and SCHe vent path piping. Other safety-class components fail safe in a closed position which minimizes spread of contamination. Electrical equipment is not capable of self-contamination.

Testing

Requirement

The design shall include provisions for periodic testing of monitoring, surveillance, and alarm systems. In addition, the design shall provide the capability to test periodically, under simulated emergency conditions, safety-class items that are required to function under emergency conditions.

Implementation

HNF-SD-SNF-DRD-002, Rev 2, Section 5 1 3 describes the testing, surveillance, and maintenance requirements for all equipment, including general-service and safety-class equipment and systems. These requirements will be accomplished at a sufficient level of testing capability. Process upset conditions can be simulated for periodic testing. Trip and test circuits are also provided for system testing.
Annex B — Cold Vacuum Drying Facility

- **Requirement**

  All safety-class systems for which credit is taken in the accident analysis shall be in-place testable in terms of pressure filtration or removal efficiency, alarm capability, leak resistance, and the like. Safety-class items shall be designed to be tested on a regular schedule.

- **Implementation**

  There are no safety-class ventilation features at the CVDF, therefore, ventilation stack monitoring, and HEPA filtration system testability is not applicable, although the capability is provided. Safety-class systems provided to prevent accidents that have the potential for releases that exceed the offsite accidental release criteria established for the SNF Project are tested on regular schedules established in the TSRs.

  The enhanced requirements for safety-class systems identified in DOE Order 6430 1A are specifically imposed on the CVDF design of safety-class SSCs by Section 5.1 of HNF-SD-SNF-DRD-002. Section 5.1 specifically addresses safety functional requirements, testing, surveillance, and maintenance requirements, environmental qualification, seismic qualification, and human factors. Single-failure analysis requirements are imposed for specific systems. Compliance to these requirements is documented in the DOE Compliance Matrices (Williams 1999).

  Safety-class function can be accomplished with safety-class components in safety-significant or general-service systems. Failure of general-service portions of the system results in a failure mode in which safety-class functions of the safety-class components are not required (e.g., a broken general-service helium line results in a condition where the safety-class flow meters are no longer required). The SSCs credited with a safety-class function in Chapter B3.0 and detailed in this section are identified below:

  - SCIC system
  - SCHe system
  - Cask-MCO safety-class components
  - Tempered water (annulus) system safety-class components
  - VPS safety-class components
  - General-service helium system safety-class components
  - Process water conditioning (PWC) system safety-class components

  The safety-class SSCs for the CVDF are described in Sections B4.3.1 through B4.3.7, which provide information about the safety function and the suitability of the safety analysis inputs and assumptions. These SSCs have been identified in Chapters B3.0 and B6.0 as safety class because they prevent or mitigate the potential offsite consequences of the postulated accidents or because they provide features that prevent inadvertent criticality.
Nuclear safety equivalency to comparable NRC-licensed facilities is implemented by compliance with existing and applicable DOE requirements coupled with the additional requirement items documented in HNF-SD-SNF-DB-003 that are applicable to the CVDF. Compliance with the additional HNF-SD-SNF-DB-003 requirements is documented in a compliance matrix (Williams 1999) and summarized in Table B4-4.

**B4 3 1 Safety-Class Instrumentation and Control System**

**B4 3 1 1 Safety Function** The overall safety function of the SCIC system is to protect the MCO from hazardous conditions during process upsets. The SCIC system also responds to key abnormal process parameters by providing signals to isolate the MCO and actuate the SCHe system and/or remove power to the tempered water (annulus) system heater. The SCIC system also responds to signals from the seismic detection system and the process bay high-temperature sensors by isolating the MCO and actuating the SCHe system. These responses are intended to cause actions that will prevent or mitigate a wide range of potential accidents, including the MCO overpressurization, thermal runaway reaction, and internal and external hydrogen explosion accident scenarios described in Chapter B3 0.

The SCIC system performs the following safety functions for these accidents:

- **MCO overpressurization accident** — Process parameter upsets characteristic of an MCO overpressurization are detected by the SCIC system, which responds by isolating the MCO from the process systems and actuating the SCHe system, which vents the MCO. A seismic event and/or a high process bay temperature initiates an SCIC system trip that isolates the MCO and actuates the SCHe system, thereby pressurizing and purging the MCO. The tempered water heater will be de-energized by the SCIC system. An annulus water high temperature trip will de-energize the tempered water heater. The SCIC system alarms in the control room on detection of a low annulus water level and initiates operator response.

- **Thermal runaway reaction** — The SCIC system responds to process parameter upsets (e.g., high annulus water inlet temperature, exceeding time under vacuum, and low annulus water level) that are indicative of upset conditions that may lead to a thermal runaway accident. For some process upsets, the SCIC system provides signals to isolate the MCO from the process systems and actuate the SCHe system to pressurize and purge the MCO. A seismic event or high temperature in a process bay will initiate SCIC system trips that actuate MCO isolation and activate the SCHe system. The high annulus water temperature trip will de-energize the tempered water heater. The SCIC system alarms on a low annulus water level in the control room, which requires operator action in the bay to stop the leak and to restore water to the annulus.

DOE = US Department of Energy  
FSAR = final safety analysis report  
HEPA = high-efficiency particulate air (filter)  
I&C = instrumentation and control  
NRC = US Nuclear Regulatory Commission  
QA = quality assurance  
SNF = spent nuclear fuel
Internal hydrogen explosion — The SCIC system responds to process parameter upsets that could be indicative of excessive hydrogen inside the MCO or a line break that would allow the ingress of air. If selected process parameters are found to be outside limits, the SCIC system actuates the SCHe system, which is designed to maintain the hydrogen and oxygen concentration inside the MCO below the lower flammability limit. The SCIC system also detects high process bay temperatures and seismic events that could impair the system and responds by isolating the MCO and activating the SCHe system. A high water temperature in the tempered water (annulus) system results in shutting off power to the tempered water (annulus) system heater. The tempered water (annulus) low water level is monitored to sound an alarm for operator response.

External hydrogen explosion — The SCIC process bay high temperature detection is credited to protect assumptions of the fire hazards analysis for preventing damage to safety-class equipment components in the process bay. TSR response to an ISO & PURGE alarm requires that process bay temperature be verified and high temperature returned to the acceptable range to protect the temperature assumptions used in with the fire hazards analysis combustible loading limits in the process bays.

The SCIC system is designated safety-class because of its role in preventing the occurrence of the MCO thermal runaway and MCO overpressurization accidents, which, unmitigated, would exceed offsite release limits. The SCIC system also plays a role in preventing the internal hydrogen explosion accident, which has unmitigated consequences that exceed onsite risk acceptance guidelines but do not exceed offsite release limits. The SCIC system performs a safety-significant function for prevention of this accident.

**B4 3 1 2 System Description** The SCIC system is a dedicated safety-class system whose function is to aid in the prevention of the thermal runaway, MCO overpressurization, and MCO internal explosion events by responding to abnormal conditions and actuating one or more safety-class systems or alarms. The SCIC system monitors specific cold vacuum drying process parameters for each process step, seismic condition, and process bay temperature. The system responds to anomalies that, if undetected, could result in an accident condition.

Two SCIC panels (instrument racks) are located in each process bay. One of the two panels contains a programmable logic controller (PLC) that provides one of the two logic trains for that bay. The other PLC for that bay is located in the adjacent bay. Figure B2-27 shows the layout of the SCIC system in each bay and in the control room. Redundant instruments and control functions are provided to the two SCIC logic trains, A and B. The PLC performs the various setpoint comparisons and provides safety-related timing functions (see Figure B2-26 for a summary of the SCIC system functional circuitry). Included in this logic is a vacuum limit timer that monitors the time under vacuum to limit heatup of the fuel. Vacuum conditions reduce thermal conduction from the MCO. After the vacuum cycle, a minimum time at or slightly above atmospheric pressure is required to cool down the fuel. The SCIC system ensures that exceeding the time under vacuum, or returning to vacuum without first meeting the minimum time above...
atmospheric pressure, will result in an MCO ISO & PURGE trip (i.e., the MCO is isolated by closure of the VPS, general-service helium system, PWC system, and deionized water isolation valves and the SCHe system is activated).

Physical and electrical separation is achieved in accordance with Institute of Electrical and Electronics Engineers requirements. Each process bay has instrument racks with SCIC instrument panels for monitoring and control of trains A and B for that process bay. The panels provide the following capabilities in each bay:

- A local manual ISO & PURGE button that isolates the MCO and activates the SCHe system. Activation of either the train A or the train B ISO & PURGE push button will initiate a trip that will close one set of safety-class MCO isolation valves to sufficiently isolate the MCO and will activate the SCHe system. Both ISO & PURGE buttons must be activated to provide MCO isolation by both safety-class valves in each process system line.

- ISO & PURGE trip reset button

- Tempered water high temperature trip reset button

- Trip status and indicator lights for bay ISO & PURGE trip, tempered water high temperature trip, seismic trip, process bay high temperature trip, and cask annulus low level alarm status

- Logic test switches

In a similar manner, the CVDF control room has SCIC system train A and B control room panels for each bay with the following capabilities:

- SCIC mode selection panel with duplicate key switches for the following operation sequence selections: (1) BYPASS, (2) HEATUP, (3) DRAIN, (4) PURGE/FLUSH, (5) DRYING, (6) PROOF, and (7) PRESSURE TEST. The two panels in the control room have key switches for all operations in process bays 2, 3, 4, and 5.

- An annunciator and control panel with large lighted alarms for BAY ISO & PURGE, ANNULUS LOW LEVEL and PWC LOW FLOW, alarm test capability, alarm acknowledgment, and annulus low level alarm bypass switches, and ISO & PURGE buttons for MCO isolation and activation of the SCHe system for each of the process bays.

During cold vacuum drying of an MCO, the SCIC system is placed into the mode appropriate for each processing stage, as shown in Figure B2-11. When the MCO is first received, the SCIC system is in the BYPASS mode while the cask headspace is being vented, the cask lid is being removed, the process hood seal ring assembly is being bolted on, and the two
sealing bladders are being inflated. The SCIC system is switched to the HEATUP mode after the port connectors are attached during heatup the MCO headspace is vented. When water is to be removed from the MCO, the SCIC system switch is placed in the DRAIN mode. After MCO draining is complete, the SCIC system switch is positioned in the PURGE/FLUSH mode to flush particulate from the drain line. When the MCO is to be evacuated for vacuum drying, the SCIC system switch is placed in the DRYING mode, and when the drying is completed and proof verification is to be performed, the mode switch is placed in the PROOF position. After proof checking, the SCIC system switch is placed in the PRESSURE TEST mode for the final 1-hour pressure rebound test. As a final step, the MCO port valves are closed and the MCO is prepared for shipment. During this period, the SCIC system is placed in the BYPASS mode. Each of these modes enables the SCIC system to monitor setpoints from the different sensors and make available appropriate logic circuitry for each specific processing step. Sensors located in the process systems that are connected to the SCIC system are shown in Figure B4-1. These sensors provide the following input to the SCIC system:

- MCO pressure, from the VPS (pressure transmitters with a range of 0 to 100 torr and pressure transmitters with a range of -14.7 lb/in² gauge to +12 lb/in² gauge)
- Helium purge flow rate, from the general-service helium system (flow-indicating transmitters)
- Tempered water high temperature switch, from the tempered water (annulus) system
- Cask-MCO annulus water low-level switch from the tempered water (annulus) system
- Process bay temperature switch
- Seismic recorder and trip status, integral to the SCIC system

The seismic monitors will activate the SCIC system trip independent of the logic circuits (see Figure B2-26). The seismic monitors directly trip to the SCIC system output relays, which actuate the SCH system and MCO isolation valves. A seismic event will also trip the tempered water high temperature protection circuit that shuts down the tempered water heater. In addition, the seismic trip will shut down power to the PWC system circulation pumps. Loss of electrical power will de-energize the SCIC system output relay, which will isolate the MCO, actuate the SCH system and eliminate power to the tempered water (annulus) system heater and the PWC system circulation pumps.

The SCIC system also provides safety-class alarms in the control room. The SCIC system monitors the tempered water (annulus) system low-level switch and activates an alarm that notifies the operators when the water level in the cask-MCO annulus is low. Refer to SNF-3091, SNF Project Cold Vacuum Drying Facility Safety-Class Instrument and Control System Design Description for more detailed information.
B4 3 1 3 Functional Requirements  The functional requirements needed for the SCIC system to perform its safety functions are as follows:

- **Operations and Mode Selection** — To be operational before the VPS connectors are attached to the MCO ports and then placed in the proper mode as each process step is performed.

- **Monitoring and Logic** — Monitor the input signals from the VPS pressure-transmitters and general-service helium safety-class flow meters, and perform logic and timing functions necessary to ensure that hydrogen and/or oxygen is not accumulating in the MCO. If logic or timing function parameters indicate conditions wherein hydrogen and/or oxygen could be accumulating beyond acceptable limits, the SCIC system must be capable of automatically initiating an ISO & PURGE trip. This action will bring the MCO to slightly above atmospheric pressure, prevent further ingress of air, and provide the MCO internal heat transfer medium (helium) for enhanced heat transfer to the tempered water (annulus) system.

- **Annulus Low Water Level Alarm** — Monitor the tempered water (annulus) system annulus water low level switch and provide an alarm to the operators if the level falls below the lower limit.

- **Tempered Water High Temperature Trip** — Monitor the tempered water (annulus) system annulus inlet water temperature switch and de-energize electrical power to the tempered water (annulus) system heater, if the temperature is above the setpoint limit.

- **Process Upset Conditions** — Automatically initiate an ISO & PURGE trip under process upset conditions, including loss of power.

- **Control Room Alarms** — Provide safety-class alarms for BAY ISO & PURGE ANNULUS LOW LEVEL, and the non-safety PWC LOW FLOW alarm to the CVDF control room.

- **Seismic Safe Shutdown** — To be capable of receiving signals from the seismic recorder and trip component, and, upon ground motion acceleration above the setpoint, automatically activating MCO isolation and SCHe system activation. In addition, provide shutdown of power to the tempered water (annulus) system heater.

- **High Bay Temperature** — Monitor the process bay temperature. Initiate SCIC trip, isolate the MCO, and purge via the SCHe system if the bay air temperature exceeds the setpoint.
**Nonqualified Signal Protection** — Provide protection from any nonsafety operational controls (e.g., coming from the monitoring and control system [MCS]) that could affect or degrade the safety-class operation of the SCIC system.

**Sensor Error** — Account for sensor error in trip setpoints so that operations are within specifications; process function monitoring does not lead to unsafe conditions and safe shutdown is accomplished as anticipated.

**Testing Functions** — Capable of providing periodic testing of the SCIC system functional operations.

**Seismic Qualification** — Meet performance category 3 seismic requirements for all process bay SCIC equipment.

### B4.3.1.4 System Evaluation
The SCIC systems are designed to be redundant and fail-safe. The SCIC systems identified are tied to key process parameter sensors, which when taken as a whole provide comprehensive and complete detection and response to the upset conditions identified in the accident analyses in Chapter B3.0. The systems also are designed such that internal system failures actuate the safety SSCs to which they are interlocked. This automatic actuation upon failure ensures that loss of monitoring of a key parameter does not degrade the safety function of the SCIC system.

The SCIC system provides automatic and independent active detection and response to process anomalies that, if unmitigated, would result in a safety-class or safety-significant event. To perform these functions, the SCIC system monitors process parameters, detects abnormal conditions, and actuates an ISO & PURGE or turns off power to the tempered water heater. Operator response is required if these tempered water (annulus) or PWC system components are de-activated. In addition, when required, the SCIC system provides safety-class alarms to the CVDF control room for those events that require operator actions. The SCIC system is independent of the MCS system, and the only operator function during normal operations is to control the position of the mode selector switch, including blowdown of the SCHe lines after MCO draining (the SCIC system operates the SCHe valves for 2 minutes to blowdown the system lines with helium from the general-service helium supply, when the SCIC system switch is in the PURGE/FLUSH mode), and to test the annunciator.

For the PWC system, the SCIC system provides an annunciator alarm (non-safety) unless the PWC system has been purged since entering the DRAIN mode. The alarm remains locked until the mode switch is placed in any other position than DRAIN. When the SCIC system is switched to the PURGE/FLUSH mode, an alarm will be activated after entering this mode unless the PWC system has been purged sufficiently with helium. There is about a 19-minute delay when...
the PURGE/FLUSH mode is entered, to allow for a deionized water rinse and an allowance for
flow responses that is taken into account by the PWC purge timing

Manual operation trip push buttons are provided to activate an MCO isolation and purge
from either the control room (safety-class annunciator and mode panel) or the respective bays.
The bay push buttons provide a qualified manual initiation button under all accident conditions,
however, there are no known reasons for the need for operator action to protect the MCO. The
control room manual trips are provided for nonspecific accidents or upset conditions that may
warrant a trip. Examples include control room evacuation, fire in the facility, or a loss of normal
process control. Although none of the manual trips are required to maintain the MCO in a safe
condition, operational procedures may warrant a trip. The CVDF control room and
the corresponding safety-class annunciator and mode switch panel within the control room are not
seismically qualified, as these functions are not required during a seismic event. The MCO is
protected by the safety-class seismic detection and trip function.

Operations and Mode Selection Limiting conditions for operation (see
Section B4 3 1 5) require that the SCIC system be operational before the process port
connections are made to the MCO. The mode selector switch enables or disables the interlocks,
provides selected mode status to the PLCs for enabling or disabling the protection logic, passes all
mode position status to the nonsafety MCS for process operations, and operates selected SCHe
valves to purge the SCHe piping. Table B4-5 summarizes which trips and interlocks are active
during the different mode switch positions.

Monitoring and Logic During receipt and prior to bulk MCO water drain, the thermal
runaway accident is not possible because the fuel is covered with water. An internal hydrogen
explosion will have no onsite or offsite consequence above the guidelines because no particulate is
available for release. Each of the PLC trips that are active in the various mode switch positions
are discussed in more detail in the following subsections (see Table B4-5)

To ensure safe conditions during the SCIC DRYING and PROOF modes, the MCO low
pressure purge trip remains active and additional PLC trips are activated as discussed below:

- MCO Low Pressure — After draining, when the SCIC system is in the DRAIN and
PURGE/FLUSH modes, an MCO low pressure purge trip is active and actuates the
ISO & PURGE if the general-service helium purge pressure falls below the
parameter limit of 0.24 lb/in² gauge (0.5 lb/in² gauge setpoint). This nominal
pressure parameter indicates that the MCO is pressurized with helium above
atmospheric pressure, which precludes air ingress under accident conditions. This is
discussed in SNF-4451, Cold Vacuum Drying (CVD) Set Point Determination. This
action ensures that a positive pressure is maintained in the MCO to preclude fuel
heating as a result of low thermal conductivity from operation at vacuum and
precludes further air ingress into the MCO in the event of a line break or other
accident scenario.

*Non safety (not safety class or safety significant)*

Notes
1. All PLCs have an associated PLC fault trip built into the PLC logic
2. TW annulus low level is bypassed by operations when there is no MCO or when the annulus is drained for shipment.
3. During the PURGE/FLUSH mode the SCHε valves (SCHε-GOV 5*12 and 5*31) on the long process tube side are opened for 2 minutes (de-energized by the SCIC) to blow down any water that may have collected from the drain sequence

MCO = multi-canister overpack
PLC = programmable logic controller
PWC = process water conditioning
SCHε = safety-class helium
SCIC = safety-class instrumentation and control
TW = tempered water
MCO Prepurge — The MCO prepurge trip will detect a low purge flow rate or inadequate time of purge prior to pulling a vacuum in the MCO. The MCO low pressure trip is active and the MCO prepurge bypasses this trip only if the MCO has been prepurged with helium at a flow rate of >80 standard ft³/min for about 15 minutes. This trip ensures that the gas in the MCO is below the lower flammability limit for hydrogen prior to going to vacuum, which could introduce oxygen if an undetected air leak is present. Throughout the DRYING and PROOF modes, the MCO is cycled between pressure and vacuum, which requires hydrogen to be maintained at low concentrations when entering vacuum. This requirement is accomplished with the MCO prepurge, as indicated above.

MCO Low Purge Flow MCO Low Purge Flow Bypass, and MCO 12-torr Purge Bypass — The MCO low purge flow trip monitors the general-service helium supply flow and will trip and activate an ISO & PURGE if the general-service flow is below the parameter limit of 0.7 standard ft³/min (standard temperature defined as 68 °F) when above 12 torr and after a 5-minute delay. These trips are active in the DRYING and PROOF modes. The 0.7 standard ft³/min flow rate ensures hydrogen concentrations less than 8.7% in helium gas so that flammable conditions would be precluded, if an air ingress event were to occur.

The lowest vacuum level that can be reached with helium purge active is approximately 50 to 70 torr. The MCO low purge flow bypass allows for a 5-minute period with no helium flow, which is a process requirement so that a 12 torr vacuum can be reached. At a vacuum of 12 torr, the hydrogen is below the amount capable of supporting combustion and no helium purge is required. Helium flow is stopped, which allows the vacuum pump to bring the MCO pressure below the 12-torr parameter limit. If a leak occurs when the 5-minute timer is activated, the vacuum pump is still operational, and after 5 minutes an ISO & PURGE will be activated. The MCO 12-torr purge bypass trip logic is based on the vacuum reaching <12 torr safety parameter for 10 seconds and staying <12 torr thereafter. On return above 12 torr, there is a 2-minute delay to allow the MCO low purge to reset as flow is reestablished.

MCO Pressure Decay Fail — During the transition from pressure operation to vacuum, the MCO pressure decay fail trip is activated to ensure there are no line breaks that would allow continuous air cycling and to detect a degraded vacuum pump, both of which could allow fuel heating beyond limits. This trip also provides a method of detecting a line break in the helium line (downstream of the flowmeters) that would invalidate the safety-class indication from the flowmeters.

MCO Pressure Rise Fail — Similar to the MCO pressure rise decay trip, the MCO pressure must exceed the parameter limit of 0.24 lb/in² gauge from a starting point parameter limit of -10.8 lb/in² gauge in 5 minutes or an ISO & PURGE activation will occur. This again ensures that helium flow is provided through the MCO to...
preclude developing flammable gas mixtures. Calculations that support the use of 5 minutes for the timing period are listed in SNF-4301, *Gas Composition Transients in the Cold Vacuum Drying Facility*. The 5-minute trip will identify a defective vacuum pump that precludes operating under conditions where a degraded vacuum would be insufficient to remove hydrogen generated in the MCO.

- **MCO Vacuum Limit Timer (8- or 4-Hour)** — A vacuum limit timer trip will limit the time the MCO is under vacuum, defined as being less than 0 lb/in² gauge parameter limit. This requirement ensures internal MCO temperatures stay within parameters by limiting time under vacuum, which would reduce thermal conductivity. The 4 hours at pressure will equalize the internal MCO temperatures. A limit of 8 hours for the initial vacuum cycle and 4 hours for subsequent cycles is provided. Based on thermal analysis, the 4 hours at pressure does not cool the fuel to its pre-vacuum starting temperature, and the 4 hours under vacuum is the maximum time allowed for all subsequent cycles. The MCO must be returned to pressure for 4 hours between vacuum cycles. Calculations supporting the 8-4-4 cycle requirements are provided in SNF-4301. Exceeding the 8-4-4 cycle requirements will initiate an MCO ISO & PURGE, thereby activating the SCHe system.

When the SCIC system is in PROOF mode, all of the above logic and trips are active except for the vacuum limit timer, which is not required because there is insufficient water for a thermal runaway condition caused by being under vacuum.

Once the MCO has completed the PROOF mode, it must undergo a final 1-hour rebound test to ensure the water content in the MCO is within specifications. In this case, the SCIC system is switched to the PRESSURE TEST mode. The VPS valves are isolated (interlocked closed) to ensure no possibility of water addition at the conclusion of the final pressure rebound test. During the pressure test, the MCO pressure rise fail trip is active to guard against any possible line break or leak situation because other trips cannot be used with the VPS valves closed.

- **MCO High Pressure** — An MCO high pressure trip is active in DRAIN PURGE/FLUSH, DRYING, and PROOF modes to preclude challenging the 30 lb/in² gauge rupture disk because of an improper isolation of the MCO without a normal or SCHe vent path being available. This trip provides protection against MCO overpressurization and provides defense-in-depth against the thermal runaway reaction accident. An MCO ISO & PURGE will be activated by the SCIC system if pressure in the MCO exceeds 12 lb/in² gauge (protects the parameter limit of <25 lb/in² gauge shown in Table B4-6 and is based on limit of instrumentation). The instrument upper range is +12 lb/in² gauge.

Notes:
1. Time functions are not prone to errors in setpoint, therefore no error is applied. The parameter and the SCIC setpoint are equal.
2. Bay annulus water level gauge and level switch are at least 1 ft above the level of the fuel and therefore the level setpoint is well above the required safety limit.

*SNN-4451 1999 Cold Vacuum Drying (CVD) Set Point Determination Rev 0 Fluor Daniel Hanford, Incorporated, Richland Washington

MCO = multi-canister overpack
N/A = not applicable
SCIC = safety-class instrumentation and control
standard ft³/min = 68 °F and 1 atm
TW = tempered water
8-4-4 = 8 hour initial vacuum cycle 4 hour subsequent vacuum cycles 4 hour return to pressure between vacuum cycles
Annulus Low Water Level Alarm  The tempered water (annulus) system low level switch provides protection from a thermal runaway reaction by alerting the control room operators to situations where an annulus water leak has occurred. The low level switch trips the CVDF control room alarm and operators must acknowledge the alarm and initiate response.

Tempered Water High Temperature Trip  The tempered water high temperature switch trip provides protection from a thermal runaway reaction by limiting the heat from the tempered water (annulus) system. This is done by tripping the tempered water heater if the tempered water exceeds the 50 °C parameter limit. The temperature limit is based on the parameters used for the thermal calculation for the thermal runaway accident (see Section B3.4.2.5). The SCIC system precludes adding excessive heat into the MCO to protect the assumptions of the thermal calculation, which used 50 °C as the upper water temperature value. Thermal inertia and water flow rates in the tempered water (annulus) system may result in the tempered water temperature exceeding 50 °C for short periods of time after an SCIC tempered water high temperature trip. This does not violate the safety function of this parameter limit provided the heater is de-energized when temperature exceeds 50 °C. This system is mode independent and is active throughout the MCO processes.

Process Upset and Accident Conditions  Both loss of electrical power and a seismic event are common mode failures that must be precluded from affecting the safety function of the SCIC. To meet this requirement, the design of the SCIC system ensures activation of an MCO ISO & PURGE or trip of the tempered water heater under process upset conditions (see Figure B2-27). Included in this protection are loss of electrical power and a seismic event that activate the relays for MCO ISO & PURGE and shutdown of the tempered water (annulus) system heater.

An excessive bay temperature also has the potential for adversely affecting the SCIC safety function. To preclude this situation, a high bay temperature trip is provided to initiate an MCO ISO & PURGE when the room temperature exceeds the parameter limit of 95 °F. The principle component that is affected by temperature is the MCO vacuum pressure transmitter calibration. Other components meet or exceed the maximum room temperature criterion of 115 °F.

Control Room Alarms  The SCIC system contains safety-class redundant annunciators that provide alarms for BAY ISO & PURGE, ANNULUS LOW LEVEL and PWC LOW FLOW. Activation of the ANNULUS LOW LEVEL or the PWC LOW FLOW alarms alerts the operator that corrective action is required. Although included on the safety-class annunciator, the PWC LOW FLOW alarm is not required for safe operation of the facility.

Seismic Safe Shutdown  The seismic trip is designed to detect a seismic event, isolate the MCO and actuate the SCHe system. In addition, a seismic event will shut off power to the tempered water (annulus) system heater. The parameter limit of 0.06 g was selected to ensure a seismic trip well in advance of a seismic event of significant magnitude to damage piping or equipment that is not part of the extended primary MCO boundary. The parameter level is at a point where most people would feel the effect but no damage would occur and is ~20% of the...
DBE level of 0.26 g. Two methods are used to preclude fault trips by the seismic monitoring equipment. First, the three sensors (each are triaxial) are located in three different process bays (2, 3, and 4), which precludes vibrations in one bay from tripping all three sensors. Second, each auctioneering logic circuit requires two of the three sensors to be in alarm to initiate a trip of each train. The seismic shutdown system is designed to performance category 3 criteria.

The accident analysis identified that a DBE could damage safety-class systems or components. Some components may not be operable after a seismic event to meet their safety function. To eliminate the need for seismic qualification, the seismic trip will perform the safety function (i.e., trip the MCO ISO & PURGE and de-energize the tempered water heater).

High Bay Temperature. High bay temperature sensor activation occurs when the mode selector switch is moved to the HEATUP position and continues throughout the remainder of the process. The process bay temperature monitoring system is designed to trip the SCIC system relay and activate an ISO & PURGE, if the bay temperature exceeds the parameter value. Design analysis identified the possibility that elevated temperatures in the process bay could result in instrumentation and control inaccuracy and malfunctions that could affect the function of safety-class systems. The bay temperature trip serves to mitigate temperature impacts on the two vacuum pressure transmitters PT1*08 and PT1*10. These devices have a calibration limit of 105 °F. In addition, to support assumptions in the fire hazard analysis related to combustible loading limitations, a maximum bay temperature of 95 °F was utilized to calculate safety-class instrumentation temperature protection from localized fires. Thus, an SCIC trip is initiated if bay temperatures exceed a 95 °F parameter limit. This parameter limit also protects the upper accident environmental temperature limit of 115 °F.

Nonqualified Signal Protection. The SCIC system provides non-safety class signals to the facility MCS for normal control, indication, and alarms. The signals from the SCIC system include all analog signals (flow and pressure), SCIC internal logic status, and trip and alarm contact status. All signals from the SCIC system are electrically isolated from any nonsafety system, including the MCS.

Sensor Error. Analysis has been performed for all sensors associated with functional operation of the SCIC system trip setpoints to allow for instrument error (see SNF-3091). Trip setpoints shown in Table B4-6 ensure critical parameters will not be exceeded for all functional requirements. For all analog signals coming from pressure and flow, an average of the signal is performed to remove instrument spikes that may occur.

Testing Functions. The local operating panels in each process bay provide test switches to perform operational tests on the following SCIC functions: tempered water (annulus) system high temperature trip, bay high temperature trip, and tempered water (annulus) low-level alarm. The test is enabled by a key switch on the panel. Once enabled, a trip can be simulated by pressing the appropriate test button. The bay high temperature test will isolate the MCO and start an SCHe system purge, the tempered water high temperature trip test will de-energize the tempered water heater, and the tempered water (annulus) low-level alarm will active the
safety-class annunciation in the control room. Testing associated with MCO isolation and SCHe system purge is normally conducted by using a jumper, located on the process hood support stand to provide a pathway between the process port connectors.

Other functional tests or calibrations require the use of a SCIC calibration and test computer unit that tests logic functions and allows for detailed calibration functions. The calibration and test computer is part of the SCIC system but is not normally connected to the SCIC PLC.

**Single-Failure Evaluation** The SCIC system has been designed to be single-failure proof and provides redundancy for all sensors and control modules. Single-failure analysis for the SCIC system logic controller was performed as a procurement requirement by the vendor. Single-failure analysis of the SCIC system has been performed and is documented in SNF-4290. Responses to an event are unchanged by failure of any one component due to the independent action of the second SCIC system instrumentation.

**Seismic Qualification** The whole of the SCIC system plus the sensors that provide input to the SCIC and output devices from the SCIC (valves and tempered water contactors), is seismically qualified with the following exceptions: The control room annunciator and mode control panels are not required to be qualified because these signals are protected from a seismic event by the seismic shutdown circuits. The design of the SCIC system eliminates any need for operator response to protect the MCO content against a seismic event. The loss of the annunciator after a seismic event strong enough to fail items in the control room will be obvious to the operator or to the site response team.

The SCIC system seismic trip setpoint and parameter limit are shown in Table B4-6. Process sensors (pressure and flow) are not seismically qualified for operability (only pressure boundary as required) because the seismic monitoring trip will satisfy the safety function after a seismic event. Seismically qualified local indication is provided for accident recovery monitoring. These components are not part of the SCIC system.

Engineering calculations demonstrating the adequacy of the performance category 3 SCIC system are listed in SNF-3001, *Cold Vacuum Drying Facility Supporting Data and Calculation Database*. In addition, the seismic trip portion of the SCIC system will place the MCO process system in a safe-shutdown mode if a major seismic event occurs. All active SCIC equipment that is required to maintain functional operability during and after a seismic event has been seismically qualified by shake-table testing. The safety-class cabinets are bolted to the process bay floor to meet performance category 3 seismic requirements.

**B4 3 1 5 Controls (Technical Safety Requirements)** The following assumptions associated with the SCIC system require TSRs to ensure performance of its safety functions:

- The SCIC system is operational before the MCO process port connections are made.
The other systems that provide signal input to the SCIC system (i.e., pressure transmitters, flow-indicating transmitters, tempered water high temperature switches, cask-MCO annulus water low-level switches, process bay temperature switches, and seismic trips) are operational.

- The seismic trip component is operational when an MCO is being processed.
- The process bay temperature monitor in a process bay is operational when an MCO is being processed in that bay.
- Standard calibrations of the SCIC system and functional testing of each SCIC train for ISO & PURGE trip shall be performed at periodic intervals (see setpoints in Table B4-6).

### B4.3.2 Safety-Class Helium System

**B4.3.2.1 Safety Function** The overall safety function of the SCHe system is to preclude accumulation of flammable concentrations of hydrogen and oxygen within the MCO, and to provide heat transfer within the MCO and a pressure vent pathway to the local exhaust system. The accident analyses presented in Chapter B3.0 identify four specific event scenarios in which the SCHe system is credited: thermal runaway reaction, MCO overpressurization, internal hydrogen explosion, and external hydrogen explosion.

The SCHe system performs the following safety functions for these accidents:

- **MCO overpressurization** — Upon actuation by the SCIC system or by manual operator action, the SCHe system provides a pressure-regulated discharge flow path from the MCO to the local exhaust system. In addition, the SCHe supply system pressure control valve and rupture disk in each SCHe system train protects the MCO from helium overpressurization by eliminating the possibility that the helium bottle pressure could be applied directly to the SCHe system lines.

- **Thermal runaway reaction** — When actuated by the SCIC system or by manual operator action, the SCHe system repressurizes the MCO to provide enhanced cooling of the fuel and thereby reduce the reaction heating effects during a thermal runaway reaction accident. The SCHe system also provides a pressure vent path to the local exhaust system for the helium purge of hydrogen produced in the MCO to ensure heat transfer capability within the MCO. The SCHe system, in conjunction with operation of the safety-class tempered water (annulus) system, are key systems for placing the MCO in a stable condition following a process upset.
- Internal hydrogen explosion — When actuated by the SCIC system or by manual operator action, the SCHe system pressurizes and purges the MCO to prevent the formation of flammable or explosive concentrations of hydrogen and oxygen inside the MCO. Pressurizing the MCO also prevents air ingress.

- External hydrogen explosion — When actuated by the SCIC system or by manual operator action, the SCHe system provides a pressure-regulated discharge flow path from the MCO to the local exhaust system, with backflow prevention to preclude flammable mixtures within the SCHe vent lines. The discharge flow path from the MCO to the local exhaust system is delayed more than one minute from SCHe actuation to allow standby power startup of the local exhaust fans if normal power is not available.

The SCHe system is designated a safety-class system because the unmitigated consequences of the thermal runaway reaction and the MCO overpressurization accidents could exceed offsite release limits. The hydrogen explosion accident scenarios that the SCHe system is credited with mitigating or preventing have consequences that exceed onsite risk evaluation guidelines but do not exceed offsite release limits. The SCHe system is credited with a safety-significant function for those accidents.

**B4 3 2 2 System Description** The SCHe system is a dedicated safety system that has no direct processing functions. The SCHe system is controlled and powered by the SCIC system. The SCHe system is automatically actuated by (1) loss of electrical or pneumatic power to its fail-open isolation valves or (2) the SCIC system in response to predetermined process setpoint deviations, excessive process bay temperature, or a seismic event. There are independent and identical SCHe systems for each processing bay at the CVDF. The piping and component configurations for the SCHe system are described in the composite CVDF engineering flow diagram shown in Figure B2-17 and in SNF-3068 *SNF Project Cold Vacuum Drying Facility Safety Class Helium System Design Description*.

The SCHe system for each process bay consists of four separate SCHe trains (purge A, purge B, purge C, and purge D). Each train consists of helium supplies, a rupture disk, pressure control valves, and fail-open electropneumatically operated isolation valves with associated piping and instrumentation. Purges A and B are configured identically and Purges C and D are configured identically. Both system pairs operate in parallel. Purges A and B are connected to the MCO inlet (long process tube) valve through the process hood and flexible tubing. Purges C and D connect to the filtered process exit port (port 2, which is HEPA-filtered) valve but are configured differently from purges A and B by being connected to the process vent system through pressure control valves. The two purge systems are mounted on individual panels and located back-to-back (e.g., purge A and purge C are mounted on individual panels and located back-to-back). The other two purge systems (purge B and purge D) are mounted in a similar manner. Panels and helium bottles for parallel systems are physically separated by mounting them to the east and west of the process equipment skid (PES), as shown in Figure B2-21. The SCHe bottles are mounted at each panel, and the SCHe purge systems have cage protection. The panels
that contain the valves, piping, and instrumentation are mounted above the helium bottles and are welded to the panel support structure.

The SCHe system uses two independent helium sources. Each SCHe train (A, B, C, and D) receives helium from the general-service helium supply (tube trailers) and from its dedicated SCHe bottles. The SCHe bottles are 15 ft³ compressed gas cylinders with a full capacity of 244 standard ft³ of helium at 2,480 lb/in² gauge. Pressure settings for the SCHe and general-service helium lines that connect to the MCO long axial process tube connectors are different than the pressure settings for the SCHe and general-service helium lines that are connected to the MCO filtered process exit port connectors. For each train (A, B, C, and D), the pressure regulator for the general-service helium is set higher than the regulator for the SCHe system bottles. This pressure differential allows helium to preferentially flow from the normal general-service helium process supply as long as its pressure remains above the pressure regulator setpoint for the SCHe bottles. When the general-service helium supply becomes exhausted or interrupted, helium is then provided to the system from the SCHe bottles. A minimum 30 minutes of purge volume is provided by the SCHe system bottles to purge the MCO. After this time, the MCO remains pressurized to preclude air leakages.

The general-service helium pressure in purge trains A and B is set at 15 lb/in² gauge (14 lb/in² gauge when supplied by the SCHe bottles), while the general-service helium pressure in purges C and D is set at 3 lb/in² gauge (2 lb/in² gauge when supplied by the SCHe bottles). Purges C and D are also connected to the process vent system through two pressure control valves in series set at 10 lb/in² gauge. These pressure differentials allow the general-service helium to preferentially flow from the 15 lb/in² gauge purges A and B through the MCO inlet, down the long axial process tube, upward past the fuel baskets, out through the HEPA-filtered exit, into purges C and D, and out into the process vent system through the 10 lb/in² gauge pressure control valves. Should purges A and B become blocked, broken, or empty such that the system pressure falls to the regulator setpoints in purges C and D, helium would be supplied to the MCO by the lower pressure purges C and D. In this case, helium would not vent through the process vent system because the system pressure is lower than the 10 lb/in² gauge relief valve setting. Helium would either vent through the break in purge A or B, diluting the hydrogen concentration in the MCO, or the MCO would stay pressurized above atmospheric pressure, preventing oxygen ingress. It is important to note that the pressure settings provide a delay of at least 1 minute to allow sufficient time for the backup power to activate the local exhaust fans in the event of loss of power (SNF-3001, Calculation CVD-16 [Rev. 3]). This provision ensures that hydrogen generated in the MCO will be adequately diluted in the local exhaust.

There are eight major interfaces between the SCHe system and the CVDF, as described in Table B4-7.

The SCHe system is pressurized and available any time the MCO is connected to the VPS process connectors. It is actuated by loss of electrical or pneumatic power to the fail-open isolation valves in each individual purge system or by signal from the SCIC system (see Section B4 3 1 for specific conditions that cause the SCIC system to actuate the SCHe system).

CVDF = Cold Vacuum Drying Facility  
MCO = multi-canister overpack  
PWC = process water conditioning system  
SCHe = safety-class helium  
SCIC = safety-class instrumentation and control  
VPS = vacuum purge system

Actuation of the SCHe system by the SCIC system also coincides with automatic closure of the safety-class isolation valves for the VPS, the PWC system, and general-service helium system on the process piping leading to or from the MCO as well as opening of the SCHe system isolation valves. Once initiated, the system remains actuated until reset by an operator at the SCIC panel.

The SCHe system contains instrumentation and alarms to monitor critical system parameters. Local safety-class pressure gauges are provided at each SCHe supply bottle for checking helium bottle pressure. General-service alarms for low bottle pressure (1,700 lb/in² gauge set point) are sent to the MCS. The 1,540 lb/in² gauge helium bottle pressure will achieve 30 minutes of SCHe flow to meet the system requirements. When an SCIC ISO & PURGE trip occurs, a safety-class alarm is activated in the control room and the SCHe system is actuated. Other instruments for local and remote monitoring (flow valves and flow switches) are nonsafety-class but are designed to require multiple failures to avoid impacting the safety-class systems.
B4 3 2 3 Functional Requirements  The functional requirements needed for the SCHe system to perform its safety functions are as follows

- **Helium Injection** — Provide helium into the MCO in order to prevent flammable concentrations of hydrogen and oxygen from forming inside the MCO. Maintain a positive pressure to prevent air ingress to the MCO (assuming no line break) by injecting helium.

- **Vent Path** — For an isolated MCO that is being purged with helium because of SCHe activation, provide a pressure vent path from the HEPA-filtered side of the MCO to the local exhaust system.

- **Initial Purge Delay** — The supply and discharge pressure control valve settings shall accomplish an appropriate pressure differential that results in at least a 1 minute delay between SCHe actuation and vent path discharge to the process vent system. This allows the process bay local exhaust heating, ventilation and air conditioning (HVAC) and process vent system to restart on diesel standby power to reestablish dilution flow before SCHe discharges into the ventilation system ductwork.

- **Pressure Monitoring** — Contains sufficient local pressure monitoring capability for each helium bottle to ensure verification of the required operation.

- **System Isolation** — To be capable of isolation from the VPS general-service helium, and PWC system while functioning, in order to ensure venting into the local exhaust system.

- **Helium Flow** — To be capable of supplying sufficient helium flow to preclude explosive hydrogen concentrations in the MCO and in the vent path to the local exhaust system. A minimum supply of helium at a minimum flow rate of 14 standard ft³/min is required to flow for 27 minutes.

- **Purge Duration** — Purge out any air that may have entered the MCO, thereby precluding accumulation of flammable concentrations of hydrogen and oxygen.

- **Pressure Control and Relief** — Provide pressure control and relief in the helium supply line to avoid a situation where the helium bottle pressure can be applied directly to the MCO and exceed the 150 lb/in² gauge design pressure of the SCHe lines and the MCO if the bottle pressure regulator fails.

- **Accident and Environmental Conditions** — To be capable of operation under accident conditions (including loss of power) and worst-case surrounding environmental conditions.
HNF-3553 REV 0  
Annex B — Cold Vacuum Drying Facility

- **Helium Purity** — Provide helium of sufficient purity to be acceptable for mitigation of the thermal runaway accident and prevent internal MCO flammable conditions

- **System Operability, Calibration, and Testing** — To be operable before bulk water is drained from the MCO, ascertain that the safety-class system is functioning as required and that setpoints for all safety-class pressure relief valves are as specified

- **Single-Failure Evaluation** — To be single-failure proof

- **Seismic Qualification** — Provide a leak-tight SCHe system by use of seismically qualified valves, piping, hoses and other components, and be sufficiently secured to withstand a seismic event and remain operable following the DBE

**B4 3 2 4 System Evaluation**  The SCHe system is a safety-class design that is activated by the SCIC system in response to process upset conditions, loss of power, or operator action. The SCHe system is designed to operate during all of the postulated events it is intended to prevent or mitigate, including the DBE event.

**Helium Injection**  The SCHe system uses fail-open, electropneumatically operated isolation valves that (1) provide reliable, leak-tight operation, (2) fail open upon signal from the SCIC system by de-energizing the SCIC output relay that controls power to the valves, loss of instrument air or loss of electric power, and (3) remain open until the SCIC is manually reset. Upon activation, the SCHe system provides helium to the MCO via four lines (two lines into each MCO open port). Initially, the SCHe system will use helium from the pressurized general-service helium system, but if that system is unavailable, helium will be supplied from the pressurized bottles in the SCHe system. The capacity for the SCHe system helium bottles to provide MCO purge is based on the worst-case 1-in safety-class line break inside the isolation valve boundary. Engineering calculations that support the analyses of the worst-case scenarios and that form the basis for appropriately sizing the SCHe system SSCs are listed in SNF-3001, CVD-16. If helium is not available from the general-service helium system, the operator has about ½ hour to respond to a major line break. Even if the MCO eventually goes to atmospheric pressure, diffusion of air into the MCO is time dependent, which allows considerably more time for operator response. If there is no major line break or system leaks, one set of SCHe bottles will provide purge through the MCO and the second set of bottles will maintain pressure on the MCO for at least 96 hours, which will allow facility recovery actions. The positive pressure is sufficient to prevent ingress of air into the MCO.

**Vent Path**  There are dual SCHe system lines connected to the VPS line from the MCO filtered process exit port that provide redundant vent paths through the HEPA-filtered MCO port connection to the local exhaust system. Settings on the pressure control valves ensure a delay of at least 1 minute for venting to allow time for the standby power to activate the local exhaust fans. If there is a power failure, this time delay has been shown to be sufficient to prevent hydrogen within the MCO from reaching a flammable condition in the local exhaust system.

b-cvdf04 sar  
B4-56  
November 1999
Engineering calculations that demonstrate the required pressure settings for the SCHe and general-service helium systems pressure control valves accomplish the time delay are listed in SNF-3001 Calculation CVD-33.

Initial Purge Delay The general-service helium supply pressure to SCHe purge trans A and B is set at 15 lb/in² gauge (14 lb/in² gauge when supplied by the SCHe bottles) SCHe trains C and D are each connected to the process vent system through two pressure control valves in series set at 10 lb/in² gauge. These pressure differentials allow the helium to flow from purge trains A and B through the MCO inlet, down the long axial process tube, upward past the fuel baskets, out through the HEPA-filtered exit, into purge trains C and D, and out into the process vent system through the 10 lb/in² gauge pressure control valves. The pressure settings provide a delay of at least 1 minute before discharge to the process vent system to allow sufficient time for the backup power to activate the local exhaust fans in the event of loss of power (SNF-3001, Calculation CVD-16 [Rev 3]). This provision ensures that hydrogen generated in the MCO will be adequately diluted in the local exhaust, preventing a potential external hydrogen explosion initiated by a loss of normal electrical power.

Pressure Monitoring The line from each SCHe system helium bottle contains safety-class pressure indicators. A minimum helium bottle pressure parameter of 1,540 lb/in² gauge is required to provide sufficient volume for 30 minutes of helium purge. Engineering calculations demonstrating that this pressure provides adequate purge flow are provided in SNF-4301 (see Purge Duration below).

System Isolation The SCHe system is designed to be actuated by the SCIC system and, once actuated, to remain independent of all CVDF support utilities for functional operation. Proper operation of the SCHe system requires closure of the safety-class isolation valves for the VPS, general-service helium system, and PWC system. Following an SCIC trip condition requiring SCHe actuation, the isolation valves in the other systems switch to the closed position (until reset) to establish and maintain the pressure boundary required for the SCHe system safety function.

There are four SCHe system isolation valves, two connect via VPS lines to the long process tube connector and two connect via VPS lines to the MCO filtered exit port connector. These valves are 1-in stainless steel, gas-operated valves rated at 150 lb/in² gauge and are a ball-type design that use a cylinder and piston air actuator to rotate the ball shaft. Each valve also has local position indication. Each safety-class isolation valve is controlled by an associated safety-class electronic solenoid valve. Normally, the solenoid valve is energized in the open position to allow instrument air supplied to the SCHe system isolation valve actuator, keeping the SCHe isolation valves closed. Under SCIC trip conditions, the SCIC de-energizes the solenoid, which in turn closes the solenoid valve, blocks the instrument air flow, and allows existing air in the inner chamber to vent out, which then causes the isolation valve to switch to its fail-safe open state via a spring actuator mechanism. The solenoid valve operation is fail-safe in the respect that a loss of electrical power or loss of instrument air would cause the desired safety function to occur (i.e., the SCHe isolation valves would open). Safety-class filters are required on...
the instrument air lines to the actuators on the isolation valves to prevent buildup of foreign material and preclude a potential isolation valve malfunction. Moisture in the instrument air line is eliminated to improve overall reliability of value actuators by use of a general-service dryer in the instrument air system.

**Helium Flow** The SCH e system is designed with a pressurized source of helium piping, control valves, and instrumentation and controls that deliver helium to the MCO and provide a pressure vent path for MCO gases. The SCH e supply is designed to provide more than 1.4 standard ft³/min of helium flow that is sufficient to preclude air ingress and prevent accumulation of flammable concentrations of oxygen and hydrogen in the MCO (i.e., purge air out of the MCO so that it is pressurized and does not have sufficient oxygen to reach flammable conditions).

**Purge Duration** A minimum duration of helium flow is required from the SCH e bottles to ensure that oxygen is adequately purged out of the MCO to preclude flammable conditions. Purge duration calculations provided in SNF-4301 demonstrate that purge flow at the minimum SCH e flow rate of 1.4 standard ft³/min accomplishes this safety function in 27 minutes. Bottle pressure calculations at the maximum supply flow rate (design feature [SNF-3001, Calculation CVD-161]) of 4 standard ft³/min and 30-minute duration require a minimum bottle pressure of 1,540 lb/in² gauge.

**Pressure Control and Relief** Helium is supplied from each SCH e bottle through a pressure control valve set at 25 lb/in² gauge. A 125 lb/in² gauge rupture disk that vents to the room is located between the tank pressure control valve and the system pressure control valve. This configuration prevents overpressurization of the MCO by the SCH e system. The general-service helium system also has redundant safety-class relief valves set at 25 lb/in² gauge, well below the MCO design pressure to prevent overpressurization from this source of supply.

**Accident and Environmental Conditions** The independence of the SCH e system design assures that the system will be available under conditions where accidents may occur. The SCIC system provides control and power to the SCH e system. The only power supplied to the SCH e system is to activate the isolation valves that are normally held in the closed position (i.e., they fail in the open position). Response to accident situations is assured by the interrelationship with the SCIC system that monitors processing conditions and activates the SCH e system if process upsets occur. Also, the SCH e system is designed to environmental condition B of the safety equipment list and is operable to 115 °F (at 22% humidity) well above the parameter limit of 95 °F for the SCIC system bay high temperature sensor. The SCIC system will initiate an ISO & PURGE if the bay temperature setpoint is exceeded thereby isolating the MCO and activating the SCH e system.

**Helium Purity** Purity of the SCH e system bottles, >99% (as derived from SNF-2770), is controlled through the vendor quality assurance program, tank receipt inspection under the CVDF quality assurance program, and color markings on the helium bottles.
System Operability, Calibration, and Testing  The SCHe system is designed to be functionally tested for operability. Draining of bulk water is the initial step in the cold vacuum drying operation; therefore, the SCHe system must be operable prior to initiation of the process. In addition, the SCHe system has redundancy, is fail-safe, and is routinely surveilled and maintained. SCHe components are designed to be functionally tested for operability given a simulated process condition input. System availability is verified by surveillance of the system’s supply pressure before enabling the system for each MCO process cycle. Periodic testing of SCHe safety-class components is dictated by the requirements of the individual components according to the respective manufacturer’s recommended schedules and practice, and is administered by controlled procedures for all safety-class and safety-significant SSCs.

Recalibration of signals from the pressure transmitters to the SCIC system is maintained according to the respective manufacturer’s recommended schedule and practice. The SCHe system is designed with calibration and test connections to enable periodic measurement and calibration of all setpoints and adjustments that affect the manner in which the SCHe system performs.

Single-Failure Evaluation  For single-failure considerations, the SCHe system has been designed with parallel and redundant systems and to operate without external power in a fail-safe manner. The SCHe system is actuated by the SCIC system, which is a safety-class system itself. The SCIC system uses redundant and independent safety-class sensors on process systems and monitors process bay temperatures and seismic trip sensors (which include auctioneering, 2-out-of-3 logic to preclude fault trips), to actuate the SCHe system.

The SCHe system safety-class system has been evaluated by single-failure analysis (SNF-4290). All SCHe system components that perform the helium injection and venting functions are designated safety-class and meet performance category 3 seismic, redundancy, and physical separation requirements. This includes redundant helium supply paths to each MCO port and redundant venting paths that allow the system to function following a single-point blockage or failure. Single random failures of the SCHe system have been shown to be tolerable. The MCS also provides surveillance of the general-service helium system components, thereby providing added assurance that any system malfunction will be detected and responded to by operators.

Seismic Qualification  The design provides physical separation of redundant purge trains of the SCHe system. SCHe system pairs are mounted to the facility floor via support stands designed to performance category 3 criteria, and therefore remain structurally sound following design basis natural phenomena events. Also, the process bay structure is designed and constructed to performance category 3 for natural phenomena hazards.

The SCIC system has sensors for detecting a seismic event and for indicating an excessive bay temperature that will activate the SCHe system if conditions are not acceptable for operation. All supporting systems that perform sensing, logic, actuation, and isolation functions necessary for the SCHe system to perform its functions are also designated safety-class — meeting performance.
category 3 seismic redundancy, and physical separation requirements. All components are mounted to structural components meeting performance category 3 requirements. Seismic calculations for the SCHe system components and piping are listed in SNF-3001.

**B4 3 2 5 Controls (Technical Safety Requirements)** The following assumptions associated with the SCHe system require TSRs to ensure performance of their safety functions:

- The SCHe system including vent path is operable prior to making process connections to the MCO.
- Functional tests and leak tests of the VPS, general-service helium system, deionized water system, and PWC system isolation valves have been performed on an appropriate schedule consistent with the respective manufacturer’s recommended schedule and practice.
- The purge train A and B supply pressure control valve settings in conjunction with the purge train C and D pressure control valve settings to discharge to the process vent system will accomplish at least a 1 minute delay prior to discharge of helium purge flow to the process bay local exhaust HVAC and process vent system.
- The helium gas bottles are of a purity of >99%.
- The fail-open isolation valves for the SCHe system will function on demand.
- The SCHe bottles contain a sufficient quantity of helium before each drying cycle begins (minimum pressure of 1700 lb/in² gauge including error and readability).

**B4 3 3 Cask-Multi-Canister Overpack Safety-Class Components**

In addition to their normal functions, the cask-MCO components perform safety-class functions for prevention of the MCO overpressurization accidents, thermal runaway accident, and criticality. Safety-significant functions are performed for prevention of the gaseous release, external hydrogen explosion, and internal hydrogen explosion accidents. These components are associated with the hydraulic boundary of the tempered water (annulus) system interface and the pressure boundary for the MCO. The cask-MCO also provides a safety-significant function of shielding during normal operations for worker safety. Section B4 4 1 4 provides specific positioning requirements for the cask-MCO trailer to protect assumptions in the seismic analysis.

**B4 3 3 1 Safety Function**

**Transportation Cask** Following receipt at the CVDF, the cask headspace is vented, the cask lid is removed, and a CVDF process hood-seal ring assembly is bolted to the cask. The seal ring isolates the cask annulus space via two sealing bladders provides the tempered water.
(annulus) system outflow connection, and provides a connection point for instrument air supply for annulus drying. The seal ring is described in Section B4.3.4 as a component of the tempered water (annulus) system (Figure B4-1). The cask safety function for the thermal runaway reaction accident is to contain water in the cask annulus for prevention and mitigation of the accident. The tempered water supply is connected to the quick-disconnect drain fitting, which is safety-class to ensure function and integrity of the connection.

**Multi-Canister Overpack** The MCO is designed to contain and confine its contents during all normal operations and accident conditions and to maintain fuel elements and fuel fragments in a critically safe geometry throughout the MCO's design life both before and after being subjected to the DBAs. The MCO also provides the inner hydraulic boundary of the cask-MCO annulus and one of the two sealing surfaces for the cask-MCO seal ring. The MCO is credited with prevention or mitigation functions for the gaseous release, external hydrogen explosion, internal hydrogen explosion, thermal runaway reaction, and MCO overpressurization accidents. The MCO performs the following safety functions for those accidents:

- **MCO overpressurization** — A passive function of the MCO is to maintain its pressure boundary at the design rating of 150 lb/in² gauge and to maintain the structural integrity of the cask-MCO annulus required for tempered water to provide adequate heat transfer from the MCO.

- **Thermal runaway reaction** — A passive function of the MCO is to maintain its confinement boundary and the structural integrity of the cask-MCO annulus required for adequate heat transfer from the MCO.

- **External hydrogen explosion** — The function of the MCO is to prevent hydrogen from escaping in an uncontrolled fashion and creating explosive conditions external to the MCO by maintaining its structural integrity and leak tightness.

- **Internal hydrogen explosion** — The function of the MCO is to prevent air ingress that could result in explosive conditions by maintaining its structural integrity and leak tightness and to maintain the structural integrity of the cask-MCO annulus required for adequate heat transfer from the MCO.

- **Gaseous release accident** — The MCO is credited with confinement of radioactive materials within its pressure boundary.

The prevention of a criticality accident is also a safety-class function, therefore the MCO and Mark IA fuel baskets function as safety-class components provide geometry control to prevent a criticality (see Chapter B6.0).

In addition to providing containment, the MCO shield plug is also designed to minimize radiation doses (safety significant) to personnel during processing and handling operations.
B4 3 3.2 System Description

Transportation Cask The MCO transportation cask is a vertical, cylindrical, stainless steel vessel. The cask has an outside diameter of 39.81 in and a height of 170.25 in. The overall packaging assembly, including the lifting device, has an outside diameter of 43.83 in and an overall height of 190.25 in. The cask cavity diameter is 25.19 in and is 160.50 in deep. The cask consists of a forged 7.31-in-thick 170.25-in-long stainless steel cylinder with an integrally welded stainless steel bottom head that is 6.13 in thick. A quick-disconnect fitting is positioned near the bottom of the cask and communicates with the interior cavity. This safety-class fitting provides the connection with the tempered water (annulus) system and is protected with a port cover when not in use. Refer to Figure B2-3 for the design of the MCO and cask package.

The cask lid is forged stainless steel with a 3.5-in-thick top and 3-in sides, an outer diameter of 35.5 in, an inner diameter of 25.5 in, and a height of 11 in. The lid has a 4-in-tall, 4.16-in-wide flange at its base, which makes the diameter of the lid 39.81 in at the flange. The base of the lid has an O-ring groove that has an inner diameter of 31.57 in. The interior of the base of the lid also has a 2.16-in-wide 1.09-in-tall notch that mates with a similar-sized extension in the cask shell. The lid is bolted to the cask body with 12, 1.5-in-diameter bolts that are arranged on a circle with a 36.44-in-diameter. A single, butyl, O-ring seal forms the containment boundary between the cask body and lid. Lid installation is guided by two alignment pins that are integral to the cask body.

Multi-Canister Overpack The MCO provides a confinement system for cold vacuum drying processing and storage of N Reactor SNF currently located in the K Basins. The MCO is constructed from austenitic stainless steel with high resistance to corrosion from all aspects of the environment to which the system is expected to be exposed during its lifetime. From loading at the K Basins to placement in interim storage, the interior of the MCO sees three distinct thermal-hydraulic conditions: flooded with water, vacuum or near-vacuum conditions, and dried and backfilled with helium gas. While a combination of these three distinct conditions will exist as an MCO passes from one process step to the next, the safety basis of the MCO is principally established using steady-state and transient analysis under each of these distinct operating conditions (HNF-SD-SNF-SARR-005). While at the CVDF, the MCO will see all three distinct operating conditions.

The major MCO components are the MCO shell, bottom assembly, canister collar, shield plug with attached long process tube, pressure rupture disk, locking and lifting ring, lifting cover cap, fuel baskets, and scrap baskets.

The overall dimensions of the MCO are 24 in in diameter by 160 in in height. The wall thickness is 0.5 in. The shell is welded to a stainless steel bottom forging 24 in in diameter. A 16-in-thick shield plug (including filter chamber and filter guard plate) is inserted into the top of the MCO. The MCO top shield plug is held into the MCO shell by a threaded assembly called the locking and lifting ring. For reference see Figure B2-15 for the design of the MCO.
The cylindrical shell, bottom assembly, canister collar, shield plug, and locking and lifting ring form the primary pressure-retaining boundary for the SNF.

The MCO shell provides confinement of the fuel during handling and storage. MCO materials, fabrication, welding, and examination are in accordance with the requirements of the ASME Boiler and Pressure Vessel Code (ASME 1995) Section III (HNF-SD-SNF-SARR-005). The MCO also provides support for the shield plug and fuel baskets for stacking, lifting, and handling. The top and bottom baskets may also be scrap baskets, with a design that includes a series of reed fins around it that contact the MCO inner wall to reduce gas flow up the annulus and preferentially direct it through the basket. The scrap baskets are designed to enhance thermal conductivity to the MCO. The bottom assembly welds are made during fabrication of the MCO.

The shield plug is a multifunctional component of the MCO. It provides a mechanical confinement boundary until the MCO cover cap is welded in place. The shield plug also provides for axial radiation shielding to allow personnel access to the top of the MCO for closing the MCO and for performing the drying and processing functions. The shield plug retains the main seal, which seals between the MCO collar and the shield plug. The shield plug has four ports that connect to four penetrations, two of which are connected to an internal HEPA filter. One of the two HEPA-protected penetrations allows for the filtered release of gases from the MCO during vacuum drying. The other HEPA port is blanked. Another penetration connects to the long process tube, which reaches to the bottom of the MCO, aiding in the removal of water during draining. The final penetration is for the safety-class rupture disk with a nominal 150 lb/in² gauge rating. The design of the shield plug subassembly is shown in Figure B2-16.

When the MCO is positioned inside the cask, a 0.595-in.-wide annulus is formed between the cask and the MCO. During fuel loading at the K Basins, this annulus is filled with water, which completes the heat transmission path for the nuclear decay heat and chemical corrosion heat generated by the fuel. At the CVDF, tempered water from the tempered water (annulus) system is circulated through the annulus to adjust the temperature of the fuel as one of the process parameters.

B4.3.3.3 Functional Requirements

**Transportation Cask** To perform its safety function of containing water in the cask-MCO annulus during the internal and external hydrogen explosion, thermal runaway, and MCO overpressurization accidents, the cask must remain structurally stable and not leak. The cask drain fitting must retain its integrity as a leaktight connection to the tempered water supply piping. The cask must be precisely located in the process bay such that seismic-induced motion of the cask and transporter do not result in damage to the process hood support stand piping or connections to the MCO.

**Multi-Canister Overpack** To perform its safety functions of containing water in the cask-MCO annulus and preventing water leaks to the fuel inside, the MCO is also required to remain structurally stable and not leak. It must also retain its integrity as a leaktight boundary for...
gaseous material. The 150 lb/in² gauge (nominal) rupture disk function is credited in the accident analysis as a design feature of the MCO.

**B4 3 3 4 System Evaluation**

**Transportation Cask** The cask because of its massive construction and design as safety class for transportation (HNF-SD-TP-SARP-017) will be able to maintain its dimensions and not collapse the annulus. Likewise, a leak from the cask body is improbable. The lower cask port fitting is tested and installed as safety-class to ensure its integrity.

**Multi-Canister Overpack** The anticipated normal MCO operations at the CVDF include being closed and static (no connections, cask closed), connecting and venting, water draining, purging with helium, and vacuum drying at temperatures below 50 °C (122 °F). The integrity of the MCO at the time of fabrication was verified by hydrostatic leak testing at the vendor. Verification that the fuel is sufficiently dry will be performed. Leak tests will be performed on the MCO connections and plug valves after they are closed. The 150 lb/in² rupture disk is safety-class. Engineering evaluation in HNF-SD-SNF-SARR-005, *Multi-Canister Overpack Topical Report* demonstrates the adequacy of the rupture disk to perform its design functions.

**B4 3 3 5 Controls (Technical Safety Requirements)**

**Transportation Cask—MCO** The following assumption associated with the cask—MCO requires TSRS to ensure performance of the safety function. It also is assumed that the safety-class lower cask port connection for tempered water supply has been installed in all casks as a retrofit activity before any fuel transport to CVDF.

- Design pressure of the MCO is 150 lb/in² gauge and the rupture disk is installed properly and is functional (not plugged by a blind cover plate).

**B4 3 4 Tempered Water (Annulus) System Safety-Class Components**

**B4 3 4 1 Safety Function** As described in Chapter B3 0, the thermal runaway reaction accident could occur if heat removal from the MCO is not sufficient to prevent fuel elements and scrap fuel from heating up as a result of decay heat and chemical reaction heat. As the temperature increases, the chemical reaction rate increases, producing more hydrogen and heat. To prevent such a scenario, heat must be dissipated from the MCO by the tempered water (annulus) system in conjunction with general-service helium and/or SCHe system operations. Water in the annulus between the MCO and cask is required to adequately transfer heat from the MCO to the tempered water (annulus) system. The overall safety functions of the safety-class components of the tempered water (annulus) system that prevent a thermal runaway reaction (in conjunction with the SCHe system) are to maintain the level and supply temperature of the water in the cask—MCO annulus within design limits.
The tempered water (annulus) system provides (1) safety-class functions for the thermal runaway reaction and the MCO overpressurization accidents, and (2) safety-significant functions for the internal hydrogen explosion accident. The tempered water (annulus) system performs the following safety functions for those accidents:

- **MCO overpressurization** — The safety-class functions of the tempered water (annulus) system are required to protect the analytical assumptions for heat dissipation from the MCO, by maintaining water in the annulus between the cask and the MCO. The system also provides a high inlet water temperature signal and a low annulus water level signal to the SCIC system. The SCIC system terminates power to the tempered water (annulus) system heater, which ceases heat input to the MCO. The SCIC system also provides a safety-class low annulus water level alarm to the operators for corrective action. Maintaining heat transfer out of the MCO will also reduce hydrogen generation in the MCO. The tempered water (annulus) system retains annulus water through piping integrity and antisiphon valves.

- **Thermal runaway reaction** — The functions of the tempered water (annulus) system to prevent the thermal runaway reaction accident are to provide for heat dissipation from the MCO by maintaining water in the annulus between the cask and the MCO. The system also provides a high inlet water temperature signal and a low annulus water level signal to the SCIC system. The SCIC system terminates power to the tempered water (annulus) system heater, which ceases heat input to the MCO. The tempered water (annulus) system provides a safety-class low annulus water level signal to the SCIC system, which alarms to alert the operators for corrective action. The tempered water (annulus) system retains annulus water through piping integrity and antisiphon valves, and the system design provides the capability for manual refill.

- **Internal hydrogen explosion** — The safety-significant functions of the tempered water (annulus) system to prevent the internal hydrogen explosion accident are to provide for heat dissipation from the MCO by maintaining water in the annulus between the cask and the MCO. The system also provides a high inlet water temperature signal to the SCIC system, which terminates power to the tempered water (annulus) system heater, and detects a low annulus water level, which alerts operators to manually refill the annulus. These actions cease heat input to the MCO and maintain the cask-MCO annulus water level, which reduces hydrogen generation within the MCO. Piping integrity and antisiphon valves in conjunction with the tempered water (annulus) system design ensure the annulus water is retained.

**B4 3 4 2 System Description** Two water lines are connected to the cask-MCO, one near the bottom of the cask, which serves as the tempered water inlet, and one in the cask-MCO seal ring, which serves as the annulus outlet. All tempered water (annulus) system components, from the piping between the cask ports and the valves and piping components on the process hood support stand (up to and including the antisiphon valves), form the safety-class primary barrier to prevent...
loss of annulus water  The cask inlet flex line is encased in an outer 3-in diameter flex line that forms a double-walled configuration to an elevation above the level of the fuel in the MCO  The lower end of the double wall pipe is connected to the cask via a special connector  All of these components including the quick disconnect for the supply line on the bottom of the cask, are classified as safety class  The remaining components of the tempered water (annulus) system (those on the pump side of the antisiphon valves and the connections of the flexible lines to the PES) are general-service components  Failure of the general-service equipment cannot lead to a loss of the cask-MCO annulus water  The general-service tempered water (annulus) system components include the inlet and return piping to the antisiphon valves, the system pump, heater, system cooler, holding tank and associated valves, indicators, and switches  Refer to Figure B2-17 and SNF-3085, SNF Project Cold Vacuum Drying Facility Tempered Water and Tempered Water Cooling System Design Description for more detailed information

The seal-ring assembly described in Section B4.3.3 forms part of the hydraulic boundary between the cask and the MCO  The cask-MCO seal ring is considered a part of the tempered water (annulus) system but is attached to the process hood  The seal ring's function is to form a water- and air-tight seal in two locations  (1) between the cask shell and the seal ring on a horizontal plane and (2) between the MCO and the seal ring on a vertical plane  The center of the seal ring is open to allow process system connection access to the ports on the top of the MCO  Rubber seal ring bladders are inflated by instrument air after the process hood-seal ring assembly is bolted into place  A cross-sectional view of the seal ring assembly is shown in Figure B2-14  Seal ring structural analysis was performed as discussed in SNF-4772, Evaluation of Cold Vacuum Drying Facility Seal Ring Loading and Stress

When installed and inflated, the seal rings provide the seal for the tempered annulus water at the top of the cask-MCO annulus and allows circulation of the tempered water to and from the annulus  The seal ring and process hood are bolted to the cask to resist the uplift load due to any credible water pressure from the circulating water within the cask-MCO annulus  The seal ring bladders are designed to withstand expected pressures generated by the tempered water (annulus) system  Various process connections, including the tempered water (annulus) system outlet connection and an instrument air connection, are provided

The following components of the tempered water (annulus) system are designated as safety-class

- MCO seal ring assembly tempered water outlet port with refill connection and gas vent port (inflatable seals are general service)

- Antisiphon valves

- Cask tempered water return (outlet) piping from the connection of the flexible lines to the support stand, including the portion of the line on the support stand that incorporates the antisiphon valves and connects to the seal ring outlet
- Cask tempered water supply piping from the connection of the flexible lines on the support stand to the lower cask port, including the lower cask port connection, quick-disconnect fitting, and outer flange connection and tubing

- Cask-MCO annulus inlet and outlet water low-level switches and combined water level gauges

- Cask-MCO annulus inlet water high temperature switches

- Tempered water level check petcock valves on supply piping (backup to level indicator and remote level alarm)

Both the tempered water supply and return lines have safety-class level and temperature switches and safety-class level gauges. If the level of the annulus water drops below a designated level, the low-level switches send a signal to the SCIC system (see Section B4 3 1) that initiates a safety-class alarm to signal the operators that the water level has dropped below the setpoint for the annulus. When the alarm is activated, corrective measures are taken by the operator. If refill deionized water cannot be added through the tempered water (annulus) system general-service recirculation loop, the operator can refill the annulus manually with water, using a funnel, through a fill port and valve in the outlet line attached to the cask-MCO seal ring. A vent port is provided on the seal ring to assist with the manual refill process. A level check petcock is provided on the supply piping to facilitate manual refill operation, by providing a visual indication that the annulus water level is above the level of the fuel inside the MCO. This SSC allows backup verification of an adequate cask-MCO annulus water level, if the safety-class level gauges with remote alarms cannot be reset because of leakage from the general-service seals on the process hood seal ring assembly. Note that the seal ring is significantly above the fuel level inside the MCO but below the safety-class level gauges. Two parallel safety-class antisiphon valves are connected between the safety-class portion of the inlet and outlet piping, to prevent water from being inadvertently siphoned from the annulus in the event there is a line break in the general-service piping.

The CVDF process requires that the MCO normal drying operation and dryness testing be performed between 40 °C to 50 °C. If the inlet water temperature registers high, the safety-class temperature switches send a signal to the SCIC system (see Section B4 3 1), which de-energizes the tempered water (annulus) system heater. Calculations verify that the stagnant annulus water will cool even when the decay heat of the fuel is taken into account. Tempered water temperatures are monitored via the MCS system. Low tempered water temperature during drying would be an abnormal condition and corrective actions would be in accordance with operating procedures.

**B4 3 4 3 Functional Requirements** The functional requirements for the tempered water (annulus) system safety-class components are as follows

- **Heat Transfer** — Provide heat transfer from the MCO to the cask's inner surface to accomplish the system function of removing decay and reaction heat from the fuel
Annex B — Cold Vacuum Drying Facility

- **Low Annulus Level Alarm** — Detect low annulus water level and transmit a signal to the SCIC system, which will sound a safety-class alarm that alerts operators to the low annulus water condition.

- **Supply Piping Leak Detection** — Provide a means for detecting a leak in the tempered water (annulus) system supply pipe to the MCO. Maintain capability for the operator to visually check the annulus water level and to observe possible leakage conditions during MCO processing and response to SCIC low-level alarm conditions.

- **Emergency Annulus Refill** — Provide emergency annulus water refill capability if the general-service deionized water addition in the tempered water (annulus) system is not functioning and there is a loss of annulus water.

- **Antisiphon Design** — Prevent siphoning of water from the cask-MCO annulus during MCO processing in the event of a line break accident.

- **Temperature Detection** — Detect MCO inlet water high temperature (beyond the setpoint for a specific processing step) and, in conjunction with the SCIC system, shut down the tempered water (annulus) system water heater.

- **System Operability, Calibration, and Testing** — Ascertaining that the tempered water (annulus) system is operable. Safety-class components are functioning as required and setpoints for all safety-class level and temperature switches are as specified.

- **Single-Failure Evaluation** — Ensure the safety-class portions of the tempered water (annulus) system are single-failure proof.

- **Seismic Qualification** — For the safety-class portions, provide a leaktight tempered water (annulus) system and passively prevent loss of water from the cask-MCO annulus by use of seismically qualified components, piping, and antisiphon valves.

**B4 3 4 4 System Evaluation** The tempered water (annulus) system components that are identified as safety class will maintain the water level in the annulus and prevent overheating of the annulus water to prevent the accident scenarios described in Chapter B3 0. Line breakage or valve failure may occur in other general-service portions of the tempered water (annulus) system, without impacting the annulus water level to the extent that a thermal runaway reaction, MCO overpressurization, or internal hydrogen explosion accident could be initiated.

The tempered water (annulus) system safety-class components have been designed to meet and perform their functional and safety requirements. The system evaluations of each of the functional requirements are discussed separately below.
**Heat Transfer**  The massive metal structure of the MCO cask, in conjunction with the MCO, provides an excellent heat conduction path for the fuel material contained within the MCO. Heat removal from the fuel material is accomplished by use of the tempered water (annulus) system, which circulates water through the cask-MCO annulus. Design of the tempered water (annulus) system ensures that the annulus water level will not fall below a level that is at least 1 ft above the level of the fuel in the MCO. Calculations have been made to show that transfer of heat from the MCO to the tempered water (annulus) system is sufficient to prevent or mitigate the thermal runaway accident. Engineering calculations demonstrating the adequacy of the heat transfer performance are included in SNF-2770, *Cold Vacuum Drying Facility Design Basis Accident Analysis Documentation*. Experimental heat transfer testing is documented in HNF-4057, *Cold Vacuum Drying Proof of Performance (First Article Testing) Test Results*. Verification that the heat transfer codes used for modeling are consistent with experimental results is provided in SNF-4083, *Hanford SNF Cold Vacuum Drying Process Post Test GOTH SNF Model Simulations of Proof of Performance or First Article Test and Equipment Performance Evaluations*.

**Low Annulus Level Alarm**  A low annulus water level is detected by the redundant safety-class low-level switches, which are single-failure proof (SNF-4290) and fail safe on loss of electrical power according to vendor information. These switches are set for at least 1 ft above the fuel level in the MCO to activate the SCIC system to sound a safety-class alarm that must be acknowledged by the operators. Operators must take action to bring the annulus water level above the low-level switch setpoint before the alarm can be reset. The safety requirement is to maintain the annulus water level above the height of the fuel in the MCO.

**Supply Piping Leak Detection**  The tempered water (annulus) system safety-class supply line connects to the lower port of the MCO cask through a safety-class, quick-disconnect fitting. A safety-class, double-walled design is provided up to a height above the top of the fuel inside the MCO. This design configuration leaves the outer pipe open at the top so that a leak in the inner supply line connected to the cask is captured and water flows upward and out the open end. The cask-MCO annulus water level is normally maintained above the fuel level in the MCO, however, if a leak in the inlet line occurs, it would be detected by the annulus inlet and/or outlet low-level switches, and an SCIC system alarm would be activated. This leak could be initially detected by the non-safety-class MCS low-level alarm in the tempered water receiver tank and by operator visual inspection. To ensure there is no leak in the inner supply line when MCO processing begins, a leak check is performed on the cask tempered water inlet line connection.

Another provision for monitoring the cask-MCO annulus water level during MCO processing is provided by the safety-class level gauges. These gauges (combined with the low-level switches) will indicate a water leakage condition. The gauges are placed on the process hood support stand in clear view of the operator, so that they have the capability to alert the operator to abnormal conditions. These level gauges are also utilized during responses to low-level alarms. A level check petcock also allows visual verification that the cask-MCO annulus water level is above the level of the fuel in the MCO.
Emergency Annulus Refill  In emergency situations where the water level is low and the deionized water addition in the general-service portion of the tempered water (annulus) system is unavailable, deionized water can be manually added to the annulus through a refill connection (stub-out) on the seal ring outlet line. The operator adds deionized water from a 55-gal drum with hand truck using a hand pump and gallon bucket by pouring through a funnel at the stub-out until there is visible leakage out the vent port. This response requires that there is no leakage of water past the seal ring assembly seals. If there is leakage from the tempered water inlet line lower connection to the cask, the line can be disconnected and the cover plate installed to bring the MCO into a safe-standby condition. About 27 gal of water is required to fill the cask-MCO annulus to above the height of the fuel in the MCO. As a minimum, 30 gal of deionized water must be available to have a sufficient amount of water to fill the cask-MCO annulus and allow for spillage and leakage.

Antisiphon Design  There are two antisiphon bypass lines in the safety-class portion of the tempered water (annulus) system. The flow through each line is controlled by safety-class flow control valves. The design of this system ensures that a line break in the general-service portion of the tempered water (annulus) system will not lead to siphoning of the water from the cask-MCO annulus. The two bypass flow control valves each route 1 gal/min to the cask-MCO outlet line and break the pressure path between the inlet and outlet lines that otherwise could result in siphoning of water from the annulus if a line break occurs in the general-service portion of the tempered water (annulus) system.

Temperature Detection  Detection of inlet water high temperature is ensured through use of safety-class temperature switches that signal the SCIC system to shut off power to the tempered water (annulus) system heater. The trip setpoint of the SCIC system takes into consideration the error associated with the instruments and shuts off the tempered water heater prior to exceeding the parameter limit of 50 °C. Water must be cooled to below the setpoint temperature (see Table B4-6) before the SCIC system can be reset.

System Operability, Calibration, and Testing  All tempered water (annulus) system equipment must be periodically calibrated according to the respective manufacturer’s recommended schedule and practice. Calibration and test connections have been provided to enable in-service testing and calibration where practical. Modular design has been incorporated into the tempered water (annulus) system equipment to permit easy change-out of systems requiring timely repair and/or special skills, and to reduce problems associated with equipment removal and repair.

Single-Failure Evaluation  The safety-class portion of the tempered water (annulus) system has been evaluated by single-failure analysis in SNF-4290. A single random failure can be tolerated using operator response actions. The tempered water (annulus) system design incorporates a cask-MCO annulus manual refill station for recovery under process upset conditions. Recovery action can be accomplished in much less time than the approximately 22 hours determined to be available based on the accident analysis (SNF-4290).
protection of the supply line is provided by prohibiting any movement of the overhead crane that could result in a single accident that could fail the double-walled supply piping.

**Seismic Qualification** All safety-class components are designed to performance category 3 standards. System leakage is prevented by use of safety-class piping and cask and seal ring assembly port connections in key portions of the tempered water (annulus) system. Other components that are safety-class include level and temperature switches, level gauges, and redundant antisiphon valves. All of these tempered water (annulus) system components have been seismically qualified. Also, the annulus water supply line connecting to the port at the bottom of the cask is double-walled construction, up to a level exceeding the level of the fuel in the MCO, and is connected to the process hood support stand. To ensure performance under all required conditions, the process hood support stand that supports the tempered water (annulus) system safety-class equipment has a category 3 designation. If inadvertent system leakage should occur during processing, a sump with a general-service level alarm in the floor below the cask will collect the water and send a signal to the MCS. This design provision provides a defense-in-depth capability for water leakage from the cask-MCO annulus. Engineering calculations demonstrating the adequacy of the performance category 3 structural design are listed in SNF-3001.

**B4 3 4 5 Controls (Technical Safety Requirements)** The following assumptions associated with the tempered water (annulus) system require TSRs to ensure the performance of the safety functions:

- The SCIC tempered water temperature trip system is operable whenever an MCO is connected to the tempered water (annulus) system.
- The annulus inlet and outlet line low water level switches are operable prior to heatup or draining whenever an MCO is connected to the tempered water (annulus) system.
- The annulus inlet line high water temperature switches are operable whenever an MCO is connected to the tempered water (annulus) system.
- The annulus water level gauges are operable whenever an MCO is connected to the tempered water (annulus) system.
- A functional leak check has been performed on the supply line to the lower port of the MCO cask prior to heatup or draining.
- The cask-MCO annulus low water level switches, high water temperature switches, and water level gauges are calibrated and have correct setpoints before an MCO is connected to the tempered water (annulus) system.
Approximately 30 gal of deionized water and support equipment for manually adding deionized water to the cask-MCO annulus is available in a bay for operators before MCO process operations are initiated and during processing in that bay.

### B4 3.5 Vacuum Purge System Safety-Class Components

#### B4 3.5.1 Safety Function

The VPS provides safety-class process pressure information to the SCIC system that initiates an ISO & PURGE which de-energizes the VPS fail-closed safety-class isolation valves and is credited in the Chapter B3.0 accident analysis with prevention functions for the thermal runaway reaction. The VPS is credited with safety-class functions for the thermal runaway reaction and MCO overpressurization accidents and safety-significant functions for the internal hydrogen and external hydrogen explosion accidents. Safety functions performed by the VPS for these accidents are as follows:

- **MCO overpressurization** — Safety-class functions of the VPS are to provide isolation of the MCO from the VPS including deionized water and to make a backup 30 lb/in² gauge vent path available that precludes high pressures in the MCO. The VPS isolation valves, piping, and MCO connectors form a leaktight portion of the extended MCO pressure boundary for normal operation and when an ISO & PURGE occurs. Pressure transmitters which are components of the VPS, provide signals to the SCIC system for monitoring the MCO pressure during operation sequences and activating an ISO & PURGE if setpoints are exceeded. Safety-class filters on the instrument air lines to the actuators on the isolation valves ensure functional operation of the valves.

- **Thermal runaway reaction** — Safety-class functions of the VPS are to provide isolation of the MCO from the VPS, including deionized water through use of VPS isolation valves, piping, and MCO connectors, and to form a leaktight portion of the extended pressure boundary for the MCO for normal operation and when an ISO & PURGE occurs. Pressure transmitters which are components of the VPS, provide signals to the SCIC system for monitoring the MCO pressure during operation sequences and activating an ISO & PURGE if setpoints are exceeded. Safety-class filters on the instrument air lines to the actuators on the isolation valves ensure functional operation of the valves.

- **Internal hydrogen explosion** — The VPS performs all of the functions required for the thermal runaway reaction to prevent or mitigate the safety-significant consequences of the internal hydrogen explosion.

- **External hydrogen explosion** — This accident has safety-significant consequences. The VPS performs the same functions as the MCO overpressurization accident except the pressure monitoring is not a credited safety function.
The VPS plays a major role during processing by providing additional "water isolation" of the MCO from potential water ingress sources during and after the MCO processing steps involving proof-of-dryness demonstration. Redundant safety-class deionized water isolation valves prevent water from being introduced into the MCO after the pressure hold tests have been verified. Safety-class VPS pressure instrumentation is also used during the MCO pressure hold tests.

The VPS is designated general service, but certain VPS components are designated safety-class as discussed below.

**B4 3 5 2 System Description**

One-inch VPS lines are connected to each of two MCO ports. One of the VPS lines connects to the long process tube port. This line connects to the general-service helium system and the deionized water line and also has connections to the SCHe system. The other line (MCO filtered process exit port) provides a pathway directly to the general-service VPS equipment and also has connections to the SCHe system. In general, the VPS consists of isolation valves, piping, and instrumentation in conjunction with a residual gas analyzer, a condenser (which can be bypassed after most of the water is removed from the MCO), a condenser water collection tank routed to the PWC system, a helium line to provide pressurization to remove MCO water, and a four-stage roots vacuum pump that connects to the process vent. When bulk water has been drained from the MCO, a valve to the vacuum pump is opened and pump-down is initiated to remove the remaining water in the MCO. At various stages, the water content of the MCO is monitored by checking the temperature difference across the condenser. The condenser captures the majority of the water vapor before it reaches the vacuum pump. At some point, the monitoring gauges and the condenser delta temperature readings will indicate most of the water has been removed, and pumping is continued with the condenser bypassed. Process steps involving pressure test rise are used to verify the MCO is ready for shipment. More detailed VPS information is provided in Figure B2-17 and in SNF-3062, *SNF Project Cold Vacuum Drying Facility Vacuum Purge System Design Description*.

The only components of the VPS that are safety-class are those that isolate the MCO from the VPS, monitor pressure, and provide an auxiliary vent path in situations where the MCO pressure rise is greater than can be handled by the SCHe system vent. The following VPS components are designated safety class:

- MCO process connectors and flexible piping located between the MCO process ports and the process hood support stand.
- Hard piping from the MCO flexible hose connections to just beyond the second isolation valve in each MCO process port line where the lines connect to the flexible tubing from the PES.
- Fail-closed MCO isolation valves with filters on the instrument air line to the valve actuators (mounted on the process hood support stand).
Annex B — Cold Vacuum Drying Facility

- Fail-closed deionized water isolation valves
- Pressure transmitters, pressure indicators, and flow controls (including instrument air line filters) mounted on the process hood support stand
- MCO 30 lb/in² gauge vent path to local exhaust duct

All of the above components are safety-class and are designed to performance category 3 standards. The safety-class pressure transmitters send signals to the SCIC system that activate an ISO & PURGE if process upset situations are encountered. The SCIC system will initiate an ISO & PURGE that will de-energize the fail-closed VPS and deionized water isolation valves, in conjunction with the PWC system and general-service helium system isolation valves, and begin an SCHe purge of the MCO. The 30 lb/in² gauge vent path is backup to the SCHe system vent path to ensure the pressure will not reach the MCO 150 lb/in² gauge rupture disk rating.

**B4 353 Functional Requirements** Functional requirements for the VPS safety-class components to perform their safety functions are as follows:

- **VPS Isolation** — Provide fail-closed VPS isolation valves (with instrument air line filters) to isolate the MCO from the non-safety class portion of the VPS and maintain the MCO extended pressure boundary
- **Deionized Water Isolation** — Provide fail-closed deionized water isolation valves (with instrument air line filters) to prevent water ingress and maintain the MCO pressure boundary
- **Process Piping** — Provide leak-tight process piping and flexible connection hoses from the MCO ports to the isolation valves for the MCO isolation pressure boundary
- **Connection Capability** — Provide leak-tight process connectors for joining flexible hoses to MCO processing ports
- **Pressure Detection** — Detect MCO pressure and provide a signal to the SCIC system to initiate MCO isolation and SCHe actuation during process upset conditions
- **Vent Path** — Provide a 30 lb/in² gauge vent path to the local exhaust duct
- **System Operability, Calibration, and Testing** — Ensure the VPS is operable and safety-class components are functioning as required and the pressure readings are reliable
Annex B — Cold Vacuum Drying Facility

- **Single-Failure Evaluation** — Ensure safety-class portions of the VPS are single-failure proof
- **Seismic Qualification** — Provide leaktight VPS system (safety-class portion) by use of seismically qualified valves, sensors, piping, hoses, and other components

**B4 3 5 4 System Evaluation**  
The VPS safety-class components are required to isolate the MCO and to provide signal input of process parameters to the SCIC system. Each of the function requirements is discussed separately below

**VPS Isolation**  
The VPS line connected to the MCO filtered process exit port connector includes two electropneumatically operated safety-class isolation valves mounted to the process hood support stand. The 1-in., stainless steel, gas-operated valves are rated 150 lb/in² gauge. During normal drying operations, the valves are held open by instrument air. Following an SCIC trip condition that results in an ISO & PURGE, the VPS isolation valves move to the closed position (until reset) to establish and maintain this portion of the pressure boundary required for the SCHe system safety function. The valves also provide local position indication.

The isolation valves are a ball-type design that use a cylinder and piston air actuator to rotate the ball shaft. Each safety-class isolation valve is controlled by an associated safety-class electric solenoid valve. Normally, the solenoid valve is energized in the open position allowing instrument air supply to the VPS isolation valve actuator to hold the pistons in an open position. Under SCIC trip conditions, the SCIC de-energizes the solenoid valve that in turn closes the solenoid valve, blocks the instrument air flow, and allows existing air in the inner chamber to vent, which then causes the isolation valve to close via a spring closure mechanism. The solenoid valve operation is fail-safe in the respect that a loss of electrical power or loss of instrument air would cause the desired safety function to occur (i.e., the isolation valve would close). Safety-class filters are required on the instrument air lines to the actuators on the isolation valves to prevent buildup of foreign material and preclude potential valve malfunction. A general-service instrument air dryer eliminates concerns for moisture in the instrument air line.

The VPS also contains two safety-class gauge root valves, located on instrument tap lines, between the VPS hard piping and the VPS safety-class instrumentation. These valves are required to be in the open position for the VPS safety-class instrumentation to perform its functions, and they are rated at 150 lb/in² gauge internal pressure.

**Deionized Water Isolation**  
The VPS line from the MCO long process tube also contains two electropneumatically operated safety-class isolation valves. During flushing of the PWC system line, the valves are held open by instrument air but otherwise remain closed. Following an SCIC trip condition requiring SCHe actuation, the isolation valves move to the closed position to establish and maintain a portion of the pressure boundary required for the SCHe system safety function.
Each safety-class isolation valve is controlled by an associated safety-class electric solenoid valve. For flushing operations, the solenoid valve is energized in the open position allowing instrument air supply to the VPS isolation valve actuator. Under closed or SCIC trip conditions, the SCIC de-energizes the solenoid valve, closing the solenoid valve and blocking the instrument air flow, which then causes the isolation valve to close via a spring closure mechanism. The solenoid valve operation is fail-safe in the respect that a loss of electrical power or loss of instrument air would cause the desired safety function to occur (i.e., the isolation valve would close). Filters are also required on the deionized water valve instrument air lines.

**Process Piping** Safety-class flexible piping provides a flow path between the MCO process connectors and the VPS hard piping mounted on the process hood support stand. The flexible piping forms a portion of the primary confinement boundary during times when the MCO process plugs are open. The flexible pipe has high integrity end fittings that are connected to the process connectors and to the process hood support stand VPS piping. The flexible pipe is made of Teflon with an anti-kink cover and a protective metal armor and has a 1-in inner diameter with a design pressure of 150 lb/in² gauge.

The VPS also has safety-class hard piping on the process hood support stand. This piping runs from the connection with the flexible piping to the isolation valves and (in the case of the MCO vacuum port connection) then to the flange connector at the process hood support stand that connects to the PES. The 1-in piping is made of stainless steel and forms a portion of the MCO primary confinement boundary. The pipe is rated for 150 lb/in² gauge internal pressure.

**Connection Capability** Safety-class MCO process connectors provide a leak-tight confinement attachment between the MCO shield plug process ports and the flexible piping that connects to the VPS equipment installed on the process hood support stand. The process connectors also provide MCO connection points for the PWC tubing. The connectors are manually bolted to the MCO shield plug — one connector by five bolts and the other by four bolts — to ensure installation on the correct process port. Following installation, the mechanical seal connections must pass a pressure test before CVDF operations may proceed. The space between the double O-rings on the process connectors can be leak tested to verify the connectors are leak tight. Internal to the connectors is a socket mechanism that is used to open and close the MCO port plug. This mechanism is designed so the MCO plug cannot be removed from the port while the connector is in place. The connectors are specially designed for this application and are rated for an internal pressure of 150 lb/in² gauge.

**Pressure Detection** VPS safety-class instrumentation provides signals used by the SCIC system to initiate automatic protective actions. The protective actions, depending on the process upset detected by the instruments, involve multiple systems and components. For a more detailed description of SCIC protective actions, see Section B4 3.1.2. There are two different types of pressure transmitters. In addition, there are pressure indicators. One type of safety-class pressure transmitter measures pressure over the range of -14.7 lb/in² gauge to +12 lb/in² gauge for specific

---

1Teflon is a trademark of Du Pont de Nemours & Company
MCO processing steps  The other type of pressure transmitter has a range of 0 to 100 torr and is used when the final stages of processing indicate most of the water has been removed from the MCO and the VPS is capable of reaching a vacuum below 12 torr. Both types of pressure transmitters are installed on the VPS hard piping between the connection from the flexible line to the MCO filtered process exit port and the VPS safety-class isolation valves in a redundant arrangement. Each transmitter signal is independently sent to the SCIC system.

Two safety-class local pressure indicators, which indicate MCO pressure, are also provided in the VPS. The redundant indicators are installed in the same location as the pressure transmitters. The indicators provide local indication only and are qualified to be operational after the DBE. All pressure instrumentation is rated at 150 lb/in² gauge internal pressure.

Vent Path The 30 lb/in² gauge vent path has been provided as backup in the remote possibility that the MCO pressure rise exceeds the capability of the SCHe system vent path. The vent system consists of a combination safety-class rupture disk and spring-type, safety-class check valve that will relieve pressure above 30 lb/in² gauge. The system is connected to the MCO filtered process exit port and vents into the local exhaust duct to ensure hydrogen coming from the MCO is diluted below the lower flammability limit. The 30 lb/in² gauge vent system is a redundant provision for protection of the MCO 150 lb/in² gauge rupture disk. Engineering calculations that support the design of the 30 lb/in² gauge vent path are provided in SNF-4023, *CVD External Hydrogen Management Evaluation*, and are listed in SNF-3001.

System Operability, Calibration, and Testing Safety-class VPS components are designed to be functionally tested for actuation given a simulated process condition input (see Section B4.3.1.4 for additional functional information). System operability is verified by surveillance of the system’s operability status and component states (e.g., valve positions and pressure readings) before enabling the system for each MCO process cycle. Additional periodic surveillance is required if the system is to be operated for an extended period beyond one normal processing cycle. Periodic testing of VPS safety-class components is dictated by the requirements of the individual components, according to the respective manufacturer’s recommended schedules and practice, and is administered by controlled procedures for all safety-class and safety-significant SSCs.

Recalibration of signals from the pressure transmitters to the SCIC system is maintained according to the respective manufacturer’s recommended schedule and practice. The VPS is designed with calibration and test connections to enable periodic in-service measurement and calibration of all setpoints and adjustments that affect the manner in which the VPS performs.

Single-Failure Evaluation The safety-class portion of the VPS has been evaluated by single-failure analysis in SNF-4290. This analysis shows that safety-class SSCs meet the single-failure criterion of DOE Order 6430.1A and a single random failure of the VPS safety-class components is tolerable. In general, operators will be aware of any system leakage because the system will not pump down to the required pressure, and action will be taken to eliminate the problem. The fact that there are two pressure transmitters of each type with different ranges.
allows a one-over-one check and SCIC system channel checks, train A to train B, that will immediately show where recalibration or pressure transmitter replacement is needed.

**Seismic Qualification** All safety-class components of the VPS required to perform the safety-class primary confinement functions are designed and qualified for performance category 3. The safety-class components, except for the flexible connection hoses, are mounted on the MCO or the process hood support stand, which are both seismically qualified for performance category 3. The flexible hoses in the VPS ensure there will be no line breakage during a seismic event.

**B4 3 5 5 Controls (Technical Safety Requirements)** The following assumptions associated with the VPS require TSRs to ensure performance of the safety functions:

- The VPS isolation valves have been tested and are operational prior to opening the MCO port valves whenever the VPS process port connectors are attached to the MCO.
- The deionized water isolation valves have been tested and are operational prior to opening the MCO port valves whenever the VPS process connectors are attached to the MCO.
- MCO process connectors are securely attached to the MCO and have been pressure-tested according to procedures.
- All pressure transmitters that provide signals to the SCIC system have been tested and are operational whenever the VPS process connectors are attached to the MCO.
- The pressure indicators have been calibrated and are functional prior to opening the MCO port valves whenever the VPS process connectors are attached to the MCO. The 30 lb/in² gauge vent line is connected to the filtered process exit port connector and is operational prior to processing whenever the VPS process connectors are attached to the MCO.

**B4 3 6 General-Service Helium System Safety-Class Components**

**B4 3 6 1 Safety Function** The general-service helium system has the overall safety functions of providing helium at a safe pressure with appropriate flow monitoring to different parts of the MCO processing systems, and providing fail-closed general-service helium system isolation valves that form part of the extended pressure boundary for the MCO in the event that process upset conditions are detected by the SCIC system and an ISO & PURGE occurs. Components of the general-service helium system have been analyzed in the Chapter B3 0 accident analyses to.
perform certain safety functions for four specific event scenarios: the thermal runaway reaction, MCO overpressurization, internal hydrogen explosion, and external hydrogen explosion accidents.

The general-service helium system components perform the following safety functions for these accidents:

- **MCO overpressurization** — Isolation of the MCO by the general-service helium system components is a safety-class function for this accident. Safety-class filters on the instrument air lines to the isolation valve actuators ensure functional operation. The general-service helium system safety-class safety relief valves also prevent an MCO overpressurization accident that could otherwise result from helium overpressurization of the MCO.

- **Thermal runaway reaction** — The general-service helium system components provide a safety-class function of providing isolation of the general-service helium line (connected to the VPS line to the MCO) when the safety-class valves are de-energized by the SCIC system and, in conjunction with the piping, form a portion of the extended pressure boundary for the MCO. Filters on the instrument air lines to the isolation valve actuators ensure functional operation.

- **Internal hydrogen explosion** — Isolation of the MCO by the general-service helium system components is a safety-significant function for this accident. In addition, the general-service helium system provides low helium flow signals to the SCIC system as a key process parameter to initiate an ISO & PURGE that prevents safety-significant consequences from the internal hydrogen explosion accident. Filters on the instrument air lines to the isolation valve actuators ensure functional operation.

- **External hydrogen explosion** — In this accident, isolation of the MCO by the general-service helium system is a safety-significant function. A portion of the extended pressure boundary of the MCO is provided by the general-service helium system isolation valves and piping.

The safety-class components in the general-service helium system have been designated as such because of their safety-class and safety-significant functions for process control and accident prevention. While the MCO is connected to the VPS, a safety-class confinement boundary is required during accident conditions. As a consequence, the MCO envelope is extended to include the isolation valves within the general-service helium system piping that connects to the VPS piping extending from the long process tube MCO port connector. The flow elements/flow-indicating transmitters that provide signals to the SCIC system also are designated safety class because they must provide reliable information under processing conditions to the SCIC system.

**B4 3 6 2 System Description** — The general-service helium system is located both inside and outside the CVDF. Up to two leased helium tube transporters are parked on a concrete pad located on the west side of the facility. A helium pipe penetrates the west wall and connects to a
helium header running north-south along the full length of the east wall of the transfer corridor. Branch piping connects each process bay to the helium header, and flexible piping is used to distribute the helium to the PES, the process hood, support stand, and VPS, and the SCHe system. Within the process hood support stand, the general-service helium is hard piped to the VPS piping connected to the MCO long process tube connector.

In addition to piping, the general-service helium system includes pressure regulators, pressure and flow indicators, flow control valves, and pressure relief valves. System control and alarm functions are provided by the MCS (see Section B2.5.9.1). Check valves are used to prevent backflow of one process bay from reaching the other process bays. The two tube transporters provide a minimum 2-week supply of helium at the maximum process demand rate. Continuous operation is provided by allowing an empty tube transporter to be disconnected and replaced while drawing helium from the other. More detailed general-service helium information is provided in Figures B2-17 and B2-20 and in SNF-3067, _SNF Project Cold Vacuum Drying Facility General Service Helium System Design Description_.

The safety-class portion of the general-service helium system is located within the process hood support stand and where the high pressure safety relief valves are placed on the line from the tube trailer. The following components of the general-service helium system are designated safety-class:

- Hard piping on the process hood support stand from the connection to the VPS line to the opposite end, where the piping connects to the flexible hose from the PES
- Redundant fail-closed isolation valves with associated instrument air filters
- Redundant pressure relief valves on the CVDF general-service helium supply line in the transfer corridor
- Redundant helium flow elements/flow-indicating transmitters located on the process hood support stand

The portion of the system between the MCO and the isolation valves forms part of the safety-class pressure boundary, when the MCO is isolated from the process systems by the SCIC system. The redundant flow elements/flow-indicating transmitters support the SCIC system by providing reliable helium flow information. Redundant safety relief valves protect against general-service helium system regulator failures that could cause MCO overpressurization.

**B4 3 6 3 Functional Requirements**

The functional requirements needed for the general-service helium system safety-class components to perform their safety functions are as follows:

- **General-Service Helium Isolation** — Provide fail-closed isolation valves (with instrument air line filters) to seal off the MCO from the general-service helium system normal inlet and maintain the MCO extended pressure boundary.
- **Process Piping** — Provide leaktight process piping to the VPS line (long process tube connection)

- **Helium Flow Detection** — In addition to ascertaining that helium flow to the MCO is sufficient, provide a low flow signal to the SCIC system that will initiate MCO isolation and activate the SCHe system if the helium flow is less than the setpoint

- **Helium Overpressurization Protection** — Ascertan that the general-service helium system main supply header's safety-class safety-relief valves are operational, set at the correct pressure, and are reliable

- **System Operability, Calibration, and Testing** — Ensure the general-service helium system is operable, safety-class components are functioning as required, and flow readings are reliable

- **Single-Failure Evaluation** — Ensure safety-class portions of the general-service helium system are single-failure proof

- **Seismic Qualification** — Provide leaktight general-service helium system (safety-class portion) by use of seismically qualified isolation valves and piping

**B4 3 6 4 System Evaluation** The general-service helium system safety-class components have been designed to meet and perform their functional and safety requirements. System evaluations of each of the functional requirements are discussed separately below.

**General-Service Helium Isolation** The general-service helium line has two electropneumatically operated safety-class isolation valves mounted to the process hood support stand and located in the piping that connects to the VPS line that runs to the MCO (long process tube) connector. These valves are identical to the ones used for isolating the VPS. The 1-in stainless steel, gas-operated valves are rated at 150 lb/in² gauge. During normal drying operations, the valves are held open by instrument air. Following an SCIC trip condition that initiates an ISO & PURGE, the general-service helium isolation valves move to the closed position (until reset) to establish and maintain a portion of the pressure boundary required for the SCHe system safety function. The valves are also provided with local position indication.

The isolation valves are a ball-type design that use a cylinder and piston air actuator to rotate the ball shaft. Each safety-class isolation valve is controlled by an associated safety-class electric solenoid valve. Normally, the solenoid valve is energized in the open position, allowing instrument air supplied to the general-service helium system isolation valve actuator to hold the pistons in an open position. Under SCIC trip conditions, the SCIC de-energizes the solenoid, which in turn, closes the solenoid valve, blocks the instrument air flow, and allows existing air in the inner chamber to vent out, which then causes the isolation valve to close via a spring closure mechanism. The solenoid valve operation is fail-safe in the respect that a loss of electrical power or loss of instrument air would cause the desired safety function to occur (i.e., the isolation valve...
would close) Safety-class filters are required on the instrument air lines to the actuators on the isolation valves to prevent buildup of foreign material and to preclude potential isolation valve malfunction. A dryer has been provided in the general-service instrument air system to eliminate concern for moisture buildup in the instrument air lines.

**Process Piping** Safety-class hard piping for the general-service helium system is located on the process hood support stand. At one end the hard pipe is connected to the flexible hoses from the PES, and at the other end the line joins the VPS hard piping coming from the MCO connector (long process tube). The piping is made of stainless steel and is 1-in in diameter. A major function of the piping is to form an extended primary confinement boundary for isolation of the MCO. The piping must be leak tight.

**Helium Flow Detection** Two safety-class flow element/flow-indicating transmitters are located in the hard piping line outside the MCO isolation valves and these components form the interface with the SCIC system for helium flow monitoring. These flow elements/flow-indicating transmitters are safety-class, however, they have a safety-significant function for the internal hydrogen explosion accident. The flow elements/flow-indicating transmitters are linked to the SCIC system mode switch and the required helium flow varies with each specific process step. If helium flow is not sufficient (above the setpoint) for a given process step, the SCIC system will initiate an ISO & PURGE.

Ascertaining that the general-service helium system flow is above the setpoint is necessary for the operators to be confident that the MCO processing steps are being carried out as required. Therefore these flow elements/flow-indicating transmitters also provide essential information remotely to the MCS for CVDF operations.

**Helium Overpressurization Protection** Two safety-class safety relief valves are provided in the 0.75-in stainless steel line connected to the leased tube trailers that supply helium. These safety relief valves are mounted in series and are set at 25 lb/in² gauge to ensure the MCO cannot be overpressurized in the unlikely event that the regulator and relief valves supplied with the tube trailers fail and the full pressure of the helium tanks is applied to the general-service helium line. Flow capacity of each redundant relief valve to preclude pressurization of the MCO above 150 lb/in² gauge is documented in calculation ME1-2621-ME-03, *Size the Helium Gas Piping for the Cold Vacuum Drying Facility*.

**System Operability, Calibration, and Testing** Two helium tube trailers are provided to ensure general-service helium system reliability. Both trailer tube systems can be connected to the general-service helium line but only one trailer is in use. The other acts as a standby supply. Surveillance and in-service inspections of the safety-class and safety-significant general-service helium system components are conducted in accordance with the manufacturer’s recommendations for respective components. These components are using administrative control for all testing, surveillance, and maintenance, and these activities are performed using controlled procedures. System operability is verified by surveillance of the system’s component states before.
enabling the system for each MCO process cycle. Additional surveillance is required if the system is to be operational beyond one normal processing cycle.

Safety-class general-service helium components that provide information to the SCIC system are designed to be functionally tested for operability using a simulated process condition input (see Section B4 3 1 4 for additional functional information). All safety-class and safety-significant components are calibrated according to the manufacturer's procedures and standards. Calibration and test connections are provided to enable in-service testing and calibration of equipment.

**Single-Failure Evaluation** The general-service helium system safety-class components have been evaluated by single-failure analysis (SNF-4290). A single random failure of the general-service helium system safety-class components has been shown to be tolerable. The non-safety class MCS also provides surveillance of the general-service helium system flow rates, which provides added assurance that any system malfunction will be detected early and responded to by operators.

**Seismic Qualification** The general-service helium system safety-class isolation valves and piping are seismically qualified and mounted to meet performance category 3 requirements. The isolation valves are electropneumatically operated valves that (1) fail closed upon loss of control power or instrument air, (2) ignore all other non-safety control signals and remain closed until reset by the SCIC system, and (3) provide reliable, leak-tight operation. These safety-class isolation valves are mounted on the process hood support stand, which is also seismically qualified for category 3 performance. The helium flow element/flow-indicating transmitters are not performance category-3 (seismically qualified) because they are not located within the safety-class isolation boundary and would be isolated from the MCO in a seismic event. The main supply header safety-class safety relief valves are seismically qualified and are in addition to a general-service safety relief valve provided on the helium tube trailers.

**B4 3 6 5 Controls (Technical Safety Requirements)** The following assumptions associated with the general-service helium system require TSRs to ensure performance of the safety functions:

1. The general-service helium isolation valves have been tested and are operational prior to opening the MCO port valves whenever the VPS process port connectors are attached to the MCO.
2. Flow elements/flow-indicating transmitters that provide signals to the SCIC system are functional prior to making process connections to the MCO.
3. The general-service helium line safety-class pressure relief valves are set at the correct pressure (25 lb/in² gauge) that will preclude MCO overpressurization.
Functional tests and leak testing of the isolation valves have been performed on an appropriate schedule

Calibration of the flow elements/flow-indicating transmitters has been performed on an appropriate schedule

**B4 3 7 Process Water Conditioning System Safety-Class Components**

**B4 3 7 1 Safety Function** The PWC system has an overall safety function of isolating the PWC system line to the MCO process port should process upsets occur. Components of the PWC system are analyzed in the Chapter B3 accident analyses to prevent or mitigate the safety consequences of a thermal runaway reaction, MCO overpressurization, external hydrogen explosion, internal hydrogen explosion, gaseous release, and liquid release.

The PWC system components perform the following safety functions for the above accidents:

- **MCO overpressurization** — PWC system isolation valves, instrument air line filters for isolation valves and piping are credited with a safety-class function of isolating the MCO for the MCO overpressurization accident.

- **Thermal runaway reaction** — The PWC system isolation valves and hard piping provide the safety-class function of isolating the PWC system line to the MCO and forming a portion of the extended pressure boundary for the MCO. Filters on the instrument air lines to the isolation valve actuators ensure functional operation.

- **External hydrogen explosion** — The PWC system isolation valves and hard piping provide the safety-class function of isolating the PWC system line to the MCO and forming a portion of the extended pressure boundary for the MCO. Filters on the instrument air lines to the isolation valve actuators ensure functional operation.

- **Internal hydrogen explosion** — PWC system isolation fulfills a safety-significant function for the internal hydrogen explosion.

- **Gaseous release** — Design and installation of the PWC drain line that runs through the process bays prevents safety-significant gaseous leaks into the bays that could result from corrosion and environmental conditions.

Components of the PWC system have been designated safety-class or safety-significant because they have safety-class or safety-significant functions for process control and accident prevention. The PWC system is connected to the MCO long process tube port, and during...
accident conditions, a safety-class confinement boundary must be established. When the isolation valves of the PWC system are closed, they become part of the extended isolation boundary for the MCO.

**B4 3 7 2 System Description** The PWC system is general service (except for the specific components listed in this subsection) and has two major purposes. First, the system receives bulk water from the MCO during draining operations and provides a vacuum source for aid in MCO water removal. Second, the PWC system conditions the MCO drain water by removing radioactive particulate and soluble species using filtration and ion exchange. The system is designed to service only one MCO from any one of the four bays at a time, so priority determination and scheduling are important. The PWC system vacuum source is a water jet ejector that requires continuous water circulation through a process loop arrangement. This jet ejector system has two water pumps (one for backup) to provide a vacuum for draining the MCOs, VPS condenser tanks, and the tempered water (annulus) system, or a cask-MCO annulus. Water is collected in receiver tanks, processed through an ion exchange module, and transferred to a storage tank to await return shipment to the K West Basin. The geometry of the tanks in the ion exchange modules provides defense-in-depth protection (as discussed in Chapter B6 0) to ensure that accumulation of a quantity of fissionable material that could result in an effective neutron multiplication factor ($k_{eff}$) of greater than 0.95 will not occur. Refer to Figure B2-22 and SNF-3082, *SNF Project Cold Vacuum Drying Facility Process Water Conditioning System Design Description*, for more detailed information.

The calculated operational limit for the mass of plutonium in an ion exchange module is 200 g each. The ion exchange modules are removed from service before they accumulate 80 nCi/g of transuranic material even if they have used only a fraction of their ion removal capacity. This is an operational convenience that allows the ion exchange modules to be economically disposed of as low-level waste. The criticality limit for loading of the ion exchange modules is identified in Section B6 3 5 as 875 kg of 1 25 wt% enriched UO$_2$.

An intact MCO pressure boundary is provided, in part, by the piping and the redundant isolation valves that will fail closed to isolate the MCO from the PWC. The SCIC system seismic detector is interlocked to the two water pumps, so the pumps will be de-energized in a seismic event. This interlock is not credited with a safety function and is general service.

The safety-class MCO isolation portion of the general-service PWC system is located within the process hood support stand. The components of the PWC system that are designated safety-class are as follows:

- Redundant fail-closed isolation valves with associated instrument air filters
- All piping, from the flexible piping and connection to the MCO long process tube port connector, to and including the hard piping that connects with the CVDF transfer line
The PWC drain line is a single pipe header that runs through all bays to the process water tank room for MCO free water draining. This pipe is safety-significant for confinement.

**B4 3 7 3 Functional Requirements** The functional requirements needed for the PWC system safety-class and safety-significant components to perform their safety functions are as follows:

- **PWC System Isolation** — Provide fail-closed isolation valves (with instrument air line filters) to seal off the MCO from the PWC system and maintain the MCO extended pressure boundary.

- **Process Piping** — Provide leaktight process piping from the connection with the facility PWC transfer line to the MCO long process tube connector port of the VPS.

- **PWC Transfer Line** — The PWC system transfer line to the receiver tanks shall be designed and installed to prevent random leaks caused by corrosion or environmental conditions.

- **System Operability, Calibration, and Testing** — Ensure the PWC system is operable and safety-class and safety-significant components are functioning as required.

- **Single-Failure Evaluation** — Ensure safety-class portions of the PWC system are single-failure proof.

- **Seismic Qualification** — Provide leaktight PWC system (safety-class portion) by use of seismically qualified valves, interlock trips, and piping.

**B4 3 7 4 System Evaluation** The safety-class features of the PWC system are accomplished by components that have been designed to meet and perform their functional and safety requirements. Each of the functional requirements are discussed separately below.

**PWC System Isolation** The PWC system line from the MCO (long process tube) connector has two electropneumatically operated safety-class isolation valves mounted to the process hood support stand. The 1-in stainless steel gas-operated valves are rated 150 lb/in² gauge. During the normal MCO draining and flushing operations, the valves are held open by instrument air. Following an SCIC trip condition that results in an ISO & PURGE, the PWC system isolation valves lock in the closed position (until reset) to establish and maintain the pressure boundary required for the SCHe system safety function. The valves also provide local position indication.

The isolation valves are a ball-type design with Teflon seats to accommodate particulate carried over from the MCO. These valves use a cylinder and piston air actuator to rotate the ball shaft. Each safety-class isolation valve is controlled by an associated safety-class electronic solenoid valve. Normally, the solenoid valve is energized in the open position, which allows...
instrument air supplied to the PWC system isolation valve actuator to hold the pistons in an open position. Under SCIC trip conditions, the SCIC de-energizes the solenoid, which in turn closes the solenoid valve, blocks the instrument air flow, and allows existing air in the inner chamber to vent out, which then causes the isolation valve to close via a spring closure mechanism. The solenoid valve operation is fail-safe in that a loss of electrical power or loss of instrument air would cause the desired safety function to occur (i.e., the isolation valve would close). Safety-class filters are required on the instrument air lines to the actuators on the isolation valves to prevent buildup of foreign material and to preclude potential isolation valve malfunction. A dryer has been provided in the general-service instrument air system to eliminate moisture buildup in the instrument air lines.

**Process Piping** Safety-class piping for the PWC system is located on the process hood support stand and includes both hard and flexible piping that connects with the MCO long process tube connector. At one end, hard piping (with isolation valves in the line) is connected to the hard piping from the CVDF PWC system transfer line. At the other end, the hard piping connects to flexible piping that is connected to the MCO port connector. The hard piping is made of stainless steel and has a 1-in inside diameter. The flexible pipe is made of Teflon, with an anti-kink cover and a metallic armor, and has a 1-in inner diameter with a design pressure of 150 lb/in² gauge. A major function of the piping is to form an extended primary confinement boundary for isolation of the MCO.

**PWC Transfer Line** A 1-in stainless steel transfer line runs from each of the bay process hood stations to the ejector on the PWC system. The line is mounted 23 ft above the floor, and installation is designed and secured to preclude damage from fretting and/or expansion. The use of stainless steel ensures there will be no corrosion over the design life of the facility (5 years). All line joining is conducted according to standard procedures for stainless steel that are proven by a long history of working with this material. The transfer lines are inspected for leakage after joining.

**System Operability, Calibration, and Testing** For operations, the PWC system has two water recirculation pumps to provide confidence that the system will be available for MCO processing. Periodic testing of the PWC system safety-class and safety-significant components is dictated by the requirements of the individual components, according to the manufacturer's recommended schedule and practice. The safety-class and safety-significant components of the PWC system are under administrative control for all testing, surveillance, and maintenance, and these activities are performed using controlled procedures. Safety-class PWC system components that provide information to the SCIC system are designed to be functionally tested for activation using a simulated process condition input (see Section B4 3 1 4 for additional functional information).

**Single-Failure Evaluation** The PWC system safety-class components have been evaluated by single-failure analysis in SNF-4290. A single random failure of the PWC system safety-class components has been shown to be tolerable.
Seismic Qualification  The PWC system safety-class components and piping are rated above the required pressure and are seismically qualified and mounted to meet performance category 3 requirements. The isolation valves that are electropneumatically operated (1) fail closed upon loss of control power or instrument air (2) ignore all other nonsafety control signals and remain closed until reset by the SCIC system and (3) provide reliable leaktight operation. The safety-class isolation valves and piping are mounted on the process hood support stand, which is also performance category 3 seismically qualified.

The safety-significant PWC system transfer tubing is mounted on the safety-significant CVDF building structure. The piping and mounting are in accordance with category 2 seismic performance category and is a credited design feature.

B4 3 7 5 Controls (Technical Safety Requirements)  The following assumptions associated with the PWC system require TSRs to ensure performance of the safety functions:

- Safety-class PWC isolation valves have been tested and are operational prior to opening the MCO port valves whenever the VPS port connectors are attached to the MCO.

B4 4 SAFETY-SIGNIFICANT STRUCTURES, SYSTEMS, AND COMPONENTS

As identified in Chapter B3, many of the safety-class SSCs also perform safety-significant functions. Those SSCs, including their safety-class and safety-significant functions, are discussed in Section B4 3 and are not repeated here. The SSCs credited with only a safety-significant function in Chapter B3 0 and detailed in this section are listed below:

- Building features
- Process general supply/exhaust HVAC system (HVACD system) components
- Process bay local exhaust HVAC and process vent system (HVACC/PV system)
- Process bay recirculation HVAC system (HVACB system) components
- Reference air system components
- Instrument air system components
- Standby power system
- Specialty equipment and special tools

Safety-significant SSCs were designed and fabricated in accordance with the required codes and standards identified in Table B4-3. Safety-significant SSCs were designed, fabricated and procured to the same quality assurance program as safety-class SSCs (i.e., use of an approved vendor or specific dedication). Adequate specification of codes and standards exists for safety-significant SSCs, either specific identification of items (e.g., valves and instruments) via data sheets, code and standard specification for design, fabrication, and construction (e.g., bulk commodities) or specific design (cold vacuum drying specialty items). Engineered safety significant items were designed in the same fashion as safety-class items. Seismic qualification for...
safety-significant items to performance category 2 is adequate to demonstrate required functionality. All systems and components are subject to construction and performance testing subsequent to installation in the CVDF.

Safety-significant SSCs that must retain pressure boundary/structural integrity during or after a seismic event were designed for performance category 2 seismic loadings. These designs were performed in accordance with seismic accelerations specified in HNF-PRO-097, Engineering Design and Evaluation. There is no active safety-significant equipment required to operate after a seismic event. Anchorage of performance category 2 SSCs was designed to the requirements of WHC-SD-GN-DGS-30006, Seismic Design Guide for Safety Class 3 and 4 Equipment at the Hanford Site.

B4-41 Building Features

B4-41.1 Safety Function. The CVDF structure is analyzed in Chapter B3.0 to perform the following safety functions to mitigate safety-significant consequences from the bounding accident scenarios:

- The process bay area structure (process bays 2, 3, 4 and 5) and process water tank room structure provide a confinement function in conjunction with the process general supply and exhaust HVAC system and the process bay local exhaust HVAC and process vent system. The physical structure allows for confinement of radioactive material released in the process bay during processing operations and in the process water tank room during PWC pumping. Its passive presence allows for mitigation of the radioactive release from within the CVDF after the gaseous release, liquid release, external hydrogen explosion, internal hydrogen explosion, and MCO overpressurization accidents, as indicated in Table B4-8, by allowing the ventilation systems to maintain a negative pressure in the process bays and process water tank room during facility operations as indicated.

The CVDF process building also is assumed in Chapter B3.0 to perform the following safety functions in support of safety-class systems:

- The CVDF process bay structures provide performance category 3 resistance to natural phenomena hazard events to protect the process equipment and to accomplish 3-over-1 seismic qualification to preclude damage or impairment of safety-class systems or components. Compliance with 3-over-1 requirements is documented in HNF-4291, Seismic Adequacy Review of PC012 SCEs that are Potential Seismic Hazards with PC3 SCEs — CVF Facility. Of specific concern for 3-over-1 protection is the process hood support stand and its flexible piping connections to the process connectors attached to the MCO. The SCHe and the SCIC systems must also be protected from damage. These systems and components provide preventive or mitigative functions for the accident conditions. Protection of the safety-significant SSCs is also provided.

- The CVDF structure provides seismically qualified mounting locations for safety-class items. The process hood support stand and SCHe support racks are anchored to the floor.
- The CVDF structure supports the process bay bridge cranes which are considered important-to-safety Category C. These cranes are considered part of the building features.

B4 4 1 2 System Description The CVDF process building is classified as a nonreactor nuclear facility according to DOE Order 6430 1 A, Section 1300. The office area is a nonnuclear facility rated for office or business use in accordance with the Uniform Building Code (UBC) (ICBO 1994). The CVDF is a temporary structure with a processing design life of 5 years. The building code requirements are met as defined in the UBC (ICBO 1994) for a Group H-7 occupancy for the process bay and support areas and a Group B occupancy for the administrative office areas.

b-cvdf04 sur  B4-90 November 1999
The CVDF building is an above-grade structure with approximate overall dimensions of 230 ft long by 80 ft wide. There are four significant sections to the CVDF structure: process bays, transfer corridor, process water tank room, and administrative areas.

The process bay area (60 ft by 150 ft) consists of four process bays plus one unused bay, with an adjoining process water tank room (20 ft by 35 ft). The unused bay is not outfitted with cold vacuum drying equipment or mezzanines, but does have the SCIC seismic detector electrical panels mounted on the south wall. These areas are constructed as a single-story, steel-frame building with an exterior wall of precast concrete panels. The process support areas (20 ft by 150 ft) include the transfer corridor and adjacent rooms along with the second floor mechanical room. This area is constructed as a two-story, steel-frame building with an exterior wall of metal siding. The administrative area is an adjacent single-story, pre-engineered metal building with exterior skin of insulated metal panels. All roof decks are metal. The facility is constructed in accordance with the UBC (ICBO 1994) and DOE Order 6340 1A, with egress requirements conforming to NFPA 101, Life Safety Code. Facility layout is discussed in Chapter B2.0.

The structural systems typically were constructed from one or more of the following materials: 3,000 lb/in reinforced concrete with reinforcing steel and welded wire fabric, carbon steel structural steel (ASTM A36/A36M-97a), structural tubing (ASTM A500-96 Grade B), steel pipe (ASTM A53-97 Type E or S Grade B), welding material (AWS D1 1-96, E70XX electrode), common bolts (ASTM A307-94), high-strength bolts (ASTM A325-97), nuts (ASTM A563-96), and hardened washers (ASTM F436-93). All masonry and concrete designs comply with the current UBC (ICBO 1994) ACI-207, Mass Concrete, ACI-318, Building Code Requirements for Reinforced Concrete, ACI-224, Control of Cracking, ACI-349 Code Requirements for Nuclear Safety Related Concrete Structures, and ACI-350 Environmental Engineering Concrete Structures, where applicable, and Precast Concrete Institute standard MNL-17 Manual of Quality Control for Plants and Production of Architectural Precast Concrete Products.

The CVDF building was designed to adequately resist the effects of various load combinations (dead load, live load, and accident load or seismic and wind load). The governing documents utilized in determining load combinations for performance category 3 structures were:

The following load combinations were used to determine the demand on reinforced concrete members of the CVDF building

1. $D_e = 14D + 17L + 17H$
2. $D_e = D + L + H + T + E$
3. $D_e = 0.9\ [D + L + H + T + W_t]$
4. $D_e = D + L + H + E$
5. $D_e = D + 13W$
6. $D_e = 105D + 13L + 13H + 105T$
7. $D_e = 14D + 17L + 17H + 17W$
8. $D_e = 105D + 13L + 13H + 13W$

where

$D_e$ = demand
$D$ = dead load including collateral dead load where it produces the more critical condition
$L$ = live load including applicable crane impact loads snow load
$T$ = normal operational thermal load
$W$ = wind load
$W_t$ = wind load due to tornado
$E$ = earthquake load
$H$ = earth pressure load

Where any load reduced the effects of other loads, the load factor for that load was taken as zero unless that load can be demonstrated as always present and in such a case the load factor was taken as 0.9.

The following load combinations were used to determine the demand on structural steel members of the CVDF building

<table>
<thead>
<tr>
<th>Load Combination</th>
<th>Stress Limit Coefficient$^b$</th>

</tr>
</tbody>
</table>

$^b$Stress limit coefficients were applied to primary stress limits given in ANSI/AISC N690 Sections Q1 5 1, Q1 5 2, Q1 5 3, Q1 5 4, Q1 5 5, Q1 6, Q1 10 and Q1 11
$^c$For primary plus secondary stress the allowable limits were increased by a factor of 1.5
$^d$The stress limit coefficient in shear was not allowed to exceed 1.4 in members and bolts
where all symbols have the same meanings as above except

\[ H = \text{soil pressure, which shall be combined with live load in the combinations above} \]
\[ L = \text{live loads, including applicable crane impact loads but excluding snow or roof live loads} \]
\[ L_T = \text{larger of roof live load or snow load} \]

All load combinations were checked for the no live-load condition

The loads used in the design of the structures are listed in the Design Requirements Document (HNF-SD-SNF-DRD-002) The following design assumptions were incorporated in the structural analyses performed

- Allowable basic soil bearing pressure is 71.8 kPa (1,500 lb/ft²) based on sandy soils (soil classification SW, SP, SM, SC, GM and/or GC) in accordance with the UBC (ICBO 1994) Allowable soil bearing increases for depth and width of footing are applied for a maximum allowable pressure of 215.5 kPa (4,500 lb/ft²)
- Coefficient of friction between soil and foundation is 0.25
- Active soil pressure for unrestrained conditions is 561 kg/m²/m (35 lb/ft²/ft)
- Active soil pressure for restrained conditions is 882 kg/m²/m (55 lb/ft²/ft)
- Modulus of elasticity of soil is 1,380 kPa (200 lb/in²)

Static structural calculations were performed on the building to ensure structural loads (live loads and dead loads) along with severe wind loads (straight winds and tornado winds) were accounted for in the design and analysis. The tornado wind loads provided the largest load

*Secondary stresses that were used to limit primary stresses were treated as primary stresses. In no instance was the allowable stress permitted to exceed 0.70 \( F_u \) (in axial tension, 0.7 \( F_u \) times the ratio \( Z/S \) for tension plus bending \( F_u \) is the specified minimum tensile strength of the material \( Z \) is the plastic section modulus, and \( S \) is the elastic section modulus)
demands on the structure. Two special situations were identified and evaluated to ensure that the effects of tornado wind loads were properly accounted for:

1. When the tornado wind load is applied to the front of the process bay structure, the interior walls of the process bays will flex more than the exterior walls and cause an increase in the loads on the exterior walls. A calculation was performed to show that the walls can withstand this additional loading from the effect of differential rigidity between the walls.

2. The adjacent administration area building and transfer corridor wing are not designed to withstand tornado wind loads and potential interaction with the process bays was evaluated.

Structural calculations demonstrating adequacy of the facility design are included in SNF-3001.

Metal roof decks are stitch-welded with a membrane exterior. Roofing complies with the UBC Chapter 15 (ICBO 1994) for roof construction and covering, Chapter 16 (ICBO 1994), for roof and wind design, and Factory Mutual Class I or UL Class A for materials. For the administration area and process water tank rooms, Factory Mutual Data Sheet 1-28S and the Factory Mutual Approval Guide were used for acceptable materials selection and construction practices. The minimum roof slope is 0.25 in/ft.

Each process bay includes an overhead bridge crane with a capacity of 4,000 lb. The crane is designated performance category 1 and is designed in accordance with the criteria included in CMAA 74 Specifications for Top Running and Under Running Single Girder Electric Overhead Traveling Cranes Utilizing Under Running Trolley Hoist, with class D heavy service rating. The bridge trolley and hoist are driven by electric motors and are capable of operation from the ground floor or mezzanine level.

Differential pressure indication is provided in conjunction with the reference air system and is monitored and controlled by the automatic temperature control system. Additional safety-significant differential pressure switches with alarms to the control room are also provided. This will initiate operator action if process or HVAC changes must be initiated based on confinement status.

B4 4.1.3 Functional Requirements The following functional requirements are identified in the accident analyses described in Chapter B3.0.

Natural Phenomena The CVDF process bay structure must provide performance category 3 resistance to natural phenomena hazard events to protect the process equipment and to accomplish 3-over-1 seismic qualification to preclude damage or impairment of safety-class systems or components. Of specific concern for 3-over-1 protection are the process hood support stand and its flexible tubing connections to the process connectors attached to the MCO, the tempered water supply piping to the cask, the SCHe system, and the SCIC system. The process...
water tank room must provide performance category 2 resistance to natural phenomena hazards. The cask trailer must be positioned properly in the process bay based on calculational results for sway of the top of the MCO to protect process line connections and the process support stand.

Confinement To accomplish the confinement function, the passive presence of the physical structures must assist in mitigating a radioactive release within the CVDF after a DBA by allowing the ventilation systems to maintain a negative pressure in the process bays and process water tank room (as applicable) during facility operations. A specific leak rate for the structure is not critical to the passive confinement function required. The physical structure provides a space for the ventilation systems to exhaust. The ventilation system maintains a negative pressure within the process bay structures and the process water tank room, which is the safety parameter to be ensured. The structural confinement function is required while the process general supply/exhaust and process bay local exhaust HVAC systems are operating.

Bridge Crane The process bay crane shall provide 3-over-1 seismic protection and shall not be allowed to move over the cask-MCO during processing activities.

B4.1.4 System Evaluation The following evaluation of the process general supply/exhaust HVAC system demonstrates that the functional requirements for that system have been accomplished by the system design.

Natural Phenomena The process bays are designed and constructed as performance category 3 structures. The internal structural components (e.g., the mezzanines in the process bays) also are constructed as performance category 3 structures. The process water tank room is designed and constructed as a performance category 3 structure but is now designated performance category 2. The process support area is also designed and constructed as a performance category 2 structure, including the second floor mechanical equipment room. The administrative area is designed and constructed as a performance category 1 structure. There are distinct structural boundaries between performance category 2 and performance category 3 structural interfaces. Performance category 3 SSCs are isolated from the effects of performance category 2 SSC failures, such that the performance category 3 safety functions can still be accomplished under design basis conditions. The administrative building is structurally decoupled from the process bay structure and designed to fail away from the process bay area during a performance category 3 event. The control room is not needed for response after natural phenomena events.

The design basis natural phenomena loads and conditions applied to the structural design of the performance category 3 structures in the CVDF are tabulated in Table 1 of WHC-SD-SNF-DB-010 and listed in Table B1-1. These criteria are applied to SSCs based upon the performance category 2 or performance category 3 classification. Straight wind load and missile load criteria are given in WHC-SD-SNF-DB-010 Chapter 3. Tornado missiles have been eliminated from the CVDF requirements. DBE loads and spectra are given in WHC-SD-SNF-DB-010 Section 2.2. The design requirements for ashfall are given in WHC-SD-SNF-DB-010, Section 2.2. The CVDF does not have performance category 4 SSCs.
The design basis river flood level assuming a 25% breach of Grand Coulee Dam is 460 ft, compared with the 474-ft elevation of the CVDF site; therefore, flooding will not occur. The CVDF structures are designed to resist earth and groundwater loads in accordance with DOE Order 6430 1A and DOE-STD-1020-94 as administered using the guidance of HNF-PRO-097. Dynamic earth pressures were considered in the design of performance category 3 below-grade structures.

The CVDF secondary enclosure (process bays, performance category 3 and process water tank room, although now designated performance category 2) were structurally evaluated to seismic criteria for performance category 3 structures, with analyses documented in Calculation 96004 12 (Revision 1), Seismic Evaluation of Cold Vacuum Drying Facility Secondary Enclosure and Process Water Tank Room (Advent, 1997). These dynamic analyses used three-dimensional finite element modeling (ANSYS [SASI 1989]) to evaluate combined dead, live, and seismic loads. The CVDF seismic analysis modeled and analyzed the facility using the general purpose finite element program. The model is three-dimensional and consists of beam, shell, and mass elements as appropriate. Fixed-base static analyses results were used to address dead and live loads. A 20 lb/ft² roof live load mass was included in the seismic analysis to simulate the mass from the snow load.

In accordance with the recommendations of DOE-STD-1020-94 for performance category 3 facilities, equivalent static analyses may be performed if a single degree-of-freedom representation of the structure can be justified or if it can be shown that the fundamental frequency in each direction is greater than the cut-off frequency of the corresponding response spectrum. As these criteria cannot be met for the CVDF process bays nor for the process water tank room, a dynamic analysis method was used in the evaluation of the structures. Though a transient dynamic analysis is permitted, a response spectrum analysis approach is recommended by DOE-STD-1020-94 and was used here. The response spectrum technique requires modal analysis of the structure to determine its natural frequencies and the corresponding mode shapes. The dynamic characteristics of the structure are used in calculating structural responses such as displacements, forces and moments and stresses caused by externally applied seismic forces as defined by the response spectra.

HVAC duct systems and other mechanical and electrical systems attached to the CVDF structures have been addressed in the seismic analysis by including their mass in the dead load inertia. By definition the rigid equipment items that are a part of these systems do not require a coupled analysis with the primary structure. The flexible (i.e., less than 33 Hz) components of these systems (e.g., HVAC ducting) contribute less than 1% to the mass of the primary structure, and consequently, according to the guidance offered in ASCE-4-86, Seismic Analysis of Safety-Related Nuclear Structures and Commentary on Standard for Seismic Analysis of Safety-Related Nuclear Structures, coupling between these secondary systems and the primary structure model is not necessary.

A fixed base seismic analysis was performed because the building foundation is shallow and the response spectra include the effects of free-field soil amplification and are peak-broadened to
account for soil–structure interaction-induced frequency shifts. A fixed base analysis neglects the benefits of foundation scattering (kinematic interaction) and radiation damping. The potentially detrimental effects of rocking modes induced by inertial soil–structure interaction also are excluded in this approach; however, these effects are insignificant for low buildings. The peaks of the response spectra have been broadened in the high frequency range (conservatively) to address the potential for frequency shifting associated with soil–structure interaction. This peak-broadening of the response spectra was performed in response to the requirements of DOE-STD-1020-94, which states that it is permissible to ignore the beneficial effects of soil–structure interaction and assume that the DBE ground motion applies at the foundation level of the structure, provided that any frequency shifting (primarily of the fundamental frequency of the structure) caused by soil–structure interaction is considered. The results of a multimodal three-dimensional seismic analysis do not readily allow for the identification of a single "fundamental frequency," and the extent of frequency shifting caused by soil–structure interaction is not known, so a conservative broadening of the response spectra was performed for all frequencies above that corresponding to the peak.

In accordance with the recommendations of DOE-STD-1020-94, the response spectra correspond to response level 3 damping because such damping is expected to be reached before structural failure. The response level 3 damping value recommended for welded and friction-bolted metal structures is 7%. The response level 3 damping value recommended for prestressed concrete structures is also 7%. Consequently, the response spectra (Figure B1-11) used are taken from WHC-SD-SNF-DB-010 for 7% damping.

The confinement requirements of maintaining a differential pressure do not apply for the performance category 3 DBE event, therefore, there is no limit to the amount of acceptable cracking. DOE-STD-1020-94 states that when evaluating the structural adequacy of the SSC, response level 3 damping may be used in elastic response analyses independent of the state of response actually reached because such damping is expected to be reached before structural failure. In addition, $F_p$, the inelastic energy absorption factor, is conservatively taken as one

Seismic response from modes with frequencies larger than one-half the zero period acceleration frequency, $f_a$, is calculated in accordance with ASCE-4-86. For each direction of seismic excitation, significant (mode coefficient ratio equal to or greater than 0.01) structural modes with frequencies less than the 16 5 Hz threshold frequency (flexible modes) are combined using the grouping method of NRC Regulatory Guide 1.92, Combining Modal Responses and Spatial Components in Seismic Response Analysis, as recommended in ASCE-4-86. Flexible modes are divided into groups in which the highest frequency of any mode in the group is less than or equal to 1.1 times the lowest frequency of any mode in the group. Groups are formed beginning with the first mode of the structure and ascending through the remaining flexible modes in order of frequency. Each flexible mode is contained in only one group. Responses from modes that fall into a particular group are summed absolutely to obtain the response of that group. Responses from groups are combined by taking the square root of the sum of the squares.
DOE-STD-1020-94 requires that the demand due to accidental horizontal eccentricity be included in the total seismic response. This requirement is included to account for the possible added effect of inclined seismic waves. The accidental eccentricities are specified as equal to 5% of the building dimension in each of the two horizontal directions. The response from accidental eccentricity is combined absolutely with the modal and spatial combinations response.

Response of the CVDF finite element model to seismic loading identifies drift and demand/capacity results as discussed in the following paragraphs. DOE-STD-1020-94 specifies an allowable story drift of 0.010 times the story's height when both shear and flexure contribute to drift and 0.004 times the story's height when shear deflection is the primary contributor. The maximum lateral displacement of any node in the model is 0.431 inches, well below 0.72 inches (0.004 x 180 inches [height to mezzanine level]).

In accordance with DOE-STD-1020-94, demand/capacity evaluation for reinforced concrete components of CVDF performance category 3 structures are evaluated according to the specifications of ACI 349-90 and structural steel components are evaluated according to the specifications of ANSI/AISC N690. For the precast, prestressed, reinforced concrete wall panels, final design was accomplished by the panel vendor. The seismic analysis provided load requirements on the panels, panel-to-panel connections, panel-to-footing connections and attachments to the wall that must be sustained for the D + L ± S (where D is dead, L is live, and S is seismic) load combinations. For the panels themselves, the required level of prestress in the vertical direction was determined and the horizontal axial load and moment about a vertical axis that must be sustained were provided.

The steel beams and columns in the process cell area (secondary enclosure) and in the process water storage tank room were evaluated against the requirements of ANSI/AISC N690. The member categories are tabulated on Table B4-9. For each member category (real constant number), the results were reviewed for the two seismic load combinations (D + L + S, D + L - S) and the tornado wind load D + W, W, (where W, is tornado wind load). The maximum absolute value of each load combination was determined for each member category. Table B4-9 contains a summary of the demand/capacity ratios determined for combined axial and bending stresses in each member category.

The precast prestressed, concrete wall panels that enclose the process area and the process water storage tank room were evaluated against the requirements of ACI 349-90. Each of the walls is tabulated on Table B4-10. For each identified wall, the results of the two seismic load combinations (D + L + S and D + L - S) were reviewed. The maximum value of each load combination was determined for the elements composing each wall. Each wall panel was evaluated to determine the level of prestress required to ensure that in the prestressed direction (vertically) there would be no tensile stresses developed under the subject load combinations. A level of prestress was determined for each wall and provided in the seismic report (Advent 1996). Each panel also was evaluated to determine the combination of horizontal direct load and bending moment about the vertical axis that must be sustained by the horizontal rebar provided by the panel vendor. The horizontal loads and moments about a vertical axis are also provided in the seismic report for each wall.

*The ratio was computed based on maximum component forces of each group. The value of 1.07 was determined based on envelope loading. For actual member loading, value is determined to be less than 1.0.

Four members attached to wall line E were detached to reduce demand load.

*TS4X4X1/4 members were replaced with TS5X5X1/4 supporting mezzanine floor at elevation 34.9 m (114 ft 6 in) (new demand/capacity ratio was hand calculated as 0.585).

*Due to conservatism in ZPA, 2% over is acceptable in secondary members.

D = dead load
CM = column in the processing area
BM = beam on the mezzanine floor of the processing area
BR = beam on the roof of the processing area
BMR = beam in the water tank area
CMR = column in the water tank area
L = live load
S = seismic seismic demand from design basis earthquake

f_x = axial force along the member x-axis (lb/ft)
f_y = axial force along the member y-axis (lb/ft)
m_x = moment causing bending stress in the element x-direction (lb/ft)
m_y = moment causing bending stress in the element y-direction (lb/ft)
s_x = out-of-plane shear force on surface with x-direction normal (lb/ft)
s_y = out-of-plane shear force on surface with y-direction normal (lb/ft)
s = shear force
V = shear demand
D = dead load
L = live load
S = seismic load
F = force
M = momentum
Each wall panel also was evaluated for out-of-plane shear. An effective depth of 0.8 x 6 in = 4.8 in was used in the shear evaluation in accordance with the recommendations of ACI 349-90. The shear stresses were evaluated against a capacity limit of $\phi f'_c$, where $\phi = 0.85$ (in accordance with Section 9.3 of ACI 349-90 and $f'_c$ is 34,475 kPa (5,000 lb/in$^2$). Such a capacity limit (half the concrete's capacity in shear) forgoes the requirement for minimum shear reinforcement. The resulting demand/capacity ratios for out-of-plane shear on the wall panels are reported in Table B4-10. Five wall panel elements require out-of-plane shear reinforcement. They are the central 10-ft-wide panels in each of the bays between column lines 2 and 3, 3 and 4, 4 and 5, and 5 and 6 for the wall along column line E and the western-most panel of the wall along column line 2 (at column line F). The line E panels require out-of-plane shear reinforcement from an elevation of 109 ft, 0 in to 119 ft, 0 in, for a distance of 7 ft, 0 in from its northmost edge. For the panel along column line 2, the entire panel must be reinforced for the defined out-of-plane shear. The required level of out-of-plane shear that must be sustained by these panels is reported in Table B4-10.

The wall panel connection loads between the wall panels and the footing for each connection point are reported in the Table B4-10 tabulation of loads. Units are in pounds-force.

Member connections between steel members and member connections between steel members and the prestressed concrete wall panels were also analyzed. The following maximum absolute reaction forces were determined for the two load combinations ($D + L + S$ and $D + L - S$) and listed in Table B4-11. The connections specified in the wall panel design were extensively analyzed and are adequate for performance under seismic loadings.

Footings supporting performance category 3 structures were evaluated for the two seismic load combinations ($D + L + S$ and $D + L - S$). Results are summarized in Table B4-12.

Column base reaction loads were reviewed and the maximum tensile and shear forces are reported in Table B4-13. By comparison with the uplift ($F_u$) loads reported in structural analyses (see SNF-3001 Calculation MEI-2288-ST), uplift is controlled by the wind load combination. Therefore, by inspection, the base plates evaluation for the seismic load combinations are not necessary.

Structural recommendations resulting from the analyses were incorporated into the building design, thus providing a structure that meets seismic design requirements for performance category 3.

Additional dynamic analyses (Advent 1998) were conducted to develop in-structure seismic response spectra as a basis for seismic analysis of attached performance category 3 systems and equipment. The process hood support structure was subsequently redesigned and analyzed separately as a performance category 3 structure, as reported in SNF-5038 Seismic Analysis of CVDF Process Hood Support Structure and Mounting Frame.

F<sub>x</sub> = axial force along the member x-axis lb/in
F<sub>y</sub> = axial force along the member y axis lb/in
F<sub>z</sub> = axial force along the member z axis lb/in
Seismic evaluations of the transportation trailer system at the CVDF, with resulting effects on the CVDF floor slab, were conducted as documented in HNF-2179 Seismic Analysis of TN-DE&SH Cask Transportation Trailer System for the CVDF Facility. The cask transporter has been analyzed for sway on the rubber tires and suspension to demonstrate the safety-class process lines will not be damaged. The seismic rocking of the cask-MCO will not impose accelerations on the MCO greater than the analyzed transportation loads (HNF-SD-TP-SARP-017) because the suspension is active, the trailer is not anchored, and there are no impacts with other SSCs. No seismic tie-down of the trailer is required, but specific positioning requirements for the centerline of the cask-MCO are identified. The cask is to be centered on column row C of the building in the east-west direction and the centerline of the rollup door in the north-south direction. A tolerance of ± 4 in has been specified.

There is no defined operating basis earthquake for the CVDF and no small-magnitude near-field earthquake analysis has been performed. Performance category 2 earthquake loads are those given by the UBC (ICBO 1994) for seismic zone 2B for essential facilities (DOE-STD-1020-94). Engineering calculations demonstrating the adequacy of the performance category 2 CVDF structural design are listed in SNF-3001.

The site storm and flood water drainage system was designed for a performance category 3 event. This is in conformance with DOE Order 5480 28 and its supporting document DOE-STD-1020-94. As discussed in WHC-SD-SNF-DB-010, the CVDF is also designed and constructed to have a level of safety comparable to an NRC-licensed facility. This requirement resulted in additional flood criteria. Engineering calculations demonstrating the adequacy of the CVDF soils to drain the design basis rainfall are listed in SNF-3001.

Confinement. The passive presence of the physical structures is required so the HVAC system can accomplish a differential pressure within the facility. This is ensured by the general-service CVDF structures because they were designed and constructed to performance category 3 criteria to accomplish natural phenomena hazard mitigation and 3-over-1 seismic performance for the protection of safety-class systems and components. The telescoping doors must be closed to accomplish the confinement function while processing an MCO in a bay. Engineering calculations demonstrating the adequacy of the CVDF structural design to accomplish 3-over-1 protection of all safety-class and safety-significant SSCs are listed in SNF-3001.

The structures allow the ventilation systems to maintain a negative pressure in the process bays and process water tank room during processing operations. The physical structure provides a space for the ventilation systems to exhaust. The safety-significant function of maintaining a negative pressure within the process bay structures and process water tank room does not require the normal air balance differential pressure be maintained but simply requires a negative pressure. Building confinement is required during normal process operation. Inleakage much greater than normal rates could be tolerated and still accomplish this safety function requirement as long as a negative pressure is maintained by ventilation exhaust flow. Because the ventilation systems are not required to operate after a DBE the confinement function of the structures is not required after the DBE.
**Bridge Crane**  The process bay bridge cranes are classified as general service. The process bay cranes are also classified as NRC important-to-safety category C in accordance with HNF-SD-SNF-DB-003. Controls are implemented in accordance with general-service requirements and the cranes are designated performance category 1. Engineering calculations demonstrating the adequacy of the CVDF process bay cranes to accomplish performance category 1 criteria and 3-over-1 protection of all safety-class and safety-significant SSCs are listed in SNF-3001. TSR controls are implemented to preclude crane activity over the safety-class process lines and tempered water supply piping during processing activities to preclude common mode failures.

**B4 4 1 5 Controls (Technical Safety Requirements)**  The following assumptions associated with the CVDF process bay and process water tank room structures require TSRs to ensure performance of the safety function:

- The process bay telescoping door is closed prior to and during MCO processing in a bay.
- The trailer shall be positioned properly in the process bay (see Section B4 4 1 4) before connecting process systems.
- The process crane shall not be allowed to move over the cask-MCO during processing activities.

**B4 4 2 Process General Supply/Exhaust Heating, Ventilation, and Air Conditioning System**

**B4 4 2 1 Safety Function**  The process general supply/exhaust HVAC system has been identified in Chapter B3 0 to perform the following safety functions to mitigate safety-significant consequences from the bounding accident scenarios. Only the exhaust portion of the system is credited with mitigation (HEPA filtration) and maintenance of differential pressure to accomplish confinement:

- The process general exhaust system provides confinement of radioactive material within the process bays and process water tank room during processing operations if a release from primary confinement occurs. Its operation mitigates the radioactive release from the CVDF after the gaseous release, liquid release, MCO external hydrogen explosion, MCO internal hydrogen explosion, and MCO overpressurization accidents (identified in Table B4-8) by maintaining a negative pressure in the process bays and process water tank room during facility operations, as indicated in Table B4-8, and by HEPA filtering the building air prior to discharge from the facility.
The process general exhaust isolation dampers at each process bay must fail closed upon facility loss of power to enable the process bay local exhaust HVAC and process vent system operating on standby power to maintain differential pressure in the process bays. This functional requirement is applicable for the gaseous release, MCO external hydrogen explosion, MCO internal hydrogen explosion, and MCO overpressurization accidents.

B4 4 2 2 System Description

Although the supply portion of the general supply/exhaust HVAC system supplies conditioned air to the CVDF process bay and process support areas and plays a role accomplishing normal air balance, it does not perform a safety function (as identified in Chapter B3 0) and is therefore not addressed here. The exhaust portion of the system is credited with safety-significant mitigation (HEPA filtration) and maintenance of differential pressure to accomplish confinement.

Each process bay is served by the general exhaust system, with sufficient capacity to ensure an adequately controlled ventilation flow, as required to contain contamination in the process areas. Ventilation flows are shown in Figure B2-29.

Air from the transfer corridor, associated support rooms, the process water tank room, and the mechanical room is also exhausted into the general exhaust system. The system maintains exhaust air flow and a negative pressure differential in the process bays with respect to all other areas external to the bays. The automatic temperature control system regulates the supply air inlet damper of the process bay recirculation HVAC system to control differential pressure in each bay.

Isolation dampers are provided on all duct branches connecting to the general exhaust system to prevent backflow in the event of exhaust system shutdown. These dampers fail closed on loss of air or electricity and are interlocked to the fire alarm system to close upon any fire indication in each bay. The exhaust filter enclosure is a bag-in bag-out type, three filters wide by four filters high. The four rows of HEPA filters are required for normal operation. Each row can be isolated for filter changes. The air is filtered with an 85% American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) prefilter and two stages of HEPA filters before discharging the exhaust air via the exhaust stack. The HEPA filters conform to ANSI/ASME N509, Nuclear Power Plant Air-Cleaning Units and Components. There are three test sections located within the filter box to accomplish testing in accordance with ANSI/ASME N510, Testing of Nuclear Air Cleaning System. Equipment and ductwork that make up the process general supply/exhaust HVAC systems are supported and anchored in accordance with the requirements necessary to meet the criteria of performance category 2 construction. Most ductwork for the general exhaust system is fabricated of round galvanized steel. A fire screen is located before the HEPA filter enclosure. Instrumentation in the duct includes humidity monitoring, with remote alarm and temperature/rate of rise alarm and interlock to shut down the exhaust fans. Redundant 30 horsepower variable speed exhaust fans are provided for the general exhaust system, but backup power is not provided. Flow indication ahead of the HEPA filters controls the exhaust fan speed, to compensate for filter loading by...
maintaining constant volume flow. The automatic temperature control system monitors all HVAC functions. The airflow through the general exhaust system is normally uncontaminated. Only during upset conditions (i.e., accidents) would radioactive contamination be handled by the general exhaust system. Such conditions include releases into a process bay or the process water tank room. Local readout and remote differential pressure alarms to the control room are provided from each process bay (bays 2, 3, 4, and 5) and from the process water tank room by the reference air system.

The specific components of the general exhaust ventilation system subject to designation as safety-significant components (based on the analysis in Chapter B3.0) are as follows:

- Pneumatic isolation dampers on the exhaust ducts from the process bays
- All ducting and fittings necessary to route airflow to the HEPA filters
- Exhaust HEPA filters and filter differential pressure indication (local)

**B4 4 2 3 Functional Requirements** The following functional requirements have been identified in the accident analyses described in Chapter B3.0

**Ductwork** The process general exhaust system ductwork system must route discharge air to the HEPA filters from any process bay conducting normal process operations and from the process water tank room any time the PWC pumps are operating.

**HEPA Filters** The process general exhaust system HEPA filter installation must accomplish a 99.9% filter efficiency, as credited in the Chapter B3.0 accident analyses, any time the process general exhaust system is operating.

**Differential Pressure** The general exhaust branch at each process bay or process water tank room conducting process operations, must accomplish confinement of radioactive material for the process bays and the process water tank room by maintaining a negative building pressure and by flowing discharge air through HEPA filters. Nominal setpoints are provided in Section B4 4 5 2.

**Bay Isolation** The process general exhaust isolation dampers at each process bay must fail closed upon facility loss of electrical power or loss of instrument air to enable the process bay local exhaust HVAC and process vent system operating on standby power to maintain differential pressure in the process bays and preclude back-flow and communication between process bays.

**B4 4 2 4 System Evaluation** The following evaluation of the process general supply/exhaust HVAC system demonstrates that the functional requirements for this system have been accomplished by the system design.

**Ductwork** Assurance that a filtered discharge path is available is accomplished by the performance category 2 qualification of the process general exhaust system. The performance category 2 general exhaust duct was designed in accordance with ERDA 76-21, *Nuclear Air*...
Cleaning Handbook schedule methodology The ductwork integrity is a credited design feature demonstrated by normal differential pressure in the building.

HEPA Filters A system filter decontamination factor of at least $1 \times 10^3$ is accomplished by the two installed stages of testable 99.97% efficient HEPA filtration prior to discharge to the CVDF stack. The filters are tested in accordance with ANSI/ASME N510 upon installation and annually thereafter.

Differential Pressure Confinement of radioactive material in the process bays (bay 2, 3, 4, and 5), and the process water tank room is assured by maintaining a negative building pressure in each area. This is demonstrated by the differential pressure instruments and alarms provided in the control room for each of these areas. Each process bay and the process water tank room is individually alarmed for differential pressure by the reference air system. The automatic temperature control system monitors HVAC functions and modulates the volume damper on the process bay recirculation HVAC system outside air inlet to maintain the designated differential pressure.

Bay Isolation The process general exhaust isolation dampers at each process bay fail-closed upon facility loss of electrical power or loss of instrument air to enable the process bay local exhaust HVAC and process vent system operating on standby power to maintain differential pressure in the process bays and to preclude back-flow and communication between the process bays. The nuclear grade dampers are in accordance with ANSI/ASME N509 Class 1 Construction Class B, to accomplish a “bubbletight” rating.

B4 4 2 5 Controls (Technical Safety Requirements) The following assumptions associated with the process general exhaust system require TSRs to ensure performance of the safety function:

- The HEPA filters are tested in accordance with ANSI/ASME N510 upon installation and annually thereafter.
- The isolation damper and fail-closed actuator for any process bay are functional during any processing operation in any process bay. The exhaust isolation dampers shall fail closed upon loss of electrical power and loss of air.

B4 4 3 Process Bay Local Exhaust Heating, Ventilation, and Air Conditioning and Process Vent System

B4 4 3 1 Safety Function The process bay local exhaust HVAC and process vent system is identified in Chapter B3 0 as performing the following safety functions to prevent or mitigate safety-significant consequences from the bounding accident scenarios.
Annex B — Cold Vacuum Drying Facility

- Provides confinement of radioactive material released within the process bay during processing operations. The system's operation mitigates the radioactive release from the CVDF after the gaseous release, MCO external hydrogen explosion, MCO internal hydrogen explosion, and MCO overpressurization accidents by directing the flow from the process bays through ductwork to the HEPA filters, prior to discharge from the facility. The hood isolation dampers fail closed and are provided with a instrument air reservoir for operation on standby power. The local exhaust system fans can restart with standby power and can maintain a process bay differential pressure when the process general supply/exhaust HVAC system is not operable (e.g., facility loss of electrical power).

- Maintains local exhaust flow sufficient to dilute potentially hydrogen-rich process gas discharges into the local exhaust duct to preclude flammable mixtures from being generated. Its operation prevents an external hydrogen explosion accident by diluting hydrogen gas from the process vent lines and directing the flow from the process bays through ductwork to HEPA filters prior to discharge from the facility for external and internal hydrogen explosion, thermal runaway, and MCO overpressurization accidents. The 30 lb/in² gauge vent line discharge as a result of the MCO overpressurization accident is also adequately diluted by the local exhaust flow. The hood isolation dampers fail closed on loss of power. The local exhaust system can restart with standby power and can reestablish local exhaust flow within 1 minute sufficient to dilute potentially hydrogen-rich process gas discharges into an exhaust duct and maintain a process bay differential pressure when the process general supply/exhaust HVAC system is not operable (i.e., facility loss of electrical power). The local exhaust provides a process hood low-flow alarm to the control room to preclude cask venting with inadequate dilution flow. The local exhaust also provides the cask venting connection with a flow-restricting orifice along with a shut-off valve interlocked to a local exhaust low-flow switch for each bay.

Table B4-8 summarizes the confinement functions performed by the local exhaust HVAC and process vent system in conjunction with the CVDF structures, to mitigate or prevent the DBAs.

**B4 4 3 2 System Description** The process bay local exhaust system is provided to serve four process bays. This system serves the MCO process hood and the process vent streams from each process bay and the PWC receiver tank. The process vents discharge directly into the local exhaust duct. Ventilation flows are shown on Figure B2-29. These vents are associated with the VPS cask venting system, tempered water (annulus) system tank vents, the SCHe discharges, and the 30 lb/in² vent. Hydrogen-rich streams utilize double-check valves to preclude ductwork air from entering the vent pipes. The process vents are open to the HEPA filters via the system ductwork during operation and when the system shuts down. The process vent connections are downstream from the isolation dampers provided on each duct branch connecting to the process hood. These isolation dampers fail closed upon loss of electrical power, and each damper actuator is provided a safety-significant, 8 3-gal, compressed-air reservoir to operate the damper.
during standby power operation. The isolation dampers are interlocked to close upon fire alarm signal in each process bay.

Redundant safety-significant exhaust fans of the process bay local exhaust system are provided standby power, which will reestablish flow within 1 minute. Each fan has 100% capacity to operate the local exhaust system. Safety-significant backflow dampers downstream from the exhaust fans preclude backflow into the fan that is not operating. The automatic temperature control system monitors all normal HVAC functions. Local exhaust system operation on standby power does not require control signals because all functions operate directly from the standby power system and restart circuit.

The ductwork system contains a flow switch that provides a low-flow alarm in the control room for each process bay duct branch which provides operators with information about system functionality.

All ductwork for the process bay local exhaust system is fabricated of round stainless steel duct or pipe and is of welded construction. The exhaust filter box is a bag-in bag-out type. Two filters wide by three filters high. The air is filtered with an 85% ASHRAE prefilter and two stages of HEPA filters, before discharging the exhaust air via the CVDF exhaust stack. The HEPA filters are in conformance with ANSI/ASME N509 with three test sections located within the filter box to accomplish testing in accordance with ANSI/ASME N510. All three rows of HEPA filters are required for normal operation. Each row can be isolated for filter changes. A fire screen is located before the HEPA filter enclosure. Instrumentation in the duct includes humidity monitoring with remote alarm and temperature/rate of rise alarm and interlock to shut down the exhaust fans. Redundant 15 horsepower variable speed exhaust fans are provided. Flow indication ahead of the HEPA filters controls the exhaust fan speed to compensate for filter loading, by maintaining constant volume flow. Equipment and ductwork that make up the process bay local exhaust HVAC system are supported and anchored in accordance with the requirements necessary to meet the criteria of performance category 2 construction.

The process bay local exhaust HVAC and process vent system provides special connections and dilution flow for cask and MCO venting. The process bay local exhaust system is required to provide this function during initial cask venting, using the removable cask vent jumper connected from the cask vent port to the process vent cask venting quick-disconnect fitting or for special-case MCO venting prior to processing using the MCO venting tool attached to the cask venting connection. The process bay local exhaust system is designed to provide sufficient airflow in conjunction with the flow restriction orifice and the flow valve interlocked to the low flow alarm in the cask venting connection to the ductwork in each bay, to dilute the maximum potential hydrogen release from the cask to less than the lower flammability limit for hydrogen in air.
The specific components of the process bay local exhaust HVAC and process vent system subject to designation as safety-significant components (based on the analysis in Chapter B3 0) are as follows:

- Local exhaust fans and plenum
- All ducting and fittings necessary to route airflow to the filters
- Exhaust HEPA filters and filter differential pressure (local)
- Instrumentation (flow switches and alarms) necessary to verify adequate airflow are functional
- Isolation dampers in each bay that fail closed
- Process vent lines for cask venting including orifice and flow valve interlocked to the low flow alarm in each bay
- Process vent lines for the 30 lb/in² vent path, SCHe, and VPS discharges

B4 4 3 3 Functional Requirements

**Fan operation** The process bay local exhaust system must be operating and accomplish adequate dilution of hydrogen introduced during the cask venting and processing activities to ensure that the hydrogen lower flammability limit is not reached.

**Flow alarm** A flow switch in each process bay branch to the process hood shall be provided with a remote alarm to the control room. It must be demonstrated that the flow in any process bay is adequate prior to initiating the cask venting operation, and during MCO processing in each process bay.

**HEPA filters** The process bay local exhaust system HEPA filter installation must accomplish a 99.9% filter efficiency as credited in the Chapter B3 0 accident analyses.

HEPA filter loading shall be administratively controlled to less than 9.4 g of spent fuel while in service. The HEPA filter enclosure shall have the capability to accurately take repeatable measurements for the monitored radiation dose from the prefilters and HEPA filters. Measurements may be performed with portable instruments. Physical access to minimally shielded surveillance locations must be provided.

**Ductwork** The process bay local exhaust system ductwork must route discharge air to the HEPA filters from any process bay conducting normal process operations. The process bay local exhaust system must provide a discharge path via the ductwork and HEPA filter for the SCHe pressure venting and the 30 lb/in² vent path.
**Hood isolation damper** Each isolation damper located near the process hood must fail closed upon loss of electrical power. The dampers shall have the ability to re-open while the general-service instrument air is not operating.

**Cask venting** A flow restriction orifice and a flow valve interlocked to a low-flow switch in the cask venting connection is incorporated into the ductwork to preclude flammable mixtures in the ductwork and vent lines.

**Standby operation** The process bay local exhaust HVAC and process vent system in the restart mode must be capable of maintaining differential pressure within the process bays under all design basis HEPA filter loading conditions without instrumentation or controls. It must also meet the minimum flow requirement of 1,000 ft³/min for dilution.

**B4 4 3 4 System Evaluation** The following evaluation of the process bay local exhaust HVAC and process vent system demonstrates that the functional requirements for this system have been accomplished by the system design.

**Fan operation** The process bay local exhaust HVAC and process vent system has a high degree of reliability. Redundant safety-significant exhaust fans are provided for the process bay local exhaust system. Each fan has 100% capacity of the local exhaust system flow to accomplish confinement and dilution flow requirements. The process bay local exhaust HVAC and process vent system has a “hand-off-auto” station located at each exhaust fan. When the fan’s hand-off-auto station is in the ‘auto’ position, the automatic temperature control system monitors and controls the exhaust system. The “on” position is used for fan testing only and the switch is placed in the ‘auto’ position for normal operations. The exhaust fans each have a manual isolation damper that must be placed in the open position for proper operation of the system. Engineering calculations demonstrating the adequacy of the local exhaust fan capacities are compiled in SNF-3001. Backflow dampers downstream of the exhaust fans preclude backflow into the fan that is not operating. The local exhaust fans are provided standby power that will restart the system within 1 minute. Local exhaust system operation on standby power does not require control signals, as all functions operate directly from the standby power system and restart circuit. No accidents are identified in Chapter B3.0 that require performance category 3 seismic qualification of the exhaust fans for the process bay local exhaust HVAC and process vent system.

**Flow alarm** Adequate flow in any process bay during MCO processing and prior to initiating the cask venting operation is demonstrated using safety-significant flow switches in each branch. The flow switches provide a low-flow alarm in the control room for each process bay duct branch to inform operators of system functionality. The low flow switches activate at 1,150 ft³/min (above 1,120 ft³/min to account for a 10% error band of the flow switches per SNF-4451). A minimum flow of 1,000 ft³/min is required for dilution of process vent discharge per calculation SNF-4301.

**HEPA filters** A system filter decontamination factor of at least $1 \times 10^3$ is accomplished by either of the two installed stages of HEPA filtration, prior to discharge to the CVDF stack.
Annex B — Cold Vacuum Drying Facility

time the process bay local exhaust system is operating. The air is filtered with an 85% ASHRAE prefilter and two stages of HEPA filters before discharging the exhaust air via the CVDF exhaust stack. The HEPA filters conform to ANSI/ASME N509, with three test sections located within the filter box to accomplish testing in accordance with ANSI/ASME N510. Differential pressure across each stage of HEPA filters is monitored and alarmed in the control room. Flow indication ahead of the HEPA filters controls the exhaust fan speed to compensate for filter loading by maintaining constant volume flow. Differential pressure instrumentation is provided to demonstrate HEPA filter loading and presence.

The HEPA filter loading is administratively controlled to less than 94 g of spent fuel while in service. The HEPA filter enclosure has the capability to accurately take repeatable measurements for the monitored radiation dose from the prefilters and HEPA filters. Measurements are performed with portable instruments within their calibration period. Physical access to minimally shielded surveillance locations is provided. This is accomplished by not exceeding a contact dose reading in the designated locations on the HEPA filter box of 82 mR/h (SNF-2770 Chapter 60), which incorporates a factor of 10 reduction in allowable filter loading to account for segregation on decay of gamma emitters (e.g., 82 mR/hr correlates to 9.4 g SNF).

A total of six dose readings shall be taken using an ion chamber instrument at designated points on the surface of the local exhaust filter box. These points are defined as the centerline of each of the three vertical filter rows for both the prefilter bank and the first HEPA filter bank. The readings shall be taken on the west side of the filter box at the center of each cover plate for that row of filters. A reading below 82 mR/h shall be observed at each survey point. These survey points shall be marked and numbered on the filter box for accuracy and repeatability. This accomplishes the dose reading credited in SNF-2770, Chapter 70 which states, “The dose points for the three filters were 2 in. to the side of the HEPA filter, corresponding to a likely dose rate measurement point for weekly surveys by radiation protection technicians.”

Ductwork All ductwork for the process bay local exhaust system is fabricated of round stainless steel duct or pipe and is of welded flange construction. Assurance that a discharge path is available to the HEPA filters is accomplished by the performance category 2 qualification of the process bay local exhaust system ductwork. The performance category 2 local exhaust duct was designed in accordance with ERDA 76-21 schedule methodology. Performance category 2 qualification is sufficient for discharge of the SCHe and 30 lb/in² vent path during performance category 3 events because pinching off these process vent lines in order to retain high pressures is not probable. Process bay confinement is not required after a seismic event.

Hood isolation damper The hood isolation dampers are pneumatically operated nuclear-grade dampers. The nuclear-grade dampers are in accordance with ANSI/ASME N509 Class 1 Construction Class B, to accomplish a “bubbletight rating”. Each process hood isolation damper fails closed upon loss of electrical power. The damper actuators are provided a safety-significant, compressed-air reservoir for operation on standby power. The isolation dampers are interlocked to close upon fire alarm signal in each process bay.
Cask venting Dilution of hydrogen introduced during the cask venting activity to ensure that the hydrogen lower flammability limit is not reached is accomplished by the system normal operating capacity of 1,300 ft³/min in conjunction with the cask venting orifice. A minimum flow of 1,000 ft³/min is required for dilution during cask venting. This is interlocked to the flow valve in the cask vent line to interrupt venting on loss of flow. The flow rate requirement and orifice diameter are documented in SNF-4301. For a 150 lb/in² gauge cask venting activity, an orifice of 0.041 in results in a hydrogen concentration of 1% in the local exhaust duct.

Standby operation The process bay local exhaust HVAC and process vent system in the restart mode with standby power is capable of maintaining differential pressure within the process bays under all design basis HEPA filter loading conditions without instrumentation or controls. The motor starter is energized by the standby power system and bypasses the variable speed drive for the fan, operating it at maximum capacity which is adequate for all HEPA filter loadings. Each process hood isolation damper re-opens using the safety-significant, compressed-air source provided by the compressed-air reservoir in each process bay to restart on standby power. The control signal is provided by the standby power restart circuit. To accomplish sufficient differential pressure, the isolation dampers on the general exhaust system and the outside air inlet to the process bay recirculation HVAC system must fail closed. These dampers and their safety-significant function are addressed in their appropriate system sections. HVAC flow rate and differential pressure evaluations for the standby operation of the local exhaust system are documented in SNF-3001, Calculation ME1 2621 ME 6.

B4 4 3 5 Controls (Technical Safety Requirements) The following assumptions associated with the process bay local exhaust system require TSRs to ensure performance of the safety function:

- The system minimum flow requirement of 1,000 ft³/min is met while processing an MCO in that process bay.
- The cask venting orifice is properly installed in the system.
- The installed flow switch and remote low-flow alarm on the process bay branch of the ductwork is functional in each process bay during MCO processing in that bay.
- The flow switch interlock to cask venting valve is functional.
- The HEPA filters are tested in accordance with ANSI/ASME N510 upon installation and annually thereafter.
- The HEPA filter inventory is less than 9.4 g of spent fuel to protect the assumption in the Chapter B3 0 accident analysis. (This is accomplished by not exceeding a contact dose reading in the designated locations on the HEPA filter box of 82 mR/h as described in Section B4 4 3 4.)
The isolation damper fail-closed actuator for any process bay is functional during any processing operation in that process bay.

The system restart capability with standby power is functional to reestablish minimum flow within 1 minute.

### B4 4 4 Process Bay Recirculation Heating, Ventilation, and Air Conditioning System

#### B4 4 4.1 Safety Function

The process bay recirculation HVAC system is analyzed in Chapter B3 0 to perform the following safety function to mitigate safety-significant consequences from the bounding accident scenarios:

- The system supply isolation dampers at each process bay must fail closed upon facility loss of power to enable the process bay local exhaust HVAC and process vent system operating on standby power to maintain differential pressure in the process bays. This is applicable for the gaseous release, MCO internal hydrogen explosion, MCO external hydrogen explosion, and MCO overpressurization accidents.

#### B4 4 4.2 System Description

The only portions of the process bay recirculation HVAC system that performs a safety-significant function are the fail-closed inlet isolation dampers. The isolation dampers are pneumatically operated nuclear-grade dampers located inside process bays 2 through 5 at the 24-in by 18-in supply air duct through the west wall of each bay. The external elevation is just above the roof of the mechanical equipment room. The pneumatic actuators fail to the closed position upon loss of electrical signal or loss of instrument air.

#### B4 4 4.3 Functional Requirements

**Supply isolation damper** Each inlet isolation damper located at the process bay west wall must fail closed upon loss of electrical power or loss of instrument air to support restart of the local exhaust system on standby power and establish differential pressure in the process bay.

#### B4 4 4.4 System Evaluation

**Supply isolation damper** Each supply inlet isolation damper fails closed upon loss of electricity or loss of instrument air. This supports restart of the local exhaust on standby power to establish differential pressure in the process bay because no HVAC control functions are provided by standby power, and the differential pressure calculations for standby power operation were performed with these dampers closed. HVAC flow rate and differential pressure evaluations for the standby operation of the local exhaust system are documented in SNF-3001 (Calculation MEI 2621 ME 6). The inlet isolation dampers are pneumatically operated nuclear-grade dampers. The nuclear-grade dampers are in accordance with ANSI/ASME N509, Class 1 Construction Class B, to accomplish a “bubbletight” rating.
**B4 4 4 5 Controls (Technical Safety Requirements)** The following assumptions associated with the process bay recirculation HVAC system requires TSRs to ensure performance of the safety function

- The supply inlet isolation damper and fail-closed actuator for any process bay is functional during any processing operation in any process bay

**B4 4 5 Reference Air System**

**B4 4 5 1 Safety Function** The reference air system is analyzed in Chapter B3 0 to perform the following safety functions to mitigate safety-significant consequences from the bounding accident scenarios

- The process bay and process water tank room differential pressure alarms provide a safety-significant function for mitigation of the consequence of gaseous release, liquid release MCO external hydrogen explosion MCO internal hydrogen explosion, and MCO overpressurization accidents. The alarm notifies personnel of the loss-of-confinement function, and personnel initiate appropriate action to preclude releases during the abnormal confinement condition. This requirement to demonstrate HVAC confinement function related to location and DBA is summarized in Table B4-8

- The system must provide a reliable reference air signal to the process bay and process water tank room differential pressure indicators with low differential pressure alarms so they can perform their safety-significant function

**B4 4 5 2 System Description** The process bays and the process water tank room are maintained at a slight negative pressure with respect to atmosphere and the remainder of the CVDF by the process general supply/exhaust HVAC system. The reference air system provides the capability to continuously monitor the static pressure relative to atmospheric pressure, of various spaces throughout the facility. The differential pressure-indicating transmitters (DPITs) indicate whether the HVAC confinement systems are functioning properly. The automatic temperature control system provides visual indication and alarms (general service) for differential pressure conditions in the control room. Safety-significant DPITs with local indication and remote indication of low-differential pressure alarm set points are also provided for the process bays and the process water tank room.

The reference air system consists of a series of static DPITs located throughout the CVDF that are interconnected by 0.5-in, 1-in, or 2-in copper tubing. Five manual valves along the reference air header are provided for maintenance and isolation purposes. The pressure differential is monitored in the control room and locally at each DPIT in the process water tank room, the transfer corridor and access rooms, the process bays, the mechanical equipment room, and the administration access corridor. The automatic temperature control system monitors all...
reference air pressures  Separate safety-significant DPITs and alarm circuits are also provided for
the process bays and the process water tank room as part of the reference air system.

The nominal set points are as follow:

- Process bays, -0 20 in water gauge
- Process water tank room, -0 25 in water gauge
- Transfer corridor access rooms, -0 15 in water gauge
- Transfer corridor and mechanical equipment rooms, -0 10 in water gauge
- Administration access corridor, +0 01 in water gauge

Differential pressure indication for HVAC control is considered general service and is
provided in conjunction with the reference air system and monitored by the automatic temperature
control system. Safety-significant DPITs with low differential pressure alarms to the control
room are also provided. The reference air header is also safety-significant to provide a reliable
reference air signal to the differential pressure alarms. This will initiate operator action if process
or HVAC changes must be initiated based on confinement status.

**B4 4 5 3 Functional Requirements** The following functional requirements have been identified
to ensure the reference air system performs its safety-significant function.

**Differential pressure instruments** DPITs for each process bay (bays 2, 3, 4, and 5) and
the process water tank room shall be provided with low differential pressure alarms in the control
room.

**Differential pressure alarms** The low differential pressure alarms must be able to
remotely indicate to the control room a loss of negative building pressure relative to atmospheric
pressure in the process bays (2, 3, 4, and 5), during MCO processing, and in the process water
tank room, while the PWC recirculation pump is operating.

**Reference air header** The reference air header and static pressure sensor must be
available and functional to provide a reliable reference air signal whenever the DPITs and low
differential pressure alarms are required to be functional.

**B4 4 5 4 System Evaluation** The reference air system provides DPITs alarms, and the
reference air header for safety-significant low differential pressure alarms. Each of the system
functional requirements is discussed below.

**Differential pressure instruments** Safety-significant DPITs with low differential pressure
alarm set points are provided in the process bays and the process water tank room. These DPITs
are in addition and redundant to the DPITs provided for the general-service HVAC control via
the automated temperature control system.
Differential pressure alarms  Safety-significant differential pressure alarms are provided to the control room to allow timely response to ventilation upset conditions. Engineering calculations demonstrating the adequacy of the performance category 2 reference air low differential pressure alarm system design are listed in SNF-3001.

Reference air header  The reference pressure is measured by a static pressure sensor located above the administration building roof. The reference air pipe header is fabricated of noncorrosive material (copper). Piping and instruments that make up the reference air system are supported in accordance with the requirements necessary to meet the criteria of performance category 2 construction. Engineering calculations demonstrating the structural adequacy of the performance category 2 reference air piping and installation design are listed in SNF-3001.

B4 4 5 5  Controls (Technical Safety Requirements)  The following assumptions associated with the reference air system require TSRs to ensure performance of the safety function:

- The system must be functional during processing activities in any process bay and whenever the process water pumps are operating.
- The DPITs and alarms must be able to detect a loss of negative building pressure relative to atmospheric pressure in the process bays (bays 2, 3, 4, and 5) and the process water tank room during processing activities in any of those areas.
- The process bay ventilation systems are maintaining normal differential pressures prior to initiating MCO processing in a bay.
- The process water tank room ventilation system is maintaining normal differential pressure prior to initiating MCO draining operations and at all times that any PWC pumps are operating.

B4 4 6  Instrument Air System

B4 4 6 1  Safety Function  The instrument air system is analyzed in Chapter B3.0 to perform the following safety functions to mitigate safety-significant consequences from the bounding accident scenarios:

- Provide a safety-significant function of being capable of re-opening the fail-closed process hood isolation dampers when the general supply/exhaust HVAC system is not operable and the hood exhaust fans are re-started under standby power. The system’s operation supports mitigation of potential radioactive releases from the CVDF after the gaseous release, MCO external hydrogen explosion, internal hydrogen explosion, and MCO overpressurization accidents. This requirement to demonstrate HVAC confinement functions for the process bays and each DBA is summarized in Table B4-8.
**B4 4 6 2 System Description**  The instrument air system is used to provide and distribute quality air throughout the CVDF Instrument air is supplied by duplex two-stage piston type compressors, a 250-gal receiver tank pressure control valve, instrument air dryer filters, and desiccant instrument air dryers. For normal operation, the instrument air system provides instrument air at a pressure of 100 lb/in² gauge to the HVAC isolation dampers.

HVAC system isolation dampers fail closed if there is loss of electrical power. To ensure the process hood dampers on the process bay local HVAC exhaust and process vent system are reopened when standby power is activated and the local exhaust fan restarts, safety-significant instrument air is provided to each air line to each process bay hood isolation damper. The safety-significant portion of the instrument air system in each process bay consists of an air tank, double-check valves in the inlet air supply line to each instrument air tank, piping from the tank to the hood isolation damper actuator, and a pressure-indicating gauge on the tank. Each instrument air tank reservoir has minimum capacity of 8.3 gal and is designed for a maximum pressure of 200 lb/in² gauge. The normal operating pressure of 100 lb/in² gauge (per vendor information) provides sufficient air volume in the reservoir to complete four actuations of the isolation damper. Double-check valves prevent loss of air to possible line breaks in the general service portions of the instrument air system and local air pressure indication is provided for the operator to monitor the tank pressure in each bay. The safety-significant reservoir tanks were constructed to ASME Section VIII (ASME 1995), and the safety-significant piping and valves were fabricated to ASME B31.3 and B31.9, *General Services Piping Code*.

On loss of power, the solenoid valve will block the flow of air to the actuator for the process hood isolation damper, and the damper will close. When standby power is activated, the solenoid valve is energized and will reopen, and air from the in-line safety-significant instrument air reservoir will flow to the actuator to open the damper as required. The general-service instrument air system normally maintains pressure in the reservoirs. The reservoirs are isolated from the instrument air system by safety-significant check valves when process upsets occur, which could result in loss of instrument air supply or loss of power. Periodic monitoring of the pressure in the tanks by the operators ensures the capability exists for functional operation of the dampers upon loss of power.

**B4 4 6 3 Functional Requirements**  The following functional requirements have been identified to ensure the specific portions of the instrument air system perform their safety-significant functions.

- **Operating Capacity** — Provide the safety-significant source of instrument air to provide the capability of opening the process hood fail-closed isolation dampers when standby power is activated. Have sufficient instrument air capacity to operate the process hood isolation damper actuator for four actuation cycles and the capability for operator verification of the tank air pressure.
System Operability, Calibration, and Testing — Ensure the instrument air system is operable, the reservoir is pressurized at all times, the reservoir tank pressure gauge is reading correctly, and there is periodic testing to demonstrate system functionality.

Seismic Qualification — Provide an instrument air supply for each process hood damper that is seismically qualified to performance category 2 criteria.

B4 4 6 4 System Evaluation Portions of the instrument air system provide an independent air supply for each process hood isolation damper. Each of the system functional requirements is discussed below.

Operating Capacity Under normal operation the instrument air system in each bay will be supplied at a pressure of 100 lb/in² gauge. Design of the instrument air systems for the hood isolation dampers is based on the air tanks having minimum capacity of 8 3 gal at a pressure of 100 lb/in² gauge to support isolation damper operation in a loss of power situation. Double-check valves are installed on the inlet air supply line to the instrument air tanks to provide system isolation from general-service portions of the system. This 8 3 gal air supply at 100 lb/in² gauge will provide a sufficient amount of air for four actuations (only one actuation required) of the process hood isolation damper actuators (per vendor information) that require 80 lb/in² gauge to open. Gauges on each of the air supply tanks provide a means for the operators to monitor the tank pressure and verify sufficient pressure is available for damper actuator operation.

System Operability, Calibration, and Testing Operation of each instrument air system is ensured through periodic testing of the standby power system and the process hood isolation dampers. Surveillance and in-service inspections of the instrument air system safety-significant components are conducted in accordance with operating procedures for respective components. The normal instrument air pressure is 100 lb/in² gauge, and the damper actuator requires 80 lb/in² gauge to operate. A periodic pressure hold test after closing the in-line instrument air valve to the reservoir demonstrates adequate leak tightness of the system. A pressure drop of less than 2 lb/in² gauge during a 4-hour hold test (0 5 lb/in² gauge/h 12 lb/in² gauge total drop over 24 hours) demonstrates that the reservoir can provide sufficient air supply for 24 hours to hold the local exhaust damper open. Additional surveillance of reservoir pressure during standby power operation ensures continued function. The calibration of the tank pressure gauges is conducted according to the manufacturer’s recommendations.

Seismic Qualification Piping and instruments that make up the safety-significant portion of the instrument air system are constructed and supported in accordance with the requirements necessary to meet the performance category 2 criteria. Engineering calculations demonstrating the structural adequacy of the performance category 2 instrument air reservoir and piping system design are listed in SNF-3001.
B4 4 6 5 Controls (Technical Safety Requirements) The following assumptions associated with the instrument air system require TSRs to ensure performance of the safety function

- The instrument air system in each bay must be functional whenever the process bay local HVAC exhaust and process vent system is operating in that bay

- Leak tightness of the instrument air system piping, tank and check valve components (pressure hold test showing less than 0.5 lb/in² gauge per hour drop) is verified on an appropriate schedule to ensure operation if there is loss of instrument air supply

- Instrument air system tank gauges are calibrated on an appropriate schedule

- Operators periodically verify tank pressure is above 90 lb/in² gauge pressure by observing the reservoir pressure gauges according to procedure

B4 4 7 Standby Power System

B4 4 7 1 Safety Function The standby power system provides the safety-significant function of supplying AC electrical power to the process bay local exhaust HVAC and process vent system to provide confinement in the process bays and dilution flow within the local exhaust duct during facility loss of electrical power incidents. The standby power system has been analyzed in Chapter B30 to perform the following safety functions to mitigate safety-significant consequences from the bounding accident scenarios

- Provide standby power to maintain process bay local exhaust HVAC and process vent system flow and/or to accomplish sufficient differential pressure in the process bays for confinement during an electrical outage that occurs during or after a gaseous release, external or internal hydrogen explosion, thermal runaway reaction, or MCO overpressurization accidents

- Provide a restart circuit to perform the functions necessary to restart the process bay local exhaust HVAC and process vent system, including the fan motor logic and process hood isolation damper control during or after the gaseous release, MCO external or internal hydrogen explosion, thermal runaway reaction, or MCO overpressurization accidents

B4 4 7 2 System Description The 100 kW diesel generator system supplies 3-phase power at 480 V standby power to selected equipment through an automatic transfer switch. The automatic transfer switch selects the normal power source or the emergency generator for supplied loads based on the normal source voltage and frequency. An engine start signal is provided by the automatic transfer switch if the normal source voltage drops below a set level for a duration in excess of the set delay. A load bank is also provided to test the generator.
Generator startup is accomplished using an air start system that cranks the diesel engine to sufficient revolutions per minute to start the engine. The air start system uses its own general service air compressor to supply a 400-gal safety-significant air reservoir through a pressure control valve and double-check valves. A gauge is available on the line to the air reservoir to verify reservoir pressure.

Upon receiving the signal to start, the diesel generator will come up to the rated voltage and frequency. Once these parameters are obtained, the diesel generator will then supply the required power through an automatic transfer switch to the following selected loads:

- Process bay local exhaust HVAC and process vent system exhaust fan (safety significant) (only one fan runs at a time)
- Process hood isolation damper actuator solenoid valves in each bay (safety significant)
- Bypass transformer to pickup UPS loads if batteries are depleted
- Instrument air compressors (general service)
- Heat trace for process bay fire protection and deionized water lines (general service)

The heated diesel generator building consists of two rooms that house two diesel generators (only one generator is operational) an air start system, and the control panel for the operational diesel generator. The generator is fueled from a 50-gal day tank within the building. There is also a 500-gal tank supply integrated to automatically refill the day tank that will contain at least 150 gal of fuel to allow at least 24 hours of operation without refueling. The tank is located outside the generator building aboveground on a concrete pad. The tank is double walled with leak detection within the annulus space.

**B4 473 Functional Requirements** The following functional requirements have been identified to ensure the standby power system performs its safety-significant function:

**Diesel Generator** Provide sufficient standby power to supply designated safety-significant loads for a minimum period of 24 hours.

**Diesel Generator Building** The building shall be maintained at a temperature above 40 °F when the diesel generator is not operating to meet vendor recommendations for engine start. The diesel fuel in the day tank shall be maintained above 40 °F to support engine start capability.

**Restart Circuit** Provide a restart circuit to perform the functions necessary to restart the process bay local exhaust HVAC and process vent system, including fan motor logic and damper positioning, within 1 minute after loss of normal power. Also, provide power to the facility UPS.
loads air compressor motor, and process bay heat trace, which enhances the reliability of these general-service systems, which are not mandatory but provide defense in depth during standby power operation

System Operability, Calibration, and Testing Ensure the standby power system is operable, the system instrumentation is reading correctly, and periodic testing is conducted

Seismic Qualification Provide a safety-significant standby power system that is qualified to performance category 2 criteria for natural phenomenon

B4 4 7 4 System Evaluation The standby power system provides safety-significant functional requirements as discussed below

Diesel Generator The diesel generator has been procured to have the capability to provide 100 kW of standby power to be used for selected loads. An automatic transfer switch monitors the incoming power to the building and switches to standby power if there is a loss of normal electrical power. The engine and generator are rated for performance category 2 natural phenomena criteria. The 50-gal day tank and the 500-gal fuel storage tank provide sufficient fuel capacity for 24-hour operation. These parameters are documented in SNF-3001 Calculation MEI 2621 ME 7

Diesel Generator Building The building is insulated and maintained at a temperature above 50 °F by an electric heater with thermostatic control, to meet vendor recommendations for diesel start reliability. The diesel fuel day tank is inside the diesel generator building and is maintained at building temperature. This ensures the fuel and generator are at a temperature sufficient for reliable starting in accordance with vendor recommendations.

Restart Circuit The signal to start the backup power system comes from the automatic transfer switch that monitors normal power to the CVDF. The transfer to emergency power will be initiated upon reduction of normal power to 70% of nominal voltage. When the diesel engine starts and the generator voltage and frequency have obtained setpoint values, the automatic transfer switch will disconnect the generator from the load bank and transfer to the standby power loads. Transfer back to normal power shall occur when the normal electrical power source restores to 90% of nominal voltage.

The diesel engine controls are operated by a 12V DC lead acid battery that is continuously charged and mounted on the engine skid. The control panel has readouts for all pertinent engine and generator operating parameters. Startup of the engine is accomplished by use of an air start system that will initiate upon loss of normal power. The air start system relies on air from a 400-gal reservoir tank that is continuously kept at pressure by a standby power general-service air compressor. The air compressor supplies air through a regulator and double-check valves, and a gauge is provided to monitor reservoir pressure. Air starting will crank the engine until the speed exceeds 650 revolutions per minute or until 8 seconds elapses. The start sequence is repeated up to 6 times (reservoir pressure provides a minimum of 6 start attempts), within a delay period of

November 1999
less than 4 seconds. When the engine starts, the generator voltage will build as speed increases, until the voltage and frequency are within selected pick-up values (85% to 100% voltage, 90% to 100% frequency).

The selected loads to be supplied by standby power are to either of the local exhaust fans (only one operating at a time), the solenoid valves that control the actuators to the local exhaust hood isolation dampers, the facility UPS bypass transformer, and the instrument air compressors and the process bay heat trace. The local exhaust hood isolation dampers fail closed on initial loss of power and will move to the open position once power is restored to the solenoid valves, because the actuators are provided a safety-significant source of instrument air for the power loss situation. Restoration of power to the instrument air compressors provides a defense-in-depth capability to provide air for operation of the actuators. Restoration of power via the bypass transformer to the facility UPS loads provides defense-in-depth such that differential pressure instrumentation may be available during standby power operation although it is not required as calculations demonstrate sufficient differential pressure is maintained under the controlled conditions of standby power operation (SNF-3001, Calculation MEI 2621 ME 6).

**System Operability, Calibration, and Testing** Operation of the standby power system is ensured through periodic testing according to the manufacturer's recommendations. A load bank is provided with the standby power system to conduct engine startup and operational testing. Surveillance and in-service inspections of the standby power system safety-significant components are conducted in accordance with the manufacturer's recommendations for respective components and TSR requirements. Calibration of the instrumentation including the generator starter and reservoir pressure gauge is conducted according to the manufacturer's procedures and standards.

**Seismic Qualification** The engine generator piping, fuel storage tanks, and instruments that make up the standby power system were purchased and installed in accordance with the requirements necessary to meet the criteria of performance category 2 construction. Engineering calculations demonstrating the structural adequacy of the performance category 2 design and installation are listed in SNF-3001.

**B4 4 7 5 Controls (Technical Safety Requirements)** The following assumptions associated with the standby power system require TSRs to ensure performance of the safety-significant function:

- The standby power system must be capable of startup and operation at any time MCO processing is initiated in any process bay.
- Functional testing of the diesel generator and local exhaust fan startup using the standby power system has been performed on an appropriate schedule consistent with the respective manufacturer's schedule and practice.
The gauge on the diesel engine air starter reservoir is monitored on an appropriate schedule to ensure capability for standby power activation.

Maintenance is periodically performed on the diesel generator system per the manufacturer's recommendations.

The diesel generator fuel supply is sufficient for 24-hour operation and is verified on an appropriate schedule.

The diesel generator building is to be maintained above the minimum diesel starting temperature of 40°F when the diesel generator is not operating.

The diesel fuel temperature in the day tank and associated fuel lines are to be maintained above 40°F.

B4.4.8 Cold Vacuum Drying Facility Safety—Significant Special Tools

B4.4.8.1 Safety Function Two special tools are identified in Chapter B3 0 as performing the safety functions to mitigate safety-significant consequences from the bounding accident scenarios and for worker safety. These are the “cask vent jumper tool” and the “MCO vent jumper tool.” The safety functions of these tools are listed below.

- The cask vent jumper is to contain the flow of hydrogen from the cask headspace during venting such that the hydrogen is discharged into the process vent connection of the process bay local exhaust HVAC and process vent system and not discharged unrestricted into the process bay to preclude an external hydrogen explosion and protect the facility worker.

- The MCO vent jumper is to contain the flow of hydrogen from the MCO headspace during venting under abnormal conditions such that the hydrogen is discharged into the process vent connection of the process bay local exhaust HVAC and process vent system and not discharged unrestricted into the process bay to preclude an external hydrogen explosion and protect the facility worker.

B4.4.8.2 System Description The cask vent jumper is a flexible line with attached fittings to connect between the cask lid fitting and the local exhaust cask vent connection. Before removing the cask lid, the cask vent jumper is connected between the cask lid vent port and the local exhaust system cask vent connection. The cask connector allows a bolted gasketed connection to the cask lid with the ability to open the vent port valve after the connection is completed. The line confines any hydrogen concentrations that could be flammable or explosive, if released and mixed with air in an uncontrolled fashion.
The MCO vent jumper is a flexible line with attached process connector fittings and a 30 lb/in² gauge rupture disk that connects between the MCO filtered process exit port connection and the local exhaust cask vent connection. The 30 lb/in² rupture disk vents to the room. If there is an abnormal condition that requires venting of the MCO prior to making normal process connections, this flexible hose jumper can be attached to the MCO and pressure can be vented to provide extended time prior to initiating normal processing. The line confines any hydrogen concentrations that could be flammable or explosive if released and mixed with air in an uncontrolled fashion.

The safety-significant vent jumper tools are designed and fabricated in accordance with codes and standards identified in Table B4-3 for process equipment and valves.

B4 4 8 3 Functional Requirements

Hydrogen confinement The functional requirement for the cask vent jumper is to perform its safety function of confinement of hydrogen-rich gas without leakage or rupture at system operating pressures up to 150 lb/in² gauge

The functional requirement for the MCO vent jumper is to perform its safety function of confinement of hydrogen-rich gas, without leakage or rupture, at system operating pressures up to 150 lb/in² gauge.

B4 4 8 4 System Evaluation

Hydrogen confinement The cask vent jumper has been designed to meet its functional requirements and perform its safety functions. The flex hose is rated for 150 lb/in² gauge service. The flex hose interfaces with the process bay local exhaust HVAC and process vent system through the cask vent connection, which provides sufficient dilution flow rate in the exhaust duct to preclude an external hydrogen explosion.

The MCO vent jumper has been designed to meet its functional requirements and perform its safety functions. The flex hose is rated for 150 lb/in² gauge service. The rupture disk is rated at 30 lb/in². The rupture disk interfaces with the process bay local exhaust HVAC and process vent system through the cask vent connection, which provides sufficient dilution flow rate in the exhaust duct to preclude an external hydrogen explosion.

B4 4 8 5 Controls (Technical Safety Requirements) The following assumptions associated with the vent jumpers requires TSRs to ensure performance of their safety functions:

- The cask vent jumper is not damaged prior to cask venting in a bay
- The MCO vent jumper is not damaged prior to MCO venting in a bay

B5 0 DERIVATION OF TECHNICAL SAFETY REQUIREMENTS

B5 1 INTRODUCTION

A description of the essential features of Spent Nuclear Fuel (SNF) Project derivation of technical safety requirements (TSRs) is provided in Chapter 5 0 of the SNF Project Final Safety Analysis Report (FSAR)

B5 2 REQUIREMENTS

The requirements that form the basis for the SNF Project derivation of TSRs are identified in Section 5 2 of the SNF Project FSAR

B5 3 TECHNICAL SAFETY REQUIREMENTS COVERAGE

The group of TSRs for analyzed hazards and accidents for the Cold Vacuum Drying Facility (CVDF) is summarized in Table B5-1. This table lists TSR controls in accordance with the accident analyses in Chapter B3 0 and the safety structures, systems, and components (SSCs) evaluations in Chapter B4 0. Table B5-1 provides a road map from the respective accident analysis section to the relevant subheadings within Section B5 5, where TSR derivation details are arranged by TSR control.

The necessary and sufficient TSR controls are established based upon consideration for public safety, significant defense in depth, significant worker safety, and for maintaining radiological consequences below risk evaluation guidelines. Section 5 3 of the SNF Project FSAR contains criteria and the TSR selection process applicable to all SNF Project facilities. Section B5 3 2 contains information specific to the CVDF in addition to that provided in Section 5 3 2 of the SNF Project FSAR

B5 3 1 Criteria

The control selection criteria used for the SNF Project are described in Section 5 3 1 of the SNF Project FSAR.

AC = Administrative Control  
CSB = Canister Storage Building  
HEPA = high-efficiency particulate air (filter)  
HVAC = heating, ventilation, and air conditioning  
LCO = Limiting Condition for Operation  
MCO = multi-canister overpack
B5 3 2 Safety Structures, Systems, and Components not Provided with Technical Safety Requirement Coverage

The safety-class and safety-significant SSCs discussed by section in Chapter B4 0 that have not been provided with TSR coverage are identified below. All other safety SSCs are provided with TSR coverage with a Limiting Condition for Operation (LCO) or are included in an Administrative Control (AC) program. The bases for not providing TSR coverage are provided in the following paragraphs.

B5 3 2 1 Transportation Cask The transportation cask is safety class for transportation. There are no controls for this SSC because it is a Design Feature (refer to Section B5 6) and its safety function is managed by configuration control processes. This SSC was credited as maintaining its structural integrity during the accidents.

B5 3 2 2 Multi-Canister Overpack The multi-canister overpack (MCO) is a safety-class SSC. There are no TSR controls for this safety SSC because it is a Design Feature (refer to Section B5 6) and its safety function is managed by configuration control processes. This SSC was credited as maintaining its structural integrity during the accidents.

B5 3 2 3 Cold Vacuum Drying Facility Building Structure Some functions of the CVDF structure are classified as safety-significant SSCs. There are no TSR controls for the structure because it is a Design Feature (refer to Section B5 6) and its safety function is managed by configuration control processes. The structure was not credited as a control in the analyses but was identified as a key assumption in maintaining its structural integrity during the accidents.

B5 3 2 4 Process Water Conditioning Transfer Line The process water conditioning (PWC) lines between the MCOs and the process water tank room are safety-significant SSCs. There are no TSR controls for these safety SSCs because they are Design Features (refer to Section B5 6) and their safety function is managed by configuration control processes.

B5 3 2 5 Multi-Canister Overpack and Cask Vent Jumpers The MCO and cask vent jumpers are safety-significant special tools. There are no TSR controls for these safety SSCs because they are Design Features (refer to Section B5 6) and their safety function is managed by configuration control processes.

B5 4 DERIVATION OF FACILITY MODES

B5 4 1 Operational Modes

The facility operational modes (operation, standby, and shutdown) for the CVDF were identified to indicate overall facility status. The individual process bay submodes (operation,
standby, and repair) define each process bay's status so conditions can be clearly highlighted to plant personnel.

The facility modes for the CVDF are defined as follows:

**Operation Mode** — The facility contains at least one MCO within the process bays, or the facility is administratively declared capable of receiving and/or processing MCOs although an MCO may not be present in any process bay. Maintenance activities are permitted in this mode provided the associated activities will not result in entry into the LCO action statements.

**Standby Mode** — The facility contains no MCOs within the process bays. Process water transfers to, from, or within the process water tank room may be occurring. Maintenance activities are permitted in this mode provided the associated activities will not result in entry into the LCO action statements.

**Shutdown Mode** — The facility contains no MCOs within the process bays. No process water transfers to, from, or within the process water tank room are occurring. Maintenance activities are permitted in this mode.

When the facility is in **Operation mode**, the individual process bays can be in any of the following submodes. Process bay submodes do not apply when the facility is in standby or shutdown mode.

**Operation Submode** — The process bay is receiving, containing, or processing an MCO. Maintenance activities are permitted in this submode provided the associated activities will not result in entry into the LCO action statements.

**Standby Submode** — The process bay does not contain an MCO but meets the LCO requirements necessary for it to receive an MCO. Maintenance activities are permitted in this submode provided the associated activities will not result in entry into the LCO action statements.

**Repair Submode** — The process bay does not contain an MCO and is not capable of receiving an MCO. Maintenance activities are permitted in this submode provided the associated activities will not result in entry into the LCO action statements. Note that maintenance activities involving the safety-class instrumentation and control (SCIC) system will require both of the affected process bays (i.e., those bays requiring the system's operability to meet redundancy requirements) to be in the repair submode.
B5 4 2 Minimum Staffing Requirements

The minimum operations shift complement in the Operation and Standby modes is one shift manager (or designee) and two nuclear operators. In Shutdown mode, there are no minimum staffing requirements (i.e., the facility may be unstaffed). This minimum staff in each mode is considered adequate to perform the minimum safety functions necessary to protect the health and safety of the public, onsite workers, and the environment during normal operations and abnormal and emergency conditions. The minimum staff does not necessarily include individuals necessary to fulfill the CVDF mission, goals, and objectives. The shift manager (or designee) is required to be Building Emergency Director (BED)-qualified.

Qualification training for the minimum staff (managers and nuclear operators) is addressed in Chapter 120 of the SNF Project FSAR. The program for TSR, emergency, and alarm response administrative procedures is addressed in Chapter 120. Emergency response is addressed in Chapter 150 of the SNF Project FSAR. The general considerations for determining the minimum staff are provided in Section 542 of the SNF Project FSAR, while CVDF-specific considerations are identified below.

Normal operations Determination of the minimum operations shift complement during normal operations are based on the routine surveillances required for TSR compliance. A surveillance is considered a low-difficulty task. The surveillances that must be performed during normal operations include the following:

- Verifications of process parameters such as process bay local exhaust heating, ventilation, and air conditioning (HVAC) and process vent system exhaust flow
- Verifications that equipment is in place prior to beginning specific operational tasks
- Functional tests of systems to demonstrate operability
- Instrument calibrations
- Interlock channel checks

Abnormal conditions The minimum operations shift complement during abnormal conditions is necessary to ensure compliance with required actions specified in LCO action statements with completion times of less than 8 hours or that include the term "immediately." Hanford Site experience has shown that additional staff could be provided within 8 hours, if needed (considering the most adverse weather and travel conditions), to ensure all LCO completion times are met. LCO completion times of "immediately" imply the highest sense of urgency and are given top priority over all other activities.
The minimum operations shift complement is the same in Operation and Standby modes. Specific LCO-required actions that would need to be performed immediately within a specified completion time, or prior to resuming operation (in which case a completion time is not specified), include the following:

- Manual trip of the SCIC system to provide isolation and purge of the MCO
- Verification of operating conditions (e.g., process bay local exhaust HVAC and process vent system flow)
- Restoration of system operability
- Restoration of process parameters such as tempered water (annulus) system water levels

The minimum operations shift complement is adequate during abnormal conditions to perform necessary job functions.

**Emergency conditions** The minimum operations shift complement during emergency conditions is necessary to ensure response to the spectrum of accidents analyzed in Chapter B3 (hazardous and nonhazardous). The minimum operations shift complement must make prompt initial notifications and implement initial protective actions to preclude or reduce the exposure of individuals affected by hazards or unsafe conditions during an emergency.

The shift manager (or designee) is the BED. The BED is primarily responsible for assessment of the event and protective actions at the CVDF. The BED also makes onsite notifications, implements emergency management procedures, implements facility emergency plans, classifies events, and controls event response. Two nuclear operators are considered adequate to respond to an event and support actions requested by the BED. The BED requests support services, as necessary, to perform administrative functions and the minimum functions required to ensure the health and safety of the public, onsite workers, and the environment.

DOE/RL-94-02, Hanford Emergency Management Plan, does not specify a fixed minimum staff for a particular accident at a given facility. A graded approach is used to respond to an event depending on the severity of the event. The discoverer of an event initiates response to the event. In some cases, the discoverer or other facility staff can respond adequately to the event. In other cases, resources outside the facility are required. When an emergency occurs, the event is assessed by the BED, and additional staff is obtained as necessary to respond to the accident. Two nuclear operators are considered adequate to respond to an event scene and support actions requested by the BED. Additional staff is obtained as needed.
B5 5 TECHNICAL SAFETY REQUIREMENT DERIVATION

B5 5 1 Instrumentation

B5 5 1 1 LCO 3 1 1 — Safety-Class Instrumentation and Control System

**Purpose** This control, to ensure SCIC system operability, is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents, and exceed onsite risk evaluation guidelines for the internal hydrogen explosion accident. Ensuring the capability to detect and respond to process upsets (via interlocks that result in alarms, isolation of the MCO, activation of the safety-class helium system, and/or removal of power to the tempered water (annulus) system heater) reduces the risk associated with process variable perturbations.

This LCO applies to process bays in operation submode. Specific applicability for the various control functions varies according to the MCO processing steps and is consistent with the applicability of the input systems as identified in LCO 3 1 2 through LCO 3 1 7. Once the MCO is dried sufficiently (as demonstrated by AC 5 17) and isolated, MCO overpressurization thermal runaways, and hydrogen explosions are no longer a hazard for the MCO.

The LCO will require operability of the SCIC system to provide the capability to respond to process parameter upsets by providing isolation and purge of the MCO and/or removing power to the tempered water (annulus) system heater, as appropriate, and providing remote alarm indication in the control room so that further recovery actions may be taken by the operators as appropriate. Operability requirements will include the capability to receive and respond appropriately to the following inputs from process system sensors:

- Vacuum purge system (VPS) line pressure to detect both high and low MCO pressures when in pressure operations, and unexpected pressure rises (e.g., caused by inleakage) when under vacuum drying (these events will trigger an alarm, and isolation and purge of the MCO).

  **NOTE** The high MCO pressure setpoint serves as a Limiting Control Setting (LCS) to protect the MCO maximum pressure safety limit (SL 2 1 1).

- VPS line pressure to detect insufficient time at pressure or excessive time under vacuum during vacuum drying cycles (these events will trigger an alarm, and isolation and purge of the MCO).
• General-service helium system purge flow rate and VPS pressure to detect a low helium purge flow when the MCO is above 12 torr (this event will trigger an alarm, and isolation and purge of the MCO)

• Tempered water (annulus) system water level to detect low annulus water levels (this event will trigger an alarm, manual actions will be required to restore annulus water levels [LCO 3 1 5])

• Tempered water (annulus) system water temperature to detect high tempered water temperatures (this event will trigger the de-energization of the tempered water [annulus] system heater)

• Process bay temperature to detect conditions (high temperature) that may threaten the heat sink for the MCO and the safe operation of process bay instrumentation (this event will trigger an alarm, and isolation and purge of the MCO, manual actions will be required to restore process bay temperatures [LCO 3 1 6])

• Seismic activity to detect conditions that may threaten safe facility operations (this event will trigger an alarm, and isolation and purge of the MCO and de-energization of the tempered water [annulus] system heater)

Surveillances related to this LCO include periodic functional testing of system channels to demonstrate operability as well as channel checks of the interlocks for indication of the appropriate condition. Calibrations of the process system sensors that provide input to the SCIC system, although required by their associated LCO rather than this LCO, will be included with the SCIC listing of surveillances for the sake of completeness.

This control also requires LCOs 3 1 2, 3 1 3, 3 1 4, 3 1 5, and 3 1 6 to be met in order to provide the necessary sensor inputs required for the proper functioning of the system. Although the seismic trip instrumentation is considered part of the SCIC system, it has been broken out as a separate LCO (LCO 3 1 7) because it functions independently of the SCIC logic circuits.

**Derivation Criteria** This control was selected because it can be applied to multiple accidents. In addition, it serves to prevent, rather than mitigate, many of the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.

**B5 5 1 2 LCO 3 1 2 — Vacuum Purge System Pressure Instrumentation**

**Purpose** This control, to ensure VPS pressure instrumentation operability, is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents, and exceed onsite risk evaluation guidelines for the internal hydrogen explosion accident.
When vacuum drying, excessive durations under vacuum or insufficient intermediate durations at pressure can place the MCO outside the analyzed envelope of existing thermal analyses for safe operations. In addition, an unexpected pressure rise during vacuum drying, as well as low MCO pressures when the MCO is in pressure operations, indicate undesirable process conditions (e.g., process system leaks or vacuum pump degradation) that could eventually lead to process upsets. The SCIC system is relied upon to respond to these conditions. Ensuring the capability to provide pressure indication to the SCIC system in order to detect vacuum cycles exceeding allowable durations, pressure operation cycles of less than allowable durations, unexpected pressure rises when vacuum–purge drying and low system pressures when in pressure operations is therefore necessary to support the operability of the SCIC system (LCO 3 1 1).

This LCO applies to process bays in operation submode from the time the MCO filtered process exit port (VPS-V-*010) is opened until such time that the final pressure rebound test (AC 5 17) is successfully completed and both MCO process port valves are closed. Once the MCO is dried sufficiently (as demonstrated by AC 5 17) and isolated, MCO overpressurization, thermal runaways, and hydrogen explosions are no longer a hazard for the CVDF.

The LCO will require operability of the VPS pressure instrumentation (PT 1*36, PT 1*37, PT 1*08, and PT 1*10) to provide the capability to sense MCO internal pressure and transmit the information to the SCIC system. Surveillances related to this LCO include periodic instrument calibrations to maintain operability.

**Derivation Criteria** This control was selected because it serves to prevent, rather than mitigate, the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.

**B5 5 1 3 LCO 3 1 3 — General-Service Helium System Flow Instrumentation**

**Purpose** This control, to ensure general-service helium system flow instrumentation operability, is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4. Without controls, the release of radioactive material could exceed onsite risk evaluation guidelines.

Low helium purge flows after completing MCO draining indicate undesirable process conditions (e.g., insufficient hydrogen dilution) that could eventually lead to process upsets. The SCIC system is relied upon to respond to these conditions. Ensuring the capability to provide flow indication to the SCIC system to detect low helium purge flows is therefore necessary to support the operability of the SCIC system (LCO 3 1 1).

This LCO applies to process bays in operation submode from the time the MCO long axial process tube port plug (VPS-V-*019) is opened until such time that the proof-of-dryness demonstration (AC 5 17) is successfully completed. At the start of the final pressure rebound...
test, the flow path through the MCO is isolated to preclude any water addition to the MCO. Once the MCO is dried sufficiently (as demonstrated by AC 5 17) (regardless of port valve position), helium flow is no longer required because of the low hydrogen generation rate within the MCO.

The LCO will require operability of the general-service helium system flow instrumentation (FIT 1*20 and FIT 1*21) to provide the capability to sense the helium flow rate and transmit the information to the SCIC system. Surveillances related to this LCO include periodic instrument calibrations to maintain operability.

**Derivation Criteria** This control was selected because it serves to prevent, rather than mitigate, the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.

**B5 5 1 4 LCO 3 1 4 — Tempered Water (Annulus) System Temperature Instrumentation**

**Purpose** This control, to ensure tempered water (annulus) system temperature instrumentation operability, is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents, and exceed onsite risk evaluation guidelines for the internal hydrogen explosion accident.

High annulus water temperatures indicate undesirable process conditions in the tempered water (annulus) system (e.g., excessive heater output) that could lead to process upsets. The SCIC system is relied upon to respond to these conditions. Ensuring the capability to detect high annulus water temperatures is therefore necessary to support the operability of the SCIC system (LCO 3 1 1).

This LCO applies to process bays in operation submode when the tempered water (annulus) system supply line (TW-*01-SS-1-1/2) is connected to the lower cask process port (TW-QD-*018) and power is being supplied to the tempered water (annulus) system heater. When the supply line is connected and power is supplied to the heater, excessive heater output to the annulus water is possible. The LCO will require operability of the tempered water (annulus) system temperature instrumentation (TSH 1*28 and TSH 1*29) to provide the capability to monitor tempered water (annulus) system temperature and transmit information to the SCIC system if temperatures rise too high. Surveillances related to this LCO include periodic calibrations of the switch setpoints to maintain operability.

**Derivation Criteria** This control was selected because it serves to prevent, rather than mitigate, the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.
B5 5 1 5 LCO 3 1 5 — Tempered Water (Anulus) System Level Detector

Purpose This control, to ensure tempered water (annulus) system level detector operability, is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5 and the MCO overpressurization accident in Section B3 4 2 6 Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents and exceed onsite risk evaluation guidelines for the internal hydrogen explosion accident

Low annulus water levels can, over time, lead to process upsets because of the loss of sufficient heat transfer capability The SCIC system is relied upon to alert operators to this condition so that manual corrective actions can be taken to restore tempered water (annulus) system water levels Ensuring the capability to detect low tempered water (annulus) system water levels is therefore necessary to support the operability of the SCIC system (LCO 3 1 1)

This LCO applies to process bays in operation submode from the time the tempered water (annulus) system supply line (TW-01-SS-1-1/2) is connected to the lower cask process port (TW-QD-*018) until such time that the final pressure rebound test (AC 5 17) is successfully completed Once the MCO is dried sufficiently (as demonstrated by LCO 3 2 6) (regardless of port valve position), the MCO heat generation potential is sufficiently low that annulus water loss is no longer a safety concern

The LCO will require operability of the tempered water (annulus) system level detector instrumentation (LSL 1*24 and LSL 1*25) to provide the capability to detect low annulus water levels and transmit the information to the SCIC system Manual actions will be required to restore levels to within limits Part of the required actions for this LCO will therefore include required operator response to restore adequate water levels within a specified time frame as a result of low annulus water levels Surveillances related to this LCO include periodic calibrations of the level switch to maintain operability, and verification that adequate annulus refill capabilities (i.e., special tools and water supply) are available before processing an MCO

Derivation Criteria This control was selected because tempered water (annulus) system water levels are a parameter of concern In addition, this control was selected because it serves to prevent, rather than mitigate, the associated accidents

B5 5 1 6 LCO 3 1 6 — Process Bay Temperature Instrumentation

Purpose This control, to ensure process bay temperature instrumentation operability, is derived from the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6 Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents, and exceed onsite risk evaluation guidelines for the internal hydrogen explosion accident
High temperatures in the process bay have the potential to exceed the rated performance limits of the safety-class pressure instrumentation. In addition, for stagnant tempered water conditions, the process bay becomes the heat sink for the MCO and must stay below 115 °F. The SCIC system is relied upon to respond to high process bay temperatures and take precautionary actions (via interlocks that actuate the safety-class helium system and alarm remotely) before performance limits are reached or maximum heat sink temperatures are exceeded. Ensuring the capability to detect high process bay temperatures is therefore necessary to support the operability of the SCIC system (LCO 311).

This LCO applies to process bays in operation submode from the time the filtered process exit port (VPS-V-*010) is opened until such time that the final pressure rebound test (AC 5 17) is successfully completed and both MCO process port valves are closed. Once the MCO is dried sufficiently (as demonstrated by AC 5 17) and isolated, the pressure instrumentation being protected by this LCO is no longer required to be operable, and the MCO is no longer at risk from high bay temperatures due to its low water content.

The LCO will require the operability of the process bay temperature instrumentation (TSHH 1*38 and TSHH 1*39) to provide the capability to detect high process bay temperatures and transmit the information to the SCIC system. Surveys related to this LCO include periodic calibrations of the temperature switch to maintain operability.

**Derivation Criteria**  
Process bay temperature control was selected because it is a parameter of concern. In addition, this control was selected because it serves to prevent, rather than mitigate, the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.

**B5 5 1 7 LCO 3 1 7 — Seismic Trip Instrumentation**

**Purpose**  
This control, to ensure seismic trip instrumentation operability, is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents and exceed onsite risk evaluation guidelines for the internal hydrogen explosion accident.

Seismic events can damage the tempered water (annulus) system heater protection circuits or the MCO pressure sensor, neither of which is seismically qualified. The seismic trip instrumentation will activate the SCIC system trip independent of the logic circuits as a precaution during seismic events to perform the following actions:

- Isolate the MCO from the normal processing system
- Initiate a helium purge flow through the MCO from the safety-class helium system
- De-energize the tempered water (annulus) system heater

November 1999
Ensuring the capability to detect seismic activity is therefore necessary to support the operability of the SCIC system to perform the actions listed above (LCO 3 1 1).

This LCO applies to process bays in operation submode. The LCO will require the operability of the seismic trip instrumentation (AT-5235 AT-5336 AT-5437 including auctoneering panels CP-120 and CP-121) to detect seismic activity and trip the SCIC system in all bays processing MCOs. Surveillances related to this LCO include periodic calibrations of the three independent sensors to maintain operability.

**Derivation Criteria**  This control was selected because it serves to prevent rather than mitigate, the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.

**B5 5 1 8 LCO 3 1 8 — Isolation Valve Interlocks**

**Purpose**  This control, to ensure isolation valve interlock operability, is derived from the thermal runaway reaction accident in Section B3 4 2 5 and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents.

The VPS isolation valves (on the deionized water side) prevent water from the deionized water supply from entering the MCO following MCO drying operations. The PWC isolation valves prevent water from the PWC system from entering the MCO following MCO drying operations. Inadvertent water addition to the MCO once pressure rebound testing and the dryness demonstration has begun has the potential to leave the MCO susceptible to thermal runaway reaction or overpressurization events. In addition, the PWC isolation valves ensure a premature drain of the MCO does not occur prior to placing the SCIC in the drain position.

This LCO applies to process bays in operation submode when the SCIC system is in the heatup position, as well as from the time the initial pressure rebound test begins until such time that the final pressure rebound test (AC 5 17) is successfully completed and both MCO process port valves are closed. When the SCIC system is in the heatup position, the interlock on the PWC isolation valves prevents a premature drain of the MCO when SCIC interlocks, credited while draining, are not active. During dryness testing, interlocks on both the PWC isolation valves and the VPS isolation valves (on the deionized water side) are needed to prevent water additions to the MCO once drying is complete. Once the MCO is isolated by the process port valves, water intrusion is no longer possible, and the LCO to protect against it is therefore no longer required.

The LCO will require the operability of the VPS isolation valve interlocks (on the deionized water side [VPS-GOV 1*11 and VPS-GOV 1*17]) and the PWC isolation valve interlocks (PWC-GOV 1*03 and PWC-GOV 1*30) to keep the isolation valves closed at all times when the SCIC is in the heatup position, as well as during initial pressure rebound testing, the proof-of-dryness demonstration, and final pressure rebound testing. Surveillances related to this LCO include periodic functional testing of the interlocks to ensure they are capable of performing their...
safety function  The isolation valves necessary to isolate the potential water sources must be operable to support the safety function of the interlocks. The operability of these valves is addressed in LCO 3 2 1 since these isolation valves are critical to the operability of this system as well.

**Derivation Criteria**  This control was selected because it serves to prevent, rather than mitigate, the associated accident and uses engineered controls rather than administrative programs to achieve its safety function.

**B5 5 2 Helium Systems**

**B5 5 2 1 LCO 3 2 1 — Safety-Class Helium System**

**Purpose**  This control, to ensure safety-class helium system operability, is derived from the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents and exceed onsite risk evaluation guidelines for the external hydrogen explosion and internal hydrogen explosion accidents.

The thermal runaway reaction accident analysis identified a situation in which the loss of the heat transfer capability normally provided by the helium within the MCO can increase the risk of a thermal runaway reaction. The hydrogen explosion accident analysis identified the need to maintain MCO headspace free of flammable concentrations of hydrogen and oxygen. The MCO overpressurization accident analysis identified a situation in which the loss of a pressure relief path from the MCO could lead to the slow pressurization of the isolated MCO and eventually to releases caused by overpressurization. Ensuring that the capability exists to correct process upsets through the activation of the safety-class helium system reduces the likelihood of these accidents.

This LCO applies to process bays in operation submode from the time the MCO long axial process tube port (VPS-V.*019) is opened until such time that the final pressure rebound test (AC 5 17) is successfully completed and both MCO process port valves are closed. Once the MCO is dried sufficiently (as demonstrated by AC 5 17) and isolated, thermal runaways, hydrogen explosions, and MCO overpressurization are no longer a hazard for the CVDF. The safety-class helium system controls consist of operability requirements to provide the capability to actuate the safety-class helium system. This includes the capability to isolate the MCO from the VPS and the PWC receiver tanks, and the capability to open connections between the MCO and the safety-class helium system to establish helium purge flow and a pressure vent path to the process bay local exhaust HVAC and process vent system. The settings of the pressure control valves ensure that venting to the process vent from the purge valves will not occur less than 60 seconds from system activation. This is important for protecting against the creation of flammable mixtures in
the process bay local exhaust HVAC and process vent system after a loss of facility power. The
delay allows time for the diesel generator to come up to power and for the process bay local
exhaust HVAC and process vent fans to come up to the maximum required flow for adequate
dilution. Surveillances related to this LCO include:

- A periodic verification that sufficient helium is present within the safety-class helium
  system to provide a 27-minute purge of the MCO to remove any air and preclude
  flammable conditions within the MCO.

- Periodic functional testing of pressure control valves to demonstrate system
  operability.

NOTE: the pressure control valve settings, in conjunction with the rupture disks
identified in Section B5 6 9, serve to protect the MCO maximum pressure safety limit
(SL 2 1 1).

- Periodic verification that the general-service helium system, VPS, and PWC system
  components (e.g., isolation valves and instrument air filters) necessary to isolate the
  MCO and maintain an intact pressure boundary for the safety-class helium system are
  capable of performing their support functions.

Manual operator action (e.g., to change out or refill helium bottles) may be necessary to
maintain this system operational in the event of a leak inside the qualified piping and valves or,
over long periods, as a part of recovery.

When the safety-class helium system is active and flowing, a minimum flow rate in the
process bay local exhaust HVAC and process vent system is required (refer to LCO 3 4 2) to
ensure flammable mixtures do not occur outside the MCO because of the mixture of hydrogen
from the MCO headspace and air in the local exhaust ventilation system.

Derivation Criteria: This control was selected because it serves to prevent, rather than
mitigate, the associated accidents and uses engineered controls rather than administrative
programs to achieve its safety function.

B5 5 3 Multi-Canister Overpack Pressure Protection

B5 5 3 1 Safety Limit 2 1 1 — Multi-Canister Overpack Maximum Pressure

Purpose: This safety limit, establishing the maximum allowable MCO pressure, is derived
from the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of
radioactive material could exceed offsite release limits. The resulting overpressurization may
result in an MCO pressure in excess of its 340 lb/in², which is the pressure a mechanically sealed
MCO can safely survive according to HNF-SD-SNF-SARR-005, *Multi-Canister Overpack Topical Report*

This safety limit applies to the process bays in Operation submode prior to the successful completion of the final pressure rebound test (AC 5 17) and the closure of both MCO process port valves (VPS-V-*010 and VPS-V-*019). Upon completion of the final pressure rebound test, the MCO is no longer capable of reaching pressures in excess of the safety limit value. Once the MCO is isolated from CVDF processing systems, it is no longer capable of being pressurized by either the normal or safety-class helium supply.

This safety limit establishes the maximum pressure an MCO at the CVDF can tolerate. Beyond this limit, primary passive barrier failure may occur if no controls are applied, with a resulting uncontrolled release to the onsite worker with unacceptable consequences. The three sources of high pressure identified in Chapter B3.0 are addressed as follows:

- LCO 3 1 1 (Safety-Class Instrumentation and Control System) provides an MCO high pressure trip setpoint that serves as the supporting LCS for this safety limit against MCO overpressurization due to isolation. In addition, LCO 3 3 1 provides additional pressure protection from MCO overpressurization by providing another controlled release path from the MCO.

- LCS/LCO 3 3 2 (Pressure Safety Relief Valves) provides the supporting LCO and LCS for this safety limit against normal helium supply overpressurization.

- In the event of safety-class helium supply overpressurization, the MCO is protected by the pressure control valves of the safety-class helium system and associated rupture disks. LCO 3 2 1 addresses the pressure control valves, while the passive design features of the rupture disks are identified in Section B5 6 9.

**Derivation Criteria.** Although this pressure parameter does not meet all the criteria identified within Section 5 3 1 2 of the SNF Project FSAR required for selection of this parameter as a safety limit, it was deemed necessary by the U.S. Department of Energy, Richland Operations Office. It is therefore included in order to define acceptable pressure values for the CVDF. It is important to note, however, that the MCO is capable of being isolated from CVDF pressure instrumentation systems during processing. In this configuration, the MCO is capable of exceeding pressure limits, even though the pressure is neither under operator control nor directly measurable at these times. While controls are credited in Chapter B3 0 and applied with the TSRs to prevent excessive pressures in this configuration, the parameter does not conform to the typical convention of a safety limit.
B5 5 3 2 LCO 3 3 1 — Multi-Canister Overpack Vacuum Purge System Connections

**Purpose** This control, to ensure MCO VPS connections are properly made and proper confinement boundaries are established, is derived from the gaseous release accident in Section B3 4 2 1, the MCO internal explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction accident and the MCO overpressurization accident, and exceed onsite risk evaluation guidelines for the gaseous release accident and the MCO internal hydrogen explosion accident. Functionality of the MCO vent path and VPS connection interfaces provides a method of both ensuring a controlled release from the MCO in overpressurization situations, and preventing leakage from the MCO caused by faulty process connections.

This LCO applies to process bays in Operation submode from the time the filtered process exit port (VPS-V-*010) is opened until such time that the final pressure rebound test (AC 5 17) is successfully completed and both MCO process port valves are closed. Once the MCO is properly dried and isolated, pressure control from the 30 lb/in² gauge VPS vent path (VPS-PSE-1*33) is no longer needed, and system leakage no longer is a hazard for the MCO. This LCO consists of requirements to properly establish the MCO process connections to relieve high MCO pressures in a controlled manner. Surveillances related to this LCO include the following:

- Verifications while making process connections that the vent path is aligned properly, this ensures that overpressurization protection is in place for MCO processing.

- VPS system process connections (VPS-V-*010 and VPS-V-*019) are verified to be leak-tight (performed by a vacuum decay test or by pressurizing the MCO long axial process tube port and process vent port with helium and using mass spectrometer leak detection capability or other available means to detect any helium leakage), this protects safety analysis assumptions in relation to air inleakage into the MCO.

- Periodic verifications that the active components of the 30 lb/in² gauge vent path (VPS-PSE-1*33) are capable of performing their safety function (e.g., that the spring-loaded pressure relief valve [VPS-CKV-*112]) cracks open at pressures ≤35 lb/in² gauge and reseats at pressures ≥20 lb/in² gauge), these settings ensure that any hydrogen vented to the process bay local exhaust HVAC and process vent system does not result in the creation of flammable mixtures.

**Derivation Criteria** This control was selected because the VPS connection points are part of the isolation boundary of the MCO, making this control necessary for a wide range of accident scenarios (e.g., those involving isolation of the MCO). Once connected to the MCO, the MCO 30 lb/in² gauge vent path actually becomes part of the primary confinement boundary.
B5 5 3 3 LCS/LCO 3 3 2 — Pressure Safety Relief Valves

Purpose This control, to ensure general-service helium system safety relief valve operability, is derived from the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for this accident. Ensuring the operability of these valves reduces the likelihood of this accident to within the offsite release limits and onsite risk evaluation guidelines.

This LCS/LCO applies to the facility in Operation mode. The general-service helium system safety relief valve controls consist of operability requirements that ensure that helium supply pressures are reduced to acceptable levels prior to the helium supply entering the process system. The setpoint of the pressure safety valves (He-SRV-5026 and He-SRV-5031) is <30 lb/in² gauge and serves as an LCS to protect the safety limit. Surveillances related to this LCS/LCO include functional testing of the pressure safety relief valves to verify operability.

Derivation Criteria This control was selected because it serves to prevent, rather than mitigate, the associated accidents and uses engineered controls rather than administrative programs to achieve its safety function.

B5 5 4 Heating, Ventilation, and Air Conditioning Systems

B5 5 4 1 LCO 3 4 1 — Process General Supply/Exhaust Heating, Ventilation, and Air Conditioning System

Purpose This control, to ensure process general supply/exhaust HVAC system operability, is derived from the gaseous release accident in Section B3 4 2 1, the liquid release accident in Section B3 4 2 2, the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, and the MCO overpressurization accident in Section B3 4 2 6. Without HVAC controls, the release of radioactive material could exceed onsite risk evaluation guidelines for these accidents. Ensuring the operability of this system reduces the consequences of these accidents to within the onsite risk evaluation guidelines.

The process general supply/exhaust HVAC system high-efficiency particulate air (HEPA) filtration is required to accommodate the presence of general ventilation flow within the bay at the time of a postulated event, drawing radioactive material through the system. This LCO applies when the facility is in operation and standby modes when the process general supply/exhaust HVAC system fans are operating. When the fans are not operating, no differential pressure is being provided by this system, so filtration requirements no longer apply. The process general supply/exhaust HVAC system controls consist of an operability requirement that the exhaust HEPA filter provide a testable HEPA filtration of no less than 99.9%. Surveillances related to this LCO include an annual aerosol test of efficiency to demonstrate operability.
Derivation Criteria  This control was selected because it serves to mitigate multiple accidents to minimize implementation cost

B5 5 4 2 LCO 3 4 2 — Process Bay Local Exhaust Heating, Ventilation, and Air Conditioning and Process Vent System

Purpose  This control, to ensure process bay local exhaust HVAC and process vent system operability, is derived from the gaseous release accident in Section B3 4 2 1, the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without HVAC controls, the release of radioactive material could exceed onsite risk evaluation guidelines for these accidents. Ensuring the operability of this system reduces the likelihood and consequence of these accidents to within the onsite risk evaluation guidelines.

The process bay local exhaust HVAC and process vent system is required to provide a reliable source of differential pressure (i.e., confinement) between the process bays and the environment, and to filter any releases to the process vent. The process bay local exhaust HVAC and process vent system controls consist of operability requirements that include the following elements. The elements apply for process bays in Operation submode from the time the process bay doors are closed until such time that the final pressure rebound test (AC 5 17) is successfully completed and the MCO process port valves are closed (Flow switch interlock requirements only apply when cask venting is occurring).

- A minimum flow rate of 1,000 standard ft³/min shall be maintained through the system (as adjusted for instrumentation error). This ensures confinement and prevents flammable mixtures of air and hydrogen in the process bay local exhaust HVAC and process vent system. Operability requirements include the instrumentation necessary to verify flow (FS-8*07) and remote alarms to alert facility personnel when this minimum flow is not met.

- When the process bay doors are closed, the portion of the system between (and including) the process hood isolation dampers, the exhaust fans, and the safety-class helium system must be intact and must provide a testable HEPA filtration of no less than 99.9%. This ensures the capability to adequately filter particulate release from the MCO, both during normal flow states (should an accidental release occur while normal flow is active) and during safety-class helium system purging.

- The instrument air system piping, tank, and check valve (PI-5*20) shall be leak tight and have a tank pressure of ≥90 lb/in². This ensures the capability exists to open the hood isolation damper as part of system restart during a loss of power.

- A flow switch interlock (FS-8*52) shall be present and operable to ensure safe cask and MCO venting. The interlock shall close the flow valve when process bay local...
HVAC and process vent system flows drop below 1,000 standard ft\(^3\)/min (as adjusted for instrumentation error), effectively terminating the venting operation until proper flows can be reestablished.

Surveillances related to this LCO include annual aerosol testing of efficiency, as well as instrumentation and setpoint calibrations and functional checks. The system will be functionality tested periodically to ensure 1,000 standard ft\(^3\)/min (as adjusted for instrumentation error) can be achieved within 30 seconds of receiving diesel power (Diesel power must be supplied within 30 seconds of power loss to meet the overall requirement to establish the minimum flow within 60 seconds of facility power loss.) This is necessary to ensure adequate flows are present in the process bay local exhaust HVAC and process vent system before safety-class helium purge flow vents to the system.

**Derivation Criteria** This control was selected because the local exhaust ventilation system serves to mitigate multiple accidents to minimize implementation cost.

**B5 4 3 LCO 3 4 3 — Reference Air System**

**Purpose** This control, to ensure reference air system differential pressure instrumentation operability, is derived from the gaseous release accident in Section B3 4 2 1, the liquid release accident in Section B3 4 2 2, the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, and the MCO overpressurization accident in Section B3 4 2 6. Without HVAC controls, the release of radioactive material could exceed onsite risk evaluation guidelines for these accidents. The operability of this system plays a role in reducing the consequences of these accidents to within the onsite risk evaluation guidelines.

The differential pressure instrumentation of the reference air system is necessary to alert facility personnel to a loss of confinement being provided by the balance of general, local, and recirculation HVAC systems. The reference air system controls consist of operability requirements that include the following elements:

- Instrumentation (PDI-8*20 and PDI-8080) necessary to measure differential pressures between the area of concern (process bay or process water tank room) and the reference air system (a relative negative pressure [i.e., confinement] must be maintained within the areas of concern in order for the process bay's confinement function to be considered met).

- Remote differential pressure alarm instrumentation indicating the loss of confinement.

This LCO applies when the facility is in operation and standby modes. Individual process bay confinement monitoring and alarm requirements are applicable only if an MCO is present within the bay and the process bay door is closed. Process water tank room confinement monitoring and alarm requirements are applicable only if the circulation pump is running.
Surveillances related to this LCO include periodic calibrations of the differential pressure instrumentation and functional checks of the remote alarm.

**Derivation Criteria**

This control was selected because it serves to mitigate multiple accidents to minimize implementation cost.

**B5 5 4 4 LCO 3 4 4 — High-Efficiency Particulate Air Filter Loading**

**Purpose**

This control derives from the MCO external hydrogen explosion accident in Section B3 4 2 3. The purpose of this control is to limit the radioactive inventory available for release from the HEPA filters contained in the process bay local exhaust HVAC and process vent system based on the results of the analysis, the release of radioactive material without controls could exceed onsite risk evaluation guidelines. This LCO will require that HEPA filter and prefilter housing contact dose radiation levels be maintained equal to or less than 82 mR/h consistent with the source term assumed within the accident analysis to ensure that controls identified for the risk reduction of this accident remain valid by limiting the inventory on the filters available for release.

This LCO applies to the facility in operation mode. In other facility modes, there are no sources of hydrogen present within the facility to cause a hazard associated with explosions in the process bay local exhaust HVAC and process vent system. Surveillances related to this LCO include periodic checks of HEPA filter housing contact dose rates.

**Derivation Criteria**

This control protects an assumption within the analysis relative to filter loading available for release.

**B5 5 5 Standby Power**

**B5 5 5 1 LCO 3 5 1 — Diesel Generator**

**Purpose**

This control, to ensure diesel operability, is derived from the gaseous release accident in Section B3 4 2 1, the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents, and exceed onsite risk evaluation guidelines for the gaseous release, MCO external hydrogen explosion, and MCO internal hydrogen explosion accidents.

Upon loss of facility power, the diesel generator will be relied upon to provide power to the local exhaust fans and isolation damper actuator solenoids such that satisfactory local exhaust flow is maintained. This flow is necessary both to dilute hydrogen releases to the local exhaust from the MCO, as well as to maintain adequate differential pressure within the process bays.
Without differential pressure detection (because of the power loss), a configuration is required that ensures an adequate differential pressure. A local exhaust restart circuit will place the process bay local exhaust HVAC and process vent system in the required configuration (including fan motor logic) to ensure adequate system flow within 60 seconds after a loss of facility power. (Diesel power must be supplied to the process bay local exhaust HVAC and process vent system within 30 seconds, and the process bay local exhaust HVAC and process vent system fans must come up to the necessary speed within an additional 30 seconds.)

This LCO applies when the facility is in Operation mode. The LCO will require operability of the diesel generator to provide power to the local exhaust HVAC and process vent system within 30 seconds of loss of offsite power. Surveillances related to this LCO will include the following:

- Periodic verifications of sufficient diesel fuel volume
- Periodic verification of fuel quality that could affect its performance
- Periodic inspections of the starting air system
- Periodic functional testing of the diesel generator including the local exhaust restart circuit to demonstrate that the diesel generator will automatically start when required and is capable of assuming the required loads

**Derivation Criteria**  This control was selected because power is a support function required for the continued operability of the process bay local exhaust HVAC and process vent system flow. The diesel was broken out as a separate control in order to highlight its critical function in the maintenance of continued HVAC flow for differential pressure and hydrogen mitigation and to provide a means for identifying the specific requirements for required actions upon loss of diesel availability.

**B5 5 6  Transportation-Related Activities**

**B5 5 6 1  LCO 36 1 — Receipt Transportation Window**

**Purpose**  This control derives from the MCO external hydrogen explosion accident in Section B3 4 2 3. The purpose of this control is to limit the maximum cask–MCO receipt pressure to within the initial condition assumptions of the analysis.

This LCO applies to the facility in Operation mode. This LCO will require that the transportation cask be vented to the process bay local exhaust HVAC and process vent system within 24 hours of completing the helium purge of the MCO headspace at the K Basins. Required actions will identify any additional precautionary measures needed for the handling of out-of-
specification MCOs at the CVDF. A surveillance to verify the venting of the cask within the transportation window time limit will be part of this LCO.

**Derivation Criteria.** This control was selected to protect initial condition assumptions relative to maximum cask-MCO receipt pressure and hydrogen concentrations.

**B5 5 7 Administrative Controls**

**B5 5 7 1 AC 5 7 — Nuclear Criticality Safety**

**Purpose.** This control will protect the assumptions of the nuclear criticality evaluation in Chapter B6 0 to ensure that CVDF operations minimize the risk of nuclear criticality. Key elements of this programmatic AC are derived from contractor procedures that include requirements for criticality safety evaluations, criticality prevention specifications, and criticality training. The criticality controls identified in Chapter B6 0 are derived from HNF-SD-SNF-CSER-005, *Criticality Safety Evaluation Report for the Multi-Canister Overpack*, and HNF-SD-SNF-CSER-006, *Criticality Safety Evaluation Report for the Cold Vacuum Drying Facility's Process Water Handling System*.

**Derivation Criteria.** A nuclear criticality program is required according to DOE Order 5480 22, *Technical Safety Requirements*, Section 9 e (5) as one of the standard ACs.

**B5 5 7 2 AC 5 8 — Measurement and Test Equipment**

**Purpose.** This control provides a support control for the measuring and test equipment used to verify process parameters to comply with the TSRs when specific instrumentation and associated surveillances are not included in the TSR. This control applies to (1) optional instrument systems allowable in accordance with the LCO bases, and (2) instrumentation used to verify parameters for the ACs in the TSR. This control on the measuring and test equipment ensures that process parameters are properly monitored.

The program key elements include maintaining identification and traceability of TSR-related instrumentation and equipment, periodic testing of the instrumentation and equipment used, and maintaining records that demonstrate that the instrumentation and equipment were used while in calibration.

The program applies to installed and portable measuring and test equipment when used to verify process parameters specified in the TSRs where specific instrumentation and associated surveillances are not already identified in the TSR. This program does not apply to equipment such as rulers, tape measures, levels, and other measurement devices if commercial equipment provides accuracy adequate to meet the measurement specifications.
Annex B - Cold Vacuum Drying Facility

Derivation Criteria: This control was included because for some process parameters in the TSR, it is not essential to specify the particular instrumentation or measuring equipment used to demonstrate compliance with the parameter involved provided the instrumentation or equipment used to monitor the parameter is maintained. This support control was selected because it provides operational flexibility to use various instrumentation and equipment to measure TSR parameters provided it complies with this AC while ensuring the safety functions assumed in the accident analysis are met.

B5 5 7 3 AC 5 9 — Configuration Management

Purpose: This configuration management AC was deemed necessary to protect the safe operation of the facility against uncontrolled changes to Design Features. A sitewide institutional safety program for configuration management is in place to control such changes. In addition, the Spent Nuclear Fuel Project has developed its own plan, HNF-SD-SNF-CM-001, Spent Nuclear Fuel Project Configuration Management Plan, to handle configuration management at the Spent Nuclear Fuel Project facilities. The plan defines the process that the Spent Nuclear Fuel Project has approved to secure configuration management and it is formatted to include the elements and functions established in DOE-STD-1073-93, Guide for Operational Configuration Management Program. The plan includes compliance requirements with the overall Site configuration management system and criteria for change control, document control, configuration management implementation, and periodic assessments. This AC heightens attention to the need for CVDF compliance with these configuration management plans.

Derivation Criteria: This control was deemed necessary by the Project Hanford Management Contract Contractor to protect the safe operation of the facility against uncontrolled changes to Design Features. HNF-PRO-700, Safety Analysis and Technical Safety Requirements, states that configuration management is a candidate AC when Design Features have been identified for a facility.

B5 5 7 4 AC 5 10 — Transporter Placement

Purpose: The transporter placement control is derived from the accident analysis for an MCO internal hydrogen explosion in Section B3 4 2 4, the accident analysis for a thermal runaway reaction in Section B3 4 2 5, and the accident analysis for MCO overpressurization in Section B3 4 2 6. Without controls, the thermal runaway reaction and MCO overpressurization accidents have consequences that could exceed offsite release limits, and the internal hydrogen explosion accident has consequences that could exceed onsite risk evaluation guidelines.

This control will require that a program be established and maintained to ensure that before connecting CVDF systems to the MCO, the cask, which is located upon the trailer, is positioned such that the cask is no greater than an established safe distance from the ideal horizontal placement, as identified in Chapter B4 0. This control protects the MCO during seismic events. Seismic calculations indicate that in the event of an earthquake, the transporter movement will not
be sufficient to damage the key process lines or equipment required to maintain the MCO in a safe configuration provided the cask location is within a specified distance of the ideal

**Derivation Criteria**  This control protects an assumption within the safety analysis regarding limits on expected seismic responses

### B5 5 7 5  AC 5 11 — Helium Cylinder Receipt Acceptance

**Purpose**  The helium cylinder receipt acceptance control is derived from the accident analysis for an MCO external hydrogen explosion in Section B3 4 2 3, for an MCO internal hydrogen explosion in Section B3 4 2 4, and for a thermal runaway reaction in Section B3 4 2 5. Without controls, the thermal runaway reaction accident has consequences that could exceed offsite release limits, and the external hydrogen explosion and internal hydrogen explosion accidents have consequences that could exceed onsite risk evaluation guidelines.

This control will require that a program be established and maintained to ensure that the manufacturer's paperwork and shipping papers are checked upon helium cylinder receipt at the CVDF, both the normal and safety-class supply, to verify that the cylinder's contents were sampled by the supplier and that the sample met the required purity specification of >99% helium. This control, in conjunction with the facility's institutional quality assurance program, protects against impurities or improper gases being fed by the normal or safety-class helium gas supply into the MCO during processing operations.

**Derivation Criteria**  This control protects an assumption within the safety analysis regarding helium supply purity. Sampling the cylinder's contents reduces the likelihood of connecting helium cylinders into the helium system with contents that could lead to accident conditions.

### B5 5 7 6  AC 5 12 — Process Bay Telescoping Door

**Purpose**  The process bay telescoping door control supports LCO 3 4 3, "Reference Air System," for the gaseous release accident in Section B3 4 2 1, the accident analysis for an MCO external hydrogen explosion in Section B3 4 2 3, for an MCO internal hydrogen explosion in Section B3 4 2 4, and for an MCO overpressurization accident in Section B3 4 2 6. Without HVAC confinement controls, the onsite consequences of these accidents could exceed onsite radiological risk evaluation guidelines.

This control will require that a program be established and maintained to ensure that the process bay telescoping door be closed before connecting any CVDF process systems to the MCO. Opening the telescoping door during processing has the potential to negate the confinement function within the process bay that the various HVAC systems provide. The telescoping door may not be opened again until all process connections have been removed from the MCO except when such action is required as part of an approved recovery plan.
**Derivation Criteria** This control was selected to protect the confinement function of the process bay local exhaust HVAC and process vent system during processing operations.

**B5 57 7 AC 513 — Combustible Loading Limits**

**Purpose** The combustible loading limits control is derived from the liquid release accident in Section B3 4 2 2, the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. This control is established based on Chapter B3 0 assumptions made regarding combustible loading limits in relation to the fire hazard implementation plan (SNF-4942).

This control applies in the facility Operation and Standby modes. A program shall be established and maintained to limit the combustible loadings as determined by the fire hazard implementation plan (SNF-4942).

**Derivation Criteria** This control was selected to protect Chapter B3 0 assumptions relating to the fire hazard analysis. Without this control, the safety analysis conclusion that no release of radioactive material to the environment will result due to the evaluated fire scenarios could be invalidated.

**B5 57 8 AC 514 — Bridge Crane Movement Restrictions**

**Purpose** The bridge crane movement restriction control is derived from the MCO external hydrogen explosion accident in Section B3 4 2 3, the MCO internal hydrogen explosion accident in Section B3 4 2 4, and the thermal runaway reaction accident in Section B3 4 2 5. Without controls, the thermal runaway reaction accident has consequences that could exceed offsite release limits, and the external and internal hydrogen explosion accidents have consequences that could exceed onsite risk evaluation guidelines.

This control applies to process bays in the Operation submode. This control will require that a program be established and maintained to ensure that overhead bridge crane movement is not allowed from the time the tempered water (annulus) system supply line (TW-*01-SS-1-1/2) is connected to the lower cask process port (TW-QD-*018) until such time as the final pressure rebound test is successfully completed and both MCO process port valves (VPS-V-*010 and VPS-V-*019) are closed (except when such action is required as part of an approved recovery plan). Bridge crane movement has the capability to shear key process lines and lead to unacceptable accident conditions. Restricting bridge crane movement when the MCO is susceptible to external and internal hydrogen explosions and thermal runaway reactions reduces the likelihood of these events.

**Derivation Criteria** This control was selected because it serves to prevent, rather than mitigate the associated accidents.
B5 5 7 9 AC 5 15 — Multi-Canister Overpack Process Port Valve Isolation

**Purpose** The MCO process port valve isolation control is derived from the MCO internal hydrogen explosion accident in Section B3 4 2 4, the MCO thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the thermal runaway reaction and high pressure blowdown have consequences that could exceed offsite release limits for the thermal runaway reaction and MCO overpressurization accidents, and could exceed onsite risk evaluation guidelines for the MCO internal hydrogen explosion accident.

This control applies in the process bay Operation submode. This control will require that a program be established and maintained to ensure that when isolating the MCO with the process port valves, the long axial process tube port (VPS-V-*019) must be closed at least 5 minutes prior to closing the filtered process exit port (VPS-V-*010). This will ensure that an MCO still processing will initiate an SCIC trip during the MCO isolation steps. This SCIC trip serves as a means of detecting human errors in which the incorrect bay was entered for MCO shipment preparation, prior to the MCO actually meeting shipment criteria.

**Derivation Criteria** This control was selected because it serves to prevent, rather than mitigate, the associated accident. The human error of mistakenly entering the wrong bay for MCO isolation has the capability to defeat most of the engineered features of the CVDF. This is because the premise of MCO isolation is that disconnection from the process systems which protect the MCO is an acceptable action to take. By requiring the proper process port isolation sequence and delay as part of the MCO isolation process, the likelihood of discovery of the error is increased significantly. This program ensures that control room alarms that are not expected during the disconnection process occur for MCOs not meeting dryness criteria.

B5 5 7 10 AC 5 16 — Preparing the Multi-Canister Overpack for Shipment

**Purpose** The control for preparing an MCO for shipment is derived from the assumptions in the safety analyses in Annex A, the Canister Storage Building (CSB) FSAR. A maximum MCO leakage rate of less than $10^{-5}$ standard cm$^3$/s is assumed in the analyses to prevent unacceptable onsite consequences caused by external hydrogen explosions.

This control applies to process bays in the Operation submode. This control will require that a program be established and maintained to ensure that the MCO mechanical seal and cover plate seals are leak tested to confirm seal integrity. Shipment of the MCO to the CSB is not allowed until an MCO leakage rate of less than $10^{-5}$ standard cm$^3$/s is demonstrated.

**Derivation Criteria** This control was selected to protect safety analysis assumptions in the safety analyses in Annex A, the CSB FSAR, and serves to prevent, rather than mitigate, the associated CSB accidents.
B5 5 7 11 AC 5 17 — Dryness Testing

**Purpose** This AC derives from the gaseous release accident in Section B3 4 2 1, the MCO external hydrogen explosion accident in Section B3 4 2 3, the thermal runaway reaction accident in Section B3 4 2 5, and the MCO overpressurization accident in Section B3 4 2 6. Without controls, the release of radioactive material could exceed offsite release limits for the thermal runaway reaction accident and MCO overpressurization accident, and exceed onsite risk evaluation guidelines for the gaseous release accident and the MCO external hydrogen explosion accident. The dryness tests conducted at the CVDF demonstrate adequate dryness levels within an MCO to proceed to the next processing step and, finally, to proceed with shipment preparation. Ensuring that each of these critical decision steps is adequately performed prevents hazards associated with excessive MCO water content following vacuum drying.

This AC applies to process bays in Operation submode. This AC will require meeting an initial pressure rebound test surveillance (pressure rise test) before entry into the proof-of-dryness demonstration is allowed. Similarly, a proof-of-dryness demonstration surveillance must be met before the final pressure rebound test steps can begin. Finally, a final pressure rebound test must be met before shipment preparation steps that involve MCO reconfiguration can begin.

These control requirements are established to prevent accidents at the CVDF related to excessive MCO water content following vacuum drying. In addition, they protect an interface between the CVDF and CSB. Dryness testing is critical for ensuring the CVDF mission has been successful (i.e., the applicable CSB receipt acceptance criteria are met) and the MCO may safely be shipped to the CSB.

**Derivation Criteria** This control was selected to protect safety analysis assumptions within the CVDF and CSB FSAR Annexes. It serves to prevent, rather than mitigate, the associated accidents.

B5 5 7 12 AC 5 18 — Safety Programs

**Purpose** This AC provides commitment to the following Environment, Safety, and Health Organization programs:

- In-service surveillance and maintenance
- Procedures and training
- Quality assurance

**Derivation Criteria** The commitment to an in-service surveillance and maintenance program is based on the complexity of the safety equipment relied on for prevention of accidents. The commitment to a procedures and training program is based on the high level of dependence placed on operator actions. The commitment to a quality assurance program is based on the need to ensure vendors’ quality assurance programs (important for ensuring cylinder gas purity) is adequate.
B5 6 DESIGN FEATURES

Design Features for the CVDF that, if altered or modified, would have a significant effect on safe operation are listed below. Descriptions of these Design Features are provided in Chapter B2. The safety functions they perform are provided in Chapter B4.

B5 6.1 Process Bay Local Exhaust Heating, Ventilation, and Air Conditioning and Process Vent System

Design Features for the process bay local exhaust HVAC and process vent system include the following:

- The ductwork from the fail-closed process hood isolation dampers, the safety-class helium system, and the 30 lb/in² gauge vent path must route discharge air to the process bay local exhaust HVAC and process vent system HEPA filter.
- The MCO and cask vent jumpers shall direct the flow of hydrogen through an orifice device located in the process bay local exhaust HVAC and process vent system.
- The orifice device to restrict the flow rate of hydrogen into the process bay local exhaust HVAC and process vent system. The orifice diameter must be sufficiently small such that the minimum process bay local exhaust HVAC and process vent system flow rate will dilute hydrogen concentrations below the lower flammability limit.

B5 6.2 Tempered Water (Annulus) Water System

Design Features for the tempered water (annulus) system include the following:

- The lines from the cask must rise above the minimum acceptable water level in the annulus.
- The lines identified above must be seismically qualified and have antisiphon devices to prevent draining of the cask annulus (see LCO 3 1 5 for surveillance and verification of annulus refill capabilities).
- The system must have the appropriate piping and refill port to accommodate a manual fill of the cask annulus with water.
B5 6.3 Transportation Cask

Design Features for the transportation cask include the following:

- The transportation cask must provide a pressure boundary prior to cask venting.
- The transportation cask must be dimensionally stable and provide a boundary to maintain adequate annulus water levels in conjunction with the tempered water (annulus) system.
- The transportation cask must provide adequate personnel shielding during process operations.
- The cask drain fitting must retain its integrity as a leak-tight connection to the tempered water supply piping.

B5 6.4 Multi-Canister Overpack

Design Features for the MCO include the following:

- The MCO must provide primary confinement for the fuel elements and fuel fragments.
- The MCO must provide a pressure boundary for the safety-class helium system.
- The MCO shell and closure plug, including the internal filter guard, must have a geometrically favorable design to prevent criticality.
- The MCO Mark IA fuel and scrap baskets’ center posts and baseplates must have a geometrically favorable design to prevent criticality.
- Any MCO scrap baskets must have flow bypass restricters (wipers) and copper inserts adequate to ensure the heat transfer in the MCO remains consistent with thermal analysis assumptions.
- The MCO shield plug must provide adequate personnel shielding during process operations.
- The MCO shield plug must have an active rupture disk with a setting of 150 lb/in² during CVDF processing.
Annex B — Cold Vacuum Drying Facility

B5 6 5 Cold Vacuum Drying Facility Building Structures

Design Features for the CVDF building structures include the following

- The process bays and the process water tank room floor, slab, walls, and roof, in conjunction with the process general supply/exhaust HVAC system, must provide confinement for gaseous releases

- The structural supports of the process bays must maintain structural integrity throughout all design basis natural phenomena hazard events (performance category 3)

- The structural supports of the process water tank room and process support area (including the second floor mechanical equipment room) must maintain structural integrity throughout all design basis natural phenomena hazard events (performance category 2)

- The CVDF exhaust stack must maintain structural integrity throughout all design basis natural phenomena hazard events (performance category 2)

- The remaining structure (administrative area) must be designed such that should it fail because of a seismic event, it fail in a manner that does not impact the seismically qualified portions

- Fire-rated structures identified in the fire hazard analysis (SNF-4268) and fire hazard implementation plan (SNF-4942) must provide the necessary fire protection characteristics as specified within the analysis

B5 6 6 Process Water Conditioning Transfer Line

Design Features for the PWC transfer line between the MCO and the process water tank room include the following

- The line height must be at least 8 ft above the floor to protect against vehicle impacts within the bay

- The line must be qualified to withstand all anticipated environmental factors (e.g., corrosion)
B5 6 7 Multi-Canister Overpack and Cask Vent Jumpers

Design Features for the MCO and cask vent jumpers include the following

- The MCO and cask vent jumpers must route discharge gas to the process bay local exhaust HVAC and process vent system

B5 6 8 Reference Air System

Design Features for the reference air system include the following

- The reference air system must provide a common reference point for comparisons of differential pressure within the facility

B5 6 9 Safety Class Helium System

Design Features for the safety class helium system include the following

- Each leg of the safety class helium system must contain an active rupture disk with a setting of 125 lb/in^2 gauge during CVDF processing

B5 6 10 Process Bay Recirculation Heating, Ventilation, and Air Conditioning System

Design Features for the process bay recirculation HVAC system include the following

- The supply dampers of the process bay recirculation HVAC system must fail closed upon a loss of power

B5 6 11 Process General Supply/Exhaust Heating, Ventilation, and Air Conditioning System

Design Features for the process general supply/exhaust HVAC system include the following

- The pneumatic isolation dampers for the process bays must fail closed upon a loss of power or instrument air

- The ductwork from the process bays and the process water tank room must route discharge air to the process general supply/exhaust HVAC system HEPA filter
B5 6 12 Vacuum Purge System

Design Features for the VPS include the following

- The MCO primary vent path must contain an active rupture disk with a setting of 30 lb/in² gauge during CVDF processing

B5 7 INTERFACES WITH TECHNICAL SAFETY REQUIREMENTS FROM OTHER FACILITIES

The TSRs of other facilities that affect the SNF Project facilities safety basis are briefly summarized in Section 5.7 of the SNF Project FSAR. TSRs of other facilities that affect the CVDF are summarized in the following subsections

B5 7 5 Receipt and Transfer of Spent Nuclear Fuel

The CVDF interfaces with other facilities through the receipt of SNF from the K Basins and the transfer of the dried fuel to the CSB. This section describes the SNF material transfers to and from the CVDF and applicable controls

B5 7 5 1 Spent Nuclear Fuel Transfers from K Basins to the Cold Vacuum Drying Facility

The K Basins sends spent nuclear fuel to the CVDF in accordance with established controls that require a program to maintain compliance between the K Basins TSRs and the TSRs of interfacing facilities through the use of approved and controlled operating specifications and procedures. As discussed in Section 5.7.5.1 of the SNF Project FSAR, SNF shipments from the K Basins must meet the criteria and assumptions identified in Chapter B3.0

B5 7 5 2 Spent Nuclear Fuel Transfers from the Cold Vacuum Drying Facility to the Canister Storage Building

The CVDF sends spent nuclear fuel to the CSB based upon dryness testing (AC 5.17). AC 5.17 requires that proper testing be conducted to establish that the MCO water content is within acceptable levels to ensure that key parameters assumed in the CSB safety analysis are protected. AC 5.16 requires that an acceptable MCO leakage rate be demonstrated before the MCO is shipped to the CSB to ensure CSB leak rate assumptions are protected

B6 0 PREVENTION OF INADVERTENT CRITICALITY

B6 1 INTRODUCTION

This chapter evaluates the potential for criticality of spent nuclear fuel (SNF) and the fissionable materials in the water drained from the multi-canister overpacks (MCOs) during normal processing and off-normal conditions in the Cold Vacuum Drying Facility (CVDF). It further describes the engineered features and administrative controls that prevent any credible occurrence of a criticality event during handling and processing of the SNF at the CVDF.

Transportation casks containing loaded MCOs are transported on a trailer from the K Basins to the CVDF (HNF-SD-TP-SARP-017). Both the MCO and shipping cask annulus remain flooded with water during transport. The CVDF has four individual processing bays. A tractor-trailer carrying the loaded transportation cask is backed into a bay, the tractor is removed, the bay door is closed, the cask lid is removed, a processing hood is installed, and the water is drained from the MCO. All processing takes place with the cask-MCO on the trailer.

The internal temperature of the MCO is maintained within process limits by circulating water in the cask annulus. The water in the MCO is drained into receiver tanks in the process water conditioning (PWC) system and a helium blanket is maintained in the MCO. Following draining, the MCO is vacuum-dried to remove as much free water as possible. The water in the receiver tanks is filtered, deionized, and stored in the PWC large storage tank (PWC-TK4001). When the tank is full, the water is returned to the K Basins by truck. The design, processing operations, and equipment are described in detail in Chapters B2.0 and B4.0, and a flow diagram is provided in Figure B2-12. The CVDF design aspects that are pertinent to criticality prevention are summarized in Section B6.4, which also includes the administrative controls required to prevent inadvertent criticality.

Many conceivable spent fuel geometrical configurations that could lead to criticality events under both normal and abnormal conditions were postulated. Normal loading of the MCOs and baskets is described in WHC-SD-WM-SAR-062, K Basins Safety Analysis Report. Each MCO may be loaded in one of three normal configurations:

- All fuel baskets
- One scrap basket and four or five fuel baskets
- Two scrap baskets and three or four fuel baskets

Mark IA and Mark IV baskets are not mixed in an MCO. It is permissible to mix Mark IV fuel or scrap with Mark IA fuel or scrap in Mark IA baskets. As described in WHC-SD-WM-SAR-062, the only situations in which Mark IA fuel or scrap would be loaded into Mark IV baskets occur when the 12 long-length Mark IA fuel assemblies in the K West Basin are loaded into a Mark IV fuel basket and when the small amount of Mark IA fuel and scrap in the K East Basin is loaded into Mark IV baskets. Only two types of abnormal conditions for the MCO are considered.
credible at CVDF a misloaded MCO and a flooded MCO with a drained cask–MCO annulus. These normal and abnormal configurations have been analyzed in the criticality safety evaluation report, HNF-SD-SNF-CSER-005, *Criticality Safety Evaluation Report for the Multi-Canister Overpack*. The criticality analysis for the PWC system is described in HNF-SD-SNF-CSER-006, *Criticality Safety Evaluation Report for the Cold Vacuum Drying Facility’s Process Water Conditioning System*. Normally, only a small amount of fissile material in suspension is expected to be transferred to the PWC system during the draining and drying process. This material is expected to be removed by a combination of ion exchange and mechanical filtering. The abnormal condition would be for these mechanisms to fail, allowing fissile material to be discharged to the PWC storage tank. A selected set of the bounding analyses applicable to the CVDF is described in Section B6.3. The criticality safety design limits, their bases, and the parameters to be applied for prevention of criticality at the CVDF, are discussed in Section 6.3.3.1 of the SNF Project Final Safety Analysis Report (FSAR).

The double contingency criterion requires at least two unlikely, independent, and concurrent events to occur before a criticality is possible. A contingency is a possible but unlikely change in a condition or control identified as an important barrier in preventing a nuclear criticality accident. The analyses presented in this chapter demonstrate that the double contingency principle is satisfied by showing that the allowed fuel and scrap configurations in the MCO and fissile material buildup in the PWC system will not exceed a $k_{\text{eff}}$ of 0.95 for the violation of any single contingency.

The scope of the criticality analysis presented in this chapter does not include handling of the spent fuel assemblies and the MCOs at the K Basins, transport of the MCOs from the K Basin area to the CVDF, or transport of the MCOs to the Canister Storage Building. This chapter addresses the administrative controls at the K Basins only to the extent those administrative controls, more specifically their failures, could affect criticality safety at the CVDF. The K Basins administrative controls and their failure modes are described in detail in WHC-SD-WM-SAR-062. Criticality information applicable to all SNF Project facilities is provided in Chapter 6.0 of the SNF Project FSAR.

This chapter also addresses implementation of requirements to achieve U.S. Nuclear Regulatory Commission equivalency in the design of the CVDF with respect to criticality prevention. The double contingency requirements in Title 10, *Code of Federal Regulations*, Part 72, "Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste" (10 CFR 72), Section 72.124, are identical to those delineated in DOE Order 5480.24, *Nuclear Criticality Safety*. 
As discussed in Section B6.3, the $k_{\text{eff}}$ of fuel is determined with full density water, the limiting condition prior to draining. The $k_{\text{eff}}$ of fuel scrap is analyzed for fuel with optimum-sized particles and an optimum water-to-fuel volume ratio prior to draining. The $k_{\text{eff}}$ of the MCO as it is drained is discussed in HNF-SD-SNF-CSER-005. To meet the double contingency criterion the MCOs and the casks are designed to maintain structural integrity and confinement during normal and off-normal conditions, as described in Section B6.3.3.

The $k_{\text{eff}}$ of fissionable material in the process water drained from the MCO is determined by analyzing the optimum fuel-to-moderator ratio of a homogeneous suspension. This optimized suspension was analyzed in the various geometries of the equipment of the PWC system and in a slab on the floor of the PWC room.

Section B6.4 describes the safety features implemented in the design of the spent fuel containers (i.e., fuel baskets and MCOs) and in the vessels and components of the PWC system, to preclude or prevent any criticality event during handling and processing of the MCOs at the CVDF. The administrative controls applied during the operation phase to preclude and prevent criticality are also discussed in Section B6.4.

B6.2 REQUIREMENTS

The requirements that form the basis of criticality protection are identified in Section 6.2 of the SNF Project FSAR.

B6.3 CRITICALITY CONCERNS

B6.3.1 Criticality Hazards

See Section 6.3.1 of the SNF Project FSAR for identification of the fissile material available in SNF Project facilities and loaded into MCOs.

B6.3.2 Multi-Canister Overpack Criticality Analysis Conditions

Each of the four CVDF process bays can contain a single trailer containing a single loaded transportation cask (see Figure B2-8). Neutronic interaction between the loaded cask in each bay is minimized by both the distance between the casks, the bay walls, and by the cask itself. The transportation cask has a shielded central region, a removable lid, and an annulus between the outer wall of the MCO and the inner wall of the transportation cask. The transportation cask is received at the CVDF with the lid installed and the annulus flooded with water. After the trailer is secured in a CVDF process bay, the lid of the cask is removed and a process hood is installed allowing the process equipment to be connected. Two process lines are connected to the...
transportation cask annulus to circulate water through the annulus region for temperature control while the water inside the MCO is pumped out through the process suction line connected to the long axial process tube in the MCO. The MCOs are sealed after drying for transport to the Canister Storage Building.

Under normal conditions, each type of spent fuel is contained in the baskets designated for that type of fuel (see Figures 6-1 and 6-2 in the SNF Project FSAR), and the baskets in turn are stacked in an MCO (see Figure 6-3 in the SNF Project FSAR). The Mark IA basket holds a maximum of 48 Mark IA fuel assemblies and has a central, 6.625-in. outer diameter, stainless steel center post specifically designed for criticality control. The Mark IA fuel scrap basket has a similar center post. This center post reduces the amount of fuel or scrap the MCO basket can contain to a critically favorable geometry in the MCO and has a hole 1.75 in. in diameter in the center for the long axial process tube. The Mark IV fuel basket holds a maximum of 54 fuel assemblies. Neither the fuel basket nor the Mark IV scrap basket have the centrally located pipe for criticality control but do have a 2.6-in. outside diameter, centrally located tube for installation of the long axial process tube used for draining and vacuum drying the MCO.

The MCO has a shield plug installed and is always inside a transportation cask while at the CVDF, the transportation cask lid is removed at the CVDF. For the purposes of criticality analysis, the configuration of a loaded MCO with the largest \( k_{\text{eff}} \) was determined. For both a Mark IA and Mark IV MCO, this configuration includes two scrap baskets, one at the top and the other at the bottom, with partially loaded fuel baskets. Each partially loaded Mark IA fuel basket contains 47 fuel assemblies with an empty location in the middle row of the fuel assemblies, and each partially loaded Mark IV fuel basket contains 53 fuel assemblies with an inner element only loaded in the outer fuel assembly row (Figures 6-4 and 6-5 of the SNF Project FSAR). Each processing bay may contain only one transportation cask, but all processing bays may contain a transportation cask at the same time.

A complete description of the codes used to perform the criticality analyses, their modeling assumptions, and their validations is provided in HNF-SD-SNF-CSER-005. The effect on \( k_{\text{eff}} \) of changes in moisture content, fuel length selections, corrosion, and sludge deposition have been investigated in HNF-SD-SNF-CSER-005 by performing calculations over the range of possible variations of the individual parameters. These calculations show that \( k_{\text{eff}} \) typically increases as the fuel length approaches the basket diameter. The \( k_{\text{eff}} \) decreases as fuel length gets greater than the basket diameter in the case of Mark IV fuel. Corrosion of the fuel reduces \( k_{\text{eff}} \) because the uranium oxide that is produced is neutronically less reactive than the metal fuel. The longest length assemblies for the Mark IV fuel (26.1 in. long) and the 20.9-in. long elements for the Mark IA fuel were chosen to represent "normal conditions" to compensate for these uncertainties. Only 12 Mark IA fuel assemblies are left in the K West Basin that are longer than 20.9 in. There is also a small amount of Mark IA fuel and scrap in the K East Basin. Normally, Mark IA material is not loaded into Mark IV baskets. However, HNF-SD-SNF-CSER-010, Criticality Safety Evaluation Report for the K Basin Fuel Retrieval Subproject, allows the loading of Mark IA fuel and scrap into Mark IV baskets under two specific conditions. In the K West Basin, the twelve 26.1-in. long Mark IA assemblies may be loaded into a Mark IV fuel basket containing...
42 Mark IV fuel assemblies. The small amount of Mark IA fuel and scrap in the K East Basin also may be loaded into Mark IV fuel or scrap baskets. A maximum of seven Mark IA fuel assemblies may be loaded into a Mark IV fuel basket containing 47 Mark IV fuel assemblies. Mark IA scrap may be loaded into a Mark IV scrap basket and is limited to 105 kg. The total mass in the basket may not exceed 980 kg (Kessler and Peck 1999).

The potential exists for significant amounts of fuel material to be entrained in the MCO water, and the PWC system may contain sludge or particulate from an MCO. Therefore, after each MCO is drained, the lines are flushed and drained to the receiver tank and the water is processed and monitored before being sent to the storage tank. Water in the PWC system is drained to the storage tank before processing the next MCO. The criticality analysis documented in HNF-SD-SNF-CSER-006 assumed 15 kg of material is transferred to the PWC system. According to the test results using cerium oxide, 6% to 7% of the particulate will be transferred from the MCO to the PWC system. For conservatism, the safety basis assumes a maximum of 1.5 kg of 1.25 wt% $^{235}$U as UO$_2$ enters the system for each MCO processed (SNF-2770).

B6 3.3 Multi-Canister Overpack Criticality Analysis Results

This section presents a summary of the results of the analyses performed to evaluate the potential for criticality in the MCO under normal and off-normal conditions. The specifics are documented in HNF-SD-SNF-CSER-005. The scrap basket designs have been modified to include a small region around the center post to contain small pieces of fuel that make it through the cleaning process. Since these particles are approximately the same size as optimized scrap and the criticality analyses assumed the scrap baskets were loaded with optimized scrap, no additional analyses have been performed using the new design.

This section also provides the bases for establishing the criticality safety design limits, the requirements for engineered design features, and the administrative controls for prevention of inadvertent criticality. The double contingency requirements were implemented to ensure that more than one unlikely, independent, and concurrent event has to occur to challenge criticality safety during handling and processing of the spent fuel contained in the MCOs.

The following sections summarize the criticality scenario conditions that need to be addressed for the CVDF. Sections B6 3.3.1 and B6 3.3.2 address all credible MCO scenarios. Drop scenarios are not considered credible at the CVDF because the MCO is not lifted, and the cask will not spill or fall from the transporter during a design basis earthquake (HNF-2179).

B6 3.3.1 Normal Conditions — Multi-Canister Overpack Handling

This section summarizes the results of the analyses for normal operating conditions. At the CVDF, the MCO is processed in seven stages:

- Bypass
- Heatup

b-cvdf06 sar  B6-5  November 1999
Section B2 5 1 presents an overview of the drying process. The seven stages of the drying process correlate to the switch positions on the safety-class instrumentation and control system panels. Table B6-1 lists the condition of the cask-MCO and the maximum calculated k\text{eff} for partially loaded MCOs at each stage. These calculations do not include the long-length Mark IA assemblies loaded into Mark IV baskets.

**B6 3 3 1 1 Multi-Canister Overpacks during Draining Process** The maximum k\text{eff} of the MCO exists before draining. As the MCO is drained, k\text{eff} initially decreases then increases very slightly as neutrons are reflected from drained regions to flooded regions. As the water is drained from the lower fuel baskets, k\text{eff} decreases. The peak k\text{eff} during the drain does not exceed the k\text{eff} of a flooded MCO. These results are shown in Tables B6-2 and B6-3 and Figure B6-1.

**B6 3 3 1 2 Drained Loadings** Cases cvd1 8 and cvd4 8 in Table B6-1 represent the final drained state of a transportation cask containing a fully loaded MCO at the CVDF. These dry cases assume 3 kg of water with a water density of 0.005 g/cm^3 as residual water left in the MCO after drying.

**B6 3 3 2 Abnormal Conditions for Multi-Canister Overpacks at the Cold Vacuum Drying Facility** Two bounding abnormal conditions at the CVDF were analyzed: draining the cask annulus while the MCO is still flooded, and receipt of a misloaded MCO. Three types of misloaded MCOs were analyzed: an MCO containing two adjacent scrap baskets, an MCO containing an extra scrap basket, or a Mark IV MCO containing a single basket misloaded with one canister of Mark IA fuel or scrap. As discussed in HNF-SD-SNF-CSER-005, the credible misloaded basket scenarios are for one Mark IA canister containing 14 Mark IA fuel assemblies to be loaded into a Mark IV fuel basket, or for the mass equivalent of 14 Mark IA assemblies, 233 kg, to be loaded into a Mark IV scrap basket. A receipt inspection will be performed on the MCO at the CVDF. Loading of the MCOs is done in the K Basins and the technical safety requirements for loading are described in Chapter 50 of the K Basins safety analysis report (WHC-SD-WM-SAR-062). The quality assurance documentation for MCO loading will be verified to ensure loading corresponds to the approved configurations for CVDF. The analyses of these abnormal conditions are summarized below.

MCO = multi canister overpack
6 3 3 2 1 Draining the Annulus of a Flooded Multi-Canister Overpack. If the cask annulus is drained before the MCO is dried, reflection of neutrons by the cask back into the MCO increases, and \( k_{\text{eff}} \) will increase but remain below 0.95. This scenario is shown in Table B6-4. Included in this table are the results for the long-length Mark IA assemblies that will be loaded into Mark IV fuel baskets containing Mark IV fuel. Eighteen Mark IA assemblies were modeled, which bounds the actual loading of 12 Mark IA assemblies. The assemblies were modeled in all rows of the fuel basket to bound all possible loadings. The fuel baskets were partially loaded giving the largest \( k_{\text{eff}} \) (see Section 6 3 2 of the SNF Project FSAR) and the largest \( k_{\text{eff}} \) was calculated for the case with the Mark IA assemblies in the center of the bottom fuel basket.

\(^b\)MCO = multi canister overpack

6 3 3 2 2 Misloaded Multi-Canister Overpacks or Multi-Canister Overpack Baskets

Baskets are loaded into the MCOs by the MCO cask loading system at the K Basins. There are no engineered features that prevent loading scrap baskets adjacent to each other or loading extra scrap baskets in an MCO. The system does sense the basket stack height, which prevents loading Mark IA and Mark IV baskets into the same MCO. Detailed analyses for misloaded MCOs are discussed in HNF-SD-SNF-CSER-005, Sections 5 2 3 and 5 2 4, using the reference case with the highest \( k_{\text{eff}} \) for partially loaded fuel baskets. For all credible scenarios involving misloaded
MCOs, $k_{\text{eff}}$ stays well below 0.95. The most limiting scenario is loading two Mark IV scrap baskets adjacent to each other, which has a $k_{\text{eff}}$ of approximately 0.934. There are also no engineered features that prevent loading Mark IA fuel or scrap into a Mark IV basket. The effect of loading a canister of Mark IA fuel or scrap into a Mark IV basket has been evaluated and shown not to exceed a $k_{\text{eff}}$ of 0.926 (HNF-SD-SNF-CSER-005). These results are listed in Table B6-5 for the misloaded cases with the highest $k_{\text{eff}}$.

- $k_{\text{calc}}$ is based on the partially loaded MCO
- $k_{\text{eff}} = k_{\text{calc}} + 0.0004 + ((0.01)^2 + (1.645)^2)(\sigma_e^2 + 0.002083^2)$ as defined in Section 6.3.3 of the SNF Project FSAR. This value should be less than or equal to 0.95.
- The MCO drop model containing five scrap baskets bounds all misloading for the Mark IV MCO.

**B6 3.4 Process Water Conditioning System Criticality Analysis Conditions**

The liquid in the MCO is drawn with a water jet ejector into the PWC receiver tank loop, which cycles water from the receiver tanks, through the water jet ejector, and back into the receiver tanks. The liquid is then cycled through the ion exchange modules and back into the receiver tank. When the liquid is sufficiently cleaned by the ion exchange modules, it is pumped from the receiver tank, through the ion exchange modules, through a filter, and into the storage tank.

On the average, it is expected that approximately 66 g of fissionable material oxides will be generated in an MCO from the time the fuel is cleaned in the K Basins until the water in the MCO is drained (HNF-SD-SNF-TI-015). In the bounding case, it is calculated that approximately 15 kg of fissionable material oxide could be generated (SNF-2770, Chapter 2.0). Because the combination of helium pressure and water jet ejector suction is low, draining the MCO takes approximately 30 minutes, and the only material transferred to the PWC system will be small.
particles in suspension. The small particles contained in the center region of the scrap baskets will not be removed from the MCO during the draining process, and no additional analyses were performed after the scrap baskets were redesigned to isolate a small region around the center post to contain fuel “fines.” Modeling the scrap basket as filled with optimized scrap bounds calculations that model the fines center region of the basket. As discussed in Chapter B3.0, approximately 10% or 1.5 kg, of the oxide generated after cleaning will be transported by the MCO process water into the PWC system during draining (SNF-2770). If each MCO released 1.5 kg of UO₂ into the PWC system, the total amount of UO₂ would be 660 kg. This is approximately 75% of the minimum spherical 0.95 mass of 875 kg. Clearly, a criticality in the PWC system, any of its components, or on the floor of the PWC room is impossible. However, the criticality analysis assumed that a maximum amount of 15 kg was transported to the PWC system (HNF-SD-SNF-CSER-006).

B6 3.5 Process Water Conditioning System Criticality Analysis Results

The components of the PWC system have been evaluated for criticality safety in HNF-SD-SNF-CSER-006. Dimensional limits have been imposed to ensure geometrically favorable components. All geometrically favorable piping, pumps, receiver tanks, and filters have a maximum inner diameter of 23.5 in. Interaction between components has been evaluated (HNF-SD-SNF-CSER-006), and even if the receiver tanks, filter, and piping have no spacing between them and the PWC room is flooded, $k_{\text{eff}}$ does not exceed 0.62.

The ion exchange modules are designed in accordance with design specification HNF-3904, *Procurement Specification for Ion Exchange Modules*, and have been shown to be geometrically favorable (WHC-SD-NR-CSER-011). Their maximum height is 42.25 in, and each column has an outer diameter of 16 in, with a 0.25-in wall thickness. The columns are housed in concrete and have been shown not to interact with other equipment (WHC-SD-NR-CSER-011). To exceed a $k_{\text{eff}}$ of 0.95, the ion exchange module would have to collect a minimum of 13 kg of PuO₂ with no UO₂ (WHC-SD-NR-CSER-011). The corrosion products in the MCO will contain both UO₂ and PuO₂. Typical uranium-to-plutonium ratios for the sludge in the K East Basin, where uncapped canisters are stored is greater than 400 to 1 (HNF-SD-SNF-TI-009). At a 400 to 1 ratio, the safe mass for an optimally moderated, optimally reflected hemisphere is 77.88 kg of PuO₂ and 31,022 kg of UO₂ (WHC-SD-NR-CSER-014). Based on 1.5 kg of oxide per MCO, a total of 660 kg of particulate could be carried over into the PWC system. Thus, if the ion exchange module collected all the particulate from each MCO, it would contain 1.6 kg of PuO₂ and 658 kg of UO₂, well below the safe mass for the UO₂ - PuO₂ - H₂O system.

The limit on the total mass in both the storage tank and the system is 875 kg of 1 25 wt% enriched UO₂ (HNF-SD-SNF-CSER-006).

B6 3.5.1 Normal Process The receiver tanks have a capacity of 300 gal (1,140 L), with an initial 23 gal (120 L) of water used to prime the water jet ejector. Flow from the receiver tanks circulates from the tanks, through the pumps, through the water jet ejector, and returns to the
The water jet ejector draws approximately 165 gal (625 L) of water from the MCO into the receiver tank loop. The emptying of the MCO water occurs over approximately 30 minutes. Once the water and fissionable material particulate from the MCO are in the receiver tank, the drain lines from the MCO to the receiver tanks are flushed with clean water to remove any buildup of contaminants. When this step is completed, the receiver tanks contain about 300 gal of water.

After the MCO is drained, the process water is pumped from the receiver tanks, through the ion exchange modules, and back into the receiver tanks. During the process, samples will be taken upstream and downstream from the ion exchange modules to determine the removal efficiency and the ion exchange module loading. The water will also be sampled after processing before being pumped to the storage tank. Personnel will transport these samples to a laboratory for analysis. The samples will be analyzed for fissionable material content. There are no criticality controls for transporting these samples (HNF-SD-SNF-CSER-006).

The water in the storage tank will be transferred to a tanker truck when the tank is full (15 to 20 MCOs have been processed) and taken to the K Basins. Because this truck may be used to transfer liquids at other facilities, limits are placed on the transfer by HNF-SD-SNF-CSER-006. If the truck has not been used to transfer water from sources other than CVDF, there are no limits on the transfer from CVDF. However, if the truck has been used for other transfers, the following limits apply before water is transferred from the PWC storage tank to the truck:

- The truck tank must be verified to have been cleaned and flushed following any transfer from a facility other than the CVDF.
- The water left in the truck as a "heel" must be sampled and the following verified:
  - Particle size is less than 500 μm
  - The amount of fissile material is less than 200 kg

**B6 3.5.2 Abnormal Conditions** The following abnormal conditions in the PWC system were evaluated from a criticality standpoint:

- Ion exchange module failure (release of particulate or resin into the system)
- Chronic or acute particulate filter failure
- Seismic event causing spill of PWC system contents to the floor
- Unsafe amount of fissionable material accumulated in the storage tank

The criticality considerations for these accidents are addressed with a combination of geometrically favorable components and controls on the amount of material allowed to build up in the storage tank for defense in depth. These considerations are discussed in Section B6 4.2.
B6 4 CRITICALITY CONTROLS

B6 4 1 Multi-Canister Overpack Criticality Controls

B6 4 1 1 Multi-Canister Overpack Engineering Controls  The MCO and its internals, including fuel baskets, are designed to maintain their structural integrity and perform their safety function under credible accident conditions, such as a design basis earthquake or a design basis accident impact during an MCO drop accident. The design details for the MCO and its internals are summarized in HNF-SD-SNF-SARR-005, Multi-Canister Overpack Topical Report.

Various components of both the baskets and MCOs are required to be safety class. These include the MCO shell and shield plug assembly, including the internal filter guard and the center post and baseplate of the Mark IA fuel and scrap baskets. None of the components of the Mark IV fuel and scrap baskets have been identified in Chapter B4 O as being safety class.

B6 4 1 2 Multi-Canister Overpack Administrative Controls  Basket loading and MCO loading will be performed in the K Basins. Criticality evaluations have been performed that specify the limits for these evolutions. Fuel basket loadings are limited by basket design to 48 Mark IA assemblies and 54 Mark IV assemblies. Scrap basket limits are 575 kg for Mark IA scrap and 980 kg for Mark IV scrap (HNF-SD-SNF-CSER-010). Additional analyses were performed to show it is acceptable to load the twelve 26.1-in.-long Mark IA fuel assemblies into a Mark IV fuel basket. Table B6-4 shows the results of these analyses for the contingency of a drained cask-MCO annulus at the CVDF. These results bound the expected loading (HNF-SD-SNF-CSER-005).

Loading the Mark IA material stored in the K East Basin into Mark IV baskets has also been evaluated and shown to be acceptable (HNF-SD-SNF-CSER-010). Table B6-5 shows the results of the credible misloading of Mark IA material into Mark IV fuel or scrap baskets. These results bound the loading of the small amount of Mark IA material in the K East Basin into Mark IV baskets. The MCO handling in the CVDF will not affect the geometric configuration of the fuel or baskets (HNF-SD-SNF-CSER-005). There are no operations involving lifting the MCO off of the transporter, and the transporter is designed not to fail during a seismic event (HNF-2179).

B6 4 1 3 Application of Double Contingency Principle in the Multi-Canister Overpack  Abnormal events for the MCO at the CVDF are identified in Section B6 3 3 2. Correct basket and MCO loading will be verified at the K Basins before the MCO is shipped to the CVDF and will be verified again by reviewing the loading documentation upon receipt at CVDF before the MCO is connected to the PWC system. As shown in Table B6-5, the maximum $k_{eff}$ for a credible misloaded MCO is well below the 0.95 limit. The only other abnormal event is one in which the cask annulus is left drained while the MCO remains flooded. Even should this happen, the $k_{eff}$ will stay well below the 0.95 limit as shown in Table B6-4. Thus, a single event will not exceed the safety limit.
B6 4 2  Process Water Conditioning System Controls

The following sections describe PWC system requirements that provide defense in depth.

B6 4 2.1  Process Water Conditioning System Engineering Controls For defense in depth, the receiver tanks, pumps and piping, ion exchange modules, and filter housing of the PWC system have been designed to be geometrically favorable (HNF-SD-SNF-CSER-006, HNF-SD-SNF-CSER-009).

B6 4 2.2  Process Water Conditioning System Administrative Controls Three defense-in-depth requirements have been established to monitor the potential for criticality in the PWC system.

- Samples of the water drained from each MCO will be taken upstream and downstream of the ion exchange module and on the inlet to the storage tank to determine concentrations and accumulations of fissionable materials and effectiveness of the PWC equipment.
- Radiation levels in the PWC room will be monitored by area radiation monitors.
- The storage tank will be flushed to prevent fissionable material buildup. The requirements for flushing will be specified in the criticality safety specifications.

B6 4 2.3  Application of Double Contingency Principle in the Process Water Conditioning System Section B6 3 5 2 identifies abnormal events for the PWC system, which include component failure. Each event is analyzed for criticality safety using the bounding limit of the fissionable material, 15 kg. For each event, the component is assumed to be at its process limit before the event occurs. Criticality safety is maintained because no single event can cause a criticality. Additionally, if the amount of material entering the system from a single MCO was at the bounding value of 15 kg, radiation levels in the PWC room would reach unacceptable levels (HNF-2850). This would occur long before any criticality limits are approached because the water contains radioactive fission products not considered in the criticality analysis. Using a maximum expected value of 1.5 kg per MCO and assuming an enrichment of 1.25 wt% $^{235}\text{U}$ shows that there is not enough material removed from all 440 MCOs to produce a minimum critical mass in any of the PWC components (i.e., 660 kg total removed where 875 kg is the minimum fuel mass that will exceed the $k_{\text{eff}}$ of 0.95). For spills to the PWC room floor to a depth of 10.5 in at optimum conditions of moderation, enrichment, and reflection (HNF-SD-SNF-CSER-009), the amount of fissionable material required for $k_{\text{eff}}$ to exceed 0.95, 43,000 kg, is greater than the maximum amount of material available in each of the 440 MCOs, making this event incredible.
B6 4 3 Design Basis Earthquake

A design basis earthquake has a very low probability of occurrence and little impact on the MCO and PWC system criticality (see Chapters B2 0, B3 0, B4 0, and the preceding paragraphs). The design basis earthquake is defined in Chapter B1 0. A design basis earthquake will cause slight structural damage to the CVDF building, but the transportation cask geometry, which is required for criticality safety, will remain functional (see Chapter B2 0).

B6 5 CRITICALITY PROTECTION PROGRAM

An overview of the organizational structure and interfaces and the technical and administrative practices of the criticality protection policy and programs that are developed for SNF Project operations is provided in Section 6 5 of the SNF Project FSAR. There are no unique requirements for the CVDF.

B6 6 CRITICALITY INSTRUMENTATION

A criticality alarm system or criticality detection system is not required for the CVDF in either the process bays or the PWC room. ANSI/ANS-8 3-1997, Criticality Accident Alarm System, and DOE Order 5480 24 state that neither a criticality alarm nor criticality detection system is required where the probability of a criticality accident is determined to be less than $1 \times 10^{-6}$ per year. Interpretive guidance on the probability determination (Holten 1993) states that “the use of $10^{-6}$ does not necessarily mean that a PRA [probabilistic risk assessment] has to be performed. Reasonable grounds shall be presented on the basis of commonly accepted engineering judgement.”

Section 5 2 of HNF-SD-SNF-CSER-006 contains a detailed evaluation of the PWC room and its components. The only component in the PWC system without a critically favorable design is the 5,000-gal storage tank. Only two scenarios could lead to a significant buildup of fissionable material in the storage tank:

- Both the ion exchange module and filter fail undetected while processing several MCOs.
- The transfer of liquid from the storage tank to the transfer truck does not contain any fissionable material and this accumulates in the bottom of the storage tank over time.

In addition, area radiation monitors in the PWC room must fail or be ignored by the operators, and the health physics technicians must fail to detect or report high radiation readings during routine surveys. Based on a maximum of 1.5 kg of fissionable material released to the PWC system per MCO (SNF-2770), only 660 kg of fissionable material could build up in the PWC system for the entire campaign of 440 MCOs. This is less than the minimum 0.95 mass of 875 kg.
The process bays have also been evaluated, and the probability of a criticality accident has been shown to be less than $10^{-4}$ per year based on engineering judgement. Each process bay can only contain a single cask-MCO on a trailer. The highest $k_{\text{eff}}$ that results from the worst-case accident, a drop of a flooded MCO in which all the fuel rubbilizes to optimized scrap, is less than 0.94 (HNF-SD-SNF-CSER-005). An evaluation has also been performed for the process bay sumps, which normally collect uncontaminated rain water and snow melt that drops from the trailer. The sumps are small, 5 ft by 5.5 ft by 2 ft. Based on the safe slab height of 10.5 in (HNF-SD-SNF-CSER-009), the sumps would have to contain more than 2,300 kg of 12.5 wt% enriched UO$_2$ for a criticality to be possible. This would require all the material from more than all 440 MCOs to be drained to the sump rather than to the PWC system. It further requires that the sumps not be cleaned out and that high radiation levels in the process bay be ignored, clearly an incredible series of events.

The liquid in the sumps is either pumped into drums for disposal or gravity drained to a retention basin outside the CVDF. Pumping the liquid containing the maximum expected amount of material from an MCO into a drum would produce high radiation levels. This would have to be done repeatedly, and the high radiation levels ignored, in order for a criticality to be possible (HNF-SD-SNF-CSER-006). For a criticality to be possible in the retention basin, over 50 metric tons of fissionable material would have to be drained from the sumps. This is more material than can possibly be extracted from 440 MCOs (HNF-SD-SNF-CSER-006). These events are clearly incredible. Therefore, neither a criticality alarm nor criticality detection system is required.

B6.7 U.S. Nuclear Regulatory Commission Equivalency

The U.S. Nuclear Regulatory Commission equivalency in HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements, is implemented in the design of the CVDF for criticality prevention considerations by using a $k_{\text{eff}}$ limit of 0.95. This is the only requirement from HNF-SD-SNF-DB-003 related to criticality for the CVDF.

B7 1 INTRODUCTION

The essential features of radiation protection programs that provide for radiation exposure control, radiological monitoring, and radiological protection instrumentation at all the Spent Nuclear Fuel (SNF) Project facilities are addressed in Chapter 7 of the SNF Project Final Safety Analysis Report (FSAR). Additional features of radiation protection specific to the Cold Vacuum Drying Facility (CVDF) are addressed in this Chapter B7. The CVDF’s primary function is to dry the spent fuel packed within the multi-canister overpack (MCO) to make it safe for transport, and for staging and interim storage at the Canister Storage Building. Water must be controlled to limit pressure in the MCO and the buildup of hydrogen during transportation, staging, and interim storage. A shipping cask–MCO is loaded with fuel underwater at the K Basins and transported still filled with water to the CVDF. The cask–MCO is transported to the CVDF by a tractor and trailer, and processing at the CVDF occurs with the cask–MCO remaining on the trailer. The CVDF process drains the basin water from the MCO and performs vacuum drying to remove as much additional water as possible from the MCO. At the end of the vacuum drying process, each MCO is tested for pressurization rate to ensure safe MCO conditions for the Canister Storage Building.

The major risk of radiation exposure occurs when the cask lid is removed to allow connection and removal of the seal ring and process hood and connecting and disconnecting the process connectors. With the cask lid off, the top of the MCO shield plug is exposed. Radiation fields within the radius of the cask above the MCO are expected to be less than 5 mrem/h (less than 0.05 mSv/h) for the hands and arms used to perform the process line connection and disconnection operations. Dosimetry records for personnel working near the uncovered MCO will be maintained initially for both beta/gamma and neutron exposures. Based on the review of the dosimetry results from the validation program, monitoring of neutron doses may be discontinued. During normal drying operations, processing is controlled remotely from the control room, and personnel are required to be in the process bay only for routine operational surveillances. Exposures to airborne radioactive material are expected to be minimal.

B7 2 REQUIREMENTS

The requirements that form the basis for the radiation protection program are identified in Section 7 2 of the SNF Project FSAR.

B7 3 RADIATION PROTECTION PROGRAM AND ORGANIZATION

The SNF Project radiation protection program and its organization, including safety management policies and philosophies, are described in Section 7 3 of the SNF Project FSAR.
B7.4 ALARA POLICY AND PROGRAM

See Section 7.4 of the SNF Project FSAR for a discussion of the SNF Project ALARA (as low as reasonably achievable) policy and program. The SNF Project policy regarding ALARA principles during CVDF design and construction is described in HNF-3552, *Spent Nuclear Fuel Project Execution Plan*, HNF-SD-SPN-DB-003, *Spent Nuclear Fuel Project Path Forward Additional NRC Requirements*, requires that the SNF Project incorporate U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide 8.8, *Information Relevant to Ensuring that Occupational Radiation Exposures at Nuclear Power Stations will be as Low as is Reasonably Achievable*. The NRC Regulatory Guide 8.8 requirements were appropriately implemented in the design during the design evaluation process described below.

The three main radiation sources considered in the design of the cold vacuum drying process are (1) the cask-MCO filled with SNF (the principal source), (2) the process bay local exhaust heating, ventilation, and air conditioning (HVAC) system and process vent system high-efficiency particulate air (HEPA) filters, and (3) the process water conditioning (PWC) system tanks.

A block flow diagram for the CVDF process was developed during the conceptual design phase and revised during the definitive design phase. Throughout the CVDF design process, durations were extracted from the block flow diagrams and dose constraints were established based on the expected dose at each facility location. The current flow diagram, which is documented in the CVDF operations manual (SNF-2356), identifies each step in the cold vacuum drying process and provides an estimate of the time required for each. The time estimates, along with dose rate maps for a typical process bay and the process water tank room, were used as a basis for calculating personnel radiation exposures. The dose rate maps, which are documented in HNF-2850, *Shielding Analysis for the Cold Vacuum Drying Project*, were produced for various elevations in a processing bay and in the process water tank room, from the potential radiation sources within these areas.

By combining information from the block diagram and the contour maps, a model of the CVDF was developed to determine the personnel exposure to radiation that could be expected during operation of the facility. Each activity was evaluated to determine the integrated radiation exposure of the personnel performing the activity. By using this model, the activities that produced the highest personal exposure were identified and investigated for possible exposure reduction as part of the ALARA review process. SNF-4207, *Design Features of the Cold Vacuum Drying Facility to Keep Worker Doses As Low As Reasonably Achievable*, documents the ALARA assessment and includes assumptions and conclusions. Several design changes have resulted from this process.

Specific design features credited with reducing radiation exposure and achieving ALARA program objectives include:

- MCO shipping cask and lid
Shield walls between the bays to reduce exposure from an MCO in an adjacent bay

The tempered water shield ring provides a shield collar over the annular space between the MCO and cask. This eliminated the need to use long-handled tools to perform the operations over the MCO, thereby reducing the durations and total exposure from these tasks.

A local process hood over the manually accessed process ports to capture releases from this potential source and thereby protect operators. Airborne release could occur when MCO connections are made or broken.

A shielded room was provided for collection of the water removed from the MCO and for the removal by the PWC system of the entrained SNF. In addition, major PWC components, such as the ion exchange modules and filter, were designed with integral shielding. These design changes were incorporated to mitigate an increase in the estimated source term in the SNF water that was identified during the design process.

As the previous discussion indicates, the basic principles adhered to in the design of the CVDF were to (1) determine the major contributors to the dose and examine methods for making the process more efficient, (2) provide shielding to reduce the dose, (3) examine the cost-effectiveness of using remote operations, and (4) incorporate confinement features in the design (e.g., special fittings) to confine possible fluid and gas releases. The process was an iterative one that addressed ALARA issues as the design evolved.

Several design measures were incorporated into the CVDF design to reduce the collective dose estimates resulting from maintenance activities. An effort was made to select process equipment with a long service life. In general, components were specified to have a minimum five-year design life. In addition, an effort was made to select equipment with a low frequency of maintenance and calibration. For example, the tempered water and PWC pumps are self-contained pumps with canned rotors and stators that will not need lubrication. During early design activities, one of the major anticipated contributors to maintenance dose was the PWC filter change out. To minimize this contribution, a backwash system was included in the PWC design, which results in an anticipated lifetime of the filter in excess of the facility lifetime.

**B7.5 RADIOLOGICAL PROTECTION TRAINING**

SNF Project requirements and criteria for radiological protection training are described in Section 7.5 of the SNF Project FSAR.
B7 6 RADIATION EXPOSURE CONTROL

A description of SNF Project radiation exposure control measures is provided in Section 7 6 of the SNF Project FSAR. HNF-SD-SNF-DB-003 requires that the Canister Storage Building and CVDF incorporate, as applicable, the following NRC requirements:

- Apply the hourly dose limit of Title 10, Code of Federal Regulations, Part 20, “Standards for Protection Against Radiation,” Section 20 1301, “Dose Limits for Individual Members of the Public” (10 CFR 20 1301), to the design and safety analysis.

- Incorporate control devices for access to high-radiation areas that conform to the requirements of 10 CFR 20, Section 20 1601 “Control of Access to High Radiation Areas”.

For the CVDF, the radiological exposure annual dose criteria of 10 CFR 72 104 have been incorporated into the CVDF design. These criteria apply to design measures to protect any offsite public individual during normal operations and anticipated occurrences. These annual dose equivalent criteria for effluents and direct radiation are 25 mrem (0.25 mSv) to the whole body, 75 mrem (0.75 mSv) to the thyroid, and 25 mrem (0.25 mSv) to any other critical organ. Section 20 4 of HNF-SD-SNF-RD-001, Spent Nuclear Fuel Project Standards/Requirements Identification Document, and Title 40, Code of Federal Regulations, Part 61, “National Emission Standards for Hazardous Pollutants” (40 CFR 61), require that doses received by the maximally exposed individual from emissions of radionuclides shall not exceed 10 mrem/yr. To meet these standards, engineered ventilation systems (as described in Chapter B2 0) have been provided to abate radioactive particulate emissions. Analysis results (DOE/RL-96-110, Radioactive Air Emissions Notice of Construction Cold Vacuum Drying Facility Phase II) indicate that the abated emissions from normal operations will be 0.0042 mrem/yr to the maximally exposed individual. The highest calculated radiation level in the CVDF (HNF-2850) is 100 mrem/yr. Considering the attenuation of this source over the distance to the offsite public individual, the total exposure from direct radiation and anticipated release is considerably less than the 10 CFR 72 104 and 40 CFR 61 criteria. The abnormal events (anticipated occurrences) are identified in Section 3 3 3. That discussion indicates that there are no events that cause a release of radioactive material.

For the CVDF, the criteria for the hourly dose limit to the public, as described in 10 CFR 20 1301, have been incorporated into the design. This hourly dose limit (0.002 rem) is assumed to be from external sources for any unrestricted area during normal operations and anticipated occurrences.
Access to the radiological area of the CVDF (see Figure B7-1) is controlled using one or more of the methods listed and discussed in Section 7.6.2 of the SNF Project FSAR. The potential for the highest dose rates in the CVDF occurs in the process water tank room. To avoid unnecessary and inadvertent doses to personnel, the doors to the process water tank room are provided with locks that can be used to control access. Primarily, access control will be by the use of signs and barricades. Other measures, described in Section 7.6.2 of the SNF Project FSAR, will be used when needed.

At the CVDF, the main sources of shielding for worker protection are the transportation cask, cask lid, the MCO shield plug, and the tempered water surrounding the MCO. See the discussion of MCO and transportation cask shielding in Section 7.6.2 of the SNF Project FSAR.

Permanent shielding is provided by the walls separating the process bays, the process bay support areas, and the administrative area. The PWC ion exchange modules and PWC filter have shielding built into their design. The PWC piping system is designed to allow field installation of lead shielding, if dose monitoring indicates this operational mitigation feature is required. The process water transfer line in the process bays is rinsed after each transfer to minimize retention and buildup of SNF particulate.

Engineering and administrative controls have been included in the CVDF design to minimize airborne radioactivity. The CVDF ventilation system is designed to maintain appropriate building ventilation zone pressure such that air flow is from less to more potentially contaminated areas. In addition, the process bay local exhaust HVAC and process vent system, open-faced process hoods, and process vent connections provide local and system airborne radioactive material control functions. The process bay recirculation HVAC system provides two-stage HEPA filtration of recirculated air within each process bay. This system accomplishes six air changes per hour. The process general supply/exhaust HVAC system is also provided with two-stage HEPA filtration prior to discharge via the CVDF stack. Section B4.4 provides a detailed description of the ventilation system design and confinement philosophy. These systems are used to control any potential airborne material as close to the source as possible and to provide confinement ventilation of the facility. In addition to these installed systems, portable HEPA filter ventilation systems will be used as needed by the radiological job planning of maintenance work.

The ventilation system HEPA filters are accepted by the Washington State Department of Health as the best available radionuclide control technology. Calculations of projected emissions (required by 40 CFR 61) result in the requirement for continuous airborne emission monitoring. The CVDF HVAC airborne emissions monitoring system described in Chapter B2.0, satisfies the 40 CFR 61 monitoring system requirements. This system provides sampling and monitoring functions only and provides no operational control functions.
B7 7 RADIOLOGICAL MONITORING

The radioactive material sampling and monitoring programs conducted internal and external to SNF Project facilities are addressed in Section 7.7 of the SNF Project FSAR. As fuel begins to arrive at the CVDF, a startup surveillance and monitoring program will be implemented to define and characterize exposure rates. The program will include characterization of the MCO receipt, process connections, and drying operations. It will cover grid surveys, exposure rate determinations with initial equipment use, and the change in exposure rates as shielding practices improve.

Several potential areas to be controlled as contaminated areas have been identified at the CVDF. These include small sampling areas associated with the PWC system and small areas on the mezzanine of each process bay where process connections are made.

The CVDF stack emission monitoring instrumentation is described in Chapter B2.0.

B7 8 RADIOLOGICAL PROTECTION INSTRUMENTATION

A summary of the SNF Project plans and procedures governing radiation protection instrumentation is provided in Section 7.8 of the SNF Project FSAR. A description of the types and locations of radiation detection instruments used at the CVDF is presented in Table B7-1 and in Section B2.7.11.

B7 9 RADIOLOGICAL PROTECTION RECORD KEEPING

Radiological protection record-keeping requirements are described in Section 7.9 of the SNF Project FSAR.

B7 10 OCCUPATIONAL RADIATION EXPOSURES

For the CVDF, occupational radiation exposures to the operating staff are estimated based primarily on the manual operations performed in the presence of the radiation field surrounding the cask. The total exposure of CVDF personnel during MCO processing is 62.9 mrem (0.63 mSv) per MCO (including an 11.1 person-mrem [0.11 person-mSv] PWC processing exposure). The ALARA analysis (SNF-4207) assumes 147 MCOs are processed in a year, and therefore, the annual personnel exposure incurred is 9,246 mrem (92.5 mSv). Adding the annual maintenance and calibration dose of 853 mrem (8.53 mSv) and the annual dose of 1,387 mrem (13.87 mSv) from routine surveillance, patrol, housekeeping, and contamination control, gives a total CVDF annual dose of 11,500 mrem (115 mSv). The CVDF staffing plan calls for 25 operators and 15 radiological control technicians to be involved in the accomplishment of these tasks. Thus, the average worker dose per year is 287 mrem (2.87 mSv) total effective dose equivalent, which is well below the 500 mrem (5 mSv) ALARA design goal. In addition, traveling crews associated with MCO transport (15 additional operators) help CVDF personnel in handling the MCO transporter and cask, and there are 35 persons associated with the shared maintenance response crew. When consideration is given to the shared staff, the average operating staff dose is reduced even further. Calculations of the dose rate from neutrons have been performed using conservative methodology and indicate that this dose is negligible.

B8 0 HAZARDOUS MATERIAL PROTECTION

B8 1 INTRODUCTION

The major provisions of the occupational safety and health program, as the program applies to hazardous material protection for the Spent Nuclear Fuel (SNF) Project are addressed in Chapter 8 0 of the SNF Project Final Safety Analysis Report (FSAR)

B8 2 REQUIREMENTS

The requirements that form the basis for the hazardous material protection program are identified in Section 8 2 of the SNF Project FSAR

B8 3 HAZARDOUS MATERIAL PROTECTION PROGRAM AND ORGANIZATION

The SNF Project has an established, visible, and comprehensive occupational safety and health program. This program is described in Section 8 3 of the SNF Project FSAR

B8 4 ALARA POLICY AND PROGRAMS

While there is no established formal SNF Project as-low-as-reasonably-achievable (ALARA) program for nonradiological hazardous materials, the SNF Project has expanded the classic concept of ALARA (i.e., minimization of radiological exposures) to the application of exposure minimization for hazardous substances and conditions. The SNF Project's policy is described in Section 8 4 of the SNF Project FSAR

Work practices for hazardous material protection and control of chemical exposures, as stated in Section 8 4 of the SNF Project FSAR, will be implemented at the Cold Vacuum Drying Facility (CVDF) using approved SNF Project implementing procedures. The occupational safety and health program will use the additional provisions of Section 8 4 of the SNF Project FSAR. These provisions will also be implemented at the CVDF using approved SNF Project implementing procedures.

Applicable ergonomics considerations, included in DOE Order 5480 10, Contractor Industrial Hygiene Program (Section 9B), under the occupational safety and health program, industrial hygiene subprogram, are included in Chapter B13 0. Ergonomics considerations, along with risk factor control processes and the ergonomics program are described in the SNF Project human engineering program plan (see Section 8 4 of the SNF Project FSAR and SNF-4399)
B8 5 HAZARDOUS MATERIAL TRAINING

Plans and procedures for training SNF Project workers regarding hazardous materials are summarized in Section 8 5 of the SNF Project FSAR

Section 8 5 of the SNF Project FSAR states that SNF Project management provides training professional education, and certification opportunities necessary to support, maintain, and enhance industrial hygiene staff proficiency to meet or exceed U S Department of Energy industrial hygiene training objectives and goals in accordance with HNF-SD-SNF-RD-001, Spent Nuclear Fuel Project Standards/Requirements Identification Document CVDF management is responsible for ensuring that workers assigned to any task involving hazardous materials are trained in the safety and health hazards associated with such hazardous materials Workers will perform only those tasks for which they have received the proper training As the CVDF mission changes, CVDF management will review the training requirements and modify worker training requirements accordingly CVDF management is also responsible for ensuring that retraining is provided within the time allowed by training course requirements

B8 6 HAZARDOUS MATERIAL EXPOSURE CONTROL

Worker safety features at the CVDF are an integral part of facility design and operation The CVDF design encompasses human factors considerations to ensure that operations can be conducted safely SNF Project occupational exposures to hazardous materials and the spread of hazardous material contamination are controlled by a combination of engineered, operational, and administrative controls, and by the use of personal protective clothing and equipment These controls are described in Section 8 6 of the SNF Project FSAR

No significant hazardous materials have been identified at the CVDF as a result of a hazard analysis that was performed and documented in HNF-SD-SNF-HIE-004, Cold Vacuum Drying Facility Hazard Analysis Report, except for the radionuclide content in the multi-canister overpacks (MCOs) Major features of worker protection are presented in Table B3-3 and are categorized by hazard These features are in addition to safety-class or safety-significant features for design basis accidents No safety-significant structures, systems, and components or technical safety requirements have been identified for the CVDF based solely on worker safety considerations

All work activities in the CVDF will receive adequate advance planning so that if potential hazardous materials are identified due to changing conditions in the future, specific precautions will be applied The exposure controls identified in Sections 8 6 1 through 8 6 4 of the SNF Project FSAR will then be implemented at the CVDF using approved SNF Project implementing procedures

Results of detailed CVDF hazard analysis are presented in table form in HNF-SD-SNF-HIE-004 The primary inventory of hazardous material in the CVDF involves the
radionuclide content in the MCOs. Other hazardous material identified by the hazard identification process includes pyrophoric metals and hydrides, oxidizers, potential asphyxiants, hydrogen, diesel fuel, and other flammable or combustible materials. No routine chemical processes will be conducted in the CVDF. Some chemicals, such as those used for equipment decontamination, may be used occasionally. Section 1.2.1 of SNF-2770, *Cold Vacuum Drying Facility Design Basis Accident Analysis Documentation*, states that there are no chemical inventories of safety concern. Table B3-1 identifies hazards by form, type, location, and total quantity.

The hydrogen control strategy includes inerting the MCOs at the CVDF and backfilling them with helium. Technical safety requirements are developed to govern activities associated with potentially high concentrations of hydrogen. CVDF hydrogen management features that provide worker safety are presented in Table B3-3. These features include the heating, ventilation, and air conditioning system, which sweeps hydrogen away from workers and continuous air and oxygen monitors with alarms.

Operating procedures will contain warning or caution statements to alert personnel to operations that could potentially result in oxygen-deficient atmospheres. Personnel performing activities that require the use of inert gas are trained on the appropriate precautions to be taken, including evacuation of the area if the continuous air or oxygen monitor alarm sounds. The monitoring portion of the hydrogen control strategy is described in Section B8.7.

Other hazardous materials at the CVDF (maintenance materials) will be properly inventoried and stored to control hazards inherent to the material, in accordance with SNF Project implementing procedures.

### B8.7 HAZARDOUS MATERIAL MONITORING

Summaries of the hazardous material sampling and monitoring programs that are conducted internally and externally for SNF Project facilities are provided in Section 8.71 of the SNF Project FSAR. The workplace and external monitoring program described in Sections 8.71 and 8.72 of the SNF Project FSAR will be implemented at the CVDF using approved SNF Project implementing procedures. An environmental, radioactivity, and chemical emissions monitoring program, including requirements, is presented in Section 8.72 of the Project FSAR. This program will be implemented for the CVDF in accordance with approved SNF Project implementing procedures.

As discussed in Chapter B3.0, the MCO is prone to hydrogen gas generation from metal oxidation reactions and radiolysis of bound and free water. The hydrogen control strategy includes inerting the MCOs and dilution with inert gas at the CVDF. This inerting and dilution is controlled by the safety-class instrumentation and control system described in Chapter B4.0.
B8 8 HAZARDOUS MATERIAL PROTECTION INSTRUMENTATION

Summaries of plans and procedures governing hazardous protection instrumentation are provided in Section 8 8 and Table 8-2 of the SNF Project FSAR. As stated in Section 8 8 of the SNF Project FSAR, safety and health specialists will determine any need for hazardous protection instrumentation and the number and placement of instruments in the CVDF under normal and emergency conditions in accordance with the requirements stated in Section 8 8 of the SNF Project FSAR. As noted in Section B8 6 and in Table B3-3, oxygen monitors with a local area alarm will be provided as a worker safety feature for several events, including high-pressure helium blowdown, hydrogen explosions, and ion exchange module explosions.

B8 9 HAZARDOUS MATERIAL PROTECTION RECORD KEEPING

The SNF Project has an established document control and records management program. This program is summarized in Section 8 9 of the SNF Project FSAR.

B8 10 HAZARD COMMUNICATION PROGRAM

The hazard communication program applies to the purchase, receipt, transportation use, and storage of hazardous chemicals and products. This program is summarized in Section 8 10 of the SNF Project FSAR. The hazard communication program for the CVDF will be implemented in accordance with the provisions of Sections 8 10 1 through 8 10 6 of the SNF Project FSAR, including hazard posting in work areas, chemical management, chemical labeling, chemical product list, material safety data sheets, information and training. This program will be accomplished in accordance with approved SNF Project implementing procedures.

B8 11 OCCUPATIONAL CHEMICAL EXPOSURES

Predicted annual exposures to workers from hazardous material sources are identified in Section 8 11 of the SNF Project FSAR. Also see Section 8 10 of the SNF Project FSAR for identification of chemical hazard locations, posting, chemical management, and other controls to limit occupational chemical exposure.

B9 0 RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT

B9 1 INTRODUCTION

The essential features of the radioactive and hazardous waste management programs that provide for the safe control, collection, and handling of wastes generated during routine operations at the Spent Nuclear Fuel (SNF) Project facilities are detailed in Chapter 9 of the SNF Project Final Safety Analysis Report (FSAR). This Chapter B9 only applies to waste generated within the Cold Vacuum Drying Facility (CVDF) and those processes and systems designed to deal with that waste. Within the CVDF, bulk water will be drained from the multi-canister overpack (MCO) and processed through ion exchange modules to remove the majority of the radioactivity. There are no chemical inventories of concern for safety analysis considerations.

Potentially radioactive waste from normal operations at the CVDF is generated from:

- Replacement of the process water conditioning (PWC) ion exchange modules
- Replacement of radioactively contaminated high-efficiency particulate air (HEPA) filter elements
- Normal radiation monitoring and decontamination processes
- Waste and debris from failed process equipment
- Contamination-control activities

Small volumes of nonhazardous and potentially hazardous wastes will also be generated (Table B9-1).

B9 2 REQUIREMENTS

The requirements that form the basis for the radioactive and hazardous waste management program are identified in Section 9 of the SNF Project FSAR.

B9 3 RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT PROGRAM AND ORGANIZATION

The facility administrative procedures for solid waste management contain the procedural guidance for the planning, generation, and disposal of generated waste in compliance with applicable requirements. The administrative procedures cover characterization, preplanning, designation, containerization, disposal, and programmatic requirements. A summary of the SNF Project waste management program is provided in Section 9 of the SNF Project FSAR.

PWC = process water conditioning

B9.4 RADIOACTIVE AND HAZARDOUS WASTE STREAMS AND SOURCES

The following subsections identify the CVDF waste streams, their sources, and their management.

B9.4.1 Waste Management Process

The goals and policies of the CVDF hazardous and radiological waste management process are described in Section 9.4.1 of the SNF Project FSAR.
B9 4 2 Waste Sources and Characteristics

At the CVDF, both solid and liquid wastes will be generated and gas emissions will be released. The expected generation rates of each CVDF waste stream are listed in Table B9-1. The following subsections describe the sources of the solid and liquid waste summarized in Table B9-1.

B9 4 2 1 Solid Waste Streams and Sources
The major sources of radioactive waste at the CVDF are ion exchange modules that are part of the PWC system. The ion exchange elements remove dissolved radioactive ions and radioactive particles that are suspended in the MCO water. The frequency of changeout of the PWC ion exchange modules is based on ALARA (as low as reasonably achievable) concerns and on maintaining transuranic inventories below the threshold for designation as transuranic waste. In addition, loaded HEPA filters will be generated as a solid waste or potentially radioactive waste. HEPA filter elements will be used for the process water storage tank vents, the process bay local exhaust heating, ventilation, and air conditioning (HVAC) and process vent system, the general supply/exhaust HVAC system, and the process bay recirculation HVAC systems. The filters are not expected to have hazardous materials deposited on them. Solid waste debris is generated during normal operations, equipment maintenance, and any necessary cleanup following abnormal events. Radioactive wastes will be generated from efforts to control contamination and from decontamination necessary for maintenance and repair of contaminated equipment. The debris wastes will consist of contaminated protective clothing, small tools, equipment, vegetation, animal carcasses, and plastic and paper used to control contamination and to decontaminate the shipping casks. At the CVDF, spills of radioactive liquids may result in the use of adsorption and cleanup materials that will be designated as low-level waste. Office trash is also generated on a routine basis but is nonradioactive and nonhazardous.

B9 4 2 2 Liquid Effluents and Sources
The major liquid stream will be the conditioned water that is removed from the MCO and casks during facility operation. Liquid waste oil from maintenance of the vacuum systems is also anticipated on an infrequent basis. At the CVDF, spills of radioactive liquids in the processing bays are contained by the floor sumps, sampled, and disposed of based on the sample results. There will be no sanitary sewer connection to the CVDF. Sewage will be collected in a tank and transported by truck to an offsite sewage treatment facility. A small amount of condensate from the CVDF HVAC cooling coils (less than 40 gal/yr) will be generated during the more humid months.

B9 4 2 3 Gaseous Effluents and Sources
The CVDF is permitted for airborne emissions by DOE/RL-96-110 Radioactive Air Emissions Notice of Construction Cold Vacuum Drying Facility Phase II Section 20 2 2 of HNF-SD-SNF-RD-001 Spent Nuclear Fuel Project Standards/Requirements Identification Document, describes the requirements for clean air permits and their application to the construction, startup, and operation of facilities. See Section 9 4 2 3 of the SNF Project FSAR for general information regarding gaseous effluents and sources. See Chapters B2 0 and B7 0 for information regarding CVDF airborne emission criteria and the
stack monitoring system. Helium will be used in the water removal and drying operations and will be released to the atmosphere after use as part of the air emissions.

**B9 4.3 Waste Handling or Treatment Systems**

The ion exchange modules will be loaded to below transuranic levels so they can be disposed of onsite in the low-level burial ground as low-level category III radioactive waste. Solid radioactive wastes including HVAC HEPA filters (classified as radioactive waste) and other operational wastes (including rags, wipes, plastic, protective clothing, failed equipment, vegetation, and any contaminated animals) will be packaged per the Waste Management Federal Services of Hanford, Incorporated waste acceptance requirements (WHC-EP-0063-5)—described in Section 16 of the SNF Project Standards/Requirements Identification Document (HNF-SD-SNF-RD-001) and in facility waste administrative procedures—and then transported to Waste Management Federal Services of Hanford for disposition. Some of the debris wastes may also be managed under *Comprehensive Environmental Response Compensation and Liability Act (CERCLA)* of 1980 and sent to the Environmental Restoration Disposal Facility for disposal.

Hazardous materials (e.g., fluorescent light bulbs) will be picked up by commercial treatment and disposal facility operators within 90 days of accumulation. Mixed wastes will be transferred to Waste Management Federal Services of Hanford within 90 days of accumulation. Office trash will be picked up and handled as other site nonradioactive and nonhazardous wastes by the site contractor. Office waste (e.g., copier paper) will be recycled to the extent possible.

The PWC water will be taken back to the K Basins in a tanker truck and managed with the other water in the basins. Waste oils are expected to be mixed radioactive and hazardous wastes and will be managed by Waste Management Federal Service of Hanford per approved waste acceptance and management requirements.

Sewage will be sent to an offsite sewage treatment facility. The condensate from the CVDF cooling coils will be collected for sampling and disposal.

Airborne wastes are filtered by HEPA filters and then released per the air permit (DOE/RL-98-30) as noted in Section B9 4.2.3.

Fire suppression water is collected in the effluent drain system sumps in each processing bay and then is automatically directed to the covered retention basin located west of the facility. The contents of this basin are sampled and appropriately disposed of based on the results of the sample.

B10 0 INITIAL TESTING, IN-SERVICE SURVEILLANCE, AND MAINTENANCE

B10 1 INTRODUCTION

Essential features of the initial testing program, the operational readiness review, the in-service surveillance program, and the maintenance program implemented at Spent Nuclear Fuel (SNF) Project facilities are described in Chapter 10 0 of the SNF Project Final Safety Analysis Report (FSAR). Cold Vacuum Drying Facility (CVDF)-specific features of these programs are described in this Chapter B10 0.

B10 2 REQUIREMENTS

The requirements that form the basis for the initial testing program, the operational readiness review program, the in-service surveillance program, and the maintenance program are identified in Section 10 2 of the SNF Project FSAR.

B10 3 INITIAL TESTING

The SNF Project initial testing program ensures the operability of equipment and facilities before facility operation. Project details of this program are provided in Section 10 3 of the SNF Project FSAR. Other than a first-article testing program, no special testing requirements prior to startup activities have been identified for CVDF structures, systems, and components.

B10 4 IN-SERVICE SURVEILLANCE PROGRAM

The SNF Project in-service surveillance program is designed to maintain the integrity of facility systems and to ensure that systems perform their function of protecting the health and safety of the public, workers, and facility staff by preventing or mitigating accident consequences. Details of this program are provided in Section 10 4 of the SNF Project FSAR. The technical safety requirements that include the surveillance requirements for the CVDF are described in Chapter B5 0 and in HNF-3673, Cold Vacuum Drying Facility Technical Safety Requirements.

B10 5 MAINTENANCE PROGRAM

The maintenance program for the SNF Project facilities is conducted in accordance with DOE Order 4330 4B, Maintenance Management Program, which provides the general policy and objectives for establishing cost-effective maintenance and repair programs for U S Department of Energy property. The maintenance program will incorporate the results of considerable project...
Annex B — Cold Vacuum Drying Facility

and subsystem vendor interface activities aimed at ensuring an acceptable design and acceptable operating practices relative to reliability, availability, and maintainability.

Policies and procedures are in place to effectively manage SNF Project facility maintenance activities. Section 10.5 of the SNF Project FSAR summarizes the maintenance policies and procedures that are implemented at the CVDF and also describes the process used during the development of the detailed maintenance plan. The structures, systems, and components that are important in the mitigation and prevention of analyzed accidents, and included in the formal CVDF maintenance program, are identified in Chapters B3.0 and B4.0. The design and length of service of the CVDF result in no code requirements for in-service testing.

The basis for operation of the CVDF is to safely vacuum dry K Basins SNF over a period of three years. Operational tasks and drying cycle times have been defined by project design authorities and are discussed in SNF-2356, 

_Spent Nuclear Fuel Project Cold Vacuum Drying Facility Operations Manual_. The planned CVDF drying cycle includes a retest of the main process systems prior to each multi-canister overpack (MCO) drying cycle.

Operational design information has been used as input to a process system design basis capacity study of the SNF Project (HNF-SD-SNF-RPT-011). This study used a summary-level model of major SNF Project facilities to determine the impact of facility interactions on the overall time to complete fuel removal operations. The results indicated that a facility containing four vacuum drying stations satisfies the project goal of completing operations in three years. The study also shows that the fourth drying station will have a low usage factor. An operating efficiency of 70% was used for each drying station, included in the 70% figure was an approximate 20% allowance for equipment breakdown and repairs.

HNF-SD-SNF-DRD-002, _Cold Vacuum Drying Facility Design Requirements_, includes maintainability and availability requirements for the CVDF and specifies a five-year minimum design life for process components and subsystems. Redundancy of major process components is an additional CVDF requirement (HNF-SD-SNF-DRD-002). Operations, startup, and maintenance personnel participated in the design process through performance of design reviews and participation in a failure modes, effects, and criticality analysis, as described in HNF-2576, _Cold Vacuum Drying Facility Phase I FMEA/FMECA Session Report_. Operations also participated in the first-article testing program and provided comments regarding operability and maintainability. Proposed changes resulting from these reviews have been documented, presented to the design organization, and evaluated in subsequent design activities. First-article testing used a full-scale test setup to verify CVDF process design and component performance, to determine drying cycle characteristics including heat-up and cool-down cycles, and to validate the thermal model.

The design organization has included in sub-component purchase requests requirements that vendors provide maintenance recommendations for their components and subsystems based on past performance and failure history. These recommendations are to include spare parts inventories and requirements for special maintenance tools. Since most of the process equipment
design requires commercially available equipment that is provided as skid-mounted packages, vendors have been required to provide maintenance accessibility and testability information Design reviews to date have identified no high-maintenance components First-article testing provided another way to obtain operability, maintainability, and testability input Results from first-article testing have provided numerous design improvements as described in HNF-3342, Hanford Spent Nuclear Fuel Project Cold Vacuum Drying Facility First Article Initial Test Finding Report, and HNF-4057, Cold Vacuum Drying Proof of Performance (First Article Testing) Test Results

In summary, considerable interface has occurred between organizations contributing to the design of the CVDF relative to availability, operability, and maintainability and the results have been considered in the present design This interchange of information will continue as the facility progresses into the startup testing and operational phases

The SNF Project has completed failure mode and effects analyses and fault tree analyses as part of the FSAR hazards assessments, which includes evaluating routine maintenance activities There are no maintenance activities identified other than the specific technical safety requirement surveillance items required to remain in the authorization basis The structures, systems, and components are designed to place the MCO in a safe and stable state without operator action Preventive maintenance and calibrations are utilized to provide continued operability of facility systems and components

The maintenance plan to be described in the CVDF maintenance implementation plan, which will be submitted to the U S Department of Energy, Richland Operations Office for approval, will implement a graded approach to maintenance activities based on sound engineering judgement and knowledge of the facility and will take into consideration the following items

- The design life for the process systems is a minimum of five years, whereas the intended operational life of these systems is three years This short operating life does not warrant an extensive predictive maintenance program but would justify a simple maintenance history program

- In general, most of the process equipment designs require commercially available equipment that is provided as skid-mounted packages that have been tested as part of the first-article test program

- The four-drying-station design allows for considerable downtime for repairs This built-in flexibility and increased availability of equipment for maintenance will allow time for procurement of unanticipated spares and will tend to minimize the size of the required maintenance support
The operational procedures will include a requirement to functionally test the assigned drying station before receiving an MCO at the CVDF. Maintenance problems identified by functional testing will be resolved without interfering with MCO processing.

- Process systems (i.e., process water conditioning, vacuum purge system) have an appropriate level of redundancy that will lead to increased overall availability.

- Utility systems (i.e., instrument air, helium supply, heating, ventilation, and air conditioning) have an appropriate level of redundancy that will lead to increased overall facility availability.

B11 0 OPERATIONAL SAFETY

B11 1 INTRODUCTION

Features of the Spent Nuclear Fuel (SNF) Project conduct of operations program and fire protection programs are described in the following sections and in Chapter 110 of the SNF Project Final Safety Analysis Report (FSAR).

B11 2 REQUIREMENTS

The requirements that establish the basis for conduct of operations and general aspects of operational safety are identified in Section 112 of the SNF Project FSAR.

B11 3 CONDUCT OF OPERATIONS

"Conduct of operations" is a set of principles that establishes an overall philosophy for achieving excellence in the operation of the SNF Project facilities. SNF Project application of conduct of operations principles is described in Section 113 of the SNF Project FSAR.

B11 4 FIRE PROTECTION

The SNF Project facilities' fundamental fire protection programs are addressed in Section 114 of the SNF Project FSAR. The elements of the fire protection program that are specific to the Cold Vacuum Drying Facility (CVDF) are described in the following subsections. The results of a CVDF fire hazard analysis (FHA), documented in SNF-4268, Fire Hazard Analysis for the Cold Vacuum Drying Facility, are addressed in Section B3 323 and are summarized in the following subsections.

B11 4 1 Fire Hazards

The CVDF FHA (SNF-4268) was developed in accordance with Section 123 of HNF-SD-SNF-RD-001, Spent Nuclear Fuel Project Standards/Requirements Identification Document. The analysis comprehensively assessed the risk from fire at the CVDF to determine that: (1) the potential for occurrence of fire is minimized, (2) a fire would not cause an onsite or offsite release of radiological and other hazardous materials that would threaten the public health and safety or the environment, (3) requirements that will provide an acceptable degree of life safety to SNF Project and contractor workers are in place, (4) property damage from fire and related perils would not exceed an acceptable level, and (5) the safety systems are not damaged by fire. In addition, the FHA evaluates the CVDF design to confirm that DOE Order 5480 7A, Fire
Protection, and DOE Order 6430 1A, General Design Criteria, provide adequate fire protection requirements to achieve nuclear safety equivalency to U S Nuclear Regulatory Commission fire protection requirements.

The FHA (SNF-4268) was prepared to meet the requirements of DOE Order 5480 7A and to evaluate compliance to U S Department of Energy (DOE) fire protection criteria. As required, this analysis addressed the following elements. Proposed changes to the FHA will be screened to the following elements to determine whether safety issues could be created:

- Description of construction
- Protection of essential safety-class equipment
- Fire protection features
- Description of fire hazards
- Life safety considerations
- Critical process equipment
- High value property
- Damage potential: maximum credible fire loss and maximum possible fire loss
- Fire department or brigade response
- Recovery potential
- Potential for toxic, biological, and/or radiological incident due to a fire
- Emergency planning
- Security considerations related to fire protection
- Natural hazards (earthquake, flood, wind) impact on fire safety
- Exposure fire potential, including the potential for fire spread between fire areas

The FHA (SNF-4268) identifies four fire hazards, as follows:

- SNF ignition — The FHA takes credit for the safety-class systems designed to prevent a thermal runaway accident as being effective in the prevention of SNF ignition.

- Hydrogen gas hazards — The FHA concludes that hydrogen gas hazards are adequately controlled by the CVDF design, as analyzed in Chapter B3 4 2 3.

- Fuel oil — SNF-4942, Spent Nuclear Fuel Cold Vacuum Drying Facility Implementation Plan for Fire Hazard Analysis Suggested Actions, takes credit for administrative controls aimed at preventing diesel fuel from igniting the tractor tires during the limited time that the tractor is allowed in the process bay. This approach has been accepted by DOE and the Hanford Fire Department.

- Ordinary combustibles — The FHA takes credit for administrative controls that severely limit the amount and location of transient combustibles in the processing bays and in the auxiliary spaces adjacent to the bays. These controls are described in Section B5 5 7 7. Concentrated fuel loads (e.g., step-off pad combustibles and...
waste) will be isolated with fire-rated enclosures or containers. Limiting combustibles such as those associated with step-off pads, eliminates sources of ignition for the transporter tires, which are the major heat source for most process bay fire scenarios.

The CVDF consists of three adjoining areas: the process bays, the process bay support areas, and the administrative area. The FHA (SNF-4268) divides the facility into two fire areas: the administrative area and a combined process bay and process bay support area. Analysis of the consequences and probabilities of a worst-case fire for the CVDF indicates that the maximum possible fire loss would be realized in a fire in a process bay and process support area. An operations support area fire was also evaluated, but losses from this fire event were determined to be bounded by a process bay and process support area fire because of the equipment replacement costs in the process bay and restart costs. The total cost of facility cleanup and equipment and structure replacement of a process bay and process bay support area fire would be about $77 million.

The FHA (SNF-4268) describes the effects of postulated fires on safety-class equipment. Fires as small as those associated with the combustibles included in a typical step-off pad can affect this equipment, primarily due to temperature affects on the wiring. Fires of concern are located in the process bay fire area because of the location of the safety-class equipment, instrumentation, and the process bays. Temperature effects on this equipment can affect the ability of the equipment to perform its processing functions, but detection of off-normal conditions by the local safety-class instrumentation and control system in each process bay will cause an automatic safety-class instrumentation and control system trip, placing the affected multi-canister overpack (MCO) in a safe, stable condition. Refer to the FHA for additional detail.

Limiting the amount and location of combustibles as specified in the FHA (SNF-4268) and Section B5 5 7 7, prevents the spread of a fire from one CVDF area to another. No release of radionuclides to the environment from the cask and MCO is identified in the FHA as a result of the maximum possible fire loss event due to the ability of the MCO cask to withstand the effects of the fire. No toxicological or biological consequences resulting from fire are anticipated.

B11 4 2 Fire Protection Program and Organization

The fire protection program for SNF Project facilities is structured and implemented in accordance with the operating contractor's safety management policies, philosophies, and criteria described in Section 11 4 2 of the SNF Project FSAR. CVDF-specific aspects of the fire protection program are described in the following paragraphs.

Sprinklers are located throughout the CVDF and are supplied by a connection to the 100 K service water system. The CVDF fire protection system is classified as general service. All areas of the CVDF are automatically monitored for fire and smoke by ionization-type smoke detectors. The fire alarm features include the transmission of signals to the Hanford Fire...
Department and to local building fire alarm annunciators, and shutdown of the appropriate heating, ventilation, and air conditioning units. Life safety criteria are met as required by NFPA 101, *Life Safety Code*. Life safety in the facility is satisfactory. Refer to Section B2.7.2 for additional descriptions of the fire protection system.

DOE Order 6430 1A requires a minimum of two reliable independent sources of water, and RLID 5480 7, *Fire Protection*, requires that two supply points to a looped fire water grid be provided. An exemption and deviation to the second fire water source requirement has been approved by the U.S. Department of Energy, Richland Operations Office (Sellers 1998).

The FHA, Section 18.0, identifies 12 findings (and recommended corrective actions) dealing with the CVDF design, construction, and response to postulated fires. Several of the findings identify areas where the facility does not comply with DOE Order requirements. The CVDF project has responded to these concerns as discussed in SNF-4942. Five of the concerns have been addressed by design changes that implement the applicable requirements. One concern was closed by Letter 99-SFD-167 (Loscoe 1999) and one finding specified that the FHA be updated, as needed, as the SNF Project progresses. The five remaining FHA findings are:

1. A maximum possible fire loss-type fire as noted in the fire model will cause a major fire loss of this facility. The operations could be shut down for up to 18 months as a result of major building and equipment damage.

2. The high-efficiency particulate air (HEPA) filters lack adequate automatic fire protection systems, 2-hour fire-rated enclosures, and heat detection. RLID 5480 7 requires fire protection of the final exhaust and confinement HEPA filters in nuclear facilities as identified in RLID 5480 7, Section 8.2.e, "Filter Plenum Fire Protection Criteria."

3. The fire modeling indicates that the tractor tire fire will cause unacceptable damage levels to the process bays.

4. The processing bays contain safety-class systems. These safety-class systems are not protected from the effects of a fire event as required by DOE Orders 6430 1A and 5480 7A.

5. RLID 5480 7, Paragraph 8.1.e, requires that fire department standpipe connections be provided in areas that have the potential of radioactive contamination. These standpipes need to be Underwriter's Laboratory-listed or Factory Mutual-approved and installed to allow the fire hoses into the confinement structure without blocking open doors.

The SNF Project's response to these remaining concerns is to implement the performance-based program for combustible control described in Section B11.4.3, and to submit and justify equivalencies or exemptions to address the following:
- The RLID 5480 7 requirement for fire protection of the final exhaust and confinement HEPA filters
- The DOE Orders 6430 1A and 5480 7A requirement to protect safety-class systems from the effect of a fire
- The RLID 5480 7 requirement that fire department standpipe connections be provided in areas that have the potential for radioactive contamination

In addition, the process bay support area rooms will be upgraded to a 2-hour equivalent fire rating (Finding 18-1), and the Hanford Fire Marshall has concurred with an exemption to the requirement for standpipes in the process bays (Finding 18-10)

The effects on facility safety of the FHA findings are addressed in Section 5.3 of that document. All of the findings are related to property loss concerns except for FHA Findings 18 2, 18 4, and 18 10. The issues identified in Findings 18 10 and 18 2 are related to reducing the potential for radiological release during fire conditions. Finding 18 4 addresses the issue that redundant safety-class structures, systems, and components (such as the safety-class instrumentation and control system and safety-class helium system), related to a particular CVDF process bay, are located in the same fire area. This equipment must not be subjected to general area temperatures in excess of 461 °C (115 °F) or radiant exposure to fire in a process bay. Table 3 1 1 1 of LCO 3 1 1, “Safety Class Instrumentation and Control Systems,” specifies a high-temperature control at <95 °F where the safety-class instrumentation and control system isolates the MCO (de-energizes eight normally-closed MCO isolation valves) and initiates safety-class helium system purge. These actions ensure that most safety-class equipment will have shifted to a fail-safe mode prior to general area temperatures reaching 461 °C (115 °F). The remainder of the process bay safety-class equipment has been shown to not experience spurious operations below the 461 °C (115 °F) temperature level. Implementation of the performance-based program for combustible control will ensure that the 461 °C (115 °F) temperature limit is not exceeded for the worst-case fire. Two pieces of safety-class equipment (PT-1*08 and PT-1*10) have a temperature limit of 405 °C (105 °F). The SNF Project prevents exceeding these limits by implementing the performance-based program for combustible control plus the installation of a heat shield on the mezzanine between the accepted transient combustible container and the two pressure transmitters.

The SNF Project’s response to Finding 18-2 is to implement the performance-based program for combustible control, which will ensure that the final HEPA filter plenums and associated filters will not plug, burn, or blow out when subjected to the worst-case fire.

B11 4.3 Combustible Loading Control

Control of combustibles in the CVDF is critical to the safety of the facility, as described in the FHA (SNF-4268) and in Section B3 3 2 3 Section 11 4 3 of the SNF Project FSAR.
summarizes the SNF Project program used to prevent unnecessary combustible loadings in the project facilities. For the CVDF, the quantity of combustibles anticipated to be present in the process bays and their support area is very limited and will include cable, piping, and duct insulation, transient combustibles such as contamination control supplies and waste, and anti-contamination clothing. When an MCO is being processed in the bay, trailer tires will also be present.

Per the FHA (SNF-4268) and Section B5 5 7 7, a performance-based program for combustible control will be established to strictly control, within the facility, the quantity and location of transient combustibles. The FHA (Table 2 as modified by SNF-4942) identifies the maximum allowable quantities of transient combustibles and the allowable locations for the combustibles. Allowable containers for transient combustibles are described in Appendix A of SNF-4942. The transient combustibles controls program is required by technical safety requirement Administrative Control 5 13 and will be implemented through operating procedures, as prescribed in Section 12 1 2 of the SNF Project Standards/Requirements Identification Document (HNF-SD-SNF-RD-001).

**B11 4 4 Fire Fighting Capabilities**

The Hanford Fire Department maintains a training program for fire fighting, fire system testing and maintenance, and building inspections. Fire fighting capabilities that apply to all SNF Project facilities are addressed in Section 11 4 4 of the SNF Project FSAR. CVDF-specific fire response procedures are addressed in the following paragraphs.

All areas of the CVDF are automatically monitored for fire and smoke by ionization-type smoke detectors. Manual pull stations are provided at each facility exit. The fire alarm features include transmission of signals to the Hanford Fire Department via a radio fire alarm reporter box. Fire alarm annunciating devices are provided for occupant notification.

A fire brigade is not required at the CVDF due to the nearby presence of the Hanford Fire Department. The standard response to an alarm condition in the 100 K Area is by the Hanford Fire Department from the 100 Area Fire Station. The 100 Area Fire Station may be relocated—including personnel, trucks, and equipment—to some undetermined location in the 100 K or 100 N Areas. Hanford Fire Department response time from the 100 Area Fire Station to the CVDF is approximately five minutes. A crew from the 200 Area Fire Station will be dispatched simultaneously with an estimated response time of 15 to 20 minutes. Because the 100 Area Fire Station is not manned full-time, the 200 Area response team will be the primary responders at times when the 100 Area Station is unmanned. These are the response times and the responder locations assumed in the FHA (SNF-4268). Refer to WHC-SP-1180, *Hanford Site Emergency Response Needs*, and HNF-SP-1180, *Hanford Site Emergency Response Needs Implementation Plan*, for additional description of the Hanford Fire Department response capabilities. Vehicle access to the CVDF is provided by a paved access road. The Hanford Fire Department is fully staffed, trained, and equipped for emergency response.
Facility personnel are trained on the expected actions to be taken in case of a fire. Personnel are expected to notify the Hanford Fire Department, evacuate the facility, and follow approved fire response plans specific to the facility.

**B11 4.5 Fire Fighting Readiness Assurance**

A prefire plan for the CVDF will be prepared by the Hanford Fire Department prior to facility operations. The FHA (SNF-4268) provides a description of fire-fighting methods that will be employed in the plan.

A summary of SNF Project fire prevention inspections, fire safety drills and exercises and program record-keeping requirements is provided in Section 11 4.5 of the SNF Project FSAR.

B12 0 PROCEDURES AND TRAINING

B12 1 INTRODUCTION

A description of the essential features of Spent Nuclear Fuel (SNF) Project procedures and training is provided in Chapter 12.0 of the SNF Project Final Safety Analysis Report (FSAR).

B12 2 REQUIREMENTS

The requirements that form the basis for the SNF Project training and procedures programs are identified in Section 12.2 of the SNF Project FSAR.

B12 3 PROCEDURE PROGRAM

SNF Project activities are conducted in accordance with written procedures. A summary of the facility procedures program, including development and maintenance of procedures, is provided in Section 12.3 and its subsections in the SNF Project FSAR.

B12 4 TRAINING PROGRAM

The objective of the SNF Project personnel training program is to provide and maintain a qualified work force for safe and efficient facility operations. A summary of the SNF Project personnel training program—including training development, maintenance of training, and modification of training materials—is provided in Section 12.4 and its subsections in the SNF Project FSAR. Qualification of the Cold Vacuum Drying Facility initial crews will use knowledge-based training presented in the classroom, and skills-based tasks primarily addressed by on-the-job training activities. On-the-job activities for the initial crews will include involvement in dry-run demonstrations and special training evolutions.

B13 0 HUMAN FACTORS

B13 1 INTRODUCTION

General features of the Spent Nuclear Fuel (SNF) Project human factors engineering (HFE) process are described in Chapter 13 0 of the SNF Project Final Safety Analysis Report (FSAR) Specific application of the human factors process to the Cold Vacuum Drying Facility (CVDF) is described in this Chapter B13 0

This chapter will show that human factors were considered by the design team throughout the design process for the CVDF Almost all human factor issues have been identified and have either been resolved or are being resolved as design change information becomes available An example of an issue that has not been fully defined is the process for manually moving the mezzanine bridge to the cask multi-canister overpack (MCO) work platform This issue is being followed as final design decisions are made

An assessment team conducted a hazard analysis to identify potential hazards to the CVDF operator, co-located personnel, the public, and the environment (HNF-SD-SNF-HIE-004) Hazards were analyzed based on energy source and material, and established “defense-in-depth or worker safety features” were presented In addition, the final HFE analysis (SNF-4213) outlined possible areas of human error during a task analysis and recommended ways to mitigate the potential human error, however, this HFE analysis was not a human reliability study Chapter 3 0 of the SNF Project FSAR describes the hazard analysis methodology, and results for the CVDF are summarized in Chapter B3 0

In addition, a review of Hazards Analysis of SNF CVD System - Off-Normal Assessment (Ares 1998) was completed The team performing the off-normal assessment identified and assessed operational upsets (e g , valve failures, control upsets, mechanical equipment failures) that potentially could occur during normal operating conditions The team is finishing work on specific pre-approved operational responses that will be needed following an off-normal event to ensure that the facility safety envelope and boundaries are not challenged

The design team developed and revised SNF-2356 Spent Nuclear Fuel Project Cold Vacuum Drying Facility Operations Manual, which contributed to understanding the role of humans in the operation of the CVDF The formality and the extent of the systematic inquiry into the human factors associated with the CVDF were determined based on the extent of human interaction, the system design effort, and the risk associated with human performance failures

The CVDF design is ready to begin the validation and testing phase This phase will provide an opportunity to observe humans in the performance of allocated tasks within the context of full system simulation or operation
B13 1 1 Brief Description of Facility Purpose

The CVDF classification is a hazard category 2 nonreactor nuclear facility. The CVDF purpose essentially is outlined in three parts: (1) to accept casks with inserted MCOs containing SNF, (2) to remove free water from the SNF using a technical process, and (3) to prepare the cask-MCOs for transport to the Canister Storage Building (CSB). The CVDF provides the required technical process systems, supporting equipment, and facilities needed to support this purpose. The cold vacuum drying process involves draining bulk water from the MCOs and subsequent vacuum drying. After vacuum drying, the MCOs are backfilled with helium. Removal of free water from the MCOs is necessary to reduce the potential for fuel-water corrosion reactions that could lead to MCO overpressurization at the CSB. Figure B13-1 shows an overview of the CVDF process.

The CVDF includes four process bays that can each accommodate an MCO on a specially designed trailer that has been shipped from the K Basins. The CVDF also conditions contaminated process water from the MCO for transport back to the K Basin West facility.

Human system interaction within the CVDF mainly focuses on two important areas: the process bay(s) and the control room. The process bay provides direct human access to the cask-MCO and exposes the human operator to some risk. The control room provides the human operator a means for management and control over the cask-MCO processing operation(s). For purposes of the human factors safety basis, the control room is a nonreactor control room. Chapter B2 0 presents a complete facility description.

B13 1 2 Scope

This chapter presents a systematic inquiry of CVDF human factors and defines the CVDF human factors safety basis, as required by DOE Order 5480 23, Nuclear Safety Analysis Reports. Human factors is one of three aspects of facility safety assurance. The other two aspects are design and management. Therefore, the systems approach to design is applied whereby systems, structures, and equipment are built in accordance with the best available design practices. The essential features of the human system interaction relating to facility safety are the primary scope of this chapter, however, human factors are not limited to only safety-class or safety-significant applications but are intended to cover the gamut of CVDF operations. This chapter presents a discussion of the SNF Project incorporation of human factors and HFE into the design and operation of the CVDF. This annex provides additional plans for continuing to incorporate HFE as the design enters the final test and validation phase. This annex uses DOE-STD-3009-94, Preparation Guide for U S Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, for additional guidance and format description.
B13 1 3 Objectives

The CVDF is in the final design phase with all significant human–machine interfaces (HMIs) defined, requirements produced, and most of the hardware and software procured mocked-up, or built. The objectives of this chapter are to:

- Review, incorporate, and complete the HFE efforts accomplished earlier in the design stage during development of the preliminary human factors analysis, as documented in HNF-SD-SNF-SAR-002, Safety Analysis Report for the Cold Vacuum Drying Facility, Phase 2, Supporting Installation of Processing Systems.

- Review and incorporate applicable customer (U.S. Department of Energy [DOE]) comments made during review of the preliminary human factors analysis documented in HNF-SD-SNF-SAR-002.

- Demonstrate a systematic inquiry into the importance of safety pertaining to reliable, correct, and effective HMI, including an HFE review of the safety-related structures and components that include HMI.

- Describe applicable human interaction in areas of surveillance, maintenance, normal, off-normal, and emergency operations, and summarize the results of the current facilities hazard analysis regarding human operations.

- Ensure appropriate optimization of the design to enhance reliable human performance, while reducing the risk of human error.

- Review the findings from SNF-2825, Spent Nuclear Fuel Project Cold Vacuum Drying Facility Human Factors Engineering Analysis Results and Findings.

- Include the results from SNF-4213, Final Human Factors Engineering Report for the Cold Vacuum Drying Facility Analysis, Results and Findings (which addresses the issues identified in SNF-2825).

- Make recommendations for subsequent human factors support, as appropriate.

B13 2 REQUIREMENTS

This section details the design codes, standards, regulations, and DOE orders applicable for establishing the safety basis of the SNF Project facilities. The intent is to provide only the requirements that are specific for HFE and pertinent to the HFE safety analysis. This section does not provide a comprehensive listing of all the industrial standards, codes, or criteria.
B13 2 1 U S Department of Energy Orders and Standards

The following DOE orders and standards are applicable to the human factors safety analysis:

- **DOE Order 4330 4B, Maintenance Management Program**, provides consideration of written procedures to guide applicable operations and maintenance.

- **DOE Order 5480 19, Conduct of Operations Requirements for DOE Facilities**, considers the allocation of control functions for operations and maintenance to humans and machines. This order also considers staffing and the qualifications of personnel for operations and maintenance as well as written procedures to guide operations and maintenance.

- **DOE Order 5480 20A, Personnel Selection Qualification and Training Requirements for DOE Nuclear Facilities**, provides consideration of staffing and qualification and training of personnel for operations and maintenance.

- **DOE Order 5480 23, Nuclear Safety Analysis Reports, Attachment 1, Section 3 c**, provides the rationale for upgrading the safety analysis requirements to include HFE. Topic 14 of this order details provisions affecting the systematic inquiry of the importance to safety of reliable, correct, and effective HMI. Topics 12, 13, and 15 of this order provide consideration of staffing and qualification and training of personnel for operations and maintenance.

- **DOE Order 6430 1A, General Design Criteria, Section 1300-12**, provides general criteria for incorporating HFE considerations into the system design process. It also provides HFE considerations for system and component displays, controls, alarms, labeling, and communications that are generally applicable to a wide range of human-machine systems. This order also provides considerations for the work environment for personnel, including such matters as ventilation, lighting, noise control, workspace layout, and equipment design and layout.

- **DOE-STD-3009-94, Preparation Guide for U S Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, Chapter 13**, provides guidance in providing information that will satisfy the applicable HFE requirements of DOE Order 5480 23.
B13 2 2 U S Nuclear Regulatory Commission Requirements

- NUREG-0700, *Human System Interface Design Review Guideline*, provides HFE guidelines for use in reviewing a specific human—system interface (HSI) design implementation. This ensures that the HSI supports safe, efficient, and reliable personnel task performance. Aspects of the HSI design review process that are important to the identification and resolution of human engineering discrepancies are also described.

- NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Plants*, Section 18, "Human Factors Engineering, Control Room" provides guidance to staff reviewers in the Office of Nuclear Reactor Regulation who perform safety reviews of applications to construct or operate nuclear power plants. This document is included in the requirements list to provide the SNF Project with a review of the U S Nuclear Regulatory Commission (NRC) guidance on DOE Order 6430 1A, Section 1300-12 4. NUREG-0800 assists in the identification of appropriate additional NRC guidance for the SNF Project facilities. HFE design support. More specifically, NUREG-0800 considers the complexity differences between a nuclear reactor control room and the control room being provided by the SNF Project.

B13 3 HUMAN FACTORS PROCESS

HFE is important in ensuring the safe operation of the CVDF. This section summarizes the human factors process for systematically evaluating the importance of human factors in CVDF safety. The overall purpose of this process is to ensure that the HSI with the CVDF supports safe, efficient, and reliable personnel task performance. The objective is to identify and resolve human engineering discrepancies that could adversely affect CVDF safety. This section also presents a discussion of the means by which the SNF Project has incorporated HFE into the current CVDF design and operation.

The incorporation of HFE considerations into the CVDF facility design and operational processes ensures enhanced human contributions to operational success while reducing abnormal situations resulting from human error. NUREG-0700 provides insight into processes for systematically evaluating the insertion of the human into the CVDF system. Relevant HSIs include all alarms, displays, controls, labeling, job performance aids, workstation and workplace layouts, and physical accessibility as well as environmental conditions such as lighting, noise, temperature, humidity, and protective clothing.

For the CVDF, the design engineering goal is to reduce HSI to a very low level. This decision reduces the chances for human error, increases the efficiency of the system, and reduces the personal risk of injury and illness to the operators. Allocating most of the process functions to automation and software technology, the principal design purpose for humans in this system is preparing the cask—MCO for processing (bay activity) and monitoring the process through
human–computer interfaces (HCI), with occasional permission commands that tie the human into the normal operating process. To achieve this goal, the human factors process involves the following strategies:

- Conceptualizing the design and initially allocating broad-based functions to either the human or machine
- Identifying and creating design requirements documents
- Developing the system safety-class requests for proposals (RFPs) that include HFE criteria
- Developing system design descriptions that include operator and maintenance personnel actions and HFE considerations
- Examining both system responses and operator actions during off-normal and emergency conditions
- Developing maintenance, training, and staffing based on system design descriptions and allocations of human functions
- Developing full-scale mock-ups of proposed designs including the CVDF process skid, cask–MCO, process connectors, and human-computer software
- Providing CVDF cognizant engineer formal design reviews at design stages (e.g., preliminary [30% complete] and final [90% complete]) to ensure incorporation of HFE criteria, as applicable, completion of HFE comprehensive review checklists to compare the design structures, systems, and components (SSCs) against standard human error design criteria, principles, and practices
- Resolving human engineering discrepancies as revealed during the human error comprehensive checklist review, using additional resources involving actual CVDF building and vendor-submitted components and tools to further evaluate human interfaces
- Providing for continuing human error review of design changes as changes occur and incorporation of applicable changes
- Reviewing programmatic concerns, if any
- Verifying and validating the entire HFE effort using step-by-step procedures just before operational startup of the entire CVDF system
- Reporting final results of the human factors evaluation process
Figure B13-2 shows the human factors process integrated with the total design effort

B13.3.1 Process Background

HFE is the application of knowledge about human performance capabilities and behavioral principles to the design, operation, and maintenance of human-machine systems. Application of this knowledge ensures that personnel can function at their optimum level of performance with a system optimally designed for human use. Though optimum design is the goal, humans do have the ability to adapt to a less-than-optimum design, however, exceeding human adaptability limitations will cause the system to become inefficient and potentially unsafe.

CVDF HFE considerations are commensurate with the following:

- Planned SNF Project mission
- Hazard category 2 classification
- Complexity of the CVDF
- Level and type of human interfacing with the SSCs and the SNF Project processes

The extent of the human interaction, the overall level of the current design effort, and the risk associated with human performance failures (human error) guide the formality and the extent of the systematic inquiry into the human factors associated with the CVDF. Emphasis is on the HMI required for ensuring the safety function of SSCs that are important to safety. Throughout the design effort, the evidence demonstrates that human factors are considered in facility operations where humans are relied on for preventive actions (e.g., surveillance and maintenance activities during normal operation) and for operator mitigative actions during off-normal and emergency operations.

Chapter B10.0 and Chapters 12.0 and 17.0 of the SNF Project FSAR discuss the staffing and qualifications of personnel, the required operator and maintenance personnel training, and the written procedures to guide operations and maintenance. The human factors process also reviewed this material for HFE adequacy. Equipment design effects on maintenance efficiency are consistently shown to be greater than such personnel variables as behavior or training. A description of HFE impacts during design for maintainability efforts are described in SNF-4399, Spent Nuclear Fuel Project Human Engineering Program Plan (HEPP).

Per SNF-4399, engineering of the HMI aspects of design should reflect the following HFE/Erg considerations, annotated below, as applicable. In addition, these features are captured in the HFE/Erg design review through use of the INEL-95/0117, Human Factors Engineering Checklists for Application in the SAR Process, located in the SNF Project Office. INEL-95/0117 also captures elements of UCRL-15673, Human Factors Design Guidelines for Maintainability of Department of Energy Nuclear Facilities, for example, accessibility requirements. Examples of the SNF-4399 HFE/Erg features considered for design are...
Compatibility of the design, location, and layout of controls, displays, work spaces, maintenance accesses, stowage provisions, etc., with the clothing and personal equipment to be worn by personnel operating, riding in, or maintaining DOE systems or equipment

Design features to assure rapidity, safety, ease and economy of operations and maintenance in normal, abnormal, and emergency maintenance environments

Adequate space for personnel, their equipment, and free volume for the movements and activities required during operations and maintenance tasks under normal, abnormal and emergency conditions

Efficient arrangement of operation and maintenance workplaces, equipment, controls, and displays

Adequate natural or artificial illumination for the performance of operation, control, training, and maintenance

Satisfactory working conditions including pressure, temperature, humidity, vibration, and acoustic considerations

Satisfactory remote handling provisions and tools

The human-machine interface shall represent the simplest design consistent with functional requirements and expected service conditions. Personnel shall be capable of operating, maintaining, and repairing equipment in their operational environment with a minimum of training

Design will include minimization of potential human error in the operation and maintenance of the system, particularly under emergency or non-routine conditions

Equipment and systems shall be designed so that they can be easily maintained. Considerations for this should include time, cost, safety, reliability, minimum expenditure of support resources, and radiological exposure. To ensure that costly maintenance or redesign are avoided, ease of maintenance shall be designed into facilities, systems and equipment

The essential HSI analyses are complete with the recommended human error design modifications provided to the design authorities through methods such as HFE analysis reports, tracking of human engineering discrepancies, and direct contact between human factors personnel and the design authorities. Any significant changes affecting the operators will be evaluated for human factors effects and reported in subsequent updates to this annex. The HMI detail review is provided in Section B13.4 and in SNF-4213.
As described in SNF-4213, the CVDF is well designed from the HFE perspective. The CVDF process and equipment designers have given much consideration to HFE issues brought to the attention of the designers were handled in a professional manner and, after design trade-off evaluation and cost-benefit analysis, were incorporated as deemed appropriate.

Applicable HFE requirements and criteria found in DOE orders and standards have been applied to the CVDF design. Four outstanding concerns were identified and investigated for possible improvement:

- Manual cask-multi-canister overpack (MCO) bolt removal and replacement
- Manual water hookup at the bottom of the cask and associated newly designed tools
- The bridge structure to cross from the mezzanine to the cask-MCO work platform
- The MCO process connectors connection to MCOs

The SNF Project is addressing these concerns. For example, the manual water hookup at the bottom of the cask is being design with a lighter, shorter extension and with an improved connector that provides a better leakproof connection and improves the ease of inserting and hooking up the hose.

Two focus areas identified in the Preliminary HFE Analysis report (SNF-2825) were the monitoring and control system (MCS) and safety-class instrumentation and control (SCIC). These areas were studied in detail and found to meet or exceed HFE checklist criteria, as reported in SNF-4213. The MCS comprises a total of three control room computers, two operator workstations, and one engineering workstation. A fourth computer station is provided as a supervisor station in the manager’s office. The main programmable logic controller control panel is also located in the control room and includes a local alarm and silence button. Four remotely controlled input/output modules with termination panels are located in the bays—one is in the mechanical room, and one is in the PWC tank room. Human interaction uses a keyboard, mouse, and monitor. All CVDF processing systems information is presented to the operator at the MCS. The MCS in association with the SCIC provides the operator control over the processing system, throughout various modes of operation.

The MCS HCI is heavily dependent on object-oriented color graphic displays on computer screens. All central processing units are connected on a local area network, which allows simultaneous access to the control system from multiple graphic displays. The system design description for the MCS is contained in SNF-3090, Monitoring and Control System. SNF-2408, System Design Description for the Cold Vacuum Drying Facility Monitoring and Control System, provides for the CVDF MCS software engineering. Also, HNF-2058, Specification for Cold Vacuum Drying (CVD) Project Monitoring and Control System Computer Software Requirements Specification, supports the software design description (SNF-2408) by providing specific requirements in the software engineering (e.g., the exact meaning of colors used in the...
graphical displays) "IEEE Standards Collection: Software Engineering" (IEEE 1997) is also consulted by the software engineer(s) to provide additional guidance, as applicable. These references include elements of HFE that are applied across industrial computer-based systems.

During operations, the human operator interfaces with the SCIC system through the mode switch panel in the control room and the safety-class annunciator. Numbers as well as text describing the mode position were added to the mode switches to provide two indications of the required switch position(s). For example, the procedure will state to select "Dryng Mode for Bay 2, HS-6000." The annunciator provides standard industrial format for alarm receipt, acknowledgment, and reset.

Overall, the design of the CVDF will meet HFE requirements. No significant changes are anticipated during the system test, verification, and validation phase. Human factors emphasis on the four items listed above, must continue as the design evolves into the system validation phase. In reference to the Preliminary HFE Analysis report (SNF-2825), the CVDF was found to be in compliance with 99% of the HFE criteria that it measured.

The following information is also provided.

**Crane** The overhead crane meets all applicable checklist items. Crane design and human interface (control) are in accordance with standard industry specifications, and control design is typical of that used elsewhere on the Hanford Site for similar operations. No human-interface concerns with the CVDF crane were identified.

**SCIC** The HMI meets all applicable checklist items. The SCIC panel design was studied for HFE inputs and found to be acceptable. The SCIC alarm system is differentiated from the MCS alarm to indicate to the operator which alarm system is activated. The SCIC is virtually automatic in operation. Main human interfacing is testing the system and operationally placing the mode switch in the proper position during the phases of the process cycles.

**Process Skid** Evaluation of the mock-up indicated some minor concerns with the gauges and with accessibility. The procurement specification addresses these concerns and indicates that HFE must be considered (e.g., all gauges must be designed to be read by a person standing on the floor). It is possible for maintenance personnel to access the necessary functions for routine maintenance. Labeling on the skid is called out in detail in the design/procurement specification and meets or exceeds HFE standards.

**MCO and Equipment** The process connectors "T-handle" mechanisms were evaluated by the operators at the mock-up facility. It was decided that the T-handle mechanisms were superfluous and a hindrance. The operator simply maneuvers the process connectors while holding onto the connector piping itself. The piping serves as a "handle," and there appears to be no engineering problem with using the piping as a "handle." The process hood is maneuvered into place using the overhead crane, the operator manually guides the hood into proper position. Other concerns with the cask are as follows.
• The 12 bolts must be manually un-torqued and re-torqued with 300 ft-lb (±10%) of force. The plan is to use a torque multiplier to assist in this task. The torque multiplier will use a ratio of 6:1 to bring the physical human effort down to 50 ft-lb. The torquing sequence for the bolts must be followed exactly according to engineering requirements. Thus, this job will require two persons working with six bolts per person per cask. Weighing considerations such as cost-benefit and duty time with this task, it was determined that the task can be successfully performed as planned. Consulting MIL-STD-1472E (Department of Defense Design Criteria Standard, "Human Engineering") and using the high friction case (coefficient of >0.9), it is possible that a manual push/pull force of 70 lb may be applied with both hands.

• The other concern involves the method of removing and installing both the lower cask access plate and the water hookups, using two tools. The tools to do these tasks are being redesigned to shorten their lengths. The redesign strikes a balance between the ALARA requirements and the ease of use of the tools.

MCS The MCS is located in the Central Control Room. The design of screen presentations and alarms meets applicable HFE criteria presented on the checklist review. The HCI appears well designed using the computer software requirements specification (HNF-2058). NUREG-0700 design criteria have been incorporated as applicable. The design provides for two operators in the Central Control Room, each monitoring two bays using video display terminals (VDTs). All systems can be monitored through the computer systems in the control room. The operators will be able to interact with the systems via the VDTs (mouse and separate keyboard based). Operators are alerted to off-normal conditions and take the appropriate actions. The Central Control Room work environment is planned for installation of fully adjustable ergonomically designed seating and fully adjustable computer workstations, both for the keyboard and for the monitor platforms. Operators will be able to adjust the VDT workstations to accommodate their particular needs. Operators using the mock-up facility have interacted well with the design engineers to make changes in the system design, as appropriate, and to allow increased operator efficiency in using the system. Information overload is being considered and reduced, as appropriate.

One of the primary human concerns with the MCS is the efficiency of the MCS. The system will run virtually automatically in the normal mode of operation. The human provides the permission signal for the system to move from one sequence to another. This is a relatively inactive mode of operation for the human, so other administrative considerations may need to be included (to introduce variability in operator tasking). Also, shift scheduling will be important to manage.

The work environments are well designed regarding ventilation, lighting, noise, and temperature. The facility design criteria meet applicable codes and call out specific temperature and humidity criteria with seasonal adjustments. These are well within the comfort zone for the personnel working within the facility. Lighting calculations and examination of the Central...
Control Room data were completed. These calculations appear to meet illuminance requirements for the VDT work surfaces. Since the lighting calculations were completed, a third ceiling fixture is being added to the Central Control Room. New calculations may need to be completed. One possible concern is the presence of glare on monitor screens. This may be examined during the test and validation phase, and glare filters may be used on the computer monitor screens. Lighting control (brightness) should be an operator function.

**B13 3.2 Human Factors Engineering Checklist Procedure**

This chapter describes the process of applying the preferred HFE checklist (INEL-95/0117) during the analysis. The checklist process methodology supplements the overall human factors process (described above) during evaluation of the CVDF SSCs for HFE considerations. The checklist process analysis follows the following logical course:

- Becoming familiar with CVDF SSCs
- Reviewing the facility hazards evaluation (HNF-SD-SNF-HIE-004)
- Selecting the HMI to be evaluated based on the systems that fall into one of two categories (1) safety class SSCs, or (2) pertinent to the effective operation of the CVDF
- Conducting a tabletop task analysis to determine the task performance, the sequence of operations, and the maintenance activities, reevaluation with the mock-up and identified tools
- Interviewing design authorities and other cognizant project personnel to determine the current level of design and anticipated design efforts
- Reviewing the design requirements process, pertinent subcontract RFPs, and overall facility design process for inclusion of human factors requirements, particularly design requirements called out in DOE Order 6430 1A, Section 1300-12, HFE
- Applying the appropriate HFE checklists to the existing and final SSCs and design requirements documents
- Sorting checklist evaluation results into one of four categories (1) complied, (2) not complied, (3) not applicable, and (4) to-be-determined (usually the case if design is not complete or pending change)
- Resolving noncompliance issues by reapplication of the HFE checklist
Charging the design authorities with commitments to follow up with the "to-be-determined" cases to ensure their inclusion in further design efforts.

- Reviewing programmatic issues (staffing, maintenance, procedures and training) and resolving any programmatic concerns.

- Reporting the results of the HFE evaluation process both in this chapter and in the detailed HFE report.

HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward Additional NRC Requirements, Item 9, calls out a review of the NRC guidance in NUREG-0700 and NUREG-0800 against DOE Order 6430 1A, Section 1300-12 4, and draft DOE-STD-1062-94 Ergonomics and Human Factors Engineering Design Criteria Volume 1, to identify appropriate additional NRC guidance for design of the CVDF. The goal of NUREG-0800 is to ensure that the design of a nuclear power plant control room complies with accepted HFE principles, focusing on the following areas:

A. Control room work space
B. Workspace environment
C. Annunciator warning systems
D. Controls
E. Visual displays
F. Auditory signal systems
G. Labels and location aids
H. Process computers
I. Panel layout
J. Control-display integration

In reviewing NUREG-0800 against DOE Order 6430 1A, it is apparent that the applicable items of interest (A through J) above, are also represented in the DOE Order 6430 1A requirements. The DOE requirements are then captured in INEL-95/0117 Human Factors Engineering Checklists for Application in the SAR Process, which uses the design criteria from various sources, including NUREG-0700 and DOE-STD-1062-94, as called out in HNF-SD-SNF-DB-003, Item 9. Using a graded approach and focusing on significant human-machine interfacing, the systems listed in the SNF Project FSAR and this facility FSAR Annex were deemed appropriate for HFE checklist evaluation using applicable INEL-95/0117 checklists (which cover items A through J above in great detail) for each system.

Figure B13-3 depicts the human factors checklist procedure.
B13 3 3 Engineering Design and Analysis

Engineering design encompasses the design process and analysis in support of both original design and design change activities. Design preparation is in accordance with criteria established in DOE Order 6430.1A, Section 1300-12, where human factors are considered through the system development process (planning, requirements analysis, system design, and system test and evaluation). Pursuant to DOE Order 6430.1A, Section 12.4, the design, operation, and maintenance of the CVDF consider appropriate human factors technology to improve human performance through enhancements in the work environment and HMI. HFE applies at a level commensurate with the safety importance, complexity, and degree of HMI of the SSCs.

In completing the final design for the CVDF (HNF-SD-SNF-DRD-002), human factors design analyses encompassed design criteria such as operational aids, the control and display relationships, visual displays, transilluminated displays, scale indicators, audio displays, general controls, hand-operated controls, foot-operated controls, HCI, labeling, remote-handling environment, operation and maintenance, hazards and safety, physical access, protective clothing, and communications, as applicable and appropriate. The final design review is in accordance with the DOE orders listed in Section B13 2. The results are described in SNF-4213.

Human factors criteria are included in the system design descriptions for each SSC in the CVDF (SNF-2356). Each system design description includes a separate section that discusses the human actions performed while operating the system and the pertinent human factors issues associated with those actions.

The design requirements include HFE aspects at each step. For the purposes of developing requirements and ensuring their appropriate inclusions, the project engineers responsible for design are responsible for the applicable HFE requirements. This process is similar to promoting accountability downward to the lowest practical level. In addition, CVDF safety-class equipment RFPs include HFE requirements, as applicable. Finally, CVDF project personnel are aware of applicable HFE criteria, and their design reports and activities make reference to HFE considerations (see Figure B13-3).

B13 3 4 Designing for Off-Normal and Emergency Operations

An assessment team conducted a hazard analysis to identify potential hazards to the CVDF operator, co-located personnel, the public, and the environment (HNF-SD-SNF-HIE-004). Potential events considered ranged from normal operations to design basis accidents and natural events (e.g., seismic). The hazard analysis process consists of identifying the various operational steps to be conducted within the CVDF, and by doing so, considered HMI. The hazard analysis identifies both engineered and administrative safety features. Engineered safety features are design features that prevent or mitigate the potential accident and may require HMI. Administrative safety features are procedures and programs designed to ensure that engineered safety features continue to be available for accident prevention or mitigation.
safety features also include programs that implement a particular set of safety practices
SNF-4213 outlined possible areas of human error during a task analysis and recommended ways
to mitigate the potential human error, however, this HFE analysis was not a human reliability
study Chapter 3 of the SNF Project FSAR describes the hazard analysis methodology and
results for the CVDF are summarized in Chapter B3 0

In addition, the CVDF design team and Operations personnel reviewed off-normal
assessments, and reported via facilitated discussions (Ares 1998) on their hazard analysis of the
cold vacuum drying system. The team performed the off-normal assessment and identified and
assessed operational upsets (e.g., valve failures, control upsets, mechanical equipment failures)
that potentially could occur during normal operating conditions. The team examined each upset
condition to identify design and operational effects. The main objectives of this assessment were
to (1) identify and develop automatic monitoring and control system (MCS) actions to protect
against unacceptable operational consequences for the upset, (2) identify and develop
administrative protective actions, (3) identify any safety impacts that could result from the upset
or recovery from the upset, and (4) identify MCO “safe states” to be operationally achieved, if
necessary, from each step in the operations sequence. Ultimately, if an operational “safe state”
cannot be established or maintained, the safety-class instrumentation and control (SCIC) system
will trip to ensure that a “safe and stable” condition is provided. This effectively shuts down the
process in a safe condition until the original cause of the trip of the SCIC is determined and
remedied. The team is finishing work on specific pre-approved operational responses that will be
needed following an off-normal event to ensure that the facility safety envelope and boundaries
are not challenged.

The following information identifies what the operators at the CVDF are doing during
various stages of system processing (in addition, Section B13 3 1, “Process Background,”
provides additional detail of the HMI along with Table B13-1, as indicated above) Human
system interaction within the CVDF focuses mainly on two important areas: the process bay(s)
and the Central Control Room. The process bay provides direct human access to the cask-MCO
and exposes the human operator to a moderate risk. The control room provides the human
operator a means for surveillance, management, and control over the cask-MCO processing
operation(s). For purposes of the human factors safety basis, the control room is a non-reactor
control room.

The normal human operations at the CVDF are detailed in SNF-2356 Spent Nuclear Fuel
Cold Vacuum Drying Facility Operations Manual. These operations are outlined below

- Operators connect hoses to the tractor exhaust and hook up building air

- Operators raise the bay door to allow the tractor-trailer to back into the
  predetermined position. Location marks are painted on the floor to facilitate the
  trailer parking position. The tractor drives out of the bay, and the bay door closes
  achieving process bay confinement. The trailer is stabilized and leveled. The security
  system for the specific bay activates. The radiological control technician conducts...

<td>Safety-class instrumentation and control system</td>
<td>Control panels located in the control room provide an audible alarm to differentiate this system from the MCS. Responses to the SCIC annunciator are by operator action, the primary HMI is the MODE SWITCH, ANNUNCIATOR SWITCH, and the LOW ANNUlus LEVEL BYPASS SWITCHES. HMI is through test switches and reset functions. The SCIC system provides active detection and response to process anomalies. Specifically, actuation of the SCIC system performs two safety-class functions: (1) signal closure of isolation valves leading to and from the MCO to the process systems and signal opening the SCHel system isolation valves to provide MCO purging and pressurization, and (2) to remove power from the tempered water heater and pump motor. The SCIC system also provides safety significant annunciation to the control room if the PWC system prepurge or PWC system post purge process fails. The SCIC system is a fully automatic system that requires no operator action to detect and respond to process upsets within the SCIC system controls.</td>
<td>Yes meets applicable HFE general design criteria</td>
</tr>
<tr>
<td>Safety-class helium system</td>
<td>Check gauges and test/replace helium cylinders as required. The SCHel system is a dedicated safety system that actuates upon SCIC signal trip or is manually activated by a control room operator. The key function of the SCHel system is to pressurize and purge the MCO with sufficient helium pressure and flow to preclude flammable concentrations of hydrogen. A safety-class alarm is provided in the control room to signal that an actuation of the SCHel system has commenced.</td>
<td>Yes meets applicable HFE general design criteria</td>

radiation surveys on the cask and trailer CVDF shift operations management receives the shipping data package. The operators install a bridge from the process bay mezzanine to the trailer work platform. The operators prepare the cask lid for removal.

Special venting hardware and flex lines connect to the cask lid port and the CVDF process vent system. After cask venting is completed, the CVDF process bay overhead crane removes the cask lid, the process hood-seal ring is installed on the cask, process connectors are manually attached to MCO process port covers, and the MCO is prepared for process operations.

There are minimal manual operator actions in the process sequences other than field operator actions (e.g., connecting the MCO valves and flex lines) or control room operator actions (e.g., acknowledging alarms or instructing the MCS to proceed with the next step in the operation). Control room operators direct the MCS to initiate a certain sequence based on status updates from field operators and the MCS, previous sequence completion notification, and operating procedures. This includes draining the cask-MCO annulus.

Following the cold vacuum drying process and MCO testing, the cask-MCO transporter is prepared for shipment to the Canister Storage Building. This operation is basically the reverse of the receipt operation. Through operations controlled via the MCS, the cask-MCO is cooled and the MCO is inerted and pressurized with helium, sealed, and leak tested. The cask annulus is drained and dried with an instrument air purge, and the cask lid is reinstalled. The bay is isolated from the ventilation systems, and the telescoping door is opened. The trailer is reconnected to the tractor and released for shipment to the Canister Storage Building.

There are periodic nonintrusive routine maintenance requirements (the CVDF does not need shutting down) that require recalibration of instruments and possible high-efficiency particulate air (HEPA) filter changes. The probability of major failure with the resulting removing and replacing of major items, such as pumps, is extremely low. The systems are expected to last the entire time that SNF is being removed from the K Basins, which is expected to be 2 to 5 years.

Almost all human operator functional activities will be in the process bay, the PWC tank room (ion-exchange module changeout), and the Central Control Room. The tasks in the bay areas include connecting and disconnecting hoses, tightening applicable bolts, using tools identified in SNF-4213, manipulating the crane, fitting and unfitting the cask hood, and general “housekeeping” to keep the areas clean and safe.

The CVDF system is designed to respond to an incident and place the MCO in a safe configuration to ensure little opportunity for contaminated material release. Human interaction at this time will be to confirm that the MCO is in fact in a safe configuration, through the MCS and SCIC, and then take the appropriate actions per checklist, including fault isolation actions, as appropriate.
The HMIs for the engineering safety features were analyzed in accordance with the same criteria established in Section B13.2. Resolutions of noncompliance issues are documented in SNF-2825. In addition, SNF-4399 provides detailed information on how noncompliance issues are handled.

During the design of the CVDF, the architect-engineer used the hazard analysis or other analysis methods (e.g., failure mode and effects analyses) to evaluate the need for features or actions to increase safety and reliability. These analyses identified equipment items that were either included in, or removed from, the design of the CVDF to simplify the operations or improve reliability. The hazard analysis process also identified hazards resulting from identified maintenance activities. These hazards, if they result in accidents or contribute to an accident, will result in preventive or mitigative features or features that will decrease the frequency of the initial maintenance problem.

A job analysis was performed to identify the scope of the job and associated critical tasks. Based on the results of the job analysis, training is developed as described in Section 12.4 of the SNF Project FSAR. This process, along with design authority and management input, is the basis for determining the specialized maintenance capabilities required (e.g., vendor support or in-house journeyman knowledge). In addition, the SNF Project analyzed the types and complexity of equipment included in CVDF design and, applying past experience with these equipment types, identified the types and numbers of the various craftsmen needed for the maintenance support. During initial full operation of the CVDF, maintenance response teams will be assigned to each shift. The maintenance response teams will be composed of a cross-section of craft and technical support, including an engineer, a millwright, an electrician, and an instrument technician. This diversified team will have the capability to identify, diagnose, and repair problems with equipment that is essential to the facility function.

DOE Order 4330 4B specifies that maintenance facilities, equipment, and tools should efficiently support facility maintenance and maintenance training. The SNF Project has evaluated the maintenance needs in this area and the necessary office areas, tool and equipment storage, equipment access, and utility services layout (e.g., instrument air, water, electric power) to support safe and effective maintenance at the facility.

Measuring and test equipment includes all devices or systems used to inspect, test, calibrate, measure, or troubleshoot an instrument or piece of equipment to verify conformance to specified requirements. Only measuring and test equipment that is calibrated to standards that are traceable to the National Bureau of Standards or other nationally recognized standards are authorized for use by SNF Project personnel. Instruments are calibrated at specified intervals, before and after use, or just prior to use as determined by required accuracy, intended use, frequency of use, stability characteristics, and other conditions affecting performance.

There are no known limitations at the SNF Project facilities imposed by design and operation on routine maintenance, renewal, or repair of SSCs. Equipment in hazardous and radiological areas is designed to be free of maintenance as much as possible and is operated in a...
“run-to-failure” mode. Accessibility (physical access) for maintenance and provisions to support effective maintenance were considered in the facility design.

B13 4 IDENTIFICATION OF HUMAN–MACHINE INTERFACES

This section summarizes the safety-class and safety-significant SSCs that require HMI to function and the associated HMI. Also annotated are the significant HMIs that are pertinent to the operation of the CVDF. The intent during design was to reduce, as much as possible, HMI at the CVDF. The system is designed to run very efficiently in an automated state, however, human input (e.g., providing permission for the system to move from one process to the next process) assures that the system is maintained under human control through all processes and keeps the human involved at critical stages of the process operation. The human will also monitor system operation. When there is an off-normal occurrence, the human physically checks the discrepant part of the system. Periodic human inspection of the system and routine periodic maintenance will also be required.

Using the DOE-recommended graded approach and DOE Order 6430.1A, the analyst performs a systems requirements analysis as an integral part of the design. Therefore, the systems approach to design is applied whereby systems, structures, and equipment are built in accordance with the best available design practices. HNF-SD-SNF-DRD-002, Cold Vacuum Drying Facility Design Requirements, includes a number of human factors considerations in the CVDF design. The application of these human factors interface guidelines to the CVDF is documented for the safety-related SSCs. Table B13-1 shows the systems that were reviewed for human factors considerations, additional detail concerning HFE analyses of these systems is provided in SNF-4213. SNF-4399 describes human engineering processes to be used in design analyses. Subsequent analyses are reported in SNF-4213.

B13 5 OPTIMIZATION OF HUMAN–MACHINE INTERFACES

In considering the optimization of HMI, the reduction of human involvement to the minimum levels necessary to ensure complete facility safety stands out as a premier design concept. The staffing levels, training, special tools required, HCl, and response to off-normal conditions consider human interfaces. Optimized alarms allow the human operators to quickly and accurately identify the condition generating the alarm and to determine the next course of action.

Tools are being selected with consideration of optimizing human performance. Optimization does involve a cost-benefit trade-off and one such area is the trade-off involving the 300 ft-lb bolt torquing requirements for the cask lid. Machinery would have been a logical choice, however, a technique using a torque multiplier on the manual torque wrenches is appropriate and more cost effective under these circumstances. The multiplier will have a six-to-one ratio designed to reduce the actual human-provided push and pulling forces to manageable levels.
Layout and design of controls, instruments, and provisions for labeling that apply the principles of ergonomics and human engineering were evaluated using the applicable INEL-95/0117 checklists and applying those checklists to a mock-up of the CVDF bay work platform surrounding the cask (as if the trailer-cask was parked in the bay). Also, the support skids were mocked up and evaluated, along with simulation of the control room with computer displays for monitoring and controlling the CVDF operation. With input from the checklists and interviewing operators, the system provides for effective HMI design.

Consideration is given to minimum staffing levels, training, and periodic maintenance, these considerations are described in Section B13. As stated above, the premier design concept was to minimize allocation of control functions to humans, creating automated processes where appropriate. However, the human component retains control over the entire process because the process will stop after appropriate sequences and wait for the human to initiate the next required sequence.

The work environments meet general operating HFE environmental design criteria, based on available calculated engineering design requirements and comparing the results to existing criteria found in the HFE standards and checklist. For example, calculated room lighting in the control room appears to meet acceptable standards. Physical access was evaluated using the mockup and appears acceptable. Also, input from the operators was solicited and provided to the skid vendors. Local Hanford Site procedures and requirements provide personal protective clothing requirements.

Information about temperature, humidity, and other environmental conditions is provided in Chapter B2.0 and in the system design description for the heating, ventilation, and air conditioning system. The available calculated values and available design information from system design descriptions were compared to DOE-STD-1062-94, as captured in INEL-95/0117. The HFE checklist examines temperature, humidity, ventilation, noise, illumination and other factors impacting human operations during normal operations, including routine periodic maintenance. SNF-2825 and SNF-4213 provide an examination of the facility environment.

Software design is being optimized by using the required engineering standards and guidelines, and includes operator input via the mock-up and software designer experience. These experiences and mock-up lessons learned contribute to the software development, making the operation of the CVDF intuitive and easy to follow for the operator(s). The system software manages the physical computer resources on behalf of the application software. The MCS is the interface between the control room operator and the process system. It provides process values and status in graphical (mimic) formats to the operator via a computer screen. The MCS accepts operator commands and overrides.
Functionally, the MCS monitors the instrumentation, controls equipment, displays status information, and accepts operator input. The MCS design and program provide the following process functions:

- Monitor and display the status and performance of each selected cold vacuum drying treatment process subsystem and component group.
- Provide a means to remotely control selected process control loops by the operator during operation (e.g., adjust the tempered water operation setpoint).
- Provide audible and visual alarms for out-of-limit conditions on various process parameters and facility systems.
- Provide automated computer control of system processes and provide the means to take manual control (operated from the computer console) of a discrete process component.
- Provide process control, interlock, and alarm logic as programmed into the programmable logic controller, which provides for all proportional/integral/derivative loop controls.
- Provide for storage of selected data and method(s) for archiving data.
- Provide for retrieval, display, and printout of historical data, real time data, and selected trends.
- Provide a prioritized and time/date-stamped alarm summary on the MCS display, alarm status printouts are available on demand only.

The CVDF sequences are automatic, once initiated. There will be points in the sequence where the operator or supervisor will be required to interact with the control system. Adjusting a setpoint and other control parameters requires operator input. The control system will maintain operator-entered values.

The MCS software design considers the use by process operators. All computer displays and windows are representative of the operating sequence, the process flow, and components. All persons who operate this equipment will receive training on the MCS and its use.

Visual displays and annunciator panels include coding and display integration methods in accordance with DOE Order 6430 1A, Section 1300-12 4 7, and its references that include applicable sections of both NUREG-0700 and MIL-STD-1472E, *Human Engineering*. Technical HCI work is evident and has received special attention by the design engineers.
The MCS consists of two operator workstations, an engineering workstation, a redundant programmable logic controller, and locally mounted input/output modules with termination panels and interfacing relays. The operator interfaces are object-oriented color graphic displays on computer screens located in the central control room and management office. An open systems network connects displays but can only be accessed (changed) in the central control room by the operators. This allows simultaneous access to the control system from multiple graphic displays. The MCS is proprietary and there is full control from any of the stations in the control room. The supervisory computer, located in the supervisor’s control room, is read-only.

The MCS boundary includes all components starting at the workstations and ending at the wiring terminations at the process bay skids. The actual sensors, valves, and other process equipment are outside the MCS boundary. The MCS interfaces with the following processes in each of the four bays (2 through 5):

- Helium supply system
- Tempered water system
- Vacuum pumping system
- De-ionized water system
- Process water conditioning

Also, the MCS interfaces with:

- Radiation monitoring
- Stack monitoring

Checklists support the optimization process of integrating the human into the system design. An HFE checklist is similar to a questionnaire. It contains a list of items pertaining to the human engineering aspects of equipment. One or more evaluators can rate the adequacy of the equipment on each applicable item of the checklist. Checklists are most useful in the early phases of systems development and design where concern is primarily with static human engineering design properties. For example, the placement of displays and controls for adequate viewing, the labeling of instruments and equipment, and other features not directly related to human-machine performance. Checklists have limited usefulness in the evaluation of dynamic human interaction with equipment. Measurements of this kind need to be observed and recorded directly. The checklists used for CVDF HFE and ergonomics evaluation are constructed from several standards that typically evaluate the design based on 5th to 95th percentile personnel population expected to operate and maintain the facility. Design optimization for this range of personnel generally has been considered as optimum based on the cost of the design, the time to design, and other factors (e.g., materials available at the time of design). Checklists developed from HFE standards ensure the design will meet minimum HFE criteria based on best available information and consensus.
Normal human operations were reviewed and reported in a human factors report, SNF-2825, and a follow-up human factors report, SNF-4213. These human factors study reports document the tabletop task analysis, systems reviews, direct interviews with design authorities and cognizant engineers, and reviews of applicable design documentation. The INEL-95/0117 checklists are used to supplement the task analyses, interviews, and design documentation reviews. In addition, the task analysis done by the training professional staff was captured in the draft procedures training document, which also was reviewed. The training document provides the step-by-step procedure that an operator will accomplish during a task activity. These procedures will be validated during the dry run test and evaluation phase of the project, as described in SNF-4399.

The normal human operations at the CVDF are detailed in SNF-2356. These operations are outlined as follows:

- Operators connect hoses to the tractor exhaust

- Operators raise the bay door to allow the transporter to back into the predetermined position. Location marks are painted on the floor to facilitate the transporter parking position. The tractor drives out of the bay and the bay door closes, achieving process bay confinement. The transporter is stabilized and leveled. The security system for the specific bay activates. The radiological control technician conducts radiation surveys on the cask and transporter. CVDF shift operations management receives the shipping data package. The operators install a bridge from the process bay mezzanine to the transporter work platform. The operators prepare the cask lid for removal.

- Special venting hardware and flex lines connect to the cask lid port and the CVDF process vent system. After cask venting is completed, the CVDF process bay overhead crane removes the cask lid, the process hood-seal ring is installed on the cask, process connectors are manually attached to MCO process ports, and the MCO is prepared for process operations.

- There are minimal manual operator actions in the process sequences other than field operator actions (e.g., connecting the MCO valves and flex lines) or control room operator actions (e.g., acknowledging alarms or instructing the MCS to proceed with the next step in the operation). Control room operators direct the MCS to initiate a certain sequence based on status updates from field operators and the MCS, previous sequence completion notification, and operating procedures. This includes draining the cask–MCO annulus.

- Following the cold vacuum drying process and MCO testing, the cask–MCO transporter is prepared for shipment to the CSB. This operation is basically the
reverse of the receipt operation. Through operations controlled via the MCS, the cask-MCO is cooled and the MCO is inerted and pressurized with helium, sealed, and leak tested. The cask annulus is drained and dried with an instrument air purge and the cask lid is reinstalled. The bay is isolated from the ventilation systems, and the telescoping door is opened. The transporter is reconnected to the tractor and released for shipment to the CSB.

There are periodic nonintrusive routine maintenance requirements (the CVDF does not need shutting down) that require recalibration of instruments and possible high-efficiency particulate air filter changes. The probability of a major failure with the resulting removal and replacement of major items (e.g., pumps) is extremely low. The systems are expected to last the entire life cycle of the facility, which is stated as five years.

Almost all human operator functional activities will be in the process bay, the process water conditioning tank room (ion-exchange module changeout), and the central control room.

B13 5 2 Staffing and Training

B13 5 2 1 Operator Capabilities. Skills, knowledge, and abilities to meet job standards are defined to ensure that personnel have the appropriate capabilities to perform the required activities in a safe and reliable manner. As stated in Chapter 17 of the SNF Project FSAR, minimum education and experience requirements for management and technical personnel meet the requirements of DOE Order 5480.20A Qualification criteria define the experience, education, and training required to perform a designated job. Chapter 17 of the SNF Project FSAR and Chapter B5 also provide a discussion of the minimum staffing requirements.

Verification of operator capabilities occurs throughout the testing and validation review programs. Specifically, the operational readiness reviews will include dry run demonstrations that ensure operators and procedures are in a satisfactory state of readiness to safely and efficiently receive, handle, and process MCOs. The dry run demonstrations permit certification of both procedures and the operations staff by confirming that personnel have the appropriate knowledge and capabilities to perform their duties.

The completed safety analysis report process for selecting safety-class and safety-significant SSCs and technical safety requirements also serves as a systematic inquiry into the ability of facility staff to accomplish their responsibilities and duties during normal and abnormal operations.

B13 5 2 2 Staffing Levels. A current staffing plan exists for the CVDF through 2002. A review of this plan indicates that appropriate consideration was given to the following:

- Learning curves
- Loss of trainees through the process
- Appropriate job titles and functions for operations personnel
One factor that appears to weigh heavily in the operations staffing requirement concerns the occupational radiation exposure calculations. For the CVDF, occupational radiation exposures to workers are estimated based on the manual operations performed in the presence of the radiation field surrounding one cask-MCO in the CVDF. As discussed in Section B 7.10, the planned staffing level supports the annual MCO processing goal (147 MCOs) with a resulting annual exposure to the working staff well below the ALARA goal set by HSRCM-1, *Hanford Site Radiological Control Manual*.

Consideration for retaining a three-shift work day concerns the commute to and from the CVDF. Operators at the MCS control station may be mentally fatigued from constant surveillance and monitoring. Having operators work longer hours under these conditions may impose a greater safety risk to the operator when commuting from work to home while mentally fatigued. The commute will most likely be by privately owned vehicle.

**B13 5 2 3 Personnel Training** Training ensures that all staff have the knowledge, skills, and abilities required to safely operate and maintain the facilities and processes. As discussed in Chapter 12.0 of the SNF Project FSAR, the SNF Project training organization applies DOE-mandated performance-based training to specific job requirements. This is being implemented using a systematic approach to training development that is in compliance with the requirements of DOE Order 5480.20A.

The SNF Project uses HNF-PRO-170, *Analyzing Training Requirements*, HNF-PRO-171, *Designing Training*, and HNF-PRO-174, *Evaluating Training*, as guidelines in developing and implementing an effective training program. As identified in Section 12.4 of the SNF Project FSAR, this systematic approach to training ensures that the training program will have the following characteristics:

- Training based on a systematic analysis of each CVDF job position
- Measurable learning objectives derived from the systematic analysis
- Desired post-training performance described
- Trainee mastery of objectives evaluated during training
- Job performance of trainees used as a basis for evaluation and revision of training

Operators receive on-the-job training that consists of learning to operate the specific components, equipment, and systems in the CVDF. The majority of on-the-job training package development and operator evaluations will be performed during pre-operational testing and validation. Pre-operational testing and validation includes dress rehearsals using mock-ups and in situ equipment and systems to provide verification of the operators' knowledge of facility procedures, readiness of tools, equipment, and instrumentation, and off-normal and emergency procedures. The major focus is incorporating job and task analysis information into the on-the-job training material and ensuring that the operators are trained and evaluated on this material.

Schedules, material, and evaluations for continuing training are being developed. These include (1) classroom training on fundamentals, systems, administrative controls, and emergency
response, and (2) on-the-job training for normal and abnormal operation. Job and task analyses also assist in defining those tasks that require continuing training. To ensure that training properly reflects the current operating practices, conditions, and procedures, a training materials maintenance system is used to track items that may affect the content of the training programs. Chapter 12.0 of the SNF Project FSAR provides additional details on the maintenance of training programs and the use of a training materials maintenance system.

Operational drills and exercises are an integral part of the facility training program. Drills are an effective means of providing training in the handling of off-normal conditions and situations. Drills also provide management with an assessment tool to help evaluate the staff's ability to respond to off-normal events and conditions. Drills and exercises provide the means for testing crew proficiency and validating procedures.

Task statements and task elements within the scope of the training task analysis are complete for the CVDF first article process equipment skid. A student training manual is being developed from the training task analysis.

B13 5 2 4 Procedures DOE-STD-1029-92 states, "The overall safe operation of the facility depends upon the structured interrelationship among DOE requirements and guidance, the bases documentation (senior management, technical, management control, and design) and the facility’s procedures — generally referred to as its safety envelope.” In other words, a facility’s procedures define how requirements, management philosophies and strategies, and technical knowledge are integrated and applied to performing work in the facility. See Section 12 3 of the SNF Project FSAR for a complete discussion of the SNF Project procedures program.

DOE-STD-1029-92 was created by the Human Factors Area Council to ensure writers of technical documents will follow basic human factors principles in their content, layout, and format of written technical procedures. Because DOE-STD-1029-92 complies with accepted human factors principles, implementation of this standard demonstrates that human factors considerations are included.

In addition to training or day-to-day supervision, providing sound procedures and requiring workers to use them are among the most formal, direct, and effective methods available to facility managers to ensure that operations meet DOE’s objectives. Procedures provide managers with a critical tool to communicate detailed expectations for how individual workers are to perform specific tasks. In other words, the facility’s operating procedures provide the mechanism for ensuring that facility operation is maintained within the safety basis.

During the validation portion of the review process for draft procedures, the procedure will be tested for correctness, compatibility with system equipment, and human factors considerations and usability. Validation includes determining whether the user can perform each step correctly and ensuring the units used in the procedure are consistent with the facility instrumentation and possess the required precision for operation. Validation ensures the sequence of steps is logical and can actually be performed, all documentation (e.g., labels, equipment representations, and
diagrams) contained in the procedure is accurate, and tasks required by the procedure can be effectively performed by operations personnel during normal, off-normal, and emergency conditions. Alarm response procedures are developed on the basis of the monitoring and control functions of the system or component providing the alarm output. All operating procedures are validated by procedure walk-through and simulated operation before they are used. End-user or operator participation in both the procedure writing and the review processes is solicited.

Procedures will be periodically reviewed. This periodic review process ensures the technical accuracy and the proper considerations of human factors issues in procedures. Included in the review process are CVDF operating procedures, alarm response procedures, and surveillance and test procedures. The process involves verification of the technical basis and procedural steps, validation of the usability of the procedure by operations personnel, and verification of human factors elements that may affect the effectiveness of the procedure.

### B13 5 3 Abnormal Operations

Scenarios for abnormal operations involving human recovery, initiator, or mitigator actions are being completed (see Section B3 3 4). Typically, basic recovery response by operators is to acknowledge the abnormal occurrence and investigate the cause. The MCS and SCIC will automatically take the applicable action and wait for operator acknowledgment before restarting the procedure. Abnormal operations are fully covered in training and validation during pre-operational testing.

The minimum operations shift complement in the facility modes (i.e., normal operations, abnormal operations, and emergency operations) is established and based on the minimum staff in each mode considered adequate to perform the minimum safety functions necessary to protect the health and safety of the public, onsite workers, and the environment during normal, abnormal, and emergency conditions. The minimum staff during abnormal conditions is necessary to perform the required actions specified in the limiting conditions for operation action statements with completion times of "immediately" or less than eight hours to ensure technical safety requirement compliance. Hanford Site experience has shown that additional staff could be provided within eight hours, if needed (considering the most adverse weather and travel conditions) to ensure all limiting conditions for operation completion times are met. Limiting conditions for operation completion times of "immediately" imply the highest sense of urgency and are given top priority over all other activities. The minimum staff is not given tasks that could interfere with meeting technical safety requirements.

The minimum staff during emergency conditions is necessary to respond to the spectrum of accidents analyzed in Chapter B3 0. The minimum staff must make prompt initial notifications and implement initial protective actions to preclude or reduce the exposure of individuals affected by hazards or unsafe conditions during an emergency. Specific functions that must be performed by the minimum staff in an emergency include the following:
Implemention of alarm response, plant response, and emergency management procedures

- Classification of events
- Initial prompt notifications
- Performance of administrative functions (e.g., preparing occurrence reports)
- Communication of facility status and response to questions
- Support for the DOE, Richland Operations Office Emergency Operations Center

An emergency response plan is developed to be compatible and integrated with the disaster, fire, and/or emergency response plans of local, state, and federal agencies. The emergency response plan shall be rehearsed regularly as part of the overall training program for site operations. An employee alarm system is installed to notify employees of an emergency situation, to stop work activities if necessary, to lower background noise in order to speed communication, and to begin emergency procedures.

A spectrum of potential accidents ranging from minor to beyond design basis are postulated and realistically analyzed. While not every conceivable situation will be analyzed, the hazards assessments provide the framework for response to virtually any declared emergency. The methodology, assumptions, models, and evaluation techniques used in the hazard assessments are documented.

Operations response emergency equipment is stored in designated SNF Project locations. This equipment is used in all types of emergency events and includes Emergency Response Organization staff identification vests, emergency response procedures, personal protective equipment, spill kits, flashlight, barricade rope, and first aid kits.

The SNF Project emergency response training program ensures the readiness of the SNF Project emergency preparedness organization, and general employee awareness of hazards and response actions. This program is part of the overall Hanford Site training program and includes classroom instruction, tabletop exercises, walkthroughs, on-the-job training, and drills. Drills and exercises for this program are of sufficient scope and detail to ensure demonstration of adequate response capability in all areas and by all populations.

Develop full scale mock-up of proposed designs skids, cask, MCS, etc

Examine human actions in mock-up environment and HCI

Provide CVDF cognizant engineer reviews at design stages

Complete HFE checklists against human engineering design criteria

Resolve human engineering deficiencies as revealed during checklist reviews

Further evaluate human interfaces

Provide continuing HFE review of design changes and incorporate solutions

Includes HFE criteria

Review programmatic concerns

Preoperational start-up

Verify and validate the entire HFE effort

Report final results of the HFE evaluation process

MCS = monitoring and control system
HFE = human factors engineering
HCI = human-computer interface
Figure B13-3 Human Factors Checklist Procedure

- Familiarization with CVDF systems, structures, and components
- Review the Facility Hazards Evaluation
- Select HMI to evaluate based upon those systems that are either Safety Class or pertinent
- Tabletop task analysis to determine task performance, sequence, and maintenance
- Interview cognizant project personnel to determine level of design and design efforts
- Review design requirements process, pertinent subcontract RFPs, and facility design process for inclusion of HFE criteria
- Application of HFE checklists to existing SSCs and design requirements documents
- Checklist evaluation results sorted into one of four categories: 1) complied, 2) not complied, 3) not applicable, and 4) to be determined
- Resolve any non-compliances
- Generate commitments to consider TBDs in continuing design efforts
- Review programmatic issues (staffing, maintenance, procedures, and training)
- Resolve any programmatic concerns
- Report on the results of the HFE evaluation

B14 0 QUALITY ASSURANCE

B14 1 INTRODUCTION

An introduction to the quality assurance program that includes the objectives and scope that apply to all Spent Nuclear Fuel (SNF) Project quality assurance activities is provided in Chapter 14 of the SNF Project Final Safety Analysis Report (FSAR).

B14 2 REQUIREMENTS

The requirements that form the basis of the quality assurance program are identified in Section 14 of the SNF Project FSAR. Additional requirements for the Cold Vacuum Drying Facility (CVDF) are identified in the following paragraphs. These requirements ensure the quality assurance requirements for federal repository acceptance of SNF and U.S. Nuclear Regulatory Commission (NRC) equivalency requirements are satisfied.

The U.S. Department of Energy, Richland Operations Office (DOE-RL), has directed (Sellers 1995) that DOE/RW-0333P, Quality Assurance Requirements and Description (QARD), published by the Office of Civilian Radioactive Waste Management, be applied as the principal quality assurance document to the SNF Project office of Civilian Radioactive Waste Management program. DOE-RL has directed application of DOE/RW-0333P to the following SNF Project activities as they relate to disposal in the repository:

- Characterization or data collection for input and use
- Conditioning into final form
- Handling, packaging, and transportation

Items activities and documentation determined to be important to safety are presented in Table 3-1 in HNF-SD-SNF-RPT-007, Application of the Office of Civilian Radioactive Waste Management Quality Assurance Requirements to the Hanford Spent Nuclear Fuel Project. HNF-SD-SNF-RPT-007 identifies certain high-level structures, systems, components, activities, and documentation that require application of DOE/RW-0333P requirements to ensure compliance with the DOE-RL direction. Application at the CVDF includes, but is not limited to, the following:

Items

- Equipment that ensures adequacy of water removal from a multi-camster overpack (MCO) at the CVDF and ensures that site safety bases requirements are satisfied for limiting particulate generation
Activities and Documentation

- Process validation tests and operational tests where necessary to demonstrate adequacy of process conditions for removal of water from the MCO and for limiting particulate generation

- Equipment acquisition and acceptance (e.g., specification, calibration) where necessary to ensure adequacy of water removal from the MCO and ensure that site safety bases are satisfied for limiting particulate generation

- CVDF process design specifications, design, design analyses, and design verification where necessary to ensure adequacy of water removal from the MCO and ensure that site safety bases limits are satisfied for particulate generation

- Measures to ensure unapproved materials are not introduced into the MCOs

- Data developed by CVDF personnel that are also needed by the U.S. Department of Energy (DOE) Office of Civilian Radioactive Waste Management, based on formally transmitted data requirements from DOE-RL

In addition, HNF-SD-SNF-RPT-007, Appendix B, identifies, at a lower level, specific items, activities, and documentation that require application of QARD requirements, including the following

**Items requiring application of QARD requirements**

**Components**

- **PT 1*08, PT 1*10**  
  MCO pressure transmitter (vacuum 0-100 torr)

- **TIT 3*05, 3*12**  
  Tempered water temperature, inlet and outlet

- **CP 210, 311, 410, 511**  
  Safety-class instrumentation and control system programmable logic controller panels with programmable logic controller analog card for PT and TIT signals (1 card each panel)

- **CP 201, 301, 401, 501**  
  Monitoring and control system (MCS) input/output panels with analog card for PT and TIT signals (2 cards each panel, modules 3 and 6)
Loops

- MCO pressure: Signal from pressure element to MCS printer output
- Tempered water temperature: Signal from temperature element to MCS printer output

Software

- MCS computer program: Plot routine and analog conversion of PT and TIT signals

Activities and items requiring application of QARD requirements

- Analysis and characterization test results showing the correlation of pressure and temperature to water quantity in the MCO
- Analysis (HNF-SD-W441-CN-001) to show corrosion generation will not exceed safety basis limits
- Design specification and design necessary to ensure adequacy of water removal and that particulate generation will not exceed site safety basis requirements
- Validation plan for CVDF water removal strategy, test procedures, and test results
- Selected operating procedures for CVDF drying
- Operating procedures for helium hookup, receipt inspection records on helium purity, and helium purity sample data
- Operating data records from QARD components
- Calibration records for QARD components
- Training records for operations and maintenance personnel involved with processes and components associated with QARD requirements

Data collected and controlled during the cold vacuum drying process to show compliance with the QARD requirements will be summarized and inserted into each MCO data package (traveler) prior to shipping the respective MCO to the Canister Storage Building, consistent with QARD requirements.
DOE has established a regulatory policy (Grumbly 1995) that new SNF Project facilities achieve nuclear safety equivalency with NRC-licensed facilities. An evaluation, documented in WHC-SD-SNF-DB-002, *Spent Nuclear Fuel Project Path Forward Nuclear Safety Equivalency to Comparable NRC-Licensed Facilities*, identified requirements to establish nuclear safety equivalency that are to be met in addition to existing and applicable DOE requirements. These requirements, except those related to the design basis earthquake, are contained in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward Additional NRC Requirements* HNF-SD-SNF-DB-004 *SNF Project Seismic Design Criteria — NRC Equivalency Evaluation Report*, contains the design basis earthquake requirements.

NRC nuclear safety equivalency requirements identified in HNF-SD-SNF-DB-003 that will be applied to the CVDF include:

- Incorporation of requirements into safety-class procurement specifications that requires suppliers to report defects and noncompliances in items or services (Item 15)
- Review and approval by DOE-RL of changes to HNF-MP-599, *Project Hanford Quality Assurance Program Description*, that could be interpreted as decreasing the quality assurance program’s existing commitments for the CVDF (Item 16)
- Implementation of the Project Hanford Management Contract occurrence reporting system for the design and construction of the CVDF (Item 17)
- Ensure the appropriate quality requirements in existing Project Hanford Management Contract procedures and instructions identified in WHC-SD-SNF-DB-002 remain in effect (Item 18)
- Institute a process to identify safety-class equipment that has been identified in the commercial nuclear power industry as being potentially defective (Item 19)
- Ensure the areas of vendor and subcontractor quality assurance records and control of purchased material, equipment and services considered important to safety receive emphasis during CVDF audits, surveillances, and assessments (Item 19)

Additional requirements apply to an MCO when it resides in the CVDF. These requirements are identified in HNF-SD-SNF-DB-005, *Spent Nuclear Fuel Project Multi-Canister Overpack Additional NRC Requirements*. Design requirements for natural phenomena hazards, other than seismic design requirements, are identified in WHC-SD-SNF-DB-010, *Cold Vacuum Drying System Natural Phenomena Hazards*.

The documents cited in this chapter identify the requirements to achieve nuclear safety equivalency with NRC-licensed facilities and to meet the requirements of DOE/RW-0333P. The quality assurance program plan for SNF Project facilities provides for implementation of these requirements. A graded approach will be used for items and activities important to safety.
B14.3 QUALITY ASSURANCE PROGRAM ORGANIZATION

A summary of the SNF Project quality assurance program, including summaries of safety management policies and philosophies used as a basis for the program, is provided in Section 14.3 of the SNF Project FSAR.

The SNF Project organizational structure, responsibilities, authorities, and interfaces that apply to the CVDF are addressed in Chapter 17.0 of the SNF Project FSAR.

B14.4 QUALITY IMPROVEMENT

Descriptions of SNF Project management programs and processes used to correct adverse conditions affecting quality at all SNF Project facilities are provided in Section 14.4 of the SNF Project FSAR.

B14.5 DOCUMENTS AND RECORDS

A description of the SNF Project document control and records management program associated with quality assurance is provided in Section 14.5 of the SNF Project FSAR.

B14.6 QUALITY ASSURANCE PERFORMANCE

An overview of the SNF Project process to ensure that the performed work meets requirements is provided in Section 14.6 and subsections in the SNF Project FSAR. The subsections address work processes, design activities, the procurement process, program tests and inspections, management assessments, and independent assessments.

B15 0 EMERGENCY PREPAREDNESS PROGRAM

B15 1 INTRODUCTION

A description of the generic philosophy, objectives, and organization of the Spent Nuclear Fuel (SNF) Project emergency preparedness program for response to emergencies at the SNF Project facilities is provided in Chapter 15 0 of the SNF Project Final Safety Analysis Report (FSAR). This Annex B chapter presents emergency management information specific to the Cold Vacuum Drying Facility (CVDF).

B15 2 REQUIREMENTS

The requirements that form the basis for the SNF Project emergency preparedness program are identified in Section 15 2 of the SNF Project FSAR.

B15 3 SCOPE OF EMERGENCY PREPAREDNESS

Potential CVDF emergencies could span the spectrum of identified emergencies for SNF Project facilities from worker injuries to general emergencies with potential public impact. The spectrum of emergencies that the CVDF emergency preparedness program is designed to encompass is described in Section 15 3 of the SNF Project FSAR.

B15 4 EMERGENCY PREPAREDNESS PLANNING

SNF Project emergency preparedness planning includes identification of emergency organizations, assessment actions, notification processes, emergency facilities and equipment, protective actions, access control, training, drills, exercises, and recovery actions. A summary of the emergency response organization that is activated during CVDF emergencies is provided in Section 15 4 of the SNF Project FSAR and its subsections.

B15 4 1 Emergency Response Organization

Section 15 4 1 of the SNF Project FSAR presents information related to the organizational structure and support resources to meet emergency event requirements. This organization structure and support resources are applicable to the CVDF. The Hanford Site Emergency Response Organization (ERO) has the responsibility to take actions in response to a CVDF emergency to prevent or minimize impacts to workers, the public, facilities and the environment. Initial direction and control of emergency response at the CVDF, prior to establishment of an...
Incident Command Organization as described below, is the responsibility of the CVDF ERO. Key Hanford Site ERO positions and responsibilities are discussed below.

**B15 4 1 1 Organization Structure**

The Hanford Site ERO, responding to a CVDF emergency, will consist of two components, an Incident Command Organization and a U.S. Department of Energy (DOE) Hanford Emergency Operations Center as stated in Section 15 4 1 1 of the SNF Project FSAR.

**B15 4 1 2 Incident Command Organization** The Incident Command Organization will consist of the CVDF ERO and site contractor emergency personnel (i.e., Hanford Fire Department and Hanford Patrol). The Incident Commander (IC) is the senior Hanford Fire Department official, the Hanford Patrol will provide the IC for security emergencies. The IC will direct all emergency response efforts at the CVDF and has overall responsibility for the health and safety of all personnel at the event scene.

The CVDF ERO, including the BED, will become part of a consolidated Incident Command Organization and function under the direction of the Incident Commander. In this role, the BED retains responsibility for CVDF operations and direct configuration control over CVDF systems and components, the IC controls the overall management strategy associated with the emergency event and ensures that all functional areas are staffed and working effectively to mitigate the accident.

The Incident Command Organization has the authority to commit all SNF Project resources (equipment and personnel) in response to any emergency and to request supporting resources. Other responsibilities include (1) implementing the CVDF building emergency plan, (2) assuring that the CVDF ERO is fully staffed and trained, (3) initially assessing, categorizing and classifying events, (4) notifying the Patrol Operations Center and applicable contractor and DOE management through the Occurrence Notification Center, (5) implementing protective actions, (6) establishing an initial CVDF Incident Command Post, (7) controlling the event scene, (8) initiating mitigating activities, and (9) initiating recovery actions when directed. At the CVDF, the BED is a certified operations shift manager.

A listing of the primary and alternate BEDs by title, work location, and work telephone numbers is contained within the CVDF building emergency plan. The BED is on the CVDF premises during hazardous operations and is available through an "on-call" list 24 hours a day at all other times. Operations maintains a listing of on-call BED names, with work and home telephone numbers, at the Occurrence Notification Center.

The Incident Command Organization is also composed of a Hanford Fire Department Operations Section Chief (assigned by the Incident Commander), trained support staff (including Health Physics and Industrial Hygiene staff), and (as required) Hanford Fire Department medical responders and Hanford Patrol. In addition, accountability aides are responsible for facilitating the implementation of protective actions (evacuation or take cover) and for facilitating the
accountability of personnel after the protective actions have been implemented. Staging area managers are responsible for coordinating/conducting activities at the staging area. Personnel accountability aides assist the staging area managers by ensuring that personnel and visitors are properly evacuated from designated staging areas to a safe location. The Incident Command Organization supports actions requested by the Incident Commander and the BED.

B15 4 1 3 U.S. Department of Energy Hanford Emergency Operations Center As stated in Section 15 4 1 3 of the SNF Project FSAR, the DOE Hanford Emergency Operations Center is an emergency response facility, maintained by DOE, Richland Operations Office/Office of River Protection, to convene personnel providing essential emergency response functions. The DOE Hanford Emergency Operations Center will be activated for Alert and higher emergencies at the CVDF.

B15 4 2 Assessment Actions

Provisions of Section 15 4 2 of the SNF Project FSAR cover development and implementation of the hazards survey and hazards assessment, consequence assessments, and monitoring activities. These provisions apply to the CVDF.

The CVDF hazards survey will identify the conditions contained in the comprehensive emergency management program. A CVDF emergency planning hazards assessment will be developed for the CVDF for hazards that have the potential to generate an Alert or higher emergency. The hazards assessment will be prepared from the hazards survey and safety analyses that are developed and summarized in Chapter B3 0. The hazards assessment will also be derived from other pertinent facility documentation (e.g., safety assessment documents, interim safety basis documents, and special nuclear material accountability documents). The hazards assessment will provide the technical basis for the emergency management program. The scope and extent of planning and preparedness will directly correspond to the type and scope of hazards present and the potential consequences of events.

The hazards assessment will identify and characterize the hazards relevant to potential CVDF operational emergencies. This includes determination of the following:

- A broad range of initiating events
- Accident mechanisms
- Equipment or system failures
- Event indications
- Contributing events
- Source terms
- Material release characteristics
- Topography
- Environmental transport and diffusion
Annex B — Cold Vacuum Drying Facility

- Exposure considerations
- Chemical hazards

The hazards assessment will characterize the potential consequences to workers, the public, and the environment for each postulated accident and determine the emergency planning zone (EPZ) for each facility. The assessment will also determine the emergency class, protective actions, and observable indications and criteria (emergency action levels) corresponding to the range of identified accidents.

A spectrum of potential accidents ranging from minor to beyond design basis are postulated and will be realistically analyzed for the CVDF. While not every conceivable situation will be analyzed, the hazards assessments will provide the framework for response to virtually any declared emergency.

The methodology, assumptions, models, and evaluation techniques used in the hazards assessments are documented in Sections 15.4.2.1 and 15.4.2.2 of the SNF Project FSAR. Results from the CVDF hazards assessment will be used to develop the CVDF building emergency plan. Hazards assessments will be reviewed at least annually and updated, as necessary, in accordance with Section 15.4.2 of the SNF Project FSAR, to delineate significant changes to the CVDF or hazardous inventories, and be maintained in accordance with the site contractor document control requirements.

**B15.4.3 Event Categorization and Classification**

Event categorization and classification for CVDF emergency events will be accomplished in accordance with Section 15.4.3 of the SNF Project FSAR.

**B15.4.4 Notifications**

Notifications, in the event of an emergency event at the CVDF, will be made in accordance with the provisions of Section 15.4.4 of the SNF Project FSAR in order to mitigate consequences and to protect the health and safety of workers, the public, and the environment.

**B15.4.5 Emergency Facilities and Equipment**

The building emergency plan for the CVDF will be prepared and issued in accordance with HNF-IP-0263-GEN, *Building Emergency Plan Guidance*. A description of the facilities that will be available for coordinating CVDF emergency response activities will be specified in the building emergency plan.
Emergency equipment consisting of materials and tools that may be required to measure, control, or mitigate the consequences of an emergency at the CVDF is provided in Table B15-1. Detection ranges and types of instruments for radiological and nonradiological hazardous materials will be adequate for CVDF emergency conditions, as determined in Section B15 4.2. The emergency planning organization will ensure that sufficient emergency equipment is available. Location of this emergency equipment will be stated in the CVDF building emergency plan.

**B15 4.6 Protective Actions**

Protective actions are those actions that will be taken to preclude or reduce the exposure of individuals or the environment impacted by hazards or unsafe conditions during an emergency event at the CVDF. These protective actions are presented in Section 15 4.6 of the SNF Project FSAR and are applicable to the CVDF. Protective actions for the CVDF will reflect use of the emergency response planning guidelines identified in Section 15 4.3.1 of the SNF Project FSAR. The planning guidelines published in the Emergency Response Planning Guidelines (AIHA 1988) will be used during a CVDF emergency response to determine protective actions for unique exposures to chemical releases (see Table 15-5 of the SNF Project FSAR). The protective action guides are also used during an emergency response to determine protective actions for unique exposures to radiological releases (see Table 15-2 of the SNF Project FSAR). Protective action guides adopted by the states of Washington and Oregon (EPA-400) are published in DOE/RL-94-02, Hanford Emergency Management Plan.

The Hanford Site emergency management program uses the EPZ concept to focus emergency planning activities. EPZs are designated areas where protective actions may be required. The size of a zone is determined primarily by the expected dispersion distance of a particular concentration of a substance. The two exposure pathways for both radiological and nonradiological hazardous materials are the plume exposure pathway and the ingestion exposure pathway. See Section 15 4.6 of the SNF Project FSAR for a description of the exposure pathways. Figure B1-1 indicates the location of the K Basins and CVDF (also see Figure B1-12).

The plume exposure pathway EPZ is the probable area of exposure to a passing cloud, or plume, of the substance potentially resulting in direct contact with the substance through the exterior of the body or through inhalation. The plume exposure pathway EPZ includes the area where emergency planning is conducted (1) to ensure that prompt and effective actions are taken in the event of an emergency, (2) to protect onsite personnel, and (3) to ensure public health and safety. The plume exposure pathway for the CVDF (5 m) is shown in Table 15-6 and Figure 15-5 in the SNF Project FSAR.

The ingestion exposure pathway EPZ is the probable area of exposure to contaminated foodstuffs or water potentially resulting in deposition of the material in various internal organs following ingestion (eating or drinking). The ingestion exposure pathway EPZ for radiological and nonradiological incidents at all Hanford Site facilities corresponds to the 80-km (50-mi) EPZ for Energy Northwest’s (formerly Washington Public Power Supply System) Nuclear Plant 2. The circle in Figure 15-6 in the SNF Project FSAR represents the ingestion EPZ for the Hanford Site.

The protective actions required to minimize the exposure of workers and the public are summarized in Section 15.4.6 of the SNF Project FSAR. Examples of protective actions as a function of accident category and consequences are illustrated in Table 15-7 in the SNF Project FSAR.

B15 4.7 Training and Exercises

Emergency organizations for the CVDF will be formed, trained, and tested in accordance with the provisions of Section 15.4.7 of the SNF Project FSAR. Drills and exercises will be developed in accordance with the provisions of Section 15.4.7 of the SNF Project FSAR with sufficient scope and detail to emphasize the facility-specific emergency events and response actions applicable to the CVDF.

B15 4.8 Reentry and Recovery

The provisions applicable to a CVDF emergency event termination, facility entry, transition from an emergency organization to a recovery organization, and the recovery process are provided in Section 15.4.8 of the SNF Project FSAR.
B15 5 DOCUMENT CONTROL

The CVDF building emergency plan, implementing procedures, reports of drills and exercises, and emergency event documentation will be controlled and updated in accordance with the provisions of Section 15 5 of the SNF Project FSAR.

PROVISIONS FOR DECONTAMINATION AND DECOMMISSIONING

INTRODUCTION

The provisions that apply to future decontamination and decommissioning (D&D) of Spent Nuclear Fuel (SNF) Project facilities are addressed in Chapter 16 0 of the SNF Project Final Safety Analysis Report (FSAR). Provisions specific to the Cold Vacuum Drying Facility (CVDF) are addressed in this Chapter B16 0.

The CVDF has been given a final designation of a hazard category 2 nuclear facility because of the potential for release of the radioactive inventory contained in the temporarily housed multi-cask overpacks (MCOs). The facility and a majority of the process systems will not contain significant, if any, contamination once the MCOs have been processed and delivered to the Canister Storage Building for interim storage. Facility hazards will be relatively low after MCO processing, and the CVDF processing equipment is not complex and is easy to access and decontaminate. Once the CVDF inventory has been removed, the facility process systems will be deactivated and the CVDF transitioned to the D&D program at the end of its useful life. The end state of the CVDF is not known at this time, but several options, ranging from facility reuse to complete dismantlement and removal, are available.

REQUIREMENTS

The requirements that form the basis for D&D provisions are identified in Section 16 2 of the SNF Project FSAR.

DESCRIPTION OF CONCEPTUAL PLANS

This section describes the design features and operational considerations pertinent to the CVDF that will facilitate decontamination and ultimate decommissioning and environmental restoration activities. Final decontamination activities are simplified when design and operations are combined to limit and identify the residual quantities and form of contamination, and the structures, systems, and components that have been exposed to or contaminated with material are identified. The design features that are of importance to D&D will be controlled through the design change control process to ensure that changes to the facility consider the impact on D&D. General considerations applicable to all SNF Project facilities are provided in Section 16 3 of the SNF Project FSAR.

The MCOs, the MCO transportation cask, and the CVDF are designed to operate so the facility is free from radioactive contamination and to also prevent the spread of radioactive contamination from inside the MCOs. Baseline operations for the CVDF ensure that the spread of radiological contamination from the MCOs or the transportation cask to the interior surfaces of...
the CVDF process areas is minimal during normal operations. The fuel loading operation is designed to minimize MCO and transportation cask contamination during fuel loading.

**B16 3 1 Design Features**

The CVDF has several features that are designed to control the radiological materials of the cold vacuum drying process and preclude the spread of these materials into nonprocess equipment and areas. These design features include confinement, compartmentalized systems and equipment, and selected safety features for prevention and mitigation of the postulated accidents identified in Chapter B3.0.

The ventilation systems are designed such that normally contaminated air is routed to only one system, the process bay local exhaust HVAC and process vent system, to minimize the expected amount of ventilation ducting for decontamination. During normal operation, this system receives contaminated air from the process bay hoods, process vents, MCO vents, and/or process water system tank vents. All other ventilation systems receive contaminated air only under abnormal operations and/or accident conditions. During an accident event, backflow preventers provided in the ducting prevent cross-contamination of other areas through the ventilation system.

During transportation to the CVDF, confinement for the SNF consists of (1) the MCO, and (2) the transportation cask. At the CVDF, the tractor-trailer is decoupled, leaving the trailer with the loaded cask–MCO in one of the four bays for processing. At this time, the cask lid is removed temporarily breaching secondary confinement, and a process hood is installed over the cask–MCO to provide contamination control.

Primary confinement acts as a barrier separating the material contained in the MCO and the process piping from surrounding areas. The CVDF primary confinement of liquid and airborne effluents consists of the MCO and the process piping, vessels and equipment in the vacuum purge system, and the process water conditioning (PWC) system connected to the MCO via the process hood. Secondary confinement is provided by the building structures in conjunction with the process general supply/exhaust HVAC system. Secondary confinement ventilation air is also exhausted through a dual-stage HEPA filter prior to release through the exhaust stack. For further description of the confinement philosophy, refer to Chapter B2.0.

**B16 3 1 1 Compartmentalized and Modular Systems and Equipment**

**B16 3 1 1 1 Multi-Canister Overpack** Contamination from routine operations or from accident conditions within the processing bay enclosures is precluded by providing a hood over the cask–MCO during opening and process connection activities and by designing processing...
systems to be a primary confinement boundary against the release of liquid or airborne contaminants from the MCO. The MCO's rupture disk relief and vent paths are vented through the process hood to the process bay local exhaust HVAC and process vent system HEPA filter to direct any overpressure or accident release through a filtered source instead of into the processing bay.

**B16 3 1 1 2 Process Bays** The design of the CVDF provides enclosed processing bay confinements during operation. The processing bays remain free from contamination during normal operation and would only be contaminated by an accidental release. Contamination of the processing bays is expected to be minimal during abnormal operations and during some accident conditions. The design of the process systems (the vacuum purge system, the PWC system, and the tempered water (annulus) system) precludes the spread of contamination from the cask-MCO to the bay during normal operations. The vacuum purge system and tempered water (annulus) system are contained on relatively compact skids that contain all necessary equipment and piping for system operation. To contain small leaks, the process equipment skid contains a retention basin covering the full bottom of the skid. In addition, each process bay contains a sump to collect any potentially contaminated liquid.

An epoxy coating covers the concrete floors and extends 4 ft up the walls of the bays to provide protection and ease of decontamination. The sumps will be protected with a stainless steel liner. Surveys and periodic decontamination of the bays may take place as necessary to maintain processing enclosures as clean as possible. The operating area floor is specified to have a sealer-hardener applied to its trowel-finished surface. This is sufficient to meet the intent of the ANSI/ANS-57.9-1992, *Design Criteria for an Independent Spent Fuel Storage Installation (Dry Type)*, requirement in paragraph 6 14(1) to provide concrete with an impervious surface.

**B16 3 1 1 3 Process Water Tank Room** The PWC system feeds the MCO process water to the process water tank room, which contains the receiver tanks, pumps, ion exchange modules, automatic sampling equipment, and a temporary storage tank that is used prior to transferring the process water by tanker truck to the K West Basin integrated water treatment system. All PWC system components, including connecting pipe, are located within the confinement of the process bays or the process water tank room. Unlike the process bays, the process water tank room may receive a minimal release from the receiver tanks during tank pressure relief conditions; the release is exhausted to the room through a HEPA filter. All releases will be contained within the process water tank room.

Piping is installed to drain and not normally retain fluid. To contain small leaks, the PWC skid contains a catch pan 1-in deep covering the full bottom of the skid. The process water tank room is designed as a sump to contain any liquid releases that may occur. Access to the room is only through the transfer corridor and change room to prevent the spread of contamination throughout the facility. The concrete floors and walls are designed to retain liquids and prevent leakage to below grade from any liquid spills. An epoxy coating covers the concrete floors and extends 4 ft feet up the walls of the process water tank room for protection and ease of decontamination, in case contamination occurs.
B16 3 1 2 Safety Features  Chapters B3 0, B4 0, B5 0, and B6 0 identify the selected safety features for preventing or mitigating the postulated accidents (see tables identified in Chapter B3 0 for each accident) These implemented engineered barriers and administrative programs will prevent or greatly reduce the consequences of any postulated upset event or accident, thus the amount and location of any radiological material releases inside the CVDF will be diminished for D&D cleanup activities  No design basis accident will result in offsite dose consequences (prevented) or onsite dose consequences exceeding the evaluation guidelines (mitigated)

B16 3 2 Operational Considerations

The potential for personnel, equipment, and building contamination within the CVDF is minimized by the design of the facility and equipment, and by administrative controls, radiological practices, and work guidelines defined in operating procedures and work permits  The general design features and operating practices described in Sections 16 3 1 and 16 3 2 of the SNF Project FSAR were considered in the design of the CVDF to minimize the spread of contamination, simplify D&D operations, and help minimize site and environmental contamination

Because baseline operations assume no spread of contamination from the cask-MCO or process equipment, no special facilities for the support of decontamination activities have been provided  Although the risk of contamination is minimal, operating procedures address requirements for radiological control surveys in various areas of the facility and at specified points in the operating activities  For example, surveys will be performed to verify that the cask-MCO is received from K Basins with the exterior free of contaminations  In addition, the process bay enclosure and the cask transport system are surveyed and decontaminated as necessary before opening the bay to remove a cask for transport  This will minimize the spread of contamination outside the bay enclosure during entry and exit of the transport vehicle  Surveys and periodic decontamination of the process water tank room may take place as necessary to maintain processing enclosures as clean as possible

The secondary confinement will be operated so that it is held at a negative pressure under normal operations and accident conditions  Negative pressure will ensure that air leakage flows from the noncontaminated outside environment to the potentially slightly contaminated systems and areas

Additional operational considerations to facilitate D&D include the following

- The process equipment will be leak tested prior to each use
- System flushes will take place in the drain systems after each draining step
Process bay sumps will be sampled whenever liquid is detected, and the sump content will be appropriately disposed based on the results of the sample.

During CVDF operations, site environmental contamination is minimized because of the following protection features:

- No expected liquid releases
- HEPA-filtered final exhaust
- Negative building pressure maintained by the heating, ventilation and air conditioning system

**B16 3 3 Decommissioning**

The CVDF and its process equipment may be removed at a future time in compliance with applicable regulations. See Section 16.3.3 of the SNF Project FSAR for the process used to develop the CVDF D&D plan. Conceptual plans for D&D will include an updated facility hazard analysis for the D&D activities, which will be used to prepare the plan to administer the expected D&D strategy. Conceptual plans also will include a preliminary deactivation plan that contains at least information about:

- Structures, systems, and components in their final configuration
- Review and determination of status for structures, systems, and components based on mission and life cycle phase
- Configuration management for missing or inaccurate design baseline documentation, voiding and downgrading of design documents, and turnover of design baseline documents to the environmental restoration contractor

Decommissioning plans for the CVDF facility will be developed and reviewed against the existing environmental impact statement. The environmental impact statement will be updated to include D&D activities in accordance with the *National Environmental Policy Act* process, if deemed appropriate.

The construction of the CVDF processing areas as an above-grade steel frame and prestressed concrete panel structures, and the process support and administrative areas as metal frame and siding buildings, will simplify decontamination and dismantling. The dose resulting from decommissioning has been limited in a number of ways. One is by reducing the amount of residual radioactive material within process and ventilation equipment. This is accomplished primarily by the use of surfaces made of smooth, nonporous materials with a minimum of cracks or crevices. For example, the process water receiver tanks have conical bottoms in addition to...
being made with an electro-polished interior surface, and ventilation ducts are designed with runs as short as possible. In addition, the receiver tanks and the PWC filters have flushing provisions.

A second method of reducing the decommissioning dose is by the use of skid-mounted processing equipment connected to other equipment by flanged couplings rather than welding. Also, process piping is located to provide easy access. These features limit the amount of time required to perform dismantling and the amount of time that workers will be required to work in areas where exposure will be received. In addition, components with the highest potential for containing radioactivity are segregated in the process water tank room, and the PWC ion exchange modules and filters are provided with integral shielding. Removing such components with their shielding as one unit will reduce the time workers will need to be in a radiation field, while the shielding will continue to protect them during the activity.

To reduce contamination, the floors and bottom 4 ft of the facility walls are coated with epoxy coatings.

B17 0 MANAGEMENT, ORGANIZATION, AND INSTITUTIONAL SAFETY PROVISIONS

B17 1 INTRODUCTION

A description of the organizational structure, responsibilities, and interfaces that support safe design, construction, and operational activities of the Cold Vacuum Drying Facility (CVDF) as a subproject of the Spent Nuclear Fuel (SNF) Project are addressed in Chapter 17 0 of the SNF Project Final Safety Analysis Report (FSAR).

B17 2 REQUIREMENTS

The requirements that form the basis for management, organizational, and safety provisions are identified in Section 17 2 of the SNF Project FSAR.

B17 3 ORGANIZATIONAL STRUCTURE, RESPONSIBILITIES, AND INTERFACES

The overall organizational structure, responsibilities, and interfaces for CVDF operations are identified in Section 17 3 of the SNF Project FSAR.

B17 4 SAFETY MANAGEMENT POLICIES AND PROGRAMS

The safety management policies and programs applicable to CVDF are identified in Section 17 4 of the SNF Project FSAR.

EXECUTIVE SUMMARY

DE.1 FACILITY BACKGROUND AND MISSION

The 200 Area Interim Storage Area (200 Area ISA) at the Hanford Site provides for the interim storage of non-defense reactor spent nuclear fuel (SNF) housed in aboveground dry cask storage systems. The 200 Area ISA is a relatively simple facility consisting of a boundary fence with gates, perimeter lighting, and concrete and gravel pads on which to place the dry storage casks. The fence supports safeguards and security and establishes a radiation protection buffer zone. The 200 Area ISA is nominally 200,000 sq. ft. and is located west of the Canister Storage Building (CSB). Interim storage at the 200 Area ISA is intended for a period of up to 40 years until the materials are shipped off-site to a disposal facility. This Final Safety Analysis Report (FSAR) does not address removal from storage or shipment from the 200 Area ISA.

Three different SNF types contained in three different dry cask storage systems are to be stored at the 200 Area ISA, as follows:

- **Fast Flux Test Facility Fuel** – Fifty-three interim storage casks (ISC), each holding a core component container (CCC), will be used to store the Fast Flux Test Facility (FFTF) SNF currently in the 400 Area.

- **Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA¹) Fuel** – One Rad-Vault² container will store

---

¹ TRIGA is a registered trademark of Gulf General Atomics Company, Inc.

² Rad-Vault is a trademark of Chem-Nuclear Systems, Inc.
two U.S. Department of Transportation (DOT)-6M containers and six NRF TRIGA casks currently stored in the 400 Area.

- **Commercial Light Water Reactor Fuel** – Six International Standards Organization (ISO) containers, each holding a Nuclear Assurance Corporation (NAC)-1 cask with an inner commercial light water reactor (LWR) canister, will be used for commercial LWR SNF from the 300 Area.

An aboveground dry cask storage location is necessary for the spent fuel because the current storage facilities are being shut down and deactivated. The spent fuel is being transferred to interim storage because there is no permanent repository storage currently available.

**DE.2 FACILITY OVERVIEW**

The 200 Area ISA is located within the Hanford Site 200 East Area and will provide safe outside storage of the SNF, while protecting the fuel through the use of storage systems resistant to man-made and natural phenomena hazards. The majority of the fuel to be stored within the 200 Area ISA will consist of FFTF SNF. However, the 200 Area ISA will also store other SNF from the Hanford Site, including NRF TRIGA fuel from the 400 Area and commercial LWR fuel, currently stored in the 300 Area.

The 200 Area ISA is located a few hundred feet west of the CSB. The footprint of the ISA is nominally 500 ft. by 400 ft., surrounded by a 7-ft. chain-link fence topped with barbed wire. Five gates in the fence control access of vehicles and personnel. Lighting is provided on the perimeter. Within the fenced area are two concrete pads for placement of ISCs and one concrete pad for the ISO containers. The Rad-Vault container will be placed on level gravel.

An equipment storage building (pre-engineered metal building) is proposed near the 200 Area ISA to house lifting devices, impact limiters, transfer casks, and various other types of
equipment associated with storage, movement, or transport of casks. This storage building will be located outside the 200 Area ISA fence and provides no safety-related function.

The 200 Area ISA facility components (excluding the dry cask storage systems) are classified as General Service; the dry cask storage systems are designated Safety Significant. The CCCs and the LWR canisters are designated Safety Class for criticality geometry control.

No uncontained radioactive materials will be handled at the storage area. Therefore, decontamination and decommissioning efforts should be minimal.

There is interaction of the ISA with existing CSB facilities for surveillance activities.

DE.3 FACILITY HAZARD CLASSIFICATION

A final hazards categorization of the 200 Area ISA facility was performed based on the final hazard analysis (SNF-4820) and accident analyses documentation (Chapter D3.0) for the facility. Consistent with DOE-STD-1027-92, Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports, the final categorization was based on the material-at-risk quantities identified in an individual cask inventory. The ISA material-at-risk quantities were compared against the DOE-STD-1027-92 threshold quantities. The ISA facility final hazard categorization found the ISA facility to be a Hazard Category 2 facility. This categorization level is consistent with the bases and guidance described in DOE-STD-1027-92. Hypothetical release source terms were developed for each fuel type. The 200 Area ISA inventory assumed for the analysis is based on a per cask basis and either includes seven FFTF driver assemblies, all 101 TRIGA elements, or one LWR assembly.

---

DE.4 SAFETY ANALYSIS OVERVIEW

The 200 Area ISA is a passive storage facility designed to hold up to 70 storage containers of SNF for up to 40 years. Potential hazards associated with receipt handling and storage of these containers are the release of radioactivity, loss of shielding, or loss of configuration control for criticality. Seven design basis accidents (DBAs) were identified and analyzed to evaluate the potential consequences of these hazards to on-site workers and the public. The seven DBAs analyzed are as follows:

- Cask handling/drop
- Mobile crane mechanical failure
- Cask tip over
- Fuel rod rupture
- Seismic event
- Tornado/wind
- Fire.

In all but one case, the consequences for all three fuel types were prevented by the passive design features of the storage systems. In the case of the mobile crane mechanical failure, credit was not taken for the integrity of the NRF TRIGA storage systems and an unmitigated release was assumed. The consequences for this accident and fuel type were found to be significantly below both the off-site limits and the on-site guidelines.

Preventive and mitigative aspects relied on in the accident analyses are shown in Table DES-1.
# Table DES-1. Structure, System, and Component Safety Classification Summary.

(1) This item is designated as Safety Class for structural integrity to provide criticality geometry control.
(2) This item upgraded to Safety Significant to accomplish NRC equivalency based on important-to-safety Category B classification.
(3) Critical lift requirements imposed using DOE/R1-92-36, *Hanford Site Hoisting and Rigging Manual*, to accomplish NRC equivalency for important-to-safety Category B.

CCC = core component container.  
DOT = U.S. Department of Transportation.  
FFTF = Fast Flux Test Facility.  
GS = general service.  
ISC = interim storage cask.  
ISO = International Standards Organization.  
LWR = light water reactor.  
NA = not applicable.  
NAC = Nuclear Assurance Corporation.  
NRC = U.S. Nuclear Regulatory Commission.  
NRF = Neutron Radiography Facility.  
SAR = safety analysis report.  
SC = safety class.  
SS = safety significant.  
TRIGA = Training, Research and Isotope Production, General Atomics.
DE.5 ORGANIZATIONS

Fluor Hanford is responsible to the DOE for planning, integrating, and managing SNF Project activities, including programs, projects, and operations. Organizational responsibilities related to the SNF Project are summarized in the executive summary, and described in detail in Chapter 17.0, of the SNF Project FSAR.

DE.6 SAFETY ANALYSIS CONCLUSIONS

This FSAR Annex concludes that the 200 Area ISA can be operated safely without exceeding the off-site limits or on-site guidelines.

One remaining open issue is that the NAC-1 inner LWR canister design is not yet approved. The analyses in this SAR are based on a canister design that is in the final stages of design, review, and approval. The design provides a welded closure and dimensional constraints to accommodate future packaging in standard containers. Characteristics of the canister (e.g., design pressures or structural strength) are expected to be unchanged from the canister design used as the basis for evaluation. Calculations and text in this section will be verified upon design completion and approval of a design analysis report for the LWR canister. Revision will be required only if the characteristics and features of the canister are changed significantly. All affected discussions will be reviewed for applicability based on the final LWR canister design.

DE.7 FINAL SAFETY ANALYSIS REPORT ORGANIZATION

The 200 Area ISA FSAR is based on the format and content guidance of DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, and the requirements of DOE Order 5480.23, Nuclear Safety

---

Analysis Reports. This report also includes content guidance from NRC Regulatory Guide 3.26, Standard Format and Content of Safety Analysis Reports for Fuel Reprocessing Plants, as a result of the DOE regulatory policy described in HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements. Due to the similar mission of the ISA and the CSB for SNF dry storage, HNF-SD-SNF-SP-012, Additional Guidance for Including Nuclear Safety Equivalency in the Canister Storage Building and Cold Vacuum Drying Facility Final Safety Analysis Reports, supplemental requirements for the CSB (Table 3) were used for guidance in the preparation of SNF-3446, Spent Nuclear Fuel Project - Criteria Document, Spent Nuclear Fuel Final Safety Analysis Report, Rev. 1, Appendix E, “FSAR Format and Content - Volume 5: Annex D, 200 Area Interim Storage Area FSAR.” Annex D was written in accordance with the criteria document (SNF-3446).

CHAPTER D1.0

SITE CHARACTERISTICS
This page intentionally left blank.
D1.0 SITE CHARACTERISTICS

D1.1 INTRODUCTION

The 200 Area Interim Storage Area (ISA) is in the 200 East Area of the U.S. Department of Energy (DOE) Hanford Site immediately to the west of the Canister Storage Building (CSB), as shown in Figure D1-1. The ISA will be used to provide interim storage of non-defense reactor spent nuclear fuel (SNF), as described in DOE/EA-1185, Environmental Assessment, Management, of Hanford Site Non-Defense Production Reactor Fuel, Hanford Site, Richland, Washington.

The objective of this chapter is to describe the characteristics of the site on which the ISA is located. This chapter and Chapter 1.0 of the SNF Project Final Safety Analysis Report (FSAR) contain information about regional and Hanford Site characteristics. A detailed description of the ISA structure and storage system is provided in Chapter D2.0. Chapter D1.0 supports the hazard analysis and accident analyses in Chapter D3.0.

D1.2 REQUIREMENTS

The requirements that establish the basis for ISA siting are identified in this chapter and in Section 1.2 of the SNF Project FSAR. A discussion of U.S. Nuclear Regulatory Commission (NRC) equivalency requirements is also provided in Section 1.2 of the SNF Project FSAR.

In addition to the pertinent requirements identified in Section 1.2 of the SNF Project FSAR, the following industry standards are applicable to the ISA safety basis:

- ASCE 7-93, Minimum Design Loads for Buildings and Other Structures

D1.3 SITE DESCRIPTION

A description of the Hanford Site and associated areas is provided in Section 1.3 of the SNF Project FSAR. The following sections address the geography, demography, and regional land and water use of the area encompassed by and surrounding the CSB and the adjacent ISA. Siting evaluations performed for the CSB are applicable to the adjacent ISA.
D1.3.1 Geography

D1.3.1.1 Hanford Site Vegetation. Information applicable to all SNF Project facilities is provided in Section 1.3.1.1 of the SNF Project FSAR.

D1.3.1.2 Hanford Site Facilities. Information applicable to all SNF Project facilities is provided in Section 1.3.1.2 of the SNF Project FSAR.

D1.3.1.3 Boundaries for Evaluation of Accident and Effluent Release Limits. The ISA is within the DOE-controlled zone. Consequences of accident releases from the ISA to collocated workers are calculated in Section D3.4.2 at 100 m from the point of release, in accordance with approved procedures. Routine and accidental releases to the public (off-site receptor) are calculated at the Site boundary shown in Figure D1-2. This is also the location of the controlled area boundary, as the term is defined in Title 10, Code of Federal Regulations, Part 72, “Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste,” Section 106, “Controlled Area of an Independent Spent Fuel Storage Installation or Monitored Retrievable Storage” (10 CFR 72.106).

Radiological consequences calculated in Section D3.4.2 were developed considering only the current Hanford Site boundary. Consequences for a receptor located on Highway 240 were calculated for information purposes only (Scott 1995). DOE and its contractors can control access during emergency and accident conditions. This access control meets the requirements of 10 CFR 72.106(b). Before changes to the Site boundaries are placed into effect by the proper authorities, the calculations in this FSAR Annex will be reviewed (and reanalyzed if required) in accordance with DOE Order 5480.21, Unreviewed Safety Questions.

D1.3.2 Demography

A description of the demography surrounding the Hanford Site is provided in Section 1.3.2 of the SNF Project FSAR. Figure D1-3 shows the 1996 200 East Area on-site employee population.

D1.4 ENVIRONMENTAL DESCRIPTION

D1.4.1 Meteorology

Meteorology information applicable to all SNF Project facilities in provided in Section 1.4.1 of the SNF Project FSAR.

The specific air transport factors used for accident consequence analyses, and the basis for their calculation and use, are discussed in further detail in HNF-SD-SNF-TI-059, A
Discussion on the Methodology for Calculating Radiological and Toxicological Consequences for the Spent Nuclear Fuel Project at the Hanford Site, and in Section D3.4.1.2. Data is provided for ground-level releases. To support the accident analyses of Section D3.4.2, air transport factors (X/Q and X/Q'), representing the dilution of a contaminant by atmospheric turbulence and diffusion as the contaminant travels downwind, were calculated (HNF-SD-SNF-TI-059). The symbol X/Q is the ratio of the average air concentration at the receptor to the average release rate at the release point. This ratio is used to assess potential radiological dose and noncorrosive chemical concentration at downwind locations. The symbol X/Q is the normalized peak air concentration at the center of a puff, divided by the quantity released, and is used to assess the consequences to a receptor for corrosive chemicals. The X/Q's for the analyses were calculated using joint frequency distribution data so as to be exceeded only 0.5% of the time (99.5 percentile) for each sector, or to be exceeded only 5% of the time (95 percentile) for data from all sectors combined (the greater of the two calculated values is used in the analyses).

The GXQ computer code, Version 4.0 (WHC-SD-GN-SWD-30002), was used to generate X/Q and X/Q' values. GXQ incorporates the methods described in NRC Regulatory Guide 1.145, Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants.

The wind rose data (Figures D1-4 and D1-5) indicate that winds from the west-northwest sector occur most frequently (nearly 20% of the time). That is, the emissions are transported toward the east-southeast sector. Winds out of the northwest and west also occur with a relatively high frequency (12% and 11%, respectively). The information provided in these figures was obtained from data presented in HNF-SD-SNF-TI-059.

D1.4.2 Hydrology

Hanford Site hydrology information that is applicable to all SNF Project facilities is provided in Section 1.4.2 of the SNF Project FSAR.

D1.4.2.1 Surface Water. Surface water information is provided in Section 1.4.2.1 of the SNF Project FSAR.

D1.4.2.2 Vadose Zone. A definition of the vadose zone is provided in Section 1.4.2.2 of the SNF Project FSAR.

D1.4.2.3 Aquifers. The 200 Area aquifer systems are discussed in Section 1.4.2.3 of the SNF Project FSAR.
**D1.4.3 Geology**

A description of the Hanford Site geology that applies to all SNF Project facilities is provided in Section 1.4.3 of the SNF Project FSAR.

**D1.4.3.1 Physiographic Setting of the Hanford Site.** Information on the physiographic characteristics applicable to the ISA is provided Section 1.4.3.1 of the SNF Project FSAR.

**D1.4.3.2 Stratigraphy.** Information on the stratigraphy of the Pacific Northwest and the Hanford Site that is applicable to the ISA is provided in Section 1.4.3.2 of the SNF Project FSAR.

**D1.4.3.3 History of Cataclysmic Flooding in the Pasco Basin.** Information on geologic structures that is applicable to the ISA is provided in Section 1.4.3.3 of the SNF Project FSAR.

**D1.4.3.4 Geologic Structures of the Columbia Basin and Hanford Site.** Information on geologic structures that is applicable to the ISA is provided in Section 1.4.3.4 of the SNF Project FSAR.

**D1.4.3.5 Geology of the Interim Storage Area.** The geology of the 200 East Area is summarized in Figures D1-6 through D1-8. The suprabasalt sediments consist of the Ringold formation and Hanford formation. The Ringold formation conforms to the basalt bedrock surface and tilts southeast toward the axis of the Cold Creek syncline. The Ringold formation is dominated by gravel units E and A, which are separated by the Lower Mud unit. These are the main unconfined aquifers. The Ringold formation thins from 164 ft at the south end to nearly pinching out at the north end. The beds have been truncated and are unconformably overlain by the Hanford formation. The Hanford formation is mainly sands and gravelly sands that are between 246 and 328 ft thick at the site. Additional information on the geology at the ISA site is provided in Section 1.4.3 of the SNF Project FSAR.

**D1.4.3.6 Tectonic Development of the Hanford Site.** Information on geologic structures and faults that relate to the Hanford Site seismic hazard analysis that is applicable to the ISA is provided in Section 1.4.3.6 of the SNF Project FSAR. Additional information is provided in WHC-SD-W236-TI-002, *Probabilistic Seismic Hazards Analysis, DOE Hanford Site, Washington.*

**D1.4.3.7 Contemporary Stress and Strain.** Information on earthquake activity, contemporary stress measurements, and subsidence history that is applicable to the ISA (WHC-SD-W236-TI-002) is provided in Section 1.4.3.7 of the SNF Project FSAR.
D1.4.3.8 Geologic Hazards.

D1.4.3.8.1 Seismic Hazard Assessment. The ISA is a Hazard Category 2 facility, as stated in HNF-1755, Initial Hazard Classification for the 200 East Area Interim Storage Area Project W-518. Performance Category 3 is applicable for a Hazard Category 2 facility. Per WHC-SD-SNF-DB-009, Appendix C, 200 Area Interim Storage Area Natural Phenomena Hazards, the seismic loads for the ISA Performance Category 3 structures, systems, and components (SSCs) follow the DOE design requirements specified in HNF-PRO-097, Engineering Design and Evaluation, which implements DOE Order 6430.1A, General Design Criteria, Section 1300-3, “Safety Class Criteria.” This approach is consistent with the application of seismic criteria within the SNF Project. The Performance Category 3 horizontal and vertical design response spectra values were taken from Table 6, “Design Response Spectra for Performance Category 3 in the 100 and 200 Areas” of HNF-PRO-097. The values for various damping levels umbrella the 100 Area, 200 West Area, and 200 East Area and are slightly higher than 200 East Area-specific values (0.26 g rather than 0.24 g).

D1.4.3.8.2 Volcanic Hazard Assessment. Information about volcanic hazards applicable to all SNF Project facilities is provided in Section 1.4.3.8.2 of the SNF Project FSAR.

D1.4.3.8.3 Subsurface Stability. The ISA is constructed in flood sediments, the youngest sediments being approximately 13,000 years old. There are no areas of potential surface or subsurface subsidence, uplift, or collapse except for the low geologic deformation discussed in Section 1.4.3.6 of the SNF Project FSAR. With the exception of the loose, surficial, wind-deposited silt, soils are competent and form good foundations. Several geotechnical studies have been completed in and around existing tank farms. Liquefaction of soils beneath the tank farms is not a credible hazard because the water table is greater than 215 ft below ground surface. Liquefaction cannot occur in dry sediments. Liquefaction is also not a concern because of the results of evaluations discussed below for the Hanford Waste Vitrification Plant (HWVP), which is in close proximity to the ISA.

A geotechnical investigation was performed at the site in 1989 (Dames and Moore 1989) to evaluate subsurface conditions for the design and construction of the HWVP. The HWVP Project was canceled and the site is being used for the CSB. Subsurface conditions were investigated by 17 borings ranging in depth from 20 to 100 ft at the site and in the surrounding area. Geophysical tests, including a series of downhole seismic tests, were conducted in boring VP-8, approximately 400 ft from the ISA/CSB. Borehole VP-15 (Figure D1-9) is at the ISA/CSB site.

The 17 geotechnical investigation borings were advanced without drilling fluid by driving a 6-in. diameter, steel “core barrel” with a “split jar” downhole hammer. As the borings were advanced, an 8-in. diameter steel casing was driven to prevent caving of soils above the sampling depth. Water was occasionally poured into the hole to prevent caving of the loose, dry soils and to aid in recovering samples. Slightly disturbed soil samples were taken at 5-ft intervals by driving a sampler using either a 705-lb hammer falling through a distance of 18 in. or a 825-lb
hammer falling through a distance of 28 in. During the sampling process, resistance to penetration of the sampler, in blows per foot, was recorded.

The soil profile in the upper 100 ft consists essentially of the three strata shown in Figure D1-10. Borehole VP-14 is approximately 230 ft west of the ISA/CSB. The stratigraphy in VP-15 (Figure D1-9) is the same as at VP-14. The dynamic soil properties of the site are summarized in Figure D1-11. More detailed descriptions of the geotechnical investigations and interpretations are found in Report of Geotechnical Investigations for the Proposed Hanford Waste Vitrification Plant, Hanford Washington (Dames and Moore 1989) and in Section 1.4.3.8.2 of the SNF Project FSAR.

D1.5 NATURAL PHENOMENA THREATS

Section 2.3 of HNF-2524, 200 East Interim Storage Area Preliminary Safety Evaluation, states that recommendations for the classification of safety-class and safety-significant SSCs are derived from DOE Order 6430.1A and HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements. Design requirements for natural phenomena hazards are established in Engineering Change Notice 643545 to WHC-SD-SNF-DB-009, Canister Storage Building Natural Phenomena Hazards, and Section 2.3.2 of HNF-2524. A listing of safety-class and safety-significant SSCs required for the ISA are presented in Table D4-2. Table D1-1 presents a summary of natural phenomena design loads and criteria for ISA safety-class SSCs.

D1.6 EXTERNAL HUMAN-GENERATED THREATS

This section identifies and investigates specific potential human-generated threats to ISA operation. Threats to the ISA from human activities that are not known at this time will be evaluated when identified by the unreviewed safety question process.

D1.6.1 Aircraft Activity

The methodology used in aircraft activity analysis is provided in Section 1.6.1 of the SNF Project FSAR. There are nine active airports within a 24-mi radius of the ISA (HNF-1786). Eight of these are small airports that serve only general aviation aircraft. The Richland Airport, 21 mi southeast of the ISA, supports primarily general aviation operations, but two commercial freight carriers per day land and take off from the airport's runways. The nearest airport with significant commercial and military air activity is the Tri-Cities Airport, 29 mi southeast of the ISA.

ANS = American Nuclear Society.
ANSI = American National Standards Institute.
ASCE = American Society of Civil Engineers.
DOE = U.S. Department of Energy.
NRC = U.S. Nuclear Regulatory Commission.
The major contributor to the frequency of aircraft impact into the ISA is general aviation aircraft during in-flight operations. The overall frequency of aircraft impact from all sources is $3.55 \times 10^{-4}$/yr (HNF-1786). DOE-STD-3014-96, *Accident Analysis for Aircraft Crash into Hazardous Facilities*, specifies that if the total impact frequency, calculated according to the method it gives, is less than $10^{-4}$/yr conservatively calculated, or $10^{-7}$/yr realistically calculated, the safety risk is below the level of concern and no design basis accident analysis is required.

Information on rotary wing aircraft is provided in Section 1.6.1 of the SNF Project FSAR. Medical evacuation helicopters’ closest approach to the ISA will be a landing pad to the west of the 2704 Building, which is about 0.9 mi from the ISA.

### D1.6.2 Other Transportation Accidents

A discussion regarding guidance for evaluating transportation accidents is provided in Section 1.6.2 of the SNF Project FSAR.

Highway 240 is 5 mi from the ISA. The nearest railroad not controlled by DOE is at the 1100 Area, located approximately 20 mi south of the ISA. DOE currently owns and controls the railroad north of this point, as discussed in Section 1.3.1 of the SNF Project FSAR. At these distances, explosive shipment on roads and railroads not controlled by DOE do not represent a threat to the ISA.

The main roadway and railroad controlled by DOE that pass nearest to the ISA are Route 4, which passes 1,155 ft to the west, and the mainline of the Hanford Railroad, which passes 9,000 ft to the north. The mainline of the Hanford Railroad is outside the above-listed safe distance, but Route 4 is not.

Regulatory Guide 1.91, * Evaluations of Explosions Postulated to Occur on Transportation Routes Near Nuclear Power Plants*, allows for a risk assessment when the safe distance criterion is not met. If the exposure rate is less than $10^{-7}$ events/yr by best estimate analysis or less than $10^{4}$ events/yr by conservative analysis, then the risk of damage being caused by explosion is sufficiently low. The exposure rate, $r$, is defined as follows:

$$ r = n \times f \times s $$

where

- $n =$ explosion rate for the substance and transportation mode in question, per kilometer
- $f =$ frequency of shipment for the substance in question in shipments per year
- $s =$ exposure distance in km. This is the length of the roadway that would be within the safe distance of any portion of the facility. It is a function of the building dimension.
parallel to the roadway, the setback of the building from the roadway, and the calculated safe distance, R.

A recent study (H&R 522-1) concludes that a Hanford Site truck accident rate of $5.5 \times 10^8$ accident/mi should be used for risk analysis. This study was performed for shipment of radioactive materials and took credit for risk reduction factors that would be associated with such shipments. These included driver participation in special safety programs, the road conditions north of the Hanford Site Wye Barricade, and making shipments during off-peak traffic hours. A risk reduction factor of 40 was obtained for Hanford Site two-lane roads such as Route 4 (H&R 522-1). This risk reduction factor also would be appropriate for shipment of large quantities of explosive materials. For this analysis, it is conservatively assumed that the conditional probability that an explosion will result as a consequence of an accident is 0.1. Therefore, the explosion rate, $n$, is $5.5 \times 10^8$ explosions/mi.

There are currently no routine shipments of explosives on Route 4 of a quantity that would place the ISA at risk. However, such shipments could occur during the facility’s lifetime. For this analysis, the number of such shipments per year, $f$, was conservatively assumed to be six (H&R 522-1). The exposure distance, $s$, for the ISA was calculated to be 0.51 mi based on a building length of 257 ft, a setback from Route 4 of 1,155 ft, and a safe distance of 1,683 ft.

With these data, the exposure rate, $r$, was conservatively calculated to be $4.36 \times 10^8$ events/yr. As this is less than $10^6$ events/yr, no additional analysis is required.

Based on the above analyses, it is concluded that explosive shipments on roadways and railways, controlled and not controlled by DOE, do not represent a risk to the ISA.

### D1.7 NEARBY FACILITIES

Accidents in certain facilities in the 200 East Area (Figure D1-3) have the potential to impact the ISA facility and its operations, as discussed in Section D1.7.1. Conversely, certain nearby facilities can potentially be affected by accidents in the ISA, as discussed in Section D1.7.2.

Threats to the ISA from nearby facilities that are not known at this time will be subsequently evaluated by the unreviewed safety question process. This also applies to those activities that have been identified but that may change significantly in terms of a potential increased risk to the facility.
**D1.7.1 Potential Effects from Nearby Facilities**

Potential hazards to the ISA from on-site or off-site hazardous operations or facilities are examined under three general classifications:

- Non-reactor nuclear and non-nuclear industrial facilities within 5 mi of the ISA, including all activities conducted in and near the 200 East Area
- Nuclear reactors within a 50-mi radius of the ISA
- Military activities.

**D1.7.1.1 Hazards to the Interim Storage Area from Non- Reactor Nuclear Facilities.**

Facilities currently operating, recently operating, or with potential to operate at the 200 East and 200 West Areas were screened along with the area between the 200 East and 200 West Areas. For the ISA FSAR Annex, selected facilities were those believed to pose the most risk to safe operations at the ISA. Safety analysis reports and accident analyses prepared for these facilities were reviewed to determine possible hazards (e.g., radiological doses to personnel resulting from direct radiation, release of airborne radioactivity, or exposure to toxic chemicals).

Considered, but not included in this FSAR Annex, were the 200 East Area Burial Grounds, the Liquid Effluent Retention Facility, and the 200 Areas Effluent Treatment Facility in the 200 East Area. In the 200 West Area, the T Plant, U-Plant, Reduction-Oxidation (REDOX) Plant, and the 222-S Laboratory were considered, but not included. These facilities have insufficient radiological or toxicological inventories in a dispersible form to represent a risk to the ISA operation. The U-Plant and REDOX facilities have been shutdown for many years and are awaiting decontamination and decommissioning.

The specific facilities discussed here include the CSB, Plutonium-Uranium Extraction (PUREX) Facility, the Grout Treatment Facility, B Plant, the Waste Encapsulation and Storage Facility (WESF), the Tank Waste Remediation System (TWRS) facilities, 242-A Evaporator/Crystallizer, Plutonium Finishing Plant (PFP), and the Low-Level Waste Disposal Site. The worst-case scenarios for each of these facilities may challenge ISA habitability. Requirements for safely performing response actions are addressed in the CSB emergency response procedures. It should be noted that the following discussions address the worst-case scenarios and that safety-class and safety-significant SSCs and administrative controls have been provided at each facility to prevent or mitigate these potential accidents. During much of the ISA’s 40-year life, the facility will not be particularly sensitive to these hazards, as it will be simply a storage facility and will require little human presence.

**Canister Storage Building.** The CSB is located 0.25 mi. west of the ISA facility. Hazards from the CSB are described in detail in the SNF Project FSAR Chapter 3.0 and Annex A, Section A3.3. The analysis identifies hazard sources, hazardous conditions, potential accident scenarios and their initiators, and preliminary assessments of event frequencies and
consequences. Hazards are identified by form and location and represent a complete spectrum of events that could occur throughout the facility and have an impact on the ISA. The CSB has been assigned a final designation of hazard category 2 facility based on material at risk.

Six potential design basis accidents were analyzed for the CSB, as follows:

- Rearrangement of Multi-Canister Overpack (MCO) internals
- Gaseous release from the MCO
- MCO internal hydrogen explosion
- MCO external hydrogen explosion
- Thermal runaway reactions inside the MCO
- Violations of design temperature criteria.

The maximum 24-hour unmitigated 100 m dose (from the CSB) resulting from these design basis accidents was determined to be 300 rem and has the potential to require the evacuation of any personnel at the ISA facility.

**Plutonium-Uranium Extraction Facility.** The PUREX facility is located in the 200 East Area, 1.5 mi east-southeast of the ISA. It is the most recently constructed of the irradiated fuel separation facilities and was used for processing N Reactor fuel. The principal product was a solution of plutonium nitrate that was transferred to the PFP for further processing. Another product was uranyl nitrate solution, which was processed at the Uranium Trioxide Plant. The facility has been cleaned out to the extent practical and has been transitioned to surveillance and maintenance mode awaiting a final decision on disposal of the facility. The processing canyon area and the tunnels still contain loose contamination from previous processing activities. If the status of PUREX changes (i.e., active decontamination and decommissioning), potential impacts to the ISA will be re-evaluated.

The bounding accident for the PUREX facility in the surveillance and maintenance mode is a seismic event that releases a portion of the residual contamination in the ventilation gallery above the canyon. This accident would not impair the ability of personnel at the ISA facility to perform required safety actions because the quantity of material available for release is small.

**Grout Treatment Facility.** The Grout Treatment Facility is located on the eastern perimeter of the 200 East Area, approximately 2.7 mi east of the ISA. The Grout Treatment Facility combined tank wastes with grout-forming solids to form a grout slurry. The waste feed stream constituent of this slurry consisted of low-level fractions of radioactive wastes. The slurry was pumped into near-surface, concrete-lined vaults for permanent disposal. Only one vault has been filled with grout (completed in 1987) even though additional vaults have subsequently been
designed and constructed. This facility is currently not operational but has the potential to operate again in the future.

If the Grout Treatment Facility resumes operation, the maximum credible accident release postulated involves a double-ended jumper leak on the grout feed line, with the pit cover blocks left off. This postulated release would spray low-level waste as an aerosol for a maximum period of 24 hours before detection by a visual inspection. If the status of the Grout Treatment Facility changes (i.e., begins operations), potential impacts to the ISA will be re-evaluated. If the ISA habitability is challenged by an event at the Grout Treatment Facility, the appropriate action (i.e., notification, take-cover, emergency shutdown, evacuation) will be initiated using CSB emergency response procedures.

B Plant Facility. The B Plant is located approximately 1,500 ft east of the ISA. Until 1952, B Plant was operated as a fuel separation facility. In 1968, it was converted to a waste fractionation plant to remove $^{137}$Cs and $^{90}$Sr from radioactive waste streams. This had the effect of reducing heat loads in the double-shell tanks. The B Plant currently is deactivated and has been transitioned to surveillance and maintenance mode.

The worst-case credible accident at B Plant is a postulated flooding of the 291-B high-efficiency particulate air filters and a subsequent hydrogen explosion. The dose to the collocated worker at 100 m from B Plant was calculated to be 952 rem, and the maximum off-site dose to be 0.368 rem at the Columbia River, 16.8 mi east of B Plant (HNF-SD-WM-BIO-003). Systems and administrative controls are in place at B Plant to mitigate the releases. The worst-case credible accident at the B Plant involves the filters, until they are decontaminated and decommissioned. This scenario has the potential to require evacuation of any personnel at the ISA facility. CSB emergency response procedures will describe the action to be taken by personnel at the ISA facility in the event take-cover or evacuation actions are required by events at nearby facilities.

Waste Encapsulation and Storage Facility. The WESF is distinct from B Plant, even though it is located on the west end of B Plant and shares a common wall with the plant. Historically, WESF was involved in converting the cesium and strontium removed from waste streams at B Plant into cesium chloride and strontium fluoride salts. These materials were then encapsulated in double-walled metal containers and stored in a water-filled cooling basin. Strontium fluoride and cesium chloride capsules are still being stored in this fashion at WESF, but no new capsules are being produced.

The worst-case credible accident postulated at WESF involves a loss of cooling water in the storage pool, with a subsequent rupture of capsules and aerosolization of the capsule contents (HNF-SD-WM-BIO-002). The maximum dose to the public receptor at the near bank of the Columbia River, about 18 miles from WESF, is calculated to be 9 rem. The 24-hour unmitigated dose at 100 m is 1,700 rem from inhalation and 32 rem from radiation shine. Systems and administrative controls are in place at WESF to mitigate the releases. However, this scenario has the potential to require evacuation of ISA operating personnel. CSB emergency response
Annex D - 200 Area Interim Storage Area

procedures will describe the action to be taken by personnel at the ISA facility in the event take-cover or evacuation actions are required by events at nearby facilities.

**Tank Waste Remediation System.** The TWRS facilities include 149 single-shell tanks and 28 double-shell tanks for the storage of liquid radioactive mixed waste solutions from the Hanford Site's chemical processing plants and associated support facilities, which include holding tanks, transfer lines, and valve pits. The TWRS facilities are located in both the 200 East and 200 West Areas.

The TWRS facilities nearest to the ISA are the B, BX, and BY Tank Farms, located approximately 0.8 mi northeast of the ISA. Each of the farms has 12 single-shell tanks. The B and BX single-shell tanks are rated at 500,000 gal each, and those in the BY Tank Farm are rated at 750,000 gal each. In addition, there are four 55,000-gal tanks in the B Tank Farm, and a double-contained receiver tank serves the BX and BY Tank Farms. The tanks in these tank farms were constructed between 1943 and 1949.

The worst-case accident postulated for the TWRS facilities is the inadvertent pumping of liquid waste through an open valve into a valve pit and consequent overflow of the pit, which results in a dose of 330 rem at 100 m. The postulated cause of the accident is mis-routing of waste during transfer operations (HNF-SD-WM-BIO-001). Waste transfers into Hanford Site single-shell tanks are no longer allowed. Most of the tanks in these three farms have been interim stabilized, meaning that as much of the liquid has been removed from the waste as practicable, leaving solids with a minimum liquid content. Two tanks, 241-BY-105 and 241-BY-106, have not yet been interim stabilized, so pumping activities involving these tanks and double-contained receiver tank 244-BX are expected in the future (HNF-EP-0182-116). Administrative controls are in place at the tank farms for early detection and mitigation of a release caused by mis-transfer during waste transfer operations. Also considered was a flammable gas deflagration in a tank that could result in a dose of 650 rem at 100 m. However, because of the site distance (0.8 mi) and the flammability controls, this scenario would not significantly impact the ISA. Even though the cross-site transfer line passes near the ISA, a leak from the line is not considered a credible event because of its safety-class, encased-pipe design (HNF-SD-WM-BIO-001, Addendum 2).

If there was a release from a TWRS accident, the immediate action for personnel at the ISA facility would be to respond to the take-cover sirens. Depending on the specific conditions, follow-up actions could include evacuation per CSB emergency response procedures.

Eventual retrieval of the tank wastes for final disposal is planned for the future. Activities involving waste removal and decontamination and decommissioning of the tanks will be evaluated at that time for their effect on the ISA safety analysis.

**242-A Evaporator/Crystallizer.** The 242-A Evaporator/Crystallizer is located 1.5 mi east of the ISA. The 242-A Evaporator/Crystallizer uses evaporative concentration to reduce the volume of liquid wastes. The concentrated slurry, reduced in volume, is transferred and stored in
underground double-shell waste storage tanks. The process condensate is routed to the Liquid Effluent Retention Facility for storage and treatment at the Effluent Treatment Facility.

The worst-case accident scenario reported in the 242-A Evaporator/Crystallizer Safety Analysis Report (HNF-SD-WM-SAR-023) involved a release from a spray leak in the pump room and a failure of the exhaust system's high-efficiency particulate air filters. Although this event is considered extremely unlikely, the event was analyzed for safety-class determinations at the 242-A Evaporator/Crystallizer. The release from a spray leak is comprised of a liquid component and an aerosol component. The analysis assumed that the liquid component would remain in the pump room; however, the aerosol component would be released to the environment via the K1 exhaust stack. The maximum dose consequence to the on-site individual at 100 m from the evaporator would be 14 rem effective dose equivalent. This scenario might require action to prevent exposure of ISA operators to the release (i.e., take cover), but it is not likely to require shutdown of ISA operations. CSB emergency response procedures will describe the action to be taken by personnel at the ISA facility in the event take-cover or evacuation actions are required by events at nearby facilities.

Plutonium Finishing Plant. Located near the western boundary of the Hanford Site in the 200 West Area, the PFP is 5.0 mi west of the ISA. The PFP converts plutonium nitrate solution to plutonium oxide and performs plutonium handling and storage operations. Contaminated liquid waste streams from the PFP are routed to the tank farms. This facility is in transition from its previous special nuclear material processing mode to preparation for decontamination and decommissioning.

During its previous mission of processing special nuclear materials, plutonium-bearing materials were produced and still exist in the facility. These include pure and mixed oxides, fluorides, oxalates, silicates, and organic-based sludge and residues. The current PFP missions are defined as (1) receiving, sorting, storing, and shipping special nuclear material, (2) stabilizing the reactive materials that remain in the plant, (3) providing laboratory support for other Hanford Site facilities, (4) handling radioactive and mixed waste, and (5) shutdown facility surveillance (WHC-SD-CP-SAR-021). As part of the material stabilization activities, preparations are being made for startup of a calcining operation. Revisions to the safety analysis report to include this operation are in progress.

The bounding accident for the PFP is a seismic event with a horizontal ground acceleration of 0.2 g. The consequences for this event are calculated to be 15.2 rem effective dose equivalent at the nearest occupied facility in the worst-case direction, 1,800 ft west-northwest of PFP, and 0.31 rem at the Site boundary, 7.8 mi west. Because of the distance separating the ISA from the PFP, the release would not adversely affect ISA operations and would not require evacuation of personnel at the ISA facility.

Low-Level Waste Disposal Site. The commercial low-level waste disposal site operated by U.S. Ecology, Inc., is the only non-DOE industrial facility within 5 mi of the ISA (Figure D1-1). The disposal site is on land leased from Washington State located 1 mi southwest
of the ISA. The low-level waste is buried in U.S. Department of Transportation-approved shipping containers. Monitoring of groundwater and vegetation is performed as required by the facility’s NRC operating license and environmental impact statement. This facility is not likely to have a significant accidental airborne radioactive release that could adversely affect the ISA.

D1.7.1.2 Hazards to the Interim Storage Area from Non-Nuclear Hanford Site Facilities. A number of non-nuclear industrial facilities operating in the 200 Areas pose the potential for accidental fires, explosions, or releases of toxic fumes. These include the Essential Materials Warehouse (Building 275-EA), oil and paint storage buildings, fabrication shops, gas cylinder storage buildings, the spare parts and electrical warehouse, B Plant storage buildings, maintenance facilities, gasoline service stations, and the powerhouse complexes in each area (284-E and 284-W). Considering its location, Building 275-EA may have the potential to pose a risk to ISA operations and personnel and is detailed below. The 2,000-lb chlorine bottles previously located at Building 283-E have been removed and are no longer a hazard to the ISA.

Building 275-EA. Building 275-EA, the Essential Materials Warehouse, was constructed in 1955 and is located near the PUREX facility about 1.5 mi east-southeast of the ISA. It is classified as an unprotected wood frame structure and is susceptible to collapse as a result of an external event (e.g., earthquake, wind, snow, or ash loading) or an internal event (e.g., forklift collision with a bearing wall, or fire). Building 275-EA currently stores more than 100 different types of potentially hazardous solids and liquids including acids, bases, solvents, fluorides, pesticides, and herbicides. Radioactive materials are not stored in this building.

The worst-case chemical release postulated in the safety analysis occurs following a building collapse whereupon 2,450 kg of 1,1,1-trichloroethane evaporates under adverse atmospheric conditions. The maximum concentration at the PUREX facility gatehouse and environs is calculated to be 187 ppm, which is below the time-weighted average threshold limit value of 350 ppm (i.e., the concentration for this chemical that an industrial worker may be repeatedly exposed to without adverse effects) as given in Threshold Limit Values and Biological Exposure Indices for 1989-1990 (ACGIH 1989). Concentration levels at the ISA would be significantly less than this because of the 1.5 mi separation.

D1.7.1.3 Hazards to the Interim Storage Area from Nuclear Reactors. Three recently operating reactors, the N Reactor, Fast Flux Test Facility (FFTF), and the Critical Mass Laboratories, no longer pose a threat to the ISA. The N Reactor is undergoing decontamination and decommissioning, the FFTF is in standby mode and may operate again in the future, and the Critical Mass Laboratories in the 200 East Area north of the PUREX facility are currently being used as tank farm office areas.

The N Reactor was a 4,000 MW, dual-purpose, pressure tube, light-water cooled, graphite-moderated reactor (UNI-M-90). It is located in the 100 N Area and is about 5.5 mi from the nearest Hanford Site boundary and about 9 mi from the ISA. The N Reactor began operating in 1964 and produced plutonium for the defense program and steam for electrical power generation. The reactor was shut down in 1987 for safety improvements and then subsequently
defueled and placed in cold standby in 1988. It is currently being decontaminated and decommissioned. Current plans are to remove the reactor building structures for the production reactors down to the reactor block and then cocoon the reactor block for 75-year safe storage.

The FFTF is a 400 MW, sodium-cooled, mixed-oxide-fueled reactor that is currently in standby status with the fuel removed from the core. Sodium is kept circulating in the loops at 400 °F until a decision is made to either restart the reactor for future missions or decommission it. The FFTF is located in the 400 Area and is approximately 4.5 mi from the nearest Hanford Site boundary, which is to the east of the facility (Figure D1-2) and about 13.5 mi. from the ISA. Spent FFTF fuel, removed from storage in liquid sodium and packaged in double-walled casks with an inert cover gas, is stored in the ISA at the 400 Area.

The bounding accidents for the FFTF in its current status involve (1) a liquid sodium spill and (2) damage to a cask and its contents in the ISA (HEDL-TI-7500-FSAR). The sodium spill scenario postulates a spill of 180,000 lb of activated liquid sodium. The 2-hour dose at 1.5 mi from the FFTF is 0.015 mrem. The dose at 4.5 mi from the facility for a 30-day exposure is 0.26 mrem. The maximum credible cask release at the 400 Area ISA postulated cracking in 100% of the fuel pins of one cask, with crushing and exposure of 1% of the fuel material. The dose at 100 m from the facility was 4.5 rem, the maximum dose at the Site boundary was 4.0 mrem. Because of the distance from the 200 Area ISA, these accidents do not pose a hazard to ISA operations.

The only operating nuclear reactor on the Hanford Site is Washington Nuclear Plant (WNP)-2. The location of this reactor is shown in Figure D1-2. WNP-2 is an operating commercial nuclear power plant using a boiling-water reactor steam supply system. The design power level was increased to 3,486 MW in 1995 (Docket No. 50-397). The reactor was designed by the General Electric Company and is designated as a BWR/5 with a Mark II containment.

By the requirements of 10 CFR 100, “Reactor Site Criteria,” the following are the maximum allowable doses for WNP-2:

<table>
<thead>
<tr>
<th>Location</th>
<th>Duration</th>
<th>Whole body dose</th>
<th>Thyroid</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exclusion area boundary</td>
<td>2 hours</td>
<td>250 mSv (25 rem)</td>
<td>3,000 mSv (300 rem)</td>
</tr>
<tr>
<td>Low population zone</td>
<td>30 days</td>
<td>250 mSv (25 rem)</td>
<td>3,000 mSv (300 rem)</td>
</tr>
</tbody>
</table>

The exclusion area boundary for WNP-2 is 1.2 mi and the low population zone distance is 3 mi. The ISA is located approximately 11 mi from WNP-2. Using the atmospheric diffusion guidance provided in NRC Regulatory Guide 1.3, Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss of Coolant Accident for Boiling Water Reactors, to estimate the dose reduction as a function of distance, it was determined that the 2-hour and
30-day doses at the ISA would be reduced by a factor of 20. Review of the site-specific meteorology provided in the WNP-2 FSAR (Docket No. 50-397) shows there would be no significant reduction for the change in wind direction. The factor of 20 reduction for distance would result in a whole body dose of 12.5 mSv (1.25 rem) and a thyroid dose of 150 mSv (15 rem). The expected dose that would be received at the ISA if a loss of coolant accident occurs would be significantly less than this. NRC Regulatory Guide 1.3 requires an assumption that 25% of the radioactive iodine and all of the noble gases are released to the containment. In fact, the emergency core cooling system would prevent most of these releases, as little fuel damage would occur as a result of the loss of coolant accident.

Energy Northwest (formerly known as Washington Public Power Supply System) plans to add an independent spent fuel storage installation on their leased property. The independent spent fuel storage installation will be licensed following the requirements in 10 CFR 72. According to 10 CFR 72.106, an individual located at the installation’s controlled area boundary shall not receive a dose greater than 5 rem. At the ISA, this would result in a dose not exceeding 0.25 rem. CSB emergency response procedures will describe the action to be taken by personnel at the ISA facility in the event take-cover or evacuation actions are required by events at nearby facilities.

**D1.7.1.4 Hazards to the Interim Storage Area from Industrial Facilities Off the Hanford Site.** There are no oil or gas pipelines in the vicinity of the ISA. The nearest major natural gas pipeline to the ISA site is about 29 mi. A 20-in. gas transmission line of the Northwest Pipeline Corporation is located east and essentially parallel to U.S. Highway 395 between Pasco and Ritzville, Washington. A second pipeline system consisting of parallel 36-in. and 42-in. lines, owned by Pacific Gas Transmission Company, passes through Wallula, approximately 33 mi from the site (Hosler 1996). These distances eliminate any potential hazard to plant operations from a natural gas fire or explosion.

The nearest petroleum product storage tanks are located 38 mi from the site. These tanks include 23-million-gallon capacity tanks at the Chevron Pipeline Company and 21-million-gallon capacity tanks at the Tidewater Barge Lines. There are no plans to use a third petroleum storage facility at the Port of Pasco (Hosler 1996).

Located within the Richland city limits is the Siemens Power Corporation’s Richland Engineering and Manufacturing Facility. All operational steps for the manufacture of nuclear fuel for light water reactors are conducted within the facility, including the conversion of UF₆ to UO₂. The most limiting postulated accident at this facility is a fire in the UF₆ cylinder storage area (Siemens 1994). Fusible plugs in twelve cylinders are assumed to melt causing the release of UF₆, which reacts with moisture in the air to form UO₂F₂ (solids in the form of uranyl fluoride hydrates) and 4HF (as hydrogen fluoride gas). UF₆ is a radiological hazard by inhalation. However, UF₆ is also a concern because of its chemical toxicity and the associated HF that can cause skin and eye burns and lung impairment. This accident results in a dose that exceeds 10 mSv (1 rem) out to 1.2 mi. The accident also exceeds the Emergency Response Planning Guide-2 (ERPG-2) toxicology limits out to 8.8 mi (ACGIH 1989). The ERPG-2 is the maximum...
The airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action. The ISA is located 19 mi from the Siemens facility. Therefore, operators would not be placed at risk by an accident at the Siemens facility.

No other non-nuclear industrial facilities or operations have been identified that can impact ISA operations.

D1.7.1.5 Hazards to the Interim Storage Area from Military Facilities. The Yakima Training Center is a sub-installation under the command of Fort Lewis (Tacoma, Washington). Further information is given in the *Final Environmental Impact Statement — Ft. Lewis Military Installation* (DOA 1979). The southeastern boundary of the Yakima Training Center is located about 23 km (14 mi) from the ISA (see Figure D1-12). The Yakima Training Center is used for military maneuvers and weapons training and is the only significant military activity in the vicinity of the Hanford Site.

The only weapon currently in use at the Yakima Training Center known to present a hazard to the Hanford Site is the Multiple Launch Rocket System (MLRS). With a range of approximately 16 mi, the MLRS could potentially impact the ISA site. However, the MLRS is only fired from the perimeter of the Yakima Training Center into a centrally located impact zone. The safety fan for the MLRS is shown in Figure D1-12. The MLRS is fired away from the Hanford Site and is only fired with dummy warheads. Given this information, additional safety features, and the administrative controls in place at the Yakima Training Center, a weapons accident having an impact on the Hanford Site is very improbable.

A more probable hazard to Hanford Site facilities is a scenario in which a fire started within the Yakima Training Center boundary spreads to the Hanford Site. Exploding artillery shells, sparks from tracked vehicles or other machines, and careless smoking by troops might start brush fires that, under adverse meteorological conditions, could spread rapidly beyond the Yakima Training Center boundaries. The hazards associated with range fires are discussed in Chapter 3.0 of the SNF Project FSAR.

D1.7.2 Potential Effects to Nearby Facilities

ISA accidents with the potential to affect the maximum on-site individual (which may include persons at some of the facilities discussed above) are discussed in Section D3.4.2. Section 15.4.2.2 of the SNF Project FSAR requires that a hazards assessment for each SNF Project facility be prepared based on the facility-specific hazards and safety analyses that are contained in each SNF Project Annex. The scope of the hazards assessment is provided in Section 15.4.2.2 of the SNF Project FSAR. The hazards assessment characterizes the potential consequences on workers, the public, and the environment for each postulated accident and determines the emergency planning zone for each facility as well as the emergency class.
protective actions, and the observable indications and criteria (emergency action levels) corresponding to the range of identified accidents. The hazards assessment provides the framework for response to virtually any declared emergency.

As stated in Section 15.4.3 of the SNF Project FSAR, prompt and accurate emergency notifications would be made to mitigate consequences and to protect the health and safety of workers, the public, and the environment in accordance with DOE/RL-94-02, Hanford Emergency Management Plan. The Emergency Operations Center (EOC) is responsible for notification of affected areas and other contractors on-site. The DOE Richland Operations Office EOC is responsible for follow-up notifications when emergencies are reclassified or terminated in accordance with Section 15.4.3.4 of the SNF Project FSAR.

D1.8 VALIDITY OF EXISTING ENVIRONMENTAL ANALYSES

No significant discrepancies have been identified between the site characteristic assumptions made in this chapter and those made in the site-wide SNF Project Environmental Assessment (DOE/EIA-1185).

Figure D1-12. The Location of Yakima Training Center with Respect to the Hanford Site.
CHAPTER D2.0

FACILITY DESCRIPTION
This page intentionally left blank.
The 200 East Area Interim Storage Area (200 Area ISA) at the Hanford Site provides for the interim storage of non-defense reactor spent nuclear fuel (SNF) housed in dry cask storage systems. The 200 Area ISA is a relatively simple facility consisting of a boundary fence with gates, lighting along the perimeter, and pads on which to place dry storage casks. The pads are concrete and level gravel placed by the project based on HNF-2524, 200 East Area Interim Storage Area Preliminary Safety Evaluation, approved Site Evaluation Form (#2E-96-10), and an "Approval to Construct" authorization (Hanson 1998). The fence supports safeguards and security and provides a radiation protection buffer zone.

An equipment storage building (pre-engineered metal building) is proposed near the 200 Area ISA to house lifting devices, impact limiters, transfer casks, and various other types of equipment associated with storage, movement, or transport of the casks. This storage building will be located outside the 200 Area ISA and provides no safety-related function.

The three different dry cask storage systems used at the 200 Area ISA are as follows:

- Interim Storage Cask (ISC) used for the Fast Flux Test Facility (FFTF) SNF
- Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA\(^1\)) casks and U.S. Department of Transportation (DOT)-6M containers within a Chem-Nuclear Services, Incorporated, Rad-Vault\(^2\) storage vault used for NRF TRIGA SNF
- Nuclear Assurance Corporation (NAC)-I casks within International Standards Organization (ISO) containers used for commercial light water reactor (LWR) SNF from the 300 Area.

The 200 Area ISA is located approximately 0.25 mi west of the Canister Storage Building (CSB). The footprint of the ISA is nominally 500 ft. by 400 ft. surrounded by a chain-link fence, with gates in the fence that control access of vehicles and personnel. Light poles provide illumination for the 200 Area ISA. Within the fenced area are concrete pads for placement of the ISC and the NAC-I casks within the ISO containers. The Rad-Vault holding NRF TRIGA casks and DOT-6M containers is to be placed on a level gravel pad placed by the project.

---

\(^1\) TRIGA is a registered trademark of Gulf General Atomics Company, Inc.

\(^2\) Rad-Vault is a trademark of Chem-Nuclear Systems, Inc.
Interim storage at the ISA is intended until shipment of the materials to a disposal facility. Loaded containers are to be stored at the ISA for a period of up to 40 years.

D2.1 INTRODUCTION

This chapter provides information that satisfies the safety analysis report requirements of U.S. Department of Energy (DOE) Order 5480.23, Nuclear Safety Analysis Reports, paragraphs 8.b.(3)(d), as amplified in Attachment 1, paragraphs 4.f. (3) (d) 4 a, and 4.f. (8) (b) and (c)2 of the Order, and DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports. Facility and component descriptions are provided in support of assumptions used in the hazard analysis and accident analysis discussed in Chapter D3.0. This chapter provides summary level facility and storage system descriptions. Additional information at the level of functional requirements and performance evaluation of the safety structures, systems, and components (SSCs) is provided in Chapter D4.0.

Consistent with DOE-STD-3009-94 guidance, descriptions in this chapter provide a model of the facility systems necessary to develop an understanding of the structures, equipment, and operations without extensive consultation of more controlled design references.

The following topics are discussed in this chapter to the level of detail specified by the precepts of the graded approach described in DOE Order 5480.23:

1. Overview of the facility (Section D2.3)
2. Description of the facility structure and design basis (Section D2.4)
3. Description of the facility process systems and components, and relationships of the SSCs (Section D2.5)
4. Description of confinement systems (Section D2.6)
5. Description of facility safety support systems (Section D2.7)
6. Description of facility electrical systems (Section D2.8)
7. Description of facility auxiliary systems and support facilities (Section D2.9).
D2.2 REQUIREMENTS

D2.2.1 U.S. Department of Energy Regulations, Orders, and Standards

The following DOE Orders, regulations, and standards are applicable to the safety basis of the facility:

- Title 10, Code of Federal Regulations (CFR), Section 830.120, "Quality Assurance Requirements." This rule requires that a sufficient quality assurance program be in place.

- 10 CFR 835, "Occupational Radiation Protection." This rule provides requirements for radiation protection programs.

- DOE Order 5480.23, Nuclear Safety Analysis Reports. This order provides nuclear safety analysis report content requirements.

- DOE Order 6430.1A, General Design Criteria. This order for nonreactor nuclear facilities presents the main reference standards and guides for facility design. In addition, Division 13, "Special Facilities," Section 1300, "General Requirements," and Section 1320, "Irradiated Fissile Material Storage Facilities," requirements are imposed for the 200 Area ISA.

- DOE-STD-1027-92, Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports. This standard is used to determine hazard categories for nuclear facilities.

- DOE Order 5480.28, Natural Phenomena Hazards Mitigation. This order is used to define design requirements for seismic events and straight wind.

- DOE-STD-1020-94, Natural Phenomena Hazards Design and Evaluation Criteria for Department of Energy Facilities. This standard provides natural phenomena hazard design and evaluation criteria. The 200 Area ISA was designed and evaluated for seismic events and straight wind in accordance with this standard.

- DOE-STD-1021-93, Natural Phenomena Hazards Performance Categorization Guidelines for Structures, Systems, and Components. This standard is used to define the specific performance category for SSCs.
D2.2.2 U.S. Nuclear Regulatory Commission Requirements and Guidance

In Letter 95-SFD-167, Implementation of K Basins Spent Nuclear Fuel Project (SNFP) Regulatory Policy (Sellers 1995), DOE established the requirement for new SNF Project facilities to achieve "nuclear safety equivalency" to comparable U.S. Nuclear Regulatory Commission (NRC)-licensed facilities. The SNF Project identified the NRC requirements that were needed in addition to existing and applicable DOE requirements to establish nuclear safety equivalency. These NRC requirements and the process used to identify them are documented in HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements, and in WHC-SD-SNF-DB-009, Canister Storage Building Natural Phenomenon Hazards. 10 CFR 72.3, "Definitions," defines SSCs that are considered "important to safety." 10 CFR 72.122, "Overall Requirements," requires that the design bases for SSCs important to safety reflect appropriate combinations of effects on normal and accident conditions and the effects of natural phenomena.

For the 200 Area ISA, important-to-safety SSCs have been identified based on the analysis performed in Chapter D3.0 and in accordance with 10 CFR 72.3. Once SSCs have been identified as having a function meeting the definition of important to safety, the requirements for SSCs important to safety specified in 10 CFR 72, "Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste," are imposed. A graded approach is applied to an SSC important to safety by using the guidance provided in NUREG/CR-6407, Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety. This classification process is described in more detail in Section D4.2.

D2.2.3 Other Codes and Standards

Appendix A of HNF-SD-SNF-PMP-218, Site-Wide Spent Nuclear Fuel Project Management Plan, summarizes the requirements of the 200 Area ISA. The 200 Area ISA Standards/Requirements Identification Document identifies federal, state, and local regulations and laws with applicability to the 200 Area ISA. These requirements provide the basis for the design, development, and testing of equipment to safely store SNF at the 200 Area ISA.

DOE/RL-92-36, Hanford Site Hoisting and Rigging Manual, provides the requirements for lifting and rigging equipment. All lifts of SNF or packages containing SNF are considered critical lifts.

The documents identified in this section establish the design requirements for the 200 Area ISA.
D2.3 FACILITY OVERVIEW

The ISA is located within the Hanford Site 200 East Area. Its purpose is to provide the location for aboveground dry cask storage of SNF. The 200 Area ISA will provide safe outside storage of the SNF, while protecting fuel integrity through the use of storage systems resistant to natural phenomena hazards. While the majority of the fuel to be stored within the ISA will consist of FFTF SNF, the ISA will also store other SNF from the Hanford Site, including NRF TRIGA and Material Characterization Center (MCC) commercial LWR fuel.

An equipment storage building (pre-engineered metal building) is proposed near the 200 Area ISA to house lifting devices, impact limiters, transfer casks, and various other types of equipment associated with storage, movement, or transport of casks. This storage building will be located outside the 200 Area ISA fence and provides no safety-related function.

An aboveground dry cask storage location (the ISA) is necessary for the spent fuel because the current storage facilities are being shut down and deactivated. The spent fuel will be transferred to interim storage because there is no permanent repository storage currently available.

The 200 Area ISA is located west of the CSB. The footprint of the ISA is nominally 500 ft. by 400 ft. surrounded by a 7-ft. tall chain-link fence topped with three strands of barbed wire. Five manual gates in the fence, four 30-ft sliding and 1 personnel gate, control access of vehicles and personnel to the 200 Area ISA. Light poles within the perimeter provide illumination. Within the fenced area are three concrete pads; two for placement of ISCs and one for the NAC-1 casks within ISO containers. The Rad-Vault holding NRF TRIGA casks and DOT-6M containers will be placed on graded, compacted gravel.

The two pads for ISC storage are approximately 171 ft. by 26 ft. by 1.5 ft. thick constructed of reinforced concrete. The NAC-1 pad is approximately 88 ft. by 28 ft. by 1 ft. thick constructed of reinforced concrete. This smaller pad runs parallel to the two larger ones.

The three pads are laid out along their length on the north-south axis. The two ISC pads are separated nominally by 43 ft., and the ISO/NAC-1 pad is separated by 80 ft. from the nearest ISC pad.

The level gravel area for the Rad-Vault is located ~30 ft. northwest of the NAC-1 storage pad. A representation of the facility and its relation to the CSB are provided in Figure D2-1.

The 200 Area ISA facility components (excluding the dry cask storage systems) are classified as General Service; the dry cask storage systems are designated Safety Significant. The core component container (CCC) and the NAC-1 canister are designated as Safety Class and have both safety-class and safety-significant functions.
The ISA is surrounded by a galvanized steel chain-link fence at least 7 ft. high to restrict personnel access. Access to the facility is provided via four manually operated truck gates and one personnel gate. 10 CFR 72, Sections 72.180, 72.182, 72.184, and 72.186 require physical security plans and system designs in accordance with 10 CFR 73, "Physical Protection of Plants and Materials." Security aspects are not addressed in this final safety analysis report (FSAR).

Sodium lamps mounted on poles located inside the 200 Area ISA at the fence line are provided for illumination of the facility. There are eight light poles located two per side of the fenced enclosure.

No uncontained radioactive materials will be handled at the storage area. Therefore, decontamination and decommissioning efforts should be minimal.

There is interaction of the ISA with existing CSB facilities for surveillance activities and central alarm notification.

Table D2-1 summarizes the specific casks and containers to be used at the 200 Area ISA. The NAC-1 cask generically refers to either the NAC-1 or Nuclear Fuel Services (NFS)-4 SNF shipping casks that will satisfy both on-site transportation and storage requirements. The NAC-1 and NFS-4 casks were fabricated to the same design drawing, but at different times by different corporate owners. Both model casks will be referred to as the NAC-1 cask throughout this document.

TRIGA = Training, Research and Isotope Production, General Atomics.
D2.3.1 200 Area Interim Storage Area Hazards

A final hazard category classification of the facility is presented in Chapter D3.0, with the 200 Area ISA classified as a Hazard Category 2 facility. This classification was made in accordance with DOE-STD-1027-92.

The 200 Area ISA hazard analysis is documented in SNF-4820, *200 Area Interim Storage Area Final Hazard Analysis Report*. The only significant inventory of hazardous material in the 200 Area ISA is the radiological content of the dry cask storage systems. The 200 Area ISA does not house nor will it routinely conduct any chemical processes. Radiological guidelines applicable to the radionuclide inventory were found to be more limiting than the toxicological guidelines for the release of SNF particulate. Other hazardous materials identified in the dry cask storage systems include potentially pyrophoric metals and hydrides, oxidizers, and hydrogen.

The results of a fire hazards analysis (SNF-4932) concluded that no release of radioactive material to the environment resulted from any facility fire scenario.

D2.3.2 200 Area Interim Storage Area Operations Summary

200 Area ISA operators, supervisors, and managers will be provided by CSB staff.

Placement of Fast Flux Test Facility Fuel Containers

Receipt and set up of the mobile crane precedes the arrival of the transporter carrying the ISC. After the tie-downs are removed from the ISC, the lifting fixture will be attached to the mobile crane, as shown in Figure D2-2. Once the ISC lifting fixture is securely attached to the ISC lifting lugs, the ISC will be hoisted and removed from the transporter. The ISC will be placed in its assigned storage position on the concrete pad. The environmental cover on top of the ISC will be installed. The transporter used to carry the ISC can then be released.

Placement of the NRF TRIGA Cask and DOT-6M Containers in the Rad-Vault

The Rad-Vault, Figure D2-3, is not designed to be moved in a loaded condition or with the lid installed. Therefore, loading of the TRIGA casks (see Figure D2-4 and D2-5) and DOT-6M containers (see Figure D2-6) into the Rad-Vault will take place in the 200 Area ISA. Each Rad-Vault is capable of receiving two DOT-6M containers and six TRIGA casks. The casks and the containers are transported two at a time to the 200 Area ISA. Only a single cask or container is allowed to be moved into the Rad-Vault at a time. The TRIGA cask and the DOT-6M container have no specified loading order. Specific details, drawings, and operational restrictions for cask movement are provided in separate procedures. Empty 55-gallon drums are used as spacers inside the Rad-Vault and swapped out one at a time as loaded fuel casks are placed into the Rad-Vault. Final loading will have six TRIGA casks, two DOT-6M containers,
and one spacer drum (located in the center position), as shown in Figure D2-7. The spacer drums are only used for ease of loading and provide a passive function of providing a close packed array such that the containers cannot tip over during or after placement.

Prior to the receipt of the transporter carrying the Rad-Vault body, the mobile crane will be positioned and set up. Once the transporter carrying the Rad-Vault lid has been received, the Rad-Vault body can be placed at the assigned storage location. The Rad-Vault lid is placed adjacent to the Rad-Vault body. The transporters used to carry the Rad-Vault and lid can then be released.

Reception of the transporter carrying two DOT-6M containers can proceed. Using a 55-gallon drum lifter, a spacer drum will be sequentially removed from the Rad-Vault and replaced with a loaded DOT-6M container. This process will be repeated for the second DOT-6M container. The transporter that carried the DOT-6M containers can then be released.

A similar substitution process is used for loading the Rad-Vault with the NRF TRIGA casks. Once the mobile crane is positioned and set up, the reception of the transporter carrying two TRIGA casks in impact limiters will be permitted. Attachment of the cask lift beam assembly to the crane will occur after removing the upper impact limiter from one of the TRIGA casks. The TRIGA cask lift beam assembly will be connected to the TRIGA cask and the cask removed from the lower impact limiter. The cask will then be placed in the Rad-Vault. This process will be repeated for the remaining TRIGA casks. Once the Rad-Vault is loaded, the upper impact limiters will be placed on the empty lower impact limiter located on the transporter and the transporter used to carry the TRIGA cask can be released. The lid is then placed on the Rad-Vault.

PlACEMENT OF COMMERCIAL LIGHT WATER REACTOR FUEL CONTAINERS

Operations at the 200 Area ISA start with the receipt and set up of the mobile crane and the receipt and staging of the hydraulic lifting device for the ISO containers. Subsequent to arrival of the transporter carrying a NAC-I cask in an ISO container, the hydraulic lifting device is attached to the mobile crane and then attached to the ISO container. The ISO container is then lifted from the transporter and placed on the assigned position on the storage pad. The transporter can then be released.

Surveillance and Maintenance

There are maintenance activities necessary to ensure long-term storage of the fuel at the ISA (e.g., preventative maintenance including painting of storage cask systems). Minimal, non-safety-related maintenance activities will include periodic inspection of the fence, lighting replacement, and repair, if required. Periodic weed removal is performed to minimize the potential for a fire at the pad.
Interim Storage Cask

Periodic inspection of the ISCs is required to support analysis assumptions. Annual surveillance of the ISC includes a visual inspection, radiation survey, and smear sampling about the ISC environmental cover.

Rad-Vault, NRF TRIGA Cask, and DOT-6M Container

Annual surveillance of the TRIGA cask and DOT-6M containers shall include (1) visual inspection and radiation surveys of the Rad-Vault, (2) vault lid removal to allow visual inspection and radiation surveys of the fuel casks/containers, and (3) smear sampling of the fuel casks/containers and subsequent vault lid placement. As the Rad-Vault is constructed of concrete, an annual visual inspection of the underside is not required.

NAC-1 Casks

Annual surveillance of the NAC-1 casks in ISO containers shall include (1) a visual inspection of the external surface of the ISO container, (2) radiation surveys of the exterior surface of the ISO, (3) a radiation survey of the top of the NAC-1 casks upon opening the ISO container doors, (4) smear samples from the top of the NAC-1 casks, and (5) visual inspections of the interior of the ISO container and exteriors of the NAC-1 casks. As the ISO has structural members constructed of ferrous material, an inspection of the underside will be performed every 5 years to maintain ISO certification. This inspection will be performed in accordance with the requirements of the ISO standards. Operating procedures/work plan will be approved for this activity at that time. Again, critical lift procedures are imposed.

D2.3.3 200 Area Interim Storage Area Confinement

Confinement of radioactive material at the 200 Area ISA is a design feature of each spent fuel storage system. These features are summarized below, with additional details provided in Section D2.6 and Chapter D4.0.

Fast Flux Test Facility Fuel

The ISC is an aboveground concrete and steel shielded, top-loading spent fuel storage cask that is used to provide safe interim dry storage of a CCC (see Figures D2-8 and D2-9) loaded with intact FFTF spent fuel assemblies or pin containers. One CCC can be stored in the cavity of each ISC. The ISC design consists of an all-stainless steel internal confinement structure surrounded by steel and concrete shielding. The fully loaded cask weighs a maximum of 114,200 lbs, including a loaded CCC with a gross payload of 5,000 lbs, the closure hardware, and the weather cover. Outer cask dimensions are 85 in. in diameter and 181 in. tall. The internal cavity of the ISC is 21 in. in diameter and 147 in. tall.
The ISC has been designed and fabricated to meet the requirements of WHC-S-4100, *Specification for FFTF Interim Storage Cask*, in accordance with 10 CFR 72. "Canning" of the spent fuel is provided by the CCC, as discussed in Section D2.6.2.1. The ISC is designed to provide confinement for the fuel, passive heat removal, and environmental protection for the CCC. It also provides radiological shielding protection for site personnel by limiting the dose rate to acceptable levels at normally accessible surfaces. A gasketed weather protection cover is installed on each ISC in the ISA. An additional cover plate may be seal welded over the bolted closure plug after receipt at the 200 Area ISA to enhance the long-term storage configuration.

**NRF TRIGA Fuel**

NRF TRIGA fuel from the NRF in the 300 Area is stored in NRF TRIGA casks and DOT-6M containers. Each NRF TRIGA cask, with capacity to hold up to 18 elements, is nominally 38 in. tall and 16 in. in diameter. Each DOT-6M container, holding one fuel follower control rod (FFCR) element in an inner 2R container, is nominally 70 in. tall and 23 in. in diameter.

Six NRF TRIGA casks and two DOT-6M containers are placed within a concrete Rad-Vault. The Rad-Vault provides environmental protection, supplemental shielding, and natural phenomena hazards resistance. The Rad-Vault is a concrete, vertical, right circular cylinder with light steel reinforcement. The empty Rad-Vault weighs 63,400 lbs., consisting of the 43,400-lb. body and 20,000-lb. lid. The loaded weight of the storage system is approximately 81,400 lbs. With the lid installed, the Rad-Vault is 111 in. tall and the outer diameter is 114 in.

**Commercial Light Water Reactor Fuel**

NAC-I casks within ISO containers are used to store the commercial LWR SNF retrieved from storage at the 324 Building in the Hanford Site 300 Area. Within each NAC-I cask, an inner container provides confinement for the commercial LWR SNF. Each inner container holds either an individual assembly or consolidated pins. The NAC-I cask is a metal cask that provides structural protection and shielding for the canister. Each NAC-I cask is approximated by a right circular cylinder 214 in. long, with a maximum diameter of 50 in. Loaded gross weight of the cask is approximately 49,000 lbs., excluding the weight of the ISO container. The ISO container provides weather protection and has a footprint of 8 ft. by 20 ft.

**D2.3.4 200 Area Interim Storage Area Systems**

This section is not applicable as there are no mechanical or process systems provided by the ISA. Lifting is provided by a portable Manitowoc 4600 250-ton crane.
D2.4 FACILITY STRUCTURE

The 200 Area ISA is designed to DOE Order 6430.1A requirements. It is designated as a nonreactor facility under Section 1300, "Special Facilities," which includes consideration of the design requirements under Section 1320, "Irradiated Fissile Material Storage and Handling Facility." The 200 Area ISA is a temporary facility with a design life of 40 years.

This section contains the structural descriptions for the 200 Area ISA and includes the layout for the various storage pads.

D2.4.1 Interim Storage Area Yard

The 200 Area ISA footprint is nominally 500 ft. by 400 ft. surrounded by a 7-ft. tall chain-link fence, with gates in the fence that control access of vehicles and personnel. The ISA is nominally 710 ft. above sea level. Light poles around the perimeter provide illumination. Within the fenced area are three concrete pads, two for placement of ISCs and one for placement of the NAC-1 casks within ISO containers. The Rad-Vault holding NRF TRIGA casks and DOT-6M containers will be placed on graded, compacted gravel. All concrete pads have embedded conduit that is intended to support any future monitoring needs.

D2.4.2 Equipment Storage Building

An equipment storage building (pre-engineered metal building), approximately 200 ft. to the northeast of the CSB, is proposed near the 200 Area ISA to house lifting devices, impact limiters, transfer casks, and various other types of equipment associated with storage, movement, or transport of the casks. This storage building will be located outside the 200 Area ISA and provides no safety-related function. The proposed storage building consists of a 50 ft. by 85 ft. one-story insulated metal panel wall and roof on a steel frame building. The building will have heating and cooling and a dry pipe fire protection system. Truck and personal access doors will be provided. A fire hydrant is located northeast of the proposed building.

The fence is no closer than 142 ft. to any edge of the NAC-1/ISO concrete pad and 146 ft. to the outer edge of the nearest container storage position on the concrete pad.

Excavation, backfilling, and compacting of building materials are in accordance with American Society for Testing and Materials (ASTM) standards D-653, D-1557, D-2922, and D-3017.

Concrete work on the pads is in accordance with the American Concrete Institute (ACI) standards 117, 224, 301, 306.1, 318, and SP-66; the ASTM A-615, A-853, C-33, C-94, C-150, C-260 and C-881; Hanford HNF-PRO-097, Engineering Design and Evaluation; National Ready
Mix Concrete Association (NRMCA), *Certification of Ready Mixed Concrete Production Facilities*; and the *Uniform Building Code* (ICBO 1994).

Polyvinyl chloride (PVC) externally coated galvanized rigid steel conduit (GRC) meeting the National Electrical Manufacturers Association (NEMA) Standard FW-I, *Polyvinyl Chloride (PVC) Externally Coated Galvanized Rigid Steel Conduit and Intermediate Metal Conduit*, is embedded in the concrete pads. This conduit is listed by the Underwriters Laboratory Electrical Construction Materials directory. The conduits are terminated with a rigid steel coupling and pipe plug, installed flush with the top of the concrete. Conduit ends terminating in vaults or handholds are terminated with ground bushings. Ground bushings are connected in series with a minimum of #12 American Wire Gauge (AWG) bare copper wire to six ground conduits of 0.75 in. diameter.

A fire hydrant is located outside the fence line approximately 152 ft. from the southwest corner of the NAC-1 pad. The hydrant is rated at 1.800 gal/min at 20 lb/in². Drawing H-2-829294 provides the exact location and capacity. There is also a fire hydrant located next to the northeast side of the 200 Area ISA storage building.

**D2.4.3 Fast Flux Test Facility Interim Storage Cask Pad**

The ISC storage pads comprise two pads approximately 171 ft. by 26 ft. by 1.5 ft. thick, in accordance with Drawing H-2-829293, Sheet 4. These pads are reinforced with upper and lower rebar mats (ASTM A-615, Grade 60). The concrete has a minimum compressive strength of 4,000 lbs/in². The pads include embedded electrical conduits in the concrete slabs with handholds (Utility Vault Company Model #3030-LA) installed outside the pad area. The length of these two pads is coincidental with the north-south axis. The two ISC concrete pads are separated by approximately 43 ft. for safety considerations. The western-most edge of the inner ISC concrete pad and the eastern inner edge of the NAC-1/ISO concrete pad are separated by approximately 80 ft.

Each of the ISC pads are intended to support storage of 30 ISC containers. The storage locations are two-abreast. Each position has a nominal circular contact footprint 7 ft. in diameter. There are 11 ft. between the center lines of each adjacent container. There is a minimum of 4 ft. between the edges of each storage position, and 4 ft. between each outer edge and the edge of the ISC concrete pad. A representation of the 200 Area ISA pad locations relative to the CSB are provided in Figure D2-1.

**D2.4.4 NRF TRIGA Rad-Vault Gravel Area**

The Rad-Vault will not be placed on a concrete pad; instead, a graded and compacted gravel area will be prepared by the project. The design specifications for this gravel area are
provided in Drawing H-2-829293. The gravel will be compacted to a soil-bearing capacity greater than 4,000 lbs/ft².

**D2.4.5 Commercial Light Water Reactor International Standards Organization Container Pad**

The third storage pad is approximately 88 ft. by 28 ft. by 1 ft. thick, in accordance with Drawing H-2-829293, Sheet 3 Rev. as-built. This pad is reinforced with upper and lower rebar mats (ASTM A-615, Grade 60). The concrete has a minimum compressive strength of 4,000 lbs/in². The pad includes embedded electrical conduits in the concrete slab with handholds (Utility Vault Company Model #3030-LA) installed outside the pad area. The length of this pad is coincidental with the north-south axis.

The NAC-1/ISO container pad is designed to support storage of seven containers. The storage locations are sequential with 4 ft. of space between each storage ISO container edge and 4 ft. to the edge of the concrete pad. Each position has a nominal footprint of 8 ft. x 20 ft.

**D2.4.6 Design Basis**

With more than one type of dry cask storage system stored within the ISA, specific criteria that each dry cask storage system must address will be provided as separate subsections. This section delineates the generic requirements, limits, and siting criteria that must be met by all fuel storage systems residing within the ISA independent of the fuel type and specific design.

A summary of each ISA facility design requirement and its justification or reference is presented in Table D2-2. As fuel storage systems are added, their subsection will address the outline of requirements and limits provided in this section. This will ensure that consistency of the SNF Project FSAR authorization basis is maintained and will demonstrate each cask system’s acceptability for safe, dry spent fuel storage at the 200 Area ISA.

Because the ISA provides only the general-service functions described in Section D2.3, the cask systems are the major components relied on for meeting the 10 CFR 72 requirements for safe storage of spent fuel. Accordingly, each cask storage configuration provides all the necessary confinement, shielding, criticality control, passive heat removal characteristics, and natural phenomena hazards resistance necessary for the specific spent fuel configuration to be stored.

D2.5 PROCESS DESCRIPTION

The 200 Area ISA has no active processing systems. The information provided in this section includes fuel descriptions and parameters.

D2.5.1 Fuel Description

Table D2-3 summarizes the fuel history and fuel specifics for each SNF dry storage system.

D2.5.1.1 Fast Flux Test Facility Fuel. The purpose of the FFTF was to provide testing capability to satisfy the diverse technology development needs for the advanced reactor programs. The mission included irradiation and evaluation of different types of fuel assemblies and different materials for fuel assembly construction. Also included was direct production of useful materials such as medical isotopes. In December 1993, DOE directed that the FFTF be transitioned to shutdown status. In April 1994, removal of fuel from the reactor began.

There are nominally 374 fueled components at FFTF that will be placed into storage at the 200 Area ISA. Since cessation of FFTF reactor operations in April 1992, the fuel has decayed and a substantial reduction in associated fission products and noble gases has occurred. As of August 1995, 351 fueled components were below 200 W decay heat; the highest decay heat assembly was 329 W. The average decay heat, considering all fuel components, is 81 W. All assemblies currently are below 250 W decay heat.

All fuel assemblies fall into two general categories; driver fuel assemblies (DFAs) and test assemblies. The primary purpose of the DFAs was to hold the fuel that creates the neutron flux environment to carry out the various FFTF tests. The primary purpose of the test assemblies was to hold the fuel and non-fuel materials being tested. The fueled test assemblies also contributed to the neutron flux within the reactor.

The test assemblies have been further categorized for the purpose of this document. The test assemblies that are identical to or very similar to the DFAs are categorized as test DFAs. The test assemblies that contain experimental fuel are categorized as test fuel assemblies, even if they also contain some standard driver fuel pins. The remaining test assemblies did not contain fuel.

\(^{(1)}\) Enrichments greater than 29.3% must be analyzed on a case-by-case basis.

\(^{(2)}\) Burnups greater than 150,000 MWd/MTHM are analyzed on a case-by-case basis.

BWR = boiling water reactor.
DFA = driver fuel assemblies.
DOT = U.S. Department of Transportation.
FFCR = fuel follower control rod.
FFTF = Fast Flux Test Facility.
MTHM = metric ton of heavy metal.
PWR = pressurized water reactor.
TRIGA = Training, Research and Isotope Production, General Atomics.
The following FFTF fuel types have been authorized for storage at the 200 Area ISA (based on fuel previously authorized for storage at the FFTF 400 Area ISA):

- Standard DFAs.
- Driver evaluation, core characterizer assemblies, and run-to-cladding-breach assemblies are also included based on their similarities to a standard DFA.
- Experimental assemblies and Ident-69 pin containers listed in Table D2-4 have been authorized based on the analyses summarized in WHC-SD-FF-RPT-005, *Review of FFTF Fuel Experiments for Storage at ISA*. Table D2-5 shows experimental assemblies not listed in Table D2-4 that have been disassembled and loaded into Ident-69s.

\(^{(1)}\) Maximum pins per type: 69 = 109, 69A = 55, 69C = 217.

\(^{(2)}\) Experimental fuel pins.

\(^{(3)}\) PO-4 and ACN-1 are currently intact assemblies but will be disassembled and placed in pin containers.

\(^{(4)}\) IFR-1 pins are sodium-bonded metal fuel.

\(^{(5)}\) The MFF-LA pins stored at the Fast Flux Test Facility are mixed oxide; all of the sodium-bonded pins from this assembly were shipped to Argonne National Laboratory - West.
The remaining fuel and test assemblies require further evaluation before they can be accepted at the ISA. An Engineering Change Notice to this document is required to authorize the additional fuel assemblies listed in Table D2-6.

(1) SRF-3 and SRF-4 have a thermal limit of 62.5 watts for storage in the core component container/interim storage tank.
As noted in Section D6.3.3.1.1, various FFTF experimental pins, cropped fuel pins, and fuel drillings are to be returned to FFTF. Fuel debris is not currently authorized for storage at the 200 Area ISA, as FFTF fuel received at the ISA is required to have intact cladding upon receipt. Experimental fuel debris has been shown acceptable with respect to criticality safety in Chapter D6.0 even though it is not currently authorized for storage at the ISA. However, impacts of fuel debris on radiological accident releases must still be evaluated.

There are 210 DFAs, 65 test DFAs, and 54 test fuel assemblies irradiated at the FFTF. Of these, 1 DFA, 14 test DFAs, and 13 test fuel assemblies have been disassembled. Also, there were 55 DFAs, 1 test DFA, and 2 test fuel assemblies that had been fabricated but not irradiated. Unirradiated FFTF fuel is not permitted to be stored at the 200 Area ISA for safeguards consideration.

There are 8.6 metric tons of uranium (MTU) and 2.4 metric tons of plutonium in the FFTF fuel, as shown in Table D2-7. The plutonium and uranium content of the individual assemblies varies depending on the assembly exposure and its pre-irradiation content.

</tbody>
</table>

The driver fuel is plutonium-uranium mixed oxide enriched in fissile plutonium (239 and 241). The essential design features that affect performance are as follows:

- Fuel column length: 36 in.
- Cladding outside diameter: 0.230 in.
- Cladding thickness: 0.015 in.
- Beginning of life (BOL) diametrical gap/pellet diameter: 0.0055/0.1945 in.
- Smear density: 85.5% theoretical density
- Fill gas composition and pressure: helium (plus tag gas), 1 atmosphere at room temperature
The fuel pins contain mixed uranium/plutonium oxide clad in 20% cold-worked Type 316 stainless steel and are wire wrapped to maintain pin spacing. The 217 pins are oriented on a triangular pitch in the subassembly with a spacer wire 0.056 in. in diameter.

**Driver Fuel Assembly**

The DFAs are hexagonally shaped components, which are composed of 217 fuel pins, a surrounding duct, a shield orifice assembly, an inlet nozzle, load pads, and a handling socket. The assembly is 12 ft. long, 4.575 in. wide across the hexagon flats, 5.16 in. wide across the hexagon points, and weighs 38.1 lbs.

The principle structural component is the Type 316 stainless steel, hexagonal duct that extends from a handling socket at the top, to a shield/orifice region located below the fuel pins. The duct wall thickness is nominally 0.120 in., but varies from 0.065 in. through 0.190 in. along the length to facilitate lateral positioning of assemblies within the core and the distribution of force among the assemblies within the core.

The fuel pins are 0.23 in. in diameter, approximately 93.5 in. long, and have a 36-in. fuel bearing region that is centered 65.5 in. from the bottom end of the fuel assembly. Each fuel pin is helically wrapped with a 0.056-in. diameter steel wire to provide lateral spacing along its length. The fuel region contains approximately 150 pressed and sintered, mixed uranium-plutonium oxide pellets. Enrichment details are shown in Table D2-3.

**Test Driver Fuel Assemblies**

The test DFAs are either identical or very similar to the standard DFA. Each contains fuel with only one of the standard four plutonium enrichments used in the DFA. Some test DFAs have components made of D9 or HT9 stainless steels versus Type 316 stainless steel.

Fuel pins were removed from some test DFAs and shipped off-site for examination. Some of these removed fuel pins were returned whole in Ident-69 containers or as pieces in a cask. Specific details are provided in WHC-SD-SNF-TI-001, *Hanford Spent Fuel Inventory Baseline*. Only intact pins will be stored in Ident-69 containers.

**D2.5.1.2 NRF TRIGA Fuel.** A 250 kW TRIGA experimental research reactor was operated in the 300 Area intermittently from the late 1970s until its last power run in May 1989. The reactor was manufactured by Gulf General Atomics Company, Incorporated, of San Diego, California, and was used primarily for neutron radiography of FFTF fuel elements and test assemblies. The fuel from the reactor core/pool storage has been removed as part of the decommissioning of the facility. The NRF TRIGA irradiated fuel inventory consists of 99 TRIGA fuel elements and two FFCRs. The standard fuel elements are stored in the NRF TRIGA casks, and the FFCRs are stored in DOT-6M containers. The NRF TRIGA casks and the DOT-6M containers are stored in a Rad-Vault, as described in Section D2.3.2. The fuel elements are clad with either aluminum or Type 304 stainless steel. The FFCRs are clad with Type 304 stainless steel.
There are a total of 66 aluminum clad elements. Fifty-six elements were used in the NRF TRIGA core for various periods of time during the thirteen years of operation, one was rejected in the first year because of dimensional changes (bowing), and nine were never used in the NRF TRIGA core. All of these aluminum clad fuel elements were received previously irradiated. There were 33 fuel elements received from the Armed Forces Fuel Research Institute Reactor and 33 from the Nevada Test Site.

There are a total of 33 stainless steel clad fuel elements. Twelve elements were new from General Atomics and were used in the core for the entire thirteen years. Twenty elements were received from the deactivated Diamond Ordnance Reactor Facility; however, none of these elements were used in the 300 Area reactor core. One element was an instrumented fuel element from Oregon State University, also never used in the 300 Area reactor core. This instrumented fuel element had a thermocouple tube attached at the upper end. This 8-in. long tubing was bent to 90° with a 0.25 in. radius so it would not interfere with the closure lid of the inner container. There are two stainless steel clad FFCRs that also were previously irradiated at the Diamond Ordnance Reactor Facility reactor but never used in the 300 Area reactor core.

The design parameters of the TRIGA fuel are summarized in Table D2-8. All the fuel elements are 28.37 in. long and 1.47 in. in diameter. The aluminum clad elements have a fuel core length of 14 in., while the stainless steel clad elements have a core length of 15 in. The FFCRs are 45.75 in. long and 1.375 in. in diameter. The fuel length for the FFCR is 15 in. The FFCR also includes a borated graphite column above the fuel core that is 14.24 in. long.

The fuel columns in all fuel assemblies are ceramic zirconium hydride with 8 to 8.5 wt% uranium that is nominally 20 percent enriched $^{235}U$ dispersed throughout the hydride. The $^{235}U$ content of the fuel assemblies before irradiation ranged from 32 to 40.5 g each. The FFCR typically contained 32 g $^{235}U$ each. Table D2-9 lists each fuel element and FFCR, including serial number, operating hours in the 300 Area TRIGA reactor, kWh (exposure), fuel source, date received, cladding type, fuel column length, and gram quantity of $^{235}U$. The estimated dose rates, based on reported comparisons with underwater measurements in the NRF TRIGA pool, are for single TRIGA fuel elements at midplane. The irradiated fuel elements have limited burn-up from use in the 300 Area TRIGA reactor; the $^{235}U$ burn-up is probably less than one percent (30 to 35 g) of the total grams of $^{235}U$ in all of the fuel elements.

¹ Fuel-follower control rod.

AFFRI = Armed Forces Fuels Research Institute.
AL = aluminum.
DORF = Diamond Ordnance Reactor Facility.
GA = General Atomics Company, Incorporated.
NRF = Neutron Radiography Facility.
NTS = Nevada Test Site.
SS = stainless steel.
TRIGA = Training, Research and Isotope Production, General Atomics.
The low burn-up has produced only a small amount of fission products. The relatively
long period since shutdown (May 1989) has allowed all of the halogens and most of the noble
gas inventory to decay.

The two FFCRs are irradiated and also have less than one percent burn-up. They were
last irradiated in 1976 and most of the high activity, short-lived fission products have decayed.

The source term was developed using ORIGEN2 code (WHC-SD-TP-ANAL-001). The
hypothetical maximum irradiated single fuel element radiation source term is 9.1 Ci, assuming a
minimum of six years decay from last irradiation. The total radionuclide inventory of
99 irradiated fuel elements and the two FFCRs is estimated to be a maximum of 920 Ci of
radioactive material, including less than 7.5 g of plutonium based on the maximum element. The
maximum total decay heat rate of the 99 fuel elements and 2 FFCRs is 2.7 W. The thermal
source for a single TRIGA fuel element is $2.51 \times 10^2$ W, with a design capacity of 18 elements
per cask yielding a total of 0.45 W per cask (WHC-SD-TP-ANAL-001, Part B, Chapter 8.0).
There was no previous operating history provided with the used fuel elements from the Armed
Forces Fuel Research Institute, Diamond Ordnance Reactor Facility, or the Nevada Test Site.
Operating history has been estimated and correlated to actual direct dose rate readings. Based on
this characterization effort, estimated exposures were normalized and ORIGEN2 runs generated
for all fuels (WHC-SD-TP-ANAL-001).

The TRIGA pool water quality was maintained with a purification system. Impurities
and minerals were removed to inhibit corrosion or filming. The purification system was
carefully monitored and recorded in a weekly log book. The pool water was sampled monthly
and tested by analytical chemistry to determine conductivity and pH balance and to verify that no
fission products were present in the water, demonstrating fuel cladding integrity.

**D2.5.1.3 Commercial Light Water Reactor Fuel.** Seven commercial LWR SNF assemblies
were delivered to the Pacific Northwest National Laboratory (PNNL) MCC at Hanford in 1985
in support of DOE spent fuel repository studies. Five were pressurized water reactor (PWR)
assemblies and two were boiling water reactor (BWR) assemblies. As part of the DOE spent fuel
repository studies, PNNL removed several fuel rods from the assemblies and designated them
Approved Testing Materials (ATMs) to support laboratory investigations of nuclear waste
disposal forms. As a result, the fuel from these assemblies has been well characterized.

Two of the five PWR assemblies supplied to PNNL contained three designations of spent
fuel from the Calvert Cliffs Unit No. 1 PWR operated by Baltimore Gas and Electric, located
near Lusby, Maryland. The first designation of fuel consisted of one full assembly containing
176 rods of moderate burn-up fuel and was identified as assembly D101. The second designation
consisted of a partial assembly containing 135 rods of high burn-up fuel and was identified as
assembly D047. Assembly D047 also contained twenty rods from a third designation of fuel that
was taken from assembly BT03 and inserted into assembly D047 to facilitate fuel shipment to the
PNNL facility.
For the PNNL MCC examinations, fuel rods taken from assemblies D101, D047, and BT03 were designated as ATM-103, ATM-104, and ATM-106, respectively. Assembly D101 had eight rods removed, leaving 168 rods remaining in the assembly. Six of the eight removed rods remain as intact loose rods for consolidation and shipping to storage. Assembly D047 had a total of sixteen rods removed, nine from assembly D047 fuel, and seven of the BT03 rods—leaving a total of 139 rods remaining in the assembly. Seven of the D047 rods and four of the BT03 rods remain intact for consolidation with the other loose rods for shipping and storage.

Fuel from the Point Beach assemblies was never used as sample material, consequently ATM designations were not assigned to this fuel and the assemblies have remained intact with none of the fuel rods removed. The three remaining PWR assemblies were supplied to PNNL from the Point Beach Unit No. 1 PWR operated by Wisconsin Electric Power Company in Wisconsin. These assemblies were received as three complete fuel assemblies, each containing 179 rods, with assembly identification numbers H-07, H-12, and H-25.

The segmented rod program (SRP) segmented rods from GE Vallecitos, which are actually quarter-length BWR fuel rods designed to screw together forming rod assemblies for irradiation in rod positions in standard BWR fuel assemblies, were irradiated in Quad Cities 1 (1-rod assembly) and Monticello (2-rod assemblies). Following destructive examination of six of these rods, one rod from Quad Cities (SRP-1) remains intact and five rods from Monticello (SRP-2) remain intact. Characterization data for the segmented rods includes axial core positions (i.e., top-center, bottom-center, or bottom) during irradiation. Table D2-10 provides a summary of the dimensions of the various fuel assemblies and fuel rods.

The BWR fuel rods are from two assemblies from Cooper Nuclear Power Plant, in Brownsville, Nebraska. These assemblies, CZ346 and CZ348, were designated as ATM-105, except for 10 rods (five from each assembly) that contain Gadolinia, which were designated as ATM-108. Twelve rods were removed from CZ346, of which three were destructively examined (including one ATM-108 rod) and nine loose rods remain intact. The remaining 37 rods from CZ346 and the 49 rods from CZ348 will be disassembled from the fuel bundle hardware for consolidation with the loose PWR and SRP rods in a container, which allows for handling and packaging comparable to a fuel assembly.

ID = inner dimension, OD = outer dimension.
The five PWR fuel assemblies and two BWR fuel assemblies were delivered to Hanford and received by PNNL from October through December 1985. Subsequently, the assemblies, except for the rods removed for the ATM, have been stored in thimbles in air in a 324 Building hot cell. The removed rods were stored in a different hot cell during the time when the outer surface of the fuel assemblies became contaminated (primarily with cesium) from other hot cell activities. The contaminated assemblies will be spray-decontaminated with air and water prior to removal from the hot cell and subsequent cask loading for transfer to the 200 Area ISA.

The principal design parameters of the five PWR fuel assemblies, the two BWR assemblies from which the BWR rods are taken, and the SPR rod segments are described in this section. Table D2-11 also summarizes the assemblies and fuel rods, their fuel data, and cask designations.

Six NAC-1 spent fuel transport casks will provide on-site transport and interim storage of the spent fuel. Each of the five PWR fuel assemblies and a rod container consolidating the loose rods will be loaded into a seal-welded canister that will be placed within each NAC-1 cask. The following sections provide the principle design parameters of each fuel assembly by cask designation. The casks have been redesignated for the 200 Area ISA storage as follows:

- NAC-1A to NAC-1/ISA-A D101
- NSF-4B to NSF-4/ISA-B D047
- NAC-1C to NAC-1/ISA-C H-07
- NAC-1D to NAC-1/ISA-D H-12
- NAC-1E to NAC-1/ISA-E H-25
- NSF-4A to NSF-4/ISA-F Consolidated rods

PNL-11273, UC-812, Inventory of LWR Spent Nuclear Fuel in 324 Building, provides specific details concerning the fuel composition.

Cask NAC-1/ISA-A (Calvert Cliffs Fuel)

Cask NAC-1/ISA-A will contain fuel assembly D101. This assembly contains 176 fuel rods of moderate burnup fuel. Assembly D101 is a standard Combustion Engineering (C-E) 14x14 PWR fuel assembly. The assembly length is 157.25 in. The width of the fuel bundle is 8.125 in., and the fuel rods are 147 in. in length. All of the fuel rods are clad with Zircaloy-4 tubing. Additional fuel dimensional data are provided in Table D2-11.

The fuel rods from assembly D101 were irradiated during cycles 2, 3, and 4 of the Calvert Cliffs reactor operation between March 1977 and October 1980. The fuel assembly was discharged from the reactor October 18, 1980, and stored wet in the reactor fuel storage basin until September 1985, when it was shipped dry to PNNL. The fuel contains no burnable poisons and had an initial enrichment of 2.72 wt%. The initial total mass of uranium contained in assembly D101 with the actual remaining rods is 372.1 kg U. The burn-up of the assembly is 30,700 MWd/MTHM, and the calculated decay heat is 302.5 W.

(1) Average
(2) Initial enrichment
(3) Estimated from decay heat per BWR rod.

Information derived from:
WHC-SD-SNF-TA-010, 1996, Appendix A, Other Spent Nuclear Fuel Inventory Descriptions.
Cask NSF-4/ISA-B (Calvert Cliffs Fuel)

Cask NSF-4/ISA-B will contain fuel assembly D047. This assembly contains 126 original fuel rods and thirteen fuel rods from another assembly (BT03), for a total of 139 rods. Assembly D047 is a standard C-E 14x14 PWR fuel assembly. The assembly length is 157.25 in. The width of the fuel bundle is 8.125 in., and the fuel rods are 147 in. in length. All of the fuel rods are clad with Zircaloy-4 tubing. Additional fuel dimensional data are provided in Table D.2-11.

The fuel rods from assembly D047 were irradiated during cycles 2, 3, 4, and 5 of operation of the Calvert Cliffs reactor between March 1977 and April 1982. The fuel assembly was discharged from the reactor April 17, 1982, and stored wet in the reactor fuel storage basin until September 1985, when it was shipped dry to PNNL. This fuel contains no burnable poisons and had an initial enrichment of 3.04 wt%. The initial total mass of uranium contained in the remaining D047 fuel rods (excluding the BT03 rods) is 279.1 kg U. The burn-up of the assembly is 41,800 MWd/MTHM, and the calculated decay heat is 336.7 W.

The fuel rods from assembly BT03 were irradiated during cycles 1, 2, 3, and 4 between October 1974 and October 1980. The fuel assembly was discharged from the reactor October 18, 1980. Thirteen fuel rods from this assembly are contained within assembly D047 and will be stored within cask NAC-1-LWR2-D047. This fuel contains no burnable poisons and had an initial enrichment 2.45 wt%. The initial total mass of uranium contained in the thirteen BT03 fuel rods is 29.2 kg U. The burn-up of the fuel is 42,700 MWd/MTHM, and the calculated decay heat for the 13 remaining fuel rods is 34.7 W.

The D047 fuel rods combined with the BT03 fuel rods in the D047 assembly result in 308.2 kg U for the total mass of uranium contained within the assembly. The combined heat load for the assembly results in 371.5 W. This value is the bounding heat load expected from any of the PWR assemblies.

Cask NAC-1/ISA-C (Point Beach Fuel)

Cask NAC-1/ISA-C will contain fuel assembly H-07. This assembly contains 176 fuel rods. Assembly H-07 is a standard Westinghouse 14x14 design. The assembly length is 159.8 in. The width of the fuel bundle is 7.76 in., and the fuel rods are 151.85 in. in length. All of the fuel rods are clad with Zircaloy-4 tubing. Additional fuel dimensional data are provided in Table D2-11.

The fuel rods from assembly H-07 were irradiated during cycles 5, 6, 7, 8, and 9 between November 1976 and October 1981. The assembly was discharged from the reactor October 9, 1981. This fuel contains no burnable poisons and has an initial enrichment of 3.19 wt%. The
initial total mass of uranium contained in the assembly is 401.1 Kg U. The burn-up for assembly H-07 is 32,300 MWD/MTHM, and the calculated decay heat is 356.4 W.

Cask NAC-1/ISA-D (Point Beach Fuel)

Cask NAC-1/ISA-D will contain fuel assembly H-12. This assembly is identical in fuel description and irradiation history to assembly H-07. This fuel has an initial enrichment of 3.19 wt%. The initial total mass of uranium contained in the assembly is 401.1 kg U. The burn-up of the fuel is 32,300 MWD/MTHM, and the calculated decay heat is 356.4 W.

Cask NAC-1/ISA-E (Point Beach Fuel)

Cask NAC-1/ISA-E will contain fuel assembly H-25. This assembly is identical in fuel description and irradiation history to assemblies H-07 and H-12. This fuel has an initial enrichment of 3.19 wt%. The initial total mass of uranium contained in the assembly is 401.1 kg U. The burn-up of the fuel is 32,300 MWD/MTHM, and the calculated decay heat is 356.4 W.

The BT03 fuel contained within the D047 assembly is the most recent fuel of the five PWR assemblies to have been irradiated in a reactor. The BT03 rods were last irradiated in 1982. The remaining PWR fuel was discharged from the reactor before this date. Therefore, a minimum acceptable cooling time after removal from the reactor, before storage of the PWR assemblies at the ISA, is established at 14 years. During this storage period, unburned uranium and fission by-products from reactor irradiation of the fuel have continued to radioactively decay.

Cask NSF-4/ISA-F (Cooper, Calvert Cliffs, Quad Cities I, and Monticello Fuel)

Cask NSF-4/ISA-F will contain 95 163.8-in. rods from two standard, GE 7 x 7 BWR assemblies, CZ346 and CZ348; six 147-in. rods from D101, seven 147-in. rods from D047; four 147-in. rods from BT03; one 38-in. GE BWR rod from SRP-1; and five 38-in. GE BWR rods from SRP-2. The D101, D047, and BT03 fuel and irradiation history are described with the contents of Cask NAC-1/ISA-A and Cask NSF-4/ISA-B. Additional fuel dimensional data are provided in Table D2-11.

Fuel assembly CZ346 and CZ348 were irradiated in cycles 1, 2, 3, 6, and 7 of the operation of the Copper Nuclear Power Plant between July 1974 and May 1982. The two assemblies were shipped from the Cooper storage pool to the pool at the GE Morris Facility, used in a dry storage cask test, and shipped to Pacific Northwest Laboratory in January 1986. No adverse effects on fuel rod integrity were found after testing. Nine of the rods contain Gadolinia. The initial enrichment of the fuel was 2.5 wt%. The initial total mass of uranium in the remaining rods is 370 kg U. The burn-up of the fuel is 28,000 MWD/MTHM, and the calculated decay heat is 272 W.
The irradiation history and shipments to PNNL for the PWR rods is included in the descriptions in the above paragraphs. The SRP-1 rods from Quad Cities I reactor were irradiated during cycles 2 through 5, between July 1974 and August 1980, for a burnup of 22,600 MWd/MTHM. SRP-2 rods from Monticello reactor were irradiated during cycles 3 through 8 (three rods) and 3 through 9 (two rods), between May 1974 and April 1981 and between May 1974 and September 1982, respectively. The average burnup is 23,700 MWd/MTHM. The initial total mass of uranium in the SRP-1 is 0.81 kg U. and 3.17 kg U in the five SRP-2 rods. The decay heat of the SRP rods is estimated to be 4.3 W. The combined heat load for this cask is 316.4 W.

D2.6 CONFINEMENT SYSTEMS

10 CFR 72.122(h)(1) requires that (1) confinement barriers and systems be provided such that the spent fuel cladding is protected during storage against degradation that leads to gross ruptures of the fuel, or (2) the fuel must be otherwise confined such that degradation of the fuel during storage does not pose operational safety problems with respect to its removal from storage. This section identifies and describes the functional, physical, and operational features of the confinement systems that provide protection against release of radioactive or hazardous material. Detailed system descriptions are provided in Chapter D4.0.

D2.6.1 Confinement Approach and Configuration

The primary confinement feature in the three different types of dry cask storage systems is the intact fuel cladding. The inner or outer storage container provides a second confinement boundary. Specific details for each storage system are provided in the subsections that follow.

D2.6.2 Confinement System Descriptions

D2.6.2.1 Fast Flux Test Facility Fuel. The primary confinement feature is the intact fuel cladding, which serves to ensure cladding equivalency is maintained during the spent fuel dry storage design lifetime. The secondary confinement feature consists of the ISC, which serves as the main pressure boundary and leakage barrier to the environment to ensure that environmental, worker, and public safety is maintained. The ISC design is consistent with commercial spent fuel dry storage practice. This design restricts oxygen and moisture in-leakage to minute levels such that degradation of the spent fuel is expected to be effectively controlled to an inconsequential rate over the 50-year storage lifetime. The CCC provides fuel retrieval capability, if degradation does occur.
Interim Storage Cask Confinement Boundary

The ISC confinement structure consists of the 1.5-in. thick annular wall, an 8-in. thick bottom head, an 8-in. thick top closure plate, a 4-in. thick top flange, two test-port welded covers, and double metal seals between the top closure and the flange. The top closure of the ISC is held in place by sixteen 1.5-in. diameter bolts. The test port through the closure is provided for evacuation and helium backfill of the cask, once the CCC is installed. After the cask is inerted with helium and the main closure seals certified to a leak rate of \( <1 \times 10^{-7} \text{scc/sec} \), the two 0.5-in. thick test port covers are sequentially seal welded in place and dye penetrant tested. The test port also allows sampling of the cask atmosphere, but no such sampling is currently required or anticipated during normal storage operations. The confinement barrier design conforms to the requirements of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (ASME 1995, Section III, Subsection NC, for safety-significant components. Guidance for application of the ASME Code was taken from NRC Regulatory Guide 7.6, Design Criteria for the Structural Analysis of Shipping Cask Containment Vessels.

Core Component Container Boundary

The CCC is constructed to "can" the spent fuel and provide a barrier, in addition to the intact FFTF spent fuel cladding. This barrier is provided to ensure retrievability of the spent fuel in the unlikely event of significant cladding degradation. The CCC confinement boundary consists of the seven closed-bottom storage tubes welded to a single upper support plate, which provides the sealing surface, and the bolted cover that has a metallic seal (see Figure D2-9). The metallic seal between the cover and the container is positioned to pass radially inward of the bolt holes and outward of the upper rim of the storage tubes, thus excluding the closure bolts from this boundary. Additional elastomer seals are located at the outer circumference of the outer plate and at each bolt. A 0.375-in. diameter test port is provided to access the space between the metal and elastomer seals for leak testing. Before acceptance from the manufacturer, each CCC was certified to a leak rate of \( <1 \times 10^{-3} \text{scc/sec} \). After loading the CCC with spent fuel in the interim examination and maintenance (IEM) cell, the seal leak rate was verified at \( <1 \times 10^{-1} \text{scc/sec} \). The IEM cell atmosphere was the inerting atmosphere for long-term storage of the spent fuel because the CCC was closed prior to transfer out of the IEM cell. This atmosphere is argon with minor (<200 ppm) levels of oxygen and water impurities. The potential levels of oxygen and water within the IEM cell were evaluated in WHC-SD-FF-TA-039, Radiological Consequences of a Hypothetical Disruption of a Maximally Loaded FFTF Fuel Cask, and determined to have no significant effect on the spent fuel storage. Maintaining an argon atmosphere is not a safety function.

The CCC (Figure D2-9) is an unshielded, sealed fuel storage container with seven fuel storage positions. The CCC provides canning for the fuel to ensure fuel retrievability is maintained during the spent fuel dry storage design lifetime. The CCC also provides the geometry to ensure criticality control during handling and storage of the fuel. The CCC is
designed such that it is fully retrievable from the storage configuration, although the capability to remove individual fuel components from a CCC is not required or guaranteed. The center storage location can accept a fuel assembly that has had the bottom 15.5 in. removed. However, due to the indented CCC handling socket, an Ident-69 pin container cannot be stored in the center location. Therefore, the maximum loading of a CCC will be either six Ident-69 pin containers or seven FFTF fuel assemblies. Pin containers and fuel assemblies can be mixed in a CCC with up to five Ident-69 containers and two DFAs.

The CCC is fabricated from stainless steel and nickel alloy material to provide corrosion-resistant fuel storage. The CCC's overall dimensions are 20.0 in. in diameter by 146 in. in height. The weight of the empty CCC is 1,100 lbs. The maximum gross weight of a loaded CCC occurs with seven DFAs. The weight of the seven DFAs is 3,900 lbs, giving the CCC a maximum gross weight of 5,000 lbs.

The upper portion of the outer tubes has a 6.69-in. outside diameter. There is a saddle section 14 in. above the bottom of the CCC, where each outer storage tube transitions to a smaller section measuring 4.00 in. in outside diameter. The bottom 12.4 in. of the lower section is fabricated from nickel alloy material for enhanced corrosion resistance. The center tube has a 6.54-in. outer diameter. The bottom 10.0 in. of the center tube is also fabricated from nickel alloy material. There is no size reduction at the lower end of the center tube.

The outer storage tubes are suspended from the upper support plate. The center storage tube connects the upper support plate with the lower support plate. The outer tubes are fixed only at their upper ends so they are free to accommodate thermal expansion. This design also permits the outer tubes to stretch slightly to absorb energy during a CCC drop accident onto the ISC internal impact limiter. Drop energy is absorbed by the CCC tubes until the gap between the tube stop and the lower support plate is taken up. The CCC then acts as a rigid body for final interface with the ISC impact limiter during an accident event.

The lower support plate has an 18.0-in. diameter and is 1.5 in. thick. This support plate limits downward travel of the outer storage tubes, and also provides radial positioning guidance for inserting the CCC into the ISC. The upper support plate has a 20.0-in. diameter, with an overall thickness of 3.6 in. It provides support for the outer storage tubes and the seating surface for the cover seal. There are twelve drilled holes in the upper support plate that accommodate the cover bolts.

The cover has a 20.0-in. diameter and an overall thickness of 1.63 in. The lower surface of the handling socket extends 8.35 in. below the bottom of the cover. Twelve holes are drilled in the cover and are sized to accommodate the closure bolts. The CCC atmosphere is free to pass between the storage tubes, but a metal Helicoflex\(^1\) seal is provided between the container and the

---

\(^1\) Helicoflex is a trademark of Cefilac, Societe Anonyme.
cover to establish container confinement. An impact limiter is located on the bottom of the handling socket closure cup. The impact limiter function is to reduce the loading to the cover that could occur during the CCC drop accident into the ISC due to the fuel assembly in the center storage location rebounding and hitting the cover. The top surface of the cover is provided with rigging attachment points for empty container handling, a test port for seal leak rate verification, and a sample port for container atmosphere sampling.

The CCC cover design provides a closure with a cover that mates to the CCC body, crushing a metallic O-ring between them, which provides confinement for the spent fuel. Leak testing requirements assure that the CCC will function as an effective "canning" barrier. After the CCC is loaded with spent fuel in the IEM cell, a pressure decay test to \( \leq 1 \times 10^{-1} \text{ scc/sec} \) is performed on the seal to verify correct installation of the metal Helicoflex seal. Additionally, each fuel storage tube is closed at the bottom with a nickel alloy cup to prevent potential caustic fission product solutions from degrading the ISC confinement liner in the unlikely event of a leak out of a fuel pin. Additional features of the CCC that provide "canning" assurance are: (1) all pressure boundary welds are required to be full penetration and dye penetrant inspected during the fabrication process, and (2) each CCC is hydrostatically tested to 105 lbs/in\(^2\) gauge for the design pressure of 70 lbs/in\(^2\) gauge, with a pressure of 62 lbs/in\(^2\) gauge resulting from 100% fission gas release of seven fuel assemblies.

**D2.6.2.1.1 Primary Confinement.** The FFTF fuel cladding is intact and credited as the primary confinement boundary, thus meeting the intact fuel criteria when the fuel is placed into the CCC. Cladding integrity is verified when each spent fuel assembly is washed using the sodium removal process in the IEM cell. A quantitative assessment of cladding integrity is performed before transfer to dry storage; in addition, contamination of the sodium removal wash water provides an indication of a gross cladding failure during this process.

**D2.6.2.1.2 Secondary Confinement.**

**Interim Storage Cask**

The ISC is an aboveground concrete and steel shielded, top-loading spent fuel storage cask that will be used to provide safe interim dry storage of a CCC with FFTF spent fuel assemblies or pin containers for a period of up to 50 years. One CCC can be stored in the cavity of each ISC. The ISC design consists of an all-stainless steel internal confinement structure surrounded by steel and concrete shielding. The fully loaded cask weighs a maximum of 114,200 lbs, including a loaded CCC with a gross payload of 5,000 lbs, the closure hardware, and the weather cover. Outer cask dimensions are 85 in. in diameter and 181 in. tall. The internal cavity of the ISC is 21 in. in diameter and 147 in. tall, and will accept one CCC. This cavity, which is formed by a 1.5-in. thick stainless steel cylinder and 8-in. thick top and bottom closure plates, provides the confinement boundary.
The ISC has been designed and fabricated to meet the requirements of WHC-S-4100, in accordance with 10 CFR 72. The ISC is designed to provide confinement for the fuel, passive heat removal, and environmental protection for the CCC. It also provides radiological shielding protection for site personnel by limiting the dose rate at normally accessible surfaces to acceptable levels. A gasketed weather protection cover is installed on each ISC in the ISA. An additional cover plate may be seal welded over the bolted closure plug after receipt at the 200 Area ISA to enhance the long-term storage configuration.

The ISC confinement boundary design and analysis were performed by General Atomics (1995), which holds an ASME Certificate of Authorization N for design and overall fabrication responsibility for ASME Code, Section III, Division 1 and 2 components. The ISC design analysis and material properties were based on the requirements of the ASME Code, Section III, Subsection NC. Fabrication of the ISC is based on ASME Code, Section III, Article NC-4000. The ISC confinement boundary is constructed of ASTM materials. Additionally, all ISC design and fabrication activities were required to be performed using a 10 CFR 72 quality assurance program or equivalent.

The bottom of the ISC cavity is fitted with an aluminum crush pad to limit CCC impact loads in the unlikely event that it is dropped into the ISC during loading. The surfaces of the cavity are finished to remove burrs, sharp corners, and weld beads that potentially could interfere with cask loading operations. The confinement structure described above also is surrounded by annular steel shield plates that are surrounded by concrete reinforced with rebar. As discussed in the FFTF Spent Fuel Interim Storage Cask Design Analysis Report (General Atomics 1995), the concrete shielding structure is designed to meet ACI-349, Code Requirements for Nuclear Safety Related Concrete Structures. The concrete design mix was selected to ensure strength and long life over the range of temperature conditions expected during normal operations and the more extreme short-term temperatures that could occur during off-normal or accident conditions.

The ISC heat dissipation is totally passive. All required heat removal will occur by conduction, thermal radiation, and convective cooling of the outer surface. The ISC also is provided with a passive cooling system that removes heat by using an internal natural circulation airflow system. The airflow system is formed by two inlet ducts, an annular gap between the confinement boundary cylinder and the inner shield, and two outlet ducts. The inlet and outlet ducts are steel-lined penetrations through the concrete that take non-planar paths to minimize radiation streaming. These penetrations consist of two 4-in. outer diameter ducts that supply air to the bottom of a 0.75-in. wide annulus gap between the confinement boundary cylinder and the inner shielding cylinder. Natural convection circulates air up the annular space and out two similar ducts at the top of the annulus.

The ISC provides several layers of shielding to ensure worker ALARA (as low as reasonably achievable) radiation protection. This protection is based on the requirement that the 200 Area ISA is unmanned. The first layer of shielding consists of a 3.0-in. thick carbon steel
clamshell around the entire length of the cavity. Another partial length, 4.0-in. thick, carbon steel clamshell shield is provided for additional shielding at the cavity mid-plane where the fuel section is located. The clamshell shields are designed with studs that attach to the reinforced concrete cylinder shield. The concrete is a minimum of 21.25 in. thick for additional radial shielding. Supplemental axial shielding is provided by 4.0-in. thick plates below the bottom head and below the upper closure. A design dose rate of 2 mrem/hr at accessible surfaces for normal conditions and 200 mrem/hr at the (inaccessible) bottom head is defined in WHC-S-4100. Shielding acceptance criteria in the design specification allowed a localized dose rate of 5.0 mrem/hr to account for potential shielding imperfections and localized hot spots.

D2.6.2.2 NRF TRIGA Fuel. A Rad-Vault is used to store NRF TRIGA casks and DOT-6M containers, which hold TRIGA SNF from the NRF in the 300 Area. Each NRF TRIGA cask can hold up to 18 elements and is nominally 38 in. tall and 16 in. in diameter. The weight of the outer vessel is approximately 1,637 lbs. The entire NRF TRIGA cask weighs a total of 2,013 lbs when filled with 18 elements (WHC-SD-TP-SARP-008). Each DOT-6M container holding one FFCR in an inner 2R container is nominally 70 in. tall and 23 in. in diameter. The weight of the loaded DOT-6M container is approximately 640 lbs. The Rad-Vault is a concrete right circular cylinder with light steel reinforcement. The empty Rad-Vault weight is 63,400 lbs (43,400-lbs body and 20,000-lbs lid) and the maximum design weight with payload is 81,400 lbs; however, the maximum expected weight is approximately 77,000 lbs. With the lid installed, the Rad-Vault is 111 in. tall, with an outer diameter of 114 in.

The concrete Rad-Vault is a low-level radioactive storage unit. The Rad-Vault will be placed on compacted gravel at the ISA, and top loaded with the NRF TRIGA casks and DOT-6M containers. The Rad-Vault is equipped with a removable lid that fully exposes the available internal storage volume. The lids' mating surface to the main container is sloped to prevent rain intrusion. Opposing lifting lugs are interlaced into the steel rebar and welded wire fabric, and cast into the concrete structure. Lift capacity is sufficient to allow an empty Rad-Vault to be lifted and moved by crane to a transporter. The lid must be transported separately. The Rad-Vault is not designed to be lifted loaded or with the lid installed.

Sampling and/or drain capability is provided through a siphon-type arrangement that prevents leakage in and out of the Rad-Vault. Each Rad-Vault is also equipped with a pop-up vent. No gas is expected to be vented; however, the pop-up vent and siphon will provide a vented system. There are no safety requirements for the vent or the drain functions.

NRF TRIGA Cask/DOT-6M Container Confinement Boundary

The outer container of the NRF TRIGA cask is the qualified and tested confinement barrier for storage. This container has a Helicoflex metallic seal for long-term storage integrity, an elastomeric flange seal to facilitate leak testing, and an elastomeric bore seal. The quick-disconnects used for leak testing are also fitted with metallic O-ring seals at the thread interface.
The port lids covering the quick-disconnects used for helium leak testing are also provided with single metallic Helicoflex seals.

The 2R inner container of the DOT-6M system is the qualified and tested confinement barrier. This 5-in. diameter pipe vessel has a bolted flange assembly retaining an elastomeric seal and a Helicoflex metallic seal; helium leak test capability is included.

Helicoflex seals are fabricated using an inner spring covered by an inner lining and a soft outer lining. The Helicoflex seal for the NRF TRIGA and DOT-6M has a Nimonic 90 Spring\(^4\) covered by an inner lining of Inconel\(^5\) Alloy 600 and an outer jacket of aluminum. The materials used in the linings are application-dependent and are a function of temperature and pressure. The sealing principle of Helicoflex is based, in part, on plastic deformation of the seal’s outer lining. The inner helical spring provides an elastic core under bolt preload. Each coil of the spring behaves independently during radial compression. The all-metal design is the reason for its long life.

The Rad-Vault provides shielding, safeguards, and weather protection, but it is not a sealed system and is not designed to provide confinement.

The NRF TRIGA cask provides multiple barriers. The inner container has an elastomeric seal on the lid and a metallic seal on the clamping eye bolt. The outer container has redundant seals provided by both an elastomeric bore seal O-ring and a Helicoflex combination metallic/elastomeric O-ring seal. Both the bore seal and the Helicoflex seal are leak tested before transport and/or storage.

The closure devices on the NRF TRIGA cask include the closure lid and the three leak test port lids. The closure lid is attached to the cask body with twelve 0.50-in. diameter cap screws. All leak test port lids are attached to the cask lid with six 0.25-in. diameter cap screws.

The NRF TRIGA cask is provided with removable test port covers that permit access to the helium leak test components in the outer container. The container is leak tested upon initial loading according to the standards of American National Standards Institute (ANSI) N14.5, American National Standard for Radioactive Materials - Leakage Tests on Packages for Shipment, for a maximum leak rate of $1.0 \times 10^{-7}$ scc/s (air), with the exception that the test port covers are tested to $1 \times 10^{-3}$ scc/s (air). No additional testing is anticipated or required.

\(^4\) Nimonic 90 Spring is a trademark of Inco Alloys International, Inc.

\(^5\) Inconel is a trademark of Inco Alloys International, Inc.
The DOT-6M containers used for storage of the TRIGA FFCRs provide multiple confinement barriers. The intact cladding is a barrier. The 2R inner container provides a confinement barrier with the combination metallic and elastomeric O-ring seals.

The DOT-6M container’s outer stainless steel drum can be opened to permit access to the helium leak test port on top of the 2R inner container. The 2R inner container within the DOT-6M is secured by eight 0.75-in. diameter bolts. This vessel is leak tested in accordance with ANSI N14.5 standards, for a maximum leak rate of $1.0 \times 10^{-7}$ scc/s (air).

**D2.6.2.2.1 Primary Confinement.**

### NRF TRIGA Cask

For the NRF TRIGA cask, the intact cladding is the primary barrier. In order to demonstrate fuel cladding integrity, the TRIGA pool water quality was maintained with a purification system. Impurities and minerals were removed to inhibit corrosion or filming. The purification system was carefully monitored and recorded in a weekly log book. The pool water was sampled monthly and tested by analytical chemistry to determine conductivity and pH balance and to verify that no fissionable gases were present in the water, thereby demonstrating fuel cladding integrity.

### DOT-6M Container

For the DOT-6M system, the intact cladding is the primary barrier. As noted above, the TRIGA pool water quality was maintained with a purification system. Impurities and minerals were removed to inhibit corrosion or filming. The purification system was carefully monitored and recorded in a weekly log book. The pool water was sampled monthly and tested by analytical chemistry to determine conductivity and pH balance and to verify that no fissionable gases were present in the water, thereby demonstrating fuel cladding integrity.

**D2.6.2.2.2 Secondary Confinement.**

### NRF TRIGA Cask

The inner container has an elastomeric seal on the lid and a metallic seal on the clamping eye bolt. No credit is taken for confinement provided by this barrier.

The outer container of the TRIGA cask provides confinement and has redundant seals provided by both an elastomeric bore seal O-ring and a Helicoflex combination metallic-Viton O-ring seal. Both the bore seal and the Helicoflex seal are leak tested before transport and storage. Leak test port covers have a single Helicoflex metallic seal that is also leak tested.
DOT-6M Container

The 2R inner container of the DOT-6M is a qualified and tested confinement barrier. This 5-in. pipe vessel has a bolted flange assembly retaining an elastomeric seal and a Helicoflex metallic seal; helium leak test capability is included.

The stainless steel 6M drum provides a barrier for normal conditions only. This barrier contains pressure relief capability via the penetrations covered with pressure-sensitive adhesive filament (WHC-S-0393). This drum does not provide a safety-related confinement function, but acts as an impact absorber for the 2R container.

D2.6.2.3 Commercial Light Water Reactor Fuel. The commercial LWR fuel storage system consists of six storage units, each comprised of a canister, a NAC-1 cask (Figure D2-10 and D2-11), and an ISO shipping/storage container (Figure D2-12 and D2-13). Each canister will contain a single PWR fuel assembly, or in the case of the consolidated loose rods, a rod container (basket) designed to maintain the positioning upon which the criticality safety analysis is based. The canister provides the secondary containment, as required by 10 CFR 72. Analysis shows that damage to the canister is not credible. The canister will be placed within the NAC-1 cask, which will provide shielding and structural protection of the fuel during storage.

The NAC-1 casks, previously licensed by the NRC to transport LWR spent fuel and waste material, will be modified for use at Hanford for both transportation and storage purposes. The NRC license will not be retained. Modifications to the cask include the removal or plugging of several valves connected to the confinement cavity. The NAC-1 casks are mounted to supports within the ISO container for transportation and will remain in the containers in this configuration during storage at the 200 Area ISA.

The storage units will be placed by crane alongside each other (1 x 6 array) and evenly spaced 4 ft. apart. This spacing is not required for criticality or other safety analysis purposes, but rather for personnel access considerations and maintaining personnel radiation doses ALARA, since this is an unmanned facility.

Light Water Reactor Canister Description

The canisters are based on SNF Project acceptance criteria for the LWR fuel dry cask storage system at the 200 Area ISA (SNF-4894). These criteria include the specification that the design and fabrication meet the requirements of ASME Code, Section III, where necessary to maintain geometry control such that 0.95 k$_{\text{eff}}$ is not exceeded. The design life expectancy of the canisters is 40 years.

The canister provides the secondary confinement boundary for the fuel. The canister is fabricated from a 12-in. schedule 40 stainless steel pipe, with a welded base cap and top closure.
It has a maximum outside diameter of 13.0 in., including the end cap, and a total length of 165.25 in. The bottom cap is machined, so the pipe-to-cap weld is inspectable at the side of the canister. The top closure lid weld will be tested for leak tightness per the requirements of ANSI N14.5. The closure lid contains a penetration that allows the canister to be evacuated for vacuum drying of the fuel assemblies, filled with helium, leak tested, and welded closed. The canister end cap allows the installation of handling attachments for cask loading and subsequent transloading operations. Figure D2-14 provides an illustration of the canister.

The canisters are provided with safety class internal supports for the fuel assemblies or the loose rod container, which provide geometry control such that a loaded canister will have a $k_{\text{eff}} < 0.95$ when fully moderated and reflected under all credible accident conditions. Gamma shield plugs will be provided to be placed in the cask cavity under and on top of the canister.

The maximum loaded weight of the canister is not to exceed 3,300 lbs. The maximum internal design pressure of the canister is 50 lbs/in$^2$ gauge testable to a pressure of 85 lbs/in$^2$ gauge.

The canister for the consolidated loose rods requires the rods be provided with safety-class containment within the canister so that criticality limits are not exceeded. The $k_{\text{eff}}$ of the optimum pitch of the "bundle" of fuel rods in a canister with full water moderation and reflection was calculated to be $>0.95$ and $<0.97$. To limit $k_{\text{eff}}$ to $<0.95$, the diameter of the bundle of rods must be limited to 10.9 in. The design shall provide for this requirement. A bounding design solution for purposes of providing for this requirement in a manner conservative for calculations of pressure releases, a 10-in. safety-class pipe sleeve is installed into the canister to back up the rod container. The rod container is proposed to be an 8-in. schedule 80 diameter pipe that is split to accommodate rod loading, after which it is closed and fastened prior to loading into the canister. Figures D2-14 and D2-15 depict this approach. The rod container and the backup pipe sleeve provide for helium flow to be in contact with the fuel rods for vacuum drying and helium backfill.

**Cask Description**

The acceptance criteria require that the NAC-1 cask is designed and fabricated to the requirements of the ASME Code, Section III (1971). The external shape of the NAC-1 spent fuel shipping cask approximates a smooth-surface, right circular cylinder that is modified, in that impact limiters protrude radially at both ends. The internal cross-section of the cask cavity is circular. The overall dimensions of the cask include a length of 214 in. (including lid impact limiter) and a maximum cross-sectional envelope diameter of 50 in. The internal cavity of the cask is 178 in. long and 13.5 in. in diameter. The maximum loaded gross weight of the cask, including the maximum fuel and canister weight (3,300 lbs.), is approximately 49,000 lbs. The principle design features of the cask are the transportation confinement boundary, shielding and heat dissipation systems, and the lifting and tie-down systems.
The structures of the NAC-1 cask are constructed of stainless steel. The cask cavity is formed by the inner shell, which is a 14.125-in. outside diameter, 0.3125-in. thick stainless steel shell. The upper end of the shell is welded to the cask cavity flange; the bottom end of the shell is welded to the cask bottom casting. Surrounding the inner shell of the cask is a nominal 6.6875-in. thick annulus of chemical grade lead (gamma) shielding. The lead is shaped such that approximately 5 in. from the bottom and 30 in. from the top, the thickness is reduced to 5.4375 in. There is an annular void, 5 in. long by 1.25 in. thick, at the bottom end of the gamma shield to allow for any lead expansion during the fire accident. The upper axial shaping is accomplished by reducing the diameter of the outer shell 2.50 in. over a 30-in. length. The lead/steel interface of the inner and outer shell have axial copper fins that are imbedded in the lead and welded to the inner and outer shells to transfer heat across the interface with a minimum temperature gradient.

The confinement boundary of the NAC-1 cask is the inner shell, lower end casting, upper end casting, bolted closure lid with double neoprene O-ring seals and seal test port, a helium fill/vent valve, rupture disks, and lower casting drain valves. Because the welded canister provides the final confinement boundary for storage, it will not be required to inspect and replace the O-ring seals. The NAC-1 cask will be modified to accept the designed canister and further minimize worker exposure by eliminating unnecessary surveillance and maintenance activities during storage at the 200 Area ISA. The modifications, in accordance with SNF-4894, Spent Nuclear Fuel Project Acceptance Criteria for LWR Fuel Storage System, consist of removing the anti-rotational lugs in the cask cavity and replacing drain, relief, and fill valve penetrations and rupture disks with pipe plugs. The cover plates will be reinstalled over the ports, as designed, to serve as heat shields during the postulated design basis fire accident. Also, the neutron shield tank burst disk assembly port penetrations will have the existing assembly nut, rupture disk, and muffler removed. Solid plugs will be installed in place of the assembly nuts.

The outer shell is formed by a 30-in. diameter, 1.25-in. thick stainless steel cylinder reduced to a 27.50-in. diameter at one end. The cask bottom consists of a shaped stainless steel disc with a 30-in. outer dimension, and an 8-in. thickness that functions as a gamma shield for the bottom end of the cask. The cavity flange is a stainless steel ring with a 29.75-in. outer dimension, 17.50-in. inner dimension, and an 8.625-in. thickness. The bottom disc end and top flange are welded to the inner and outer shells to form the enclosure for the lead gamma shield.

Neutron shielding tanks are provided in the 4.50-in. thick annular space formed between the outer shell of the lead gamma shield and a thin stainless steel shell that constitutes the outer cask surface. The neutron shield tanks will not be used for the storage configuration at the 200 Area ISA and will contain air.

Upper end shielding is provided by the 7.50-in. thick stainless steel cask lid. The cask lid is a stainless steel casting that also serves as a gamma shield. The lid is a flanged frustum of a cone, 7.50 in. thick with a maximum diameter of 25.50 in. The conical portion of the stainless
The flanged portion of the lid is a 2-in. thick, 25.50-in. diameter disc. There are six counter-bored clearance holes for the lid bolts and four 1-in. diameter blind-threaded holes for attaching the lid impact limiter. The cask lid is bolted to the cavity flange by six 1.25-in. diameter hex-head bolts. Bolt heads bear on the cask lid; the shanks penetrate through the lid flange and thread into the cavity flange. Six 1.25-in. diameter holes with HeliCoil\textsuperscript{\textregistered} thread inserts are provided in the cavity flange for bolting the cask lid to the flange. The bolt heads are drilled for a wire security seal.

The lower end impact limiter structure is a ring that surrounds the cask lower casting, formed from a stainless steel sheet and/or plate welded to the cask outer shell and flange areas. The impact limiter was designed to absorb the energy of the design basis 30-ft. free drop. It contains a balsa wood disc placed adjacent to the cask bottom. A 0.125-in. thick sheet of asbestos is placed between the balsa and the cask bottom, and is contained internally. Within the impact limiter, extending radially from the center of the cask, are eight 0.375-in. thick stainless steel gussets. The bottom section of the impact limiter also functions as a pedestal for supporting the cask in the vertical position.

An impact limiter is located at the upper end of the cask body, designed to absorb the energy of the design basis side drop accident. The upper impact limiter is a stainless steel-sheathed, balsa-filled ring that surrounds the cask cavity flange. A 0.125-in. sheet of asbestos is positioned between the balsa and cask outer shell, and is contained internally. Within the impact limiter, extending radially from the center of the cask, are eight 0.375-in. thick stainless steel gussets. The upper impact limiter is also a cask support member in the storage configuration, resting in the ISO cradle frame cross-member.

The cask lid is protected during impact by a 12-in. thick, balsa-filled lid impact limiter that covers and overlaps the cask lid and cavity flange. The balsa is enclosed within a 0.109-in. thick stainless steel container. A 0.125-in. sheet of asbestos is positioned between the balsa and the sheet material adjacent to the cask, and is contained internally. The impact limiter is attached to the cask lid by four 1-in. diameter bolts. There are elastomer O-rings in grooves under the heads of the 1-in. bolts and a neoprene gasket on the perimeter of the impact limiter. These impact limiter seals are for weather protection and do not provide a confinement function. Radiation exposure to the seals is not a failure concern. Removal of the lid impact limiter allows access to the cask lid.

Lifting devices for the NAC-I cask are designated as lifting trunnions and rotation trunnions. The lifting trunnions are two 8.625-in. diameter by 3-in. long trunnions located on the perimeter of the upper impact limiter. The cask is lifted by a special handling yoke attached to the two trunnions. The rotation trunnions are two 6.625-in. diameter by 3-in. long trunnions for

\textsuperscript{6} HeliCoil is a trademark of Cefilac, Societe Anonyme.
rotating the cask to and from the horizontal position in the ISO container. The lower trunnions are offset from the cask centerline so that when the cask is lowered into the ISO container, it will rotate to a horizontal position as the crane hook is lowered.

Transportation of the NAC-1 cask is in the normal storage configuration with the cask in a horizontal position, secured within the ISO container. Two structural cross-member sections serve as cradles for the cask within the ISO container. The lower (rotation) trunnions of the cask are captured by a notch and clamping plate on the aft cradle. The upper lifting trunnions are also captured by clamping plates, to hold the upper end of the cask as it rests on the impact limiter within a neoprene-lined forward cradle. The lid impact limiter is bolted to the cask lid. The lid impact limiter can be unbolted and rolled away from the cask on a track. The cask and ISO container are lifted by crane from the transport trailer and placed in the storage array on the assigned concrete pad.

**International Standards Organization Container Description**

The NAC-1 cask is transported and stored within a specially designed ISO shipping container. These containers are similar in design and appearance to SEALAND containers. The ISO container provides weather protection for the cask and does not perform a safety function. The ISO containers were fabricated in two heights, 6-ft. and 8-ft. high models. All containers are painted carbon steel construction. Figures D2-12 and D2-13 show the basic details of the ISO and internal structural support members.

The 8-ft. ISO container, fabricated by Evergreen Heavy Industrial Corporation, is nominally 8 ft. high x 8 ft. wide x 20 ft. long and has an empty weight of 8,624 lbs. The container has single full-width doors at each end and a removable roof. The frame of the container is structural steel channel construction, with a 0.50-in. carbon steel floor. The sides are fabricated of 0.063- and 0.079-in. corrugated carbon steel. The roof is fabricated of 0.063-in. carbon steel sheet metal supported by 1.575-in. x 1.575-in. angle iron on a 23.622-in. grid, and is slightly pitched to prevent ponding of precipitation. The doors and roof are provided with weather seals. Two of these containers will be used to house NAC-1 casks during fuel transport and storage.

The 6-ft. ISO container, fabricated by Adamson Containers Ltd., is 6 ft. high x 8 ft. wide x 20 ft. long and has an empty weight of 4,400 lbs. The container has two half-width doors at one end and a removable roof. Materials of construction and dimensions are similar to those used in fabricating the 8-ft. containers, except the roof material is 0.063-in. carbon steel sheet metal and the roof is flat. Four of these containers will be used to house NAC-1 casks during fuel transport and storage.

**D2.6.2.3.1 Primary Confinement.** Past inspection of the fuel assemblies and rods has shown no visible damage, cracks, or pin holes, and verification will be made during loose rod
packing, washing, drying, and loading into containers. This verification process meets the requirements of 10 CFR 72 for cladding inspection to ensure the integrity of the primary confinement. No additional testing is required.

**D2.6.2.3.2 Secondary Confinement.** With fuel cladding providing the primary confinement, the seal-welded canisters provide the secondary confinement boundary and eliminate the need to rely on the storage cask for confinement. The welded canister also satisfies the fuel retrieval requirement of 10 CFR 72. Prior to seal welding, the inner canisters will be backfilled with helium (at approximately 1 atm) for leak detection purposes. The presence of helium is not required for heat transfer purposes, nor to maintain fuel integrity. The canister is designed to eventually be transloaded into a transportation system using the DOE standardized SNF canister (18 in.). Each spent fuel canister will be contained within a NAC-1 cask for shipment and storage at the Hanford Site.

**D2.7 SAFETY SUPPORT SYSTEMS**

This section identifies and describes the principal systems that perform safety support functions.

**D2.7.1 Criticality Prevention**

**D2.7.1.1 Fast Flux Test Facility Fuel.** A criticality safety evaluation was performed for storage of the FFTF SNF in the 400 Area ISA (WHC-SD-FF-CSER-004) and provides the bases for satisfying the criticality prevention criteria of double contingency to $K_{\text{eff}} < 0.95$. Since the configuration will not change for the 200 Area ISA, the calculations and evaluations performed for the 400 Area ISA are valid. In particular, the CCC was analyzed with respect to its structural and confinement effectiveness as a canning structure for FFTF fuel. The results for the CCC demonstrate that the CCC retains its confinement and structural integrity under all normal and accident conditions where all loads were found to be within the Code Class limits, g allowables, and stress allowables for the CCC.

**D2.7.1.2 NRF TRIGA Fuel.** There are no components performing a criticality prevention function requiring safety classification (Chapter D6.0). The criticality safety evaluation was performed for the storage of NRF TRIGA SNF in the 400 Area ISA and provides the bases for satisfying the criticality prevention criteria including double contingency and $K_{\text{eff}} < 0.95$. The TRIGA fuel configuration at the 200 Area ISA is identical to the 400 Area configuration.

**D2.7.1.3 Commercial Light Water Reactor Fuel.** Separate criticality safety evaluation reports were prepared to address interim storage of PWR fuel assemblies and loose fuel rods including BWR fuel in the NAC-1 casks in the ISA. These reports and Chapter D6.0 address specific
criticality aspects of LWR fuel storage in the ISA as individual casks and in the storage array. The LWR canister is required for criticality geometry control and is designated Safety Class.

The canisters for the PWR fuel assemblies, and the canister internals, will provide the safety-class support to retain the fuel material within the square cross-sectional geometry of the fuel assembly. For the BWR and PWR loose rods, the rod container and/or canister and internals will provide the safety-class limit for the fuel pitch of the bundle of rods to a corresponding diameter of 10.9 in.

D2.7.2 Fire Protection

The ISA is constructed of non-combustible materials and there are no fire hazards inherent to the ISA (SNF-4932). Administrative controls ensure that the area within the fence is kept free of debris and vegetation. The fence, provided for access control and radiological exposure control purposes, will also keep transient debris from entering the ISA. The only credible fire hazard associated with the ISA is the equipment used to transfer and handle the storage systems. Accidents associated with the ISA have been determined to be bounded by the transportation fire scenario of 10 CFR 71.73(c)(3). Specific accidents that are bounded include the transporter tractor vehicle, mobile crane fire, and runaway fuel truck. Therefore, the maximum credible fire for the ISA is bounded by the transportation fire scenario.

D2.7.2.1 Fast Flux Test Facility Fuel. The ISC is constructed of nonflammable materials. The design basis storage fire for the ISC is bounded by the design basis transportation fire defined in 10 CFR 71, as discussed in the 200 Area ISA fire hazards analysis (SNF-4932).

D2.7.2.2 NRF TRIGA Fuel. The TRIGA cask is constructed of nonflammable materials. The survival of the TRIGA cask is demonstrated by the analysis of the design basis fire. Since the NRF TRIGA cask is removed from the impact limiters that were analyzed as part of the transportation fire in the SARP (WHC-SD-TP-SARP-008), a supplemental fire analysis was performed for the storage configuration inside the Rad-Vault.

The DOT-6M container is constructed of nonflammable and fire retardant materials.

D2.7.2.3 Commercial Light Water Reactor Fuel. The NAC-1 and the ISO are constructed of nonflammable materials. The survival of the NAC-1 is demonstrated by the analysis of the design basis fire.
D2.7.3 Cask Instrumentation

Continuous monitoring of parameters of the dry storage systems (e.g., interseal pressure and temperature) are not provided. While such monitoring is recommended for mechanical closures (NUREG-1536, page 7-3), all three types of fuel—FFTF, TRIGA, and LWR—have demonstrated intact fuel cladding prior to placement into storage, and the storage system confinement boundaries are tested to a leak tight condition, where leaktight is as defined by ANSI N14.5. The FFTF and TRIGA fuels are protected by multiple confinement barriers and have smaller releasable gas and volatile radionuclide source terms compared to commercial LWR fuel dry storage systems. The LWR fuel stored in the NAC-1 casks is confined in a seal welded container, which is also tested to leaktight conditions. Large margins in the thermal design of the storage systems precludes the need for temperature monitoring to ensure fuel integrity. The dry storage systems are described below.

Surveillance of the ISA is required to assure safe storage (NUREG-1536, page 7-3), when cask parameter monitoring is not used. This surveillance assists in the early identification of conditions that could lead to unsafe storage. The surveillance requirement is met by a combination of closed circuit television (CCTV) monitoring and/or frequent (daily) walk through (or walk by) inspections for fence security, fire watch, roving patrol, or other periodic checks. Surveillance procedures and closed circuit television design will be implemented prior to ISA operation. CCTV monitoring will be in a continuously manned location (i.e., CSB control room or patrol headquarters).

D2.7.3.1 Fast Flux Test Facility Fuel. Only intact FFTF fuel is contained within the FFTF ISC, which is a stainless steel and concrete cask, with the confinement boundary provided by the stainless steel shell, closure lid, and double metallic O-ring seals. The confinement boundary is designed to the ASME Code, Section III, Subsection NC. The double metallic O-ring seals are tested to leaktight conditions, and then the penetration port between the O-ring seals is closed by welding the penetration port covers in place. An additional cover plate may be seal welded over the bolted closure plug after receipt at the 200 Area ISA to enhance the long-term storage configuration.

Because none of the DBAs can result in a breach of the ISC confinement boundary, and normal storage environmental conditions are well within the design parameters of the metallic Helicoflex double seals, continuous pressure monitoring is not provided for the interseal space.

The FFTF ISC uses air channels to provide for cooling air flow along the walls of the vessel that provide confinement. Historically, the NRC has required the monitoring of outlet temperatures of casks to demonstrate that the thermal performance of the cask is not degrading. Thermal analysis (WHC-S-4100) has determined that the cask thermal performance is acceptable with the absence of cooling air flow. Thus, no loss of confinement events occur due to high
temperature. No monitoring of the outlet air temperature of the FFTF ISC is required or provided.

The FFTF ISC design incorporates provisions for continuous monitoring of cask parameters, if needed for future use. Conduit runs for wiring have also been provided in the FFTF storage pad of the 200 Area ISA.

**D2.7.3.2 NRF TRIGA Fuel.**

**NRF TRIGA Cask**

TRIGA fuel that is considered to be intact is loaded into NRF TRIGA casks. The TRIGA casks are closed after loading and leak tested to leaktight conditions by testing between a metallic closure seal and a Viton O-ring.

This design does not meet the requirement for double metallic O-rings (NUREG-1536, page 7-2), but this fuel has a very small source term for gas and volatile radionuclides. Since the potential releasable source term is small and there are no DBA mechanisms for seal failure, monitoring of the confinement boundary does not seem justified and is not provided.

The TRIGA cask incorporates passive heat rejection from the body of the cask and does not require thermal performance monitoring.

The TRIGA cask design incorporates provisions for continuous monitoring of cask parameters, if needed for future use. Conduit runs and wiring can also be provided to the Rad-Vault gravel area, if necessary.

**DOT-6M Container**

TRIGA FFNCRs are loaded into a DOT specification 2R container. The 2R container incorporates a leak test port and double O-rings (one metallic and one elastomer). When closed, the 2R is tested to demonstrate a leak tight seal.

The design of the 2R container incorporates a metal seal in the outer groove of the container and an elastomer Viton O-ring in the inner groove. If the Viton O-ring fails, the interscell test port becomes part of the confinement boundary. To preclude possible leakage from the test port, it is welded closed after receipt at the 200 Area ISA. Radiation exposure to the seals is not a failure concern.

Since the potential releasable source term is very small and there are no DBA mechanisms for seal failure, monitoring of the confinement boundary does not seem justified and is not provided.
The 6M drum incorporates passive heat rejection from the body of the drum and does not require thermal performance monitoring.

There are no design features that can be used for parameter monitoring of the 2R/6M drum configuration. Consequently, parameter monitoring cannot be implemented for this configuration.

**D2.7.3.3 Commercial Light Water Reactor Fuel.** The LWR fuel stored in the NAC-I casks is considered to be intact. The fuel is confined in the LWR canister, which is closed by welding. After it is welded closed, the canister is tested to leaktight conditions, as defined by ANSI N14.5. This configuration provides two confinement boundaries and is considered to meet the requirement of assured confinement. In accordance with NUREG-1536, *Standard Review Plan for Dry Cask Storage Systems* (page 7-4), no confinement monitoring will be required. After loading the LWR canister into the cask, the cask will be closed using the containment boundary neoprene O-rings for transportation, but these O-rings are not required to maintain integrity for extended storage.

The NAC-I cask incorporates passive heat rejection from the body of the cask and does not require thermal performance monitoring. The decay heat of the stored LWR fuel is significantly less than the design basis heat load of the cask. The NAC-1 cask is designed for heat loads up to 750 W (NAC 1990).

Since the LWR canister is a welded closure, no confinement monitoring is required. The NAC-1 cask and LWR canister designs do not incorporate provisions for continuous monitoring of any cask parameters.

**D2.7.4 Radiation Monitoring**

10 CFR 72, Sections 122(1) and 126(c)(2), require the ability to monitor radiation levels. At the ISA, since the radiation doses are not anticipated to change after cask placement, the most appropriate means of doing this is dosimetry, alarming supplemental dosimetry, and periodic measurements by radiological control technicians. An area radiation monitor is not provided. Thermoluminescent dosimeter monitoring on the 200 ISA perimeter fence will demonstrate compliance with radiation dose limits imposed by 10 CFR 72 and monitored in accordance with 10 CFR 835.
D2.7.5 Cranes

The cranes to be used include the following:

- 150-ton Manitowoc 4000W crawler
- 250-ton Manitowoc 4600 crawler
- Hydro-Crane for TRIGA.

The above cranes have been analyzed for the crane fall accident in Section D3.4.2. A Technical Safety Requirement precludes use of other cranes in the ISA unless analyzed and approved.

D2.7.6 Lifting Equipment

All hoisting and rigging evolutions will be conducted in accordance with DOE/RL-92-36. All lifts of SNF or casks containing SNF will be critical lifts.

D2.7.6.1 Fast Flux Test Facility Fuel. The lifting equipment interfaces with the three removable ISC lifting lugs attached to the 150-ton crane (Figure D2-2). The three ISC lifting lugs are equally spaced on a 62.0-in. diameter circle on the top of the ISC. The spacing aligns directly with the existing spreader assembly (drawing H4-65153-A1). Three existing tension-ties (drawing H4-65153-A2) are used to connect the spreader assembly to the 1.75-in. thick lifting lugs. The fully loaded ISC weighing 114,200 lbs. uses 86% of the safe working load of the three tension-tie assemblies. Lifting will be covered by an approved procedure.

D2.7.6.2 NRF TRIGA Fuel. Lifting of the TRIGA cask is performed with two swivel hoist rings that thread into the cask cover. These rings are connected with two slings to a lifting beam, which connects to the crane hook with single slings and a load cell. The loaded TRIGA cask weighs approximately 1,900 lbs. (see Figure D2-16). Lifting will be covered by an approved procedure.

The DOT-6M is lifted with a commercial drum lifter rated at 1,000 lbs. capacity, which connects to the crane hook using single slings and a load cell. The DOT-6M weighs approximately 650 lbs. (see Figure D2-17). Lifting will be covered by an approved procedure.

The Rad-Vault lid is lifted with four slings connected to a lifting beam, which then has two slings to the crane hook with a minimum sling angle of 60 degrees. The Rad-Vault lid weighs approximately 20,000 lbs. (see Figure D2-18). Lifting will be covered by an approved procedure.
**D2.7.6.3 Commercial Light Water Reactor Fuel.** The lifting equipment interfaces with the four ISO top corner lifting lugs, the hydraulic ISO lifting fixture, and with the 250-ton crane. The fully loaded ISO weighs a maximum of 56,000 lbs. Lifting will be covered by an approved procedure.

**D2.8 UTILITY DISTRIBUTION SYSTEMS**

**D2.8.1 Interim Storage Area Power Supply System**

The ISA has power at the fence for the sodium lighting system. The lighting provides a security function for the required drive-by inspections.

The conduit embedded in the concrete pads is PVC GRC meeting the NEMA Standard RN-1. The conduits are terminated with a rigid steel coupling and pipe plug, installed flush with the top of the concrete. Conduit ends terminating in vaults or handholds are terminated with ground bushings. Ground bushings are connected in series with a minimum of #12 AWG bare copper wire to six ground conduits of 0.75 in. diameter.

The ISC pads have conduits for power or signals. There are five handholds located along the outer longer edges of each ISC pad. The first being ~2.5 ft. from the north edge, and the next four being spaced at approximately 30 ft. to each successive one. After the fourth handhold, to the south, the PVC GRC drops from a 4-in. to 2-in. diameter, and is a single run to the fifth handhold. Signal conduit runs from the handhold out under the concrete pad and terminates to the six successive storage locations. This conduit is buried at a depth of 24 in. below grade. The power and signal conduits become coincidental at 24 ft. from the northern-most outer edge of each ISC concrete pad.

The NAC-1/ISO pad has conduits for power and signals. The single handhold for the NAC-1 ISO seven conduits of 0.75-in. PVC GRC run from the handhold, and one of the seven is terminated at each of the seven proposed storage locations. They are located 1-ft. north and 3-ft. west of the northeast corner of each storage container. This conduit is buried at a depth of 24 in. below grade. The power and signal conduits become coincidental, as the pad is centrally located along the northern 28-ft. edge at 2.50 ft. from the pad, 35 ft. from the northern-most outer edge of each NAC-1/ISO concrete pad.
D2.8.2 Interim Storage Area Piped Utility System

One fire hydrant (1,000 gal/min) is located approximately 152 ft. from the southwest corner of NAC-1/ISO pad, just outside the fence line (Drawing H-2-829294). There is also an 8-in. fire main connection at the proposed ISA storage building.

D2.8.3 Interim Storage Area Communications System

Currently, no monitoring system is identified for use at the ISA. Conduit is provided for flexibility and future use. Communication will be provided via portable handheld equipment.

The conduit embedded in the concrete pads is PVC GRC meeting the NEMA Standard RN-1. The conduits are terminated with a rigid steel coupling and pipe plug, installed flush with the top of the concrete. Conduit ends terminating in vaults or handholds are terminated with ground bushings. Ground bushings are connected in series with a minimum of #12 AWG bare copper wire to six ground conduits of a 0.75-in. diameter.

The ISC pads have 4-in. and 2-in. conduits for signal wires. There are five handholds located along the outer longer edges of each ISC pad. The first being ~2.5 ft. from the north edge, and the next four being spaced at approximately 30 ft. to each successive one. After the fourth handhold, to the south, the PVC GRC drops from a 4-in. to 2-in. diameter and is a single run to the fifth handhold. Signal conduit runs from the handhold out under the concrete pad and terminates to the six successive storage locations. This conduit is buried at a depth of 24 in. below grade. The power and signal conduits become coincidental at 24 ft. from the northernmost outer edge of each ISC concrete pad.

The NAC-1/ISO pad has 2-in. conduits for signal wires. The single handhold for the NAC-1/ISO pad is centrally located along the northern 28-ft. edge, 2.50 ft. from the pad. Seven conduits of 0.75-in. PVC GRC run from the handhold, and one of the seven is terminated at each of the seven proposed storage locations. They are located 1-ft. north and 3-ft. west of the northeast corner of each storage container. This conduit is buried at a depth of 24 in. below grade. The power and signal conduits become coincidental at 35 ft. from the northern most outer edge of each NAC-1/ISO concrete pad.
D2.9 AUXILIARY SYSTEMS AND SUPPORT FACILITIES

D2.9.1 Lightning Protection

D2.9.1.1 Fast Flux Test Facility Fuel. A lightning analysis has been performed for the FFTF ISC (SNF-4791), demonstrating that lightning strikes will not credibly lead to the release of radioactive materials from the ISC. The analysis shows that effects of a lightning strike to the ISC cask are minimal. A direct strike on the cask would not produce significant temperature rise or damage to the cask contents. Subsequent to a likely voltage breakdown in the top concrete layer during a direct, worst-case 218,000 amp lightning strike to the cask, current flow during the discharge would pass along the concrete reinforcing rod structure and from there to ground. Current flow through the internal cask materials inside of the inner shield would be negligible due to the electrical skin effect. Lightning cannot lead to the release of radioactive material; therefore, no lightning protection is required.

D2.9.1.2 NRF TRIGA Fuel. A lightning analysis was performed (SNF-4793, Section 3.0) that evaluated the effects of a lightning strike on a Chem-Nuclear Systems, Inc. Type 14-215 Rad-Vault storage container. The container consists of a concrete structure with steel reinforcement. The analysis assumed that the cask was struck with the full energy of the maximum credible lightning strike. The analysis shows that effects of a lightning strike to the Rad-Vault cask are minimal. A direct strike on the cask would not produce a significant temperature rise or damage to the cask contents. Subsequent to likely voltage breakdown in the top concrete layer and during the event of a direct worst-case 218,000 ampere lightning strike to the cask, current flow during the discharge would pass along the concrete reinforcing rod structure and from there to ground. Current flow through the internal regions of the Rad-Vault wall would be negligible due to the electrical skin effect. Spalling of concrete at both the top and bottom areas of the cask could occur at the regions where the current penetrates the concrete and enters or exits the steel reinforcing wires. Arc discharge would likely occur in the gasket area, possibly exposing interior gases to an ignition source. No flammable gases are anticipated inside the vented Rad-Vault containing leaktight containers. Lightning cannot lead to the release of radioactive material; therefore, no lightning protection is required.

D2.9.1.3 Commercial Light Water Reactor Fuel. An analysis was performed that evaluated damage as a result of a lightning strike to the cask/container system (SNF-4795). The analysis concludes that even in the most severe case where the cask is not protected by the surrounding ISO shipping container, a direct lightning strike would not produce significant temperature rise or damage to the cask surface materials, fuel contents, or confinement function.

Current flow during the discharge of a lightning strike would pass along the stainless steel surface of the cask and from there to the ground. Adequate electrical bonding between the cask and storage container is provided by the cask rotation trunnion clamps. Current flow
through the interior of the cask would be much less than the surface due to the electrical "skin
effect." In the event that a maximum current level strike occurred on the cask top end, current
flow would spread along the surface on its path to ground. Because of the metal-to-metal contact
near the outer surface and far from the seals, negligible current would pass through the
Helicoflex metallic seals. Maximum temperature rise at the surface of the cask during the
lightning strike is estimated to be 28 °F. With negligible current flow through the metallic seals,
the temperature rise in the seals would be even lower than the cask surface temperature. Since
the metallic seals are designed for a maximum temperature of 700 °F, the temperature rise
expected during a lightning strike would not result in damage to the metallic seal, and
confinement of the fuel would be preserved.

The lightning analysis does not take credit for the cask being stored in the ISO shipping
container. The ISO shipping container provides additional lightning protection for the cask, as it
will dissipate current in a similar manner as the cask surface during a lightning strike, preventing
any flashover of electrical current to the cask. No lightning protection is required.

CHAPTER D3.0

HAZARD AND ACCIDENT ANALYSES
This page intentionally left blank.
D3.0 HAZARD AND ACCIDENT ANALYSES

D3.1 INTRODUCTION

This chapter presents a summary of the key methodology, assumptions, and results of the final safety hazard analysis and design basis accident (DBA) analyses performed for the final design and operation of the 200 Area Interim Storage Area (ISA). These analyses form a safety basis for the final safety analysis report (FSAR) and present a comprehensive evaluation of the ISA handling- and storage-related activities and the natural phenomena and external hazards that can affect the public, workers, and environment. Single and multiple initiating events from equipment and human-error failures in the facility, and human and natural events outside of the facility, have been considered.

The contents of this chapter are as follows:

- The requirements for establishing the safety basis for the ISA are listed in Section D3.2. The requirements listed consist of U.S. Department of Energy (DOE) Orders and standards and applicable U.S. Nuclear Regulatory Commission (NRC) rules and guidance.

- The ISA hazard analysis is summarized in Section D3.3. The complete hazard analysis is contained in SNF-4820, 200 Area Interim Storage Area Final Hazard Analysis. The analysis identifies hazard sources, hazardous conditions, potential accident scenarios and their initiators, and preliminary assessments of event frequencies and consequences. Hazards are identified by form and location and represent a complete spectrum of events that could occur throughout the facility. An initial set of safety features that would serve to prevent or mitigate the postulated accident scenarios is identified in the hazard analysis, with a final set of safety features identified in the accident analyses in Section D3.4.2 and in Chapters D4.0 and D5.0. Hazard analysis methodology and evaluation criteria are discussed in further detail in Section D3.3.

- The final facility hazard classification, determined in accordance with DOE-STD-1027-92, Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports, is addressed in Section D3.3.2.2. The ISA has been assigned a final designation of a Hazard Category 2 facility based on material at risk.

- Section D3.3.2.3 contains discussions of defense in depth, worker safety, and environmental protection, including a detailed tabulation of engineered and administrative features that have been identified as providing for worker safety.
High-risk events that pose a challenge to off-site release limits and on-site radiological dose evaluation guidelines have been selected from the hazard analysis for further detailed quantitative evaluation as DBAs. These DBAs are presented in Section D3.4.2.

Three receptor locations were used for the DBA analysis:

- Hanford Site boundary (17,390 m east of the ISA) — defined release limits; used for calculation of off-site doses and selection of safety-class features.
- Collocated worker (100 m from the ISA) — defined risk evaluation guidelines; used for calculation of on-site doses and selection of safety-significant features.
- Highway 240 (on-site, approximately 9,280 m west of the ISA) — no defined evaluation guideline; doses calculated for information purposes only (Scott 1995).

Safety-class and safety-significant features have been selected for each of the analyzed DBAs from the candidate structures, systems, and components (SSCs) identified in the hazard analysis. When required by the Spent Nuclear Fuel (SNF) Project’s commitments to meet equivalent NRC requirements, candidate features have been identified as "important to safety" and designed, engineered, and procured consistent with safety-class or safety-significant classification requirements. Safety-class and safety-significant features are presented first in Section D3.4.2, with the discussion of each accident, and described in more detail in Chapters D4.0 and D5.0.

Each of the DBAs that have been quantitatively analyzed represents a bounding case for a category or type of hazards and accidents. An in-depth review was performed of all significant accidents identified by the hazard analysis. The table and text that accompany each DBA in Section D3.4.2 include the preventive and mitigative features and the associated Technical Safety Requirements (TSRs) for the bounding case presented and for all other events binned within the accident category. Defense-in-depth features are also identified in these tables.

Chapter D3.0 interfaces with several other SNF Project safety documents. The planned scope and content of various other SNF Project safety reports, TSRs, and supporting safety documents are defined in Administrative Procedure MS-1-039, Spent Nuclear Fuel Project ISMS Description. The hazards associated with transport and accident scenarios that are postulated during shipment are analyzed in the following safety analysis report for packaging (SARP) documents:

- WHC-SD-TP-SARP-010, 1996, Safety Analysis Report for Packaging (Onsite) Interim Storage Cask

D3.2 REQUIREMENTS

Chapter 3.0 of the SNF Project FSAR lists the design codes, standards, regulations, and DOE Orders that contain requirements and guidance for establishing the safety basis for the SNF Project. Specific codes, standards, and requirements applicable to the 200 Area ISA are defined in the SNF Project Standards/Requirements Identification Document (HNF-SD-SNF-RD-001). Only the requirements that are specific for the ISA and that pertain to the safety analysis are provided here.

- **DOE Order 5480.23, Nuclear Safety Analysis Reports**, in conjunction with its Attachment 1, "Interim Guidance for DOE Order 5480.23," sets the requirements for analysis. This chapter complies with the requirements by documenting the performance of hazard and accident analyses. The analyses were performed to the guidance of HNF-PRO-704, Hazard and Accident Analysis Process, which ensures that the hazards and accident analyses comply with DOE Order 5480.23. The methodology, assumptions, and criteria used to identify facility hazards, hazard rankings, candidate accidents, DBAs, preventive and mitigative features and controls, and the classification of these features (along with the definition of safety functions, performance criteria, and applicability) are described in Chapter 3.0 of the SNF Project FSAR and documented in this chapter.

- **DOE Order 5480.22, Technical Safety Requirements.** This Order sets the requirements for developing and preparing a TSR document. This chapter complies with the requirements by documenting the performance of hazard and accident analyses in accordance with HNF-PRO-704 and DOE Order 5480.23. The results of the analyses were used to identify specific SSC safety functions, performance requirements for the SSCs, and the times for application of the safety functions.

- **DOE Order 6430.1A, General Design Criteria.** This Order provides requirements for the identification of safety-class items. The analyses documented in this chapter used the SSC classification requirements of DOE Order 6430.1A in the identification of safety-class SSCs. Compliance with DOE Order 6430.1A is demonstrated in SNF-5139, **DOE 6430.1A Compliance Analysis for the 200 Area Interim Storage Area.**

The following standards are used for content and guidance:

- **DOE-STD-1027-92, Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports.** This
standard provides guidance for the preparation and review of hazard categorization and accident analysis techniques, as required by DOE Order 5480.23. Of particular importance to this chapter is the guidance pertaining to the hazard categorization methodology and the accident analysis techniques that are appropriate for the graded approach required by DOE Order 5480.23. Section D3.3.2.2 documents the final facility categorization of the ISA, determined in accordance with DOE-STD-1027-92.

- **DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports.** This standard supplements DOE Order 5480.23 by providing guidance specific to nonreactor nuclear facilities. In this regard, the standard provides detailed information on the performance of accident analyses for Hazard Category 2 and 3 facilities. The standard also provides guidance for establishing defense-in-depth measures and addresses safety-significant SSCs. This chapter has been organized and prepared consistent with the specifications of DOE-STD-3009-94.

In Letter 95-SFD-167, *Implementation of K Basins Spent Nuclear Fuel Project (SNFP) Regulatory Policy* (Sellers 1995), DOE established the requirement for new SNF Project facilities to achieve "nuclear safety equivalency" to comparable NRC-licensed facilities. The SNF Project identified the NRC requirements that were to be met, in addition to existing and applicable DOE requirements, to establish nuclear safety equivalency. These NRC requirements, and the process used to identify them, are documented in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements*, and in WHC-SD-SNF-DB-009, *Canister Storage Building Natural Phenomena Hazards*, Appendix C, "200 East Area Interim Storage Area Natural Phenomena Hazards."

The requirements for achieving NRC equivalency include the following:

- **Title 10, Code of Federal Regulations, Part 72, "Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste" (10 CFR 72).** This rule is used for licensing independent spent fuel storage installations. Section 72.122, "Overall Requirements," requires that the design bases for SSCs important to safety reflect appropriate combinations of the effects of normal and accident conditions and the effects of natural phenomena. Section 72.24, "Content of Application: Technical Information," provides requirements in Paragraph 72.24(m) for the analysis of accidents and natural phenomena events that could result in a dose at the controlled area boundary.

- **NRC Regulatory Guide 3.48, Standard Format and Content for the Safety Analysis Report for an Independent Spent Fuel Storage Installation or Monitored Retrievable Storage Installation (Dry Storage).** This guide establishes the format and content for safety analysis reports for license applications of fuel storage facilities.
Important-to-safety SSCs have been identified in accordance with 10 CFR 72.3. Once SSCs have been identified as having a function meeting the definition of important to safety, the requirements for SSCs important to safety specified in 10 CFR 72 are imposed. A graded approach is applied to an SSC important to safety by using the guidance provided in NUREG/CR-6407, Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety, as follows:

- **Category A — Critical to Safe Operation**

  SSCs in this category include those whose failure or malfunction could directly result in a condition adverse to public health and safety. Important-to-safety SSCs in this category are classified as Safety Class, as defined in DOE Order 6430.1A with the additional requirements therein.

- **Category B — Major Impact on Safety**

  SSCs in this category include those whose failure or malfunction could result in a condition adversely affecting collocated worker health and safety. Note that from the definition of Category C, Category B is understood to include events that could significantly damage the storage containers without severe impact to public health and safety. SSCs in this category are classified as Safety Significant.

- **Category C — Minor Impact on Safety**

  SSCs in this category include those whose failure or malfunction would not significantly reduce containment and would not be likely to create a situation adversely affecting public or collocated workers' health and safety. SSCs in this category are classified as General Service.

While these documents have particular significance to this chapter, they do not, by themselves, establish requirements for the ISA or the Chapter D3.0 accident analyses. Requirements identified in HNF-SD-SNF-DB-003 and WHC-SD-SNF-DB-009 address NRC equivalency. It is noted that the SNF storage casks are "important to safety" based on the 10 CFR 72.3 definitions. The SNF Project has committed to comply with select NRC requirements. Additional requirements include safety documentation for (1) determining important-to-safety classifications for preventive and mitigative features; (2) identifying and resolving worker safety issues in DOE Order 6430.1A, DOE Order 5480.23, and DOE-STD-3009-94; and (3) evaluating nearby activities. The determination of important to safety is directly incorporated into the identified preventive or mitigative safety function features at the end of each DBA scenario in Section D3.4.2, and external human-generated threats are discussed in Section D3.3.2.3. Requirements of WHC-SD-SNF-DB-009 are incorporated into the natural phenomena hazard (NPH) design criteria and are considered in the hazard evaluation.
Letter 97-SFD-172, *Risk Evaluation Guidelines (REGs) to Ensure Inherently Safer Designs* (Sellers 1997), provides another SNF Project requirement significant in the development of this chapter (e.g., safety-significant SSCs).

**D3.3 HAZARD ANALYSIS**

The hazard identification and evaluation process provides a thorough, predominantly qualitative evaluation of the spectrum of risks to the public, workers, and the environment caused by accidents that involve the hazards identified in the hazard analysis. This process is further described in Section 3.3 of the SNF Project FSAR. An initial hazard analysis (HNF-2015) was prepared to support HNF-2524, *200 East Area Interim Storage Area Preliminary Safety Evaluation Report*, and to integrate all previous ISA hazard analyses. A final hazard analysis has been performed to support the accident analysis and is documented in SNF-4820. The final hazard analysis systematically reviewed the final ISA design, as described in Chapter D2.0, associated supporting design documentation, and design references to identify any additional hazardous materials or energy sources that have the potential to initiate an accident that could require further review or analysis. This process resulted in the selection of seven DBAs for more comprehensive analysis in Section D3.4.2.

**D3.3.1 Methodology**

The methodology used to identify and evaluate the SNF Project facility hazards is described in detail in Section 3.3 of the SNF Project FSAR. This section discusses the areas of this methodology that are specific to the ISA. The hazard evaluation process identified hazardous conditions, determined causes and preventive and mitigative features, and qualitatively estimated the consequences and frequencies of occurrence. The results of the application of this methodology to the ISA are presented in Section D3.3.2. The hazard analysis was performed in accordance with DOE-STD-3009-94 and implements the requirements of DOE Order 5480.23.

**D3.3.1.1 Hazard Identification.** No adverse consequences for the public or workers, or that cause contamination of the environment, are expected under normal operations or storage. The hazard analysis focused on abnormal and accident conditions, as described in SNF-4820. The hazards associated with transport and the accident scenarios that are postulated during shipment are analyzed in the SARPs.

The ISA cask handling and storage activities that can take place within the boundary of the storage area were identified, and the hazards were identified by form (e.g., electrical, thermal, friction), type (e.g., motors, power tools, wiring), and location. A standardized hazardous material/energy source checklist (see Section 3.3.1.1, Table 3-2, of the SNF Project FSAR) was used to group the potentially hazardous materials and energy sources. The methodology of the
hazards identification process is described further in the Section 3.3.1.1 of the SNF Project FSAR.

**D3.3.1.2 Hazard Evaluation.** As described in Section D3.3.1.1, hazards associated with abnormal and accident conditions at the ISA were identified. The hazards identified were evaluated to determine the causes of the hazard, potential accidents that could result from the presence of each hazard, and consequences to the public off-site, the collocated and facility workers on-site, the environment, or the ISA. Safety features, segregated into preventive and mitigative features, were identified for each hazard based on the ability of the feature to prevent or mitigate the consequences. Qualitative estimates of the frequency and consequences of the hazardous condition also were assigned (see Section 3.3.1.2 of the SNF Project FSAR for the criteria used in assigning the consequence and frequency categories).

**D3.3.2 Hazard Analysis Results**

The hazard analysis process is described in SNF-4820 and summarized in Section D3.3.1 and in Section 3.3.1 of the SNF Project FSAR. The products of that process, in the order of progression, are as follows:

1. Develop a series of checklist-style tables describing hazardous materials and energy sources, organized by fuel type. These tables were used to develop hazard analysis accident scenarios.

2. Develop a series of tables describing the standard industrial hazards considered, organized by fuel type. These events were judged to have no contribution to uncontrolled radiological and/or hazardous materials releases and were not considered in the selection of DBAs, safety-class or safety-significant features, or TSRs. They were among the hazards considered and, therefore, are included in this analysis for completeness.

3. Develop a series of tables describing potential hazard scenarios. These tables include hazardous energy sources and materials, hazardous conditions, causes and initiators, potential accidents, qualitative determinations of event frequencies and consequences, safety features for prevention and/or mitigation of the consequences, and defense-in-depth or worker safety features.

4. Compile a table assigning risk bins to causes associated with significant consequences to off-site and on-site receptors. Consistent with DOE-STD-3009-94, the events located in risk bins representing "situations of concern" or "situations of major concern" were evaluated as candidate DBAs.
5. Prepare a final list of candidate DBAs sorted by risk ranking and energy change or release. This list formed the basis for selection of the DBAs presented in Section D3.4.2.

DBA selection is addressed in Section D3.3.2.3.5 and its accompanying Table D3-5. In terms of the risk binning process, the accidents chosen from the hazard analysis for further analysis as DBAs were all events identified in consequence categories S3 and S2. These categories indicate significant effects to off-site and on-site receptors.

The final hazard analysis has been reconciled with the up-to-date ISA facility design described in Chapters D2.0, D4.0, and D5.0.

D3.3.2.1 Hazard Identification. The final ISA hazard analysis tables are shown in SNF-4820. The main inventory of hazardous material in the ISA is the radionuclide content of the stored fuel. The toxicological hazards of the radionuclide inventory were reviewed. As described in Section D3.4.1.1, the radiological guidelines are more limiting than the toxicological guidelines for the release of SNF particulate. Other hazardous material identified by the hazard identification process includes pyrophoric metals and hydrides, sodium, oxidizers, hydrogen, diesel fuel, and other flammable or combustible materials. A specific and comprehensive analysis of all fire hazards associated with the ISA (SNF-4932) was completed to augment the standard hazard analysis.

The ISA does not have an operating history, so major hazards resulting from facility operation cannot be identified or summarized as suggested by DOE-STD-3009-94. However, as described in this section, the ISA spent fuel handling and storage activities are similar to those used by the independent spent fuel storage installations that were issued licenses under 10 CFR 72. These hazards include generation of combustible gases, failure of confinement barriers, defects in cask integrity, and the spread of external contamination.

D3.3.2.2 Hazard Classification. A final hazards categorization of the ISA facility was performed based on the final hazard analysis (SNF-4820) and accident analyses documentation for the facility. Consistent with DOE-STD-1027-92, the final categorization was based on the material-at-risk quantities identified in an individual cask inventory, as described in Section D3.4.1.1. The ISA material-at-risk quantities were compared against the DOE-STD-1027-92 threshold quantities. The ISA facility final hazard categorization found the ISA facility to be a Hazard Category 2 facility. This categorization level is consistent with the bases and guidance described in DOE-STD-1027-92.

The radioactive inventory for the 200 Area ISA is established in HNF-1755, *Initial Hazard Classification for the 200 Area Interim Storage Area, Project W-518*. HNF-1755 defines an inventory for safety analysis based on selecting the high-burnup fuel and fuel type that would result in the highest estimated dose to people exposed to the material, and then treating all the ISA fuel types as high-burnup fuel. The radioactive inventory for each of the ISA fuel types, as identified in HNF-1755, is presented in Tables D3-1, D3-2, and D3-3 for Fast Flux Test Facility
(FFTF) SNF; Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA) SNF; and light water reactor (LWR) SNF, respectively.

The established safety basis radiological nuclide inventory of each fuel type was used to estimate the material quantities available for release by multiplying the material at risk and the specific nuclide inventories for each fuel type. The material at risk was taken as the amount of fuel stored in an individual cask for each fuel type. These quantities were compared against the Category 2 threshold values from DOE-STD-1027-92, Table A.1 (see Tables D3-1, D3-2 and D3-3). The sum of the material inventory/Category 2 quantity thresholds is 354 for the FFTF fuel, 0.03 for the NRF TRIGA fuel, and 82.2 for the commercial LWR fuel. Since the sum of ratios is greater than one when compared to Category 2 threshold criteria for both the FFTF and LWR fuel, the ISA remains a Category 2 facility as identified during the preliminary hazard classification.

**D3.3.2.3 Hazard Evaluation.** The final ISA facility hazard analysis identified hazards associated with handling and storage operations to be used in the ISA. Standard industrial hazards were identified and removed from the list of facility hazards used to identify the DBAs. The results of the hazard analysis identified hazard scenarios in the ISA. These scenarios were used to define the ISA DBAs selected for further analysis in Section D3.4.2.

The external hazards from human-generated threats to ISA operation identified in Section D1.6 involve only those from aircraft activity. Nine active airports within a 24-mile radius of the ISA (HNF-1786) define a maximum credible evaluation basis aircraft impact for the ISA. Therefore, the ISA facility is adequately protected from this external hazard.

Evaluation of the hazards of nearby external human-generated activities that could represent a threat to the facility is an NRC-equivalency requirement that is specified in HNF-SD-SNF-DB-003. Section D1.7 identifies and addresses the threats to the ISA from nearby external facilities. As stated in Section D1.6, other threats to ISA operation from external human-generated activities that are not currently well known at this time will be evaluated by the unreviewed safety question process.

The ISA fire hazard analysis (SNF-4932) identified the fire hazards, fire loading criteria, and appropriate requirements for addressing fire hazards during ISA operation based on applicable DOE Orders and regulations. The findings of the ISA fire hazard analysis were incorporated into the design and engineering of ISA SSCs and controls (e.g., fire loads, inspections, and watches). Therefore, credible fire hazards are addressed in the design of the facility. Threats from nearby facilities are identified in Section D1.7 based on applicable DOE Orders and regulations. Credible threats from nearby facilities are addressed in Section D1.7.

Sum of the ratios: 82.17

LWR = light water reactor.
D3.3.2.3.1 Planned Design and Operational Safety Improvements. This section discusses commitments for planned, but not yet implemented, major design, handling, or storage improvements for the facility. However, there are currently no outstanding major improvements for improved safety identified or planned as a result of the hazard evaluation that are not part of the current design and planned facility operations.

D3.3.2.3.2 Defense in Depth. A summary of fundamental points relevant to the concept of defense in depth are described in Section 3.3.2.3.2 of the SNF Project FSAR.

Features Chosen to Provide Defense in Depth for the 200 Area Interim Storage Area

Defense-in-depth features for the ISA were selected based on a relative ranking of the hazards from the hazard identification process, followed by selection of the safety-class and safety-significant features and TSRs for the DBAs, which are described in Section D3.4.2. Preventive and mitigative features identified in the hazard analysis (SNF-4820) but not identified in the accident analysis as safety-class, safety-significant, or TSRs are identified as additional defense-in-depth features. The defense-in-depth features are presented in the tables that accompany each DBA in Section D3.4.2. The NRF TRIGA cask and DOT-6M container would be upgraded to Safety Significant for their significant contribution to defense-in-depth, but have already been designated Safety Significant based on the NRC important-to-safety classification. Administrative features identified in these tables are in addition to those already identified in Chapters D4.0 and D5.0, and the programmatic chapters of this Annex (e.g., Chapters D7.0, D8.0, and D11.0).

All SSCs are designed in accordance with applicable codes and standards with a high degree of reliability and simplicity, and the design encompasses human factors considerations to ensure that operations can be conducted safely. Defense-in-depth features for preventing and mitigating hazards and accidents have also been identified. An abnormal or accident cask is defined as one received out of specification or one that is dropped, impacted, or damaged at the ISA. Such casks will be handled using recovery operations under operations-related procedures. Recovery will be based on analysis and the development of a recovery plan by an appropriately qualified recovery team.

Safety-Significant Structures, Systems, and Components

Safety-significant SSCs are predominantly required to prevent or mitigate consequences of postulated accident events to the collocated on-site worker. In addition, DOE-STD-3009-94 suggests that SSCs be designated as Safety Significant, if they play a key role in defense in depth or worker safety. The severity of the event being prevented or mitigated, and the number of barriers present, are provided in DOE-STD-3009-94 as guidance for the identification of defense-in-depth safety-significant SSCs.
Technical Safety Requirements

TSRs were identified for postulated accident events that could challenge accident consequence release limits and evaluation guidelines for the off-site public and collocated on-site worker. These TSRs are identified in the individual DBA sections and further explained in Chapter D5.0. In addition, criticality prevention features are controlled by the TSRs, as identified in Chapter 5.0 of the SNF Project FSAR and in Chapters D5.0 and D6.0. No defense-in-depth features are identified as requiring TSR coverage.

D3.3.2.3.3 Worker Safety. Worker safety for the ISA is ensured by a combination of design features that reduce exposure to radioactive, toxic, and industrial hazards, and by institutional practices that, in total, provide protection of workers from these hazards. Protection of the facility worker from the standard industrial hazards identified for the ISA is achieved through adherence to the institutional safety programs described in Chapters 7.0, 8.0, 9.0, 11.0, 15.0, and 17.0 of the SNF Project FSAR and documented in lower-tier documents (e.g., health and safety plans and job hazards analyses). These industrial hazards do not require specific safety-significant SSCs or TSR-level administrative features. Therefore, in accordance with the guidance of DOE-STD-3009-94, the remainder of this section deals with protecting workers from the hazards of facility operation that are exclusive of standard industrial hazards.

The final ISA hazard analysis provides an overview of the major features that protect facility workers at the ISA (SNF-4820). Worker safety features are an integral part of facility design and operation. The major features of worker protection are identified in Table D3-4 and are categorized by hazard. The features presented in Table D3-4 are in addition to those identified as safety-class or safety-significant features in the DBA sections. The hazard energy source or material and hazardous condition are identified along with protective worker safety features, which include passive, active, and administrative features. SSCs are identified as Safety Significant for the ISA based on their ability to prevent or mitigate serious impacts to worker safety. The NRF TRIGA cask and DOT-6M container would be upgraded to Safety Significant for their significant contribution to worker safety, but have already been designated Safety Significant based on the NRC important-to-safety classification.

D3.3.2.3.4 Environmental Protection. The hazard to the environment from ISA operations involves the potential release of contaminants. The release pathway for these contaminants is only via the air to the boundaries and receptors discussed in Section D1.3.1.3. No liquid release hazards or accidents have been identified, and no contaminant releases to the ground or groundwater are involved for the ISA.

Based on the ISA design and operating information, no use of toxic chemicals has been identified. The toxicological hazards of the radionuclide inventory have been reviewed. As described in Section D3.4.1.1, the radiological guidelines are more limiting than the toxicological guidelines for any release from the material stored in the ISA. Implementation of the prevention and mitigation features will prevent large releases that could have significant environmental impact.

DOT = U.S. Department of Transportation.
FFT = Fast Flux Test Facility.
ISA = interim storage area.
ISC = interim storage cask.

LWR = light water reactor.
NAC = Nuclear Assurance Corporation.
TRIGA = Training, Research and Isotope Production, General Atomics.
TSR = Technical Safety Requirement.
The project features that protect the on-site collocated worker and the off-site public against radiological exposure also serve to prevent and mitigate radiological release to the environment. In addition, sitewide programs for environmental monitoring provide for assessment of the impact of facility releases. Normal ISA handling or storage activities are expected to have a minor impact on the local and regional environment.

**D3.3.2.3.5 Accident Selection.** The methodology for the selection of DBAs is specified in DOE-STD-3009-94. DBAs are to be selected so that the range of accident scenarios analyzed in the accident analysis represents a complete set of representative and bounding conditions. This is a common requirement among the SNF Project facilities and is described in Section 3.3.2.3.5 of the SNF Project FSAR. The list of candidate accidents resulting from the hazards binning process for the ISA facility is presented in Table D3-5. The table contains all identified Category S3 and S2 events. All of these events, and the controls selected for their prevention and mitigation, are described in Sections D3.4.2.1 through D3.4.2.7.

D3.3.3 Abnormal Events for the 200 Area Interim Storage Area Facility

Abnormal events are operating conditions resulting from situations outside of normal operations, where normal operations are defined by operation and maintenance procedures. These abnormal events encompass malfunctions of systems, operating upset conditions, or operator error. Abnormal events can be expected to occur annually or several times during the lifetime of the facility.

Abnormal events may impact operational or programmatic schedules; however, the consequences of the events are near zero or are standard industrial hazards that may include worker radiation exposure. Events having radiological consequences greater than allowed by the facility radiological protection and ALARA (as low as reasonably achievable) programs do not fit the abnormal event profile and are required to be analyzed as accidents by the DOE safety analysis process.

D3.4 ACCIDENT ANALYSIS

This section presents the methodology used to develop the DBAs identified in Section D3.3 and the results of the quantification of the consequences of those events. Also presented are the safety-class and safety-significant SSCs and TSRs related to these accident events that are necessary for protection of the off-site public and on-site workers. For each DBA, the following standard topics are discussed:

- Scenario development
- Source term analysis
- Consequence analysis
- Comparison to guidelines
- Summary of safety SSCs and TSRs.

D3.4.1 Methodology

This section identifies any ISA-specific methods, assumptions, or methodology used to quantify the consequences of the DBAs. The methods, assumptions, or methodology used to quantify the consequences of DBAs that are common or generic to all SNF Project facilities at the K Basins, Cold Vacuum Drying Facility, Canister Storage Building, and 200 Area ISA are described in Chapter 3.0 of the SNF Project FSAR.

D3.4.1.1 Source Term. Hypothetical release source terms are developed for each fuel type in this section. The 200 Area ISA inventory assumed for the analysis is based on a per cask basis and either includes seven FFTF interim storage cask (ISC) assemblies, all 101 TRIGA elements, or one LWR assembly.
For this report, values for the "inhalation dose factor" were taken from Federal Guidance Report Number 11, *Limiting Values of Radionuclide Intake and Air Concentration and Dose Conversion Factors for Inhalation* (EPA 1988). The computed committed dose for each radionuclide identified in the individual fuel types is calculated in Tables D3-6, D3-7, and D3-8. To indicate the relative importance of the various radionuclides to the total dose, the last column shows the fraction contributed by each nuclide to the total dose per gram inhaled. As can be seen from the table, the radionuclides that account for a majority of the unit doses are $^{238}$Pu, $^{239}$Pu, $^{240}$Pu, $^{241}$Pu, $^{242}$Am, and $^{244}$Cm.

Note that the unit dose value presented in these tables assumes the uniform mixture of spent fuel is present in the airborne material. In other words, all nuclides have the same release fraction. The hypothetical accident scenarios have a preferential release of gaseous nuclides and require summing of the contributions of individual radionuclides.

The SNF is primarily uranium oxide, and mixed uranium and plutonium oxide, which is known to have toxicological effects. However, the toxicological consequences of the release of these substances will not require additional mitigating features beyond those already required by the radiological doses.

**D3.4.1.2 Consequence Analysis.** For each SNF type, there is a bounding credible accident for which a maximum credible radiological release and dose consequence is determined. These radiological doses to a maximum duration exposed on-site and off-site receptor are estimated by using the following equation:

$$D = M \times \left[ \frac{X}{Q'} \times BR \times UD \right]$$

where

- $D$ = committed effective dose equivalent (CEDE) (Sv [rem])
- $M$ = unit mass of respirable material released (radionuclide mass per assembly)
- $X/Q'$ = time-integrated atmospheric transport factor (s/m³)
- $BR$ = breathing rate (m³/s)
- $UD$ = dose per unit respirable radioactive material inhaled (Sv/g [rem/assembly]).

The quantity of respirable material released ($M$) is determined by the specific accident scenario (e.g., crane fall or cask drop) for each accident. The parameters and values of $X/Q'$ and breathing rate ($BR$) are defined and specified in their respective analyses. The accident-specific, location-specific, release fraction and fuel type-specific on-site and off-site dose consequences are estimated from this formulation.

---

(2) Internal dose factor for tritium was increased by 50% to include skin absorption.

(3) The unit dose is the product of the normalized activity and the inhalation dose factor. To convert Sv/g to rem/g, multiply by 100.

(4) Kr-85 is a noble gas. It does not accumulate in the body; therefore, its internal dose factor is zero. The value shown is the external dose rate factor for submersion in an infinite cloud divided by the light activity breathing rate.

DP = daughter products (included with parents and not tracked individually).

Total: 2.82E+04 (Sv/Total)

\(^{(2)}\) Internal dose factor for tritium was increased by 50% to include skin absorption.
\(^{(3)}\) The unit dose is the product of the normalized activity and the inhalation dose factor. To convert Sv/g to rem/g, multiply by 100.
\(^{(4)}\) Kr-85 is a noble gas. It does not accumulate in the body; therefore, its internal dose factor is zero. The value shown is the external dose rate factor for submersion in an infinite cloud divided by the light activity breathing rate.

DP = daughter products (included with parents and not tracked individually).

Total: 1.62E+10 (Sv/Asmbly)

(2) Internal dose factor for tritium was increased by 50% to include skin absorption.
(3) The unit dose is the product of the normalized activity and the inhalation dose factor. To convert Sv/g to rem/g, multiply by 100.
(4) Kr-85 is a noble gas. It does not accumulate in the body; therefore, its internal dose factor is zero. The value shown is the external dose rate factor for submersion in an infinite cloud divided by the light activity breathing rate.

DP = daughter products (included with parents and not tracked individually).
The atmospheric transport factor \( \left( \chi/Q \right) \) is based on specific release conditions (e.g., ground level or elevated, long or short duration) and the receptor's distance from the release. While the methodology is common to the SNF Project, the atmospheric transport factor is the time-integrated normalized air concentration at the receptor's location, which is a measured distance from the Canister Storage Building. The transport factor includes the dilution of an airborne contaminant caused by atmospheric mixing and turbulence. The air transport values used in this report have been generated using the GXQ computer program (WHC-SD-GN-SWD-30002 and WHC-SD-GN-SWD-30003). Table D3-9 contains the air transport values used to determine on-site and off-site consequences.

Air transport factors were calculated using methods found in NRC Regulatory Guide 1.145, *Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants*. In each wind direction, the observed frequencies of particular wind speed and stability class combinations are used to compute a value that is exceeded only 0.5% of the time. This is repeated for all 16 compass directions to determine the worst-case location.

Exposures to the collocated worker on-site are calculated for the individual at the 100-m location. The risk evaluation guidelines apply to this individual. For assessment purposes, DOE has directed (Sellers 1996) that the Hanford Site boundary be considered the location of the off-site receptor. Highway 240 is not used as the nearest public access because DOE and its contractors can control access during emergency and accident conditions. This access control meets the requirements of 10 CFR 72.106(c).

\(^{(1)}\) Units for these values are seconds per cubic meter. In all cases, the releases are assumed to be point sources at ground level to maximize the dose consequences.

None of the accidents analyzed in this document adjusts the air transport factors for the finite size of the source (i.e., cask wake effects) or for the elevation of the release above ground level (i.e., stack effects). Section 1.4.1 of the SNF Project FSAR provides additional information on the calculation of the air transport factors. The basis for defining the location of the on-site and off-site receptors is provided in Section D1.3.1.3.

The breathing rate (BR) depends on individual activity factors and exposure duration. This methodology is common to the SNF Project facilities and is described in Chapter 3.0 of the SNF Project FSAR.

The dose per unit intake (UD) is the 50-year dose commitment for all relevant exposure pathways per gram of radioactive material inhaled. The major radiation exposure pathway for the identified accidents is inhalation of radioactive material. This methodology is common to the SNF Project facilities and is described in Chapter 3.0 of the SNF Project FSAR.

Hypothetical Release Fractions

An unmitigated release from each fuel type cask is evaluated to determine the appropriate safety classification of the engineered barriers that prevent an uncontrolled release. The hypothetical accident scenario developed in this analysis assumes a major failure of the cask with crushing of some fuel pellets. Some credit is taken for the physical presence of the cask around the fuel, even though its design confinement integrity has been breached. The hypothetical unmitigated release is developed based on the quantity of radioactive material that might be released if the fuel assembly or assemblies within the storage cask are damaged when the cask is breached. Although this scenario is hypothetical and non-mechanistic, the scenario establishes the magnitude of a potential release. Based on the postulated consequences of the unmitigated release, appropriate safety classification of the protection SSCs can then be accomplished.

For hypothetical purposes, a scenario is proposed involving a crane hook structure, with a weight of 2 tons falling from a height of 80 ft (but hypothetically retaining significant energy to crush the fuel after puncturing the cask sidewall). The tapered shape of the hook bottom is assumed to be about 2 in. across the leading edge, tapering out to about 5-in. thick at the throat of the hook. This hook creates a strong rigid projectile that (for this scenario) is hypothetically proposed to have enough energy to penetrate the cask sidewalls and shear all fuel rods contained within the cask and inner canister. This hypothetical accident results in clad damage to all of the elements and pulverization of some of the fuel that was directly struck by the crane hook. This accident would conservatively damage about a 7-in long cross-section of the fuel assembly. In this scenario, it only has sufficient energy remaining to crush half of the material damaged, which equates to about 2.5% of the fuel inventory in the cask. The effective impact energy density calculated for the hook structure falling from a height of 80 ft is 1.7E9 ergs/cm^3. Figure 4.11 of NUREG-1320 indicates that the mass fraction of particulate material less than
10 μm generated from this energy density is about 1.0% for ceramic fuel. Figure 4.15 (NUREG-1320) indicates that about 10% of the less than 10 μm particles are less than 3 μm, which is considered respirable for a particle with a density like uranium oxide. Credit is taken for the damaged cask structure retaining 90% of the particulate generated.

The parameters relating to fuel damage and release fractions for the postulated scenarios are listed below and in Table D3-10.

- Fraction of fuel pins damaged: 2.5%
- Gap noble gases, iodine, tritium: 100% released from damaged pins
- Gap particulates released: 1% released from damaged pins
- Particulates from crushed pins: 1%
- Respirable fraction of particulates: 10%
- Fraction of noble gases, iodine, tritium released from crushed pins: 100%
- Fraction of noble gases, iodine, tritium released from cask: 100%
- Fraction of particulates released from casks: 10%

The release is modeled to enter the environment as a ground level airborne release with a 1-hour duration. Radiological doses resulting from each of the postulated accidents were calculated for the maximum on-site worker and off-site individual. The analysis shown in the tables indicates that even for the extremely conservative postulated accident of an unmitigated release, radiation exposure to maximum off-site individuals would be less than 0.5 rem.

D3.4.1.3 Frequency Estimates. DOE Order 6430.1A requires that safety-class SSCs be identified if they are required to place or maintain an operating process in a safe condition when that process prevents or mitigates consequences to the public greater than 500 mrem (5 mSv) total effective dose equivalent, independent of the estimated event frequency. Therefore, the determination of frequency estimates is based on methodology common to the SNF Project facilities and is described in Chapter 3.0 of the SNF Project FSAR.

D3.4.1.4 Risk Guidelines. The DOE-recommended radiological risk evaluation guidelines (Sellers 1997) are applied across the SNF Project and are described in Chapter 3.0 of the SNF Project FSAR.

D3.4.1.5 Safety Structures, Systems, and Components. Safety-class and safety-significant designations, as related to the SSCs, are defined consistently for the SNF Project in Chapter 3.0 of the SNF Project FSAR.

(1) The average breathing rate is: light activity breathing rate.
(2) Guideline is for the "anticipated" accident category.

EDE = effective dose equivalent.

**D3.4.2 Design Basis Accident Analysis**

Although the 200 Area ISA is a new facility, the development of safety documentation for a new project per HNF-PRO-703, Safety Analysis Process - New Project, is different for this FSAR. The safety bases for the FFTF SNF and the TRIGA SNF storage systems and the 400 Area ISA site were approved under a DOE Richland Operations Office-approved safety
authorization basis at FFTF (WHC-TI-75002, Appendix H, Amendment 77 and Wagoner 1996). These storage systems and SNF types have been analyzed and approved for storage at the 400 Area ISA. Although these analyses were performed for the 400 Area ISA, information relevant to the performance of the FFTF and TRIGA storage systems at the 200 Area ISA can be derived from many of the analyses.

The existing analyses for the FFTF, TRIGA, and LWR spent fuel were evaluated for their applicability to the 200 Area ISA. The evaluations reviewed the assumptions, methodology, parameters, parameter values, results, and conclusions of the 400 Area ISA analyses for application to the 200 Area ISA. The results of these evaluations are provided in this section. The evaluations generally found that the analyses that relied solely on the performance and functional characteristics of the storage systems could be applied from the 400 Area ISA to the 200 Area ISA, but where site characteristics of the 400 Area ISA were not enveloped by the site characteristics of the 200 Area ISA, new analyses were performed.

The results of these evaluations and the 200 Area ISA site-specific analyses provide the bases to: (1) identify the hazards, energy sources, potential accident sequences, available mitigating barriers and controls, and qualitative estimates of accident frequency and consequence; (2) evaluate the most significant accident(s) to provide the technical bases for the conclusions related to safety, health, and the environment (e.g., final safety designation and comparison with risk guidelines); and (3) provide a final assessment of the design relative to maintaining its confinement function under normal, abnormal, and accident conditions.

This section presents a summary of the key assumptions and results of the DBA analyses that have been performed for the ISA. The DBAs are summarized based on the guidelines provided in DOE-STD-3009-94, and include the following categories:

- Cask handling/drop
- Mobile crane fall
- Cask tipover
- Fuel rod rupture
- Seismic
- Tornado/wind
- Fire.

The DBAs have been analyzed to quantify consequences and compare them with release limits for off-site consequences and evaluation guidelines for on-site consequences. The process is iterative, starting by taking no credit for mitigative features and comparing the results to the limits or guidelines. Credit is then taken for safety SSCs that prevent or mitigate the consequences to show that the results are below the release limits and evaluation guidelines. The process continues after the release limits and evaluation guidelines are met by identifying other SSCs that, while not designated as Safety Class or Safety Significant, provide additional mitigative features as defense in depth.
D3.4.2.1 Handling and Drop Accidents.

D3.4.2.1.1 Scenario Development. While handling the storage casks, an accidental drop or other handling impact could possibly occur. If the drop or impact caused a cask to undergo accelerations and forces beyond the design strength, the cask confinement could be breached. Breach of the cask confinement could result in radiological releases. In addition, as a passive design feature, each FFTF ISC and Nuclear Assurance Corporation (NAC)-1 cask protects the geometry of the stored SNF during and after impact to assure criticality safety. The handling and drop scenarios are developed in this section for each fuel type. A summary of the safety features required to prevent handling and drop accidents is provided in Table D3-11.

Fast Flux Test Facility Fuel

The FFTF fuel package consists of fuel assemblies or pin containers contained within a core component container (CCC), which in turn is contained within an ISC. One of the CCC drop analyses consists of a postulated drop into the ISC. Although the scope of this analysis does not include CCC removal from or placement in the ISC, the analysis provides a measure of the impact strength of the CCC to ensure that the CCC can remain intact inside the ISC for geometry (criticality) control. The ISC, with payload, has also been analyzed to ensure that confinement of the fuel is maintained.

The CCC was analyzed (WHC-SD-FF-DA-077) to confirm that it can safely withstand accident conditions. Fully loaded CCCs (six or seven fuel assemblies, or six pin containers) are addressed in WHC-SD-FF-DA-077, Stress and Structural Analysis of the Core Component Container (CCC), and SNF-4790, 200 Area ISA Design Basis Accident Analysis Documentation for FFTF Fuel. Partially loaded CCCs are not analyzed, and must be evaluated on a case-by-case basis. Material properties were evaluated using a peak CCC temperature condition of 600 °F. Normal CCC conditions were evaluated in accordance with stress limits of the ASME Code, Section VIII, Division 2 (ASME 1989), and the accident conditions were evaluated in accordance with stress limits of the ASME Code, Section III, Appendix F (ASME 1989).

The accident conditions analyzed for the CCC are as follows:

- 18-ft drop of the CCC into the ISC
- 4-ft sideways drop of the CCC while inside the ISC.

Several drop analyses have been performed for the ISC. Under normal operations, the ISC is lifted vertically by attaching the lifting fixture to three anchor attachments imbedded in the concrete of the ISC. No side lifting is allowed. In accordance with the critical lift requirements of DOE/RL-92-36, Hanford Site Hoisting and Rigging Manual, the ISC lift points are designed to lift five times the weight of the cask, without exceeding the ultimate stress of the material, or three times the weight, without exceeding the yield strength of the material, whichever is less. Therefore, the normal ISC lifting and handling loads generate low stresses.

(1) Checklist designators are from SNF-4820, 1999, 200 Area Interim Storage Area Final Hazard Analysis, Rev. 0, Fluor Daniel Hanford, Incorporated, Richland, Washington.

2R = inner container of DOT-6M.
CCC = core component container.
DOT = U.S. Department of Transportation.
FFTF = Fast Flux Test Facility.
ISC = interim storage cask.
LWR = light water reactor.
NAC = Nuclear Assurance Corporation.
NRF = Neutron Radiography Facility.
TRIGA = Training, Research and Isotope Production, General Atomics.
TSR = Technical Safety Requirement.
The weakest link in the ISC attachment design is the anchor lug, which screws into the anchor bolt of the cask. If a lifting accident occurs whereby a lift point fails, this anchor will fail before the ISC concrete embedment. Thus, the ISC integrity or shielding will not be affected.

The accident conditions analyzed for the ISC are as follows:

- 18-ft drop of the CCC into the ISC
- 4-ft sideways drop of the ISC
- 4-ft ISC drop onto an unyielding surface
- 8-ft ISC drop with the CCC inside onto a 1.5-ft thick concrete pad
- ISC drop onto another object
- 40-in. ISC drop onto a 6-in. diameter mild steel punch.

**18-ft drop of the CCC into the ISC.** The ISC internal impact limiter is used to absorb the impact of a fully loaded CCC from a height of 18 ft. The impact limiter consists of a 1.5-in. layer of aluminum honeycomb, with a compressive strength of 4,400 lbs/in², and a CCC impact area of 153 in².

The dynamic finite-element analysis (WHC-SD-FF-DA-077) shows that the CCC will remain intact during and after the 18-ft vertical drop into the ISC, and the CCC boundary will provide adequate sealing during and after the drop. The results of the stress evaluation indicate that the stresses in some of the components exceed the yield strength but they are within the stress limits of the ASME Code, Section III, Appendix F (ASME 1989). The magnitude of the CCC tube plastic deformation does not affect the integrity of the CCC or the seals. The critical component of the CCC for membrane stress is the central tube of the CCC. The maximum membrane compressive elastic stress is 37,313 lbs/in², which is less than the allowable 39,360 lbs/in².

If an assembly is stored in the center tube of the CCC, it will rebound and hit the CCC cover and the bolts, and the seal region will remain elastic. The impact limiter over the central tube limits the load to the socket region of the CCC cover to 8,000 lbf. The metal O-ring seal of the CCC cover will have a maximum opening of 0.005 in., which is within the manufacturer's deformation limit to retain sealing effectiveness. The seal will neither lose contact with the cover nor with the upper support flange. The CCC cover bolts are subject to a tensile stress of 61,666 lbs/in², which is less than the allowable 119,000 lbs/in².

**4-ft sideways drop of the CCC while inside the ISC.** The CCC, inside the ISC, is subjected to a 96.1-g maximum side loading during a 4-ft drop (General Atomics 1995). The ISC remains leaktight during this event. If it is assumed that the CCC rests on the ISC wall, the results show that the CCC material will not exceed the yield strength of the materials. Thus, no permanent deformation will occur.
If it is assumed that the CCC has 0.5 in. that can be deflected within the ISC liner, the dynamic finite-element analysis case shows that the elastic stresses in some of the components exceed the yield strength, but they are within the stress limits of the ASME Code, Appendix F, Section III, Division 1 (ASME 1989). The conditions of this analysis assume that the fuel element within the CCC hits the tube wall, and then the tube wall and element move together and hit the side of the ISC. The stress results show the bending stress in the storage tube is 51,608 lbs/in², which is less than the membrane-plus-bending stress allowable of 59,040 lbs/in². The magnitude of the plastic deformation is not expected to affect the integrity of the CCC because stresses are within allowable limits. Note that a 0.5-in. gap is not expected because the CCC will rest on the wall of the ISC during the drop.

4-ft ISC drop onto an unyielding surface. The 4-ft drop analysis consists of two separate drops: an end-drop and an angle drop with slap down. The maximum stresses on the ISC confinement barrier due to the 4-ft end-drop condition onto an unyielding surface occur in the 1.5-in. thick inner cylinder. A shell/ring discontinuity analysis was used to determine the stress at the upper flange-to-cylinder junction, and the maximum stresses were determined to be only 16.54 ksi. The g-level during a 4-ft drop onto an unyielding surface is between 70 g and 96 g. The stresses are within the normal condition allowable limits. Additionally, the bolt stress due to the flange rotation is within normal limits. Therefore, the ISC closure will not be affected during the accident conditions, and the sealing integrity is maintained.

The maximum calculated stress on the ISC confinement barrier occurs during the ISC slap down from an angled 4-ft drop. The maximum stress component is the inner 1.5-in. thick cylinder. The maximum stress that occurs for this condition is 17.4 ksi, and the maximum shear stress is 3.9 ksi. These stresses are within limits.

For the drop accidents, strength of material calculations following the methods of ACI-349, Code Requirements for Nuclear Safety Related Concrete Structures, indicate that the steel and concrete composite shielding sections of the cask will not be compromised during the drop events. The maximum amount of concrete crush during this accident is 6 in.

8-ft ISC drop onto a 1.5-ft thick concrete pad. The 4-ft drop analyses were conducted assuming a hard, unyielding surface. However, the ISA storage pad is a 1.5-ft thick concrete pad that will absorb much of the impact energy. To ascertain the effects of a yielding surface, an analysis was also performed for an 8-ft drop onto a 1.5-ft thick concrete pad. The highest g-level is 46 g. Analyses of these drops (SNF-4790) show that they are bounded by the 4-ft drop onto an unyielding surface.

Based on the drop scenarios postulated, confinement and geometry control are not lost for an 8-ft drop of the ISC package (including the CCC and fuel payload) onto the 200 Area ISA storage pad.
**ISC drop onto another object.** The ISC could be moved over other objects during handling. If the ISC drops onto an object, the ISC could strike the object and then tip over, resulting in a horizontal drop onto the 200 Area ISA storage pad. If the object struck by the ISC is taller than 4 ft, the horizontal drop will be outside of the bounds of the drop analyses. Therefore, the ISC is assumed to not be moved over objects that are taller than 4 ft. Note that the cask trailer is less than 4 ft tall.

**40-in. ISC drop onto a 6-in. diameter mild steel punch.** The ISC was evaluated for the hypothetical accident condition 40-in. drop of the ISC onto a 6-in. diameter mild steel punch. Conservatively, 1.3 times the weight for casks with diameters less than 30 in. was used. Only the concrete is used to stop the punch, even though there is enough steel to stop the punch also.

It was concluded that the ISC is of sufficient thickness to preclude punching shear failure. The primary stresses across the cask cross-section and the closure and bottom plates due to a puncture drop event are always less than 26.2 ksi, which are less than the allowable values of 63.3 ksi for primary membrane plus bending stress. The stainless steel closure, and bottom plate, and the cask body sidewall are of sufficient thickness to preclude punching sheer failure.

**NRF TRIGA Fuel**

The NRF TRIGA fuel could arrive at the ISA storage pad in either casks or U.S. Department of Transportation (DOT)-6M containers, which are then placed into the Rad-Vault storage container for long-term storage. During handling operations, an NRF TRIGA cask, DOT-6M container, or Rad-Vault could be involved in a drop accident. Handling and drop analyses were performed to analyze the effects of drops. The following are the types of drops that could result in significant impact to one of the NRF TRIGA packages:

- Cask drop onto another cask or Rad-Vault
- Rad-Vault lid drop
- NRF TRIGA cask drop
- DOT-6M container drop.

**Cask drop onto another cask or Rad-Vault.** The cask drop onto another cask or Rad-Vault is bounded by the crane boom impact analysis discussed in Section D3.4.2.2, and is not addressed further in this section.

**Rad-Vault lid drop.** The Rad-Vault is not lifted while loaded with contents or with the lid in place (CNSI 1992). The Rad-Vault lid will be placed over the body after the cask or DOT-6M container is placed inside. The lid of the Rad-Vault, if dropped, will not drop onto the cask or DOT-6M containers stored in the Rad-Vault because the cylindrical design physically precludes this event (the outside diameter of the lid [114-in.] is much greater than the inside diameter [79-in.] of the vault body). Rad-Vault handling limits (TSR) preclude lifting the Rad-Vault cover more than 0.3 m (12 in.) above the top of the Rad-Vault in order to minimize...
potential structural damage to the Rad-Vault. Therefore, no scenario has been identified that would release radioactive material as a result of dropping the Rad-Vault lid.

**NRF TRIGA cask drop.** During handling operations, any one or all of the NRF TRIGA casks, DOT-6M containers, or the Rad-Vault could be involved in a drop accident that threatens the confinement. A handling/drop analysis was performed (WHC-SD-FF-TI-043) to analyze the effects of a credible drop. In reality, the worst-case off-normal handling scenario would be the dropping of an NRF TRIGA cask onto one or more other casks. The Rad-Vault is in place before any fuel is moved, and the DOT-6M containers are the last to be loaded into the Rad-Vault and the first to be removed. A cask-on-cask drop is bounded by the crane boom drop accident. The lid of the Rad-Vault, if dropped, will not drop onto the fuel casks or containers already stored in the Rad-Vault because the cylindrical design physically precludes this event. The analysis demonstrates that under credible drop conditions, the NRF TRIGA casks and DOT-6M containers do not release radioactive material. The 10 ft/min set down load was equated to a 1-ft drop and determined to be bounded by the 109-in. NRF TRIGA cask drop without the impact limiters and the 30-ft DOT-6M container drop with impact limiters. However, to preclude exceeding the design criteria and the analyzed conditions, lifting limits have been imposed and are identified in Section D3.4.2.1.5.

**DOT-6M container drop.** Tests were performed on DOT-6M shipping packages (with 2R inner containers) to evaluate their response to a drop from 9 m (30 ft) onto an unyielding surface, and a 1-m (40-in.) drop onto a steel punch bar. A detailed observation of the packages following the drop testing showed the bolts to be tight and no damage to other areas that would indicate the possible loss of confinement (Martin Marietta 1992).

The two DOT-6M containers will have TRIGA fuel follower control rod (FFCR) payloads instead of the standard fuel payload. The only differences between the packages tested and the TRIGA FFCR configuration are the type of seal used in the 2R inner container, and the anticipated contents within the packages. The drop-tested packages used an elastomeric O-ring seal, whereas the TRIGA FFCR shipping packages will use a metallic O-ring seal to assure that long-term storage requirements are met. In addition, the drop-tested package used can-and-bottle internal containers, whereas the TRIGA FFCR shipping packages will contain stainless steel clad fuel rods enclosed in stainless steel pipe. The TRIGA FFCRs are not externally contaminated and the solid hydride fuel itself is enclosed within the stainless steel cladding, which has been demonstrated not to leak.

The loaded DOT-6M container has been shown to survive drops at heights greater than the NRF TRIGA cask. However, to ensure that administrative controls are easily promulgated into field operations, the administrative restriction for the NRF TRIGA cask maximum lift height is conservatively applied to the DOT-6M containers (21 in. above the top of the Rad-Vault, with the lid removed).
Light Water Reactor Fuel

A 250-ton crane is used to place the NAC-1 storage casks within the associated International Standards Organization (ISO) shipping containers at the 200 Area ISA. The worst-case handling or drop scenario is for the NAC-1 cask to be dropped during cask handling or transfer operations. Administratively, only one cask/container will be handled at a time, and maximum lift heights are imposed based on this analysis.

The NAC-1 casks are transported and placed at the 200 Area ISA while inside ISO containers. The presence of the NAC-1 cask within the ISO shipping container was not considered in the NAC-1 SAR bounding cask drop scenario. However, the cask tie-down devices (cask rotation trunnions) are designed to fail under excessive loads in the trunnion tubes, such that cask integrity and shielding are not affected. During the postulated drop events, the cask mounted within the ISO shipping container provides additional energy absorption capabilities that were conservatively ignored in the accident analysis. Thus, the NAC-1 cask drop is assumed to be bounding over the ISO container drop.

The types of handling and drop impacts analyzed for the NAC-1 cask are as follows:

- Drop onto unyielding surface in various orientations
- Drop onto steel rod
- Drop onto another object.

**Drop onto unyielding surface in various orientations.** Lawrence Livermore National Laboratory document UCID-21246, *Dynamic Impact Effects on Spent Fuel Assemblies*, assessed the effects of dynamic impacts (to be expected from cask drop or tipover incidents) on the integrity of the fuel rod cladding for zircaloy-clad LWR spent fuel assemblies during cask handling and storage. The conclusions of this report define acceptable g-load limits for fuel assemblies internal to the package and state:

"The analysis of the capability of spent fuel rods to resist impact loads caused by storage cask accidents indicates that, for the most vulnerable fuel assembly, axial buckling varies from 82 g at initial storage to 95 g after 20-year storage. In a side drop, no yielding is expected below 63 g at initial storage to 74 g after 20-year storage. For storage casks designed to limit loads at or below these g levels, it is not likely that damage will occur to the spent fuel rods."

Individual fuel rods stored in the NAC-1 casks are packaged in containers that retain the cross-sectional geometry within the inner canisters. The individual rods therefore remain oriented similar to the rods in the fuel assemblies and are subject to similar buckling loads and conclusions.
The drop onto an unyielding surface also considers potential impacts to the shielding associated with the NAC-1 cask. The drop analyses (NAC 1990) consist of a postulated 30-ft drop onto an unyielding surface in the following orientations:

- Top end impact
- Top corner impact
- Side impact
- Bottom end impact
- Bottom corner impact.

**Top end impact.** The top end impact analysis focuses on the crush strength and crush area of the balsa wood in the upper impact limiter, and assumes that the balsa crush strength and crush area are constant during the impact event. The analysis also investigates the bending of the cask ring structure to ensure that the ring structure has sufficient rigidity as a base for the compressive loads of the balsa. This analysis concludes that the stress of the material in the ring structure is well below the yield strength and will provide a sufficient base (without yielding) for the impact limiter to crush against. The analysis also determined the impact deceleration loads for the top impact condition would not exceed 44.67 g, which is within the 82 g allowable.

**Bottom end impact.** The analysis for the bottom end impact assumes that the impact energy transferred to the bottom of the cask is attenuated by the lower ring structure. During normal operation, the lower ring structure is designed with enough rigidity to be used as a pedestal when the cask is in the upright configuration. However, it also functions as a sacrificial structure that deforms to dissipate impact energies. The representative analysis of the impact indicates that the bounding deceleration load is 76.6 g, which is within the allowable load of 82 g.

This calculated information was used as an input value to determine if the lead shielding (located between the inner and outer cask shell) settles or slumps, based on the magnitude of the deceleration load. The analysis determined that the 1-in. step provided in the top flange between the shells is adequate to keep the lead from slumping. This analysis neglected the resistance imposed by the copper heat transfer fins and the radial support provided by the inner and outer stainless steel shells. It was also determined that the lead will not yield in direct shear to allow the lead to slump by shear into a void region left by the original placement melt.

**Side impact.** Impact on the side of the cask is attenuated by deformation of the top and bottom ring structures, the expansion chamber, and the neutron shield chamber. Since the neutron shield chamber is empty, these four components are considered to be sacrificial. The analysis documented the energy capacity of the various components separately and plotted the values versus a common parameter. The composite energy absorption capacity of the structure was then equated to the total impact energy to arrive at the deformation impact to the sacrificial structures. From this approach, it was determined that the bottom ring structure will deform.
approximately 8.75 in. and the top ring structure will deform 7.5 in., absorbing the impact energy as designed, which results in an adequate and acceptable condition.

The ring structure was analytically checked for buckling in the side drop analysis. The analysis determined that the critical buckling stress of the inner portion of the ring structure is in excess of the dynamic compressive yield strength of the material. Therefore, compression yielding precludes buckling, and the side impact deformation analysis is adequate.

The side impact deceleration load was determined in order to evaluate whether the load imposed by the lead shielding on the inner stainless steel liner is great enough to cripple the liner. The deceleration load was determined to be 96 g on the lead between the inner and outer shells. The analysis assumed that the lead will act as a fluid. As such, it was determined that the hydrostatic pressure on the inner shell imposed by the lead will be 260 lbs/in². Analyses in the NAC-1 SAR for the contraction of molten lead around the inner shell during cask fabrication indicate that the inner shell withstands hydrostatic pressures of up to 506 lbs/in². Thus, the 260 lbs/in² imposed by the lead during the drop is within allowable pressures for the inner shell.

The side impact deceleration load was also compared against the allowable g-loads for the fuel assemblies. The 96 g deceleration load includes a peaking factor of 2.0, multiplied in the equation to calculate the force on the lead shielding and the inner shell due to the lead. The acceleration within the inner shell does not require the peaking factor, since it was used to consider local effects at the end stiffening rings, which are subject to large deformation. These deformations were calculated to be 8.75-in at the lower ring and 7.5-in at the top ring. The maximum g load is calculated as the drop height (30 ft or 360 in.) divided by the minimum crush distance (7.5 in). Therefore, \( G = \frac{360}{7.5} = 48 \) g applied to the fuel assemblies for the side drop of the NAC-1 cask. This is below the 63 g load required to cause yielding of the fuel assembly; therefore, no loss of structural integrity is expected for the side drop of the NAC-1 cask.

**Top corner impact.** This analysis investigates the loads imposed on the top of the cask structure when subjected to a top corner impact. Component calculations include the shearing resistance of the top impact limiter, the top corner impact deceleration loads, and the top corner impact bolt stress. The calculation determines that the loads imposed by the top corner impact are less than the bolt preload stress, which results in an adequate and acceptable condition.

**Bottom corner impact.** The bottom corner impact energy was analyzed assuming the maximum damage to the cask would be in the area where a drain valve is directly over the point of impact. The kinetic energy in the cask was assumed to primarily be dissipated by the major impact limiter components (i.e., the balsa, the shock tube, the gusset plates and the fin plates). Load models were developed to determine deformation loads and dissipation energies. The analysis concluded that cask kinetic energy can be absorbed by deformation of the sacrificial components external to the base of the cask that contains and surrounds the drain penetrations and minor deformation of the cask boundary. This area was considered safe during this design impact loading.
For the 30-ft drop in various orientations onto an unyielding surface, the NAC-1 SAR analyses conclude that the confinement and shielding integrity of the NAC-1 cask will be maintained, although significant damage will occur to the exterior, sacrificial structures of the cask.

**Drop onto steel rod.** This accident scenario evaluated the cask free-fall of 40-in. onto the end of a mild steel pin to ensure that no loss of confinement occurs. The analysis (NAC 1990) evaluated three locations determined to be the most likely for maximum damage to occur. These locations are as follows:

- Impact on the midspan of the cask body
- Impact of the side of the cask lid
- Direct impact on a valve.

For the impact on the midspan of the cask body, the outer shell of the cask was analyzed in relation to the 40-in. free drop. Dropping the cask such that the pin impacts the midsection of the outer shell imposes the greatest bending moment into the cask. The analysis determined that the maximum stress is small compared to the allowable stresses and that little, if any, damage to the cask will result from this drop.

The second analysis investigated the impact of the pin on the cask lid from the 40-in. drop height. The analysis determined that the cask lid bolts are not loaded in shear since the clearance between the cask lid and flange is less than the bolt hole clearance. The analysis concluded that the cask lid would be radially displaced $4.4 \times 10^{-3}$ in. at the flange seal interface. Since the NAC-1 cask is not a confinement boundary, this result has no safety consequence.

The third analysis for this section evaluated the pin loading from the 40-in. free drop of the cask on a confinement valve. The valves are recessed within the stainless steel flanges at the closure (top) end of the cask. The valves do not protrude from the cask nor are they located in trunnions. This design approach provides protection for the valves by the inherent stability of the flange sections in this hypothetical accident scenario. The analysis of the valve impact on the steel rod concluded that steel flanges will adequately protect the valves.

For the 40-in drop onto a steel rod, the NAC-1 SAR analyses concluded that the confinement and shielding integrity of the NAC-1 cask will be maintained. Only minimal damage to the cask, namely the localized deformation and slight puncture of the shield tank, will be incurred.

**Drop onto another object.** The analysis for the drop of the NAC-1 cask does not consider impact onto another object and subsequent potential slapdown. Therefore, it is assumed that the NAC-1 casks will not be lifted over other objects except the transport trailer.
D3.4.2.1.2 Source Term Development. For handling and drop accidents, there is no source term from any of the fuel packages for the events postulated and analyzed in the scenario development for any of the package types. However, the events and analysis depend on initial conditions that could be violated during operations. For example, the ISC has been shown to survive an 8-ft drop onto the 200 Area ISA pad, but a drop from a higher distance will represent an unanalyzed condition. If a drop occurs from a distance higher than those analyzed, catastrophic damage is not expected because of the margin and conservatisms in the analyses. But since the package responses are unknown, a drop from heights greater than those postulated in the scenario development are bounded by the source terms calculated for the worst-case, non-mechanistic release shown in Section D3.4.1 for each fuel type.

D3.4.2.1.3 Consequence Analysis. All of the package types have been shown to maintain confinement of the fuel for the handling and drop events postulated and analyzed in the scenario development. In addition, the analyses have shown that shielding is maintained. For the events analyzed, there are no on-site or off-site releases of hazardous materials and no direct radiation hazards to workers greater than those expected during normal operations. A consequence analysis is not needed for the FFTF, TRIGA, or LWR fuel storage systems.

D3.4.2.1.4 Comparison to Guidelines

Unmitigated event – For drops that exceed the initial conditions of the analyses, the bounding consequences for each fuel type show that the off-site release limits are not challenged. Therefore, no safety-class confinement SSCs are necessary.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following a handling or drop accident, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However, the NRF TRIGA casks do provide structural protection of the SNF payload in the event of a drop, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

For the FFTF fuel and the LWR fuel in the NAC-I casks, the bounding on-site consequences for drops outside of the initial conditions analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

While no safety-class SSCs are required to provide confinement, some SSCs are required to protect the geometric configuration of the fuel for criticality safety. SSCs credited with retaining the critically safe geometry of the fuel are designated as Safety Class.

Mitigated event – For the handling and drop events postulated and analyzed in the scenario development, the potential releases are prevented. These events take credit for the
packaging components and limitations on handling (e.g., lift height) that have been shown to provide the impact protection and confinement of the fuel for the analyzed drop events.

**D3.4.2.1.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls.** The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from inadvertent nuclear criticality during and following a drop event.

**Fast Flux Test Facility Fuel**

The following SSCs are designated as Safety Significant or Safety Class:

- **FFTF ISC** – The ISC is designated as Safety Significant to maintain confinement of radioactive materials after a credible drop and to provide passive protection of the CCC such that it retains structural integrity.

- **CCC** – The CCC is designated as Safety Class to maintain structural integrity to provide criticality geometry control.

The following TSR controls are necessary to protect the assumptions made in the drop analyses:

- **Lift height restriction** – The ISC cannot be lifted more than 8 ft from the surface of the 200 Area ISA pad.

- **Lift over object restriction** – The ISC cannot be lifted over an object that is taller than 4 ft or contains radioactive material.

**NRF TRIGA**

The following SSCs are designated as Safety Significant:

- **NRF TRIGA casks** – The TRIGA casks are designated as Safety Significant for NRC important-to-safety considerations to maintain confinement of radioactive materials after a credible drop.

- **DOT-6M container** – The DOT-6M containers are designated as Safety Significant for NRC important-to-safety considerations to provide impact absorption to maintain structural integrity for the 2R container.

- **2R container** – The 2R containers are designated as Safety Significant for NRC important-to-safety considerations to maintain confinement of radioactive materials after a credible drop.
The following TSR controls are necessary to protect the assumptions made in the drop analyses:

- **Lift restriction** – Based on the assumptions made in the drop analyses, the NRF TRIGA casks and DOT-6M containers cannot be lifted more than 109 in. (approximately 9.1 ft) from the surface of the ground at the 200 Area ISA.

- **Lift restriction** – The Rad-Vault cover shall not be lifted more than 12 in. above the top of the Rad-Vault.

**Light Water Reactor Fuel**

The following SSCs are designated as Safety Significant or Safety Class:

- **NAC-1 cask** – The NAC-1 cask is designated as Safety Significant to provide passive protection of the inner canister such that it retains structural integrity after a credible drop.

- **LWR canister** – The LWR canister is designated as Safety Significant to maintain confinement of radioactive materials after a credible drop and Safety Class to maintain structural integrity for criticality geometry control.

The following TSR controls are necessary to protect the assumptions made in the drop analyses:

- **Lift restrictions** – The NAC-1 package cannot be lifted more than 30-ft from the surface of the 200 Area ISA storage pad.

- **Lift over object restriction** – The NAC-1 package cannot be lifted over other objects except the transport trailer.

**D3.4.2.2 Mobile Crane Fall.**

**D3.4.2.2.1 Scenario Development.** While handling the storage casks, an accident could possibly occur. The casks will be picked up and transferred from current locations at the 400 Area ISA and the 300 Area, and set down at the 200 Area ISA by a substantial crane. It is likely that different mobile cranes will be used in the different areas. The FFTF crane is the Manitowoc 4000W crawler, and the 200 Area ISA crane will be a Manitowoc 250T mobile crane. The 250T Manitowoc crane is considered bounding, and analyses were performed based on the structural components of this crane.

A mechanical failure could initiate a drop of a crane boom onto the SNF storage systems. If the impact caused forces beyond the design strength, the cask containment could be breached.
Breach of the cask containment could result in radiological releases. The casks also protect the inner canister, which maintains the geometry of stored SNF to meet any criticality safety concerns. The crane boom was demonstrated to buckle under the lateral impact load before it can impart sufficient energy to breach the cask systems (SNF-4794). A summary of the safety features required to prevent the mobile crane fall accident is provided in Table D3-12.

Table D3-12. Summary of Safety Features Required to Prevent Mobile Crane Fall Accident.

TSR = Technical Safety Requirement.
Fast Flux Test Facility

Previous 400 Area ISA analyses (WHC-SD-FF-DA-078) were performed to assess the damage that a crane boom drop onto the ISC could have on its containment function. The analysis assumed that the crane was a Manitowoc 4000W crawler and stated that the results required additional evaluation for any other crane or for the same crane at a different elevation above the top of an ISC. A supplemental analysis has been prepared for the 200 Area ISA that evaluates the effects of using the 250T Manitowoc crane at the 200 Area ISA (SNF-4794).

Conservative analysis shows significant damage to the outer concrete of the ISC from the crane boom drop or crane hook drop, but the inner steel confinement and shields will not be damaged by the event. Under these conditions, the ISC will not credibly lose its containment.

NRF TRIGA

A mobile crane fall event was assessed that assumed a mechanical failure of the crane that resulted in the boom falling onto the Rad-Vault. The Rad-Vault and NRF TRIGA cask were originally procured as general-service items, so no credit was taken for the protection they provide to the fuel assemblies. The Rad-Vault is 2.9 m (114 in.) in diameter by 2.8 m (111 in.) high. Failure of the crane would only impact a fraction of the fuel assemblies. It is not expected that the full length of any assembly would be crushed. It is assumed that the isotope activity of the entire inventory of the Rad-Vault (101 fuel elements) is equal to 101 times the isotope activity of the maximum irradiated fuel element. The assumptions used to model the unmitigated release bound this potential boom drop accident scenario and are within guidelines. No features are credited to prevent or mitigate this TRIGA fuel accident.

Light Water Reactor Fuel

An analysis was performed to determine if the impact on the NAC-1 storage cask from the postulated crane boom drop was sufficient to breach cask confinement (SNF-4794). The analysis compared the boom drop accident to the cask 30-ft drop and 40-in. puncture drop accident events that were previously analyzed in the NAC-1 SAR (NAC 1990). The presence of the ISO shipping container was not included in the analysis. This assumption is conservative since the shipping container is assumed to act as protection for the cask by absorbing some of the energy and distributing the load imparted to the cask during the crane boom drop. The analysis of the crane boom drop concludes that the crane boom will fail before it can impart sufficient load on the cask to breach confinement. Local lacing members in the boom fail at the point of impact and the boom structure collapses, relieving the load and subsequent energy imparted to the cask.
Cask Energy Absorption. The response of the cask to the 30-ft side impact drop is appropriate for comparison to the boom drop effects. In a side drop, the SAR analyses show that the cask top and bottom end ring support structures, along with the neutron shield chamber, can absorb approximately $23 \times 10^6$ in-lbs of energy without breach of confinement. These members are considered totally sacrificial structures and energy absorption is achieved by means of considerable crushing of these structures. The crane boom is 80 ft long and weighs 22,490 lbs. The potential energy of the boom falling from the vertical position is $11 \times 10^6$ in-lbs. The reaction forces on the cask at the end ring support structures for the crane boom drop are therefore enveloped by the existing 30-ft drop accident analysis.

Cask Bending Moment. The maximum bending moment of the cask was also evaluated during the crane boom drop event and compared with the bending moment imparted to the cask during the 40-in. puncture drop (SNF-4794). Impact on the midspan of the cask was considered the most critical point for beam-bending of the cask. The analysis of the cask bending moment during the crane boom drop shows that the maximum reaction force the boom can impart on the cask during impact is $2.9 \times 10^5$ lbs at the mid-point of the crane boom. This value compares with an allowable force of $6.8 \times 10^5$ lbs that would be required to impart the equivalent bending moment analyzed in the 40-in. drop analysis. Thus, the bending moment of the cask during the crane boom drop event is approximately a factor of two times less than that found acceptable in the previous NAC-1 SAR analysis.

Cask Puncture Resistance - Crane Boom. The cask’s resistance to puncture during the crane boom drop event was also analyzed (SNF-4794). The analysis concluded that the maximum reaction force that the crane boom could impart to the cask was $2.9 \times 10^5$ lbs. This compares to the calculated value of $6.9 \times 10^5$ lbs required for the bottom cord members of the crane boom to puncture the cask’s ¾-in. outer shell. Thus, puncture of the cask’s outer shell by the crane boom is not expected.

Cask Puncture Resistance - Load Block. An analysis was performed to evaluate the ability of the 4,000-lb load block at the end of the crane boom to puncture the cask (SNF-4794). The load block has a massive hook with about a 2.5-in. leading edge that results in an initial contact area between the block and the cask that is less than the area of the 6-in. diameter pin in the 40-in. drop accident. The maximum lift height of the load block above the cask is 75 ft. The results of the analysis conclude that although the cask will suffer physical damage, the integrity of the cask will be maintained in the maximum block height condition. Conservatively, a value of 56 ft will be used as limiting criteria for the block height over a cask/ISO container system (SNF-4794). This height provides sufficient overhead clearance to perform all rigging and hoisting activities at the ISA.

Cask Puncture Resistance - Hydraulic Spreader Bar. An analysis was performed to evaluate the capability of the 20,610-lb hydraulic spreader bar, connected at the crane hook, to puncture the cask if accidentally dropped (SNF-4794). The hydraulic spreader bar is a massive lifting fixture for the ISO containers. It has a frame of large tubular channels that allow it to
telescope in length. It also has attached positioning guides at each corner that protrude downward 15 in. beneath the corner connecting devices. These alignment plates are 0.75 in. thick by 8 in. across. The analysis evaluated bending loads from a drop accident where the fixture lands at a single point on its side, and then assessed the puncture potential from a flat drop that lands on a single alignment plate as the worst-case leading edge for the puncture. The results of the analysis conclude that bending is the controlling parameter that establishes the requirement for a maximum permissible lift height. Although the cask may suffer physical damage, the confinement integrity of the cask will be maintained by imposing a maximum height condition of 6 ft above the ISO container lid, approximately 14.75 ft above the ground (SNF-4794). This height provides sufficient overhead clearance to perform all rigging and hoisting activities at the ISA.

The analysis of crane boom, load block drop, and hydraulic spreader bar drop scenarios do not take credit for the presence of the ISO shipping container. The cask, as mounted in the ISO shipping container, is designed to shear at the lifting and rotation trunnions during an impact event, while maintaining cask integrity (NAC 1990). Since the ISO shipping container is not required to survive the crane boom and load block drop accidents, it provides no safety function for this accident.

D3.4.2.2.2 Source Term Analysis. Current analyses for the FFTF and LWR NAC-1 casks demonstrate that complete confinement of the SNF will be maintained during and after the analyzed crane boom fall. No source term analysis is required for the ISC or NAC-1 cask.

The source term analysis developed for the unmitigated TRIGA accident in Section D3.4.1.1 is applicable for this scenario.

The events and analysis depend upon initial conditions; however, these conditions can be violated during operations. For example, a crane might be taken out of service and replaced with a different crane, which would represent an unanalyzed condition. If a boom drop were to occur with a different boom, catastrophic damage is not expected because of the margin and conservatisms in the analyses. But since the package responses are unknown, a boom drop from a crane that has not been analyzed in the scenario development is considered bounded by the source terms calculated for the worst-case, non-mechanistic release shown in Section D3.4.1 for each fuel type.

D3.4.2.2.3 Consequence Analysis. The postulated crane fall accident consequences have been prevented by the passive design features of the ISC and the NAC-1 cask. A consequence analysis is not needed for the FFTF or LWR NAC-1 casks.

The consequence developed for the unmitigated TRIGA accident in Table D3-10 is applicable for this scenario.
D3.4.2.2.4 Comparison to Guidelines.

Unmitigated event – For events that exceed the initial conditions of the analyses, the bounding consequences for each fuel type show that the off-site release limits are not challenged. Therefore, no safety-class confinement SSCs are necessary.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following a handling or drop accident, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However, the NRF TRIGA casks do provide structural protection of the SNF payload in the event of a drop, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

For the FFTF fuel and the LWR fuel in the NAC-I casks, the bounding on-site consequences for drops outside of the initial conditions analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

Mitigated event – The postulated crane fall accident consequences have been prevented by the passive design features of the FFTF and NAC-I casks; therefore, there is no release from this event.

For TRIGA SNF, the consequence analysis was performed for the 200 Area ISA based on the unmitigated release discussed in Section D3.4.1.2. Using appropriate air transport and unit dose factors, this particulate has been used to calculate on-site and off-site receptor dose estimates. The total off-site and on-site individual doses are estimated to be 3.4E-06 rem and 9.01E-03 rem, respectively.

The radiological dose consequences from the crane fall accident for the 200 Area ISA are below the off-site release limits and the on-site dose consequence guidelines; therefore, no safety-class or safety-significant equipment is required to mitigate the potential effects of this accident for TRIGA fuel.

D3.4.2.2.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from mobile crane fall accidents.
Fast Flux Test Facility Fuel

The following SSC is designated as Safety Significant:

- **FFTF ISC** – The ISC is designated as Safety Significant to maintain confinement of radioactive materials after the crane fall and to provide passive protection of the CCC such that it retains structural integrity.

The following TSR control is necessary to protect the assumptions made in the mobile crane fall analyses:

- **Lift restriction** – A TSR shall be in place to restrict crane use to that bounded by the calculational analysis for the FFTF ISC. Only the Manitowoc 4000 150T crane with Model 22 80-ft boom or the Manitowoc 4100 250T crane with Model 27 80-ft boom shall be used to lift the ISC (SNF-4794).

NRF TRIGA

No SSCs credited with a preventive or mitigative function.

Light Water Reactor Fuel

The following SSC is designated as Safety Significant:

- **NAC-1 cask system** – The NAC-1 cask has been designated Safety Significant to provide passive structural integrity protection of the inner canister.

The following TSR control is necessary to protect the assumptions made in the mobile crane accident:

- **Lift restriction** – A TSR shall be in place to restrict use of the crane, lifting equipment, and lift height to that bounded by the calculational analysis for the NAC-1 casks. Only the Manitowoc 4000 150T crane with Model 22 80-ft boom or the Manitowoc 4100 250T crane with Model 27 80-ft boom shall be used to lift the ISC (SNF-4794).

D3.4.2.3 Cask Tipover.

**D3.4.2.3.1 Scenario Development.** Cask handling, operations near the storage casks, or external forces could cause an accident that would lead to the tipover and slap-down of a cask. If the impact caused a cask to undergo accelerations and forces beyond the design strength, the cask containment could be breached. Breach of the cask containment could result in radiological releases. Casks also maintain the geometry of stored SNF to meet any criticality safety concerns,
and a cask breach or deformation could lead to the violation of a criticality control limit. A summary of the safety features required to prevent or mitigate the cask tipover accident is provided in Table D3-13.

Table D3-13. Summary of Safety Features Required to Prevent Cask Tipover Accident.

(1) Checklist designators are from SNF-4820, 1999, 200 Area Interim Storage Area Final Hazard Analysis, Rev. 0, Fluor Daniel Hanford, Incorporated, Richland, Washington.

2R = inner container of DOT-6M.  
CCC = core component container.  
DOT = U.S. Department of Transportation.  
FFTF = Fast Flux Test Facility.  
ISC = interim storage cask.  
ISO = International Standards Organization.  
NAC = Nuclear Assurance Corporation.  
NRF = Neutron Radiography Facility.  
TRIGA = Training, Research and Isotope Production, General Atomics.
Fast Flux Test Facility

The ISC design analysis report (General Atomics 1995) describes the cask tipover accident analyses performed for the ISC. The analysis considers an unrestrained rotational fall from a vertical to a horizontal position onto a flat unyielding surface. This analysis demonstrates that the ISC will survive a tipover accident onto any flat horizontal surface. The cask forces during this accident are bounded by those for the accident analysis for a 4-ft free drop of the cask side onto an unyielding surface (General Atomics 1995). Under these conditions, the ISC will not credibly lose its confinement and criticality control geometry and, thus, will not lead to credible radioactive releases.

NRF TRIGA

The 200 Area ISA analysis performed for the Rad-Vault containing six NRF TRIGA casks and two TRIGA FFCR DOT-6M shipping containers demonstrated that the Rad-Vault will not tip over during a 360 mph design basis tornado (DBT) or seismic event (SNF-4792).

While no analysis specifically addresses a TRIGA cask tip over, drop analyses have been performed that would bound such an accident. The TRIGA cask has been analyzed for a 109-in. drop height onto concrete, with the cask in a horizontal position. The concrete used in the analysis has a thickness of 16 in., a strength of 4000 lbs/in², and is reinforced with #7 rebar that is spaced 14 in. apart and placed 2 in. below the concrete surface. A simple unrestrained tipover accident of a TRIGA cask onto any flat surface, with compressive strength less than or equal to the described concrete, is not expected to lead to a breach of cask confinement.

While no tipover testing was performed for the DOT-6M, severe drop tests were completed that will bound such an accident. The drop tests onto an unyielding surface showed no breach of confinement for a 30-ft drop. These tests were conducted with the container in a horizontal orientation (Martin Marietta 1992). Any tipover accident onto a flat horizontal surface will be bounded by the results of this horizontal drop test, which demonstrated that containment will not be breached. Under these conditions, the DOT-6M will not credibly lose its confinement and will not lead to credible radioactive releases.

Light Water Reactor Fuel

While an unrestrained tipover accident has not been analyzed, the NAC-1 cask was analyzed previously for a 30-ft free drop onto a flat, horizontal unyielding surface for end, side, and corner impact orientations (NAC 1990, Section 2.7.1). The NAC-1 cask will not breach from this 30-ft drop for any orientation, and the analysis is expected to easily bound any consequences of a simple unrestrained tipover onto any flat surface. Under these conditions, the NAC-1 cask will not credibly allow damage to the LWR canister resulting in loss of criticality control geometry or credible radioactive releases.
D3.4.2.3.2 Source Term Analysis.

Fast Flux Test Facility

All ISA analyses demonstrate that complete confinement of the SNF will be maintained during and after the postulated and analyzed tipover events. All current analyses assumed that the impact surface is unyielding. The ISA storage pad will yield to the impact of an FFTF cask drop, and absorb drop energy at least as well as the analyzed concrete. The tipover or drop analysis assumes, in general, that the drop surface is flat. The ISA storage pad and any areas that a cask could tip over onto should be flat. The confinement of each cask will be maintained in each of the considered tipover events and, therefore, a source term analysis is not required.

NRF TRIGA

The Rad-Vault has not been analyzed for a tipover accident, but has been demonstrated to not tip during a DBT or seismic event. A tipover accident is not considered credible for the Rad-Vault in the 200 Area ISA.

Light Water Reactor Fuel

The existing ISA analyses demonstrate that complete confinement of the SNF will be maintained during and after the postulated and analyzed tipover events.

D3.4.2.3.3 Consequence Analysis.

Fast Flux Test Facility

The postulated tipover accident consequences have been prevented by the passive design features of the FFTF ISC. A consequence analysis is not needed.

NRF TRIGA

The postulated tipover accident consequences have been prevented by the passive design features of the Rad-Vault and each TRIGA container. A consequence analysis is not needed.

Light Water Reactor Fuel

The postulated tipover accident consequences have been prevented by the passive design features of each NAC-1 cask. A consequence analysis is not needed.
D3.4.2.3.4 Comparison to Guidelines.

**Unmitigated event** – For scenarios with conditions that exceed the initial conditions of the analyses, the bounding consequences for each fuel type show that the off-site release limits are not challenged. Drop analyses have been performed that would bound the cask tipover accident. Therefore, no safety-class confinement SSCs are necessary.

For the FFTF fuel and the LWR fuel in the NAC-1 casks, the bounding on-site consequences for drops outside of the initial conditions analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following a handling or drop accident, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However, the NRF TRIGA casks do provide structural protection of the SNF payload in the event of a drop, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

While no safety-class SSCs are required to provide confinement, some SSCs are required to protect the geometric configuration of the fuel for criticality safety. SSCs credited with retaining the critically safe geometry of the fuel are designated as Safety Class.

**Mitigated event** – For the tipover events postulated and analyzed in the scenario development, the potential releases are prevented. These events take credit for the packaging components and limitations on handling (e.g., lift height) that have been shown to provide the impact protection and confinement of the fuel for the tipover drop events.

D3.4.2.3.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from inadvertent nuclear criticality during and following a tipover event.

**Fast Flux Test Facility Fuel**

The following SSCs are designated as Safety Significant or Safety Class:

- **FFTF ISC** – The ISC is designated as Safety Significant to maintain confinement of radioactive materials after the tipover and to provide passive protection of the CCC such that it retains structural integrity.

- **CCC** – The CCC is designated as Safety Class to maintain structural integrity to provide criticality geometry control.
NRF TRIGA

The Rad-Vault has been analyzed to not tip over or slide as a result of NPH or DBAs.

Light Water Reactor Fuel

The NAC-1 cask in the ISO container has been analyzed to not tip over or slide as a result of NPH or DBAs.

D3.4.2.4 Fuel Rod Rupture.

D3.4.2.4.1 Scenario Development. Fission gases generated in the SNF are contained by the fuel cladding. Deterioration of the clad by oxidation or stress cracking could result in a release of the contained fission gas to the storage container. If the design pressure value for the sealed storage container is exceeded, these fission gases could be released to the environment. A summary of the safety features required to prevent the fuel-rod rupture accident is provided in Table D3-14.

Fast Flux Test Facility Fuel

Based on the ISC design analysis report (General Atomics 1995, page 4.1-4), the cavity internal pressure for normal long-term conditions is 33.9 lbs/in² gauge, based on an average fuel cavity temperature of 245 °F. The maximum pressure occurs for volcanic ash accumulation with plugged ducts and is 36.7 lbs/in² gauge based on the highest fuel cavity temperature of 286 °F (WHC-SD-FF-ER-100). These pressures are calculated at the end of the cask’s 50-year life assuming fission gas generation and no reduction in decay heat. Per Specification WHC-S-4110, Specification for FFTF Interim Storage Cask, Section 3.2.2.3, the generation of gases produced by radioactive decay is expected to be 5.4 gram-atoms (moles) per assembly or 37.8 gram-atoms per ISC for a 50-year period, assuming that all free gases contained within the fuel rod cladding are released. The design pressure is based on a CCC containing seven fuel assemblies.

</tbody>
</table>

(1) Checklist designators are from SNF-4820, 1999, 200 Area Interim Storage Area Final Hazard Analysis, Rev. 0, Fluor Daniel Hanford, Incorporated, Richland, Washington.

2R = inner container of DOT-6M.
CCC = core component container.
FFTF = Fast Flux Test Facility.
ISC = interim storage cask.
LWR = light water reactor.
NRF = Neutron Radiography Facility.
TRIGA = Training, Research and Isotope Production, General Atomics.
TSR = Technical Safety Requirement.
These results have assumed that the casks are spaced no closer than 5.5 ft from surface to surface. Smaller spacings will cause temperatures to rise. If, for example, the casks are spaced 24 in. in one direction and 44 in. in the other, the temperature will increase by approximately 5 to 10 °F. This is due partly to the restricted radiant heat transfer to the sky and partly to the increase in ambient temperature at the interior of the array. All temperatures will still be within limits, but margins will decrease accordingly. The planned spacing for the 200 Area ISA is 4 ft in both directions. The temperature variation from 5.5-ft to 4-ft spacing was not reevaluated, as the tightened array described above had minimal effect. No temperature limits will be exceeded if the cask is positioned on its side due to an accidental drop or tipover. Although the ventilation flow will be ineffective, the situation will be no worse than the case of ash accumulation with plugged ducts, with temperatures remaining within the limits.

**NRF TRIGA**

The NRF TRIGA cask design pressure is 11.2 lbs/in² gauge. The design pressure is based on the maximum pressure differential obtained from the 10 CFR 71.71(c)(3) reduced external pressure of 3.5 lbs/in² absolute. The DOT-6M/2R design pressure is 40 lbs/in² gauge. The NRF TRIGA cask was pressure-tested at 17.3 lbs/in² gauge, and the DOT-6M/2R container was pressure-tested at 60 lbs/in² gauge. The pressure boundary for the DOT-6M/2R is the 2R container.

The low burnup of the SNF has produced a small quantity of fission products. Most of the fission product gases are captured within the fuel matrix. The fission product gases within each element (25 lbs/in² maximum initial pressure) will result in negligible pressure in the cask or container (less than 2 lbs/in²), if all of the fuel elements are breached within the cask (WHC-SD-FF-TI-043). By-products from elastomeric seal degeneration will have minimal effect. Therefore, it is expected that the NRF TRIGA cask pressure will remain less than the design limit of 11.2 lbs/in² gauge.

**Light Water Reactor**

Analysis determined the maximum canister pressures, due to fuel-rod rupture of worst-case hypothetical pressurized water reactor (PWR) and boiling water reactor (BWR) SNF assemblies for both normal and fire accident conditions. Analyses using the existing design of the NAC-1 cask (NAC 1990) determined the maximum cask pressures due to fuel-rod rupture of a worst-case hypothetical PWR SNF assembly for both normal and fire accident conditions (SNF-4794). The pressure within the inner canister cavity due to rod rupture at maximum normal conditions for consolidated BWR and PWR fuel rods is 30.86 lbs/in² absolute, which is 16.16 lb/in² gauge. This is within the design pressure of 50 lb/in² gauge and test pressure of 85 lb/in² gauge established for the inner canister. This also bounds the consolidated BWR and PWR rod normal conditions with the NAC-1 cask cavity that has a design pressure of 65 lb/in², which is tested to 100 lb/in².
Worst case consolidated fuel rod canister pressures were also calculated for 100% rod rupture during the design basis fire conditions (SNF-4794) resulting in an inner canister cavity maximum average temperature of 540 °F. The resultant pressure at this temperature for the consolidated BWR and PWR fuel rods is 22.44 lb/in². This consolidated BWR and PWR rod accident condition pressure is also well within the design pressures for both the inner canister and the NAC-1 cask.

D3.4.2.4.2 Source Term Analysis. No source term is calculated because no release of radioactive material is identified for the conditions discussed in the subsections that follow.

Fast Flux Test Facility

The internal storage container pressure calculated for the release of all fission gases from the fuel rods is within the design pressure of the storage vessel.

NRF TRIGA

For TRIGA SNF, the internal storage container pressure calculated for the release of all fission gases from the fuel rods is within the design pressure of the storage vessel. Consequently, the casks will not release radioactive material.

Light Water Reactor Fuel

For the LWR fuel, the internal storage container pressure calculated for the release of all fission gases from the fuel rods is within the design pressure of the storage vessel.

D3.4.2.4.3 Consequence Analysis. The postulated fuel rod rupture consequences have been prevented by the passive design features of the SNF casks. A consequence analysis is not needed.

D3.4.2.4.4 Comparison to Guidelines.

Unmitigated event – For events that exceed the initial conditions of the analyses, the bounding consequences for each fuel type show that the off-site release limits are not challenged. Therefore, no safety-class confinement SSCs are necessary.

For the FFTF fuel and the LWR fuel, the bounding on-site consequences for hypothetical releases outside of the initial conditions analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following fuel rod rupture, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However,
the NRF TRIGA casks do provide structural protection of the SNF payload, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

While no safety-class SSCs are required to provide confinement, some SSCs are required to protect the geometric configuration of the fuel for criticality safety. SSCs credited with retaining the critically safe geometry of the fuel are designated as Safety Class.

**Mitigated event** – The postulated accidents have been prevented by the passive design features of the casks; therefore, there is no release from this event.

**D3.4.2.4.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls.** The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from heat loads, and keep the cask internal pressure within design values.

**Fast Flux Test Facility Fuel**

The following SSCs are designated as Safety Significant or Safety Class:

- **FFT F ISC** – The ISC is designated as Safety Significant to maintain confinement of the radioactive materials after the rupture of all fuel pins.

- **CCC inner container** – The CCC is designated as Safety Class to maintain structural integrity to provide criticality geometry control at the pressure generated from the rupture of all fuel pins.

The following TSR controls are necessary to protect the assumptions made in the cask internal pressure analyses:

- A minimum spacing array area shall be no less than 24 in. by 44 in.
- There shall be no more than seven fuel assemblies in a CCC.

**NRF TRIGA**

The following SSCs are designated as Safety Significant:

- **NRF TRIGA casks** – The TRIGA casks are designated as Safety Significant to maintain confinement of the radioactive materials after the rupture of all fuel pins.

- **2R container** – The 2R containers are designated as Safety Significant to maintain confinement of the radioactive materials after the rupture of all fuel pins.
Light Water Reactor Fuel

The following SSC is designated as Safety Significant and Safety Class:

- **LWR canister** – The LWR canister is designated as Safety Significant to maintain confinement of the radioactive materials and Safety Class to maintain structural integrity to provide criticality geometry control at the pressure generated.

The following TSR control is necessary to protect the assumptions made in the cask pressure analysis:

- The number of individual fuel rods in the LWR canister does not exceed a maximum of 179 PWR rods or 96.5 BWR rods consolidated with 17 PWR rods.

**D3.4.2.5 Seismic.**

**D3.4.2.5.1 Scenario Development.** A summary of the safety features required to prevent consequences after the seismic accident is provided in Table D3-15.

While the SNF storage systems are located at the 200 East Area, a design basis earthquake (DBE) could occur. The SNF storage systems could sustain seismically induced accelerations and forces, or impacts with nearby obstacles by overturning or sliding, which could potentially damage the structure of the storage system. These seismic accelerations and forces could affect the structural integrity or functionality of the SNF storage systems and potentially release radioactive materials out of the SNF storage system. All seismic g forces are well bounded by the drop accelerations.

**Fast Flux Test Facility**

200 Area ISA site-specific analyses (HNF-2183) determined the margins of safety of the ISC in the 200 East Area against overturning and sliding during a seismic event. Other analyses were previously performed for a lower level earthquake than that currently considered for the 200 East Area (General Atomics 1995). Under the 200 East Area site-specific loadings (zero-period acceleration [ZPA] horizontal spectra of 0.26 g and vertical of 0.18 g, with a second earthquake of horizontal ZPA of 0.50 g and a vertical ZPA of two-thirds of the horizontal), the normal storage condition of the ISC was found to have a margin of safety against overturning of +0.20 (a factor of safety of +1.20) and against sliding of +0.33 (a factor of safety of +1.33). NRC criteria state that a minimum factor of safety of +1.1 must be maintained against sliding and overturning during a seismic event. These calculations found that the ISC had sufficient margins of stability during the DBE to not overturn and not slide.

(1) Checklist designators are from SNF-4820, 1999, 200 Area Interim Storage Area Final Hazard Analysis, Rev. 0, Fluor Daniel Hanford, Incorporated, Richland, Washington.

**Abbreviations:**
- 2R = inner container of DOT-6M.  
- CCC = core component container.  
- DOT = U.S. Department of Transportation.  
- FFTF = Fast Flux Test Facility.  
- ISC = interim storage cask.  
- ISO = International Standards Organization.  
- LWR = light water reactor.  
- NAC = Nuclear Assurance Corporation.  
- NRF = Neutron Radiography Facility.  
- SSC = structure, system, and component.  
- TRIGA = Training, Research and Isotope Production, General Atomics.  
- TSR = Technical Safety Requirement.
Previous 400 Area ISA analyses (General Atomics 1995) also evaluated for overturning by simultaneously applying static loads to the ISC in the horizontal and vertical directions. The seismic motions from the DBE (0.25 g) earthquake were evaluated. These design response spectra were applied for the horizontal motion in the free field. For the vertical motion, the design response spectra were taken as two-thirds the response spectra for the horizontal motion. This analysis found that the ISC has a margin of safety of 0.29 against overturning during the DBE seismic event. Additionally, even if the seismic g level was higher and the ISC were to tip over, the tipover accident analysis performed for the ISC found that the cask still retains the stored SNF in a safe configuration.

Movement of the ISC during an earthquake was evaluated. The analysis of the ISC for sliding shows that a coefficient of friction of at least 0.3 is required to prevent sliding motion. This result was compared to the coefficient of friction of concrete on concrete as determined from the ACI Manual of Concrete Practice (ACI 1989, Part 4, Section 11.7.4.3). Since this value is 0.6, there is a large margin against sliding motion during an earthquake.

**TRIGA**

Using the current 200 East Area site-specific loadings, analyses were performed that demonstrate structural margins exist for the 200 Area ISA movement. The analyses (SNF-4792) found that the design of the Rad-Vault is well within the DBE for the site, and seismic stability is assured. The Rad-Vault will not overturn or slide on the soil. The lid lip will not fail, and the lid will remain on the Rad-Vault. The NRF TRIGA casks inside the container will not suffer loss of integrity, as their design for use in ground transport provides capacities far in excess of 0.26 g (WHC-SD-TP-SARP-008). Likewise, the DOT-6M containers that will be used for the FFCR are qualified for conditions that are in excess of the 0.26 g ground acceleration earthquake analyzed for the 200 Area ISA (SNF-4792).

The margin of safety for overturning the loaded Rad-Vault is 1.1. Sliding was also examined using a friction factor of 0.35 between the gravel and the concrete base of the Rad-Vault. This factor was taken from the values shown in the Uniform Building Code for sandy gravel and/or gravel (ICBO 1994). The margin of safety against sliding was 0.104.

The soil-bearing pressure beneath the Rad-Vault was not exceeded under seismic overturning loads. The margin of safety for soil bearing pressure was 0.59. As such, the Rad-Vault is not expected to overturn due to soil compaction loads.

**Light Water Reactor**

Current seismic criteria is specified in Table D2-2. Calculations were performed for the 200 Area ISA to evaluate the cask/container’s resistance to overturning during the DBE (SNF-4794). The margin of safety against overturning the cask/container unit onto its left or right side is 2.7. The margin of safety against overturning the cask/container unit onto its front...
or back is 3.9. Based on these results, it was concluded that the cask/container units will not overturn.

Sliding of the cask/container was also examined using a friction factor of 0.5 between the concrete and the bottom side of the ISO shipping container. The margin of safety against sliding was found to be 0.58, which indicates that the cask/container will not slide.

Tipping of the storage system due to soil compaction beneath the pad under seismic overturning loads was also calculated for the 400 Area ISA. The margin of safety is 4.7.

**D3.4.2.5.2 Source Term Analysis.** No source term is calculated because no release of radioactive material is identified.

**D3.4.2.5.3 Consequence Analysis.** The consequences from the postulated seismic event are prevented by the passive design features of the SNF cask. A consequence analysis is not needed for the FFTF, TRIGA, or LWR fuel storage systems.

**D3.4.2.5.4 Comparison to Guidelines.**

**Unmitigated event** – For drops that exceed the initial conditions of the analyses, the bounding consequences for each fuel type show that the off-site release limits are not challenged. Drop analyses have been performed that would bound the seismic event. Therefore, no safety-class confinement SSCs are necessary.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following a seismic event, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However, the NRF TRIGA casks do provide structural protection of the SNF payload, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

For the FFTF fuel and the LWR fuel in the NAC-I casks, the bounding on-site consequences for a seismic event outside of the initial conditions analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

**Mitigated event** – For the seismic events postulated and analyzed in the scenario development, the potential releases are prevented. These events take credit for the packaging components and limitations on handling (e.g., lift height) that have been shown to provide the impact protection and confinement of the fuel for the analyzed seismic events.
D3.4.2.5.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from the seismic event within design values.

Fast Flux Test Facility Fuel

The following SSCs are designated as Safety Significant or Safety Class:

- **FFTF ISC** – The ISC is designated as Safety Significant to withstand seismic accelerations without loss of confinement or structural integrity, tipover or sliding, or to survive a tipover accident.

- **CCC** – The CCC is designated as Safety Class to withstand seismic accelerations without loss of structural integrity for geometry control.

The following TSR control is necessary to protect the assumptions made in the seismic analyses:

- The FFTF ISC shall be placed on a concrete pad.

NRF TRIGA

The following SSCs are designated as Safety Significant or Safety Class:

- **NRF TRIGA casks** – The TRIGA casks are designated as Safety Significant for NRC important-to-safety considerations for providing confinement for the SNF payload.

- **Rad-Vault** – The Rad-Vault is designated at Safety Significant for seismic stability and structural integrity protection.

- **DOT-6M containers** – The DOT-6M containers are designated as Safety Significant for NRC important-to-safety considerations for providing seismic stability and structural protection of the SNF payload.

- **2R container** – The 2R containers are designated as Safety Significant for NRC important-to-safety considerations to maintain confinement of radioactive materials.

The following TSR control is necessary to protect the assumptions made in the seismic event:

- The Rad-Vault shall be placed on compacted gravel.
Light Water Reactor Fuel

The following SSCs are designated as Safety Significant or Safety Class:

- **LWR canister** – The LWR canister is designated as Safety Class to provide a critically safe geometry for the SNF payload. In addition, the LWR canister provides a Safety Significant confinement function for the SNF payload.

- **ISO container** – The ISO container is designated as Safety Significant for seismic stability and structural integrity protection.

The following TSR control is necessary to protect the assumptions made in the seismic event:

- The NAC-1 cask shall be placed on a concrete pad.

**D3.4.2.6 Tornado/Wind.**

**D3.4.2.6.1 Scenario Development.** While the SNF storage systems are located at the 200 East Area, DBAs of straight wind and tornado wind could occur. Tornado missiles are not analyzed since probabilistic risk assessment analyses have concluded that tornado missiles do not need to be considered (HNF-1785). The SNF storage systems could sustain wind loadings or wind effects that could move the SNF storage systems to impact with nearby obstacles. Additionally, the SNF storage systems could suffer impacts from wind-driven missiles. These effects could affect the structural integrity or functionality of the SNF storage systems and potentially release radioactive materials out of the SNF storage system. A summary of the safety features required to prevent tornado and wind accident releases is provided in Table D3-16.

**Fast Flux Test Facility**

Analyses using the current 200 East Area site-specific requirements have been performed (SNF-4790). Calculations show that the loaded ISC will not tip over or slide. The increase in internal pressure due to differential pressure loading is negligible. Wind-driven missiles result in concrete penetration of less than 1 in.

**TRIGA**

Supplemental analyses using the current 200 East Area site-specific requirements have been performed demonstrating adequacy of the Rad-Vault to withstand the DBT and the wind-driven missile (SNF-4792).

- TSR = Technical Safety Requirement
Light Water Reactor

Analyses were performed for the 200 Area for a tornado wind speed of 200 mph and a differential pressure of 0.90 lbs/in² over 3 seconds. The NAC-1 cask inside the ISO container does not slide or tip (SNF-4794). Wind missile damage does not reduce confinement.

D3.4.2.6.2 Source Term Analysis. For spent fuel storage, the calculations determined that the design criteria were met and no releases are expected to occur as a result of this event. As such, source term analysis is not required.

D3.4.2.6.3 Consequence Analysis. The consequences from the postulated tornado wind and wind-driven missile events are prevented by the passive design features of the robust SNF cask systems. A consequence analysis is not needed for the FFTF, TRIGA, or LWR fuel storage systems.

D3.4.2.6.4 Comparison to Guidelines.

Unmitigated event – For the bounding tornado/wind events, consequences for each fuel type show that the off-site release limits are not challenged. Therefore, no safety-class confinement SSCs are necessary.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following bounding tornado/wind events, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However, the NRF TRIGA casks do provide structural protection of the SNF payload, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

For the FFTF fuel and the LWR fuel in NAC-1 casks, the bounding on-site consequences for the hypothetical accident outside of the initial conditions analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

Mitigated event – For the tornado/wind events postulated and analyzed in the scenario development, the potential releases are prevented. These events take credit for the packaging components that have been shown to provide the impact protection and confinement of the fuel for the analyzed bounding tornado/wind events.

D3.4.2.6.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from the bounding tornado/wind events within design values.
Fast Flux Test Facility Fuel

The following SSC is designated as Safety Significant:

- **FFTF ISC** – The ISC is designated as Safety Significant to withstand DBT winds (excluding DBT missiles) without sliding or tip over. The ISC must also withstand the design basis wind and wind-driven missiles established for the 200 Area ISA without loss of confinement, as well as provide structural integrity protection.

The following TSR control is necessary to protect the assumptions made in the tornado/wind event analyses:

- The FFTF ISC shall be placed on a concrete pad.

**NRF TRIGA**

The following SSCs are designated as Safety Significant:

- **NRF TRIGA cask** – The NRF TRIGA cask is designated as Safety Significant for confinement.

- **Rad-Vault** – The Rad-Vault is designated as Safety Significant for NRC important-to-safety considerations to withstand DBT winds (excluding DBT missiles) without sliding or tip over. The Rad-Vault also withstands the design basis wind and wind-driven missiles established for the 200 Area ISA.

- **2R container** – The 2R container is designated as Safety Significant for confinement.

The following TSR control is necessary to protect the assumptions made in the tornado/wind:

- The Rad-Vault shall be placed on compacted gravel.

**Light Water Reactor Fuel**

The following SSCs are designated as Safety Significant:

- **ISO container** – The ISO container is designated as Safety Significant for structural integrity.

- **NAC-1 cask system** – The NAC-1 cask is designated as Safety Significant to withstand DBT winds (excluding DBT missiles) without sliding or tip over. The NAC-1 cask system must also withstand the design basis wind and wind-driven
missiles established for the 200 Area ISA without structural damage to the inner canister.

- **LWR canister** - The LWR canister is designated as Safety Significant for confinement.

The following TSR control is necessary to protect the assumptions made in the tornado/wind events:

- The NAC-1 cask shall be placed on a concrete pad.

**D3.4.2.7 Fire.**

**D3.4.2.7.1 Scenario Development.** A fire of unspecified origin can be assumed to occur, which subjects the exterior of the SNF storage containers to a high, short-term heat load that could ultimately threaten the confinement capability of the containers. A summary of the safety features required to prevent the design basis fire accident is provided in Table D3-17. The fire hazard analysis (SNF-4932) concluded that all fire scenarios are bounded by the transportation fire event. The transportation fire event is defined as an exposure of the exterior surface of the container system to a temperature of 1,475 °F for a period of 30 minutes.

**Fast Flux Test Facility**

In previous 400 Area ISA analyses (General Atomics 1995), the cask was evaluated for a hypothetical accident condition resulting from an external fire. In this transient case, the cask was subjected to a radiative environment of 1,475 °F with an emissivity of 0.9. After 30 minutes of exposure, the environment returned to normal ambient temperature, with no artificial cooling applied. The initial conditions for the transient were the steady-state temperatures for long-term normal conditions. In this accident case, the hot gas is assumed to enter the ventilation ducts and flow up the annulus between the liner and inner shield. The same flow model was used as for long-term normal conditions, except that the inlet temperature during the 30 minutes was taken to be 1475 °F instead of 94 °F. The fuel cavity average temperature calculated for this case was 261 °F, resulting in a cavity pressure that is below the design pressure seal temperature limits, and the cladding temperature limits are not exceeded. Therefore, a radioactive release will not occur.

NRF TRIGA

Previous 400 Area ISA analyses (WHC-SD-FF-TI-043) assumed that during a very hot summer, a fire (e.g., range fire, spilled fuel) engulfs the concrete Rad-Vault. The conditions of the fire are such that the outer wall of the Rad-Vault experiences a temperature of 1,475 °F for a period of 30 minutes. After 30 minutes of exposure, the environment returns to normal ambient temperature, without means of artificial cooling, and the Rad-Vault commences to cool down. An analysis for the 400 Area ISA was performed to determine the peak transient temperature profile of the vault wall, the peak temperature of the inner vault wall, and the fuel element cladding maximum temperature. This analysis showed a quasi steady-state temperature for the vault wall of 177 °F. Assuming equilibrium conditions, the inner vault wall temperature will result in a fuel cladding temperature of 193 °F, where the maximum allowable fuel cladding temperature is 302 °F. Therefore, radiological material releases will not result from exceeding the temperature limits; however, the design specifications for the concrete Rad-Vault may be exceeded for a short period of time at the exterior surface and should be evaluated if this event were to occur.

Light Water Reactor Fuel

The thermal analysis for the 400 Area ISA of the NAC-1 cask subjected to the transportation fire scenario of 10 CFR 71.73(c)(3) was previously performed in the original transportation SAR (NFS 1972). The original analyses assumed an internal thermal load of 11.5 kW and the NAC-1 SAR assumed an internal 750 W thermal load. These analyses considered the NAC-1 cask with and without the ISO shipping container and assumed bounding conditions for the fire accident scenario, which has a maximum internal thermal load of 405 W. Examination of the previous fire accident has shown that these temperature limits are not exceeded for an internal thermal load of 11.5 kW or 750 W. The maximum temperature at the center of the fuel during a hypothetical fire accident is 589.8 °F (SNF-4794). The 644 °F temperature limit for the cladding is not exceeded anywhere in the array of stacked rods. The transportation SAR and the NAC-1 SAR analyses found that the integrity of the NAC-1 cask was not lost for the design fire accident conditions and consequently, no credible radioactive releases occur for this event.

D3.4.2.7.2 Source Term Analysis. The SNF storage systems will not release radioactive material and fuel cladding temperature limits are not exceeded; therefore, a source term analysis is not required.

D3.4.2.7.3 Consequence Analysis.

Fast Flux Test Facility

The fire event does not result in a condition where the storage casks release radioactive material; therefore, a consequence analysis is not needed for this event.
NRF TRIGA

The fire event does not result in a condition where the storage casks release radioactive material; therefore, a consequence analysis has not been developed.

Light Water Reactor Fuel

The fire analyses do not result in a scenario that causes the release of radioactive material; therefore, a consequence analysis has not been developed.

D3.4.2.7.4 Comparison to Guidelines.

Unmitigated event – For the hypothetical accidents described in Section D3.4.1, the bounding consequences for each fuel type show that the off-site release limits are not challenged. Therefore, no safety-class confinement SSCs are necessary.

For the NRF TRIGA fuel, the on-site consequences do not exceed the on-site risk evaluation guidelines. Therefore, for the purposes of controlling accident releases following a fire accident, no safety-significant SSCs are required to confine the NRF TRIGA fuel. However, the NRF TRIGA casks do provide structural protection of the SNF payload, and as such, are designated as important-to-safety Category B for NRC equivalency. On this basis, the NRF TRIGA casks are designated as Safety Significant.

For FFTF fuel and the LWR fuel in NAC-1 casks, the bounding on-site consequences for the hypothetical accident analyzed exceed the on-site risk evaluation guidelines. Therefore, safety-significant SSCs are required to prevent or mitigate the dose consequences.

While no safety-class SSCs are required to provide confinement, some SSCs are required to protect the geometric configuration of the fuel for criticality safety. SSCs credited with retaining the critically safe geometry of the fuel are designated as Safety Class. Temperatures from the design basis fire were evaluated to demonstrate the materials of construction can continue to perform their safety function.

Mitigated event – For the fire events postulated and analyzed in the scenario development, the potential releases are prevented. These events take credit for the packaging components providing confinement of the fuel for the analyzed fire events.

D3.4.2.7.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. The following SSCs and TSR controls ensure that the SNF is adequately confined and protected from the fire events within design values.
The following TSR control is necessary to protect the assumptions made in the fire analyses:

- Fire loadings are to be controlled per the fire hazard analysis.

**Fast Flux Test Facility Fuel**

The following SSCs are designated as Safety Significant or Safety Class:

- **CCC** – The CCC is designated as Safety Class to maintain structural integrity for criticality geometry control.

- **FFTF ISC** – The ISC is designated as Safety Significant to withstand transportation design basis fire conditions without the loss of confinement or exceeding the temperature limits for fuel cladding or cask components, as well as to provide structural integrity protection.

**NRF TRIGA**

The following SSCs are designated as Safety Significant:

- **DOT-6M container** – The DOT-6M container is designated as Safety Significant for structural integrity protection.

- **2R container** – The 2R container is designated as Safety Significant for structural integrity protection.

- **NRF TRIGA cask** – The TRIGA casks are designated as Safety Significant for NRC important-to-safety considerations to provide structural integrity protection against the fire event.

- **Rad-Vault** – The Rad-Vault is designated as Safety Significant for structural integrity protection.

**Light Water Reactor Fuel**

The following SSCs are designated as Safety Significant or Safety Class:

- **LWR canister** – The LWR canister is designated as Safety Class to maintain structural integrity for criticality geometry control. In addition, the LWR canister is designated as Safety Significant for confinement.
• **NAC-1 cask system** – The NAC-1 cask is designated as Safety Significant to provide structural integrity protection against the fire event.

• **ISO container** – The ISO container is designated as Safety Significant for structural integrity protection.

### D3.4.3 Beyond Design Basis Accidents

DOE Order 5480.23 requires the evaluation of accidents beyond the design basis to provide a perspective of the residual risk associated with the operation of the facility. The beyond design basis accidents (BDBAs) are not analyzed to the same level of detail as DBAs, but do provide insight into the magnitude of consequences of BDBAs. This insight from BDBA analysis has the potential for identifying additional facility features that could prevent or reduce severe BDBA consequences. While these events would be beyond requirements of further safety-class or safety-significant functions, they might provide guidance to the prioritization of long-term safety improvements for a facility. The Order specifically excludes evaluation of human-generated external events as BDBAs.

Hypothetical release source terms are developed for each fuel type in Section D3.4.1.1 for an unmitigated release from each fuel type cask to determine the classification of engineered barriers that prevent an uncontrolled release. The scenarios are hypothetical and non-mechanistic. These hypothetical scenarios also establish the magnitude of a release from a BDBA.

Given the extremely low likelihoods associated with such BDBAs and the calculated consequences for the hypothetical scenarios in Section D3.4.1.1, no new insights into facility operations are expected.

CHAPTER D4.0

SAFETY STRUCTURES, SYSTEMS, AND COMPONENTS
This page intentionally left blank.
D4.0 SAFETY STRUCTURES, SYSTEMS, AND COMPONENTS

D4.1 INTRODUCTION

This chapter provides details of the structures, systems, and components (SSCs) that are necessary for the facility to meet off-site release limits, satisfy on-site risk guidelines, provide significant defense in depth, or contribute to worker safety. This chapter meets the requirements of U.S. Department of Energy (DOE) Order 5480.23, Nuclear Safety Analysis Reports, follows the format guidance of DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, and includes the following information:

- A list of safety-class SSCs and subsections containing safety function details, a system description, functional requirements, a system evaluation, and a list of assumptions requiring Technical Safety Requirements (TSRs) to ensure performance of the safety function.
- A list of the safety-significant SSCs and subsections containing safety function details, a system description, functional requirements, a system evaluation, and a list of assumptions requiring TSRs to ensure performance of the safety function.

In general, safety-class SSCs are those items required for protection of the off-site environment and the public, or the prevention of an inadvertent criticality. Safety-class SSCs include items designated as "Safety Class" in accordance with DOE Order 6430.1A, General Design Criteria. Safety-class SSCs also encompass items that are designated as "important to safety" and have been classified as Category A, as defined in Item 29 of HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward Additional NRC Requirements.

Safety-significant items are those SSCs required for the protection of on-site personnel not directly involved in facility operations. Safety-significant SSCs also encompass items that have been designated important-to-safety Category B in accordance with Item 29 of HNF-SD-SNF-DB-003. SSCs that would prevent or mitigate an on-site fatality or protect large numbers of facility workers (not industrial safety), or those SSCs that would prevent or mitigate toxic chemical exposures are also designated Safety Significant.

All SSCs that are not classified as Safety Class or Safety Significant are general-service SSCs. The SSCs that have been designated as important-to-safety Category C are also included in general-service SSCs. General-service SSCs protect workers from standard industrial hazards or are controlled by Site safety programs.

The majority of the equipment in the 200 Area Interim Storage Area (ISA) is classified as General Service (excluding the dry cask storage systems). The dry cask storage systems have
been classified as Safety Significant. The core component container (CCC) for Fast Flux Test Facility (FFTF) fuel and the light water reactor (LWR) canister for commercial LWR fuel have been classified as Safety Class. This classification was based on NUREG/CR-6407, Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety, and DOE 6430.1A, Section 1300-4, because of their credited function for criticality prevention.

The accident analyses in Chapter D3.0 identified one or more design basis accidents (DBAs) whose unmitigated consequences bound all accident sequences and scenarios identified for that category in the hazard analysis. The process identified criticality-related safety-class considerations requiring that the FFTF interim storage cask (ISC) CCC and the LWR canister provide criticality geometry control of the stored fuel. The analysis also identified safety-significant considerations for components of the cask storage systems that mitigated potential consequences in excess of on-site guidelines. No events were identified that had off-site consequences in excess of allowable limits.

Each accident analysis section in Chapter D3.0 concludes with a summary of safety SSCs that provides the basis for this chapter. A summary of the accident categories and the designated safety SSCs that prevent or mitigate their consequences is provided in Table D4-1. Table D4-2 provides a summary of the safety SSCs identified and provides the level of safety credited for each accident category. Many SSCs provide a safety function for prevention or mitigation of more than one accident. Detailed definitions of safety-class and safety-significant SSCs are provided in Sections D4.3 and D4.4.

A probabilistic risk analysis was performed to determine the frequency of a tornado wind-borne missile striking any of the dry cask storage systems planned for the 200 Area ISA (HNF-1785). The analysis concludes that the rate at which storage area safety is compromised is less than $10^{-8}$ per year. Generation of tornado-based, wind-borne missiles that could compromise cask system integrity is therefore not credible and evaluation is not required.

(1) This item is designated as Safety Class for structural integrity to provide criticality geometry control.
(2) This item upgraded to Safety Significant to accomplish NRC equivalency based on important-to-safety classification and due to its significant contribution to defense-in-depth and worker safety.
(3) Critical lift requirements imposed using DOE/RL-92-36, Hanford Site Hoisting and Rigging Manual, accomplish NRC equivalency for important-to-safety Category B.

D4.2 REQUIREMENTS

This section identifies design codes, standards, regulations, and DOE Orders that are required for establishing the facility safety basis. The intent is to provide only the requirements that are specific to this chapter and pertinent to the safety basis. Specific codes, standards, and requirements applicable to the 200 Area ISA are defined in the Spent Nuclear Fuel (SNF) Project Standards/Requirements Identification Document (HNF-SD-SNF-RD-001).

The following DOE Orders, regulations, and standards are applicable to the safety basis for the facility:

- **Title 10, Code of Federal Regulations (CFR), Section 830.120, "Quality Assurance Requirements."** This rule requires that a sufficient quality assurance program be in place.

- **10 CFR 72, "Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste."** This rule is used for the licensing of independent spent fuel storage installations. 10 CFR 72.3, "Definitions," defines SSCs that are considered "important to safety."

- **10 CFR 835, "Occupational Radiation Protection."** This rule provides requirements for radiation protection programs.

- **DOE Order 5480.22, Technical Safety Requirements.** This order sets the requirements for the development and preparation of a TSR document, which is prepared separately.

- **DOE Order 5480.23, Nuclear Safety Analysis Reports.** This order provides nuclear safety analysis report (SAR) content requirements.

- **DOE Order 6430.1A, General Design Criteria.** This order provides general criteria and guidance for facility and system design. In addition, Division 13, "Special Facilities," Section 1300, "General Requirements," and Section 1320, "Irradiated Fissile Material Storage Facilities," requirements are imposed for the 200 Area ISA. Compliance with DOE Order 6430.1A is demonstrated in SNF-5139, **DOE 6430.1A Compliance Analysis for the 200 Area Interim Storage Area.**

- **DOE/RL-92-36, Hanford Site Hoisting and Rigging Manual.** This manual provides the requirements for lifting and rigging equipment and material.
The following standards are used for content and guidance:

- **DOE-STD-1027-92, *Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports.* This standard is used to determine hazard categories for nuclear facilities.

- **DOE Order 5480.28, *Natural Phenomena Hazards Mitigation.* This order is used to define design requirements for seismic events and straight wind.

- **DOE-STD-1020-94, *Natural Phenomena Hazards Design and Evaluation Criteria for Department of Energy Facilities.* This standard provides natural phenomena (NPH) design and evaluation criteria. The 200 Area ISA was designed and evaluated for seismic events and straight wind in accordance with this standard.

- **DOE-STD-1021-93, *Natural Phenomena Hazards Performance Categorization Guidelines for Structures, Systems, and Components.* This standard is used to define the specific performance category for SSCs.

- **DOE-STD-3009-94, *Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports.* This standard supplements DOE Order 5480.23 by providing guidance specific to nonreactor nuclear facilities. In this regard, the standard provides more detailed information on the performance of accident analyses for Hazard Category 2 and 3 facilities. The standard also establishes additional requirements for the establishment of defense in depth and the identification of safety-significant SSCs.

In Letter 95-SFD-167, *Implementation of K Basins Spent Nuclear Fuel Project (SNFP) Regulatory Policy* (Sellers 1995), DOE established the requirement for new SNF Project facilities to achieve "nuclear safety equivalency" to comparable U.S. Nuclear Regulatory Commission (NRC)-licensed facilities. The SNF Project identified the NRC requirements that were needed in addition to existing applicable DOE requirements to establish nuclear safety equivalency. These NRC requirements and the process used to identify them are documented in HNF-SD-SNF-DB-003 and WHC-SD-SNF-DB-009, *Canister Storage Building Natural Phenomena Hazards,* Appendix C, "200 East Area Interim Storage Area Natural Phenomena Hazards." The NRC requirements are used for licensing independent spent fuel storage installations. 10 CFR 72.3, "Definitions," defines SSCs that are considered important to safety. 10 CFR 72.122, "Overall Requirements," requires that the design bases for SSCs important to safety reflect appropriate combinations of effects of normal and accident conditions and the effects of natural phenomena.

For the 200 Area ISA, important-to-safety SSCs have been identified in accordance with 10 CFR 72.3. Once SSCs have been identified as having a function meeting the definition of important to safety, the requirements for SSCs important to safety specified in 10 CFR 72 are
imposed. A graded approach is applied to an SSC important to safety by using the guidance provided in NUREG/CR-6407, as follows:

- **Category A – Critical to Safe Operation**

  SSCs in this category include those whose failure or malfunction could directly result in a condition adverse to public health and safety. Important-to-safety SSCs in this category are classified as Safety Class, as defined in DOE Order 6430.1A with the additional requirements therein.

- **Category B – Major Impact on Safety**

  SSCs in this category include those whose failure or malfunction could result in a condition adversely affecting collocated worker health and safety. Note that from the definition of Category C, Category B is understood to include events that could significantly damage the storage containers without severe impact to public health and safety. SSCs in this category are classified as Safety Significant.

- **Category C – Minor Impact on Safety**

  SSCs whose failure or malfunction would not significantly reduce containment and would not be likely to create a situation adversely affecting public or collocated workers’ health and safety. SSCs in this category are classified as General Service.

In conjunction with the requirements noted above, ANSI/ANS-57.9-1992, *Design Criteria for an Independent Spent Fuel Storage Installation (Dry Type)*, provides guidance on design and performance criteria specific to a dry storage concept. These criteria are intended to be consistent with meeting the 10 CFR 72 requirements.

Additional discussion of the NRC criteria for mitigation of natural phenomena is provided in Section B1.2 of the SNF Project Final Safety Analysis Report (FSAR), Annex B. Specific NPH design requirements implementing NRC equivalency requirements have been established for the 200 ISA in WHC-SD-SNF-DB-009, Appendix C.

Letter 97-SFD-172, *Risk Evaluation Guidelines (REGs) to Ensure Inherently Safer Designs* (Sellers 1997), provides SNF Project guidance for design criteria with regard to exposure limits to be used in evaluating risk to the public and to on-site personnel.

These documents establish the design requirements for the 200 Area ISA.
D4.3 SAFETY-CLASS STRUCTURES, SYSTEMS, AND COMPONENTS

Safety-class items are SSCs, including portions of storage systems, whose failure could adversely affect the environment or the safety and health of the public. Detailed definitions of safety-class SSCs are provided in Section D4.2.

The SSCs credited with a safety-class function in Chapter D3.0 are described in the subsections that follow.

D4.3.1 Core Component Container for Fast Flux Test Facility Spent Fuel

The CCC is designated Safety Class for criticality geometry control only.

D4.3.1.1 Core Component Container Safety Function. The CCC is designated Safety Class for criticality geometry control, which is the only safety-class function identified for this SSC. The criticality safety evaluation summarized in Chapter D6.0 demonstrates that criticality is not credible for storage of fuel assemblies within the CCCIISC. The assumption of full water flooding is considered to be not credible and the fixed geometry of the closely packed, CCC, seven-tube arrangement physically restrains the assemblies/pin containers such that criticality is not possible.

The DBAs identified in Chapter D3.0 that could impose structural loads or accelerations on the CCC inside the ISC have the potential to change the criticality geometry control structure (Tables D4-1 and D4-2). Criticality safety evaluation reports (CSERs) discussed in Chapter D6.0 credit the CCC with providing the structure that maintains the critically safe geometry. The functional requirements and evaluations for the CCC (Sections D4.3.1.3 and D4.3.1.4) include summary discussions of the bounding DBAs using the following analyses:

- Handling/drop - Maintain structural integrity within the ISC to provide criticality geometry control after credible drops.

- Cask tipover - Maintain structural integrity to provide criticality geometry control.

- Fuel rod rupture - Maintain structural integrity to provide criticality geometry control up to and including the pressure generated from the rupture of all fuel pins.

- Seismic - Withstand seismic accelerations to maintain structural integrity for criticality geometry control.

- Fire - Withstand transportation design basis fire (DBF) conditions inside the ISC, without exceeding temperature limits for fuel cladding or container components, to maintain structural integrity for criticality geometry control.
D4.3.1.2 Core Component Container Description. The CCC (Figure D2-9) is an unshielded, sealed fuel storage container with seven fuel storage positions. As a defense-in-depth feature, the CCC provides canning for the FFTF fuel during the spent fuel dry storage 40-year design lifetime. The CCC also provides the geometry to ensure criticality control during handling and storage of the fuel. The CCC is designed such that it is fully retrievable from the storage configuration, although the capability to remove individual fuel components from a CCC is not required nor is it guaranteed. The center storage location can accept a fuel assembly that has had the bottom 15.5 in. removed. However, due to the indented CCC grapple handling socket, an Ident-69 pin container cannot be stored in the center location. Therefore, the maximum loading of a CCC will be either six Ident-69 pin containers or seven FFTF fuel assemblies. Pin containers and fuel assemblies have also been analyzed for a mixture of up to five Ident-69 containers and two driver fuel assemblies (DFAs) in a CCC. The Ident-69 container is allowed to contain a maximum of 217 pins, the same number as in a DFA.

The CCC was designed and fabricated in accordance with the American Society of Mechanical Engineers (ASME) *Boiler and Pressure Vessel Code* (ASME Code), Section VIII, Division 2 (ASME 1989). The CCC is fabricated from stainless steel and nickel alloy material (approved American Society for Testing and Materials [ASTM] materials for both ASME VIII and ASME III) to provide corrosion-resistant fuel storage, with overall dimensions of 20.0 in. in diameter by 146 in. in height. The weight of the empty CCC is 1,100 lbs. The maximum weight of a loaded CCC occurs with seven DFAs. The weight of the seven DFAs is 3,900 lbs, giving the CCC a maximum gross weight of 5,000 lbs. The storage positions of the CCC are formed by seven steel tubes arranged with six equally spaced, radial storage positions surrounding the seventh center storage position. There is minimal clearance between storage tubes in the bundle orientation. The materials used in the fabrication of the CCC are primarily ASTM-certified 304 stainless steels except for the lower approximately 12-in. portions of the tubes and the lower cups, which are ASTM-certified nickel alloy material UNS06625, and the closure bolts, which are certified to ASTM A-574 (ASTM 1989). The bottom cups provide extra corrosion resistance for each cleaned and dried fuel assembly. These cups are free to move axially (0.12 in.) within the lower support plate to accommodate thermal expansion. The lower support plate provides guidance and spacing for each of the six tube assemblies. The reducing section (saddle) maintains the outside envelope of the container and supports the fuel assemblies.

The upper portion of the outer tubes has a 6.69 in. outside diameter, with 109-mil thick walls. There is a saddle section 14 in. above the bottom of the CCC, where each outer storage tube transitions to a smaller section measuring 4.0 in. in outside diameter, with 226-mil thick walls. The bottom 12.4 in. of the lower section is fabricated from nickel alloy material for enhanced corrosion resistance. The center tube has a 6.54 in. outside diameter, with 120-mil thick walls. The bottom 10.0 in. of the center tube is also fabricated from nickel alloy material. There is no size reduction at the lower end of the center tube.

The outer storage tubes are suspended from the upper support plate. The center storage tube connects the upper support plate with the lower support plate. The outer tubes are fixed only at their upper ends so they are free to accommodate thermal expansion. This design also
permits the outer tubes to stretch slightly to absorb energy during a CCC drop accident onto the ISC internal impact limiter. Drop energy is absorbed by the CCC tubes until the gap between the tube stop and the lower support plate is taken up. The CCC then acts as a rigid body for final interface with the ISC impact limiter during an accident.

The lower support plate has an 18.0-in. diameter and is 1.5 in. thick. It limits downward travel of the outer storage tubes and also provides radial positioning guidance for inserting the CCC into the ISC. The upper support plate has a 20.0-in. diameter, with an overall thickness of 3.6 in. It provides support for the outer storage tubes and the seating surface for the cover seal. There are twelve drilled holes in the upper support plate that accommodate the cover bolts.

The cover has a 20.0-in. diameter and an overall thickness of 1.63 in. The lower surface of the handling socket extends 8.35 in. below the bottom of the cover. Twelve holes are drilled in the cover and are sized to accommodate the closure bolts. The CCC atmosphere is free to pass between the storage tubes, but a metal Helicoflex seal is provided between the container and the cover to establish container confinement. An impact limiter is located on the bottom of the handling socket closure cup. Its function is to reduce the loading to the cover that could occur during the CCC drop accident into the ISC due to the fuel assembly in the center storage location rebounding and hitting the cover. The top surface of the cover is provided with rigging attachment points for empty container handling, a test port for seal leak-rate verification, and a sample port for container atmosphere sampling.

The CCC cover design provides a closure with a cover that mates to the CCC body, crushing a metallic O-ring between them, which provides a primary boundary for storage of the spent fuel. This boundary is not credited for confinement. Leak-testing requirements assure that the CCC will function as an effective "canning" barrier. Each CCC body and closure will be certified at the manufacturer to a leak rate of \( \leq 1 \times 10^{-3} \text{ scc/sec} \). After the CCC is loaded with spent fuel in the interim examination and maintenance (IEM) cell, a pressure decay test to \( \leq 1 \times 10^{-1} \text{ scc/sec} \) is performed on the seal to verify correct installation of the metal Helicoflex seal. Additionally, each fuel storage tube is closed at the bottom with a nickel alloy cup to prevent potential caustic fission product solutions from degrading the ISC confinement liner in the unlikely event of a leak out of a fuel pin. Additional features of the CCC that provide "canning" assurance are as follows: (1) all pressure boundary welds are required to be full penetration and penetrant inspected during the fabrication process; and (2) each CCC is hydrostatically tested to the design pressure of 105 lbs/in² gauge, which is the pressure resulting from 100% fission gas release of seven fuel assemblies.

**D4.3.1.3 Core Component Container Functional Requirements.**

**Handling/Drop** – The CCC is analyzed as an integral part of the FFTF cask/container system. The CCC shall withstand the induced loads from all normal operation and handling/drop accidents. The CCC structural integrity required to maintain criticality geometry control shall not be compromised.
Cask Tipover – The CCC is analyzed as an integral part of the FFTF cask/container system. This analysis is discussed in Section D4.4.1. The CCC structural integrity required to maintain criticality geometry control shall not be compromised.

Fuel Rod Rupture – The CCC is analyzed as an integral part of the FFTF cask/container system. The CCC shall withstand the induced loads from rupture of all pins in seven fuel assemblies. This analysis is discussed in Section D4.4.1. The CCC structural integrity required to maintain criticality geometry control shall not be compromised.

Seismic – The CCC is analyzed as an integral part of the FFTF cask/container system. The CCC shall withstand the 200 Area design basis earthquake (DBE) of 0.26 g, as discussed in Section D4.4.1. The CCC structural integrity required to maintain criticality geometry control shall not be compromised.

Fire – The CCC is analyzed as an integral part of the FFTF cask/container system. The atmosphere internal to the ISC can be either dry argon or dry helium gas. For the different inerting cases evaluated, the maximum inner-cavity wall (liner) temperature limit is 495 °F (argon) or 640 °F (helium), respectively, at the fuel mid-plane (78.5 in. from the top of the CCC) to satisfy a maximum pin cladding temperature limit of 900 °F. The CCC structural integrity required to maintain criticality geometry control shall not be compromised.

D4.3.1.4 Core Component Container System Evaluation. The CCC is designed to "can" the spent fuel. This feature will allow for effective retrieval of the spent fuel in the event of excessive cladding degradation, but does not require a leaktight confinement boundary. This feature was provided for personnel protection during retrieval of the CCC from the ISC after storage. The CCC is not designated as a confinement boundary for storage or on-site shipment. Consequently, a demonstration of confinement requirements was not imposed on the CCC "canning" boundary.

10 CFR 72 requires two independent barriers be maintained between the fuel and the environs. 10 CFR 72.122(h)(1) states that the spent fuel cladding is considered the primary confinement and must be protected during storage against degradation that leads to gross ruptures or the fuel must be otherwise confined, "canned," such that degradation of the fuel during storage does not pose operational safety problems with respect to its removal from storage.

As described in a memo to R. A. Almquist (Guttenberg 1995), even though the FFTF spent fuel cladding will meet the requirements noted above upon initial placement into the dry storage cask or ISC, the FFTF spent fuel storage system also "cans" the fuel within the CCC. The function of the CCC is to provide added assurance that the long-term primary boundary of the FFTF spent fuel storage system can maintain performance equivalent to commercial spent fuel cladding. The approach to "can" the fuel within the CCC was implemented due to: (1) the concern that cladding degradation by a phenomenon known as "hot cell rot," which results in fuel
rubblization, may occur during the dry storage life, and (2) a lack of long-term data specific to a
dry cask storage environment for the FFTF spent fuel.

The concern with "hot cell rot" is based on several isolated cases of fuel cladding
degradation that were observed during post-irradiation storage examination of liquid metal
reactor assemblies at several U.S. facilities, as well as in Europe and Japan. In all observed
cases, the phenomenon was strictly associated with degradation of the fuel cladding. The
phenomenon by itself does not produce gross degradation of the oxide fuel. Most documented
instances were associated with storage or handling in air, or where air and moisture in-leakage
was not strictly controlled. "Hot cell rot" was never observed during IEM cell fuel handling at
FFTF.

The cladding degradation mechanism associated with "hot cell rot" is thought to be a
form of caustic stress-corrosion cracking. The irradiated fuel cladding can have large residual
stresses during its storage period, and the presence of minute amounts of residual sodium
hydroxide on pin surfaces and crevices after cleaning with a moist gas-water rinse process is
possible. Exposure to moisture and air could create conditions favorable to stress-corrosion
cracking. The observed cladding degradation associated with "hot cell rot" ranges from scattered
cracks along the fuel pin to cracking around the entire circumference of the fuel pin in the most
severe case. This cracking can result in structural failure during handling of individual fuel pins;
however, the experience to date has been that the cladding provided fuel retention even for the
most severe case.

These isolated failures are not expected to be indicative of how the FFTF fuel will
perform in "leaktight" dry storage. This is because the leaktight ISC limits the in-leakage of
oxygen and moisture impurities to extremely small amounts. Preventing in-leakage of moisture
and air effectively limits the conditions required for stress-corrosion cracking of the cladding to
occur. Extremely small amounts of impurities are contained in the relatively pure inert backfill
gas. These impurities are trapped inside the storage cask when it is sealed and can only react
with a finite number of molecules before the oxidation/degradation reaction stops. Because the
cask is leaktight, it prevents further significant introduction of impurities.

Even though limiting air and moisture in-leakage will effectively limit "hot cell rot"
during dry storage, there remain inherent differences between the FFTF spent fuel and
commercial spent fuel that prevent direct correlation of acceptable dry storage conditions. These
differences include higher burn-ups of FFTF fuel that create different pin pressure characteristics
and more concentrated fission product inventories, different irradiation histories and conditions,
different cladding materials, and the use of sodium versus water coolant. Additionally, there are
no long-term data for storage of FFTF fuel in dry cask storage conditions.

The CCC canning criterion is based on comparison to the expected storage performance
of commercial fuel cladding. Additionally, studies on commercial fuel cladding performance in
long-term dry storage indicate that some failure of fuel rods can be expected in dry storage and
that the resultant defects are in the form of pinholes or hairline cracks that vary in size from
1 to 30 μ (WHC-SD-FF-ES-024). A CCC leak rate of $1 \times 10^{-3}$ scc/sec correlates to a single leakage hole size of 2.5 μ in diameter using American National Standards Institute (ANSI) N14.5, *American National Standard for Radioactive Materials - Leakage Tests on Packages for Shipment*, Table B2. This leakage hole size determination is conservative because it assumes that only one leakage path exists (i.e., maximum hole size) and an effective "cladding replacement" boundary is easily demonstrated when compared to the commercially accepted range of 1 to 30 μ for pinhole breaches. Furthermore, the single hole leakage path assumption is extremely conservative and, in reality, the 2.5-μ hole size would be overestimated. In the case of the actual CCC design, any leakage past the seal would be through multiple minor machining marks or imperfections that run perpendicular to the seal surface. Any realistic leakage hole size would be a function of the number of surface imperfections and would be correspondingly smaller.

Further conservatism is demonstrated for particulate retention. The CCC provides a bolted closure seal at the top, and the rest of the assembly is full-penetration welded. The sealed CCC is then leak tested to $1 \times 10^{-3}$ scc/sec. Therefore, it is reasonable to assume that only the seal would have minor leaks based on the unlikely 2.5-μ single leak path hole size discussed above. For a fuel fragment to approach the CCC seal, it would have to overcome gravity and traverse a highly tortuous path up and around the pin plenum region approximately 5 ft in length to the leak path. Additionally, the CCC materials have not experienced the severe environment of a reactor and would not be expected to have degraded properties. The nickel alloy cup closure located at the bottom of each CCC storage tube will retain any potentially damaging caustic mixture and prevent it from contacting the ISC confinement structure in the event of caustic material release outside a fuel pin. The CCC will provide structurally sound retrievability for a case where spent fuel degradation exceeds expectations.

**Handling/Drop** - The CCC was analyzed to confirm that it can safely withstand the following normal, off-normal, and accident conditions. Fully loaded CCCs (six or seven fuel assemblies, or six pin containers) are addressed in WHC-SD-FF-DA-077, *Stress and Structural Analysis of the Core Component Container (CCC)*, and SNF-4790, *200 Area ISA Design Basis Accident Analysis Documentation for FFTF Fuel*. Partially loaded CCCs are not analyzed, and must be evaluated on a case by case basis.

Normal loading conditions:

- Vertical lift and set down by a crane.

Accident conditions:

- 18-ft drop of the CCC into the ISC
- 4-ft sideways drop of the ISC with the CCC inside
- 8-ft drop of the ISC with the CCC inside onto a concrete storage pad.
These conditions are analyzed for the DBA in Chapter D3.0, with the analysis summarized in Section D3.4.2.1. Material properties were evaluated using a peak CCC temperature condition of 600 °F. Normal CCC conditions were evaluated in accordance with the stress limits of the ASME Code, Section VIII, Division 2 (ASME 1989), and the accident conditions were evaluated in accordance with the stress limits of the ASME Code, Section III, Appendix F (ASME 1989).

Nuclear safety equivalency to NRC requirements would require the CCC to be designed and fabricated to ASME Code, Section III, Subsection NB or NC, for providing criticality geometry control. This was identified during final reviews for initial loading of the FFTF fuel in 1996. A decision was made, with DOE approval, to continue with the ASME Section VIII container since it provided sufficient structural capacity for storage purposes. It was acknowledged that the FFTF fuel would require repackaging into an approved ASME Section III container prior to off-site transport for final disposal at a repository. This repackaging was assumed to occur in a future "hot cell" to be co-located near the 200 Area ISA and Canister Storage Building facilities.

A thermal stress analysis was performed on the CCC. The results indicate that the average temperature around the circumference of the storage tube at the mid-plane of the core component fuel section is well below the 600 °F design temperature used to bound the structural calculations. The thermal analysis, WHC-SD-FF-ER-100, Thermal Analysis of the Core Component Container Within the Interim Storage Cask, shows that both normal and accident conditions will result in ISC liner temperatures that are well below the limiting design requirement parameter of 495 °F. The CCC structural integrity required to maintain criticality geometry control was not compromised.

**Cask Tipover** – The CCC is an integral part of the FFTF cask/container system and is analyzed for the DBA in Chapter D3.0. This analysis is summarized in Section D3.4.2.3 and discussed in Section D4.4.1. Analyses performed for the ISC tipover show that induced stresses and loads are bounded by the 4-ft drop onto an unyielding surface analyzed in Section D3.4.2.1. The CCC structural integrity required to maintain criticality geometry control is not compromised.

**Fuel Rod Rupture** – The accident condition of all fuel rods being ruptured is analyzed for the DBA in Chapter D3.0, and the analysis is summarized in Section D3.4.2.4. The inventory of fission gas and those gases produced during 50 years of radioactive decay are analyzed. The analysis assumes the worst-case ISC cavity average temperature of 286 °F. The maximum pressure is determined to be 62 lbs/in² gauge for the CCC worst-case loading of seven DFAs. The design pressure of the CCC is 70 lbs/in² gauge, thus providing a pressure margin of 8 lbs/in² or about 11%. A finite element stress analysis was also performed for the pressure load of 70 lbs/in² gauge (WHC-SD-FF-DA-077). The analysis determined that CCC structural integrity required to maintain criticality geometry control is not compromised. Each CCC is hydrostatically tested to the design pressure of 105 lbs/in² gauge.

HNF-3553 REV 0
Annex D – 200 Area Interim Storage Area
Seismic — The design basis seismic event for the CCC, as an integral part of the FFTF cask/container system, is analyzed for the DBA in Chapter D3.0 and the analysis is summarized in Section D3.4.2.5. The CCC structural integrity required to maintain criticality geometry control was not compromised as the ISC does not slide or tip over. All seismically induced loads are well bounded by the drop impact accelerations.

Fire — The conditions of peak thermal temperature during and after the transportation DBF are analyzed for the DBA in Chapter D3.0. These analyses are summarized in Section D3.4.2.7. The fuel cladding temperature limit of 900 °F and CCC closure seal temperature limit of 500°F are evaluated.

The accident fire results in a short-term thermal loading on the ISC. Section D3.4.2.7 summarizes the ISC temperatures in the cask during a fire. Most of the concrete remains below the 350 °F accident temperature allowable by American Concrete Institute (ACI) 349-90, Code Requirements for Nuclear Safety Related Concrete Structures. For the conditions representing the fire accident, the large mass of concrete helps keep the interior temperatures of the cask relatively cool. The maximum liner temperature reaches 309 °F, within the allowable limit of 495 °F (with argon-inerting gas). At least 17 in. of concrete remain below the 350 °F ACI 349-90 temperature limit defined for accident conditions.

D4.3.1.5 Core Component Container Controls (Technical Safety Requirements). The assumptions associated with the CCC that require TSRs to ensure performance of its safety function are as follows:

- Each CCC shall contain six DFAs in the outer positions, seven DFAs including the center position, or six Ident-69 containers in the outer positions. The loaded CCC can contain a mixture of fuel assemblies and pin containers such that the total is either six or seven, and the number of pin containers is five or less. No partially filled CCCs are permitted.
- There shall be no more than a total of 1,519 pins in a CCC container to protect the fuel rod rupture pressure calculation assumptions.
- Only intact fuel shall be placed into a CCC.

D4.3.2 Light Water Reactor Canister

The LWR canister structure provides required criticality geometry control and is therefore designated Safety Class, as identified in Table D4-2. The canister also has safety-significant functions, as discussed in Section D4.4.5.

The Nuclear Assurance Corporation (NAC)-1 inner LWR canister design performance requirements are established by SNF-4894, Spent Nuclear Fuel Project Acceptance Criteria for
LWR Fuel Storage System. The following discussions are based on a canister design that is in the final stages of design, review, and approval. The design provides a welded closure and dimensional constraints to accommodate future packaging in standard containers. Characteristics of the canister (e.g., design pressures or structural strength) are expected to be unchanged from or improve upon the canister design used as the basis for evaluation. Calculations and text in this section will need to be verified upon design completion and approval of a design analysis report for the LWR canister. Revision will be required only if the characteristics and features of the canister are changed significantly. All affected discussions will be reviewed for applicability based on the final LWR canister design.

D4.3.2.1 Light Water Reactor Canister Safety Function. The LWR canister provides the structure that ensures criticality geometry control of the LWR fuel during storage at the 200 Area ISA and is designated Safety Class for criticality prevention only. No other safety-class functions were identified by the accident analysis (Chapter D3.0) for the NAC-1 cask system components. The analyses did identify safety-significant functions of the inner canister. The safety-significant functions for individual components of the NAC-1 cask system are discussed as an integral part of the NAC-1 cask evaluation provided in Section D4.4.5. This includes the inner canister, the NAC-1 cask, and the International Standards Organization (ISO) shipping/storage container. Specific individual component evaluation is addressed in Section D4.4.5.4.

The DBAs identified in Chapter D3.0 that could impose structural loads or accelerations on the LWR canister inside the NAC-1 cask have the potential to change the criticality geometry control structure (Tables D4-1 and D4-2). CSERs discussed in Chapter D6.0 credit the inner canister with providing the structure that maintains the critically safe geometry. The functional requirements and evaluations for the LWR canister (Sections D4.3.2.3 and D4.3.2.4) include summary discussions of the bounding DBAs using the following analyses:

- Handling/drop – Maintain confinement of radioactive materials after a credible drop (Safety Significant) within the NAC-1 cask and maintain structural integrity to provide criticality geometry control (Safety Class).
- Fuel rod rupture – Maintain confinement of radioactive materials (Safety Significant) and maintain structural integrity to provide criticality geometry control (Safety Class) at the pressure generated.
- Seismic – Withstand seismic accelerations without loss of confinement (Safety Significant) and maintain structural integrity to provide criticality geometry control (Safety Class).
- Fire – Withstand transportation DBF conditions inside the NAC-1 cask without loss of confinement (Safety Significant) or exceeding temperature limits for fuel cladding.
or container components to maintain structural integrity for criticality geometry control (Safety Class).

The NAC-I cask provides a passive structure that ensures the integrity of the inner canister structure will be maintained.

**D4.3.2.2 Light Water Reactor Canister System Description.** The commercial LWR fuel storage system consists of six storage units, each comprised of an LWR canister, a NAC-1 cask, and an ISO shipping/storage container. The welded inner canister and the intact fuel cladding will provide confinement of the fuel during storage, as required by 10 CFR 72. The NAC-1 cask provides a shielding overpack that provides weather and NPH protection.

The LWR canisters are designed and fabricated to the requirements of the ASME Code Section III, Subsection NB (ASME 1995), as required by the LWR canister acceptance criteria. Canister internals, provided for positioning the fuel assemblies, and the container for consolidation of the loose rods fall under ASME Code, Section III, Subsection NG. The canisters were designed for a life expectancy of 50 years.

The LWR canister provides a confinement boundary for the 300 Area LWR fuel. The canister is fabricated from a 12-in. stainless steel pipe with welded base cap and top closures. It has a nominal outside diameter of 12.75 in., with a maximum outside diameter of 13.0 inches at the end cap, and a total length of 165.25 in. The bottom cap is machined, so the pipe-to-cap weld is inspectable at the side of the canister. The closure lid contains a penetration that allows the canister to be evacuated, filled with helium, and leak tested to the requirements of ANSI N14.5.

The canisters provide criticality geometry control such that a loaded canister will have a $k_{eff}<0.95$ when fully moderated and reflected. A 2.0-in. thick stainless steel removable handling fixture is provided for the canister upper cap. Space remains in the cask cavity for an additional 10 in. of gamma shielding.

The design weight of the canister is 1,250 lbs. The maximum loaded weight of the canister is not to exceed 3,300 lbs. The maximum internal design pressure of the canister is 75 lbs/in² gauge testable to a pressure of 100 lbs/in² gauge.

The canister used for loose boiling water reactor (BWR) and pressurized water reactor (PWR) rods incorporates an internal spacer arrangement to contain the rods (Figure D2-14). The fuel is loaded in a split 8-in. stainless steel schedule 80 pipe that is skip-welded closed. This container extends into the canister lid recess for upper external restraint and is packaged in the canister cavity within a sleeve of 10-in. stainless steel schedule 40 pipe.

The NAC-1 cask provides shielding and protection of the inner canister. The structures of the NAC-1 cask are constructed of stainless steel. The cask cavity is formed by the inner shell, which is a 14.125-in. outside diameter, 0.3125-in. thick stainless steel shell. The upper end of the shell is welded to the cask cavity flange; the bottom end of the shell is welded to the cask
bottom casting. Surrounding the inner shell of the cask is a nominal 6.6875-in. thick annulus of chemical-grade lead (gamma) shielding. The lead is shaped such that approximately 5 in. from the bottom and 30 in. from the top, the thickness is reduced to 5.4375 in. There is an annular void, 5 in. long by 1.25 in. thick, at the bottom end of the gamma shield to allow for any lead expansion during the fire accident. The upper axial shaping is accomplished by reducing the diameter of the outer shell 2.50 in. over a 30-in. length. The lead/steel interface of the inner and outer shell have axial copper fins that are imbedded in the lead and welded to the inner and outer shells to transfer heat across the interface with a minimum temperature gradient (see Figure D2-10). Additional NAC-1 cask design and fabrication details are provided in Section D4.4.5.2.

The 300 Area LWR irradiated fuel inventory addressed in this document consists of five PWR assemblies and consolidated BWR and PWR individual rods. Each PWR assembly is packaged in an individual cask in the assembly configuration. The individual rods are packaged in a single cask in a container that fits within the inner canister. Characterization of the fuel inventory is discussed in Section D2.5.1.3.

D4.3.2.3 Light Water Reactor Canister Functional Requirements

Handling/Drop – The inner canister is analyzed as an integral part of the NAC-1 cask/container system. The NAC-1 cask/container system, including the canister, shall withstand the induced loads from all normal operation, handling, and storage drop accidents sufficient to ensure that the inner canister structural integrity required to maintain criticality geometry control shall not be compromised.

Fuel Rod Rupture – The canister shall withstand the internal pressure resulting from rupture of all contained fuel rods without compromising the canister structural integrity required to maintain criticality geometry control.

Seismic – The inner canister is analyzed as an integral part of the NAC-1 cask/container system. The NAC-1 cask/container system, including the canister, shall withstand any induced stresses resulting from the design basis seismic event, with sufficient integrity to ensure that the inner canister structural integrity required to maintain criticality geometry control is not compromised.

Tornado/wind – Withstand tornado pressure differential without structural damage to the LWR canister, which could result in loss of criticality geometry control.

Fire – The inner canister is analyzed as an integral part of the NAC-1 cask/container system. The NAC-1 cask/container system, including the inner canister, shall withstand temperatures resulting from the DBF without compromising the canister structural integrity required to maintain criticality geometry control. This includes a requirement to not exceed the maximum allowable fuel cladding temperature limit to assure that the fuel remains in the analyzed geometry.
D4.3.2.4 Light Water Reactor Canister Evaluation. The LWR canister provides the structure that ensures critical geometry control of the LWR fuel during storage at the 200 Area ISA and is designated Safety Class for criticality safety reasons only. The criterion for criticality safety is that $k_{\text{eff}} < 0.95$ be demonstrated for all conditions, incorporating any bias/uncertainties associated with the analysis.

Two CSERs were prepared for the interim storage of the NAC-I casks in the 400 Area ISA. Chapter D6.0 addresses specific criticality aspects of 200 Area LWR fuel storage at the ISA as individual casks and in the storage array. The LWR canister is required for criticality geometry control and is therefore designated Safety Class. Structural integrity of the PWR fuel assembly is required by the criticality analysis to retain the fuel material within the square cross-sectional geometry of the fuel assembly contained in the inner canister. Specific structural analysis of PWR assemblies need not be performed since this has been addressed for commercial fuels in a Lawrence Livermore National Laboratory document UCID-21246, Dynamic Impact Effects on Spent Fuel Assemblies. The document was prepared to assess the effects of dynamic impacts (to be expected from cask drop or similar incidents) on the integrity of fuel rod cladding for zircaloy-clad LWR spent fuel assemblies during cask handling and storage. The study concluded that commercial LWR fuel assemblies will not yield or buckle at the impact g loads calculated for the NAC-1 cask, and their structural integrity can be assumed for safety purposes. The canisters for the PWR assemblies, however, provide defense in depth for criticality safety due to the provision of safety-class support for retention of the fuel assembly geometry.

The consolidated individual BWR and PWR fuel rods that are stored in a NAC-1 cask are packaged in a canister with internal components that retain the cross-sectional geometry limits required for criticality control. The loose rods are packaged in a split container fabricated from 8-in. schedule 80 stainless steel pipe. The split container is tack welded shut and packaged in the canister within a 10-in schedule 40 stainless steel pipe sleeve. The 10-in. pipe provides the limiting diameter for criticality geometry control. The individual rods remain oriented in a close packed restricted configuration similar to the rods in the fuel assemblies and are bounded by the assembly buckling loads and conclusions.

Handling/Drop – The LWR canister is analyzed as an integral part of the cask/container system in which the NAC-1 cask provides a passive barrier to stresses resulting from storage/handling drops. Evaluation of the cask/container system handling/storage drop-induced stresses is provided in Section D4.4.5. The NAC-1 SAR (NAC 1990) provides evaluations that examine hypothetical accidents that conservatively bound the 200 Area ISA accident-induced stresses. The details of the analysis are provided in Chapter D3.0 and summarized in Section D3.4.2.1. As required by 10 CFR 71, "Packaging and Transportation of Radioactive Material" (1995 edition), calculations were documented for the types of analyses discussed below. The original NAC-1 SAR-referenced sections of 10 CFR 71 (1971 edition) are no longer directly citable; however, the requirements are the same as those listed in the following statements.
Cask analyses evaluated to hypothetical accident conditions (10 CFR 71.73) include the following:

- Analyze a free drop of the cask through a distance of 30 ft onto a flat, essentially unyielding, horizontal surface, striking the surface in a position for which maximum damage is expected;

- Followed by a free drop of the cask through a distance of 40 in., in a position for which maximum damage is expected, onto the upper end of a solid, vertical, cylindrical, mild steel bar mounted on an essentially unyielding, horizontal surface. The bar must be: (1) 6 in. in diameter, with the top horizontal and its edge rounded to a radius of not more than 0.25 in., and (2) of a length as to cause maximum damage to the cask, but not less than 8 in. long. The long axis of the bar must be vertical.

The design of the NAC-1 cask system is predicated on the ability of the cask to transport 150-day cooled PWR spent fuel. The thermal energy of the design basis PWR fuel imposed temperature and pressure conditions on the cask structure that produced stresses that were significantly greater than the stresses imposed by the thermal energy and pressure of the 300 Area LWR fuel rods in the inner container. The calculations provided for the NAC-1 transportation calculations are therefore conservative for 200 Area ISA storage conditions.

Evaluation of the 400 Area ISA storage configuration included results from the NAC-1 SAR (NAC 1990) and additional analyses specific to the ISA. The evaluation of the analyses summarized in Section D.3.4.2.1 demonstrated the following:

- Conclusion for the 30-ft free fall analyses – The NAC-1 SAR analyses concluded that the integrity of the NAC-1 cask would be maintained, although significant damage would occur to the exterior, sacrificial structures of the NAC-1 cask.

- Conclusion for the 40-in. free fall onto a mild steel pin analyses – The NAC-1 SAR analyses concluded that the integrity of the NAC-1 cask would be maintained. Minimal damage to the cask, namely the localized deformation and/or slight puncture of the shield tank, would be incurred.

The LWR canister was designed and analyzed in accordance with the requirements of the ASME Code, Section III, Subsection NB (ASME 1995), as required by NUREG/CR-3854, Fabrication Criteria for Shipping Containers, for the Category I component safety group and 10 CFR 71. The canisters are designed for an operational environment inside the NAC-1 cask body under both normal and accident conditions of transport per 10 CFR 71, and normal and off-normal conditions of storage per 10 CFR 72.

The analysis of the LWR canister for the postulated accident conditions of transport investigated the integrity of the canister to a 96 g axial impact deceleration load and the probable initiation of buckling. Fatigue analysis was also performed to predict inner canister limitations to
mechanical and thermal cyclic loading conditions. The analysis shows that the design of the LWR canister satisfies the required design checks with an acceptable margin of safety to ensure that the stresses induced will not compromise the canister structural integrity required to maintain criticality geometry control.

**Fuel Rod Rupture** – The fuel-rod rupture analysis is provided in Chapter D3.0, and the results are summarized in Section D3.4.2.4. The Chapter D3.0 analysis includes calculation of the maximum normal operating pressure for the LWR canister and assumes cask cavity temperature as a result of the hottest summer day (115 °F ambient), along with fuel rod rupture of all rods. The pressure increase within the cask cavity is due to both a temperature increase and 100% rod rupture. This pressure is calculated in WHC-SD-FF-DA-087, *NAC-1 Cask/Canister Pressure Evaluation for PWR Fuel, 300 Area LWR Fuel Storage*, which addresses the fission gas generated during irradiation, initial pressurization within the rods, and the gas within the canister cavity from loading and leak-testing activities.

The pressure within the cavity due to rod rupture at maximum normal conditions is within the design pressure of 75 lbs/in² gauge and pneumatic test pressure of 100 lbs/in² gauge established for the canister.

Worst-case pressures are also calculated for 100% rod rupture during the DBA fire conditions. This accident condition pressure is also well within the design pressures for both the inner canister and the NAC-1 cask, and the stresses induced will not compromise the canister structural integrity required to maintain criticality geometry control.

**Seismic** – The seismic analysis is provided in Chapter D3.0 and is summarized in Section D3.4.2.5. As noted, stresses induced in the NAC-1 cask and the LWR canister during the 200 Area ISA DBE are within the cask system design capabilities. The LWR canister safety-class evaluation calculations consider all components to be part of an integral NAC-1 storage system.

Seismically induced loads are bounded by the drop impact accelerations above. The drop impact evaluation concludes that the cask system is able to withstand any induced stresses from handling/drop events without compromising the structural integrity of the LWR canister required to maintain criticality geometry control.

**Tornado** – The LWR canister design pressure is much greater than the 0.9 lb/in² gauge pressure differential of the design basis tornado (DBT). This minimal differential pressure cannot generate structural damage to the LWR canister.

**Fire** – An analysis of the thermal response of the storage system to the DBF is provided in Chapter D3.0 and summarized in Section D3.4.2.7. The NAC-1 cask SAR (NAC 1990) determined that the cask supported an internal thermal load in excess of the LWR fuel and presented analysis of the transportation fire event that concluded that the cask integrity is preserved. That analysis provides a bounding case for use of the NAC-1 cask for storage of
200 Area LWR fuel. The Chapter D3.0 analysis concludes that the stresses induced will not compromise the canister structural integrity required to maintain criticality geometry control.

**D4.3.2.5 Light Water Reactor Canister Controls (Technical Safety Requirements).** The assumptions associated with the LWR canister that require TSRs to ensure performance of its safety function of criticality geometry control are as follows:

- The number of individual fuel rods in a LWR canister does not exceed a maximum of 179 PWR rods, or 96.5 BWR rods consolidated with 17 PWR rods.
- The individual loose rods must be retained within the 10-in. diameter sleeve (design feature).
- Only intact fuel shall be placed into an LWR canister.

**D4.4 SAFETY-SIGNIFICANT STRUCTURES, SYSTEMS AND COMPONENTS**

**D4.4.1 Fast Flux Test Facility Interim Storage Cask System**

This section discusses the safety significant aspects of the ISC and CCC. The criticality safety aspects of the CCC, which relate to safety-class considerations, are discussed in Section D4.3.1.

**D4.4.1.1 Safety Function.** The ISC is designed to provide secondary confinement for the fuel and structural protection for the CCC. It also provides passive heat removal and radiological shielding protection for site personnel by limiting the dose rate at normally accessible surfaces to acceptable levels (not credited safety functions). As shown in Table D4-2, the ISC is credited with safety-significant functions for the following DBAs identified in Chapter D3.0:

- Handling/drop – Maintain confinement of radioactive materials after a credible drop and provide passive protection of the CCC such that it retains structural integrity.
- Mobile crane fall – Maintain structural integrity sufficient to maintain confinement of radioactive materials after a crane fall.
- Cask tipover – Maintain confinement of radioactive materials after the crane fall and provide passive protection of the CCC such that it retains structural integrity.
- Fuel rod rupture – Maintain confinement of radioactive materials after the rupture of all fuel pins.
Seismic – Withstand seismic accelerations without loss of structural integrity sufficient to maintain confinement, and without tip over or sliding.

Tornado/wind – Withstand DBT winds (excluding DBT missiles) without sliding or tip over. Also withstand the design basis wind and wind-driven missiles established for the 200 Area ISA without loss of structural integrity sufficient to cause loss of confinement.

Fire – Withstand transportation DBF conditions without loss of structural integrity sufficient to cause loss of confinement or exceeding temperature limits for fuel cladding or cask components.

In addition, the ISC provides a confinement boundary for all normal conditions and abnormal events.

As shown in Table D4-2, the CCC is credited with safety-class criticality control functions for the DBAs identified in Chapter D3.0 and previously discussed in Section D4.3.1, as follows:

- Handling/drop
- Cask tipover
- Fuel rod rupture
- Seismic
- Fire

D4.4.1.2 System Description. The ISC is an aboveground concrete and steel shielded, top-loading spent fuel storage cask that will be used to provide safe interim dry storage of a CCC with FFTF spent fuel assemblies or pin containers for a period of up to 40 years at the 200 Area ISA. One CCC can be stored in the cavity of each ISC. The ISC has been designed and fabricated to meet the requirements of WHC-S-4110, Specification for FFTF Interim Storage Cask, in accordance with 10 CFR 72. "Canning" of the spent fuel is provided by the CCC, as discussed in Section D4.3.1. The ISC is designed to provide secondary confinement for the fuel and environmental protection for the CCC. The ISC also provides passive heat removal and radiological shielding protection for site personnel by limiting the dose rate at normally accessible surfaces to acceptable levels. A weather protection cover is installed on each ISC in the ISA.

The ISC design consists of an all-stainless steel internal confinement structure surrounded by steel and concrete shielding. The fully loaded cask, including a loaded CCC with a gross payload of 5,000 lbs, the closure hardware and the weather cover, weighs a maximum of 114,200 lbs. Outer cask dimensions are 85 in. in diameter by 181 in. tall, excluding the weather cover. The internal cavity of the ISC is 21 in. in diameter and 147 in. tall, and will accept one CCC. This cavity, which is formed by a 1.5-in. thick stainless steel cylinder and 8-in. thick bolted top and welded bottom closure plates, provides the confinement boundary. An additional
cover plate may be seal welded over the bolted closure after receipt at the 200 Area ISA to enhance the long-term storage configuration. This cover plate would be seal welded to the vertical cylindrical stainless steel liner around and above the bolted shield closure plug. The lower end of this existing liner is welded to the top confinement flange of the ISC cavity, and there is a 3-in. recessed space above the bolted closure below the existing weather cover. Although it is not anticipated that this cover plate would be removed during the storage period, the seal weld located in this space is accessible with the weather cover removed and could be readily ground out to restore the ISC to its original configuration for future repackaging or for access to test ports in the closure plug.

The ISC confinement boundary design and analysis were performed by General Atomics, which holds an ASME Certificate of Authorization N for design and overall fabrication responsibility for ASME Code, Section III, Division 1 and 2 components. The ISC design analysis and material properties were based on the requirements of the ASME Code, Section III, Subsection NC (ASME 1989). Fabrication of the ISC is based on the ASME Code, Section III, Article NC-4000. The ISC confinement boundary is constructed of ASTM materials but was not required to be stamped or built by a certificate holder. Examples of using the ASME Code, but not requiring a code stamp, can be found in NUREG/CR-3854 and NUREG/CR-3019. Recommended Welding Criteria for Use in the Fabrication of Shipping Containers for Radioactive Materials. The fabricator was not required to be a certificate holder as the design was performed by a vendor with an ASME Certificate of Authorization N for design and overall fabrication responsibility for ASME Section III, Division 1 and 2 components, and the N stamp was not required. Additionally, all ISC design and fabrication activities were performed using a 10 CFR 72 quality assurance program or equivalent.

The bottom of the ISC cavity is fitted with an aluminum crush pad to limit CCC impact loads in the unlikely event that it is dropped into the ISC during loading. The surfaces of the cavity are finished to remove burrs, sharp corners, and weld beads that could potentially interfere with cask loading operations. The confinement structure described above is also surrounded by annular steel shield plates that are surrounded by concrete reinforced with rebar. As discussed in the FFTF ISC design analysis report (General Atomics 1995), the concrete shielding structure is designed to meet ACI 349-90 requirements. The concrete design mix was selected to ensure strength and long life over the range of temperature conditions expected during normal operations, and the more extreme short-term temperatures that could occur during off-normal or accident conditions.

The ISC heat dissipation is totally passive. All required heat removal can occur by conduction, thermal radiation, and convective cooling of the outer surface. The ISC is also provided with a passive cooling system that removes heat by using an internal natural circulation airflow system. The airflow system is formed by two inlet ducts, an annular gap between the confinement boundary cylinder and the inner shield, and two outlet ducts. The inlet and outlet ducts are steel-lined penetrations through the concrete that take non-planar paths to minimize radiation streaming. These penetrations consist of two 4-in. outside diameter ducts that supply air to the bottom of a 0.75-in. wide annulus between the confinement boundary cylinder and the
inner shielding cylinder. Natural convection circulates air up the annular space and out two similar ducts at the top of the annulus. This overall heat removal system is designed to limit localized concrete temperatures to below 200 °F on the warmest normal condition day, with the bulk of the concrete maintained below 150 °F. The ISC thermal analysis for the extreme ashfall accident (General Atomics 1995) shows that even if the ducts become plugged and natural convection cooling is eliminated, these limits will still be met. Therefore, operability of the cask ventilation system is not required to be monitored to ensure that cask thermal limits are not exceeded.

Based on the white-painted exterior surface of the ISC, the solar absorptivity of the cask is taken to be 0.3 and the emissivity is 0.9. The emissivity value is based on heavily oxidized paint. The only possible effect that could result from degradation of the paint is a possible increase in the absorptivity, but this case is bounded by the analyzed ashfall accident case (General Atomics 1995), which demonstrates normal limits are not exceeded. Therefore, the ISC paint color is not a safety requirement. The off-normal severe cold is used to evaluate the thermal distributions of the ISC for the -27 °F lowest ambient temperature reported for the Hanford Site. All temperatures are within limits and the thermal gradients are less than the normal condition case with no wind.

The ISC provides several layers of shielding to ensure worker as-low-as-reasonably achievable (ALARA) radiation protection. The first layer of shielding consists of a 3.0-in. thick carbon steel clamshell around the entire length of the cavity. Another partial length, 4.0-in. thick, carbon steel clamshell shield is provided for additional shielding at the cavity mid-plane where the fuel section is located. The clamshell shields are designed with studs that attach to the reinforced concrete cylinder shield. This shield is a minimum of 21.25 in. thick for additional radial shielding. Supplemental axial shielding is provided by 4.0-in. thick plates below the bottom head and below the upper closure. A design dose rate of 2 mrem/h at accessible surfaces for normal conditions and 200 mrem/h at the (inaccessible) bottom head is defined in WHC-S-4110. Shielding acceptance criteria in the design specification allowed a localized dose rate of 5.0 mrem/h to account for potential shielding imperfections and localized hot spots.

The design description of the CCC is presented in detail in Section D4.3.1.

D4.4.1.3 Fast Flux Test Facility Interim Storage Cask System Functional Requirements. The ISC containing a CCC shall be able to withstand the accident loads associated with handling and drops, mobile crane falls, tipovers, fuel rod ruptures, seismic events, tornado/wind events, and fire/thermal events. In addition to those loads, additional handling accident loads were evaluated to fully envelop all ISC load conditions. The ISC shall withstand these design-basis accident loads to the extent that the reduction in shielding is not sufficient to increase the external dose rate to more than 1,000 mrem/h at 1 m from the external surface of the package specified in WHC-SP-4110, and the ISC confinement integrity is maintained (i.e., stress levels in the ISC confinement boundary do not exceed the levels specified for Level D service limits of the ASME Code, Section III [ASME 1989]). Each type of accident load is discussed below.
Confinement – Two confinement boundaries shall be maintained for the fuel in normal and accident conditions. The accident loads and conditions under which confinement must be maintained are identified in Section D4.4.1.1. The ISC shall be one of the confinement boundaries and the intact fuel cladding shall be the other confinement boundary. The cask must be designed to provide redundant sealing of confinement systems.

Handling/Drop – The FFTF cask system shall be analyzed to remain functional with no loss of confinement or structural integrity for the following handling and drop scenarios:

- A free drop of 40 in. striking the top end of a vertical, cylindrical, mild steel bar mounted on an unyielding horizontal surface in the worst-case orientation.

- A free drop of 4 ft onto a flat, unyielding, concrete horizontal surface, striking the surface in a position for which maximum damage is expected.

- A free drop of 8 ft onto a flat, 1.5-ft. thick reinforced concrete horizontal surface, striking the surface in a position for which maximum damage is expected.

- A drop of a fully loaded CCC from a height of 18 ft into an ISC.

Loads shall be combined such that normal loads from pressure, temperature, and dead weight act in combination with all other loads. No two off-normal or accident events are postulated to occur simultaneously.

Mobile Crane Fall – The ISC shall be able to withstand direct impact of the mobile crane boom without loss of structural integrity sufficient to maintain confinement if a crane failure occurs.

Cask Tipover – The ISC shall be able to withstand the induced load from a tipover accident without loss of confinement, loss of shielding beyond accident limits, or loss of criticality configuration geometry control by the CCC.

Fuel Rod Rupture – The ISC design pressure of 36.7 lbs/in² gauge shall not be exceeded by fuel rod rupture regardless of thermal conditions.

Seismic – The ISC containing the CCC shall be able to withstand the 200 Area ISA DBE without loss of structural integrity sufficient to maintain confinement and without sliding or tip over.

Tornado/Wind – The ISC shall be able to withstand the DBT winds (excluding missiles) without loss of structural integrity sufficient to maintain confinement and without sliding or tip over. The ISC shall also be able to withstand the design basis wind and wind-driven missiles established for the 200 Area ISA.
Fire - The design basis storage fire is bounded by the design basis transportation fire of 10CFR71.73(c)(3) per the 200 Area ISA FHA (HNF-4932), with the following requirements:

- Fuel cladding temperatures shall not exceed 900 °F to preclude cladding breach.
- The cask shall be designed to provide adequate heat removal capacity without active cooling systems (10 CFR 72.236[f]).
- The atmosphere internal to the ISC can be either dry argon or dry helium gas. For each inerting case that is evaluated, the inner-cavity wall (liner) maximum temperature limit is 495 °F (argon) or 640 °F (helium) at the fuel mid-plane (78.5 in. from the top of the CCC) to satisfy the maximum pin cladding temperature limit of 900 °F. The acceptance criteria for the ISC peak liner temperature was based on pre-design analyses that were performed to allow the ISC design to proceed independent of a CCC thermal analysis. These criteria were established (WHC-SD-FF-ES-024) based on the 900 °F cladding limits. The ISC liner limits were determined by analysis of various inerting cases based on a worst-case concrete and steel shielded, non-ventilated, storage cask configuration containing a CCC loaded with six 250-W assemblies. For this configuration, ISC liner limits of 495 °F with argon-inerting gas, or 640 °F with helium-inerting gas, were chosen to ensure that the 900 °F cladding temperature limit would not be exceeded for any cask design. Since the CCC is inerted with argon, the 495 °F limit is conservatively imposed for the ISC liner.
- The concrete temperature limits for the ISC consist of normal localized, average, and accident temperature limits in accordance with guidelines of ACI 349-90. The ACI long-term concrete normal temperature limits are 150 °F for average temperatures and 200 °F for localized areas. The short-term accident temperature limit is 350 °F.
- The Helicoflex seal temperature limits are 700 °F for the ISC and 500 °F for the CCC. These limits are established based on the manufacturer's recommendation for the different seal materials.
- Complete blockage of the ISC ventilation ducts shall not result in temperatures that exceed any functional requirements listed above.

D4.4.1.4 Fast Flux Test Facility Interim Storage Cask Evaluation.

Confinement - The FFTF spent fuel storage system is provided with multiple systems to confine the radioactive fuel. The ISC serves as the main pressure boundary and leakage barrier to the environment to ensure that environmental, worker, and public safety is maintained and to control the storage atmosphere such that degradation of the spent fuel remains limited. The maximum permissible design leakage rate for the ISC confinement barrier is "leaktight," as defined in ANSI N14.5. At this leak rate, $1 \times 10^7$ scc/sec air, the stored spent fuel is not expected to degrade during long-term dry storage, as the leaktight boundary prevents oxygen and
moisture from entering the cask and contaminating the inert atmosphere. As such, there is no known mechanism for accelerated corrosion of the spent fuel. The FFTF spent fuel cladding must meet the intact fuel criteria when the fuel is placed into the CCC. Because each spent fuel assembly will be washed using the sodium removal process in the IEM cell, an assessment of cladding integrity is achieved before transfer to dry storage. The sodium removal wash water will provide indication of a gross cladding failure.

There are no long-term data specific to dry storage of FFTF spent fuel in the leaktight inert dry atmosphere conditions of a dry storage cask. The ISC design is consistent with commercial spent fuel dry storage practice and restricts oxygen and moisture in-leakage to minute levels such that degradation of the spent fuel is expected to be effectively controlled over the storage lifetime. Even so, because there is no long-term data, it is assumed that the FFTF spent fuel cladding may not perform in the same manner as commercial fuel. This results in the requirement to "can" the spent fuel assemblies within the CCC.

The CCC boundary consists of a cluster of seven closed-bottom tubes that form the storage basket, with a bolted closure that contains a single metal seal. The CCC body and closure seal assembly are tested and certified at the manufacturer to provide a $<1 \times 10^{-3}$ scc/sec leakage rate, in accordance with ANSI N14.5. Additionally, the final closure assembly seal, located at the top of the CCC approximately 5 ft above the fuel zone, is tested to a leak rate of $<1 \times 10^{-3}$ scc/sec after loading the spent fuel in the IEM cell. The assembly test is in addition to visual verification that the seal is correctly installed. This approach ensures the fuel is effectively " canned" and exceeds the gross visible rupture criteria for cladding confinement that is allowed for commercial spent fuel.

10 CFR 72.236(e) requires the ISC to be designed for redundant sealing of the confinement systems. The ISC is designed with redundant seals in the closure lid and redundant welds on the penetration port cover (10 CFR 72). Confinement system redundancy for the ISC is ensured by a combination of inspection techniques, which include radiographic and ultrasonic inspection, helium leak testing, and dye penetrant testing of the confinement welds. The confinement capability of the empty ISC liner assembly is assured by the manufacturer by radiographic inspection of the longitudinal and circumferential full penetration welds, and by ultrasonic inspection of the liner to upper flange and bottom plate full-penetration welds. In addition to these tests at the manufacturer, a complete helium leak test of the entire confinement liner is performed. The confinement capability of the loaded ISC is assured by helium leak-testing both closure seals after assembly and dye penetrant testing both seal welds of the penetration port cover plates.

Tests and specifications relevant to confinement integrity of the ISC at the time of cask loading include the following:

- ISC helium backfill pressure requirements
- ISC dye penetrant test of the penetration port closure welds
- ISC maximum permissible leak rate.
10 CFR 72.236(j) required the ISC to be inspected to ascertain that there are no cracks, pinholes, uncontrolled voids, or other defects that could significantly reduce its confinement effectiveness. The quality standards under which the ISC was fabricated and welded provide the assurance of confinement integrity. Additionally, the ISC was pressurized and leak tested after all confinement welding was completed.

A thermal analysis states the atmosphere internal to the ISC can be either dry argon or dry helium gas. For the different inerting cases evaluated, the maximum inner-cavity wall (liner) temperature limit is 495 °F (argon) or 640 °F (helium), respectively, at the fuel mid-plane (78.5 in. from the top of the CCC) to satisfy a maximum pin cladding temperature limit of 900 °F to preclude cladding breach. The thermal analysis shows that the bounding case is reached during the ashfall case in which the peak cladding temperature reaches 800 °F (WHC-SD-FF-ER-100). The maximum seal temperature for the CCC reaches 196 °F during the ashfall condition, as indicated in the FFTF ISC design analysis report (General Atomics 1995).

The sealing system for the ISC retains its confinement capability when subjected to normal, off-normal, and accident loading conditions because there are no normal or accident conditions that will breach the structural integrity or leaktightness of the ISC.

Handling/Drop – The FFTF cask/container system is analyzed for the DBA drops in Chapter D3.0, and the analysis is summarized in Section D3.4.2.1. Several drop analyses were performed for the ISC. Under normal operations, the ISC is lifted vertically by attaching the lifting fixture to three anchor attachments imbedded in the concrete of the ISC. No side lifting is allowed. In accordance with the critical lift requirements of DOE/RL-92-36, the ISC lift points are designed to lift five times the weight of the cask without exceeding the ultimate stress of the material or three times the weight without exceeding the yield strength of the material, whichever is less. Therefore, the normal ISC lifting and handling loads will generate relatively low stresses in the lift points. The weakest link in the ISC attachment design is the anchor lug, which screws into the anchor bolt of the cask. If a lifting accident occurs whereby a lift point fails, this anchor fails before the ISC concrete embedment. In this manner, the ISC integrity or shielding is not affected.

As discussed in Section D3.4.2.1, the ISC system is shown to survive the following drop accidents:

- 18-ft drop of the CCC into the ISC
- 4-ft sideways drop of the CCC while inside the ISC
- 4-ft ISC drop onto an unyielding surface
- 8-ft ISC drop onto a 1.5-ft thick concrete pad
- 40-in. ISC drop onto a 6-in. pin.
The CCC will be contained within the ISC for the entire duration of this project, so an independent drop of the CCC is not possible. However, the CCC drop analyses are identified to demonstrate that it will survive the drops analyzed for the ISC.

The conclusion of the accident analysis is that the ISC system survives all of the analyzed drops without loss of confinement. The 4-ft ISC drop onto an unyielding surface is the bounding case. The 8-ft ISC drop onto a 1.5-ft thick concrete pad is bounded because the pad yields and absorbs much of the impact energy. Since the 200 Area ISA concrete pad is 1.5-ft thick, an 8-ft drop is tolerable without loss of confinement.

As indicated in the accident analysis in Section D3.4.2.1, TSR controls have been applied to ensure that the ISC system is not taken outside of the analyzed bounds.

**Mobile Crane Fall** – The FFTF cask/container system is analyzed for the DBA in Chapter D3.0, and the analysis is provided in SNF-4790 and summarized in Section D3.4.2.2. The structure of the ISC withstands the induced loads from all mobile crane fall accidents without loss of confinement function. The CCC structural integrity is not compromised.

**Cask Tipover** – The FFTF cask/container system is analyzed for the DBA in Chapter D3.0, and the analysis is summarized in Section D3.4.2.3. Analyses performed for the ISC tipover show that induced stresses and loads are bounded by the 4-ft drop onto an unyielding surface analyzed in Section D3.4.2.1. The CCC structural integrity is not compromised.

**Fuel Rod Rupture** – The accident condition of all fuel rods being ruptured is analyzed for the DBA in Chapter D3.0 and the analysis is summarized in Section D3.4.2.4. The inventory of fission gas and gases produced during 50 years of radioactive decay is expected to be 5.4 gram-atoms (moles)/DFA or 37.8 gram-atoms/ISC. This assumes that all free gases contained within the cladding are released. The analysis assumes the worst-case ISC cavity average temperature of 286 °F. The maximum pressure is determined to be 62 lbs/in² gauge maximum for the CCC worst-case loading of seven DFAs (WHC-SD-FF-ER-100). The design pressure of the CCC is 70 lbs/in² gauge. A finite element stress analysis is also performed for the pressure load of 70 lbs/in² gauge (WHC-SD-FF-DA-077). The CCC structural integrity is not compromised. Each CCC was hydrostatically tested to the design pressure of 105 lbs/in² gauge.

The ISC cavity internal pressure is also calculated for the same conditions (General Atomics 1995). The maximum ISC cavity pressure, based on the maximum cavity average temperature of 286 °F for the ashfall accident case, is determined to be 36.7 lbs/in² gauge, which is the design pressure for the ISC.

**Seismic** – The design basis seismic event for the FFTF cask/container system is analyzed for the DBA in Chapter D3.0, and the analysis is summarized in Section D3.4.2.5. The CCC structural integrity is not compromised, as the ISC does not slide or tip over. All seismically induced loads are considered bounded by the drop impact accelerations.
The ISC is designed to withstand the seismic motions from the DBE conditions (0.25 g) for the 400 Area ISA. The FFTF ISC design analysis report (General Atomics 1995) states that the cask is a very stiff structure and consequently acts as a rigid body during an earthquake. During the maximum anticipated seismic event, the cask will not slide or tip over. Stresses generated by the seismic event are within the allowable defined limit for accident conditions. Supplemental analysis for the 200 Area ISA indicates the ISC will not slide or tip over when the 200 Area ISA seismic inputs of 0.26 g (identified in Table D2-2) are applied. This analysis is documented in HNF-2183, Overturning and Sliding Assessment for the Interim Storage Cask at the 200 Area Interim Storage Area.

**Tornado/Wind** – The DBT event for the FFTF cask/container system is analyzed for the DBA in Chapter D3.0, and the analysis is summarized in Section D3.4.2.6. Wind velocities are bounded by the tornado winds, but the wind missile is also analyzed. A 15-lb., 2x4 traveling at 50 mph only penetrates the concrete surface about 1 in. The tornado winds do not result in sliding or tip over of the cask. There are no induced loads to the CCC as a result of the tornado or wind events.

**Fire** – The conditions of the transportation DBF and peak thermal conditions are analyzed for the DBAs in Chapter D3.0, and the analyses are summarized in Section D3.4.2.7. The fuel cladding temperature limit of 900 °F, the CCC closure seal temperature limit of 500 °F, and the ISC closure seal temperature limit of 700 °F are evaluated.

The fire accident would result in a short-term thermal loading on the ISC. Section D3.4.2.7 summarizes the ISC temperatures in the cask during a fire. Most of the concrete remains below the 350 °F ACI 349-90 accident allowable. For the conditions representing the fire accident, the large mass of concrete helps keep the interior temperatures of the cask relatively low. The maximum liner temperature reaches 309 °F, well within the allowable limit of 495 °F (with argon-inerting gas). At least 17 in. of concrete remain below the 350 °F ACI 349-90 temperature limit defined for accident conditions.

The maximum ISC closure seal temperature for the fire accident scenario reaches 200 °F, well below the allowable limit of 700 °F for the Helicoflex metal seal.

The closure bolt stress generated during the fire accident is 65,032 lbs/in², which is much lower than the 84,000 lbs/in² allowable. Because the bolts do not yield, sealing performance is unaffected by the fire. Therefore, the cask will remain within design limits during a fire.

**D4.4.1.5 Fast Flux Test Facility Interim Storage Cask Controls (Technical Safety Requirements)**. The assumptions associated with the ISC that require TSRs to ensure performance of its safety function are as follows:

- The ISC shall not be lifted more than 8 ft above the ground or storage pad.
• Each ISC shall be placed in a storage array with spacing of at least 24-in. x 44-in. between ISCs measured edge to edge. This specification applies to all ISCs to provide adequate access to the casks and to meet thermal analysis boundary conditions.

• Crane loads other than ISC rigging shall not be operated over a loaded ISC.

• The ISC system may not be lifted over objects taller than 4-ft or containing radioactive materials.

• Only the Manitowoc 4000 150T crane with Model 22 80-ft boom or the Manitowoc 4100 250T crane with Model 27 80-ft boom shall be used to lift the ISC.

• Fire loadings are to be controlled per the fire hazards analysis.

D4.4.2 Rad-Vault System

A 250 kW Training, Research and Isotope Production, General Atomics (TRIGA) experimental research reactor was operated in the 300 Area intermittently from the late 1970s until its last power run in May 1989. The reactor was manufactured by the Gulf General Atomic of San Diego, California, and was used primarily for neutron radiography of FFTF fuel elements and test assemblies. The fuel from the reactor core/pool storage has been removed as part of the decommissioning of the facility. The TRIGA irradiated fuel inventory consists of 99 TRIGA fuel elements and two fuel follower control rods (FFCRs). The TRIGA fuel and the fuel followers will be stored in TRIGA fuel casks and U.S. Department of Transportation (DOT)-6M containers prior to shipment to the 200 Area ISA, and the sealed casks and containers will be placed in concrete Rad-Vaults at the 200 Area ISA.

The concrete Rad-Vault at the ISA will contain six Neutron Radiography Facility (NRF) TRIGA casks and two special DOT-6M containers containing one FFCR each. Each TRIGA cask holds up to 17 fuel elements.

D4.4.2.1 Rad-Vault Safety Function. The Rad-Vault provides passive protection from natural phenomena events that could damage the NRF TRIGA casks or the DOT-6M containers. Based on the results of the Chapter D3.0 consequence analysis, the Rad-Vault would be designated General Service; however, the Rad-Vault has been upgraded to a designation of Safety Significant to accomplish NRC equivalency based on the classification requirements defined in Section D4.2.2. The safety-significant function imposed to accomplish NRC equivalency for important-to-safety Category B is to ensure mitigation of events that could significantly damage storage containers.
Accidents and concerns identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the upgraded safety-significant functions for the Rad-Vault, are as follows:

- **Cask tipover** - Passive design features preclude tipping.

- **Seismic** - Withstand seismic accelerations without tip over or sliding.

- **Tornado/wind** - Withstand DBT winds (excluding DBT missiles) without sliding or tip over. Also withstand design basis wind and wind-driven missiles established for the 200 Area ISA.

- **Fire** - Withstand transportation DBF conditions such that TRIGA casks and DOT-6M/2R containers inside do not lose confinement or exceed temperature limits for fuel cladding or container components.

**D4.4.2.2 Rad-Vault System Description.** The concrete Rad-Vault (CNSI 1992), shown in Figure D2-3, is a low-level radioactive waste storage unit consisting of a right circular (5,000 lbs/in²) concrete cylinder with light steel reinforcement. The Rad-Vault will be placed on compacted gravel at the ISA, and top loaded with the NRF TRIGA casks and DOT-6M containers. The Rad-Vault was constructed in accordance with ACI-301, *Specifications for Structural Concrete for Buildings*, and ACI-318, *Building Code Requirements for Reinforced Concrete*. The Rad-Vault is 111 in. high, with an outer diameter of 114 in. The wall is 18-in. thick steel reinforced concrete, with an 8-in. thick bottom. The equivalent lead shielding is 3.1 in. The empty Rad-Vault weight is 63,400 lbs (43,400-lb body and 20,000-lb lid), and the maximum design weight with payload is 81,400 lbs. The NRF TRIGA storage system's loaded weight is 76,760 lbs. The NRF TRIGA casks and DOT-6M containers and accompanying fuel weigh approximately 13,358 lbs (CNSI 1992).

The Rad-Vault is a commercial item typically used for on-site storage of low-level radioactive waste at commercial nuclear power plants, but is not a licensed container. The Rad-Vault concept provides on-site storage for commercial power plants in the unlikely event that off-site disposal is limited or prohibited. An on-site engineered storage building is not required (CNSI 1992). The design life is not specified by the vendor, but the concrete vault is epoxy coated and has an estimated life, with proper maintenance, of 50 years.

The Rad-Vault is equipped with a removable lid that fully exposes the available internal storage volume. Its mating surface is gasketed with the main container and sloped to prevent rain intrusion. Opposing lifting lugs are interlaced into the steel rebar and welded wire fabric and are cast into the concrete structure. Lift capacity is sufficient to allow an empty Rad-Vault to be lifted and moved by crane or to a transport trailer. The lid must be transported separately. The Rad-Vault is not intended to be lifted loaded or with the lid installed.
Sampling and/or drain capability is provided through a siphon-type arrangement that prevents leakage in and out of the Rad-Vault. Each Rad-Vault is also equipped with a pop-up vent. No hydrogen gas is expected to be vented; however, the pop-up vent and siphon will provide a vented system. The criticality evaluation (WHC-SD-FF-CSER-006) was performed for a flooded vault. There are no safety requirements for the vent or the drain functions. To ensure shielding uniformity and integrity, the Rad-Vault was gamma scanned. The Rad-Vault is painted internally and externally with two coats of epoxy paint.

The fabrication materials for the storage system components for the Rad Vault are as follows:

- ASTM A-615 for bar reinforcement
- ASTM A-185 for welded wire fabric
- ASTM A-36 or equivalent for embedments
- Concrete – properties (including lid): \( f'_c = 5,000 \text{ lbs/in}^2 \) in 28 days, nominal density of \( 145 \pm 5 \text{ lbs/ft}^3 \), a water binder ratio of 0.39 to 0.42, and air entrainment of 5 to 7 percent. ACI-301 specifications were provided for structural concrete. Test reports were included that verified this information. (The wall and lid of the Rad-Vault passed the required gamma scan: all data is part of the Certificate of Compliance package.)

The six NRF TRIGA casks and two DOT-6M containers will be transported to the ISA in three shipments. Three different cask/container configurations in the Rad-Vault will be required to accommodate the fuel transports. The cask configuration in the Rad Vault after the first shipment of two NRF TRIGA casks is shown in Figure D2-7. After the fuel has been transported to the ISA, the impact limiter overpack used during transport will be removed and the NRF TRIGA casks will be lifted by crane into the Rad-Vault. After each placement of containers in the Rad-Vault, the lid will be placed on top by the crane.

Four NRF TRIGA casks will be arranged in the Rad-Vault, as shown in Figure D2-7, after the second shipment of two casks. The third shipment will transfer two additional NRF TRIGA casks and the two DOT-6M containers. The final Rad-Vault configuration of six NRF TRIGA casks and two DOT-6M containers is shown in Figure D2-7. The placement of the casks, containers, and the empty 55-gal drums is based on operational procedures and is not required for criticality safety. The single drum in the center after loading performs a passive function that results in a close packed array, which precludes tipover of the containers within the Rad-Vault.

A nuclear criticality safety evaluation was performed for the transportation of the NRF TRIGA casks to the ISA pad and is included in the NRF TRIGA SARP (WHC-SD-TP-SARP-008). A CSER (WHC-SD-FF-CSER-006) was prepared for the interim
storage of the TRIGA fuel in the ISA to address storage of NRF TRIGA casks and DOT-6M containers in the Rad-Vault. Chapter D6.0 addresses specific criticality aspects of TRIGA fuel storage at the ISA.

D4.4.2.3 Rad-Vault Functional Requirements.

Cask Tipover – The Rad-Vault shall not tip over as the result of natural phenomenon events, acting as a passive barrier and preventing damage to the TRIGA casks or the DOT-6M containers.

Seismic – The Rad-Vault shall withstand any induced stresses resulting from the design basis seismic event with sufficient integrity to act as a passive barrier and prevent damage to the TRIGA casks or the DOT-6M containers.

Tornado/Wind – The Rad-Vault shall withstand any induced stresses resulting from the design basis tornado/wind event with sufficient integrity to act as a passive barrier and prevent damage to the TRIGA casks or the DOT-6M containers.

Fire – The Rad-Vault in the 200 Area storage location shall be capable of withstanding the DBF with sufficient integrity to act as a passive barrier and prevent damage to the TRIGA casks or the DOT-6M and 2R containers.

D4.4.2.4 Rad-Vault System Evaluation. The Rad-Vault is the exterior container of the TRIGA fuel storage system in the 200 Area ISA storage configuration. The Rad-Vault is the only container that is exposed to a majority of the events analyzed. Resistance to the events precludes similar exposure to the TRIGA casks, the DOT-6M containers, and the NRF TRIGA fuel during storage and ensures that the appropriate inner components withstand the design basis events with no loss of confinement. The safety-significant function imposed to accomplish NRC equivalency for important-to-safety Category B, as defined in Section D4.2.2, is to prevent significant damage to the storage containers.

Seismic – The analysis, summarized in Section D3.4.2.5, shows the design of the Rad-Vault is well within the DBE for the site, and seismic stability is assured. The Rad-Vault will not overturn or slide on the soil. The lid lip will not fail, and the lid will remain on the Rad-Vault. The NRF TRIGA casks inside the container will not suffer loss of integrity, and the DOT-6M containers that will be used for the FFCRs are qualified for conditions that are in excess of the DBE.

The flexure and shear stiffnesses of the Rad-Vault are also analyzed in Chapter D3.0 to determine the natural periods, and hence frequencies, of the structure under seismic excitation.

A comparison between the natural horizontal frequency of the Rad-Vault and the response spectra for the Hanford Site safe-shutdown earthquake shows that the Rad-Vault will behave like a rigid body during a seismic event, and dynamic analysis is not required.
**Tornado/Wind** – The Rad-Vault weighs approximately 63,400 lbs. without a load and has a center of gravity located approximately at the geometric center. It is loaded with the six NRF TRIGA casks and two DOT-6M containers. The analysis, summarized in Section D3.4.2.6 and including calculations from the manufacturer (CNSI 1992), shows that an empty Rad-Vault will endure winds and pressure transients in excess of the 200 Area ISA DBT without sliding or tipover.

The Chapter D3.0 analysis indicates that individual NRF TRIGA casks or DOT-6M containers will be exposed to the risk of a tornado for a short time during the crane lift from the overpack to the Rad-Vault by the crane. However, DOE/RL-92-36, Section 3.0, "Critical Lifts," will be used during the lifts, and the critical lift procedure will be prepared to identify any weather-related limits (as required) for the load being transferred. Therefore, the time period in which the NRF TRIGA casks or DOT-6M containers might be exposed to inclement weather conditions is negligible and, therefore, is not analyzed.

The loads resulting from the design basis wind are bounded by the consequences of the DBT discussed above, with the exception of wind-driven missiles. The Chapter D3.0 analysis also determines the penetration of the Rad-Vault by a wind missile. The evaluation concludes that the missile penetration will be minimal.

The Chapter D3.0, Section D3.4.2.6, analysis of the effects of the wind-driven missiles and the bounding evaluation of the effects of the DBT showed that the Rad-Vault is able to withstand any induced stresses without significant damage to the internal containers.

**Fire** – The TRIGA fuel storage system is analyzed in Chapter D3.0 and summarized in Section D3.4.2.7 against the DBF specified for the 10 CFR 71 transportation fire.

The analysis was conducted to determine the thermal effect of excessive heat on the Rad-Vault storage system, and the internal containers and their contents, which results from a combined maximum temperature solar day and fire.

The analysis assumed equilibrium conditions and determined that radiological material releases will not result from exceeding the temperature limits; however, the design specifications for the exterior concrete material of the Rad-Vault can be exceeded for a short period of time and should be evaluated as part of the recovery action, if a fire event occurs.

**D4.4.2.5 Rad-Vault Controls (Technical Safety Requirements).** The assumptions associated with the Rad-Vault that require TSRs to ensure performance of its safety function are as follows:

- The Rad-Vault shall not be moved while loaded or with the lid in place.
- Crane loads other than NRF TRIGA casks, DOT-6M containers, rigging, and the Rad-Vault cover shall not be handled over a loaded Rad-Vault.
• The Rad-Vault cover shall not be handled at a height greater than 12 in. above the top of the Rad-Vault.

• The Rad-Vault lid shall be handled with any appropriate crane within the Hanford Site hoisting and rigging criteria (DOE/RL-92-36) for a critical lift, but no larger than a 250-ton crane.

• The Rad-Vault lid shall be replaced after each activity within the Rad-Vault.

D4.4.3 NRF TRIGA Cask

The fuel from the 300 Area TRIGA experimental research reactor core/pool storage has been removed as part of the decommissioning of the facility. The TRIGA irradiated fuel inventory consists of 99 TRIGA fuel elements and two FFCRs. The standard fuel elements are stored dry in the NRF TRIGA casks prior to transport to the 200 Area ISA.

D4.4.3.1 NRF TRIGA Cask Safety Function. Based on the results of the Chapter D3.0 consequence analysis, the cask would be designated General Service; however, the cask has been upgraded to a designation of Safety Significant to accomplish NRC equivalency based on the classification requirements defined in Section D4.2.2. The safety-significant function imposed is to ensure mitigation of events that could release radioactive material. The second safety function of the NRF TRIGA cask is to prevent an uncontrolled release of the TRIGA fuel material.

Accidents and concerns identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the upgraded safety-significant functions for the NRF TRIGA cask, are as follows:

• Handling/drop – Maintain confinement of radioactive materials after a credible drop.

• Cask tipover – Maintain confinement of radioactive materials after cask tipover.

• Fuel rod rupture – Maintain confinement of radioactive materials after rupture of all the fuel pins.

• Seismic – Withstand seismic accelerations without loss of confinement.

• Tornado/wind – Withstand tornado pressure differential without loss of confinement.

• Fire – Withstand transportation DBF within the Rad-Vault without losing confinement or exceeding temperature limits for fuel cladding or container components.
D4.4.3.2 NRF TRIGA Cask System Description. Each NRF TRIGA cask consists of three main components: an inner aluminum basket to hold fuel elements, a surrounding single-wall stainless steel inner container, and an outer stainless steel and lead composite vessel for shielding. There is also an external impact limiter that is not used during storage (WHC-SD-TP-SARP-008).

The inner basket, shown in Figure D2-4, is a welded assembly of machined aluminum tubing and plate 28.5 in. high. Two 1.0-in. thick circular plates, each machined with a hexagonal array of 18 thru-holes, serve as insertion guides and support members for the TRIGA fuel elements. A third aluminum plate, 2.56 in. thick, serves as the fuel seating structure. The top portion of the central aluminum tube has threads that interface with basket-lifting equipment (WHC-SD-TP-SARP-008).

The surrounding stainless steel inner container, shown in Figure D2-4, contributes to the total shielding capability of the cask. The shell of the inner container is 29.12 in. high, with a 10.25-in. outer diameter and an 8.88-in. inner diameter 304 stainless steel tube section. The shell has a machined O-ring groove at the upper face to accommodate a 9.12-in. elastomer seal. The base of the container is a 9.5-in. diameter 304 stainless steel plate that is 0.5 in. thick, which is welded to the lower end of the shell. The lid is a 9.62-in. diameter 304 stainless steel plate that is 1.0 in. thick. The closure system consists of a locking bar and a single stainless steel eyebolt. The locking bar, with a tapped thread at its upper end, is welded to the center of the interior side of the container base. To close, the eyebolt is inserted through the center of the lid and threaded into the upper portion of the locking bar until the proper seal compression is achieved (WHC-SD-TP-SARP-008).

The outer confinement vessel, shown in Figure D2-4, consists of a 12.0-in. outer diameter 304 stainless steel inner shell with a wall thickness of 0.75 in., which serves as the confinement boundary. The 304 stainless steel outer shell has a 16.0-in. outer diameter with a wall thickness of 0.5 in.

Both shells are welded at the lower end to a 4.0-in. thick by 16.0-in. diameter 304 stainless steel plate. The 1.5-in. thick annulus between the two shells is filled with ASTM B29 lead for shielding. The lid is a 16.0-in. diameter 304 stainless steel plate 3.5 in. thick, which has a machined flange that mates with the top of a seal flange using 12 bolts. The thick center portion of the lid fits closely inside of the seal flange and is provided with an O-ring bore seal. The tolerance between the seal flange and the lid are closer than the bolt tolerance. Therefore, during high loading conditions (e.g., a drop), shear is transferred by bearing to the flange. The total height of the outer vessel with lid is 37.7 in. (WHC-SD-TP-SARP-008).

The weight of the outer vessel is approximately 1,637 lbs. The entire NRF TRIGA cask weighs a total of 1,878 lbs when filled with 18 elements (WHC-SD-TP-SARP-008).
The fabrication materials for the storage system components of the NFR TRIGA cask are as follows:

- Outer vessel – ASTM A-511, 304 stainless steel tubing; ASTM B-29 poured lead; ASTM A-240, 304 stainless steel plate; and ASTM A-540, Grade B23, Class 4 low alloy cap screws.
- Combination Helicoflex O-ring, made of an Inconel spring with a copper jacket, with Viton O-ring.
- Ethylene-propylene O-ring bore seal container seals.
- Inconel X-750, Teflon-coated C-ring.
- Swagelok stainless steel quick disconnect with Viton seal.

The confinement boundary for the NRF TRIGA cask consists of the following vessels, lids, and seals:

- Outer vessel closure lid
- Outer vessel, inner shell
- Outer vessel, seal flange
- Outer vessel bottom plate
- Welds on outer vessel, inner shell
- Helicoflex metallic seals.

The outer confinement vessel closure lid uses an elastomeric O-ring bore seal, located in a perimeter groove of the closure lid step, to establish a $10^{-7}$ scc/sec (air) leak-tight seal within the bore of the cask for initial transport (Figure D2-5). This elastomeric seal has a limited life of approximately 5 years; therefore, a metallic seal is also provided for long-term storage. The Helicoflex metallic seal is located on the surface between the lid and the flange of the outer container. This seal was also tested to $10^{-7}$ scc/sec (air). A leak test port in the lid between the two seals was tested to $10^{-3}$ scc/sec (air). A Viton redundant seal is also provided to facilitate

---

1 Teflon is a trademark of E. I. du Pont de Nemours and Company.

2 Swagelok is a trademark of Crawford Fitting Company.
leak testing of the Helicoflex metallic seal. These seals are embedded and secured to the closure lid and interface with the seal flange of the outer container (Figure D2-5). The Helicoflex seal has a design life of 50 years (WHC-SD-TP-SARP-008), and the Viton seal has a design life of 20 years. A seal verification and replacement program, as described in Section D4.4.3.4, is to be implemented.

Two containment welds are located on the inner shell of the outer vessel. Ultrasonic inspection procedures performed in accordance with the ASME Code, Section V (ASME 1989), are used to inspect the top weld. During fabrication, inspections are performed per the ASME Code, Section VIII, Division 1 (ASME 1989). The bottom weld is radiographically inspected in accordance with the same ASME Code. A vendor cask confinement boundary leak test ensures these welds meet the leak-tight criteria per ANSI N14.5. A pressure test at 17.3 lbf/in² was also performed.

Another boundary is provided by the inner container, which uses an elastomeric O-ring imbedded in the step of the lid and a metallic seal around the locking eyebolt (Figure D2-5). This boundary is not leak tested, so credit is not taken for it as a confinement boundary; however, the container will enhance fuel retrieval in the future.

Leak tests can be performed on both the elastomeric O-ring bore seal and the Helicoflex metallic seal by the use of three test ports machined on the top side of the lid (Figure D2-5). The test port at Location 1 penetrates the lid into the cask cavity. The port at Location 2 penetrates the lid into the void space between the bore seal and the metallic seal. The port at Location 3 penetrates the annulus of the Helicoflex metallic seal and the outer Viton seal. Each port is fitted with a quick-connect fitting to facilitate a leak test and a cover plate to protect the fittings and provide shielding equivalent to the lid thickness (WHC-SD-TP-SARP-008). The quick-disconnect fittings are leak tested, and the cover plate’s metallic seal is leak tested to $1.0 \times 10^{-3}$ sec/sec (air) prior to transport.

To accommodate the 10 CFR 72 requirement for redundant seals for commercial fuel, credit must be taken for the Viton O-ring used in conjunction with the Helicoflex metallic seal. Since these elastomer seals have a 20-year design life (less than that of the containers), a program will be implemented to verify seal condition and to replace seals, if necessary. A congruent effort to identify long-life seals for replacement of the original seals will also be implemented.

All stresses evaluated for the NRF TRIGA packaging under normal and accident conditions are maintained below the appropriate ASME Code, Section VIII (ASME 1989) allowables. Design, fabrication, and testing of the NRF TRIGA packaging is in accordance with the requirements of the ASME Code, Section VIII, as required by the appropriate NRC Regulatory Guides. Per Regulatory Guide 7.11, *Fracture Toughness Criteria of Base Material for Ferritic Steel Shipping Cask Containment Vessels with a Maximum Wall Thickness of 4 in. (0.1 m)*, Table 1, the NRF TRIGA package is Category 3. The design follows the criteria from the ASME Code, Section VIII, Division 2, as shown in the NRF TRIGA SARP, Part B, Section 7.0 (WHC-SD-TP-SARP-008).
Fabrication of the NRF TRIGA cask is in accordance with NUREG/CR-3854. All containment welds were radiographically or ultrasonically tested per ASME Code, Section V. During fabrication, inspections and containment leak testing were performed per the ASME Code, Section VIII, Division 1 and ANSI N14.5, respectively.

D4.4.3.3 NRF TRIGA Cask Functional Requirements.

**Confinement** – The NRF TRIGA cask shall withstand potential NPH and accident events with sufficient integrity to provide a confinement boundary for the TRIGA material such that on-site risk acceptance guidelines are not exceeded.

**Handling/Drop** – The NRF TRIGA cask shall withstand any induced stresses resulting from the design basis handling/drop accidents with no significant damage and no uncontrolled release of radioactive material.

**Cask Tipover** – Maintain confinement of radioactive materials after cask tipover.

**Fuel Rod Rupture** – The NRF TRIGA cask shall withstand the internal pressure from rupture of all of the contained fuel elements with no significant damage and no uncontrolled release of radioactive material.

**Seismic** – The NRF TRIGA cask, as an integral component of the Rad-Vault system in the 200 Area storage location, shall withstand any induced stresses resulting from the design basis seismic event with no significant damage and no uncontrolled release of radioactive material.

**Tornado/Wind** – The NRF TRIGA cask, as an integral component of the Rad-Vault system in the 200 Area storage location, shall withstand any induced stresses resulting from the design basis tornado/wind with no significant damage and no uncontrolled release of radioactive material.

**Fire** – The NRF TRIGA cask, as an integral component of the Rad-Vault system in the 200 Area storage location, shall be capable of withstanding the DBF with no significant damage and no uncontrolled release of radioactive material.

D4.4.3.4 NRF TRIGA Cask Evaluation.

**Confinement** – The NRF TRIGA casks were procured with the intent to meet the leaktight requirements of 10 CFR 71 for transportation. The containers are leak tested prior to shipment.

The outer container of the NRF TRIGA cask is the qualified and tested confinement barrier for storage. This container has a HelicoFlex metallic seal for long-term storage integrity, an elastomeric flange seal to facilitate leak testing, and an elastomeric bore seal. The quick
disconnects used for leak testing are also fitted with metallic O-ring seals at the thread interface. The port lids covering the quickdisconnects used for helium leak testing also are provided with single metallic Helicoflex seals.

Helicoflex seals are fabricated using an inner spring covered by an inner lining and a soft outer lining. The Helicoflex seal for the NRF TRIGA has a Nimonic 90 Spring covered by an inner lining of Inconel Alloy 600 and an outer jacket of aluminum. The materials used in the linings are application-dependent and a function of temperature and pressure. The sealing principle of Helicoflex is based, in part, on plastic deformation of the seal's outer lining. The inner helical spring provides an elastic core under bolt preload. Each coil of the spring behaves independently during radial compression. The all-metal design is the reason for its long life.

The NRF TRIGA cask provides multiple barriers. The inner container has an elastomeric seal on the lid and a metallic seal on the clamping eyebolt. The outer container has redundant seals provided by both an elastomeric bore seal O-ring and a Helicoflex combination metallic/elastomeric O-ring seal. Both the bore seal and the Helicoflex seal are leak tested before transport and/or storage.

The closure devices on the NRF TRIGA cask include the closure lid and the three leak test port lids. The closure lid is attached to the cask body with twelve 0.50-in. diameter cap screws, torqued to a minimum of 52±5 ft-lbf. All leak test port lids are attached to the cask lid with six 0.25-in. diameter cap screws, torqued to a minimum of 42±6 in.-lbf.

The NRF TRIGA cask is provided with removable test port covers that permit access to the helium leak test components in the outer container. The container is leak tested upon initial loading according to ANSI N14.5 standards for a maximum leak rate of 1.0×10⁻⁷ sec/sec (air), with the exception that the test port covers are tested to 1×10⁻⁵ sec/sec (air).

The NRF TRIGA cask has a design life of 50 years. All components are stainless steel except the sealed lead annulus and the aluminum basket. There are no neutron poisons. The metallic Helicoflex seal on the outer container has a 50-year design life for this application. The Viton redundant seal has a 20-year design life. The elastomeric bore seal is ethylene propylene and has a 5-year design life. The outer container's elastomeric bore seal is a confinement seal provided to meet transportation requirements. The Helicoflex metallic seal and Viton O-ring are confinement seals provided to accommodate long-term (20-year) storage requirements.

The fuel is stored in untreated air. The stainless steel and aluminum fuel cladding is not susceptible to long-term degradation in unlimited air (ASM 1975 and ASM 1980). There is no corrosion catalyst within the casks. The reactor pool water was deionized, and the stainless steel casks have been passivated.

The hydride fuel has excellent corrosion resistance in water. Bare irradiated fuel specimens have been subjected to a pressurized water environment at 5,700 °F and 1,230 lbs/in² during a 400-hour period in an autoclave (Simnad 1981). The average corrosion rate was
350 mg/cm²/month, accompanied by conversion of the surface layer of the hydride to an adherent oxide film. The maximum extent of corrosion penetration after 400 hours was less than 2 mils. If somehow the cladding was removed from the fuel, the fuel was stored in a corrosive environment (water vapor) within the cask at an elevated temperature, and the cask was pressurized (externally because the fuel would not generate the gas pressure), minimal corrosion will result. For the actual storage configuration: (1) the elements will be dried, ensuring an environment that minimizes corrosion, (2) cladding will be on the fuel, (3) temperatures will not exceed 200 °F, and (4) the resulting maximum pressure will be below the design pressure of 11.2 lbs/in² gauge. Based on the minimal reactivity of the fuel with water, the design storage environment does not require purified dry air or inert gas.

Dr. Simnad’s report (Simnad 1981) and the testing performed on the fuel show there will be no degradation of the fuel, even if the cladding degrades. The fuel itself forms an oxide layer to protect it from corrosion. The environment within the cask is not corrosive for either the cladding or the bare fuel, so the fuel will remain intact. All TRIGA fuel element cladding appears to be intact, as the reactor pool water is not contaminated after 15 years of operation and fuel storage.

Hypothetical degradation of the fuel does not pose unacceptable operational safety considerations with respect to removing the fuel from storage. If repackaging is deemed necessary, it is to be performed in a confinement facility for personnel safety at a yet to-be-determined location.

To accommodate the redundant seal requirement for commercial fuel per 10 CFR 72, credit must be taken for the Viton O-ring used in conjunction with the Helicoflex metallic seal. Since these elastomer seals have a design life less than that of the containers, a program will be implemented to verify seal condition and replace seals, if necessary. An effort to identify long-life seals for replacement of the original seals will also be implemented.

The seal integrity program will include assessment, possible replacement, and verification of seals while maintaining a safe worker environment. It should be noted that due to the relatively low source/dose rates of the TRIGA fuel (maximum cask dose of 92 mrem/h contact, approximately 3 rem shine with cover removed), controlled retrieval and verification may be accomplished in accordance with approved operating procedures in an approved location providing a confinement enclosure. Since the Viton seal has a 20-year design life, this seal integrity program will be developed and included in the authorization basis as required during a later SAR update.

Drop analyses for the NRF TRIGA cask and the DOT-6M container indicate that they retain confinement and design shielding for the normal handling events and the design basis cask/container drops.

The ethylene propylene seal has a tested life of at least 1,000 hours at 275 °F (Parker Hannifin Corporation 1992). The Viton O-ring is rated for a maximum temperature of 400 °F.
The maximum normal temperature for the cask is 161 °F due to solar heating of the Rad-Vault, which is well within the design operating range. The Helicoflex metallic seal, fabricated from Inconel and aluminum, has a maximum operating temperature greater than 480 °F. The maximum normal temperature is 161 °F, which is well within the operating range. The maximum accident temperature to which these seals will be exposed results from the DBF when the interior temperature of the Rad-Vault rises to 177 °F. This temperature does not threaten the integrity of the seals due to the large amount of margin between the design limit and analysis results.

The following aspects of TRIGA fuel storage enhance confinement of the fuel:

- Intact cladding (demonstrated)
- Low burnup (cladding not stressed)
- Low fission gas pressure (cladding not stressed)
- Inner containers (not leak tested)
- Leak tested Swagelok fittings
- Leak tested Helicoflex seal (installed per procedure, tested to $1 \times 10^{-7}$ sec/sec [air]).

These features justify the bolted closure per the approved design. The removable test port covers, as configured, support the seal replacement/demonstration programs required to accommodate 40-year storage.

The inner NRF TRIGA container is fabricated of stainless steel, and the basket is fabricated of aluminum. The 2R inner container of the DOT-6M specification package is constructed of 304L stainless steel, and the support basket is fabricated of aluminum. The fuel cladding is stainless steel or aluminum. There have been reported instances of galvanic corrosion of irradiated aluminum-clad TRIGA fuel stored in stainless steel racks in water. The basket in the NRF TRIGA cask has been specifically designed and fabricated of aluminum to preclude this potential interaction. There are no historical records of stainless steel-clad degradation in aluminum racks. Both types of fuel cladding have been stored in the aluminum fuel storage racks in the 308 reactor, and the reactor core array is also fabricated of aluminum. As such, there is no anticipated interaction between the stainless steel and aluminum metals resulting in deleterious effects on the cladding or container materials.

The TRIGA fuel storage system, composed of the NRF TRIGA casks and DOT-6M containers within the Rad-Vault, can withstand the normal and natural phenomenon conditions anticipated during the 50-year design life of the system. For the DBA identified in Section D3.4.2.2, the Rad-Vault is assumed to fail, allowing damage to the NRF TRIGA casks and DOT-6M containers and resulting in a release of radioactive materials. The off-site and on-site dose consequences are below the release limits and guidelines and also are within limits prescribed in 10 CFR 72 for normal and accident conditions. Although the NRF TRIGA cask and DOT-6M container have the potential to be certified for off-site shipment (they were designed with the intent to meet 10 CFR 71), these containers and the Rad-Vault were all procured as general-service items based on the small radionuclide source term. 10 CFR 72.230
states that casks certified under 10 CFR 71 can be certified as spent fuel storage casks, if they can meet the storage requirements for 20 years. These casks with their metallic seals, in combination with the Rad-Vault, meet the 20-year storage life requirement.

Drop analyses for the NRF TRIGA cask without the impact limiter indicate that the cask retains confinement and design shielding for the normal handling events and the design basis drops. The drop analyses are provided in Section D3.4.2.1.

Under the dynamic conditions of normal transport and hypothetical accidents, the confinement remains sealed.

**Handling/Drop** – During handling operations, any one or all of the NRF TRIGA casks, DOT-6M containers, or the Rad-Vault could be involved in a drop accident that threatens the confinement or results in significant damage to a storage container. A handling/drop analysis is performed in Chapter D3.0 and summarized in Section D3.4.2.1. The analysis demonstrates that under credible drop conditions, the NRF TRIGA casks and DOT-6M containers do not release radioactive material or are not significantly damaged. It is also noted that the side drop analysis bounds a cask tipover event with no loss of confinement. However, to preclude exceeding the design criteria and the analyzed conditions, lifting limits have been imposed and are identified in Chapter D5.0.

**Fuel Rod Rupture** – The NRF TRIGA cask is analyzed in Chapter D3.0, and the analysis is summarized in Section D3.4.2.4. The TRIGA cask design pressure is based on the maximum pressure differential obtained from the 10 CFR 71.71(c)(3) reduced external pressure. The NRF TRIGA cask is pressure tested at 150% of the design pressure.

As noted in the Chapter D3.0 analysis, the low burnup of the fuel produces a small quantity of fission products. Most of the fission product gases are captured within the fuel matrix. The fission product gases within each element would result in negligible pressure in the cask or container, if all the fuel elements are breached within the cask. Byproducts from elastomeric seal degradation will have minimal effect. Therefore, it is concluded that the NRF TRIGA cask pressure will remain less than the design limit.

As noted in the analysis, the NRF TRIGA package contains stainless steel- and aluminum-clad uranium zirconium hydride fuel. This hydride fuel composition and high equilibrium pressure creates a stable, non-hydrogen-producing fuel. There is no generation of hydrogen gas or corresponding pressure rise inside the NRF TRIGA package during normal conditions. The hydride fuel is assumed to be intact and enclosed within the stainless steel or aluminum cladding. Also, the fuel itself is non-pyrophoric and non-water reactive. Therefore, no chemical reaction will occur that produces gas within the NRF TRIGA package. Also, the fuel is air dried with heat lamps prior to loading. This precludes the possibility of radiolytic decomposition of water.
The analysis also indicates that this fuel forms an oxide film that inhibits the loss of hydrogen or degradation of the fuel. Assuming the fuel cladding disintegrates under accident conditions, the temperatures reached will not exceed the temperature required to generate hydrogen.

The analysis concludes that the maximum temperature of the fuel cladding during storage, if experienced inside the cask or container, will result in an insignificant pressure increase in the fuel.

**Seismic** – The NRF TRIGA cask is analyzed as an integral component of the Rad-Vault storage system. The analysis summarized in Section D3.4.2.5 shows the design of the Rad-Vault is well within the DBE for the site, and seismic stability is assured. The Rad-Vault will not overturn or slide, and the NRF TRIGA cask will not suffer loss of integrity or loss of confinement resulting in an uncontrolled release of radioactive material.

**Tornado/Wind** – The NRF TRIGA cask is analyzed for the DBT as an integral part of the Rad-Vault storage system in Chapter D3.0, and the analysis is summarized in Section D3.4.2.6. Wind velocities are bounded by the tornado winds, but the wind missile is also analyzed. A 15-lb., 2x4 traveling at 50 mph only penetrates the concrete surface about 1 in. The tornado winds do not result in sliding or tip over, and there are no induced loads to the cask as a result of the tornado or wind events sufficient to cause a loss of integrity or an uncontrolled release of radioactive material.

**Fire** – Analysis of the DBF is addressed in Chapter D3.0 and summarized in Section D3.4.2.7. The NRF TRIGA cask is analyzed for the DBF as an integral part of the Rad-Vault storage system. An evaluation is provided in Section D4.4.2.4 for the Rad-Vault system containing the NRF TRIGA casks. Fire protection for the NRF TRIGA cask is provided by the Rad-Vault.

**D4.4.3.5 NRF TRIGA Cask Controls (Technical Safety Requirements).** The assumptions associated with the NRF TRIGA cask that require TSRs to ensure performance of its safety function are as follows:

- The maximum handling lift height shall not exceed 109-in. above ground (21 in. above the top of the Rad-Vault with the lid removed).

- The NRF TRIGA cask shall be handled with any appropriate crane within the Hanford Site hoisting and rigging criteria (DOE/RL-92-36) for a critical lift, but no larger than a 250-ton crane.
D4.4.4 DOT-6M and 2R Containers

The fuel from the 300 Area TRIGA experimental research reactor core/pool storage has been removed as part of the decommissioning of the facility. The TRIGA irradiated fuel inventory consists of 99 TRIGA fuel elements and two FFCRs. The FFCRs are stored dry in special DOT-6M containers with 2R inner containers, prior to transport to the 200 Area ISA.

D4.4.4.1 DOT-6M and 2R Container Safety Function. Based on the Chapter D3.0 consequence analysis, the DOT-6M and 2R containers would be designated General Service; however, the containers have been upgraded to a designation of Safety Significant to accomplish NRC equivalency based on the classification requirements defined in Section D4.2.2. The safety-significant function imposed is to ensure the mitigation of events that could release radioactive material. The DOT-6M package and 2R inner container provide a safety function to prevent an uncontrolled release of the FFCR fuel material.

Accidents and concerns identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the upgraded safety-significant functions for the DOT-6M container, are as follows:

- Handling/drop – Provide impact absorption for the 2R container.
- Seismic – Provide impact absorption for the 2R container.
- Fire – Withstand transportation DBF conditions within the Rad-Vault such that the 2R container inside does not lose confinement or exceed temperature limits for fuel cladding or container components.

Accidents and concerns identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the upgraded safety-significant functions for the 2R container, are as follows:

- Handling/drop – Maintain confinement of radioactive materials within the DOT-6M containers after a credible drop.
- Cask tipover – Maintain confinement of radioactive materials after container tipover.
- Fuel rod rupture – Maintain confinement of radioactive materials after rupture of all the fuel pins.
- Seismic – Withstand seismic accelerations without loss of confinement.
Fire – Withstand transportation DBF conditions within the Rad-Vault without losing confinement or exceeding temperature limits for fuel cladding or container components.

D4.4.4.2 DOT-6M and 2R Container System Description. Each of the two DOT-6M containers, shown in Figure D2-6, consists of a 16-gauge 304 stainless steel 110-gal drum that is 23 in. in diameter and 69.25 in. high. An inner (2R) vessel is fabricated from a 304 stainless steel pipe with a 5-in. diameter. A 0.5-in. thick stainless steel plate is welded to the bottom of the pipe. The top of the pipe is sealed by a bolted flange assembly containing one Helicoflex metallic seal and one Viton O-ring. The metal seal is leak tested to $1.0 \times 10^{-7}$ scc/sec (air). The helium test port plug is also leak tested to $1.0 \times 10^{-7}$ scc/sec (air). This inner vessel is partially supported by plywood treated with a fire-retardant coating. Impact-resistant insulating material fills the annulus between the two vessels (WHC-S-0393).

The design and fabrication of the DOT-6M outer and inner container were performed per 49 CFR 178.354 and 49 CFR 178.360, respectively, and the design was approved by DOE. The DOT-6M is a DOT specification packaging approved for off-site shipment as a Type B container. The fabrication of the inner vessel was performed in accordance with the ASME Code, Section VIII, Division 1 (ASME 1989). During fabrication, inspections and containment leak testing were performed per the ASME Code, Section VIII, Division 1, and ANSI N14.5. The weight of the loaded DOT-6M container is approximately 559 lbs.

The fabrication materials for the storage system components for the DOT-6M specification package are as follows:

- Drum – Type 304 or 304 L stainless steel.
- Insulation – Celotex fiber insulation in accordance with ASTM C-208; exterior grade A-C fir plywood; Miracle Type-M Black Magic adhesive; PPG-SPEEDHIDE latex 42-7 fire retardant paint; VIAC Mastic WC-5 weather coating.
- 2R inner container – ASME SA-240, grade 304L plate and sheet; ASME SA-312, grade TP304L seamless or welded pipe; ASME SA-182, grade F304L flanges; ASME SA-276, Type 304L round bar; ASME B18.8.2, Type 18-8 stainless steel dowel pins.
- Helicoflex metallic seal and Viton O-ring.

---

3 Celotex is a trademark of the Celotex Corporation.

4 Miracle Type-M Black Magic is a trademark of Miracle Adhesive Corporation.

5 PPG Speedhide is a trademark of PPG Industries, Inc.

6 VIAC Mastic WC-5 is a trademark of VIMASCO Corporation.
When the DOT-6M/2R metal packages were delivered, the 2R materials certification was listed as ASME/ASTM. This equivalency is the result of a long-term joint program by ASTM and ASME. This effort was brought on by the precipitous decrease in nuclear-related construction that made ASME-certified materials almost impossible to obtain in small lots. In many cases, the only difference between ASME steels and identical, more abundant and cheaper ASTM steels has been the testing regime. This availability and cost differential was unnecessarily costly for the nuclear transportation and storage industry. Hence, the goal to bring ASME/ASTM specifications for common steel materials into agreement. The result is an ASME specification with annotation similar to the following: ASME SA-240 specification identical with ASTM A-240 "... except for editorial differences ...

D4.4.4.3 DOT-6M and 2R Container Functional Requirements.

Confinement – The 2R container, as an integral part of the Rad-Vault storage system and as configured with the DOT-6M container, shall withstand stresses induced by potential NPH or accident events at the 200 Area storage location with sufficient integrity to maintain the 2R confinement boundary.

Handling/Drop – The DOT-6M and 2R containers, as integral components of the Rad-Vault storage system in the 200 Area storage location, shall withstand any induced stresses resulting from the design basis handling/drop accidents with no significant damage and no uncontrolled release of radioactive material.

Cask Tipover – Maintain confinement of radioactive materials after cask tipover.

Fuel Rod Rupture – The DOT-6M and 2R container shall withstand the internal pressure from rupture of all of the contained fuel elements with no significant damage and no uncontrolled release of radioactive material.

Seismic – The DOT-6M and 2R containers, as integral components of the Rad-Vault system in the 200 Area storage location, shall withstand any induced stresses resulting from the design basis seismic event with no significant damage and no uncontrolled release of radioactive material.

Tornado/Wind – The DOT-6M and 2R containers, as integral components of the Rad-Vault system in the 200 Area storage location, shall withstand any induced stresses resulting from the design basis tornado/wind with no significant damage and no uncontrolled release of radioactive material.

Fire – The DOT-6M and the 2R inner container, as integral components of the Rad-Vault storage system in the 200 Area storage location, shall be capable of withstanding the DBF and maximum anticipated thermal conditions (including volcanic ashfall) with no significant damage and no uncontrolled release of radioactive material.
D4.4.4.4 DOT-6M and 2R Container System Evaluation.

Confinement – The DOT-6M/2R containers used for storage of the FFCRs provide multiple confinement barriers. The intact cladding is a barrier, and the 2R inner container provides a confinement barrier with the combination metallic and elastomeric O-ring seals. The 2R inner container of the DOT-6M system is the qualified and tested confinement barrier, as discussed in Section D4.4.3.4. This 5-in. diameter pipe vessel has a bolted flange assembly retaining an elastomeric seal and a Helicoflex metallic seal.

Helicoflex seals are fabricated using an inner spring covered by an inner lining and a soft outer lining. The Helicoflex seal for the 2R container has a Nimonic 90 Spring covered by an inner lining of Inconel Alloy 600 and an outer jacket of aluminum. The materials used in the linings are application-dependent and a function of temperature and pressure. The sealing principle of Helicoflex is based, in part, on plastic deformation of the seal’s outer lining. The inner helical spring provides an elastic core under bolt preload. Each coil of the spring behaves independently during radial compression. The all-metal design is the reason for its long life.

Although the 2R container was inerted with helium for leak testing, the FFCR fuel can be stored in untreated air. The stainless steel fuel cladding is not susceptible to long-term degradation in unlimited air (ASM 1975 and ASM 1980). There is no corrosion catalyst within the container. The reactor pool water was deionized.

As stated in Section D4.4.3.4, Dr. Simnad’s report (Simnad 1981) and the testing performed on the fuel show there will be no degradation of the fuel, even if the cladding degrades. The fuel itself forms an oxide layer to protect it from corrosion. The environment within the cask is not corrosive for either the cladding or the bare fuel, so the fuel will remain intact. All TRIGA FFCR cladding was intact, as the reactor pool water was not contaminated after 15 years of operation and fuel storage.

The DOT-6M stainless steel 6M drum provides a barrier for normal conditions only. This barrier contains pressure relief capability via the penetrations covered with pressure-sensitive adhesive filament (WHC-S-0393). The 6M drum does not provide a safety-related confinement function.

To accommodate the redundant seal requirement for commercial fuel per 10 CFR 72, credit must be taken for the Viton O-ring used in conjunction with the Helicoflex metallic seal. Since these elastomer seals have a design life less than that of the containers, a program will be implemented to verify seal condition and replace seals, as necessary. An effort to identify long-life seals for replacement of the original seals will also be implemented, as discussed in Section D4.4.3.4.

The Viton O-ring is rated for a maximum temperature of 400 °F. The maximum normal temperature for the DOT-6M is 161 °F due to solar heating of the Rad-Vault, which is well within the design operating range. The Helicoflex metallic seal, fabricated from Inconel and
aluminum, has a maximum operating temperature greater than 480 °F. The maximum normal temperature is 161 °F, which is well within the operating range. The maximum accident temperature to which these seals will be exposed results from the DBF when the interior temperature of the Rad-Vault rises to 177 °F. This temperature does not threaten the integrity of the seals due to the large amount of margin between the design limit and the analysis results.

The aspects of TRIGA FFCR storage that enhance confinement of the fuel are as follows:

- Intact cladding (demonstrated)
- Low burnup (cladding not stressed)
- Low fission gas pressure (cladding not stressed)
- Leak tested Helicoflex seal (installed per procedure, tested to $1 \times 10^{-7}$ scc/sec [air]).

The DOT-6M outer stainless steel drum can be opened to permit access to the helium leak test port on the top of the 2R inner container. The 2R vessel was leak tested in accordance with ANSI N14.5 standards for a maximum leak rate of $1.0 \times 10^{-7}$ scc/sec (air). This test port closure was also leak tested to $1 \times 10^{-7}$ scc/sec (air).

The FFCR storage system, composed of the DOT-6M containers within the Rad-Vault, can withstand the normal and natural phenomenon conditions anticipated during the design life of the system. Although the DOT-6M container could be certified for off-site shipment, these containers and the Rad-Vault were all procured as general-service items based on the small radionuclide source term. 10 CFR 72.230 states that casks certified under 10 CFR 71 can be certified as spent fuel storage casks, if they can meet the storage requirements for 20 years. These containers with their metallic seals, in combination with the Rad-Vault, meet the 20-year storage life requirement.

Handling/Drop – The DOT-6M and 2R containers are analyzed in Chapter D3.0, and the analysis is summarized in Section D3.4.2.1. Tests were performed on DOT-6M shipping packages (with 2R inner containers) to evaluate their response to a drop onto an unyielding surface and a drop onto a steel punch bar. A detailed observation of the packages following the drop testing showed the security bolts to be tight and no damage to other areas that would indicate the possible loss of confinement. It is also noted that the side drop analysis bounds a cask tipover event with no loss of confinement.

As indicated in the analysis, the only differences between the packages tested and the TRIGA FFCR configuration are the type of seal used in the 2R inner container and the anticipated contents within the packages. The drop-tested packages used an elastomeric O-ring seal, whereas the TRIGA FFCR DOT-6M shipping packages will use a metallic O-ring seal to assure long-term storage requirements. In addition, the drop-tested package used can and bottle internal containers, whereas the TRIGA FFCR DOT-6M shipping packages will contain stainless steel clad fuel rods enclosed in stainless steel pipe. The TRIGA FFCRs are not externally contaminated and the solid hydride fuel itself is enclosed within the stainless steel cladding, which has been demonstrated not to leak.
Based on the results of the analysis, the loaded DOT-6M container has an administrative restriction to equal the NRF TRIGA cask maximum lift height and shall not be handled at a height greater than 21 in. above the top of the Rad-Vault (with the lid removed).

**Fuel Rod Rupture** – Fuel rod rupture is analyzed in Chapter D3.0, and the analysis is summarized in Section D3.4.2.4. As noted in Section D.4.4.3.4, the low burnup of the fuel produces a small quantity of fission products. Most of the fission product gases are captured within the fuel matrix. The fission product gases within each element will result in negligible pressure, if the fuel element is breached within the 2R container.

The Chapter D3.0 analysis indicates that the DOT-6M package contains stainless steel-clad uranium zirconium hydride fuel. This hydride fuel composition and high equilibrium pressure creates a stable, non-hydrogen producing fuel. There is no generation of hydrogen gas or corresponding pressure rise inside the DOT-6M/2R package during normal conditions. The analysis also indicates that this fuel forms an oxide film that inhibits the loss of hydrogen or degradation of the fuel. Assuming the fuel cladding disintegrates under accident conditions, the temperatures reached will not exceed the temperature required to generate hydrogen. The analysis concludes that the maximum temperature of the fuel cladding during storage, if experienced inside the cask or container, results in an insignificant pressure increase in the fuel.

**Seismic** – The DOT-6M and 2R containers are analyzed as an integral component of the Rad-Vault storage system. The analysis in Section D3.4.2.5 shows the design of the Rad-Vault is well within the DBE for the site, and seismic stability is assured. The Rad-Vault will not overturn or slide and the containers will not suffer loss of integrity or an uncontrolled release of radioactive material. Seismic accelerations are bounded by the drop analyses.

**Tornado/Wind** – The DOT-6M and 2R containers are analyzed for the DBT as an integral part of the Rad-Vault storage system in Chapter D3.0, and the analysis is summarized in Section D3.4.2.6. Wind velocities are bounded by the tornado winds, but the wind missile is also analyzed. A 15-lb., 2x4 traveling at 50 mph only penetrates the concrete surface about 1 in. The tornado winds do not result in sliding or tip over, and there are no induced loads to the containers as a result of the tornado or wind events sufficient to cause a loss of integrity or an uncontrolled release of radioactive material.

**Fire** – The DOT-6M and 2R containers are analyzed for the DBT as an integral part of the Rad-Vault storage system in Chapter D3.0, and the analysis is summarized in Section D3.4.2.7. Sufficient fire protection for the DOT-6M and 2R container is provided by the Rad-Vault. Exposure to the DBF or maximum thermal conditions resulted in no loss of integrity or release of radioactive material.
D4.4.4.5 DOT-6M and 2R Container Controls (Technical Safety Requirements). The assumptions associated with the DOT-6M and 2R containers that require TSRs to ensure performance of their safety function are as follows:

- The loaded DOT-6M container shall not be handled at a height greater than 21 in. above the top of the Rad-Vault (with the lid removed). (Administrative restriction to equal NRF TRIGA cask maximum lift height of 109-in.)

- The DOT-6M container shall be handled with any appropriate crane within the Hanford Site hoisting and rigging criteria (DOE/RL-92-36) for a critical lift, but no larger than a 250-ton crane.

D4.4.5 NAC-1 Cask System

The safety-significant functions for individual components of the NAC-1 cask system are discussed as an integral part of the NAC-1 cask system evaluation. The components include the inner canister, the NAC-1 cask, and the ISO shipping/storage container. Specific individual component evaluations are addressed as appropriate.

The 300 Area LWR fuel consists of irradiated commercial LWR fuel provided to the Pacific Northwest National Laboratory Material Characterization Center (MCC). The MCC was responsible for conducting laboratory investigations of nuclear waste forms for the DOE Office of Civilian Radioactive Waste Management program. The 300 Area LWR fuel inventory consists of seven commercial fuel assemblies, five PWR and two BWR fuel assemblies, and 26 individual intact fuel rods and miscellaneous segments.

The 300 Area LWR fuel is to be contained in welded inner canisters (Figure D2-14) placed within NAC-1 or Nuclear Fuel Services (NFS)-4 spent fuel shipping casks that satisfy both on-site transportation and storage requirements. The NAC-1 and NFS-4 casks were fabricated to the same design drawings, but at different times by different corporate owners. NAC purchased the NFS-4 design and fleet of casks from NFS and renamed the cask model NAC-1. Both model casks will be referred to as the model NAC-1 cask throughout this document.

The 300 Area LWR fuel storage system, composed of the NAC-1 cask and inner canister, can withstand the normal and natural phenomenon conditions anticipated during the 50-year design life of the system. As identified in Chapter D3.0 and evaluated in Section D3.4.2, the cask survives all DBAs without loss of confinement and therefore has no radiological release under normal or accident conditions. 10 CFR 72.230 states that casks certified under 10 CFR 71 can be certified as spent fuel storage casks, if demonstrated in a SAR that the casks can meet the storage requirements for 20 years. The NAC-1 cask with its metallic O-ring seals and the inner canister with welded closures exceed the 20-year storage life requirement.
D4.4.5.1 NAC-1 Cask System Safety Function. The NAC-1 cask system provides passive protection from stresses resulting from natural phenomena and accident events that could compromise the integrity of the inner canister and fuel cladding and allow an uncontrolled release of radioactive material in excess of on-site guidelines. The NAC-1 cask is a passive barrier that has been designated Safety Significant for the mitigation of potential consequences resulting from NPH and handling events.

The LWR canister is designated Safety Significant in that it provides a confinement function in the event of pressurization that results from failure of the fuel cladding during the storage life of the LWR fuel. The function is to maintain integrity sufficient to preclude uncontrolled release of radioactive material. It is also designated Safety Class for criticality geometry control, as discussed in Section D4.3.2.

Because of its configuration, the ISO container is designated Safety Significant as part of the NAC-1 cask system in that it provides a passive function in preventing tipping or sliding during accident or NPH events. The function does not require the outer panels of the ISO to remain intact following the design basis event. Neither the ISO container nor the NAC-1 cask have a confinement function.

DBAs identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the safety-significant functions for the NAC-1 cask, are as follows:

- Handling/drop – Provide passive protection of the LWR canister such that it retains structural integrity after a credible drop.
- Mobile crane fall – Provide passive protection of the LWR canister such that it maintains confinement after a crane fall accident.
- Cask tipover – The NAC-1 cask in the ISO container is credited with passive design features that preclude tipping.
- Seismic – Withstand seismic accelerations without tipover or sliding.
- Tornado/wind – Withstand DBT winds (excluding DBT missiles). Also withstand the design basis wind and wind-driven missiles established for the 200 Area ISA, without structural damage to the LWR canister.
- Fire – Withstand transportation DBF conditions such that the LWR canister does not lose confinement or exceed temperature limits for fuel cladding or cask components.
DBAs identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the safety-significant functions for the LWR canister, are as follows:

- **Handling/drop** – Maintain confinement of radioactive materials after a credible drop within NAC-1 cask.
- **Fuel rod rupture** – Maintain confinement of radioactive materials.
- **Seismic** – Withstand seismic accelerations without loss of confinement.
- **Tornado/wind** – Withstand tornado pressure differential without loss of confinement.
- **Fire** – Withstand transportation DBF conditions inside the NAC-1 cask without loss of confinement.

DBAs identified in the Chapter D3.0 analysis and listed in Tables D4-1 and D4-2, as associated with the safety-significant functions for the ISO, are as follows:

- **Seismic** – Provide structural support to the NAC-1 cask to withstand seismic accelerations without tipover or sliding.
- **Cask tipover** – The NAC-1 cask in the ISO container is credited with passive design features that preclude tipping.
- **Tornado/wind** – Provide structural support to the NAC-1 cask to withstand tornado winds without tipover or sliding.

**D4.4.5.2 NAC-1 Cask System Description.** The 300 Area LWR fuel storage system consists of six storage units, each comprised of an inner canister, a NAC-1 cask, and an ISO shipping/storage container. The welded inner canister provides confinement of the intact fuel during storage, as required by 10 CFR 72. The NAC-1 provides a shielding overpack that provides weather, accident, and NPH protection.

The NAC-1 casks, previously licensed by the NRC to transport LWR spent fuel and waste material, will be modified for use at Hanford. Modifications to the cask include the removal and plugging of several valves connected to the cask cavity. The NAC-1 casks are mounted to supports within the ISO container for transportation and will remain in the containers in this configuration during storage at the 200 Area ISA.

Additional modifications to the cask include removal of the anti-rotational lugs within the interior cask cavity to accommodate the spent fuel LWR canister and installation of a solid plug at the impact limiter test port. Also, neutron shield tank pressure relief penetrations have been removed and replaced with threaded solid plugs.
The storage units will be placed by crane alongside each other (1 x 6 array) and evenly spaced 4 ft apart. This spacing is not required for criticality or other safety analysis purposes, but rather for personnel access considerations and maintaining personnel radiation doses ALARA.

The NAC-1 cask is designed and fabricated to the requirements of the ASME Code, Section III, Subsection NB. The external shape of the NAC-1 spent fuel shipping cask approximates a smooth-surface, right circular cylinder that is modified, in that impact limiters protrude radially at both ends (see Figure D2-10). The internal cross-section of the cask cavity is circular. The overall dimensions of the cask include a length of 214 in. (including lid impact limiter) and a maximum cross-sectional envelope diameter of 50 in. The internal cavity of the cask is 178 in. long and 13.5 in. in diameter. The maximum loaded gross weight of the cask, including the maximum fuel and inner canister weight (3,300 lbs), is approximately 47,150 lbs. The principal design features of the cask are the structure, shielding and heat dissipation systems, and the lifting and tie-down systems.

The NAC-1 cask provides shielding and environmental protection of the inner LWR canister. The structures of the NAC-1 cask are constructed of stainless steel. The cask cavity is formed by the inner shell, which is a 14.125-in. outside diameter, 0.3125-in. thick stainless steel shell. The upper end of the shell is welded to the cask cavity flange; the bottom end of the shell is welded to the cask bottom casting. Surrounding the inner shell of the cask is a nominal 6.6875-in. thick annulus of chemical-grade lead (gamma) shielding. The lead is shaped such that approximately 5 in. from the bottom and 30 in. from the top, the thickness is reduced to 5.4375 in. There is an annular void, 5 in. long by 1.25 in. thick, at the bottom end of the gamma shield to allow for any lead expansion during the fire accident. The upper axial shaping is accomplished by reducing the diameter of the outer shell 2.50 in. over a 30-in. length. The lead/steel interface of the inner and outer shell has axial copper fins that are imbedded in the lead and welded to the inner and outer shells to transfer heat across the interface with a minimum temperature gradient (see Figure D2-10).

The outer shell is formed by a 30-in. diameter, 1.25-in. thick stainless steel cylinder reduced to a 27.50-in. diameter at one end. The cask bottom consists of a shaped stainless steel disc with a 30-in. outer dimension and an 8-in. thickness that functions as a gamma shield for the bottom end of the cask. The cavity flange is a stainless steel ring with a 29.75-in. outer dimension, 17.50-in. inner dimension, and an 8.625-in. thickness. The bottom disc end and top flange are welded to the inner and outer shells to form the enclosure for the lead gamma shield.

The primary structure of the NAC-1 cask is the inner shell, lower end casting, upper end casting, bolted closure lid with double O-ring seals, the plugged drain valves and rupture disk penetrations, and the vent/helium fill valve that remains operative. The seals of the cask boundary have the capacity to be continuously monitored or tested during storage via the O-ring seal test port. Credit is taken for protection of the canister by the structural characteristics of the Rad-Vault and the NAC-1 cask to demonstrate no loss of confinement during design basis events and accidents.
The inner shell of the NAC-1 cask is a 0.3125-in. thick, austenitic stainless steel right-circular cylinder with internal dimensions of 13.50 in. in diameter and 178 in. in length. At each end, the shell is welded to large austenitic stainless steel end castings. The lower end casting is 3.50 in. thick, with a central region that is an 8-in. thick frustum of a cone. The upper end cask cavity flange is an 8-in. thick annular casting with a tapered central hole that mates with the closure lid. The inner shell is joined to the austenitic stainless steel upper and lower end castings using circumferential full penetration groove welds. All weld configurations are designed and fabricated to meet the ASME Code, Section III (ASME 1971).

The closure lid is a 7.5-in. thick austenitic stainless steel frustum of a cone with a 2-in. thick flange around its circumference at the larger end. A 0.375-in. x 45° chamfer on the lower outer edge of the lid flange is optional; it has no significant effect on the lid's structural adequacy. The closure lid is retained by six, equally spaced, 1-1/4-7UNCASTM A-320, Grade L43, low alloy steel hex-head capscrews and is sealed at the upper end casting by two Helicoflex metallic O-ring seals.

The two drain valves located in the lower end casting are plugged for the storage configuration.

The pressure relief system located in the upper end casting is plugged for the storage configuration, since no postulated storage pressurization events exceed the design pressure of the cask (65 lbs/in²). Pressures within the NAC-1 cask remain below design pressure limits for both normal and accident conditions.

The valve located in the upper end casting will be used as the helium fill port for inerting the inner cavity of the cask.

There is one other penetration in the wall of the upper end casting. This penetration is used as a test port for the region between the O-ring seals to assure the adequacy of the closure lid seal prior to shipment.

Existing cover plates over cask confinement penetrations will remain in place, as designed, to serve as heat shields during the postulated DBF accident.

Neutron shielding tanks are provided in the 4.5-in. thick annular space formed between the outer shell of the lead gamma shield and a thin stainless steel shell that constitutes the outer cask surface. The neutron shield tanks are not used for the storage configuration at the 200 Area ISA and will contain air.

Upper end shielding is provided by the 7.5-in. thick stainless steel cask lid. The cask lid is a stainless steel casting that also serves as a gamma shield. The lid is a flanged frustum of a cone, 7.5 in. thick with a maximum diameter of 25.5 in. The conical portion of the stainless lid is stepped locally to minimize the gap between the lid and cavity flange, preventing displacement of the lid during the design basis drop. The flanged portion of the lid is a 2-in. thick, 25.5-in.
diameter disc. There are six counterbored clearance holes for the lid bolts and four 1-in. diameter blind-threaded holes for attaching the lid impact limiter. The underside of the lid flange has a groove for the two Helicoflex metallic O-ring seals that seal the cask cavity. The upper face of the cavity flange is machined flat to serve as the sealing surface for the cask lid metallic seals. The cask lid is bolted to the cavity flange by six 1.25-in. diameter hex-head bolts. Bolt heads bear on the cask lid; the shanks penetrate through the lid flange and thread into the cavity flange. Six 1.25-in. diameter holes with HeliCoil thread inserts are provided in the cavity flange for bolting the cask lid to the flange. The bolt heads are drilled for a wire security seal.

The lower end impact limiter structure is a ring that surrounds the cask lower casting, formed from a stainless steel sheet and/or plate welded to the cask outer shell and flange areas. The impact limiter was designed to absorb the energy of the design basis 30-ft free drop. It contains a balsa wood disc placed adjacent to the cask bottom. A 0.125-in. thick sheet of asbestos is placed between the balsa and the cask bottom, and is contained internally. Within the impact limiter, extending radially from the center of the cask, are eight 0.375-in. thick stainless steel gussets. The bottom section of the impact limiter also functions as a pedestal for supporting the cask in the vertical position.

An impact limiter located at the upper end of the cask body is designed to absorb the energy of the design basis side drop accident. The upper impact limiter is a stainless steel-sheathed, balsa-filled ring that surrounds the cask cavity flange. A 0.125-in. sheet of asbestos is positioned between the balsa and cask outer shell, and is contained internally. Within the impact limiter, extending radially from the center of the cask, are eight 0.375-in. thick stainless steel gussets. The upper impact limiter, also a cask support member in the storage configuration, rests in the ISO cradle frame cross-member.

The cask lid is protected from impact by a 12-in. thick, balsa-filled lid impact limiter that covers and overlaps the cask lid and cavity flange. The balsa is enclosed within a 0.109-in. thick stainless steel container. A 0.125-in. sheet of asbestos is positioned between the balsa and the sheet material adjacent to the cask, and is contained internally. The impact limiter is attached to the cask lid by four 1-in. diameter bolts. There are elastomer O-rings in grooves under the heads of the 1-in. bolts and a neoprene gasket on the perimeter of the impact limiter. These impact limiter seals are for weather protection and do not provide a confinement function. Removal of the lid impact limiter allows access to the cask lid.

Lifting devices for the NAC-1 cask are designated as lifting trunnions and rotation trunnions. The lifting trunnions are two 8.625-in. diameter by 3-in. long trunnions located on the perimeter of the upper impact limiter. The cask is lifted by a special handling yoke attached to the two trunnions. The rotation trunnions are two 6.625-in. diameter by 3-in. long trunnions for rotating the cask to and from the horizontal position in the ISO container. The lower trunnions are offset from the cask centerline so that when the cask is lowered into the ISO container, it rotates to a horizontal position as the crane hook is lowered.
Transportation of the NAC-1 cask is in the normal storage configuration with the cask in a horizontal position, secured within the ISO container. Two structural cross-member sections serve as cradles for the cask within the ISO container. The lower (rotation) trunnions of the cask are captured by a notch and clamping plate on the aft cradle. The upper lifting trunnions are also captured by clamping plates, to hold the upper end of the cask as it rests on the impact limiter within a neoprene-lined forward cradle. The lid impact limiter is bolted to the cask lid. The lid impact limiter can be unbolted and rolled away from the cask on a track. The cask and ISO container are lifted by crane from the transport trailer and placed in the storage array on the NAC-1 reinforced concrete storage pad.

The NAC-1 cask contains an inner LWR canister that provides a confinement boundary for the fuel. The inner canister is fabricated from a 12-in. stainless steel pipe with welded base cap and top closures. It has a nominal outside diameter of 12.75 in., with a maximum outside diameter of 13.0 inches at the end cap and a total length of 165.25 in. The bottom cap is machined, so the pipe-to-cap weld is inspectable at the side of the canister. The closure lid contains a penetration that allows the canister to be evacuated, filled with helium, and leak tested to the requirements of ANSI N14.5. Figure D2-14 provides an illustration of the PWR inner canister.

The LWR canisters are designed to provide criticality geometry control such that a loaded canister will have a $k_{eff} < 0.95$ when fully moderated and reflected. A 6.00-in. thick stainless steel gamma shield is provided at each end of the canister.

The design weight of the inner canister is 1,250 lbs. The maximum loaded weight of the canister is not to exceed 3,300 lbs. The maximum internal design pressure of the canister is 75 lbs/in$^2$ gauge, testable to a pressure of 100 lbs/in$^2$ gauge.

A fuel rod container fits within the inner canister to hold individually packaged LWR fuel rods. The container is fabricated from 8-in. schedule 80 stainless steel pipe and is split in two lengthwise and hinged to allow loading. The pipe ends are closed with tack-welded end caps fabricated from 0.125-in. stainless plate. The hinged pipe contains the loose rods within the inner canister. The container fits within a 10-in. schedule 40 pipe also located within the inner canister. Confinement of the radioactive material is provided by the LWR canister and the fuel rod cladding.

The NAC-1 cask is transported and stored within a specially designed ISO shipping container. The ISO container provides weather protection for the cask and does not perform safety functions. The ISO containers were fabricated in two heights, in both 6-ft and 8-ft high models. All containers are painted carbon steel construction.

The 8-ft ISO container, fabricated by Evergreen Heavy Industrial Corporation, is nominally 8 ft high x 8 ft wide x 20 ft long. The container has single full-width doors at each end and a removable roof. The frame of the container is structural steel channel construction with a 0.5-in. (12.7 mm) carbon steel floor. The sides are fabricated of 1.6 and 2.0 mm
corrugated carbon steel. The roof is fabricated of 1.6 mm carbon steel sheet metal supported by 40 x 40 mm angle iron on a 60-cm grid and is slightly pitched to prevent ponding of precipitation. The doors and roof are provided with weather seals. Two of these containers will be used to house NAC-1 casks during fuel transport and storage.

The 6-ft ISO container, fabricated by Adamson Containers Ltd., is 6 ft high x 8 ft wide x 20 ft long. The container has two half-width doors at one end and a removable roof. Materials of construction and dimensions are similar to those used in fabricating the 8-ft containers, except the roof material is 1.4 mm carbon steel sheet metal and the roof is flat. Four of these containers will be used to house NAC-1 casks during fuel transport and storage.

The ISO containers are modified for use at Hanford. The roofs of the containers have been strengthened to resist the design basis snow and ashfall conditions associated with storage at the 200 Area ISA. Additionally, the containers have been repainted white to produce cooler surface temperatures for industrial safety during their storage in direct sunlight at the ISA.

D4.4.5.3 NAC-1 Cask System Functional Requirements. Individual components of the NAC-1 cask system are analyzed in Chapter D3.0 as integral parts of the NAC-1 cask. The evaluation of the DBAs is discussed in Section D4.4.5.4. Specific individual component functional requirements and evaluations are addressed as appropriate.

Confinement – The LWR canister shall provide confinement of the LWR fuel. Confinement, as required by 10 CFR 72, is provided by the intact fuel rod cladding and the LWR canister. The combination of the intact fuel cladding and the LWR canister shall ensure that no uncontrolled release of radioactive material occurs.

Handling/Drop – The NAC-1 cask system shall withstand any induced stresses resulting from the design basis handling/drop accidents with sufficient integrity to act as a passive barrier and prevent damage to the inner canister. The LWR canister, analyzed as an integral part of the NAC-1 cask/container system, shall be capable of withstanding any induced stresses resulting from design basis handling/drop events with sufficient integrity to ensure that confinement of the fuel material is maintained and structural integrity is maintained for criticality geometry control.

Mobile Crane Fall – The NAC-1 cask system shall withstand any induced stresses resulting from accidents involving the crane, with sufficient integrity to act as a passive barrier and prevent damage to the safety-class LWR canister. The NAC-1 cask shall protect the LWR canister to ensure no uncontrolled release of radioactive material occurs.

Cask Tipover – The NAC-1 cask in the ISO container is credited with passive design features that preclude tipping. The NAC-1 cask in the ISO container shall be analyzed to not tip over or slide as a result of NPH or DBAs.

Fuel Rod Rupture – The LWR canister, as an integral component of the NAC-1 cask system, shall withstand the internal pressure resulting from rupture of all contained fuel rods.
without compromising the canister structural integrity required to maintain confinement of the fuel material. The design pressure of the LWR canister is 75 lbs/in² gauge, with a test pressure of 100 lbs/in² gauge. The LWR canister shall ensure no uncontrolled release of radioactive material occurs.

Seismic – The NAC-1 cask system shall withstand any induced stresses resulting from the design basis seismic event with sufficient integrity to act as a passive barrier and prevent damage to the safety-class LWR canister. The NAC-1 cask and the ISO container shall protect the LWR canister to ensure no uncontrolled release of radioactive material occurs. The LWR canister, analyzed as an integral part of the NAC-1 cask/container system, shall be capable of withstanding any induced stresses resulting from the design basis seismic event with sufficient integrity to ensure that confinement of the fuel material is maintained and structural integrity is maintained for criticality geometry control.

Tornado/Wind – The NAC-1 cask system in the 200 Area storage location shall be capable of withstanding the design basis tornado/wind with sufficient integrity to act as a passive barrier and prevent damage to the safety-class LWR canister. The NAC-1 cask and the ISO container shall protect the LWR canister to ensure no uncontrolled release of radioactive material occurs. The LWR canister, analyzed as an integral part of the NAC-1 cask/container system, shall be capable of withstanding the design basis tornado/wind and pressure differential with sufficient integrity to ensure that confinement is maintained.

Fire – The NAC-1 cask system in the 200 Area storage location shall be capable of withstanding the DBF with sufficient integrity to act as a passive barrier and prevent damage to the LWR canister. The LWR canister, as an integral part of the NAC-1 cask system, shall be capable of withstanding the DBF with sufficient integrity to ensure that confinement is maintained. The zircaloy fuel cladding has a maximum cladding temperature limit of 644 °F to ensure failure of the cladding material does not occur. The Helicoflex metallic seals of the NAC-1 cask are limited to an operating temperature of 700 °F. The LWR canister shall ensure no uncontrolled release of radioactive material occurs and structural integrity is maintained for criticality geometry control.

D4.4.5.4 NAC-1 Cask System Evaluation.

Confinement – Confinement of the spent fuel is provided by the intact cladding and by a leak-tight welded LWR canister, as described in Section D4.3.2.2. The welded canister ensures that the inert gas within the canister cavity following leak testing is maintained during the storage of the LWR fuel. The NAC-1 cask provides a credited confinement boundary of the spent fuel for transportation to the 200 Area ISA only. In storage, the NAC-1 cask is not credited for confinement. The LWR canister provides an additional confinement boundary to satisfy the confinement and/or retrieval requirements of 10 CFR 72, even though credit is taken initially for the fuel cladding integrity. The NAC-1 cask is a significant structural system that mitigates most normal, off-normal, and accident loads and conditions. It is this structure that is analyzed for most scenarios in this section. The integrity of the LWR canister remains intact for the bounding
accidents analyzed in Section D3.4.2 for each category due to the design of the NAC-1 cask, and no uncontrolled release of radioactive material occurs. The cask provides a passive safety-significant function with regard to potential consequences resulting from NPH and accident-induced stresses.

**Handling/Drop** - These analyses are addressed in Chapter D3.0, summarized in Section D3.4.2.1, and discussed in the LWR canister safety-class evaluation in Section D4.3.2.4. As indicated in the safety-class evaluation, the calculations considered all components as part of an integral cask/container system.

The cask analyses evaluated to hypothetical accident conditions (10 CFR 71.73) included (1) a free drop of the cask through a distance of 30 ft onto a flat, essentially unyielding, horizontal surface, striking the surface in a position for which maximum damage is expected, followed by (2) a free drop of the cask through a distance of 40 in., in a position for which maximum damage is expected, onto the upper end of a solid, vertical, cylindrical, mild steel bar mounted on an essentially unyielding, horizontal surface.

The postulated damage that is incurred by the NAC-1 cask during the hypothetical 10 CFR 71 accident is minimal and does not diminish the ability of the cask to protect the LWR canister and to maintain the confinement boundary. Any deformation will be highly localized, and the bending stresses in the remainder of the cask will not result in failure of the internal stainless steel shells.

The NAC-1 cask system and the LWR canister are able to withstand any induced stresses from handling/drop events without compromising the integrity or the confinement function of the LWR canister.

**Mobile Crane Fall** - This evaluation is provided in Chapter D3.0 and summarized in Section D3.4.2.2. As indicated, the calculations consider all components as part of an integral cask/containment system. The accident analysis postulates that the crane boom drop may be sufficient to breach cask confinement. The Chapter D3.0 analysis determines that the crane boom will fail before the boom can impart sufficient load on the cask to breach confinement. The analysis also investigates whether the cask could be punctured by the crane or other related lifting and rigging hardware. This analysis determines that although the cask will suffer physical damage, the confinement integrity will be maintained in the maximum crane block lift condition. The maximum crane block height that can be achieved by the crane is 80 ft above the cask.

Analysis of the hydraulic spreader bar ISO lifting fixture drop (Section D3.4.2.2) concludes that bending is the controlling parameter that establishes the requirement for a maximum lift height. Although the cask may suffer physical damage, the confinement integrity of the cask will be maintained by imposing a maximum height condition of 6 ft above the ISO container lid, approximately 14.75 ft above the ground (see Chapter D5.0 for load height restrictions). This height provides sufficient overhead clearance to perform all rigging and hoisting activities at the ISA.
The cask system, with the imposition of the maximum lift height restriction, will withstand any induced stresses from a mobile crane fall without impacting the integrity of the LWR canister.

**Fuel Rod Rupture** – This analysis is addressed in Chapter D3.0 and summarized in Sections D3.4.2.4 and D3.4.2.7. The analyzed hypothetical accident scenario postulates the rupture of all fuel pins of a worst-case hypothetical PWR assembly or the consolidated BWR and PWR individual rods under both normal and fire accident conditions, which causes an increase in cavity pressure that results in possible loss of fuel confinement. The calculation of the maximum normal pressure for the LWR canister assumes a normal cask cavity pressure at the temperature resulting from the hottest summer day (115 °F ambient) added to the pressure increase from fuel rod rupture of all rods. The pressure increase within the cask cavity is due to both a temperature increase from the indoor loading temperature at the 324 Building (68 °F) to the maximum normal cavity storage temperature (372 °F) and 100% rod rupture. The evaluation addresses the fission gas generated during irradiation, initial pressurization within the pins, and the gas within the canister cavity from loading and leak-testing activities.

The pressure within the cavity due to rod rupture at maximum normal conditions is within the design pressure of 75 lbs/in² gauge and the test pressure of 100 lbs/in² gauge established for the LWR canister. Release of this volume of gas into the cask cavity will result in a slightly lower pressure within the cask. Thus, this value bounds the LWR fuel normal conditions within the NAC-I cask cavity, which has a design pressure of 65 lbs/in² gauge that is tested to 100 lbs/in² gauge.

Worst-case pressures are also calculated for 100% rod rupture during the DBF conditions. The resultant pressure at this increased temperature is also well within the design pressures for both the LWR canister and the NAC-I cask.

Although it is not anticipated that free water will be in the cask, the potential impact of moisture within the cask is assessed. The assessment indicates that up to 100 grams of free water could be tolerated, without exceeding the design pressure limits. Since the cavity is vacuum dried, there will not be sufficient water for radiolytic decay to create an explosive atmosphere within the canister or cask cavity.

The NAC-I cask system and the LWR canister are able to withstand any induced stresses from fuel rod rupture events without compromising the confinement function of the LWR canister.

**Seismic** – The seismic evaluation is provided in Chapter D3.0, and the analysis is summarized in Section D3.4.2.5. The NAC-I cask in the ISO container is shown to not tip over or slide as a result of seismic forces. As noted, stresses induced in the NAC-I cask and the LWR canister during the 200 Area ISA DBE are within the cask system design capabilities. The LWR canister safety-class evaluation calculations consider all components to be part of an integral system.
Seismically induced loads are bounded by the drop impact accelerations, the evaluation of which concludes that the cask system is able to withstand any induced stresses from handling/drop events without compromising the confinement function of the LWR canister.

**Tornado/Wind** – The analysis of wind exposure effects of the DBT and wind-driven missiles is provided in Chapter D3.0 and summarized in Section D3.4.2.6. The analysis considered all components as integral parts of an LWR storage system.

The ISO shipping containers are provided in two heights: 6 ft and 8 ft. Since the 8-ft high container has more area exposed to the tornado wind, it was examined as the critical case for wind exposure effects (tipping and sliding). The analyses show that the cask and shipping container will not tip or slide as a result of the DBT (sum of rotational and translational velocities). Tipping of the cask/container is resisted by the force developed as a result of the dead weight of the cask/container. Sliding of the cask/container is resisted by the frictional force between the container and ground.

It is anticipated that the shipping container might sustain considerable damage during the tornado event that results in possible collapse of the side walls and dislocation of the roof sheeting. Thus, the Chapter D3.0 analyses conclude that the shipping container may require inspection and repair following a tornado event, but the cask will endure the wind effects of the DBT. For the wind effects analysis, it is conservatively assumed that the container walls and roof structure remained intact, since this is the condition that imposes the greatest resultant forces relative to tipping and sliding the fuel storage cask.

The LWR canister provides confinement for the stored fuel, but the cask inner shell is the component that must withstand the resultant pressure transient sustained during the DBT event, assuming the ISO container roof and walls collapse. The analysis indicates that the cask inner shell will withstand the pressure transient criteria for the DBT with large margins of safety, and therefore, the NAC-1 cask will endure pressure transient effects of the DBT. The LWR canister design pressure is much greater than the 0.9 lb/in² gauge pressure differential of the DBT.

As noted above, the tornado wind is capable of causing significant physical damage to the shipping container, which will require inspection and repair or possibly repackaging of the stored fuel following a tornado event.

The loads resulting from the design basis wind are bounded by the consequences of the DBT discussed above, with the exception of wind-driven missiles. The wind-driven missiles are smaller and less energetic than the analyzed tornado missile, but have a smaller effective area of impact and require separate evaluation. The consequences of tornado missiles for the NAC-1 cask storage are not required to be analyzed, as noted above. However, the analysis is performed in the NAC-1 SAR (NAC 1990) and is judged to have insufficient energy to perforate, puncture, or cause structural damage to the NAC-1 cask that is sufficient to cause the loss of the confinement function. The analysis, summarized in Section D3.4.2.6, also determines the...
minimum thickness required to prevent perforation by a wind missile. The evaluation concludes that the missile will not puncture the cask water jacket.

The analysis of the effects of the wind-driven missiles and the bounding evaluation of the effects of the DBT (Section D3.4.2.6) show that calculated energies for the design basis wind are well bounded by the cask drop analyses. These analyzed energies are found to be acceptable in Section D3.4.2.1, which concludes that the cask system is able to withstand any induced stresses from handling/drop events without compromising the confinement function of the LWR canister.

Fire – The DBF is analyzed in Chapter D3.0 and summarized in Section D3.4.2.7. The analysis determines the DBF to be bounded by the exposure of the NAC-1 cask and associated ISO shipping container to the 10 CFR 71.73(c)(3) transportation fire.

The analysis of the NAC-1 cask subjected to the transportation fire scenario of 10 CFR 71.73(c)(3) is provided in the original transportation SAR (NFS 1972) for an internal thermal load of 11.5 kW, and in the NAC-1 SAR (NAC 1990) for an internal 750 W thermal load. These analyses both analyze the NAC-1 cask with and without the ISO shipping container and provide bounding conditions for the fire accident scenario for use of the NAC-1 shipping cask for storage of the commercial LWR fuel. The LWR fuel has a maximum internal thermal load of 405 W. The transportation SAR and the NAC-1 SAR analyses are therefore considered sufficient to demonstrate the integrity of the NAC-1 cask for the fire accident conditions. The cask integrity is preserved under both of these conditions for storage of the 300 Area LWR fuel.

The analysis in Section D3.4.2.7 concludes that the NAC-1 cask and the LWR canister will withstand any stresses or temperatures induced as a result of fire, and that the canister structural integrity required to ensure that an uncontrolled release of radioactive material will not occur is not compromised.

D4.4.5.5 NAC-1 Cask System Controls (Technical Safety Requirements). The assumptions associated with the NAC-1 cask and ISO shipping container that require TSRs to ensure performance of their safety function of confinement control are as follows:

- The lift height of 30 ft is not exceeded for the ISO container.
- The crane hook and block lift height of 56 ft is not exceeded.
- The number of individual fuel rods in an NAC-1 cask does not exceed a maximum of 179 PWR rods, or 96.5 BWR rods consolidated with 17 PWR rods.
- The NAC-1 cask in the ISO container shall be handled with only the Manitowoc 4000 150T crane with a Model 22 80-ft boom or the Manitowoc 4100 250T crane with a Model 27 80-ft boom.

D5.0 DERIVATION OF TECHNICAL SAFETY REQUIREMENTS

D5.1 INTRODUCTION

A description of the essential features of the Spent Nuclear Fuel (SNF) Project derivation of Technical Safety Requirements (TSRs) is provided in Section 5.1 of the SNF Project Final Safety Analysis Report (FSAR).

D5.2 REQUIREMENTS

The requirements that form the basis for the SNF Project derivation of TSRs are identified in Section 5.2 of the SNF Project FSAR.

D5.3 TECHNICAL SAFETY REQUIREMENTS COVERAGE

The 200 Area Interim Storage Area (ISA) TSRs for the analyzed hazards and accidents are summarized in Table D5-1. This table lists TSR controls in accordance with Chapter D4.0 and the accident analyses in Chapter D3.0. Table D5-1 provides a cross-reference of the respective accident analysis section to the relevant subsections within Section D5.5, where derivation details are arranged by TSR control.

The necessary and sufficient TSR controls are established based on consideration for public safety, significant defense in depth, significant worker safety, and for maintaining radiological consequences below risk evaluation guidelines. SNF Project FSAR Section 5.3 contains details applicable to all SNF Project facilities. Section D5.3.2 contains information specific to the 200 Area ISA, in addition to that provided in Section 5.3.2 of the SNF Project FSAR.

D5.3.1 Criteria

The control selection criteria used for the SNF Project are described in Section 5.3.1 of the SNF Project FSAR.

D5.3.2 Safety Structures, Systems, and Components Not Provided with Technical Safety Requirement Coverage

All safety-class and safety-significant structures, systems, and components (SSCs) have been provided with TSR coverage, as identified in this chapter. All safety SSCs are provided with TSR coverage with an Administrative Control (AC) program. There are no Limiting Conditions for Operation (LCOs) identified for the 200 Area ISA.

D5.4 DERIVATION OF FACILITY MODES

D5.4.1 Operational Modes

Modes are used to specify when safety limits, LCOs, or surveillance requirements are required. 200 Area ISA operations include the movement and storage of the casks and inspections and surveillances. The casks and canisters are the only barriers to the uncontrolled release of radioactive material. The safety-class SSCs are passive and protect against criticality.

The normal operational mode for the 200 Area ISA (after movement and storage of the casks) is long-term interim storage, which is the "Operation" mode. There are no clear operational distinctions to provide more than one mode for safety-class SSCs. The hazard presented by the spent fuel in the casks/containers cannot be shut off or reduced by operational changes. Therefore, the 200 Area ISA will have only one mode, which will be designated as the "Operation" mode. The 200 Area ISA is capable of receiving or transferring casks between locations within the facility during this mode. Routine operational and maintenance activities will be performed (e.g., surveillances, inspections, radiological monitoring, and repairs).

D5.4.2 Minimum Staffing Levels

During long-term interim storage, there is no manned shift requirement. Assignment of radiological and maintenance personnel on a periodic basis is coordinated with the Canister Storage Building (CSB) and is considered adequate to perform the inspections, surveillance, repairs, and monitoring necessary to protect the health and safety of the public and the collocated worker.

Qualification training for the assigned personnel is addressed in Chapter D12.0. Emergency response is addressed in Chapter D15.0.
Normal long-term interim storage operations. Determination of the unmanned shifts during normal interim storage operations assumes that routine inspection and surveillance are being conducted by CSB personnel. An inspection or surveillance is considered a low-difficulty task.

Abnormal conditions. Manning during abnormal conditions is the same as for normal/long-term interim storage conditions.

Emergency conditions. The assigned personnel during emergency conditions are needed to ensure an appropriate response to the spectrum of accidents analyzed in Chapter D3.0 (hazardous and non-hazardous). The minimum assigned personnel must make prompt initial notifications and implement initial protective actions to preclude or reduce the exposure of individuals affected by the hazards or unsafe conditions during an emergency.

The CSB facility manager or designee is the building emergency director (BED) with the primary responsibility for assessing the event and implementing protective actions at the 200 Area ISA. The BED also makes on-site notifications, implements emergency management procedures, implements facility emergency plans, classifies events, and controls event response. The BED requests support services, as necessary, to perform administrative functions and the minimum functions required to ensure the health and safety of the public, on-site workers, and the environment.

D5.5 TECHNICAL SAFETY REQUIREMENT DERIVATION

Controls associated with the 200 Area ISA are derived in Table D5-1 and are discussed in this section, except for AC 5.1 through AC 5.6, which will be included in the 200 Area ISA TSR document. AC 5.1, "Purpose," AC 5.2, "Contractor Responsibility," and AC 5.3, "Compliance," define the need for subsequent AC provisions and clarify responsibility according to good management practice. AC 5.4, "Technical Safety Requirement Violation," AC 5.5, "Occurrence Reporting," and AC 5.6, "Organization," satisfy the requirements of U.S. Department of Energy (DOE) Order 5480.22, Technical Safety Requirements, Section 9.e.(5). This DOE Order requires ACs for reporting deviations and identifying staffing requirements. Worker safety program requirements are addressed in other FSAR sections based on design and operations information.

D5.5.1 Limiting Conditions For Operation

During long-term storage operation, there are no identified LCOs at the 200 Area ISA.
D5.5.2 Safety Limits

During long-term storage, there are no identified Safety Limits that could be exceeded at the 200 Area ISA.

D5.5.3 Administrative Controls

AC 5.1 through AC 5.6, in accordance with DOE Order 5480.22, are identified above. Additional controls are defined in the subsections that follow.

D5.5.3.1 AC5.7 – Nuclear Criticality Safety.

Purpose. This control protects the assumptions of the nuclear criticality evaluation in Chapter D6.0 and the accident analyses in Chapter D3.0 to ensure that operations and storage at the 200 Area ISA prevent inadvertent nuclear criticality. The purpose of this AC is to protect features that are relied on to preclude a criticality event at the 200 Area ISA. Key elements of this programmatic AC are derived from contractor procedures that include requirements for criticality safety evaluations, criticality prevention specifications, and criticality training. The criticality controls identified in Chapter D6.0 are as follows:

- Obtain the source inventory from the shipping organization to verify the containers meet the TSR for geometry control. Storage at the 200 Area ISA ensures that geometry is maintained.

- Incorporate lift restrictions as required by AC 5.9.

Derivation Criterion. A nuclear criticality program is required as one of the standard ACs, according to DOE Order 5480.22, Section 9.e.(5).

D5.5.3.2 AC5.8 – Source Inventory Receipt Acceptance.

Purpose. This AC ensures shipments received at the ISA only include hazardous and radiological materials that have been analyzed in this FSAR Annex. The key elements of this AC are as follows:

- Acceptance criteria are established such that fuel type, quantity, and configuration are limited to those authorized in this FSAR Annex. The acceptance criteria shall include the following:
  - There shall be no more than seven fuel assemblies in a core component container (CCC).
Each CCC shall contain six driver fuel assemblies (DFAs) in the outer positions, seven DFAs including the center position, or six Ident-69 containers in the outer positions. The loaded CCC can contain a mixture of fuel assemblies and pin containers such that the total is either six or seven, and the number of pin containers is five or less. No partially filled CCCs are permitted.

There shall be no more than a total of 1,519 pins in a CCC container to protect the fuel rod rupture pressure calculation assumptions.

Only authorized fuel, as identified in Chapters D2.0 and D6.0, can be received at the ISA.

Only intact fuel shall be placed into a CCC.

Only intact fuel shall be placed into an LWR canister.

The number of individual fuel rods in the Nuclear Assurance Corporation (NAC)-1 cask does not exceed a maximum of 179 pressurized water reactor (PWR) rods, or 96.5 boiling water reactor (BWR) rods (95 full-length rods plus 6 quarter-length sealed segments) consolidated with 17 PWR rods.

- Procedures are established to ensure shipments meet acceptance criteria.
- Records are kept, maintained, and available for review that document that the material stored at the ISA meets the acceptance criteria.

**Derivation Criteria.** These controls are necessary to ensure that the ISA does not accept material that has not been analyzed in the design basis.

**D5.5.3.3 AC5.9 – Lift Restrictions.**

**Purpose.** This AC focuses on the importance of the planned operational steps that were identified as critical assumptions in the accident analyses in Chapter D3.0 and delineated in Chapter D4.0. The key elements of this AC, which preclude criticality or loss of confinement accidents, are as follows:

- The interim storage cask (ISC) cannot be lifted more than 8 ft above the ground or storage pad.
- The ISC cannot be lifted over an object that is taller than 4 ft or that contains radioactive materials.
- Crane loads other than the ISC rigging shall not be operated over a loaded ISC.
The Rad-Vault can only be lifted empty with the cover removed.

The Rad-Vault cover shall not be handled at a height greater than 12 in. above the top of the Rad-Vault.

Crane loads other than Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA) casks, U.S. Department of Transportation (DOT)-6M containers, rigging, and the Rad-Vault cover shall not be handled over a loaded Rad-Vault.

The NRF TRIGA casks and DOT-6M containers cannot be lifted more than 109 in. (approximately 9.1 ft) above the ground or more than 21 in. above the top of the Rad-Vault with the lid removed.

The NAC-1 package cannot be lifted over other objects except the transport trailer.

The NAC-1 package cannot be lifted more than 30-ft from the surface of the 200 Area ISA storage pad.

The crane hook and block lift height of 56 ft is not exceeded.

The ISO spreader bar lift height of 6 ft above the ISO container shall not be exceeded.

All lifts are to be considered critical lifts, as discussed in the Hanford Site hoisting and rigging criteria (DOE/RL-92-36).

**Derivation Criteria.** These controls are necessary to support the assumptions of the safety analysis. The assumptions rely on personnel actions to ensure they remain valid.

**D5.5.3.4 AC5.10 – Spacing and Placement.**

**Purpose.** This AC focuses on the importance of the critical assumptions identified in the accident analyses in Chapter D3.0 and delineated in Chapter D4.0. The key elements of this AC, which preclude loss of confinement accidents, are as follows:

- The ISC shall be placed on a concrete pad.
- The ISC minimum spacing array area shall be no less than 24 in. by 44 in. between ISCs measured edge to edge.
- A method shall be established for indicating proper ISC placement (e.g., painting an area on the storage pad).
• After unloading an ISC from the transport vehicle, verify the ISC is properly positioned on the storage pad and the minimum spacing requirement is met.

• The Rad-Vault shall be placed on compacted gravel.

• Before loading the NRF TRIGA casks and DOT-6M containers, verify the Rad-Vault is properly positioned on the compacted gravel and the minimum and maximum spacing requirements are met.

• The NAC-1 cask shall be placed on a concrete pad.

Derivation Criteria. These controls are necessary to support the assumptions of the safety analysis, design features, and lightning protection for the Rad-Vault.

D5.5.3.5 AC5.11 – Crane Utilization.

Purpose. This AC ensures only cranes and booms that are within the calculational analysis are used. The key elements of this AC, which preclude loss of confinement accidents, are as follows:

• The ISC and NAC-1 cask are restricted to the use of the Manitowoc 4000 150T crane with Model 22 80-ft boom, or the Manitowoc 4100 250T crane with Model 27 80-ft boom.

• The NRF TRIGA cask and DOT-6M container shall be handled with any appropriate crane within the Hanford Site hoisting and rigging criteria (DOE/RL-92-36) for a critical lift, but no larger than a 250-ton crane.

• All lifts are to be considered critical lifts, as discussed in the Hanford Site hoisting and rigging criteria (DOE/RL-92-36).

Derivation Criteria. These controls are necessary to support the assumptions of the safety analysis.

D5.5.3.6 AC5.12 – Combustible Loading Limits.

Purpose. This AC provides protection against exceeding the combustible loadings assumed in the fire hazard analysis. The key elements of this AC, which preclude loss of confinement accidents, are as follows:

• The Fire Hazard Analysis shall be reviewed at least annually to ensure that the program complies with the combustible loading limits (e.g., quantity and location) within the analysis.
The facility's combustible loadings shall be evaluated at least annually and compared against the fire hazard analysis limits. Any necessary adjustments shall be made to comply with the fire hazard analysis loading limitations.

**Derivation Criteria.** These controls are necessary to support the assumptions of the fire hazard analysis.

### D5.6 DESIGN FEATURES

Design features for the 200 Area ISA that, if altered or modified, would have a significant effect on safety are listed below. Descriptions of these design features are provided in Chapter D2.0; the safety functions they perform are described in Chapter D4.0.

#### D5.6.1 Fast Flux Test Facility Spent Nuclear Fuel Core Component Container

Design features for the Fast Flux Test Facility (FFTF) CCC include the following:

- Criticality geometry control
- Corrosion-resistant spent fuel storage
- SNF protection against all credible drops
- Radiological shielding for ALARA (as low as reasonably achievable) protection
- The CCC Helicoflex seal shall have a design temperature of at least 500 °F.

#### D5.6.2 Light Water Reactor Canister

Design features for the light water reactor (LWR) canister include the following:

- Criticality geometry control
- SNF confinement
- Shielding overpack for weather and natural phenomena hazards (NPH) protection
- A gamma shield at the canister end
- The individual loose rods must be retained within the 10-in. diameter sleeve.

#### D5.6.3 Fast Flux Test Facility Interim Storage Cask

Design features for the FFTF ISC include the following:

- SNF secondary confinement
- Passive heat removal
- CCC environmental protection
• Radiological shielding for ALARA protection
• SNF drop protection
• Weather protection with the ISC cover installed.

D5.6.4 NRF TRIGA Cask

Design features for the NRF TRIGA cask include the following:

• Confinement and shielding for the TRIGA fuel
• 20-year storage life requirement of the cask metallic seals
• Seals must meet the leak-tight requirement for transportation.

D5.6.5 DOT-6M and 2R Containers

Design features for the DOT-6M package with the inner 2R container include the following:

• SNF confinement
• Radiological shielding for ALARA protection.

D5.6.6 Rad-Vault

Design features for the Rad-Vault include the following:

• Supplemental shielding for NRF TRIGA casks and DOT-6M containers
• Heat shield for fires
• NPH protection for wind, wind missiles, tornados, and volcanic ashfall
• Weather cover to mitigate snow, dust, sandstorm, and rain.

D5.6.7 NAC-1 Cask and International Standards Organization Shipping Container

Design features for the NAC-1 cask include the following:

• Radiological shielding for ALARA protection
• Protection for the LWR canister
• Protection from stresses from natural phenomena and accident events.
D5.6.8 **At-Grade Storage Pads and Compacted Gravel Structure at 200 Area Interim Storage Area**

Design features for grading include the following:

- Maintain site grading such that the probable maximum precipitation event does not allow water to degrade the storage pad (undercut concrete pad).
- Maintain site grading such that the accumulation of runoff water cannot result in a pad overflow of water.

D5.7 **INTERFACES WITH TECHNICAL SAFETY REQUIREMENTS FROM OTHER FACILITIES**

There are no TSRs of other SNF Project facilities that affect the 200 Area ISA. However, there is interaction of the ISA with existing CSB facilities for surveillance activities and central alarm notification.

PREVENTION OF INADVERTENT CRITICALITY
This page intentionally left blank.
D6.0 PREVENTION OF INADVERTENT CRITICALITY

D6.1 INTRODUCTION

This chapter provides an evaluation of the potential for a criticality accident in the 200 Area Interim Storage Area (ISA). Controls required to prevent criticality in the ISA are also discussed. Chapter 6.0 of the Spent Nuclear Fuel (SNF) Project Final Safety Analysis Report (FSAR) provides an overall description of the SNF Project criticality prevention program.

The scope of the criticality analysis and control strategy for the ISA includes criticality hazards associated with the handling and storage of SNF at the ISA. Specifically, this includes receipt and unloading of sealed casks from transportation vehicles, movement of casks within the ISA facility, and storage of casks in the facility for a period of up to 40 years. Activities excluded from the scope are: (1) transport of the SNF to the ISA facility, and (2) handling and loading of SNF into casks at the Fast Flux Test Facility (FFTF) and the 300 area prior to transport to the ISA. However, the impact of abnormal events or accidents are considered that may affect the condition or configuration of casks delivered to the ISA (e.g., the criticality hazard associated with receiving a misloaded cask is analyzed). The criticality safety of transportation of SNF to the ISA facility is analyzed in WHC-SD-TP-SARP-008, Safety Analysis Report for Packaging (Onsite) NRF TRIGA Packaging, and WHC-SD-TP-SARP-010, Safety Analysis Report for Packaging (Onsite) Interim Storage Cask.

D6.2 REQUIREMENTS

The requirements that form the basis of criticality prevention are identified in Section 6.2 of the SNF Project FSAR.

This chapter also addresses implementation of requirements to achieve U.S. Nuclear Regulatory Commission (NRC) equivalency in the design of the ISA with respect to criticality prevention based on the double-contingency principle. The double-contingency principle is stated in U.S. Department of Energy (DOE) Order 5480.24, Nuclear Criticality Safety, as follows: "Process designs shall incorporate sufficient factors of safety to require at least two unlikely, independent and concurrent changes in process conditions before a criticality accident is possible." The SNF project has established a $k_{eq}$ limit of 0.95 (including allowance for uncertainty) for the ISA (HNF-SD-SNF-DB-003). As applied in this chapter, contingencies include failure of an engineered feature incorporated in the ISA design or failure of an administrative control affecting criticality safety at the ISA.
D6.3 CRITICALITY CONCERNS

D6.3.1 Fissile Material Form and Inventory

As described in Chapter D2.0, four different dry cask storage containers will be stored in the ISA, including the following:

- Interim Storage Casks (ISC) containing FFTF fuel or experimental targets.
- Six Neutron Radiography Facility (NRF) TRIGA casks containing Training, Research and Isotope Production, General Atomics (TRIGA) fuel.
- Two U.S. Department of Transportation (DOT)-6M casks containing the TRIGA fuel follower control rods (FFCRs).
- Nuclear Assurance Corporation (NAC)-I casks containing 300 Area light water reactor (LWR) fuel.

The layout of casks on storage pads and within the Rad-Vault at the ISA facility is described in Section D2.3 and illustrated in Figure D2-1. The design and specifications of the casks themselves are described in Section D2.6. Details of the fuel design and inventory stored in the casks are found in Section D2.5. For the purposes of criticality safety, the fissile material form and contents of the fuel stored in the casks are summarized in the subsections that follow.

D6.3.1.1 Fast Flux Test Facility Fuel. Several different types of fuel pins were analyzed in the criticality safety evaluation reports (CSERs) prepared for the storage of FFTF fuel (see Section D2.5.1.1 for details), as follows:

- Mixed oxide (MOX) fuel pins - The MOX fuel pins contain uranium dioxide and plutonium dioxide in pellet form clad with stainless steel. Slight variations in the enrichment of the fuel exist within the inventory. However, enrichment is bounded by a maximum 29.28 wt% Pu (239 and 241) and a minimum 11.63 wt% Pu-240.

- Metal fuel pins - The metal fuel pins contain a sodium-bonded uranium/zirconium alloy clad with stainless steel. The metal fuel is of two enrichments: 31 wt% U-235 or 32.4 wt% U-235. Note: Storage of metal fuel is not currently authorized at the ISA (see Section D2.5.1.1), but is included in this chapter for completeness since a criticality analysis has already been performed for the metal fuel.

- Certain experimental fuel pins and repackaged fuel debris - This fuel is classified as equivalent to MOX fuel (see Section D2.5.1.1 for details). Note: Storage of experimental fuel debris is not currently authorized at the ISA (see Section D2.5.1.1),
but is included in this chapter for completeness since a criticality analysis has already been performed for the fuel debris.

Note: MOX and metal fuel were analyzed for criticality safety at the ISA. Other FFTF fuel types (e.g., those contained in certain "test fuel assemblies") (see Section D2.5.1.1) cannot be accepted at the 200 Area ISA without further criticality analysis.

The FFTF CSERs analyzed core component container (CCC) tubes loaded with a combination of the following: (Note: storage of metal fuel and experimental fuel debris are not yet authorized for the ISA. However, storage configurations of these fuels that are acceptable from a criticality safety standpoint are discussed here since they have already been analyzed in the FFTF CSERs.)

- Driver fuel assemblies (DFAs) consisting of a hexagonal array of 217 MOX fuel pins.
- Ident-69 containers with varying numbers of MOX fuel pins (up to 217).
- MOX fuel test assemblies consisting of a hexagonal array of 217 or 169 fuel pins.
- Metal fuel test assemblies consisting of a hexagonal array of 169 metal fuel pins.
- Modified Ident-69s containing returned experimental fuel pins and repacked fuel pin debris.

FFTF fuel will be stored in a given ISC subject to the following restrictions:

- No Ident-69, metal assemblies, or modified Ident-69s with repackaged fuel are allowed in the center CCC position. (Note: Ident-69 containers are too long to fit in the center position without modification.)
- The center tube of the CCC must be empty if there are six Ident-69s.
- Mixtures of metal assemblies and Ident-69s are not allowed.
- Modified Ident-69s must not contain over 4 kg of MOX fuel and the enrichment must be <31 wt% Pu.

These restrictions were developed in the FFTF CSERs to ensure safe subcritical limits are not violated during handling and loading of the ISCs at FFTF.

Numerous possibilities exist for the actual loading of the six CCC tubes with the above tube loading options. The $k_{\text{eff}}$ of various bounding configurations for the CCC tube is analyzed in Section D6.3.2.
The fissile material inventory for each fuel type and storage configuration within a CCC storage tube is shown in Table D6-1. This inventory represents the upper bound on plutonium and uranium enrichment.

**D6.3.1.2 NRF TRIGA Fuel.** As described in Section D2.5.1.2, two types of fuel elements will be stored in the six NRF TRIGA casks: (1) stainless steel-clad fuel elements with ceramic zirconium hydride/uranium fuel having 8.5 wt% uranium content with 20% enrichment, and (2) aluminum-clad fuel elements of a similar specification. Two FFCRs will also be stored in the Rad-Vault in DOT-6M casks. The uranium content (shown in Table D2-8) varies slightly by fuel element, but does not exceed 41 g of U-235.

There are a total of 66 aluminum-clad fuel elements, 33 stainless steel-clad fuel elements, and 2 FFCR elements. The total fissile material content of the Rad-Vault will not exceed 4 kg of U-235.

**D6.3.1.3 Commercial Light Water Reactor Fuel.** The fuel stored in the NAC-1 casks is described in detail in Section D2.5.3. Six casks will be used to store (1) five pressurized water reactor (PWR) assemblies and a special loose pin container with pins from two boiling water reactor (BWR) assemblies, and (2) twelve Segmented Rod Program segmented rods from several commercial power reactors. The fuel rods consist primarily of uranium oxide fuel clad in zircaloy, with U-235 enrichment varying from 2.45 to 3.6 wt%. From Table D2-11 the total U-235 content of all the fuel stored in the NAC-1 casks is calculated to be less than 63 kg.

D6.3.1.4 Total Interim Storage Area Inventory. The total ISA inventory consists of fissionable material found in 210 FFTF DFAs, 65 FFTF test DFAs, and 11 FFTF test fuel assemblies (those classified as equivalent to MOX fuel), 5 LWR fuel assemblies, 2 FFCRs, 118 loose LWR pins, and 101 TRIGA fuel pins. The total FFTF fuel inventory was inferred from the total Pu and U mass in FFTF fuel listed in Section D2.5.1.1. The fissionable material totals in Table D6-2 are upper bounds on plutonium and uranium enrichment used in the criticality analysis and may differ slightly from actual inventories due to variations in enrichment.

D6.3.2 Criticality Hazards

Table D6-3 identifies criticality hazards associated with handling and storage of the SNF. These hazards apply to all four types of casks, with exceptions as noted.

Changes in $k_{\text{eff}}$ of the casks or groups of casks due to the above hazards are analyzed in Section D6.3.3. The $k_{\text{eff}}$ analysis includes the effect of multiple hazardous conditions from Table D6-3 occurring at the same time. For example, the effect of flooding of a cask in which fuel has disintegrated due to a corrosion phenomenon called hot-cell rot is considered for the ISCs.
Table D6-3. Criticality Hazards Evaluation. (2 sheets)

<td>Yes</td>
</tr>
</tbody>
</table>

(1) Water intrusion into an ISC was judged to be not credible due to the multiple barriers that exist to prevent this hazard. For example, the ISC has an environmental cover to prevent snow and rain intrusion, and two metallic O-ring seals that must fail to allow flooding. The ISC annulus must fill with water before challenging the CCC seals. The CCC inside the ISC has one O-ring seal plus the inner metal seal that must fail. Water intrusion into the TRIGA casks was considered very unlikely. The TRIGA casks have a Helicoflex metallic seal for long-term storage integrity. Also, the Rad-Vault in which the TRIGA casks are stored has a lid designed to prevent rain intrusion. The NAC-1 casks are within an ISO container, which provides weather protection. The LWR canister is welded closed.

(2) Cladding failure at a rate anticipated for commercial LWR fuel has been shown to have a negligible effect on the LWR fuel in SNF-4875, 1999, Criticality Evaluation for Long Term Storage of Light Water Reactor Fuel in NAC-1 Casks. The zircaloy cladding will not suffer significant corrosion at the storage temperatures in the casks. A small percentage of pins might have cladding with breaches as a result of irradiation. These breaches could result in partial conversion of $\text{UO}_2$ to $\text{U}_3\text{O}_8$ in the affected pins, resulting in swelling and pin breakage. However, the number of pins affected is too small to significantly affect the $k_{\text{eff}}$ of the assemblies. TRIGA fuel is a metallic uranium hydroxide that is not susceptible to corrosion in water or air. The hot-cell rot phenomenon is unique to the FFTF fuel.

(3) The worst-case drop or crane collision has been analyzed for the ISCs in Chapter D3.0 and shown not to challenge the integrity of the CCC or ISA. However, the structural integrity of the fuel assemblies is not known and is assumed to fail in a drop. Also, hot-cell rot may occur in the FFTF fuel assemblies, so tipping the ISC could also result in fuel geometry changes. Crushing of the Rad-Vault and TRIGA casks has not been demonstrated incredible for the catastrophic impact of a crane failure. Effects of this event are analyzed in Section D6.3.3. The structural integrity of the LWR canisters and the LWR fuel rods will not be affected by the worst-case cask drop or natural phenomena hazard events, as discussed in Chapter D3.0.

(4) Misloading of Ident-69 containers into the center tube of a CCC was not considered credible, as the Ident-69 is too long to fit in the center tube without physical modification.

DBA = design basis accident.  
FFTF = Fast Flux Test Facility.  
NAC = Nuclear Assurance Corporation.  
ISA = interim storage area.  
SARP = safety analysis report for packaging.  
TRIGA = Training, Research and Isotope Production, General Atomics.  
LWR = light water reactor.
D6.3.3 Analysis of Hazardous Conditions

Evaluations of neutron multiplication factors ($k_{ef}$) for hazardous conditions affecting SNF stored at the ISA have been performed in several CSERs that are summarized in this section. These documents were prepared several years prior to development of the SNF Project safety analysis report. The existing CSERs formed the authorization basis for transportation and storage of SNF at the FFTF 400 Area ISA. These historical CSERs employed several different methods for calculating bias and uncertainty in $k_{ef}$ and determining the upper bound on $k_{ef}$, which are summarized in this section. For comparison to the safe subcritical limit of 0.95, the uncertainty and bias (at the 95% confidence level) reported by the CSERs have been added to the values of $k_{ef}$ calculated in the CSERs, as described in Section 6.3 of the SNF Project FSAR. These "upper bound" values of $k_{ef}$ have been reported in the discussion of analysis results below (as opposed to the "unadjusted" value of $k_{ef}$ calculated by the analysis models in the CSERs).

D6.3.3.1 Fast Flux Test Facility Fuel. The $k_{ef}$ of numerous normal and accident conditions for FFTF fuel stored in ISCs have been analyzed in the CSERs prepared for the storage of FFTF spent fuel (WHC-SD-FV792-DA-004; WHC-SD-FF-CSER-002 and WHC-SD-FF-CSER-004, Revs. 1, 1-A, and 1-B). The analyses in these documents are summarized in Sections D6.3.3.1.1 and D6.3.3.1.2.

D6.3.3.1.1 Analysis Models.

Criticality Safety Evaluation of Ident-69s in the Core Component Container

WHC-SD-FV792-DA-004, Criticality Safety Evaluation of Ident 69s in Core Component Container, presents an analysis of $k_{ef}$ in ISCs loaded with six Ident-69 pin containers, with the center tube of the CCC empty. The analysis was performed with the MCNP Monte Carlo program, version 3B. A parametric analysis was performed on the Ident-69 configuration for a flooded CCC. The following parameters were varied:

- Total number of pins
- Water density
- Square array vs. hexagonal array
- Number of CCC tubes loaded.

From the parametric analysis, the most reactive configuration for the Ident-69 was determined to be 97 pins in a square array. This analysis did not consider the effects of hot-cell rot. All cases relevant to ISA storage assume intact fuel pins. It is known that FFTF fuel lattices with a pin pitch less than 0.90 in. are under-moderated, thus the Ident-69 $k_{ef}$ at the optimal pin pitch of ~.5 in. corresponding to 97 pins was found to be most reactive when the CCC tubes were fully flooded with water. The optimal 97 pin configuration provides an upper bound on the $k_{ef}$ of all flooded Ident-69 configurations. This configuration was used in the later CSERs (WHC-SD-FF-CSER-002; and WHC-SD-FF-CSER-004, Revs. 1, 1-A, and 1-B) to determine $k_{ef}$ for flooded configurations reported in Table D6-4.

(1) Table D6-4 addresses fully loaded CCCs. The $k_{eff}$ for partially loaded CCCs are bounded by the fully loaded configurations.

(2) The flooded condition for storage of FFTF fuel in the ISC has been determined to be not credible.

(3) This number represents the $k_{eff}$ calculated in the analysis, plus an additional margin to account for bias and uncertainty, as reported in the CSER.

(4) Administrative controls on Ident-69 containers limit the number of pins to 217 (same as DFAs). However, Ident-69 containers could hold up to 233 pins. If all 6 Ident-69 containers are loaded with 233 pins, the total number of pins is still less than an ISC loaded with 7 DFAs (1,398 pins vs. 1,519 pins). Also, the geometry of fuel in an ISC with one tube empty is less optimal for the hot-cell rot hazard than a fully loaded ISC. Therefore, the 7 DFA case bounds the 6 Ident-69 case for hot-cell rot.

(5) Mixtures of DFAs and Ident-69s were required to minimize the number of ISCs.

(6) This case was not analyzed in the CSERs and could contain slightly more fuel than an ISC loaded with 7 DFAs, if the Ident-69 containers are overloaded with 233 pins. However, the Ident-69 pin containers are not expected to be impacted by hot-cell rot. An ISC loaded with DFAs and Ident-69 containers (with failed fuel but intact containers) is judged to be less reactive than an ISC loaded with 7 DFAs subject to complete structural failure (fuel and duct failure) from hot-cell rot.

(7) Only six metal assemblies were made.

CCC = core component container.  
DFA = driver fuel assembly.  
ISC = interim storage cask.
The assumptions used in the analysis are as follows:

- The fuel modeled is outer driver fuel, Type 4.1, with 29.28 wt% Pu (239 and 241) and 11.63 wt% Pu-240, which is the highest total Pu enrichment for any of the FFTF fuel pins.

- Unirradiated fuel was modeled; no credit was taken for burnup.

- The radial dividers in the Ident-69 were neglected (resulting in a positive bias in $k_{\text{eff}}$).

The model was validated against experiments with fast test reactor fuel pins in water, as reported in "Critical Experiments with Fast Test Reactor Fuel Pins in Water" (Bierman et al. 1979). The validation showed a small positive bias in $b_N$ of ~ 0.006 for the MCNP results when compared to the benchmark experiments. In addition, omitting the radial dividers from the Ident-69 model introduced another positive bias of 0.013 in $k_{\text{eff}}$.

**Criticality Evaluation for the Long-Term Storage of Fast Flux Test Facility Fuel in Interim Storage Containers (Rev. 0)**

WHC-SD-FF-CSER-004 (Rev. 0), Criticality Evaluation for the Long Term Storage of FFTF Fuel in Interim Storage Containers, analyzed the $k_{\text{eff}}$ of ISCs loaded with seven DFAs subject to hot-cell rot. The Monte Carlo criticality computer code, MONK6B, was used for the calculations of $k_{\text{eff}}$. Various geometries resulting from disintegration of the fuel due to hot-cell rot were studied, as follows:

- A set of parametric cases was analyzed that assumed complete fuel and cladding failure with intact assembly ducts. In this model, fuel and cladding were uniformly mixed within the intact duct. Heights from 21 in. to 36 in. for the uniform mixture were analyzed. Both dry and flooded configurations were analyzed.

- A case similar to the above cases but assuming failure of the assembly duct was also analyzed. The homogeneous mixture of fuel, cladding, and duct debris was found to have a minimum height of 12 in. Both dry and flooded configurations were analyzed. Fuel debris in pellet or powder form was also analyzed for the flooded configuration.

- A dry case was analyzed assuming that the cladding and duct debris were separated from the fuel debris, resulting in a minimum 7-in. fuel height.

The geometries analyzed provide an upper bound on $k_{\text{eff}}$ for the possible configurations resulting from hot-cell rot in an ISC loaded with DFAs.
The assumptions used in the analysis are as follows:

- The fuel modeled is outer driver fuel, Type 4.1, with 29.28 wt% Pu (239 and 241) and 11.63 wt% Pu-240, which is the highest total Pu enrichment for any of the FFTF fuel pins.

- Unirradiated fuel was modeled; no credit was taken for burnup.

The analysis also considered storage of multiple ISCs on a pad by analyzing an infinite planar array of adjacent, flooded ISCs. However, large scale flooding of the ISA is not considered credible in the hazard analysis discussed in Section D6.3.2.

In addition, the possibility of fuel heights larger than the nominal 36 in. was considered. These larger fuel heights were postulated as the result of fuel and cladding debris spreading out within the assembly duct in a horizontal ISC (e.g., due to tipping). Assembly ducts were assumed to be intact for the extended height cases.

Validation of the MONK6A computer code for WHC-SD-FF-CSER-003, *Criticality Evaluation for the Long Term Storage of FFTF Fuel in Interim Storage Containers*, can be applied to the MONK6B computer code. WHC-SD-SQA-CSWD-20019, *MONK6B Pu Validation*, demonstrated the equivalence of MONK6B to MONK6A, as the cross-section library of the two versions is identical. To validate the accuracy of the MONK6A model, WHC-SD-FF-CSER-003 made comparison calculations with the previous criticality analyses for intact DFAs in WHC-SD-FF-CSER-002, *Criticality Safety Evaluation Report of Fuel Assemblies in Core Component Containers*. The only difference between the calculations was that the MCNP calculations in WHC-SD-FF-CSER-002 used explicitly modeled fuel pins, while the MONK6A calculations used homogenized atom densities for the fuel pins and water. The MONK6A model was found to give a slightly larger $k_{eff}$ that was within the statistical uncertainty of the calculation at the 95% confidence level. The validation document, WHC-SD-SQA-CSWD-20015, *MONK6A Pu Validation*, states that a calculated value of $k_{eff} < 0.935$ is required to assure $k_{eff} < 0.95$, including bias and uncertainty. Direct comparisons of MONK6A calculations against critical experiments show that calculated $k_{eff}$ values less than 0.935 ensure that $k_{eff} < 0.95$, including uncertainty and bias at the 95% confidence level. For comparison to the safe subcritical limit of 0.95, a value of 0.015 was added to the calculated values of $k_{eff}$ to obtain the values in Table D6-4.

**Criticality Evaluation for the Long-Term Storage of Fast Flux Test Facility Fuel in Interim Storage Containers (Rev. 1)**

WHC-SD-FF-CSER-004 (Rev. 1) adds Appendix C to Rev. 0. Appendix C analyzes mixtures of DFAs and Ident-69s for flooded conditions. This analysis was performed to allow combinations of DFAs and Ident-69 containers to minimize the number of ISCs required in the storage area. The mixed configurations were analyzed using the same fuel assumptions.
discussed previously for the DFAs. All pin containers were assumed to be optimally loaded with 97 pins. The following cases were analyzed:

- One to seven Ident-69s with the remaining tubes occupied by DFAs. The center CCC tube is occupied by an Ident-69.
- Zero to five Ident-69s with one outer tube empty and the center tube with a DFA.
- Six Ident-69s in the outer tubes.
- Five Ident-69s in the outer tubes and two DFAs in the remaining tubes.

The analysis also considered storage of multiple ISCs on a pad, with mixtures of Ident-69s and DFAs, by analyzing an infinite planar array of adjacent, flooded ISCs with five Ident-69s and two DFAs. However, large scale flooding of the ISA is not considered credible in the hazard analysis discussed in Section D6.3.2.

**Criticality Evaluation for the Long-Term Storage of Fast Flux Test Facility Fuel in Interim Storage Containers (Rev. 1-A)**

WHC-SD-FF-CSER-004 (Rev. 1-A) is written as Appendix D to WHC-SD-FF-CSER-004. This document contains analysis of the k_{eff} of modified Ident-69s containing returned FFTF experimental fuel and repackaged fuel in a spent fuel container, as described in Section D6.4.2. The experimental fuel is from the following FFTF test assemblies: ACO-3, ACO-1, FO-2, MFA-1, AAD-5, DE4-1, D9-1, DE2-2, D9-4 and C-1. The pins from each of these assemblies have previously been classified as equivalent to MOX fuel for the purposes of criticality safety. The MONK6B computer code was used to calculate k_{eff}. The code validation discussion for WHC-SD-FF-CSER-004 (Rev. 1) is applicable to Appendix D as well. The configurations of the flooded, water-reflected, modified Ident-69 analyzed are as follows:

- 48 stainless steel tubes inside a spent fuel canister with 4 kg of MOX fuel homogeneously distributed within each tube volume. Fuel within the tubes is dry, all other void spaces are flooded. Tube pitch within the spent fuel canister was varied from 0.50 in. (close packed) to 0.67 in. (spread out to the volume of Ident-69).
- 4 kg of MOX fuel in pellet form (.494 cm diameter spheres) inside a flooded spent fuel canister. Pellet pitch was varied from 0.20 in. (close packed) to 0.45 in. (homogeneous distribution throughout spent fuel canister). The stainless steel of the fuel tubes was neglected.
- 4 kg of MOX fuel in pellet form (0.494 cm diameter spheres) inside a flooded, modified Ident-69. Pellet pitch was varied from 0.20 in. (close packed) to 0.88 in. (homogeneous distribution inside the modified Ident-69). The stainless steel of the spent fuel canister and the fuel tubes was neglected.
4 kg of MOX fuel in powder form inside a flooded, modified Ident-69. The stainless steel of the spent fuel canister and the fuel tubes was neglected.

The calculated $k_{\text{eff}}$ values for these configurations were compared to a calculated $k_{\text{eff}}$ value for a flooded, water-reflected, optimized Ident-69 loaded with 97 pins, as analyzed in WHC-SD-FF-CSER-004 (Rev. 1).

The following assumptions were made in the analysis:

- The modified Ident-69s contain $<4$ kg of experimental pins and repackaged fuel.
- Fuel pin cladding was ignored.

Criticality Evaluation for the Long-Term Storage of Fast Flux Test Facility Fuel in Interim Storage Containers (Rev. 1-B)

WHC-SD-FF-CSER-004 (Rev. 1-B) presents analysis of the $k_{\text{eff}}$ of CCCs loaded with mixtures of metal fuel assemblies and DFAs. The MONK6B computer code was used to determine $k_{\text{eff}}$ values. The following cases were analyzed:

- One to seven metal fuel assemblies in a CCC with a metal assembly in the center tube and the remaining tubes occupied by DFAs. The ISC was assumed to be flooded. Fuel and cladding were assumed to be homogeneously distributed over a 36-in. height (nominal fuel height) within intact fuel assembly ducts.

- Four or five metal assemblies with a DFA in the center tube and the remaining tubes occupied by DFAs. Dry and flooded configurations were analyzed. Fuel and cladding were assumed to be homogeneously distributed over a 36-in. height (nominal fuel height) or over a 12 in. height (minimum height of collapsed fuel and cladding debris) within intact fuel assembly ducts. Dry and flooded configurations were analyzed. Several cases with dry and flooded intact fuel were also considered.

- Five metal assemblies with two DFAs (one in the center tube) within a flooded ISC. Fuel and cladding were assumed to be homogeneously distributed over 36-in. to 140-in. heights (nominal fuel height) within intact fuel assembly ducts. This case represents a horizontal ISC (e.g., due to tipping during movement or vehicle collision).

- Six metal assemblies with the center tube occupied or unoccupied. The ISC was assumed to be flooded. Fuel and cladding were assumed to be either intact or completely failed due to hot-cell rot. For the hot-cell rot cases, the fuel and cladding were homogeneously distributed over a 36-in. height (nominal fuel height) within intact fuel assembly ducts.
Seven metal assemblies. The ISC was assumed to be flooded. Fuel and cladding were assumed to be homogeneously distributed over a 36-in. height (nominal fuel height) within intact fuel assembly ducts.

Several configurations having mixtures of metal assemblies and Ident-69s were also analyzed, which assumed intact ducts, a flooded ISC, and the fuel and cladding homogeneously distributed over a 36-in. height due to hot-cell rot.

The analysis used the following assumptions:

- Metal fuel has 32.4 wt% U-235 enrichment.
- Unirradiated fuel was used; no credit was taken for burnup.

Validation of the MONK6B computer code is discussed previously in the summary of WHC-SD-FF-CSER-004 (Rev. 1). For comparison to the safe subcritical limit of 0.95, a value of 0.015 for bias plus uncertainty was added to the calculated values of $k_{eff}$ and reported in Table D6-4.

**D6.3.3.1.2 Analysis Results.** Analysis results are summarized in Table D6-4. The table contains entries for all fully loaded CCC configurations and all credible hazardous conditions identified in the hazard evaluation. In addition, some CCC configurations that were found to be not credible are also presented, since they were analyzed in the CSERs. Some of these cases have $k_{eff}$ values beyond the acceptable limit, but they do not require administrative or engineered controls since they result from hazardous conditions that were considered incredible in the hazard evaluation (Section D6.3.2).

**Normal Conditions**

Normal conditions consist of dry ISCs loaded with structurally intact DFAs, Ident-69s, metal assemblies, or modified Ident-69s subject to the restrictions described in Section D6.3.1.

From Table D6-4, the highest $k_{eff}$ for normal configurations in the table (i.e., no hazardous conditions present) was calculated to be 0.4125, including bias and uncertainty, for an ISC loaded with six metal assemblies. Metal assemblies were found to be slightly more reactive than DFAs. This upper limit for normal configurations is well below the safe subcritical limit of 0.95.

For a dry ISC loaded with intact fuel, Ident-69s were found to be less reactive than DFAs. The $k_{eff}$ for intact dry fuel increases with decreasing pin pitch. The pin pitch for the DFA is 0.284 in., while the pin pitch for 217 pins within an Ident-69 is greater than 0.30 in. (WHC-SD-FV792-DA-004). Thus, the most reactive dry configuration for Ident-69s with 217 intact pins is less reactive than a dry DFA with 217 pins.
Results of the analysis for the storage of multiple ISCs indicate that the CCCs are neutronically separated within the ISC. Compared to the $k_{\text{eff}}$ of a single ISC, model results for an infinite planar array of adjacent ISCs showed an increase in $k_{\text{eff}}$ on the order of the statistical uncertainty in $k_{\text{eff}}$. Thus, for arrays of dry ISCs with intact fuel, $k_{\text{eff}}$ for the array will still fall well below the safe subcritical limit of 0.95.

Abnormal Conditions

As discussed in Section D6.3.2, individual hazardous events that were determined to be credible, but unlikely, are as follows:

- Misloading of a cask prior to transport to the ISA.
- Tipping or dropping of a cask during handling (structural damage to the CCC due to a design basis drop was shown to be not credible in Chapter D3.0).

The results of the analysis in WHC-SD-FF-CSER-004 (Rev. 1-A) for experimental fuel in a modified Ident-69 container show that for all credible hazardous conditions, the $k_{\text{eff}}$ for the modified Ident-69 will be bounded by $k_{\text{eff}}$ for an optimized, unmodified Ident-69 container, as analyzed in WHC-SD-FF-CSER-004 (Rev. 1). Therefore, all hazardous ISC configurations with modified Ident-69 containers are bounded by the configuration obtained when the modified Ident-69 containers are replaced by optimized unmodified Ident-69 containers.

The hazard analysis also identified hot-cell rot as an anticipated hazard over the 40-year storage lifetime of the casks. The actual likelihood of hot-cell rot affecting the fuel pins is highly uncertain but has been observed at several other facilities. The thickness of the stainless steel in the fuel assembly ducts is several times greater than the fuel cladding itself and is less susceptible to corrosion than the fuel cladding. Ident-69 containers have not been exposed to thermal cycling and the corrosive environment of the sodium coolant during the cleaning process prior to loading in the ISCs and are not expected to suffer from the effects of hot-cell rot. However, in order to provide an upper bound on the likelihood of the hazard, the hazard analysis assumed that the event will occur and that fuel pins and/or assembly ducts may suffer complete structural failure. The CCC tubes were assumed to be unaffected by any corrosion mechanisms due to their robust design requirements. Hot-cell rot was modeled in the $k_{\text{eff}}$ analyses by either (1) assuming that fuel and cladding was homogeneously mixed within the void space of the ducts, or (2) assuming that fuel, cladding, and assembly duct material were homogeneously mixed within the void space of the CCC tube. The height of the fuel and cladding debris, or fuel and cladding and duct debris, was varied parametrically in the $k_{\text{eff}}$ calculations to determine the geometric configuration with the largest $k_{\text{eff}}$. 

HNF-3553 REV 0
Annex D - 200 Area Interim Storage Area
**k\textsubscript{eff} of Configurations Due to Hot-cell Rot**

The largest value of \(k_{\text{eff}}\) (including bias and uncertainty at the 95% confidence level) for a dry, normally loaded ISC that has experienced hot-cell rot was found to be 0.9494. This extreme case of hot-cell rot was obtained for a CCC loaded with seven DFAs by assuming the entire assembly has disintegrated. In addition, the stainless steel of the cladding and ducts was assumed to have separated from the fuel debris by some unknown mechanism. The separated fuel was compacted to its minimum possible height of 7.2 in. within the bottom of the CCC tubes to form the most reactive configuration constrained only by the CCC tube geometry.

**k\textsubscript{eff} of Single Contingency Configurations**

Single-contingency configurations are defined as those that occur due to a single unlikely hazardous event (with or without hot-cell rot), since some form of hot-cell rot was assumed to occur in the hazard analysis. Single-contingency events were assumed to include the possibility of hot-cell rot combined with one other unlikely hazardous event.

**Misloaded cask** – From Table D6-4, the most reactive misloaded cask configuration with intact fuel pins was found to be five metal fuel assemblies and two DFAs in the CCC, with a metal assembly in the center position (a configuration with six metal assemblies and one DFA was not analyzed, but should give a slightly higher \(k_{\text{eff}}\) — still far below 0.95). Metal assemblies are slightly more reactive than DFAs.

Note: Misloading of a cask with seven Ident-69 containers was considered to be not credible by the hazard evaluation and was not systematically analyzed in the CSERs. However, two cases with seven Ident-69 containers were analyzed and are reported in Table D6-4 for information only.

**Tipped cask** – Tipping or dropping a cask could result in damaged fuel that is spread out within the void space of the CCC tubes. The \(k_{\text{eff}}\) of a tipped cask with dry fuel is bounded by the analysis for hot-cell rot (discussed previously), since dry fuel has been shown to be more reactive when placed in the most compact geometry. Tipped or dropped casks with dry fuel were not analyzed in the CSERs and are not shown in Table D6-4. Tipping or dropping a flooded cask was analyzed in the CSERs and is discussed below under "Flooded Cask."

**k\textsubscript{eff} of Other Hazardous Conditions**

The remaining hazardous conditions that have not been excluded as not credible by the hazard evaluation are as follows:

**Misloaded and Tipped Cask** – This configuration could result in damaged fuel spread out within the void space of the CCC tubes. The \(k_{\text{eff}}\) for the system is bounded by the misloaded configuration with hot-cell rot (discussed previously) since dry fuel was shown to be more reactive when compacted to its minimum possible height.
Incredible Hazardous Conditions

Hazardous conditions found to be not credible by the hazard evaluation, but were analyzed in the CSERs are as follows:

Flooded Cask – Cask flooding at the ISA was judged to be not credible by the hazard evaluation. However, flooded configurations analyzed in the CSERs are reported in Table D6-4 for completeness. The flooded configurations were analyzed in the CSERs to ensure that fuel remained safely subcritical during fuel handling operations, including washing activities.

From Table D6-4, the most reactive flooded, normally loaded cask configuration with intact fuel pins was found to be five metal fuel assemblies and two DFAs in the CCC, with a DFA in the center position. This configuration resulted in an upper bound on $k_{\text{eff}}$ of 0.9380, including bias and uncertainty at the 95% confidence level. Including the possibility of hot-cell rot raises the $k_{\text{eff}}$ slightly to 0.9453. The hot-cell rot configuration assumed that the fuel/cladding water debris extended over the normal height of the fueled region (36 in.) in order to achieve optimal moderation. In reality, hot-cell rot would tend to create debris that collects at the bottom of the CCC tube, which is a less optimally moderated geometry.

The infinite flooded array of ISCs containing five Ident-69s and two DFAs with intact fuel pins was calculated to have a $k_{\text{eff}}$ near the safe subcritical limit in WHC-SD-FF-CSER-004 (Rev. 1). However, large scale flooding of the ISA is not considered credible in the hazard analysis discussed in Section D6.3.2.

Other flooded configurations were analyzed in the CSERs. Some of these configurations resulted in $k_{\text{eff}}$ greater than the safe subcritical limit of 0.95. The highest $k_{\text{eff}}$ found in the analysis occurred for a tipped, flooded ISC loaded with seven DFAs that have experienced complete failure due to hot-cell rot. The $k_{\text{eff}}$ for this configuration was found to be 1.13. Additional criticality controls for flooded configurations for which $k_{\text{eff}} > 0.95$ are not necessary, as these conditions are not considered credible by the hazard evaluation.

D6.3.3.2 NRF TRIGA Fuel.

**D6.3.3.2.1 Analysis Models.** The $k_{\text{eff}}$ of normal and accident conditions for TRIGA fuel stored in the NRF TRIGA casks has been analyzed in the CSERs prepared for the handling and storage of TRIGA fuel (WHC-SD-TP-SARP-008, WHC-SD-FF-CSER-006, and WHC-SD-SQA-CSA-30006). The models used in these documents are summarized below.

Safety Analysis Report for Packaging (Onsite) NRF TRIGA Packaging

WHC-SD-TP-SARP-008 contains the analysis of infinite planar arrays of TRIGA casks to show the casks meet the criticality requirements for transportation from the 300 Area to the 400 Area ISA at FFTF. As such, the explicit geometry and material of the Rad-Vault are not
modeled. However, the infinite planar array of close-packed casks analyzed can be taken to represent an upper bound on casks in the Rad-Vault, which will be in a less reactive geometry.

The calculational model for MCNP included all components of a TRIGA cask loaded with 18 fuel elements. The cladding, fuel basket, inner container, and cask inner and outer shell with lead shielding were explicitly modeled. Normal fuel geometries inside dry cask arrays were analyzed with and without water occupying the interstitial space between the casks. The normal fuel geometry cases with no water occupying the space between casks represents an upper bound on the Rad-Vault configuration, since there will only be six fully fueled casks in the Rad-Vault, and the cask space will be larger than the arrays analyzed here.

In addition, abnormal fuel conditions were analyzed by removing the fuel cladding and stainless steel fuel baskets from the model. The fuel pitch inside the inner container was then varied to determine the worst-case geometry for the abnormal configuration (the geometry of the fuel elements themselves remained intact). The abnormal configurations were analyzed with or without water inside the casks or occupying the interstitial area between the infinite planar array of casks. A single case was analyzed with a homogeneous distribution of fuel and water within the region of the inner container.

The MCNP criticality computer code was used to perform the $k_{eff}$ analysis for the infinite cask arrays. Uncertainty in the $k_{eff}$ values for normal fuel geometry cases was estimated by combining the statistical uncertainty reported by MCNP with rough estimates for the error in cross-section, physical modeling, and dimensional tolerances. For normal configurations, this uncertainty in $k_{eff}$ was determined to be 0.0036, which represents the statistical uncertainty in the Monte Carlo analysis (Breimeister 1993). For the abnormal cases, a configuration error was combined with the other error factors to account for the possibility that the limited parametric study performed on the fuel geometry and water density variations did not obtain the worst-case configuration. The overall uncertainty for abnormal cases was determined to be 0.0057. MCNP has been validated against experimental benchmarks by the code development group at Los Alamos National Laboratory (Whalen. et al. 1991). The validation experiments included critical assemblies for low-enriched uranium systems, graphite and water-reflected systems, fast neutron systems (Godiva and Jezebel assemblies), and interactive (array) units. The code showed agreement to the experimental $k_{eff}$ values within 1% for all benchmarks.

Criticality Safety Evaluation Report for TRIGA Fuel Storage at 400 Area Interim Storage Area

WHC-SD-FF-CSER-006, Criticality Safety Evaluation Report for TRIGA Fuel Storage at 400 Area Interim Storage Area, provides analysis of the abnormal fuel configuration resulting from the fall of a large crane onto the Rad-Vault.

The TRIGA cask safety analysis report for packaging (WHC-SD-TP-SARP-008) determined that the cask structural integrity would be maintained in the worst-credible drop or vehicle collision accident. However, it was postulated that a large crane falling onto the
Rad-Vault could result in catastrophic structural failure of the vault and TRIGA casks, rearranging the fuel into a more reactive geometry than normal. With no geometry control, there is sufficient fuel in the Rad-Vault to go critical under idealized conditions.

The neutron transport code, WIMS-E, was used to parametrically vary the spacing of both the aluminum-clad and the stainless steel-clad TRIGA fuel elements in water. These heterogeneous lattice calculations were performed using the British Atomic Energy Authority 69-group nuclear cross-section library. Once the transport calculations were complete, WIMS-E used the 69-group radial flux solution to collapse cross-sections to a two-group set for the smeared lattice cell. The GOLF computer code then used these two-group cross-sections and performed neutron diffusion calculations to find the finite spherical and hemispherical radii required for $k_{eff} = 0.95$, given full water reflection.

The GOLF code has been validated for calculating critical dimensions for idealized geometries (such as spherical and hemispherical), when using nuclear cross-sections obtained from the WIMS-E lattice code. These validations are described in various sources, such as for uranium metal billets, N Reactor Mark IA critical experiments, lattices of uranium metal rods in water with various enrichments and rod sizes (including boron poisoned water lattices), and uranium and plutonium nitrate solutions. For the Mark IA critical experiments, WIMS-E and GOLF were used to predict the critical radius of the two-tier cylindrical arrangement that was measured to be critical. The critical prediction was slightly conservative (i.e., the predicted cylinder radius was less than what was measured as critical). The MCNP computer code was used to predict the $k_{eff}$ of the WIMS-E/GOLF prediction ($k_{eff} = 0.99203 \pm 0.0017$). This establishes a WIMS-E/GOLF bias of 0.008, which was added to the calculated results for $k_{eff}$ and then reported in Table D6-5. Statistical uncertainties in the WIMS-E/GOLF results were not reported in the analysis. Independent verification has been performed for WIMS-E/GOLF critical mass predictions using both the MCNP and MONK5 Monte Carlo computer codes (Schwinkendorf 1990; WHC-SD-NR-CSER-007, Appendices A and B; WHC-IP-0840-FMEF).

The analysis assumed a worst-case random geometry of fuel occurred as a result of the accident. The most reactive geometry that could credibly occur is a hemispherical pile of homogeneously distributed fuel and cladding. This geometry was analyzed with and without material from the casks and fuel baskets. Varying degrees of moderation in the rubble pile were also analyzed.

Criticality Safety Evaluation Report 95-012: Transfer of TRIGA Fuel from 308 Building Reactor Pool to Storage Casks

WHC-SD-SQA-CSA-30006, Criticality Safety Evaluation Report 95-012: Transfer of TRIGA Fuel from 308 Building Reactor Pool to Storage Casks, contains analysis of the $k_{eff}$ of normal and hazardous conditions that may be encountered during transfer operations from the TRIGA reactor pool into TRIGA casks. The analysis is directed at the transfer operations and does not explicitly consider hazards associated with long-term storage of the fuel. Geometric configurations with the Rad-Vault are not directly analyzed. However, the case analyzed for a
close-packed array of seven normally loaded casks can be taken as an upper bound on the $k_{\text{eff}}$ of the actual Rad-Vault configuration. The cask array was modeled as a normally configured, dry cask with 18 aluminum clad or stainless steel clad fuel elements inserted in the aluminum fuel basket.

The MONK6B computer code was used to perform the $k_{\text{eff}}$ analysis for the cask array. The documentation for the code includes results of validation calculations for several critical uranium-enriched systems. The benchmark experiments were performed on highly enriched systems or low-enriched systems, as opposed to the 20% enriched TRIGA fuel. WHC-SD-SQA-CSA-30006 judged the validity of the code for TRIGA fuel based on the benchmark results for highly and low-enriched critical experiments. The results of the validation calculations show a consistent positive bias in $k_{\text{eff}}$ for the MONK6B calculations. This positive bias was not included in the reported values for $k_{\text{eff}}$ in Table D6-5. Statistical uncertainties at the 2σ level were added to the calculated values of $k_{\text{eff}}$ and the result was reported in Table D6-5.

D6.3.3.2.2 Analysis Results. Analysis results for $k_{eff}$ of the TRIGA casks are summarized in Table D6-5. The table contains entries for all cask configurations and all combinations of hazardous conditions identified as credible in the hazard evaluation. In addition, some cask configurations that were considered not credible by the hazard evaluation are also presented for information, since they were analyzed in the CSERs.

Normal Conditions

Normal conditions for the TRIGA casks consist of six TRIGA casks loaded with up to 18 intact dry fuel assemblies. Normal configuration analyses were performed for arrays of close-packed casks or an infinite lattice of close-packed casks. This geometry provides an upper bound on $k_{eff}$, since the actual geometry in the Rad-Vault includes extra spacing and absorber material due to the DOT-6M casks and the empty 55-gal. drum inside the vault. Inclusion of the DOT-6M casks would lower the $k_{eff}$ compared to the analyzed geometries.

Analysis in WHC-SD-SQA-CSA-30006 found that the upper bound on $k_{eff}$ for an array of seven normally loaded casks was 0.5818. The analysis shows that all normal conditions for casks loaded in the Rad-Vault have an upper bound on $k_{eff}$ (including bias and uncertainty at the 95% confidence level), which is well below the safe subcritical limit of 0.95.

Abnormal Conditions

Hazardous conditions resulting from a single credible but unlikely hazardous event for the TRIGA fuel are represented by the following:

- Flooded configurations.
- Tipped/dropped configurations with fuel rubble in abnormal geometries due to fuel pin failure.
- Crushed configurations with fuel and/or cask rubble in abnormal geometries due to catastrophic failure of the Rad-Vault and casks.

Various combinations of these hazardous events were analyzed.

Note: Misloaded casks are not possible as there are no loading restrictions on the type of fuel elements loaded into the casks, and the fuel basket is to be fully loaded with the maximum number of elements.

Single-Contingency Hazardous Conditions

Single-contingency configurations are defined as those due to a single unlikely hazardous event.
Flooded Casks – The worst-case flooded cask condition analyzed in the CSERs was found to have an upper bound on $k_{\text{eff}}$ of 0.7564, including bias and uncertainty at the 95% confidence level. The configuration analyzed in WHC-SD-SQA-CSA-30006 was a seven-cask array of fully loaded casks surrounded by water. Only the central cask in the array was flooded, with the outer six casks dry inside, which does not represent the worst-case flooding configuration. However, $k_{\text{eff}}$ for a configuration with all seven casks flooded is bounded by the flooded and tipped configuration discussed below, which assumed an infinite planar array of casks and neglected fuel cladding and fuel basket stainless steel. The $k_{\text{eff}}$ for the worst-case tipped and flooded hazardous configuration was found to fall below the safely subcritical limit, and, therefore, all configurations with flooding alone will be safely subcritical.

Tipped/Dropped Casks – The worst-case cask configuration resulting from fuel damage due to cask tipping or dropping was analyzed in WHC-SD-TP-SARP-008. The configuration analyzed was an infinite planar array of dry casks fully loaded with fuel pins. Cladding and fuel basket materials were neglected to represent the effects of fuel damage. The upper bound on $k_{\text{eff}}$ for this configuration was found to be 0.799, which falls below the safe subcritical limit of 0.95.

Crushed Casks – The worst-case crushed cask configuration found in Table D6-5 gave a $k_{\text{eff}}$ of 0.858. The configuration analyzed in WHC-SD-FF-CSER-006 was an infinite planar array of optimally moderated, close-packed, intact fuel rods. The stainless steel of the inner canister was co-mingled with the fuel. This infinite planar array configuration provides an upper bound on the $k_{\text{eff}}$ of actual configurations that might result from the crushing of the Rad-Vault and dispersal of its contents. Separation of the inner canister stainless steel was not considered credible, but was analyzed in the CSER and is discussed below. This idealized debris configuration indicates that actual configurations resulting from crushing of the Rad-Vault will have a $k_{\text{eff}}$ below the safe subcritical limit of 0.95.

Other Credible Hazardous Conditions

Tipped/Dropped and Flooded Casks – The worst-case cask configuration resulting from a flooded Rad-Vault and casks with fuel damage due to tipping or dropping was analyzed in WHC-SD-TP-SARP-008. The configuration analyzed was a flooded infinite planar array of internally flooded casks fully loaded with fuel pins. Cladding and fuel basket materials were neglected to represent the effects of fuel damage. The upper bound on $k_{\text{eff}}$ for this configuration was found to be 0.939, which falls below the safe subcritical limit of 0.95.

Crushed and Flooded Casks – The hazardous configuration resulting from a combination of crushed and flooded casks is bounded by the analysis for crushed casks (discussed previously) since that analysis already assumed optimal moderation in the debris pile.
Incredible Hazardous Conditions

The most reactive abnormal condition analyzed was a hemispherical pile of fuel rubble resulting from a crane falling onto the Rad-Vault. The results of the analysis in WHC-SD-FF-CSER-006 showed that it is theoretically possible to exceed $k_{\text{eff}} = 0.95$ under optimal conditions of geometry and moderation within the rubble pile. This assumes that all absorbing material in the cask and Rad-Vault debris is somehow preferentially separated from the fuel—an event that is considered extremely unlikely. WHC-SD-FF-CSER-006 also showed that if the steel inner-liner in the cask is included in the rubble pile, the $k_{\text{eff}}$ for an infinite planar array of TRIGA fuel is $< 0.85$. The worst-case scenario consisting of a crane failure, an optimal geometry of the fuel rubble, and separation of absorbing material from the cask is not considered credible. Further engineered or administrative controls to reduce the likelihood of this criticality event are not required.

D6.3.3.3 Commercial Light Water Reactor Fuel.

D6.3.3.3.1 Analysis Models. The $k_{\text{eff}}$ of normal and accident conditions for storage of commercial LWR fuel in NAC-1 casks has been analyzed in the CSERs prepared for the handling and storage of LWR spent fuel (SNF-4875, HNF-4832). The models used in these documents are summarized in the subsections that follow.

Criticality Evaluation for Long-Term Storage of Light Water Reactor Fuel in NAC-1 Casks

SNF-4875, Criticality Evaluation for Long Term Storage of Light Water Reactor Fuel in NAC-1 Casks, contains analysis of the $k_{\text{eff}}$ of NAC-1 casks loaded with PWR assemblies. Most of the materials and geometry of the NAC-1 casks loaded with PWR fuel assemblies from Calvert Cliffs and Point Beach were explicitly modeled in the analysis. The model included the cask inner liner, lead shielding, outer liner, steel lid and cask bottom, and neutron shield tanks. The cask lid and bottom thickness differed slightly from the as-built configuration. This dimension will not affect the $k_{\text{eff}}$ calculations, since the cask is nearly an infinite system in the axial direction, and end effects are negligible. The inner canister was modeled with the design thickness, but the steel in the inner canister ribs and the structural supports for the fuel assembly were neglected. The model did not take credit for the extra steel and spacing between casks provided by the International Standards Organization (ISO) containers, in which each cask will be stored. The fuel was modeled with the following input assumptions:

- Unirradiated fuel was modeled; no credit was taken for burnup.
- The zircaloy cladding was neglected.
- Enrichment for all pins in the model was taken as the highest actual value for any single pin in the assembly.
The casks containing the Point Beach assemblies have a maximum of 179 pins, with 3.2 wt% enrichment.

The cask containing the Calvert Cliffs full assembly has a maximum of 176 pins, with 2.72 wt% enrichment.

The cask containing the Calvert Cliffs partial assembly has a maximum of 144 pins, with 2.73 wt% enrichment.

To determine an upper bound on six normal cask configurations, an infinite planar array of close-packed casks with dry inner containers and undamaged fuel was calculated using KENO-Va. Moderation in the neutron shield tanks and in the interstitial region between the casks was varied using XSDRN, with an infinite 3-dimensional array, to determine the most reactive configuration. This configuration was then analyzed with KENO-Va to determine the upper bound on $k_{\text{eff}}$ for the planar array.

The accident condition analyzed for the casks was a flooding scenario. As discussed in Section D6.3.2, hot-cell rot and fuel rearrangement due to tipping or collisions was not considered credible for the NAC-I casks. Also, vertically stacked arrays were not considered credible. To determine the most reactive flooded configuration, the XSDRN code was used to analyze a single cask flooded internally and surrounded by water reflection. The number of pins in the cask was varied from the maximum of 196 to determine the optimal number. For a given number of pins, the pin pitch was chosen such that the square array filled the entire assembly cross-section. Once the optimal pin number was determined, the KENO-Va code was used to calculate the upper bound on $k_{\text{eff}}$ (including bias and uncertainty) of the most reactive configuration. KENO-Va and not XSDRN was used for the final reported $k_{\text{eff}}$ since KENO-Va has been benchmarked to critical experiments, as discussed below. The optimal configuration for each fuel type was then used to analyze an infinite 3-dimensional array of close-packed casks with XSDRN, as for the dry case. Water density between the casks was varied to determine the most reactive configuration. The most reactive configuration was then analyzed with KENO-Va to determine the upper bound on $k_{\text{eff}}$.

The SCALE 4.2 system of codes was used to model the fuel assemblies in the casks. The NITAWL and XSDRN codes were used to generate a cell-weighted cross-section, and the KENO-Va code was used to model the cask geometry and predict $k_{\text{eff}}$. XSDRN was also used to perform scoping calculations to determine the optimal geometric configuration of the fuel in the flooded cask arrays to determine the optimal moderation between casks in the dry array calculations. XSDRN and not KENO-Va was used for the parametric variations since it is a deterministic code that does not exhibit random variations in $k_{\text{eff}}$, which could mask small changes in $k_{\text{eff}}$ over the parametric variations.
Uncertainty due to dimensional tolerances and statistical uncertainty were included in the final $k_{\text{eff}}$ values reported in Table D6-6 for the KENO-Va calculations. Dimensional uncertainties were included using a one-sided tolerance limit factor, as outlined in "A Systematic Approach to Establishing Criticality Biases" (Larson 1995). For example, the uncertainty in the fuel pellet enrichment, density, and diameter was added to the values reported in Chapter D2.0, which represents an increase in the amount of fissile material to account for uncertainty in input parameters for the fuel. In the single cask calculations, the neutron reflection from the cask structure was increased by adding the dimensional tolerances to the thickness of the lead shielding. On the other hand, the infinite planar array calculations subtracted the dimensional tolerances from the cask dimensions to maximize interaction between the casks.

Code bias in the KENO-Va calculations were also included in the $k_{\text{eff}}$ values reported in Table D6-6 for the flooded arrays. Bias was not included in the dry array calculations. Since the $k_{\text{eff}}$ values are so far below critical for the dry arrays, extrapolation of code bias from critical benchmark experiments would not be justified and is not necessary to ensure that $k_{\text{eff}} < 0.95$.

NAC = Nuclear Assurance Corporation.
PWR = pressurized water reactor.
To validate the KENO calculations, critical benchmark experiments were chosen that used UO₂ fuel pins with enrichments bounding those for the LWR fuel pins loaded in the NAC-1 casks. From the comparison of KENO-Va results to the benchmark experiments, the code bias in $k_{\text{eff}}$ was determined to be 0.004, with a standard deviation of 0.007. This bias was included in the upper bound $k_{\text{eff}}$ values in Table D6-6. Also, use of the XSDRN code for determining the most reactive configurations was validated by direct comparison to KENO-Va for optimization of the Point Beach fuel, single cask analysis. Both codes indicated that the 179 pin configuration was the most reactive.

NFS-4/NAC-1 Spent Fuel Shipping Cask Criticality Safety Evaluation Report

HNF-4832, CSER 99-004: NFS-4/NAC-1 Spent Fuel Shipping Cask Criticality Safety Evaluation Report, analyzes the $k_{\text{eff}}$ of a NAC-1 cask loaded with loose fuel pins from the 324 Building B-Cell Safety Cleanout Project. 118 loose fuel pins are to be loaded into a stainless steel pipe intended to restrict the pin spacing for the purpose of criticality safety. To ease the loading of the inner pipe containing the pins, the pipe will be cut lengthwise into two half cylinders. After loading, a steel plate will be welded over each half cylinder and the two half cylinders will be secured together for insertion into the NAC-1 cask. The $k_{\text{eff}}$ analysis assumed that the inner pipe containing the fuel pins has a circular cross-section and the steel plate welded to the half cylinders was neglected giving a more reactive configuration in the model than in the actual design.

The materials of the NAC-1 cask were explicitly modeled, including the inner cylinder of stainless steel, the lead shielding, the outer stainless steel of the neutron shield tanks, and the top and bottom of the casks. The fuel was modeled with the following assumptions:

- Unirradiated fuel was modeled; no credit was taken for burnup
- Loading of the cask is limited to 17 PWR pins with enrichment $< 3.04\%$
- Loading of the cask is limited to 101 BWR pins with enrichment $< 2.93\%$
- The zircaloy cladding was included in the model.

The $k_{\text{eff}}$ analysis considered a normal dry cask configuration with the inner pipe containing close-packed, dry fuel pins. Water reflection around the cask was assumed. The analysis also considered abnormal flooded conditions with water inside the cask and inner pipe. In addition, abnormal configurations were analyzed for a flooded cask without the inner pipe constraining the fuel. In these cases, fuel pitch within the inner cask region was varied to determine the optimal $k_{\text{eff}}$. The abnormal cases with no inner pipe were included to examine whether or not the inner pipe constraining the fuel geometry was required to fulfill double contingency for a flooded cask (flooding being the first contingency).

The MCNP computer code was used to determine $k_{\text{eff}}$. A series of benchmark experiments for low-enriched uranium systems was used to determine that the bias in $k_{\text{eff}}$ for this analysis was 0.004. A standard value of 0.005 was used for the standard deviation in $k_{\text{eff}}$ due to input uncertainties (e.g., dimensional tolerances, enrichment error, etc.). These uncertainties
were combined with the statistical error in the Monte Carlo population to determine an error in the calculated $k_{\text{eff}}$ of 0.011, including bias and uncertainty at the 95% confidence level. This value was added to all calculated values of $k_{\text{eff}}$ and the total was reported in Table D6-6.

**D6.3.3.3.2 Analysis Results.** Analysis results for $k_{\text{eff}}$ of the NAC-1 casks are summarized in Table D6-6. The table contains entries for all cask configurations and all credible hazardous conditions.

**Normal Conditions**

Normal conditions for the NAC-1 casks consist of five casks with dry intact fuel in ISO containers stored side-by-side on the ISA pad. The most reactive configuration for dry cask arrays was found to have $k_{\text{eff}} = 0.25966$ for the Calvert Cliffs partial assembly in an infinite planar array. From the parametric study of optimal moderation, a completely dry array was found to be most reactive. This result represents an upper bound on $k_{\text{eff}}$ for the actual NAC-1 cask array with three Calvert Cliffs assemblies, two Point Beach assemblies, and one cask loaded with odd pins. The normal configuration for the NAC-1 casks has a $k_{\text{eff}}$ well below the safe subcritical limit of 0.95.

**Abnormal Conditions**

The only unlikely but credible hazardous event for the NAC-1 casks is flooding, which is presented below as a single unlikely contingency event.

**Single-Contingency Hazardous Conditions**

**Flooding** – From Table D6-6, the most reactive flooded configuration of NAC-1 casks was found to be an infinite planar array of Calvert Cliffs partial assemblies that resulted in $k_{\text{eff}} = 0.948$, including bias and uncertainty at the 95% confidence level. This array represents an upper bound on the $k_{\text{eff}}$ of the actual NAC-1 cask configuration. Thus, the $k_{\text{eff}}$ of all credible single-contingency hazardous configurations for the NAC-1 casks falls below the safe subcritical limit of 0.95.

**Other Credible Hazardous Conditions**

For the loose fuel pins, a flooded cask with no inner pipe constraining the geometry of the fuel resulted in an upper bound on $k_{\text{eff}}$ of 0.976. This credible hazardous condition exceeds the safe subcritical limit of 0.95. To control this hazard, all fuel must be constrained within a cylindrical geometry with a diameter no greater than 10.9 in. within the cask, and the component(s) or structure providing this constraint must be qualified to maintain its structural integrity to the same degree as the casks. With fuel in the inner pipe (rod container), the maximum $k_{\text{eff}}$ for the system is 0.630, well below the safe subcritical limit of 0.95. This control is discussed further in Section D6.4 and Chapter D4.0.
D6.4 CRITICALITY CONTROLS

D6.4.1 Engineered Controls

D6.4.1.1 Fast Flux Test Facility Fuel. The geometry of the CCC was assumed to be intact in the criticality hazard analyses. Thus, no \( k_{\text{eff}} \) analyses were performed for double batching (the CCC geometry is assumed to prevent this hazard) or rearrangements of the CCC tubes due to structural failure. To protect the assumptions in Section D6.3.3 for the \( k_{\text{eff}} \) analysis of hazardous conditions, the ISC and the CCC are designated as system geometry controls that must be designed to maintain structural integrity for all design basis accidents (e.g., dropping, collision, etc.), including the seismic event. The design classification of the CCC and ISC structures and their detailed design requirements are discussed in Chapter D4.0.

D6.4.1.2 Commercial Light Water Reactor Fuel. From the results of the analysis in HNF-1832, the geometry constraint of the inner pipe containing the loose fuel pins is required in order to provide double-contingency protection against criticality due to flooding of the cask. Therefore, the inner pipe is a safety-class component that must be designed and structurally qualified to the same quality level as the cask. The design classification of the inner pipe containing the fuel and its detailed design requirements are discussed in Chapter D4.0.

The square lattice geometry of the fuel assemblies was assumed to be intact by the analysis in SNF-4875. Thus, no \( k_{\text{eff}} \) analyses were performed for fuel rubble or rearrangements of fuel within the inner canister due to structural failure. To protect the assumptions in Section D6.3.3 for the \( k_{\text{eff}} \) analysis of hazardous conditions, the NAC-1 cask, inner container, and fuel assembly are designated as system geometry controls that must be designed and maintained to ensure structural integrity for all design basis accidents (e.g., dropping, collision, etc.), including the seismic event. The design classification of the cask and fuel assembly structures and their detailed design requirements are discussed in Chapter D4.0.

D6.4.2 Administrative Controls

D6.4.2.1 Fast Flux Test Facility Fuel. The Identi-69 analysis presented in WHC-SD-FV792-DA-004 makes assumptions regarding the fuel form and enrichment that are protected by administrative controls to ensure that all ISC configurations remain within the analyzed envelope. Specifically, ISCs containing fuel pins having \( >29.28 \) wt\% Pu or any other experimental pins not analyzed in Section D6.3.3 cannot be accepted at the ISA without further analysis.

The criticality analysis for metal fuel assemblies in WHC-SD-FF-CSER-004 (Rev. 1-B) did not systematically analyze mixtures of Identi-69 containers with metal assemblies in a CCC. Also, the CSER did not analyze certain misloaded ISCs containing metal assemblies structurally compromised by hot-cell rot. To ensure that configurations not analyzed by the CSER cannot
exist at the ISA, acceptance of ISCs containing metal assemblies is prohibited by an administrative control until further analysis has been performed on metal assemblies with hot-cell rot and with mixtures of Ident-69 containers and metal assemblies.

The criticality analysis in WHC-SD-FF-CSER-004 (Rev. 1-A) for repackaged fuel material and experimental pins assumed that not more than 4 kg of repackaged fuel and pins were contained in the spent fuel container loaded in a modified Ident-69 container. Also, as discussed in Section D6.3.3, the analysis considered only experimental pins that have been classified as MOX fuel, with not more than 31 wt% Pu enrichment. To ensure that the existing analyses envelope all ISC configurations, these assumptions are protected by administrative controls. Specifically, the following ISC configurations cannot be accepted at the ISA without further analysis:

- ISCs containing a modified Ident-69 with more than 4 kg of repackaged fuel material and experimental pins.
- ISCs containing repackaged fuel material and experimental pins that are not packaged in stainless steel tubes packed within a spent fuel container inside a modified Ident-69, as described in Section D6.3.2.
- ISCs with experimental fuel not classified as MOX or having greater than 31 wt% Pu.
- ISCs containing fuel pieces that may be mounted in moderating material (e.g., plastic).

The criticality analysis results in Section D6.3.3 indicate that a failure of administrative controls at FFTF, resulting in any other type (i.e., other than misloading a modified Ident-69 with experimental fuel and repackaged fuel, or misloading of an ISC with metal assemblies as described previously) of misloaded ISC that is transferred to the ISA, will not create a criticality concern at the ISA. All other credible accident scenarios associated with misloading at FFTF were shown to be safely subcritical and satisfy the double-contingency principle, without the requirement for additional administrative controls on cask receipt at the ISA.

**D6.4.2.2 Commercial Light Water Reactor Fuel.** The criticality analysis for loose fuel pins showed that it is necessary to load the fuel into the inner pipe geometry for double-contingency protection against flooding. Therefore, a NAC-1 cask with loose fuel pins cannot be accepted at the 200 Area ISA unless the pins are loaded with an inner pipe configuration, as described in Chapter D2.0.
D6.4.3 Application of Double Contingency

A general discussion regarding how the double-contingency principle is applied is provided in Section 6.4.3 of the SNF Project FSAR.

D6.4.3.1 Fast Flux Test Facility Fuel. Table D6-4 shows the largest $k_{eff}$ found in the analysis for normal cask configurations was 0.45 for five metal fuel assemblies and two DFAs in the CCC. Thus, all normal cask configurations have an upper bound $k_{eff}$ well below the safe subcritical limit of 0.95.

For those hazardous configurations that result from, at most, a single unlikely contingency event (i.e., abnormal conditions that do not satisfy double contingency, such as misloading of a dry cask, etc.), the maximum $k_{eff}$ is found to be 0.9494 for a CCC loaded with seven DFAs that have experienced complete failure due to hot-cell rot. Thus, all abnormal cask configurations that do not result from two or more unlikely, independent events have an upper bound $k_{eff}$ below the safe subcritical limit of 0.95.

Some of the hazardous configurations in Table D6-4 that result from two or more unlikely contingency events have an upper bound on $k_{eff}$ that exceeds the safe subcritical limit of 0.95. Notably, the hazardous configuration with a flooded and tipped CCC loaded with seven DFAs that have failed due to hot-cell rot was found to have a $k_{eff}$ upper bound of 1.155. Not all hazardous configurations resulting from two or more unlikely events were analyzed in the CSERs, so there may be other conceivable hazardous configurations that have an even higher upper bound on $k_{eff}$, as calculated by the analysis scheme in the CSERs. Since these cases already satisfy the double-contingency principle, further controls to prevent criticality are not required in order to satisfy the double-contingency principle.

D6.4.3.2 NRF TRIGA Fuel. Table D6-5 shows the largest $k_{eff}$ found in the analysis for normal cask configurations was 0.5818 for stainless steel fuel assemblies in the Rad-Vault. Thus, all normal cask configurations have an upper bound $k_{eff}$ well below the safe subcritical limit of 0.95.

The maximum $k_{eff}$ for single-contingency hazardous events affecting the TRIGA casks was found to be 0.858 for the crushed Rad-Vault configuration represented by the infinite fuel assembly array analyzed in WHC-SD-FF-CSER-006. Thus, all abnormal Rad-Vault configurations that do not result from two or more unlikely, independent events have an upper bound $k_{eff}$ that is below the safe subcritical limit of 0.95.

One hazardous condition analyzed in WHC-SD-FF-CSER-006 resulting from two or more unlikely contingency events (e.g., crane failure, rubble formation in optimal geometry, and separation of fuel from the cask stainless steel) was found to have an upper bound on $k_{eff}$ exceeding the safe subcritical limit of 0.95. Since this case already satisfies the double-contingency principle, further controls to prevent criticality are not required in order to satisfy the double-contingency principle.
D6.4.3.3 Commercial Light Water Reactor Fuel. Table D6-6 shows that the largest $k_e$ found for normal cask configurations was 0.25966 for the Calvert Cliffs partial assembly. Thus, all normal NAC-I cask configurations have an upper bound $k_e$ well below the safe subcritical limit of 0.95.

The maximum $k_e$ for single-contingency hazardous events affecting the NAC-1 casks was found to be 0.948 for the flooded Calvert Cliffs partial assembly. Thus, all abnormal NAC-1 cask configurations that do not result from two or more unlikely, independent events have an upper bound $k_e$ that is below the safe subcritical limit of 0.95.

One double-contingent event analyzed in HNF-4832 (i.e., flooded cask with loose fuel pins not constrained by an inner pipe) was found to have an upper bound on $k_e$ exceeding the safe subcritical limit of 0.95. The pipe containing the fuel within the inner cask was designated as a geometry control to ensure that double contingency is satisfied for NAC-1 cask flooding events. With the pipe intact, $k_e$ was analyzed to be below the safe subcritical limit of 0.95.

D6.5 CRITICALITY PROTECTION PROGRAM

Section 6.5 of the SNF Project FSAR provides an overview of the organizational structure and interfaces and the technical and administrative practices of the criticality protection policy and programs that are being developed for the SNF Project operations.

D6.6 CRITICALITY INSTRUMENTATION

This section addresses the need for a criticality alarm system and a criticality detection system in the ISA. DOE Order 5480.24 references ANSI/ANS-8.3, Criticality Accident Alarm System, for requirements relating to nuclear criticality alarm systems. ANSI/ANS-8.3 states that neither a criticality alarm system or criticality detection system is required, where the probability of a criticality accident is determined to be less than $1 \times 10^{-6}$ per year. Interpretive guidance on the probability determination (Holten 1993) states: "The use of $10^{-6}$ does not necessarily mean that a PRA [probabilistic risk assessment] has to be performed. Reasonable grounds shall be presented on the basis of commonly accepted engineering judgement." Accordingly, the remaining discussion supports the judgement that no criticality alarm or detection systems are required in the ISA.

The hazard evaluation in Section D6.3.2 has identified credible hazardous conditions related to criticality at the ISA. The results of the criticality analyses (Section D6.3.3) show that with the engineered and administrative controls identified in Section D6.4.2, all credible hazardous conditions at the ISA are safely subcritical. Therefore, no criticality alarm system or criticality detection system is required at the ISA. The engineered and administrative controls in Section D6.4.2 are required to: (1) ensure that no unanalyzed hazardous configurations can exist
at the ISA, and (2) protect the NAC-1 casks from hazardous conditions resulting from flooding of the casks.

**D6.7 REFERENCES**

CHAPTER D7.0

RADIATION PROTECTION
This page intentionally left blank.
D7.0 RADIATION PROTECTION

D7.1 INTRODUCTION

The essential features of the radiation protection programs that provide for radiation exposure control, radiological monitoring, and radiological protection instrumentation at all Spent Nuclear Fuel (SNF) Project facilities are addressed in Chapter 7.0 of the SNF Project Final Safety Analysis Report (FSAR). Additional features of radiation protection specific to the 200 Area Interim Storage Area (ISA) are addressed in this Chapter D7.0. The primary function of the 200 Area ISA is to store non-defense reactor spent fuel housed in dry cask storage systems. The purpose of the 200 Area ISA is to consolidate the storage of three types of SNF at a new storage facility in the 200 Area. The fuel types are (1) Fast Flux Test Facility (FFTF) SNF, (2) Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA) SNF, and (3) 300 Area light water reactor (LWR) SNF. The main radiation protection features of the dry fuel storage systems include: (1) radiation shielding, (2) radioactive material confinement, and (3) minimizing external surface contamination.

A portion of the FFTF SNF is currently stored at the 400 Area ISA within a dry Interim Storage Cask (ISC). The NRF TRIGA SNF is also stored at the 400 Area ISA within a dry storage system consisting of either an NRF TRIGA cask or a U.S. Department of Transportation (DOT)-6M container that is housed within a right-circular cylinder concrete vault (Rad-Vault). These storage systems have been analyzed, reviewed, and approved by the U.S. Department of Energy for storage of these types of fuel at FFTF. The results, although performed for the 400 Area ISA, can be used to assess functional requirements for the storage systems at the 200 Area ISA. The LWR SNF dry storage systems consist of a Nuclear Assurance Corporation (NAC)-1 cask within an International Standards Organization (ISO) container. The LWR storage system is not presently used for SNF storage at FFTF but the system was previously analyzed with the intent to store the LWR fuel at the 400 Area ISA. The results of these analyzes provide information relative to the performance of the storage system that can be used to assess the functional requirements for the LWR SNF storage system at the 200 Area ISA.

The radiological protection features of these dry storage systems are sufficient to preclude on-site or off-site radiological doses in excess of the established requirements (10 CFR 72 and 10 CFR 835) and ALARA (as low as reasonably achievable) goals. This is true for normal storage, off-normal conditions, and accident conditions. No exposures to airborne radioactive material are expected.
D7.2 REQUIREMENTS

The requirements that form the basis for the radiation protection program are identified in Section 7.2 of the SNF Project FSAR.

D7.3 RADIATION PROTECTION PROGRAM AND ORGANIZATION

The SNF Project radiation protection program and its organization, including safety management policies and philosophies, are described in Section 7.3 of the SNF Project FSAR.

D7.4 ALARA POLICY AND PROGRAM

A discussion of the SNF Project ALARA policy and program is provided in Section 7.4 of the SNF Project FSAR. The SNF Project policy regarding ALARA principles during 200 Area ISA design and construction is described in HNF-SD-SNF-PMP-018, Site-Wide Spent Nuclear Fuel Project Management Plan.

Detailed descriptions of the FFTF SNF dry storage system (ISC) shielding configuration are contained in Chapter D4.0. Based on the radiological protection features of the ISC, design analysis results (General Atomics 1995) show that occupational exposure will be well below the ALARA requirements of 10 CFR 72, 10 CFR 835, and HSRCM-1, Hanford Site Radiological Control Manual. The maximum exposure rates allowed by the design are 200 mrem/h at contact on the bottom surface and <2.0 mrem/h for all other surface areas. This higher level for the bottom surface is acceptable because it is normally not accessible. ISC dose rate-shielding analysis calculates the highest accessible surface dose rate to be 1.99 mrem/h at the top of the cask and 99.3 mrem/h at the bottom closure.

A detailed description of the TRIGA/Rad-Vault dry storage system shielding configuration is provided in Chapter D4.0. Based on the radiological protection features of the TRIGA/Rad-Vault, design analysis results (WHC-SD-FF-TI-043) show the highest contact dose rate to be 0.76 mrem/h at the side of the concrete vault. The maximum exposure rate allowed by the design is <5.0 mrem/h at contact with the vault surface.

Detailed descriptions of the LWR SNF dry storage system shielding configuration are contained in Chapter D4.0. Based on the radiological protection features of the NAC-1 cask, design analysis results (HNF-3016) show that occupational exposure will be well below the ALARA requirements of 10 CFR 72, 10 CFR 835, and HSRCM-1. The NAC-1 dose rate-shielding analyses calculate the highest accessible surface dose to be <114 mrem/h. The maximum exposure rates allowed by the design are 200 mrem/h at contact on any surface or 10 mrem/h at 2 meters away from the external surface of the cask.
Routine and accidental releases to the public (off-site receptor) are calculated at the Site boundary shown in Figure D1-2. This is also the location of the controlled area boundary as the term is defined in 10 CFR 72.106. The shielding for all of the dry storage systems also meets the HSRCM-1 requirement for uncontrolled access by the public of <.05 mrem/h (at the ISA fence, see Figure D7-1).

Specific 200 Area ISA design features credited with reducing radiation exposure and achieving ALARA program objectives include the storage system shielding.

**D7.5 RADIOLOGICAL PROTECTION TRAINING**

SNF Project requirements and criteria for radiological protection training are described in Section 7.5 of the SNF Project FSAR.

**D7.6 RADIATION EXPOSURE CONTROL**

A description of SNF Project radiation exposure control measures is provided in Section 7.6 of the SNF Project FSAR. The SNF Project has elected to incorporate in the facility design the following U.S. Nuclear Regulatory Commission (NRC) requirements:

- Apply the radiological exposure criteria of 10 CFR 72.104, “Criteria for Radioactive Materials in Effluents and Direct Radiation from an Independent Spent Fuel Storage Installation or Monitored Retrievable Storage,” to the design and safety analyses.

- Apply the hourly dose limit of 10 CFR 20.1301, “Dose Limits for Individual Members of the Public,” to the design and safety analyses.

- Incorporate control devices in the facility design for access to high-radiation areas that conform to the requirements of 10 CFR 20.1601, “Control of Access to High Radiation Areas.”

For the 200 Area ISA, the radiological exposure annual dose criteria of 10 CFR 72.104 have been incorporated into the storage system designs and safety analysis. These criteria apply to design measures to protect any off-site public individual during normal operations and anticipated occurrences. These annual dose equivalent criteria are 25 mrem (0.25 mSv) to the whole body, 75 mrem (0.75 mSv) to the thyroid, and 25 mrem (0.25 mSv) to any other critical organ.

For the 200 Area ISA, the criteria for the hourly dose limit to the public, as described in 10 CFR 20.1301, have been incorporated into the design and safety analysis. This dose limit (0.002 rem) is assumed to be direct radiation from external sources (casks) for any unrestricted area during normal operations and anticipated occurrences.
During operation, access to the radiological area of the ISA (see Figure D7-1) is controlled using one or more of the methods listed and discussed in Section 7.6.2.6 of the SNF Project FSAR. The potential for the highest dose rates at the ISA occurs in the NAC-1 ISO containers. To avoid unnecessary and inadvertent doses to personnel, the doors to the ISO containers are provided with locks and security seals that can be used to control access. Primarily, access control will be by the use of signs and barricades and the locks on the ISA entry gates and the ISO container doors. Other measures, described in Section 7.6.2.6 of the SNF Project FSAR, will be used if needed.

D7.7 RADIOLOGICAL MONITORING

The radioactive material sampling and monitoring programs conducted within SNF Project facilities are addressed in Section 7.7 of the SNF Project FSAR.

D7.8 RADIOLOGICAL PROTECTION INSTRUMENTATION

A summary of the SNF Project plans and procedures governing radiation protection instrumentation is provided in Section 7.8 of the SNF Project FSAR. Only portable radiation protection instrumentation is used at the ISA.

D7.9 RADIOLOGICAL PROTECTION RECORD KEEPING

Radiological protection record-keeping requirements are described in Section 7.9 of the SNF Project FSAR.

D7.10 OCCUPATIONAL RADIATION EXPOSURES

For the 200 Area ISA, estimated radiation doses to on-site workers were calculated by assessing the operational procedures and planned activities that would result in occupational exposures. Using the estimated amount of time a worker would be near the storage system during handling, surveillance, and maintenance, the estimated occupational exposure to facility workers will be below the 500 mrem/yr administrative control level of HSRCM-1.

Annual surveillance of the ISCs will include visually inspecting the casks and performing a radiological survey in the immediate area of the ISC. Operational analysis indicates that these activities will involve one operator and two radiological control technicians (RCTs), and will require about one hour to complete. Using worst-case dose rates, occupational exposure calculations indicate an annual accumulated dose of approximately 320 mrem to all workers during the inspection of fifty-three casks.
Annual surveillance of the TRIGA casks and the DOT-6M containers will include removing the Rad-Vault lid, visually inspecting the casks and containers, performing a radiological survey, and replacing the lid. Operational analysis indicates that these activities will involve one operator, two RCTs, and support personnel, and will require about two hours to complete. Radiological dose rate calculations for the NRF TRIGA casks were performed using the ISOSHLD Code, conservatively based on 19 maximally exposed fuel elements with an assumed prior irradiation, and an assumed 6-year decay time. (The decay time assumed was from the last powered operation of the TRIGA reactor in May 1989.) Actual cask readings that are representative of the maximum dose rate expected have shown 35 mrem/h (versus 81 mrem/h calculated) on the top and 50 mrem/h (versus 92 mrem/h calculated) on the side. It would naturally follow that the dose at the container could also be expected to be lower than previously calculated. Using worst-case dose rates, occupational exposure calculations indicate an annual accumulated dose of approximately 210 mrem to all workers during inspection of the vault. The exposure to crane operators removing and replacing the lid of the vault would be negligible.

Annual surveillance of the NAC-1 cask will include opening the ISO container door, visually inspecting the cask, and performing a radiological survey. Operational analysis indicates that these activities will involve two operators and one RCT, and will require about two hours to complete. Using worst-case dose rates, occupational exposure calculations indicate an annual accumulated dose of approximately 600 mrem to all workers during inspection of the six casks.

The maximum anticipated exposure resulting from these surveillances and other activities involving lesser exposures is 1150 mrem/year. The majority of this exposure is received by the RCTs. Using an RCT staffing level of four individuals involved in these annual inspections, the average RCT dose per year is 288 mrem total effective dose equivalent, which is well below the 500 mrem (5 mSv) ALARA design goal. The exposure level of all other categories of workers is considerably below this RCT exposure level.

Handling of the ISCs is anticipated to include lifting fixture connection and removal, ISC movement, and installation of the environmental cover. Operational analysis indicates that these activities will involve one rigger and one RCT, and will require about one hour per ISC. These activities primarily require personnel to be near the top of the cask where the exposure is the highest. Using worst case dose rates, occupational exposure calculations indicate an accumulative dose of approximately 210 mrem to all workers during the handling of fifty-three casks.

Based on FFTF Rad-Vault loading experience, the estimated total personnel exposure time to load the Rad-Vault with two DOT-6M containers and six TRIGA casks is approximately 4 hrs. Operational analysis indicates that these activities will involve one operator and one RCT, and that the exposure levels experienced are similar to those involved with the Rad-Vault surveillance described above (i.e., each occurs with the Rad-Vault lid removed and with personnel above the open storage casks). Occupational exposure calculations indicate an accumulative dose of approximately 280 mrem to all workers during vault loading.
Handling of the NAC-1 casks is anticipated to primarily include inspection of the cask and ISO container after it is in place, since the connection and disconnection of the handling fixture is remotely operated. Operational analysis indicates that this activity will involve one operator and one RCT, and will take less than 15 minutes to complete. Using worst-case dose rates, occupational exposure calculations indicate an accumulative dose of approximately 300 mrem to all workers during handling of six casks.

The maximum anticipated exposure resulting from these handling and loading activities is 790 mrem/yr. Using a conservative staffing level of four individuals, the average worker dose per year is 197 mrem total effective dose equivalent, which is well below the 500 mrem (5 mSv) ALARA design goal. It is not anticipated that cask handling and vault loading will occur in the same year as system surveillances; therefore, only one of the anticipated annual exposures needs to be considered in evaluating compliance to the ALARA goal.

CHAPTER D8.0

HAZARDOUS MATERIAL PROTECTION
This page intentionally left blank.
D8.0 HAZARDOUS MATERIAL PROTECTION

D8.1 INTRODUCTION

The major provisions of the occupational safety and health program, as the program applies to hazardous material protection for the Spent Nuclear Fuel (SNF) Project, are addressed in Chapter 8.0 of the SNF Project Final Safety Analysis Report (FSAR).

D8.2 REQUIREMENTS

The requirements that form the basis for the hazardous material protection program are identified in Section 8.2 of the SNF Project FSAR.

D8.3 HAZARDOUS MATERIAL PROTECTION PROGRAM AND ORGANIZATION

The SNF Project has established a visible and comprehensive occupational safety and health program. This program is described in Section 8.3 of the SNF Project FSAR.

D8.4 ALARA POLICY AND PROGRAMS

While there is no established formal SNF Project as-low-as-reasonably-achievable (ALARA) program for nonradiological hazardous materials, the SNF Project has expanded the classic concept of ALARA (i.e., minimization of radiological exposures) to the application of exposure minimization for hazardous substances and conditions. The SNF Project’s policy is described in Section 8.4 of the SNF Project FSAR.

Work practices for hazardous material protection and control of chemical exposures, as stated in Section 8.4 of the SNF Project FSAR, will be implemented at the 200 Area Interim Storage Area (ISA) using approved SNF Project implementing procedures. The occupational safety and health program will use the additional provisions of Section 8.4 of the SNF Project FSAR. These provisions will also be implemented at the ISA using approved SNF Project implementing procedures.

Applicable ergonomics considerations based on DOE Order 5480.10, Contractor Industrial Hygiene Program (Section 9B), under the occupational safety and health program, industrial hygiene subprogram, are included in Chapter D13.0. Ergonomics considerations, along with risk factor control processes and the ergonomics program, are described in the SNF Project human engineering program plan (see Section 8.4 of the SNF Project FSAR and
SNF-4399). This document will be revised as necessary to address integration of this plan with HNF-MP-003, Integrated Environment, Safety and Health Management System Plan.

**D8.5 HAZARDOUS MATERIAL TRAINING**

Plans and procedures for training SNF Project workers regarding hazardous materials are summarized in Section 8.5 of the SNF Project FSAR.

Section 8.5 of the SNF Project FSAR states that SNF Project management provides training, professional education, and certification opportunities necessary to support, maintain, and enhance industrial hygiene staff proficiency to meet or exceed U.S. Department of Energy industrial hygiene training objectives and goals in accordance with the SNF Project Standards/Requirements Identification Document (HNF-SD-SNF-RD-001). ISA management is responsible for ensuring that workers assigned to any task involving hazardous materials are trained in the safety and health hazards associated with such hazardous materials. Workers will perform only those tasks for which they have received the proper training. If the ISA mission changes, ISA management will review the training requirements and modify them accordingly. ISA management is also responsible for ensuring that retraining is provided within the time allowed by training course requirements.

**D8.6 HAZARDOUS MATERIAL EXPOSURE CONTROL**

Worker safety features at the ISA are an integral part of facility design and operation. The ISA design encompasses human factors considerations to ensure that operations can be conducted safely. SNF Project occupational exposures to hazardous materials and the spread of hazardous material contamination are controlled by a combination of engineered, operational, and administrative controls, and by the use of personal protective clothing and equipment. These controls are described in Section 8.6 of the SNF Project FSAR.

Construction of the ISA has been performed to minimize the use of hazardous materials and the generation of hazardous and non-hazardous waste. No polychlorinated biphenyls or asbestos will be used. Transformers, lighting, and other electrical equipment that use an insulating oil will be polychlorinated biphenyl-free.

No significant hazardous materials have been identified for the ISA as a result of a hazard analysis that was performed and documented in SNF-4820, 200 Interim Storage Area Final Hazard Analysis Report, except for the radionuclide content in the dry cask storage systems. HNF-2524, 200 East Area Interim Storage Area Preliminary Safety Evaluation Report, states that these materials are primarily uranium oxide and mixed uranium and plutonium oxide, which are known to have toxicological effects. As stated in Section 3.1.1 of HNF-2524, the toxicological hazards of the radionuclide inventory were found to be bounded by the radiological consequences.
Small quantities of other hazardous material identified by the hazard identification process include pyrophoric metals and hydrides, oxidizers, hydrogen, diesel fuel, and other flammable or combustible materials. No routine chemical processes will be conducted in the ISA. Some chemicals, such as those used for equipment decontamination, may be used occasionally. Table D3-1 identifies hazards by form, type, location, and total quantity.

The FFTF SNF inventory includes a small amount of metallic sodium inside the sodium-bonded fuel pins. Purging and backfilling of pressure monitoring equipment will involve the use of an inert gas. In addition, some chemicals, such as those used for equipment decontamination, may be used occasionally.

An inert atmosphere (helium and argon) is maintained in storage containers for FFTF SNF. This inherently precludes a potential hazard of pyrophoric uranium or plutonium reacting with air (oxygen) that may have leaked in the SNF container. In addition, there is a potential for the sodium to react with air (oxygen). Potential for this event is low since only 8 of 329 FFTF items are metallic fuel; the remainder are not pyrophoric. In addition, the inert atmosphere will preclude reaction of air with either the metallic uranium or sodium. These eight items will be consolidated into two casks.

Major features of worker protection are presented in Table D3-4 and are categorized by hazard. These features are in addition to safety-class or safety-significant features for design basis accidents. No safety-significant structures, systems, and components or Technical Safety Requirements have been identified for the ISA based solely on worker safety considerations.

All work activities in the ISA will receive adequate advance planning so that if potential hazardous materials are identified due to changing conditions in the future, specific precautions will be applied. The exposure controls identified in Sections 8.6.1 through 8.6.4 of the SNF Project FSAR will then be implemented at the ISA using approved SNF Project implementing procedures.

Other hazardous materials at the ISA (maintenance materials) will be properly inventoried and stored to control hazards inherent to the material, in accordance with SNF Project implementing procedures.

**D8.7 HAZARDOUS MATERIAL MONITORING**

Summaries of the hazardous material sampling and monitoring programs that are conducted internally and externally for SNF Project facilities are provided in Section 8.7 of the SNF Project FSAR. The workplace and external monitoring program described in Sections 8.7.1 and 8.7.2 of the SNF Project FSAR will be implemented at the ISA, as appropriate, using approved SNF Project implementing procedures. An environmental, radioactivity, and chemical emissions monitoring program, including requirements, is presented in Section 8.7.2 of the

---

HNF-3553 REV 0
Annex D – 200 Area Interim Storage Area

---

January 2000
Surveillance and monitoring activities to ensure safe storage of SNF at the ISA are presented in Section D2.3.2. These activities include the following:

- Annual surveillance of the interim storage casks (ISC) – This surveillance involves a visual inspection, radiation survey and smear sampling about the ISC environmental cover.

- Annual surveillance of Training, Research and Isotope Production, General Atomics (TRIGA) fuels in U.S. Department of Transportation (DOT)-6M containers – This surveillance includes a visual inspection and radiation surveys of the Rad-Vault, visual inspection and radiation survey of the fuel cask, and smear sampling of the fuel casks.

- Annual surveillance of the Nuclear Assurance Corporation (NAC)-1 casks in International Standards Organization (ISO) containers – The surveillance includes a visual inspection and radiation survey of the ISO container external surface, radiation survey and smear samples of the top of NAC-1 casks, and visual inspection of the interior of the ISO container and exterior of the NAC-1 casks.

D8.8 HAZARDOUS MATERIAL PROTECTION INSTRUMENTATION

Summaries of plans and procedures governing hazardous protection instrumentation are provided in Section 8.8 and Table 8-2 of the SNF Project FSAR. As stated in Section 8.8 of the SNF Project FSAR, safety and health specialists will determine the need for hazardous protection instrumentation and the number and placement of instruments under normal and emergency conditions, in accordance with the requirements stated in Section 8.8 of the SNF Project FSAR.

D8.9 HAZARDOUS MATERIAL PROTECTION RECORD KEEPING

The SNF Project has an established document control and records management program. This program is summarized in Section 8.9 of the SNF Project FSAR.

D8.10 HAZARD COMMUNICATION PROGRAM

The hazard communication program applies to the purchase, receipt, transportation, use, and storage of hazardous chemicals and products. This program is summarized in Section 8.10 of the SNF Project FSAR. The hazard communication program for the ISA will be implemented in accordance with the provisions of Sections 8.10.1 through 8.10.6 of the SNF Project FSAR, including hazard posting in work areas, chemical management, chemical labeling, chemical
product list, material safety data sheets, information and training. This program will be accomplished in accordance with approved SNF Project implementing procedures.

**D8.11 OCCUPATIONAL CHEMICAL EXPOSURES**

Predicted annual exposures to workers from hazardous material sources are identified in Section 8.11 of the SNF Project FSAR. The identification of chemical hazard locations, posting, chemical management, and other controls to limit occupational chemical exposure is included in Section 8.10 of the SNF Project FSAR.

**D8.12 REFERENCES**

CHAPTER D9.0

RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT
This page intentionally left blank.
D9.0 RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT

D9.1 INTRODUCTION

The essential features of the radioactive and hazardous waste management programs that provide for the safe control, collection, and handling of wastes generated during routine operations at Spent Nuclear Fuel (SNF) Project facilities are detailed in Chapter 9.0 of the SNF Project Final Safety Analysis Report (FSAR). This Chapter D9.0 only applies to waste generated within the 200 Area Interim Storage Area (ISA) and those systems designed to deal with that waste. The 200 Area ISA will store SNF in dry cask storage systems. No uncontained radioactive materials will be handled. Spent fuel in shipping containers is received, unloaded, and stored at the 200 Area ISA. No chemical, toxicological, or hazardous materials will normally exist on-site except for the SNF within the storage systems. Confinement of the 200 Area ISA radioactive materials is a design feature of each dry spent fuel storage system.

D9.2 REQUIREMENTS

The requirements that form the basis for the radioactive and hazardous waste management program are found in Section 9.2 of the SNF Project FSAR.

D9.3 RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT PROGRAM AND ORGANIZATION

The facility administrative procedures for solid waste management contain the procedural guidance for the planning, generation, and disposal of generated waste in compliance with applicable requirements. The administrative procedures cover characterization, preplanning, designation, containerization, disposal, and programmatic requirements. A summary of the SNF Project waste management program is provided in Section 9.3 of the SNF Project FSAR.

D9.4 RADIOACTIVE AND HAZARDOUS WASTE STREAMS AND SOURCES

The only waste streams at the ISA are solid wastes; primarily light bulbs, vegetation and animal carcasses, and waste generated during contamination monitoring. The estimated volumes for these wastes are:

- Sodium light bulbs - < 1 L/yr (0.25 gal/yr) (recycled)
Miscellaneous solid waste (primarily rags, wipes, protective clothing, vegetation, and carcasses) - < 1 m³/yr (35 ft³/yr) (potentially radioactive).

In the unlikely event of a radioactive release, cleanup materials will be designated as low-level waste. Since the 200 Area ISA is not manned, no sanitary sewage is generated. The low-level waste will be packaged per the Waste Management Federal Services of Hanford, Incorporated waste acceptance requirements (WHC-EP-0063-5)—described in Section 16 of the SNF Project Standards/Requirements Identification Document (HNF-SD-SNF-RD-001) and in facility waste administrative procedures—and then transported to Waste Management Federal Services of Hanford for disposition. Sodium light bulbs will be delivered to the 400 Area consolidation area where they will be picked up by commercial treatment and disposal facility operators. Miscellaneous nonradioactive waste will be disposed of at an off-site waste disposal site.

CHAPTER D10.0

INITIAL TESTING, IN-SERVICE SURVEILLANCE, AND MAINTENANCE
This page intentionally left blank.
D10.0 INITIAL TESTING, IN-SERVICE SURVEILLANCE,
AND MAINTENANCE

D10.1 INTRODUCTION

Essential features of the initial testing program, operational readiness review, in-service surveillance program, and the maintenance program implemented at Spent Nuclear Fuel (SNF) Project facilities are described in Chapter 10.0 of the SNF Project Final Safety Analysis Report (FSAR). 200 Area Interim Storage Area (ISA)-specific features of these programs are described in this chapter.

D10.2 REQUIREMENTS

The requirements that form the basis for the initial testing, surveillance, and maintenance programs are found in Section 10.2 of the SNF Project FSAR. Specific requirements applicable to this chapter include the following:

- U.S. Department of Energy (DOE) O 430.1A, Life Cycle Asset Management
- DOE Order 4330.4B, Maintenance Management Program
- DOE Order 5480.19, Conduct of Operations Requirements for DOE Facilities.

D10.3 INITIAL TESTING

The SNF Project initial testing program ensures the operability of equipment and facilities before facility operation. Project details of this program are provided in Section 10.3 of the SNF Project FSAR. Due to the simple passive nature of the facility and its components, the 200 Area ISA initial testing program will consist entirely of construction acceptance testing. No special testing requirements prior to receipt of SNF have been identified for the 200 Area ISA systems and components.

D10.4 IN-SERVICE SURVEILLANCE PROGRAM

The SNF Project in-service surveillance program is designed to maintain the integrity of facility systems and to ensure that systems perform their function of protecting the health and safety of the public, workers, and facility staff by preventing or mitigating accident consequences. Details of this program are provided in Section 10.4 of the SNF Project FSAR. The Technical Safety Requirements described in Chapter D5.0 identify no safety surveillance requirements for the 200 Area ISA.
Periodic inspection of the interim storage casks (ISCs) is required to support analysis assumptions. This annual surveillance will include a visual inspection, radiation survey, and smear sampling about the ISC environmental cover.

Annual surveillance of the Training, Research and Isotope Production, General Atomics (TRIGA) cask and U.S. Department of Transportation (DOT)-6M containers will include (1) visual inspection and radiation survey of the Rad-Vault, (2) vault lid removal to allow visual inspection and radiation surveys of the fuel casks/containers, and (3) smear sampling of the fuel casks/containers. Since the Rad-Vault is constructed of concrete, an annual visual inspection of the underside is not required.

The seal integrity program for TRIGA fuel storage and related preventive maintenance and/or testing requirements shall be identified for TRIGA fuel containers prior to year 2015 to protect seal design life considerations.

Annual surveillance of the Nuclear Assurance Corporation (NAC)-1 casks in International Standards Organization (ISO) containers will include (1) a visual inspection of the external surface of the ISO container, (2) radiation surveys of the exterior surface of the ISO, (3) a radiation survey of the top of the NAC-1 casks upon opening the ISO container doors, (4) smear samples from the top of the NAC-1 casks, and (5) visual inspections of the interior of the ISO container and exteriors of the NAC-1 casks. The ISO has structural members constructed of ferrous materials, and an inspection of the underside is appropriate every 5 years (to maintain ISO certification).

D10.5 MAINTENANCE PROGRAM

The maintenance program for the SNF Project facilities is conducted in accordance with DOE Order 4330.4B, Maintenance Management Program, which provides the general policy and objectives for establishing cost-effective maintenance and repair programs for DOE property. The maintenance program will incorporate the results of considerable project and subsystem vendor interface activities aimed at ensuring an acceptable design and acceptable operating practices relative to reliability, availability, and maintainability.

Policies and procedures are in place to effectively manage SNF Project facility maintenance activities. Section 10.5 of the SNF Project FSAR summarizes the maintenance policies and procedures that are implemented at the 200 Area ISA. The 200 Area ISA facility components are classified as General Service. The dry cask systems have been designated Safety Significant. Due to the simple passive nature of the facility and its components, minimal maintenance activities have been identified by the SNF Project for this facility. Identified maintenance tasks include monitoring and maintaining the equipment for receipt of SNF storage systems. During long-term storage, maintenance tasks include painting of the storage cask systems, lamping, fence and gate inspections and repairs, and vegetation removal. The Viton
O-rings on the Neutron Radiography Facility (NRF) TRIGA cask have a 20-year design life (per vendor) and require evaluation prior to year 2015.

**D10.6 REFERENCES**

This page intentionally left blank.
CHAPTER D11.0

OPERATIONAL SAFETY
This page intentionally left blank.
**D11.0 OPERATIONAL SAFETY**

**D11.1 INTRODUCTION**

Features of the Spent Nuclear Fuel (SNF) Project conduct of operations and fire protection programs are described in the following sections and in Chapter 11.0 of the SNF Project Final Safety Analysis Report (FSAR).

**D11.2 REQUIREMENTS**

The requirements that establish the basis for conduct of operations and general aspects of operational safety are identified in Section 11.2 of the SNF Project FSAR. Specific requirements applicable to this chapter include the following:

- DOE Order 5480.7A, *Fire Protection*
- RLID 5480.7, *Fire Protection*

**D11.3 CONDUCT OF OPERATIONS**

"Conduct of operations" is a set of principles that establishes an overall philosophy for achieving excellence in the operation of the SNF Project facilities. SNF Project application of conduct of operations principles is described in Section 11.3 of the SNF Project FSAR.

**D11.4 FIRE PROTECTION**

The fundamental fire protection programs for SNF Project facilities are addressed in Section 11.4 of the SNF Project FSAR. The elements of the fire protection program that are specific to the 200 Area Interim Storage Area (ISA) are described in the following subsections. The results of a 200 Area ISA fire hazard analysis (FHA), documented in SNF-4932, *Fire Hazard Analysis for the 200 Area Interim Storage Area*, are addressed in Section D3.3. In addition, a FHA was performed for the proposed ISA storage building and the results are documented in HNF-4552, *Preliminary Fire Hazards Analysis for the 200 East Area Interim Storage Area Storage Building*. Results from these analyses are summarized in the following subsections.
D11.4.1 Fire Hazards

The FHAs (SNF-4932, HNF-4552) comprehensively assessed the risk from fire at the 200 Area ISA and storage building to determine that: (1) the potential for occurrence of fire is minimized, (2) a fire would not cause an on-site or off-site release of radiological and other hazardous materials that would threaten the public health and safety or the environment, (3) requirements are in place that will provide an acceptable degree of life safety to SNF Project and contractor workers, and (4) the safety systems are not damaged by fire.

SNF-4932 and HNF-4552 were prepared to meet the requirements of U.S. Department of Energy (DOE) Order 5480.7A and to evaluate compliance to DOE fire protection criteria. As required, this analysis addressed the following elements:

- Description of construction
- Protection of essential safety-class equipment
- Fire protection features
- Description of fire hazards
- Life safety considerations
- Critical process equipment
- High value property
- Damage potential; maximum credible fire loss and maximum possible fire loss
- Fire department or brigade response
- Recovery potential
- Potential for toxic, biological, and/or radiological incident due to a fire
- Emergency planning
- Security considerations related to fire protection
- Natural hazards (earthquake, flood, wind) impact on fire safety
- Exposure fire potential, including the potential for fire spread between fire areas.

Future changes to the FHAs will be screened to these elements to ensure that no unreviewed safety question is created.

The ISA facility FHA (SNF-4932) identifies no fire hazards inherent to the 200 Area ISA components, which include interim storage casks (ISCs), Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA) casks, U.S. Department of Transportation (DOT)-6M containers within a Chem-Nuclear Services, Incorporated Rad-Vault storage vault, and Nuclear Assurance Corporation (NAC)-I casks within International Standards Organization (ISO) containers. Potential fire hazards identified in the FHA include (1) vehicles and equipment required to move the cask storage systems (fuel truck precluded), and (2) combustible materials required during the cask storage system movement activities. Since no credible fire results in damage to the cask storage systems, the maximum possible fire loss (MPFL) is identified as the cost to inspect and evaluate the cask storage systems following exposure to fire. The MPFL value is $100,000. No release of radionuclides to the environment.
from the ISA facility is identified in the FHA, and no toxicological or biological consequences resulting from fire are anticipated. Additional information is provided in the FHA (SNF-4932).

The proposed ISA storage building will be used to store the excessed Fast Flux Test Facility (FFTF) solid waste transfer cask and ISA equipment (e.g., lifting devices, impact limiters, and the tractor-trailer unit). The ISA storage building FHA (SNF-4552) identifies two hazards associated with this building: (1) a fire starting in the tractor-trailer and spreading throughout the facility, and (2) a fire starting in stored combustibles and spreading throughout the facility. The MPFL is identified as the complete loss of the building, with the exception of the FFTF cask. The MPFL value is $3.4 million, including property and cleanup losses. The FFTF cask, which is a one-of-a-kind, high-value property, would have limited damage and could be reused following inspection and evaluation. No release of radionuclides to the environment from the ISA storage building is identified in the FHA as a result of the MPFL event because the cask internals are the only planned component to contain radioactive material. No toxicological or biological consequences resulting from fire are anticipated. Additional information is provided in the FHA (SNF-4552).

D11.4.2 Fire Protection Program and Organization

The fire protection program for SNF Project facilities is structured and implemented in accordance with the operating contractor's safety management policies, philosophies, and criteria described in Section 11.4.2 of the SNF Project FSAR. ISA-specific aspects of the fire protection program are described in the following paragraphs.

The ISC's, NAC-I casks, Rad-Vault, and NRF TRIGA casks have been analyzed to meet the radioactive material release criteria of Title 10, Code of Federal Regulations (10 CFR) Section 71.51(a)(2) from exposure to the 10 CFR Section 71.73(c)(3) fire condition. The FHA for the ISA determined that accidents associated with the ISA are bounded by the transportation fire scenario, which would bound the tractor-trailer fire, mobile crane fire, and runaway fuel truck fire. Therefore, no ISA facility fire protection system is required. Additional information is provided in the FHA (SNF-4932).

One fire hydrant is located 150 ft southwest from the NAC-1/ISO pad (just outside the fence line), and a fire main connection is included in the ISA storage building (just outside the northwest fence line intersection). A pull box is provided at the ISA storage building to facilitate reporting of fires.

Automatic sprinkler protection is provided throughout the ISA storage building and is supplied by a connection to the 200 Area raw water system. The fire protection system is classified as General Service. A fire alarm system is provided that provides for transmission of signals to the Hanford Fire Department and to local building fire alarm annunciators. Portable fire extinguishers will also be available in the ISA storage building.
Although the proposed storage building will not be occupied on a full time basis, adequate life safety features are provided (emergency exit doors and illumination) as required by National Fire Protection Association (NFPA) 101, Life Safety Code. A perimeter gate at the ISA will remain unlocked while personnel are working within the ISA. Based on the open egress point and the absence of significant combustibles, the FHA for the ISA identified no life safety concerns.

**D11.4.3 Combustible Loading Control**

Ordinary combustibles are expected at the ISA facility. The area will be kept free of debris and vegetation, and the perimeter fence will keep transient debris away from the cask storage systems. Combustibles anticipated in the FHA include plywood cribbing, minimal quantities of combustibles to support maintenance activities (fuel truck precluded), and a minimal amount of local vegetation. SNF-4932 found that a combination of plywood and fuel oil was binding to the scenarios evaluated and describes limits on the allowable quantity of plywood cribbing. Ordinary combustibles are expected in the ISA storage building; however, it will not be a general storage structure. Section 11.4.3 of the SNF Project FSAR summarizes the SNF Project program used to prevent unnecessary combustible loadings in project facilities. The transient combustibles control program will be implemented through operating procedures that address the ISA limits established in Technical Safety Requirement AC5.12 (see Section D5.5.3.6).

**D11.4.4 Fire Fighting Capabilities**

The Hanford Fire Department maintains a training program for fire fighting, fire system testing and maintenance, and facility inspections. Fire-fighting capabilities that apply to all SNF Project facilities are addressed in Section 11.4.4 of the SNF Project FSAR. 200 Area ISA-specific fire response procedures are addressed in the following paragraphs.

Due to the absence of any fire detection and alarm system in the 200 Area ISA outside the storage building, personnel action is required to notify the Hanford Fire Department in the event of a fire. No brigade is planned for the ISA and storage building facilities. The standard response to an alarm condition in the 200 Area is by the Hanford Fire Department from the 200 Area fire station. Hanford Fire Department response time from the 200 Area fire station is approximately five minutes. This is the response time and the responder location assumed in the FHAs. WHC-SP-1180, Hanford Site Emergency Response Needs, and HNF-SP-1180, Hanford Site Emergency Response Needs Implementation Plan, provide additional descriptions of the Hanford Fire Department response capabilities. Vehicle access is provided by a paved access road and compacted gravel. The Hanford Fire Department is fully staffed, trained, and equipped for emergency response.
SNF Project personnel are trained on the expected actions to be taken in case of a fire. Personnel are to notify the Hanford Fire Department, evacuate the facility, and follow approved fire response plans specific to the facility.

**D11.4.5 Fire Fighting Readiness Assurance**

A pre-fire plan for the ISA will be prepared by the Hanford Fire Department prior to facility operations. A summary of SNF Project fire prevention inspections, fire safety drills and exercises, and program record-keeping requirements is provided in Section 11.4.5 of the SNF Project FSAR.

**D11.5 REFERENCES**

CHAPTER D12.0

PROCEDURES AND TRAINING
This page intentionally left blank.
D12.0 PROCEDURES AND TRAINING

D12.1 INTRODUCTION

A description of the essential features of Spent Nuclear Fuel (SNF) Project procedures and training is provided in Chapter 12.0 of the SNF Project Final Safety Analysis Report (FSAR).

D12.2 REQUIREMENTS

The requirements that form the basis for the SNF Project training and procedures programs are identified in Section 12.2 of the SNF Project FSAR.

D12.3 PROCEDURE PROGRAM

SNF Project activities are conducted in accordance with written procedures. A summary of the facility procedures program, including development and maintenance of procedures, is provided in Section 12.3 and its subsections in the SNF Project FSAR.

D12.4 TRAINING PROGRAM

The objective of the SNF Project personnel training program is to provide and maintain a qualified work force for safe and efficient facility operations. A summary of the SNF Project personnel training program—including training development, maintenance of training, and modification of training materials—is provided in Section 12.4 and its subsections in the SNF Project FSAR.
This page intentionally left blank.
CHAPTER D13.0

HUMAN FACTORS
This page intentionally left blank.
D13.0 HUMAN FACTORS

D13.1 INTRODUCTION

DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, allows for a graded approach to the application of human factors analysis to nuclear facilities. Per DOE-STD-3009-94, final safety analysis report (FSAR) discussions are to pertain only to the human-machine interfaces with safety structures, systems, and components (SSCs) and in proportion to the importance of those human-machine interfaces to the performance of the safety SSCs. Since the safety-class SSCs at the 200 Area Interim Storage Area (ISA) are all passive devices, there are no human-machine interfaces except during storage system unloading. Events associated with unloading have been analyzed in Chapter D3.0.

All equipment used for storage system handling at the ISA exists either at other U.S. Department of Energy (DOE) facilities or on the Hanford Site. The applicable procedures, training, and staffing requirements needed for 200 Area ISA operations and the existing equipment were previously defined and are currently being used at the 400 Area ISA (Fast Flux Test Facility). The storage system handling procedures and training requirements are in compliance with the DOE-RL-92-36, Hanford Site Hoisting and Rigging Manual. DOE-RL-92-36 is updated based on lessons learned both at the Hanford Site and at other DOE facilities. ISA surveillance and maintenance procedures will be prepared using the Spent Nuclear Fuel (SNF) Project Procedures Writer's Guide, which encompasses the human factors requirements of DOE-STD-1029-92, Writer's Guide for Technical Procedures. A review of the detailed operations associated with storage system handling identified no hazards that warrant analysis by a human factors expert. The approach used to address human factors is deemed adequate based on the guidance provided in DOE-STD-3009-94.

D13.2 REQUIREMENTS

The requirements that establish the basis for human factors engineering and storage system handling are identified in the following:

- DOE Order 5480.23, Nuclear Safety Analysis Reports
D13.3 HUMAN FACTORS PROCESS

The human factors process is discussed in Section D13.1.

D13.4 IDENTIFICATION OF HUMAN-MACHINE INTERFACES

The safety-class SSCs at the 200 Area ISA are all passive devices; therefore, there are no human-machine interfaces except during storage system unloading. Events associated with unloading have been analyzed in Chapter D3.0. Critical lift procedures for cask handling activities will incorporate controls for the lifting restrictions identified in Chapter D5.0.

D13.5 OPTIMIZATION OF HUMAN-MACHINE INTERFACES

See Sections D13.1 and D13.4.

D13.6 REFERENCES

CHAPTER D14.0

QUALITY ASSURANCE
This page intentionally left blank.
D14.0 QUALITY ASSURANCE

D14.1 INTRODUCTION

An introduction to the quality assurance program that includes the objectives and scope that apply to all Spent Nuclear Fuel (SNF) Project quality assurance activities is provided in Chapter 14.0 of the SNF Project Final Safety Analysis Report (FSAR).

D14.2 REQUIREMENTS

The requirements that form the basis of the quality assurance program are identified in Section 14.2 of the SNF Project FSAR. Additional requirements for the 200 Area Interim Storage Area (ISA) are identified in the following paragraphs. These requirements ensure the quality assurance requirements for federal repository acceptance of SNF and U.S. Nuclear Regulatory Commission (NRC) equivalency requirements are satisfied. Tables D4-1 and D4-2 present listings of safety-class and safety-significant structures, systems, and components required for the 200 Area ISA.

The U.S. Department of Energy, Richland Operations Office (DOE-RL), has directed (Sellers 1995) that DOE/RW-0333P, Quality Assurance Requirements and Description (QARD), published by the Office of Civilian Radioactive Waste Management (OCRWM), be applied as the principal quality assurance document to the SNF Project OCRWM program. DOE-RL has directed application of DOE/RW-0333P to the following SNF-related activities as they relate to repository storage:

- Characterization or data collection for input and use
- Conditioning into final form
- Handling, packaging, and transportation.

Items, activities, and documentation determined to be important to safety are presented in Table 3-1 and Section 5.0 of HNF-SD-SNF-RPT-007, Application of the Office of Civilian Radioactive Waste Management Quality Assurance Requirements to the Hanford Spent Nuclear Fuel Project. This document identifies structures, systems, components, and activities that require application of DOE/RW-0333P requirements to ensure compliance with the DOE-RL
direction. Assumptions described in Section 2.2 of HNF-SD-SNP-RPT-007, applicable to the ISA and QARD compliance, include the following:

- **324 Building Light Water Reactor (LWR) SNF** will be canistered for interim storage in a manner that does not result in the need to recanister or further condition the fuel for final disposition.

- **Neutron Radiography Facility (NRF) Training, Research and Isotope Production, General Atomics (TRIGA)** casks will not be accepted by OCRWM.

- **Fast Flux Test Facility (FFTF) SNF** will be repackaged from core component containers (CCC) prior to repository acceptance.

- **Where an activity, such as data collection, and presentation have been completed outside an approved OCRWM QARD program**, the data identification, review adequacy, and usage will be validated and qualified in accordance with OCRWM Supplement III requirements.

Quantities of site-wide SNF inventories, the current storage location, and information related to each type of fuel is provided in Table 5-1 and Figure 5-1 of HNF-SD-SNF-RPT-007. Application of the QARD requirements to these fuels must address process and storage plans for each fuel type.

In addition, specific quality requirements include: (1) periodic surveillance inspections of the SNF during storage; (2) records of all inspections after acceptance of the SNF by the SNF Project; (3) record(s) of fuel damage or other nonconformances and corrective actions after acceptance of the SNF by the SNF Project; and (4) developing and maintaining OCRWM data records for the SNF inventory, as identified in formal direction from DOE-RL. Data received by the SNF Project will be considered unqualified and tracked as such until the data passes an appropriate qualification process per the QARD.

As stated in Section 5.2.2 of HNF-SD-SNP-RPT-007, the SNF Project will develop a disposition plan for Hanford Site SNF that will identify the compliance strategy for each SNF inventory. Additionally, the SNF Project will have lead responsibility for the review of guidance on final disposition requirements from the National Spent Nuclear Fuel (NSNF) Program and will provide input to the NSNF Program on the acceptability of the draft guidance.
DOE has established a regulatory policy (Grumbly 1995) that new SNF Project facilities involved in processing K Basins SNF will achieve nuclear safety equivalency with NRC-licensed facilities. An evaluation, documented in WHC-SD-SNF-DB-002, *Spent Nuclear Fuel Project Path Forward Nuclear Safety Equivalency to Comparable NRC-Licensed Facilities*, identified requirements to establish nuclear safety equivalency that are to be met in addition to existing and applicable DOE requirements. These requirements, except those related to the design basis earthquake, are contained in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements*. HNF-SD-SNF-DB-004, *SNF Project Seismic Design Criteria - NRC Equivalency Evaluation Report*, contains the design basis earthquake requirements. The SNF Project has self-imposed some of these requirements to the ISA.

NRC nuclear safety equivalency requirements identified in HNF-SD-SNF-DB-003 that will be applied to the ISA include the following:

- Review and approval by DOE-RL of changes to HNF-MP-599, *Project Hanford Quality Assurance Program Description*, that could be interpreted as decreasing the quality assurance program's existing commitments for the ISA (HNF-SD-SNF-DB-003, Item 16).

- Ensure the appropriate quality requirements in existing Project Hanford Management Contract procedures and instructions, as identified in WHC-SD-SNF-DB-002, remain in effect (HNF-SD-SNF-DB-003, Item 18).

Design requirements for natural phenomena hazards, other than seismic design requirements, are identified in HNF-2524, *200 East Area Interim Storage Area Preliminary Safety Evaluation Report*.

The documents cited in this chapter identify the requirements to achieve nuclear safety equivalency with NRC-licensed facilities and to meet the requirements of DOE/RW-0333P. The quality assurance program plan for SNF Project facilities provides for implementation of these requirements. A graded approach will be used for items and activities important to safety (i.e., safety-class, safety-significant, and certain general-service items and/or activities), in accordance with HNF-MP-599 and NUREG/CR-6407, *Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety*.

**D14.3 QUALITY ASSURANCE PROGRAM ORGANIZATION**

A summary of the SNF Project quality assurance program, including summaries of safety management policies and philosophies used as a basis for the program, is provided in Section 14.3 of the SNF Project FSAR.
The SNF Project organizational structure, responsibilities, authorities, and interfaces that apply to the ISA are addressed in Chapter 17.0 of the SNF Project FSAR.

D14.4 QUALITY IMPROVEMENT

Descriptions of SNF Project management programs and processes used to correct adverse conditions affecting quality at all SNF Project facilities are provided in Section 14.4 of the SNF Project FSAR.

D14.5 DOCUMENTS AND RECORDS

A description of the SNF Project document control and records management program associated with quality assurance is provided in Section 14.5 of the SNF Project FSAR.

D14.6 QUALITY ASSURANCE PERFORMANCE

An overview of the SNF Project process to ensure that the performed work meets requirements is provided in Section 14.6 and its subsections in the SNF Project FSAR. The subsections address work processes, design activities, the procurement process, program tests and inspections, management assessments, and independent assessments.

D14.7 REFERENCES

This page intentionally left blank.
CHAPTER D15.0

EMERGENCY PREPAREDNESS PROGRAM
This page intentionally left blank.
D15.0 EMERGENCY PREPAREDNESS PROGRAM

D15.1 INTRODUCTION

A description of the philosophy, objectives, and organization of the Spent Nuclear Fuel (SNF) Project emergency preparedness program for response to emergencies at the SNF Project facilities is provided in Chapter 15.0 of the SNF Project Final Safety Analysis Report (FSAR) and Chapter A15.0, Annex A. This Annex D chapter presents emergency management information specific to the 200 Area Interim Storage Area (ISA).

D15.2 REQUIREMENTS

The requirements that form the basis for the SNF Project emergency preparedness program are identified in Section 15.2 of the SNF Project FSAR.

D15.3 SCOPE OF EMERGENCY PREPAREDNESS

Potential ISA emergencies could span the spectrum of identified emergencies for SNF Project facilities, from worker injuries to general emergencies with potential public impact. The spectrum of emergencies that the ISA emergency preparedness program is designed to encompass is described in Section 15.3 of the SNF Project FSAR and in Chapter D3.0. Chapter 4.0 of HNF-2524, 200 East Area Interim Storage Area Preliminary Safety Evaluation Report, presents a discussion of the principal accidents that could occur at the ISA.

D15.4 EMERGENCY PREPAREDNESS PLANNING

SNF Project emergency preparedness planning includes identification of emergency organizations, assessment actions, notification processes, emergency facilities and equipment, protective actions, access control, training, drills, exercises, and recovery actions. A summary of the emergency response organization that is activated for ISA emergencies is provided in Section 15.4 of the SNF Project FSAR and Section A15.4, Annex A. ISA emergencies and responses will be covered in the Canister Storage Building (CSB) building emergency plan and emergency response procedures.

The provisions in Section 15.4.1.2 of the SNF Project FSAR are fulfilled by the building emergency director (BED) at the CSB for the ISA until an Incident Command Post is established. The shift manager is the BED for both on-site hazardous and nonhazardous facilities, as stated in Section 15.4.1.2 of the SNF Project FSAR.
**D15.4.1 Emergency Response Organization**

Section 15.4.1 of the SNF Project FSAR presents information related to the organizational structure, building emergency organization, Incident Command Post, Emergency Operations Center, and support resources to meet emergency event requirements. This information also applies to the ISA.

The CSB Emergency Response Organization is responsible for establishing an Incident Command Post to respond to events occurring at the ISA facility (Section 15.4.1.2 of the SNF Project FSAR). Event response information is conveyed to and from the U.S. Department of Energy, Richland Operations Office (DOE-RL) Emergency Operations Center. DOE-RL maintains responsibility for communication with off-site agencies, as indicated in Figure 15-2 in the SNF Project FSAR. Each hazardous SNF Project facility has an emergency staff of individuals who assist in the protection of personnel, property, and the environment. Initial direction and control of an emergency response at the ISA is the responsibility of the BED prior to establishment of the Incident Command Post. Key Emergency Response Organization positions and responsibilities are discussed in the subsections that follow.

**D15.4.1.1 Building Emergency Director.** The BED, as described in Section 15.4.1.2 of the SNF Project FSAR and Section A15.4.1.2, is the emergency coordinator for hazardous/facility-related events (WAC 173-303) and has the authority to commit all SNF Project resources (equipment and personnel) in response to any emergency and to request supporting resources. Other responsibilities include: (1) implementing a building emergency plan; (2) assuring that the ISA Emergency Response Organization is fully staffed and trained; (3) initially assessing, categorizing, and classifying events; (4) notifying the Patrol Operations Center and applicable contractor and DOE management through the Occurrence Notification Center; (5) implementing protective actions; (6) establishing an initial ISA Incident Command Post; (7) controlling the event scene; (8) initiating mitigating activities; and (9) initiating recovery actions when directed. At the ISA, the BED is a certified CSB operations shift manager.

A listing of the primary and alternate BEDs by title, work location, and work telephone numbers is contained within the ISA building emergency plan. The BED is on the CSB or ISA premises during hazardous operations and is available through an “on-call” list 24 hours a day at all other times. Operations maintains a listing of on-call BED names, with work and home telephone numbers, at the Occurrence Notification Center.

**D15.4.1.2 Incident Command Post Staff.** The Incident Command Post staff is a group of SNF Project emergency response personnel assigned to an Incident Command Post established for an event. The Incident Commander, as supported by the BED, Hanford Fire Department, and Hanford Patrol Shift Commander, directs all emergency response efforts at the event scene.

Emergency response efforts for the Hanford Site are conducted by the Incident Commander, BED, and Hanford Patrol Shift Commander. The BED becomes a member of the
Annex D – 200 Area Interim Storage Area

Incident Command Post and functions under the direction of the Incident Commander. In this role, the BED continues to manage and direct ISA operations.

D15.4.1.3 Event Scene Staff. The event scene staff is composed of a Hanford Fire Department Operations Section Chief (assigned by the Incident Commander), trained support staff (including Health Physics and Industrial Hygiene staff), and (as required) Hanford Fire Department medical responders and Hanford Patrol. In addition, accountability aides are responsible for facilitating the implementation of protective actions (evacuation or take cover) and for facilitating the accountability of personnel after the protective actions have been implemented. Staging area managers are responsible for coordinating/conducting activities at the staging area. Personnel accountability aides assist the staging managers by ensuring that personnel and visitors are properly evacuated from designated staging areas to a safe location. The event scene staff, as directed by the Incident Command Post, supports actions requested by the Incident Commander and the BED.

D15.4.2 Assessment Actions

Provisions of Section 15.4.2 of the SNF Project FSAR cover hazards survey, hazards assessment, emergency action levels, consequence assessment, and monitoring activities. These provisions apply to the ISA.

An ISA emergency planning hazards assessment will be developed for the ISA for hazards that have the potential to generate an “Alert” or higher emergency. The hazards assessment will be prepared from the hazard and safety analyses that are developed and included in Chapter D3.0. The hazards assessment will also be derived from other pertinent facility documentation (e.g., safety assessment documents, interim safety basis documents, and special nuclear material accountability documents). The hazards assessment provides the technical basis for the emergency management program. The scope and extent of planning and preparedness directly corresponds to the type and scope of hazards present and the potential consequences of events.

The hazards assessment identifies and characterizes the hazards relevant to potential ISA operational emergencies. This includes determination of the following:

- A broad range of initiating events
- Accident mechanisms
- Equipment or system failures

D15-3 January 2000
Exposure considerations
Chemical hazards.

The hazards assessment characterizes the potential consequences to workers, the public, and the environment for each postulated accident and determines the emergency planning zone (EPZ) for each facility. The assessment also determines the emergency class, protective actions, and observable indications and criteria (emergency action levels) corresponding to the range of identified accidents.

A spectrum of potential accidents ranging from minor to beyond design basis are postulated and realistically analyzed. While not every conceivable situation will be analyzed, the hazards assessments provide the framework for response to virtually any declared emergency.

The methodology, assumptions, models, and evaluation techniques used in the hazards assessments are documented in Sections 15.4.2.3 and 15.4.2.4 of the SNF Project FSAR. Results from the ISA hazards assessment are used to develop the ISA building emergency plan elements contained in the CSB building emergency plan. Hazards assessments for the ISA are reviewed annually and updated, as necessary, in accordance with Section 15.4.2.2 of the SNF Project FSAR.

D15.4.3 Notification

Notifications, in the event of an emergency event at the ISA, will be made in accordance with the provisions of Section 15.4.3 of the SNF Project FSAR in order to mitigate consequences and to protect the health and safety of workers, the public, and the environment.

D15.4.4 200 Area Interim Storage Area Emergency Facilities and Equipment

The building emergency plan for the ISA will be prepared and issued as part of the CSB building emergency plan, in accordance with HNF-IP-0263-GEN, Building Emergency Plan Guidance. A description of the facilities that will be available for coordinating ISA emergency response activities will be specified in the building emergency plan.

Emergency equipment consisting of materials and tools that may be required to measure, control, or mitigate the consequences of an emergency at the ISA is provided in Table D15-1. Detection ranges and types of instruments for radiological and nonradiological hazardous materials will be adequate for ISA emergency conditions, as determined in Section D15.4.2. The emergency planning organization will ensure that sufficient emergency equipment is available. The location of this emergency equipment will be stated in the CSB building emergency plan.
Table D15-1. Interim Storage Area Emergency Equipment.

\(^{(1)}\) SCBA respirators for emergency use will be thoroughly inspected at least once a month and after each use. Records of inspection dates and findings will be maintained.

SCBA = self-contained breathing apparatus.
D15.4.5 Protective Actions

Protective actions are those actions taken to preclude or reduce the exposure of individuals or the environment impacted by hazards or unsafe conditions during an emergency event at the ISA. These protective actions are presented in Section 15.4.5 of the SNF Project FSAR and are applicable to the ISA. Protective actions for the ISA will reflect use of the emergency response planning guidelines identified in Section 15.4.2.3 of the SNF Project FSAR. The planning guidelines published in the Emergency Response Planning Guidelines (AIHA 1988) will be used during an ISA emergency response to determine protective actions for unique exposures to chemical releases (see Table 15-4 of the SNF Project FSAR). The protective action guides are also used during an emergency response to determine protective actions for unique exposures to radiological releases (see Table 15-1 of the SNF Project FSAR). DOE-RL directs the use of the published protective action guides adopted by the states of Washington and Oregon (EPA-100) in DOE/RL-94-02, Hanford Emergency Management Plan.

The Hanford Site emergency management program uses the EPZ concept to focus emergency planning activities. EPZs are designated areas where protective actions may be required. The size of a zone is determined primarily by the expected dispersion distance of a particular concentration of a substance. The two exposure pathways for both radiological and nonradiological hazardous materials are the plume exposure pathway and the ingestion exposure pathway. A description of the exposure pathways is provided in Section 15.4.5 of the SNF Project FSAR. Figure D1-1 indicates the location of the CSB. Figure 2-1 in HNF-2524 shows the location of the ISA relative to the CSB.

The plume exposure pathway EPZ is the probable area of exposure to a passing cloud (or plume) of the substance, potentially resulting in direct contact with the substance through the exterior of the body or through inhalation. The plume exposure pathway EPZ includes the area where emergency planning is conducted (1) to ensure that prompt and effective actions are taken in the event of an emergency, (2) to protect on-site personnel, and (3) to ensure public health and safety. The plume exposure pathway for the CSB (10 mi) is shown in Figure 15-6 in the SNF Project FSAR.

The ingestion exposure pathway EPZ is the probable area of exposure to contaminated foodstuffs or water potentially resulting in deposition of the material in various internal organs following ingestion (eating or drinking). The ingestion exposure pathway EPZ for radiological and nonradiological incidents at all Hanford Site facilities corresponds to the 80-km (50-mi) EPZ for Energy Northwest's (formerly known as Washington Public Power Supply System's) Nuclear Plant 2. The gray area in Figure 15-6 in the SNF Project FSAR represents the ingestion EPZ for the Hanford Site.

The protective actions required to minimize the exposure of workers and the public are summarized in Section 15.4.5 of the SNF Project FSAR. Examples of protective actions as a function of accident category and consequences are illustrated in Table 15-5 in the SNF Project FSAR.
D15.4.6 Training and Exercises

The CSB emergency organization will be formed, trained, and tested for potential ISA emergency events in accordance with the provisions of Section 15.4.6 of the SNF Project FSAR. Drills and exercises will be developed in accordance with Section 15.4.6 of the SNF Project FSAR, with sufficient scope and detail to emphasize the facility-specific emergency events and response actions applicable to the ISA.

D15.4.7 Reentry and Recovery

The provisions applicable to a ISA emergency event termination, facility entry, transition from an emergency organization to a recovery organization, and the recovery process are provided in Section 15.4.7 of the SNF Project FSAR.

D15.5 DOCUMENT CONTROL

The ISA building emergency plan, implementing procedures, reports of drills and exercises, and emergency event documentation will be controlled and updated in accordance with the provisions of Section 15.5 of the SNF Project FSAR.

CHAPTER D16.0

PROVISIONS FOR DECONTAMINATION AND DECOMMISSIONING
This page intentionally left blank.
D16.0 PROVISIONS FOR DECONTAMINATION AND DECOMMISSIONING

D16.1 INTRODUCTION

The provisions that apply to future decontamination and decommissioning (D&D) of Spent Nuclear Fuel (SNF) Project facilities are addressed in Chapter 16.0 of the SNF Project Final Safety Analysis Report (FSAR). Provisions specific to the 200 Area Interim Storage Area (ISA) are addressed in this Chapter D16.0.

The 200 Area ISA has been given the designation of a Hazard Category 2 facility because of the inventory contained in the cask storage systems. The facility will not experience significant, if any, contamination during interim storage of the SNF. Therefore, decontamination efforts at the end of facility life will only be required in the event that an unanticipated release(s) occurs during the life of the facility. Decommissioning efforts will also be minimal based on the simplicity of the facility design (e.g., concrete slabs, graveled storage and access areas, a fence, and lighting fixtures). The end state of the 200 Area ISA is not known at this time, but several options, ranging from facility reuse to complete dismantlement and removal, are available.

D16.2 REQUIREMENTS

The requirements that form the basis for the D&D program are found in Section 16.2 of the SNF Project FSAR. Specific requirements applicable to this chapter include the following:

D16.3 DESCRIPTION OF CONCEPTUAL PLANS

General D&D considerations applicable to all SNF Project facilities are provided in Section 16.3 of the SNF Project FSAR.
D16.3.1 Design Features

Each 200 Area ISA cask storage configuration provides confinement of radiological materials during transport of the SNF to the 200 Area ISA and during storage at the ISA. The cask storage configuration design features that are important to D&D will be controlled through the design change control process to ensure that changes to the facility will provide equal or greater consideration to D&D. Further description of the confinement design is provided in Chapter D2.0.

D16.3.1.1 Safety Features. Chapters D3.0, D4.0, D5.0, and D6.0 identify the selected safety features for preventing or mitigating the postulated accidents. These implemented engineered barriers and administrative programs will prevent or greatly reduce the consequences of any postulated upset event or accident; thus, the amount and location of any radiological material releases will be diminished for D&D cleanup activities. No design basis accident will result in off-site dose consequences (prevented) or on-site dose consequences exceeding the evaluation guidelines (mitigated).

D16.3.2 Operational Considerations

The potential for personnel or equipment contamination is minimized by the design of the cask storage systems, and by administrative controls, radiological practices, and work guidelines defined in operating procedures and work permits. Because baseline operations assume no spread of contamination from the cask storage systems, no special facilities for the support of decontamination activities have been provided. Although the risk of contamination is minimal, operating procedures address requirements for radiological control surveys in the facility. For example, surveys will be performed annually to verify that each cask system remains free of contamination.

D16.3.3 Decommissioning

The 200 Area ISA components may be removed at a future time in compliance with applicable regulations. The process used to develop the 200 Area ISA D&D plan is provided in Section 16.3.3 of the SNF Project FSAR. Conceptual plans for D&D will include an updated facility hazard analysis for the D&D activities, which will be used to prepare the plan to administer the expected D&D strategy. Conceptual plans will also include a preliminary deactivation plan that contains at least the following information:

- Structures, systems, and components in their final configuration
- Review and determination of the status of structures, systems, and components based on the mission and life-cycle phase
Configuration management for missing or inaccurate design baseline documentation, voiding and downgrading of design documents, and turnover of design baseline documents to the environmental restoration contractor.

Decommissioning plans for the 200 Area ISA facility will be developed and reviewed against the existing environmental impact statement. The environmental impact statement will be updated to include D&D activities in accordance with the *National Environmental Policy Act* process, if deemed appropriate.

The construction of the 200 Area ISA as an above-grade facility will simplify decontamination and dismantling. The ISA storage building will be decontaminated as necessary and dismantled using conventional techniques. The ISA concrete pads will be dismantled and removed from the site.

D17.0 MANAGEMENT, ORGANIZATION, AND INSTITUTIONAL SAFETY PROVISIONS

D17.1 INTRODUCTION

A description of the organizational structure, responsibilities, and interfaces that support safe design, construction, and operational activities of the 200 Area Interim Storage Area (ISA), as a subproject of the Spent Nuclear Fuel (SNF) Project, are addressed in Chapter 17.0 of the SNF Project Final Safety Analysis Report (FSAR).

D17.2 REQUIREMENTS

The requirements that form the basis for management, organizational, and safety provisions are identified in Section 17.2 of the SNF Project FSAR.

D17.3 ORGANIZATIONAL STRUCTURE, RESPONSIBILITIES, AND INTERFACES

The overall organizational structure, responsibilities, and interfaces for ISA operations are identified in Section 17.3 of the SNF Project FSAR.

D17.4 SAFETY MANAGEMENT POLICIES AND PROGRAMS

The safety management policies and programs applicable to ISA are identified in Section 17.4 of the SNF Project FSAR.

EXECUTIVE SUMMARY

AE.1 FACILITY BACKGROUND AND MISSION

The U.S. Department of Energy (DOE) established the Spent Nuclear Fuel (SNF) Project to address safety and environmental concerns associated with deteriorating SNF presently stored under water in the Hanford Site K Basins, which are located in the 100 K Area near the Columbia River. Recommendations for a series of projects to construct and operate systems and facilities to manage the safe removal of K Basins fuel were made in WHC-EP-0830,汉福尔德退役核燃料项目建议路径前进，1 and its subsequent update, WHC-SD-SNF-SP-005，汉福尔德退役核燃料项目整合流程策略为K屏蔽燃料。2 The integrated process strategy recommendations include the following steps:

- Fuel preparation activities at the K Basins, including removing the fuel elements from their K Basins canisters, separating fuel particulate from fuel elements and fuel fragments greater than 0.25 in. in any dimension, removing excess sludge from the fuel fragments by means of flushing, as necessary, and packaging the fuel into multi-canister overpacks (MCOs)

- Transportation of MCOs loaded with SNF from K Basins to the Cold Vacuum Drying Facility (CVDF)

- Removal of free water by draining and vacuum drying at the CVDF in the 100 K Area

---

Dry shipment of fuel from the CVDF to the Canister Storage Building (CSB), a new facility in the 200 East Area.

Interim storage of the MCOs in the CSB until a suitable long-term repository is established.

The purpose of this final safety analysis report (FSAR) is to provide the basis for authorization to proceed with the operation of the CSB. The scope of this report includes operating and support structures and equipment required for receipt, handling, and interim storage of the MCOs.

The SNF Project FSAR is a multi-volume document. Volume 1 contains SNF Project information applicable to new SNF Project facilities. This Volume 2, facility FSAR Annex A, contains information specific to the CSB. The information contained in this Volume 2, facility FSAR Annex A, is based on the CSB design information. All topics recommended in DOE-STD-3009-94, *Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports,* are addressed, including descriptions of site and facility design, hazard and accident analyses, safety-class and safety-significant equipment, derivation of technical safety requirements (TSRs), prevention of inadvertent criticality, and other areas of facility design and operational programs. This report also is based on implementation of U.S. Nuclear Regulatory Commission nuclear safety equivalency with the additional requirements compiled and approved in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward Additional NRC Requirements.* Future changes in facility mission are anticipated to require revisions to Volume 2, CSB FSAR Annex A. These changes include the interim storage of other fuel types (e.g., fuel from the Shippingport pressurized water reactor) and the storage of glass canisters.

---

from the Hanford Waste Vitrification Plant. These future missions are not expected to impact the
current hazard classification as a Category 2 facility.

AE.2 FACILITY OVERVIEW

The CSB facility provides for receiving, sampling, monitoring, and interim storage of
MCOs. The partially constructed foundation of the canceled Hanford Waste Vitrification Plant
has been incorporated into the design of the CSB, with some modifications made to meet the
different SNF Project mission needs.

The CSB facility is a steel-framed building that encloses the operating area; the
load-in/load-out area; and three equally sized, below-grade concrete vaults. The concrete vaults
are covered by a concrete operating deck. Support functions and equipment are housed in a
steel-framed support area building adjacent to the north side of the operating area building. Only
the northernmost vault (vault 1) in the operating area is equipped with steel tubes for staging
mechanically sealed MCOs and for interim storage of the MCOs with welded caps. For
completeness, vaults 2 and 3 will be mentioned or described in this document; however,
operations in vaults 2 and 3 are outside the scope of this FSAR.

An MCO received at the CSB contains five or six baskets of dried SNF that are stacked
one on top of the other. The stainless steel outer shell and bottom of the MCO and the
mechanically-sealed top carbon steel shield plug are designed to meet the *Boiler and Pressure
Vessel Code* and to provide effective long-term confinement of the enclosed SNF. The shield
plug also provides access to the interior of the MCO through four access ports on the top of the
shield plug assembly. The access ports provide the means for sampling those MCOs that are to be
monitored at the CSB. The four access ports will be sealed at the CVDF using gasketed, bolted,

---

Engineers, New York, New York.
cover plates before the MCO is transported to the CSB. At the load-in/load-out area, a receiving crane is used to lift the transportation cask that contains the MCO off the transportation trailer in the vestibule area and then transfer the cask–MCO to the cask receiving pit. The CSB MCO handling machine (MHM) is used to lift the MCO out of its transportation cask and transport the MCO across the operating deck to the CSB sampling/weld area or down into a storage tube in vault 1.

The CSB operating deck is a 5-ft-thick, at-grade, reinforced concrete structure. The dimensions of the operating deck are approximately 230 ft (north–south) by 137 ft (east–west). The operating area deck floor is bounded to the north by the load-in/load-out area (trailer vestibule and MCO service station) and support area building foundations, and to the south by the sampling/weld area foundation. The operating deck structure contains numerous full-thickness, embedded steel sleeves that receive the storage tubes and tube plugs for standard storage tubes and overpack storage tubes in vault 1. The embeds also provide a location for securing the tube plug cover plates in vault 1 and the deck embed cover plates in vaults 2 and 3. These embeds are offset and arranged at a center-to-center distance of 4 ft, 8 in. east–west and 4 ft, 6 in. north–south. The distance between MCOs has been evaluated for prevention of inadvertent criticality and has been found to be adequate.

The sampling/weld area, located on the south end of the operating area, contains equipment for pressure-checking and sampling the MCOs and welding equipment for installing cover caps on the MCOs.

Vault 1 contains 220 standard storage tubes and 6 overpack storage tubes. Vault 1 is cooled by natural convection through an above-grade inlet structure and exhaust stack, through below-grade concrete intake and exhaust plenums. The CSB subsurface structure provides shielding for the intake and exhaust plenums. The 3-ft-thick interior walls of the subsurface structure provide shielding from the source term associated with SNF storage. The exterior walls were designed to meet the shielding criteria given in Title 10, Code of Federal Regulations,
Part 835, "Occupational Radiation Protection" (10 CFR 835),\(^6\) for uncontrolled access areas. Assuming that each MCO contains the maximum activity value associated with Mark IV fuel, shielding calculations indicate a dose rate at the base of the intake stack of less than 0.05 mrem/hour. Heating of concrete by the radiation field inside the vault has been calculated to be 6.3 x \(10^4\) W. This value has been determined to be insignificant compared with convective heat transfer of 161.2 kW (CSB-HV-0001\(^7\)).

Each standard storage tube is capable of staging or storing two MCOs. Each overpack storage tube is available to accommodate an abnormal or suspect MCO, as described in an associated recovery plan. The vault 1 storage tubes are supported from the foundation base slab of the vault and are accessed through penetrations in the operating deck. These embedments or storage tubes are normally closed with removable tube plugs. The standard tube plugs provide radiation shielding, a filtered vent, and connections for sampling the storage tube atmosphere. The overpack storage tube plugs have connections for sampling, purging, and pressure-relief of the storage tube atmosphere; pressure gauges for surveillance of the tube pressure; and lock-down devices. Each standard storage tube contains both a bottom impact absorber and an intermediate impact absorber to mitigate the impact of dropped MCOs. Each overpack storage tube is fitted with a bottom impact absorber.

The figures in Chapter A1.0 show the CSB site plan and those in Chapter A2.0 show the exterior view of the CSB structure, building floor plan and sectional views, an MCO assembly, and a general arrangement of the MHM.

---

AE.3 FACILITY HAZARD CLASSIFICATION

A final hazard categorization of the CSB facility was performed based on the final hazard and accident analyses. The categorization estimated the amount of radiological material at risk for the hazard categorization in accordance with DOE-STD-1027-92, *Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports*. Consistent with DOE-STD-1027-92, the final categorization was based on the unmitigated release of available radiological inventories. These CSB material quantities were compared against the threshold quantities contained in DOE-STD-1027-92. The final categorization of the CSB was determined to be Hazard Category 2.

AE.4 SAFETY ANALYSIS OVERVIEW

The scope of the hazard analysis included all normal, intended CSB operations for receiving, handling, and storing sealed MCOs. The analysis included reviews of operations flow diagrams and current operating procedures. CSB operations considered were those involved with bringing the transportation cask containing an MCO into the facility on the transporter, moving the cask-MCO to the load-in/load-out area and removing the cask lid, transporting the MCO from the load-in/load-out area to either the sampling/weld area or the storage tube with the MHM, conducting activities during MCO staging and interim storage, transporting the MCO from the storage tube to the sampling/weld area, and returning it from the sampling/weld area after sampling or welding.

The hazard analysis involved the identification of hazard sources, hazardous conditions, potential accident scenarios and their initiators, and preliminary assessments of event frequencies.

---

and consequences. Hazards were identified by type and quantity, and represent a complete spectrum of events that could occur throughout the facility.

Bounding and representative accidents were selected from the hazard analysis for further quantitative evaluation as design basis accidents (DBAs). These accidents are presented in detail in Chapter A3.0, Section 3.4. Each DBA analyzed represents a bounding case for a category of hazards and accidents. The six major DBA events evaluated are:

- Mechanical damage of the MCO (Section A3.4.2.1)
- Gaseous release from the MCO (Section A3.4.2.2)
- MCO internal hydrogen deflagration (Section A3.4.2.3)
- MCO external hydrogen deflagration (Section A3.4.2.4)
- Thermal runaway reactions inside the MCO (Section A3.4.2.5)
- Violation of design temperature criteria (Section A3.4.2.6).

Three receptors were evaluated in the DBA analysis:

- Hanford Site boundary receptor (offsite), defined at a distance of 17,390 m east of the CSB
- Collocated worker receptor (onsite), defined at a distance of 100 m east of the CSB
- Highway 240 receptor, defined at a distance of 9,280 m west of the CSB.

Consequences to the Hanford Site boundary receptor and collocated worker receptor were compared against defined release limits and evaluation guidelines and were used for the selection of safety-class and safety-significant features, respectively. Lacking any defined evaluation guideline for the Highway 240 receptor group, consequences to those receptors were calculated...
for informational purposes only. In addition, the hazard analysis identified required worker safety protection features on a semi-quantitative basis.

The safety-class features relied upon in the facility safety basis are described and tabulated in Chapter A4.0, Section A4.3 and are listed as follows:

- CSB subsurface structures, including vaults, air intake, and exhaust plenums
- Carbon steel base slab embeds for the standard and overpack storage tubes
- CSB at-grade structures, including operating deck (including the sampling/weld area and load-in/load-out area), bases for intake tower and exhaust stack, and support area building foundation
- Standard storage tubes, bottom impact absorbers, and tube base assemblies
- Overpack storage tubes and tube base assemblies
- CSB intake structure and exhaust stack
- MCOs
- Transportation cask
- MHM seismic restraint system
- MHM rails and rail frogs.
The safety-significant features relied upon in the facility safety basis are described and tabulated in Chapter A4.0, Section A4.4 and are listed as follows:

- Operating area shelter and support area building
- Standard storage tube plugs
- Overpack storage tube plugs
- MHM structural components, MCO grapple and hoist, and MHM interlocks P2, P6, and P21
- Tube vent and purge cart
- Receiving crane structure and hoist
- Cask receiving pit
- Transportation cask servicing system
- MCO sampling system
- Standard storage tube intermediate impact absorber
- MHM fixed shielding
- Transportation cask shielding
- MCO shield plug shielding
HNF-3553 REV 0
Annex A — Canister Storage Building

- Standard storage tube lower flange, bottom impact absorber, and standard interface guide ring funnel

- Overpack storage tube lower flange, bottom impact absorber, and overpack interface guide ring funnel

- Cask lifting yoke

- MCO centering guide

- Cask receiving impact absorber

- Sampling/weld station impact absorber and shield halves

- Shield hatch and MCO guide assembly

- Helium rupture disk.

AE.5 ORGANIZATIONS

Fluor Hanford, Incorporated, is responsible to the DOE for the planning, integration, and management of SNF Project activities, including programs, projects, and operations. Organizational responsibilities related to the SNF Project are summarized in Volume 1, "Executive Summary," and described in detail in Chapter 17.0 of that volume.

a-csbes sur AES-10 March 2000
AE.6 SAFETY ANALYSIS CONCLUSIONS

The safety analysis conclusions for the CSB DBAs are presented in detail in Chapter A3.0, Section A3.4.2 and are summarized in the following paragraphs.

 Mechanical Damage of Multi-Canister Overpack. An MCO, or the cask–MCO combination, subjected to an accidental drop, impact, or shear of sufficient magnitude could be damaged such that the MCO is breached or its internal geometry is compromised. Several potential accidents at the CSB that could damage the MCO with mechanical forces were identified in the hazard analysis. Three classifications of accidents were evaluated: drop of the MCO or cask–MCO, shear of the MCO by the MHM, and impacts to the MCO other than drops and shears. The unmitigated radiological offsite doses for all mechanical damage events are below the offsite release limits while the onsite doses are within evaluation guidelines for unlikely events. For safety features selected to protect analysis assumptions or for defense-in-depth structures, systems, and components (SSCs) that help prevent or mitigate other events within this accident category, see Section A3.4.2.

 Gaseous Release from the Multi-Canister Overpack. Events that may result in releases of radioactive material to the CSB facility from the uncontrolled release of the MCO’s internal gas pressure were evaluated. A pressurized gaseous release would lead to entrainment and release of fuel particulate from the MCO and the creation of a radiological hazard. Several potential accidents at the CSB that could lead to a gaseous release were identified in the hazard analysis, including overpressurization caused by radiolytic decomposition and gaseous release caused by sampling system failure or operator error during sampling and backfilling operations at the CSB. The unmitigated radiological offsite doses from all credible gaseous release events were calculated to be below the offsite release limits while the onsite doses were within evaluation guidelines for events in the anticipated category. For safety features selected to protect analysis assumptions or for defense-in-depth SSCs that help prevent or mitigate other events within this accident category, see Section A3.4.2.
Multi-Canister Overpack Internal Hydrogen Deflagration. Events were evaluated that could lead to the formation of flammable mixtures of hydrogen and oxygen within an MCO, which if ignited, could result in a deflagration inside the MCO. Several potential accidents at the CSB that could lead to an internal hydrogen deflagration were identified in the hazard analysis, including radiolytic decomposition of oxygen-containing compounds, introduction of oxygen into the MCO during recharging at the sampling/weld station, and ingress of oxygen following an MCO breach. The unmitigated radiological offsite doses from all internal hydrogen deflagration events were calculated to be below the offsite release limits while the onsite radiological doses were within evaluation guidelines for events in the unlikely category. For safety features selected to protect analysis assumptions or for defense-in-depth SSCs that help prevent or mitigate other events within this accident category, see Section A3.4.2.

Multi-Canister Overpack External Hydrogen Deflagration. Events were evaluated that could lead to the release of hydrogen from the MCO. The uncontrolled release of hydrogen could result in the formation of flammable mixtures of hydrogen and oxygen outside an MCO, which if ignited, could result in a deflagration. Several potential scenarios at the CSB that could lead to an external deflagration were identified in the hazard analysis, including deflagrations at the sampling/weld station, MHM, and storage tube. The unmitigated radiological offsite doses from all credible external hydrogen deflagrations events were calculated to be below the offsite release limits while the onsite doses were within evaluation guidelines for events in the anticipated category. For safety features selected to protect analysis assumptions or for defense-in-depth SSCs that help prevent or mitigate other events within this accident category, see Section A3.4.2.

Thermal Runaway Reactions inside the Multi-Canister Overpack. A thermal runaway reaction is only possible in an MCO containing extremely high temperature fuel and excessive amounts of water. The accident evaluations for this DBA demonstrate that a thermal runaway accident is not credible at the CSB provided the fuel is properly loaded into the MCO at the K Basins and the dryness tests at the CVDF are satisfied. No release results from this event and the offsite release limits and onsite evaluation guidelines are satisfied. For safety features selected...
to protect analysis assumptions or for defense-in-depth SSCs that help prevent or mitigate other
events within this accident category, see Section A3.4.2.

Violation of Design Temperature Criteria. The hazard analysis identified the scenario for
this accident as one in which the MCO and the safety-class CSB concrete structures could exceed
their design temperatures due to a lack of cooling. The MCOs and CSB have been designed to
provide sufficient heat transfer from the MCO so that unacceptably high temperatures will not be
reached during normal handling and storage of the MCO at the CSB. Evaluation of the DBA
demonstrates that situations in which a reduction in normal heat conduction causes overheating
are precluded by the design of facility features such as the CSB vault and intake and exhaust
structures. The accident is prevented and offsite release limits and onsite evaluation guidelines are
satisfied. For safety features selected to protect analysis assumptions or for defense-in-depth
SSCs that help prevent or mitigate other events within this accident category, see Section A3.4.2.

AE.7 SAFETY ANALYSIS REPORT ORGANIZATION

The purpose of this section of the Executive Summary as outlined in the guidance from
DOE-STD-3009-94 is to describe the structure and content of the document, particularly for
cases in which the Standard was not followed. This report is based on the format and content
guidance of DOE-STD-3009-94 and the requirements of DOE Order 5480.23, Nuclear Safety
Analysis Reports. This report also includes selected content guidance from Title 10, Code of
Federal Regulations, Part 72, "Licensing Requirements for the Independent Storage of Spent
Nuclear Fuel and High-Level Radioactive Waste," Section 72.24, "Contents of Application:
Technical Information," and NRC Regulatory Guide 3.48, Standard Format and Content for the

A1.0 SITE CHARACTERISTICS

A1.1 INTRODUCTION

The Canister Storage Building (CSB) is in the 200 East Area of the U.S. Department of Energy (DOE) Hanford Site. The CSB will be used to store the spent nuclear fuel (SNF) generated by the Hanford Site plutonium production reactors and previously stored under water in the 100 Area K Basins. The objective of this chapter is to describe the characteristics of the site on which the CSB is located that support the hazard analysis and accident analyses presented in Chapter A3.0. See Chapter A2.0 for a detailed description of the CSB structure and systems. This chapter and Chapter 1.0 of the SNF Project Final Safety Analysis Report (FSAR) contain information related to regional and Hanford Site characteristics.

A1.2 REQUIREMENTS

The requirements that establish the basis for CSB siting are identified in Section 1.2 of the SNF Project FSAR. Some of the requirements listed in Section 1.2 of the SNF Project FSAR were not in existence at the time the below-grade portion of the CSB was designed. The impact of the later orders and standards is reflected in WHC-SD-SNF-DB-009, Canister Storage Building Natural Phenomena Hazards. Also see Section 1.2 of the SNF Project FSAR for discussion of U.S. Nuclear Regulatory Commission (NRC) equivalency requirements.

In addition to the requirements identified in Section 1.2 of the SNF Project FSAR, the following industry standards are applicable to the CSB safety basis:

- ASCE 7-93, Minimum Design Loads for Building and Other Structures

A1.3 SITE DESCRIPTION

The following sections address the geography, demography, and regional land and water use of the area encompassed by and surrounding the CSB site. See Section 1.3 of the SNF Project FSAR for a description of the Hanford Site and associated areas.

A1.3.1 Geography

A1.3.1.1 Hanford Site Vegetation. See Section 1.3.1.1 of the SNF Project FSAR for information applicable to all SNF Project facilities.
A1.3.1.2 Hanford Site Facilities. See Section 1.3.1.2 of the SNF Project FSAR for information applicable to all SNF Project facilities.

A1.3.1.3 Boundaries for Evaluation of Accident and Effluent Release Limits. As indicated in Section A3.1, three receptor locations were used to determine the consequences of accident releases to collocated workers and to the public (offsite receptors). These three locations are as follows:

- Hanford Site boundary (17,390 m east of the CSB) — defined release limits; used for calculation of offsite doses and selection of safety-class features (Sellers 1997, Scott 1995)

- Collocated worker (100 m from the CSB) — defined risk evaluation guidelines; used for calculation of onsite doses and selection of safety-significant features (Sellers 1997)

- Highway 240 (onsite, approximately 9,280 m west of the CSB) — no defined evaluation guideline; doses calculated for informational purposes only (Scott 1995).

Consequences of accidental releases from the CSB to collocated workers are calculated in Section A3.4.2 at 100 m from the point of release in accordance with approved procedures. Routine and accidental releases to the public (offsite receptor) are calculated at the Hanford Site boundary shown in Figure A1-1. This Hanford Site boundary is also the location of the controlled area boundary as the term is defined in Title 10, Code of Federal Regulations, Part 72, "Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste" (10 CFR 72), Section 106, "Controlled Area of an ISFSI or MRS." Before changes to the Site boundaries are placed into effect by the proper authorities, the calculations in this FSAR will be reviewed (and revisited if required) in accordance with DOE Order 5480.21, Unreviewed Safety Questions.

A1.3.2 Demography

See Section 1.3.2 of the SNF Project FSAR for the description of the demography surrounding the Hanford Site. Figure A1-2 shows the 200 East Area onsite employee population.

A1.4 ENVIRONMENTAL DESCRIPTION

A1.4.1 Meteorology

See Section 1.4.1 of the SNF Project FSAR for meteorology information applicable to all SNF Project facilities.
The specific air transport factors used for accident consequence analyses, and the basis for their calculation and use, are discussed in further detail in HNF-SD-SNF-TI-059, *A Discussion on the Methodology for Calculating Radiological and Toxicological Consequences for the Spent Nuclear Fuel Project at the Hanford Site*, and in Section A3.4.1.2. Data are provided for both ground-level and stack releases. To support the accident analyses of Section A3.4.2, air transport factors \(X/Q\) and \(WQ\), representing the dilution of a contaminant by atmospheric turbulence and diffusion as the contaminant travels downwind, were calculated (HNF-SD-SNF-TI-059). The symbol \(X/Q\) is the ratio of the average air concentration at the receptor to the average release rate at the release point. It is used to assess potential radiological dose and noncorrosive chemical concentration at downwind locations. The symbol \(WQ\) is the normalized peak air concentration at the center of a puff divided by the quantity released and is used to assess the consequences to a receptor for corrosive chemicals. The \(X/Q\)'s for the analyses were calculated using joint frequency distribution data so as to be exceeded only 0.5% of the time (99.5 percentile) for each sector, or to be exceeded only 5% of the time (95 percentile) for data from all sectors combined (the greater of the two calculated values is used in the analyses).

The GXQ computer code, Version 4.0, described in WHC-SD-GN-SWD-30002, *GXQ Program User's Guide*, was used to generate \(X/Q\) and \(WQ\) values. GXQ incorporates the methods described in NRC Regulatory Guide 1.145, *Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants*. The specific air transport factors used for accident consequence analyses, and the basis for their calculation and use, are discussed in detail in HNF-SD-SNF-TI-059 and in Section A3.4.1.2. Table A3-7 provides the atmospheric transport factors used in accident analyses for the CSB. Supporting information also is provided in Section 1.4.1.2.8 of the SNF Project FSAR.

The wind rose data (Figure A1-3 and Figure A1-4) indicate that winds from the west-northwest sector occur most frequently (nearly 20% of the time). That is, the emissions are transported toward the east-southeast sector. Winds out of the northwest and west also occur with a relatively high frequency (12% and 9%, respectively). Information provided in these figures was obtained from data presented in HNF-SD-SNF-TI-059.

**A1.4.2 Hydrology**

See Section 1.4.2 of the SNF Project FSAR for Hanford Site hydrology information that is applicable to all SNF Project facilities.

**A1.4.2.1 Surface Water.** See Section 1.4.2.1 of the SNF Project FSAR for surface water information.

**A1.4.2.2 Vadose Zone.** See Section 1.4.2.2 of the SNF Project FSAR for a definition of the vadose zone.
A1.4.2.3 Aquifers. The 200 Area aquifer systems are discussed in Section 1.4.2.3 of the SNF Project FSAR.

A1.4.3 Geology

See Section 1.4.3 of the SNF Project FSAR for a description of Hanford Site geology that applies to all SNF Project facilities.

A1.4.3.1 Physiographic Setting of the Hanford Site. See Section 1.4.3.1 of the SNF Project FSAR for information on the physiographic characteristics applicable to the CSB.

A1.4.3.2 Stratigraphy. See Section 1.4.3.2 of the SNF Project FSAR for information on the stratigraphy of the Pacific Northwest and the Hanford Site that is applicable to the CSB.

A1.4.3.3 History of Cataclysmic Flooding in the Pasco Basin. See Section 1.4.3.3 of the SNF Project FSAR for information on cataclysmic floods that is applicable to the CSB.

A1.4.3.4 Geologic Structures of the Columbia Basin and Hanford Site. See Section 1.4.3.4 of the SNF Project FSAR for information on geologic structures that is applicable to the CSB.

A1.4.3.5 Geology of the 200 East Area Canister Storage Building. The topology and geology of the CSB site, located in the 200 East Area, is summarized on Figures A1-5 through A1-7. The suprabasalt sediments consist of the Ringold Formation and Hanford formation. The Ringold Formation conforms to the basalt bedrock surface and tilts southeast toward the axis of the Cold Creek syncline. The Ringold Formation is dominated by gravel units E and A, which are separated by the Lower Mud unit. These are the main unconfined aquifers. The Ringold Formation thins from 164 ft at the south end to nearly pinching out at the north end. The beds have been truncated and are unconformably overlain by the Hanford formation. The Hanford formation is mainly sands and gravelly sands that are between 246 and 328 ft thick at the site.

During excavation of the pit for the CSB, geologic mapping showed that the foundation for the building is in the fine-grained, laminated sands of the Hanford formation. No faults were found cutting the unit but clastic dikes were observed along the south wall of the site.

A1.4.3.6 Tectonic Development of the Hanford Site. See Section 1.4.3.6 of the SNF Project FSAR for information on geologic structures and faults that relate to Hanford Site seismic hazard analysis that is applicable to the CSB. See also WHC-SD-W236A-T1-002, Probabilistic Seismic Hazard Analysis, DOE Hanford Site, Washington.

A1.4.3.7 Contemporary Stress and Strain. See Section 1.4.3.7 of the SNF Project FSAR for information on earthquake activity, contemporary stress measurements, and subsidence history that is applicable to the CSB.
A1.4.3.8 Geologic Hazards.

A1.4.3.8.1 Seismic Hazard Assessment. The mean seismic hazard curves for the 200 East Area and the CSB site are shown in Figures A1-8 and A1-9 and illustrate the contributions of individual folds to the hazard. The relative contribution of crustal and Cascadia Subduction sources at the 200 East Area is illustrated in Figure A1-10 and the relative contribution of the three crustal sources for the same location is shown in Figure A1-11.

Horizontal and vertical equal-hazard response spectra were developed for the CSB site. These are shown at 5% damping for performance category 3 in Figure A1-12 (WHC-SD-SNF-DB-009). More detail and additional damping values are presented in WHC-SD-W236A-TI-002.

The CSB is using the design and completed portions of the subgrade construction of the canceled Hanford Waste Vitrification Plant (HWVP). The horizontal seismic response spectrum for the HWVP was a Newmark and Hall median spectra shape anchored at 0.35 g according to WHC-SD-SNF-DB-004, *Spent Nuclear Fuel Project Seismic Design Criteria — Nuclear Regulatory Commission Equivalency Evaluation Report*. The vertical spectrum is two-thirds of the horizontal. The horizontal and vertical Newmark and Hall response spectra envelop the horizontal and vertical equal hazards response spectra (respectively) (Figure A1-12). Therefore, use of the HWVP response spectra fulfills the requirements of performance category 3 response spectra (WHC-SD-SNF-DB-009).

A1.4.3.8.2 Volcanic Hazard Assessment. See Section 1.4.3.8.2 of the SNF Project FSAR for information about volcanic hazards applicable to all SNF Project facilities.

A1.4.3.8.3 Subsurface Stability. The CSB is constructed in flood sediments, the youngest sediments being approximately 13,000 years old. There are no areas of potential surface or subsurface subsidence, uplift, or collapse except for the low geologic deformation discussed in Section 1.4.3.6 of the SNF Project FSAR. With the exception of the loose, surficial, wind-deposited silt, soils are competent and form good foundations. Several geotechnical studies have been completed in and around existing tank farms. Liquefaction of soils beneath the tank farms is not a credible hazard because the water table is greater than 215 ft below ground surface. Liquefaction cannot occur in dry sediments.

A geotechnical investigation was performed at the site in 1989 to evaluate subsurface conditions for the design and construction of the HWVP. The results of that investigation are documented in Report 10805-385-016, *Report of Geotechnical Investigations for the Proposed Hanford Waste Vitrification Plant, Hanford Washington* (Dames and Moore 1989). The HWVP Project was canceled and the site is being used for the CSB. Subsurface conditions were investigated by using 17 borings ranging in depth from 20 to 100 ft at the site and in the surrounding area. Geophysical tests, including a series of downhole seismic tests, were conducted in boring VP-8, approximately 400 ft from the CSB. Borehole VP-15 (Figure A1-13) is at the CSB site.
The 17 geotechnical investigation borings were advanced without drilling fluid by driving a 6-in.-diameter, steel "core barrel" with a "split jar" downhole hammer. As the borings were advanced, a 6-in.-diameter steel casing was driven to prevent caving of soils above the sampling depth. Water was occasionally poured into the hole to prevent caving of the loose, dry soils and to aid in recovering samples. Slightly disturbed soil samples were taken at 5-ft intervals by driving a sampler using either a 705-lb hammer falling through a distance of 18 in. or a 825-lb hammer falling through a distance of 28 in. During the sampling process, resistance to penetration of the sampler, in blows per foot, was recorded.

The soil profile in the upper 100 ft consists essentially of the three strata shown in Figure A1-14. Borehole VP-14 is approximately 230 ft west of the CSB. The stratigraphy in VP-15 (Figure A1-13) is the same as at VP-14 (Figure A1-14). The dynamic soil properties of the site are summarized in Figure A1-15. More detailed descriptions of the geotechnical investigations and interpretations are found in Report 10805-385-016 (Dames and Moore 1989).

A1.5 NATURAL PHENOMENA THREATS

Table A1-1 (from WHC-SD-SNF-DB-009, Table 1) summarizes the natural phenomena design loads to be used for the design of safety-class structures, systems, and components (SSCs) for the CSB. The industry codes and standards used for the design, fabrication, and procurement of safety-significant SSCs are provided in Chapter A4.0. The design codes used for general service equipment follow industry-acceptable design codes and standards. These SSCs are designed to codes, standards, regulations, and orders as listed in Section 1.2 of the SNF Project FSAR. Each of these phenomena and the bases for the analysis values have been discussed in Section 1.4 of the SNF Project FSAR and Section A1.4.

A1.6 EXTERNAL HUMAN-GENERATED THREATS

This section identifies and investigates specific potential human-generated threats to CSB operation. Threats to the CSB from human activities that are not known at this time will be evaluated by the Unreviewed Safety Question process when they are identified.

A1.6.1 Aircraft Activity

See Section 1.6.1 and Figure 1-35 of the SNF Project FSAR for the methodology used in aircraft activity analysis. According to Assessment of Aircraft Impact on the Canister Storage Building and Cold Vacuum Drying Facility (Beary 1997), there are nine active airports within a 24-mi radius of the CSB. Eight of these are small airports that serve only general aviation aircraft. The Richland Airport, 21 mi southeast of the CSB, supports primarily general aviation operations, but two commercial freight carriers per day land and take off from the airport's

CSB = Canister Storage Building.

DOE-STD-3014-96, *Accident Analysis for Aircraft Crash into Hazardous Facilities*, provides the methodology to conservatively evaluate and assess the significance of aircraft crash risk on facility safety. The CSB meets the standard's guidelines for applicability because it contains enough radioactive material to be classified as a hazard category 2 nuclear facility according to the criteria established in DOE-STD-1027-92, *Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports*.

The approach used in DOE-STD-3014-96 includes the methodology to evaluate the frequency of aircraft impact into the facility. If the frequency of aircraft impact, calculated according to the methodology given in the standard, exceeds $10^6$/yr, the analysis proceeds to a consideration of whether those aircraft that have a high impact frequency could actually cause damage resulting in potential releases from the facility. Using that methodology, the frequency of aircraft impact into the CSB has been assessed (Beary 1997).

The methodology provided in DOE-STD-3014-96 considers two contributors to the overall frequency of aircraft crashes: (1) the frequency of crashes resulting from nearby airport activity (i.e., takeoffs and landings) and (2) the frequency of crashes during overflights of the facility.
Only runways within about 24 mi of the facility are included on the crash location probability tables given in Appendix B of DOE-STD-3014-96. Activities on runways at greater distances are not considered potential contributors to the frequency of a crash at the facility location for any category of aircraft. For calculating the frequency of crashes from aircraft flying over the site, DOE-STD-3014-96 provides DOE site-specific frequency data, in crashes per square mile per year centered at the site, for various classes of aircraft.

As stated above, there are 9 active airports within a 24-mi radius of the CSB (Beary 1997). All operations at these airports involve general aviation aircraft. The nearest airports serving commercial or military aircraft are the Desert Aire Airport, 19 mi west-northwest of the CSB, the Richland Airport, 21 mi southeast of the CSB, and the Tri-Cities Airport 29 mi southeast. Table A1-2 lists the 9 airports within 24 mi of the CSB and their distances from and orientation to the facility.

For nearby airports and the overflight activities, DOE-STD-3014-96 bases the calculation of frequency of aircraft crash into a facility on a "four factor formula" that considers the following:

1. The number of aircraft operations at nearby airports and overflying the site (N)
2. The probability that an aircraft will crash (P)
3. The conditional probability that, given a crash, the aircraft crashes into a one-square-mile area where the facility is located (f(x,y))
4. The site-specific effective area of the facility (Aₑ).

The formula is applied individually to each category of aircraft for both the nearby airports and the overflight activities. The overall frequency of aircraft crashes into the facility is the sum of the frequencies calculated for all categories of aircraft and for all operational modes.

The distance and orientation of the runways for the nine nearby airports were compared with tables in Appendix B of DOE-STD-3014-96 to identify the flight sources that contribute to the frequency of an aircraft crashing in a one-square-mile area in the vicinity of the CSB. The screening revealed that all of the runways are too far from the CSB to contribute to the crash frequency for nearby airport operations. Therefore, nearby airport activities do not contribute significantly to the overall frequency of an aircraft crash impacting the CSB.

Multiplying the NPf(x,y) factors by the effective impact areas gives the annual frequency of impact into the facility for each category of aircraft. These values are given in Table A1-3.
Table A1-3. Overflight Crash Frequencies for the Canister Storage Building.

</table>

The major contributor to the frequency of aircraft impact into the CSB is general aviation aircraft during in-flight operations. The overall frequency of aircraft impact from all sources is $9.8 \times 10^{-7}$/yr. DOE-STD-3014-96 specifies that if the total impact frequency, calculated according to the method it gives, is less than $10^{6}$/yr, the safety risk is below the level of concern. The calculated impact frequency for the CSB is very close to the evaluation guideline given in DOE-STD-3014-96. Therefore, for extra margin, a structural evaluation of safety-class structural features of the CSB was conducted.

General aviation was the only aircraft category that contributed significantly to the overall crash impact frequency. The selection of representative aircraft in the general aviation category was based on conversations with Federal Aviation Administration personnel at the Tri-Cities Airport. It was estimated that approximately 70% of the general aviation aircraft involved in airport operations at that airport were single-engine aircraft, with the remaining 30% dual-engine aircraft. An upper limit for size of general aviation aircraft was reported to be 12,500 lb.

Based on these data, a Cessna 172 single-engine aircraft and a dual-engine Beechcraft B200 were chosen to represent the general aviation category of aircraft for the structural analysis (Beary 1997). Using the methodology presented in Appendix C of DOE-STD-3014-96, an evaluation basis kinetic energy hazard was calculated to be $3.58 \times 10^{6}$ ft-lb. The evaluation determined that the energy generated by a Cessna 172 impact is less than the evaluation basis kinetic energy. Therefore, the analysis of safety structural features was carried out for only the impact of the Beechcraft 200 aircraft.
The safety-class structural features of the CSB are the operating deck, the air intake structure for vault ventilation, and the exhaust stack. The operating deck is a horizontal structure. The analysis conservatively assumes that the missile that impacts the operating deck falls from a direct vertical position. The vertical impact velocity of the Beechcraft 200, calculated from the evaluation basis kinetic energy and the weight of the aircraft, is 140.4 ft/s. The critical missile selected was the Beechcraft 200 engine.

The effective fly-in area of the stack was included as a separate entity in the summation of the total $A_{ef}$ for the CSB. The effective stack skid area is covered by an allowance in the building dimensions. The values of WS, cot $\phi$, and $S$ are given in tables B-16, B-17 and B-18 of DOE-STD-3014-96 for the categories of aircraft. For the military aviation categories, different values for the mean of cot $\phi$ and the mean skid distance are given for takeoff and landing. DOE-STD-3014-96 recommends using the takeoff values for the calculations involving nonairport operations. Table A1-4 presents the calculated effective areas for the CSB for all the categories of aircraft.

Table A1-4. Results of Effective Area Calculations for the Canister Storage Building.

CSB = Canister Storage Building.
cot $\phi$ = mean of the cotangent of the aircraft impact angle.
$S$ = aircraft skid distance.
WS = aircraft wingspan.
For the air intake structure, an upright, reinforced concrete structure 2 ft thick, the analysis assumes that the missile path is horizontal before impact. The horizontal impact velocity, calculated from the evaluation basis kinetic energy and the weight of the aircraft, is 74.9 ft/s.

The analysis (Beary 1997) assumes that the velocity of the engine after it is detached from the plane is equal to the velocity calculated for the plane. The structural analysis shows that both the operating deck thickness, 5 ft of reinforced concrete, and the thickness of the air intake structure's vertical wall are more than adequate to withstand the impact of the evaluation basis aircraft missile.

See Section 1.6.1 of the SNF Project FSAR for an analysis of the risk to the CSB from helicopters.

A1.6.2 Other Transportation Accidents

See Section 1.6.2 of the SNF Project FSAR for a discussion regarding guidance for evaluating transportation accidents.

For the purposes of this evaluation, the CSB critical plant structures of concern, which are similar to those in a nuclear power plant that are required for safe plant operation and shutdown, are the below-grade structure (i.e., the base slab, interior and exterior vault walls, and the intake and exhaust plenums), operating deck, and the intake and exhaust foundation bases. These are all reinforced concrete structures that are designed to withstand the tornado pressure drop of 0.9 lb/in². It is reasonable to assume that they would also withstand a 1 lb/in² overpressure (see Section 1.6.2 of the SNF Project FSAR).

The CSB operating shelter is not considered a critical plant structure relative to the need to maintain the integrity of its shell as it is not credited for limiting offsite releases. However, it is also designed to withstand the tornado differential pressure of 0.9 lb/in² as failure of the shelter may adversely impact safety-class SSCs.

NRC Regulatory Guide 1.91, Evaluation of Explosions Postulated to Occur on Transportation Routes near Nuclear Power Plants, defines the safe distance, R, in meters, as

\[ R \geq 18 \times W^{0.6} \]

where

\[ W = \text{kg of TNT}. \]
From this correlation, the safe distances for the truck and railcar capacities listed in NRC Regulatory Guide 1.91 are as follows:

- 1,683 ft for a truck (50,600 lb capacity)
- 2,316 ft for a single railcar (60,000 kg capacity).

Highway 240 is 5 mi from the CSB. The nearest railroad not controlled by DOE is at the 1100 Area located approximately 20 mi south of the CSB. DOE currently owns and controls the railroad north of this point as discussed in Section 1.3.1 of the SNF Project FSAR. At these distances, explosive shipment on roads and railroads not controlled by DOE do not represent a threat to the CSB.

The main roadway and railroad controlled by DOE that pass nearest to the CSB are Route 4, which passes 1,155 ft to the west, and the mainline of the Hanford Railroad, which passes 9,000 ft to the north. The mainline of the Hanford Railroad is outside the above-listed safe distance, but Route 4 is not.

NRC Regulatory Guide 1.91 allows for a risk assessment when the safe distance criterion is not met. If the exposure rate is less than $10^7$ events/yr by best estimate analysis or less than $10^6$ events/yr by conservative analysis, then the risk of damage being caused by explosion is sufficiently low. The exposure rate, $r$, is defined as follows:

$$r = n \times f \times s$$

where

- $n$ = explosion rate for the substance and transportation mode in question, per kilometer
- $f$ = frequency of shipment for the substance in question in shipments per year
- $s$ = exposure distance in km. This is the length of the roadway that would be within the safe distance of any portion of the facility. It is a function of the building dimension parallel to the roadway, the setback of the building from the roadway, and the calculated safe distance, $R$.

H&R 522-1, Recommended Onsite Transportation Risk Management Methodology, concludes that a Hanford Site truck accident rate of $5.5 \times 10^{-8}$ accident/mi should be used for risk analysis. This study was performed for shipment of radioactive materials and took credit for risk reduction factors that would be associated with such shipments. These included driver participation in special safety programs, the road conditions north of the Hanford Site Wye Barricade, and making shipments during off-peak traffic hours. A risk reduction factor of 40 was obtained for Hanford Site two-lane roads such as Route 4 (H&R 522-1). This risk reduction factor also would be appropriate for shipment of large quantities of explosive materials. For this analysis, it is conservatively assumed that the conditional probability that an explosion will result...
as a consequence of an accident is 0.1. Therefore, the explosion rate, \( n \), is \( 5.5 \times 10^{-9} \) explosions/mi.

There are currently no routine shipments of explosives on Route 4 of a quantity that would place the CSB at risk. However, such shipments could occur during the facility's lifetime. For this analysis, the number of such shipments per year, \( f \), was conservatively assumed to be six. The exposure distance, \( s \), for the CSB was calculated to be 0.51 mi based upon a building length of 257 ft, a setback from Route 4 of 1,155 ft, and a safe distance of 1,683 ft.

With these data, the exposure rate, \( r \), was conservatively calculated to be \( 4.36 \times 10^{-6} \) events/yr. As this is less than \( 10^{-4} \) events/yr, no additional analysis is required.

Based upon the above analyses, it is concluded that explosive shipments on roadways and railways, controlled and not controlled by DOE, do not represent a risk to the CSB.

A1.7 NEARBY FACILITIES

Accidents in certain facilities in the 200 East Area (Figure A1-2) have the potential to impact the CSB facility and its operations, as discussed in Section A1.7.1. Conversely, certain nearby facilities can potentially be affected by accidents in the CSB, as discussed in Section A1.7.2.

Threats to the CSB from nearby facilities that are not known at this time will be evaluated using the Unreviewed Safety Question process when they are identified. This also applies to those activities that have been identified but that may change significantly in terms of a potential increased risk to the facility.

A1.7.1 Potential Effects from Nearby Facilities

Potential hazards to the CSB from onsite or offsite hazardous operations or facilities are examined under three general classifications:

- Nonreactor nuclear and nonnuclear industrial facilities within 5 mi of the CSB including all activities conducted in and near the 200 East Area
- Nuclear reactors within a 50-mi radius of the CSB
- Military activities.

Events at a nearby facility that challenge CSB habitability will be defined in the CSB's emergency response plan and emergency response procedures (i.e., notifications, take-cover, emergency
shutdown, excavation). See Section A15.4.6 and Section 15.4.6 of the SNF Project FSAR for additional information on protective actions.

A1.7.1.1 Hazards to the Canister Storage Building from Nonreactor Nuclear Facilities. Facilities currently operating, recently operating, or with potential to operate at the 200 East and 200 West Areas were screened along with the area between the 200 East and 200 West Areas. For this FSAR, selected facilities were those believed to pose the most risk to safe operations at the CSB. Safety analysis reports and accident analyses prepared for these facilities were reviewed to determine possible hazards, such as radiological doses to personnel resulting from direct radiation, release of airborne radioactivity, or exposure to toxic chemicals.

Considered, but not included in this FSAR, were the 200 East Area Burial Grounds, the Liquid Effluent Retention Facility, and the 200 Areas Effluent Treatment Facility in the 200 East Area. In the 200 West Area, the T Plant, U Plant, Reduction-Oxidation Plant, and the 222-S Laboratory were considered, but not included. These facilities have insufficient radiological or toxicological inventories in a dispersible form to represent a risk to the CSB operation.

The specific facilities discussed here include the Interim Storage Area (ISA), Plutonium-Uranium Extraction (PUREX) Facility, the Grout Treatment Facility, B Plant, the Waste Encapsulation and Storage Facility (WESF), the River Protection Project (RPP) facilities, 242-A Evaporator/Crystallizer, Plutonium Finishing Plant (PFP), and the Low-Level Waste Disposal Site. The worst-case scenarios for each of these facilities may challenge CSB habitability. Requirements for safely performing such actions are addressed in the CSB emergency response procedures. During much of the CSB's 40-year life, the facility will not be particularly sensitive to these hazards as it will be simply a storage facility and will require little human supervision.

200 Area Interim Storage Area. The 200 Area Interim Storage Area (200 Area ISA) provides for the interim storage of non-defense reactor SNF housed in aboveground dry cask storage systems. The 200 Area ISA is located immediately to the west of the CSB.

The 200 Area ISA is a passive storage facility designed to hold 60 storage containers of SNF for up to 40 years. Potential hazards associated with the unloading and storage of these containers are the release of radioactivity, loss of shielding, or loss of configuration control for criticality. Seven design basis accidents were identified and analyzed to evaluate the potential consequences of these hazards to onsite workers and the public. The seven design basis accidents analyzed are: (1) cask handling/drop, (2) mobile crane mechanical failure, (3) cask tip over, (4) fuel rod rupture, (5) seismic event, (6) tornado wind, and (7) fire.

In all but one case, the consequences for all three fuel types were prevented by the passive design features of the storage systems. In the case of the mobile crane mechanical failure, credit
was not taken for the integrity of the Neutron Radiography Facility TRIGA\textsuperscript{1} storage casks and an unmitigated release was assumed. The consequences for this accident were found to be significantly below both the offsite limits and the onsite guidelines. However, if CSB habitability is challenged by an event at the 200 Area ISA, the appropriate actions (i.e., notification, take-cover, emergency shutdown, evacuation) will be defined in the CSB's emergency response procedures.

**Plutonium-Uranium Extraction Facility.** The PUREX Facility is located in the 200 East Area, 1.5 mi east-southeast of the CSB. It is the most recently constructed of the irradiated fuel separation facilities and was used for processing N Reactor fuel. The principal product was a solution of plutonium nitrate that was transferred to the PFP for further processing. Another product was uranyl nitrate solution, which was processed at the Uranium Oxide Plant. The facility has been cleaned out to the extent practical and is in transition to surveillance and maintenance mode awaiting a final decision on disposal of the facility. The processing canyon area and the tunnels still contain airborne contamination from previous processing activities. If the status of PUREX changes (i.e., active decontamination and decommissioning), potential impacts to the CSB will be re-evaluated.

The bounding accident for the PUREX facility in the surveillance and maintenance mode is a seismic event that releases a portion of the residual contamination in the ventilation gallery above the canyon. This accident would not impair the ability of CSB personnel to perform required safety actions because the quantity of material available for release is small.

**Grout Treatment Facility.** The Grout Treatment Facility is located on the eastern perimeter of the 200 East Area approximately 2.7 mi east of the CSB. The Grout Treatment Facility combines tank wastes with grout-forming solids to form a grout slurry. The waste feed stream constituent of this slurry consists of low-level fractions of radioactive wastes. The slurry ultimately is pumped into near-surface, concrete-lined vaults for permanent disposal. Only one vault has been filled with grout (completed in 1987) even though additional vaults have subsequently been designed and constructed. This facility is currently not operational but has the potential to operate again in the future.

If the Grout Treatment Facility resumes operation, the maximum credible accident release postulated involves a double-ended jumper leak on the grout feed line with the pit cover blocks left off. This postulated release would spray low-level waste as an aerosol for a maximum period of 24 hours before detection by a visual inspection. If the status of the Grout Treatment Facility changes (i.e., it begins operations), potential impacts to the CSB will be re-evaluated.

**B Plant Facility.** The B Plant is located approximately 1,500 ft east of the CSB. Until 1952, B Plant was operated as a fuel separation facility. In 1968 it was converted to a waste fractionation plant to remove $^{137}$Cs and $^{90}$Sr from radioactive waste streams. This had the effect

\textsuperscript{1}TRIGA is a registered trademark of Gulf General Atomics Company, Incorporated.
of reducing heat loads in the double-shell tanks. The B Plant currently is deactivated and in
transition to surveillance and maintenance mode.

The worst-case credible accident at B Plant is a postulated flooding of the 291-B high-
efficiency particulate air filters and a subsequent hydrogen explosion. According to
HNF-SD-WM-BIO-003, *B Plant Basis for Interim Operation*, the unmitigated dose to the
collocated worker at 100 m from B Plant was calculated to be 952 rem and the maximum offsite
dose to be 0.368 rem at the Columbia River, 27 km east of B Plant. Systems and administrative
controls are in place at B Plant to mitigate the releases. However, this scenario has the potential
to require evacuation of CSB operating personnel. As stated in Section A1.7.1, if CSB
habitability is challenged by an event at a nearby facility, such as B Plant, the appropriate actions
(i.e., notifications, take-cover, emergency shutdown, evacuation) will be followed as defined in
the CSB’s emergency response procedures.

**Waste Encapsulation and Storage Facility.** The WESF is distinct from B Plant, even
though it is located on the west end of B Plant and shares a common wall with the plant.
Historically WESF was involved in converting the cesium and strontium removed from waste
streams at B Plant into cesium chloride and strontium fluoride salts. These materials then were
encapsulated in double-walled metal containers and stored in a water-filled cooling basin.
Strontium fluoride and cesium chloride capsules are still being stored in this fashion at WESF, but
no new capsules are being produced.

According to HNF-SD-WM-BIO-002, *Waste Encapsulation and Storage Facility Basis
for Interim Operation*, the worst-case credible accident at WESF postulated involves a loss of
cooling water in the storage pool with a subsequent rupture of capsules and aerosolization of the
capsule contents. The maximum dose to the public receptor at the near bank of the Columbia
River is calculated to be 9 rem. The unmitigated dose at 100 m is 1,700 rem from inhalation and
32 rem from radiation shine. Systems and administrative controls are in place at WESF to
mitigate the releases. However, this is an accident that has the potential to require evacuation of
CSB personnel. As stated in Section A1.7.1, if CSB habitability is challenged by an event at a
nearby facility, such as the WESF, the appropriate actions (i.e., notifications, take-cover,
emergency shutdown, evacuation) will be defined in the CSB’s emergency response procedures.

**River Protection Project.** The RPP facilities include 149 single-shell tanks and 28 double-
shell tanks for the storage of liquid radioactive mixed waste solutions from the Hanford Site’s
chemical processing plants, and associated support facilities that include holding tanks, transfer
lines, and valve pits. The RPP facilities are located in both the 200 East and 200 West Areas.

The RPP facilities nearest to the CSB are the B, BX, and BY Tank Farms, located
approximately 0.8 mi northeast of the CSB. Each of the farms has 12 single-shell tanks. The
B and BX single-shell tanks are rated at 500,000 gal each, and those in the BY Tank Farm are
rated at 750,000 gal each. In addition, there are four 55,000-gal tanks in the B Tank Farm, and a
double-contained receiver tank serves the BX and BY Tank Farms. The tanks in these tank farms
were constructed between 1943 and 1949.
According to HNF-SD-WM-BIO-001, *Tank Waste Remediation System Basis for Interim Operation*, the worst-case accident postulated for the RPP facilities is the inadvertent pumping of liquid waste through an open valve into a valve pit and consequent overflow of the pit, which results in an unmitigated dose of 330 rem at 100 m. The postulated cause of the accident is misrouting of waste during transfer operations. Waste transfers into Hanford Site single-shell tanks are no longer allowed. Most of the tanks in these three farms have been interim stabilized, meaning that as much of the liquid has been removed from the waste as practicable, leaving solids with a minimum liquid content. Administrative controls are in place at the tank farms for early detection and mitigation of a release caused by mistransfer during waste transfer operations. Also considered was a flammable gas deflagration in a tank that could result in an unmitigated dose of 650 rem at 100 m. However, because of the site distance (0.8 mi) and the flammability controls, this scenario would not significantly impact the CSB. Even though the cross-site transfer line passes near the CSB, a leak from it is not considered a credible event because of its safety-class, encased-pipe design (HNF-SD-WM-BIO-001, Addendum 2).

If there were a release from an RPP accident, the immediate action for CSB would be to respond to the take-cover sirens. Depending on the specific conditions, follow-up actions could include emergency shutdown and evacuation per emergency response procedures.

Eventual retrieval of the tank wastes for final disposal is planned for the future. Activities involving waste removal, and decontamination and decommissioning of the tanks, will be evaluated for their effect on the CSB safety analysis at that time.

**242-A Evaporator/Crystallizer.** The 242-A Evaporator/Crystallizer is located 1.5 mi east of the CSB. The 242-A Evaporator/Crystallizer uses evaporative concentration to reduce the volume of liquid wastes (low-heat-generating tank wastes). The concentrated slurry, reduced in volume, is transferred and stored in an underground waste storage tank. The process condensate is routed to the Liquid Effluent Retention Facility for storage and treatment at the Effluent Treatment Facility.

The worst-case accident scenario reported in HNF-SD-WM-SAR-023, _242-A Evaporator Safety Analysis Report_, involved a release from a spray leak in the pump room and a failure of the exhaust system's high-efficiency particulate air filters. Although this event is considered extremely unlikely, the event was analyzed for safety-class determinations at the 242-A Evaporator/Crystallizer. The release from a spray leak is comprised of a liquid component and an aerosol component. The analysis assumed that the liquid component would remain in the pump room; however, the aerosol component would be released to the environment via the K1 exhaust stack. The maximum unmitigated dose consequence to the onsite individual at 100 m from the evaporator would be 14 rem committed effective dose equivalent. Such a scenario might require action to prevent exposure of CSB operators to the release (i.e., take cover). As stated in Section A1.7.1, if CSB habitability is challenged by an event at a nearby facility, such as the 242-A Evaporator/Crystallizer, the appropriate actions (i.e., notifications, take-cover, emergency shutdown, evacuation) will be defined in the CSB's emergency response procedures.
Plutonium Finishing Plant. The PFP is located near the western boundary of the Hanford Site in the 200 West Area, 5.0 mi west of the CSB. It converts plutonium nitrate solution to plutonium metal and performs plutonium handling and storage operations. Contaminated liquid waste streams from the PFP are routed to the tank farms. This facility is in transition from its previous special nuclear material processing mode to preparation for decontamination and decommissioning.

During its previous mission of processing special nuclear materials, plutonium-bearing miscellaneous materials were produced and still exist in the facility. These include pure and mixed oxides, fluorides, oxalates, silicates, and organic-based sludge and residues. The current PFP missions are defined in WHC-SD-CP-SAR-021, Plutonium Finishing Plant Final Safety Analysis Report, as (1) receiving, sorting, storing, and shipping of special nuclear material, (2) stabilizing the reactive materials that remain in the plant, (3) providing laboratory support for other Hanford Site facilities, (4) handling radioactive and mixed waste, and (5) shutdown facility surveillance. As part of the materials stabilization activities, preparations are being made for startup of a calcining operation. Revisions to the safety analysis report to include this operation are in progress.

The bounding accident for the PFP is a seismic event with a horizontal ground acceleration of 0.2 g. The unmitigated consequences for this event are calculated to be 15.2 rem committed effective dose equivalent at the nearest occupied facility in the worst-case direction, 1,800 ft west-northwest of PFP, and 0.3 rem at the Site boundary, 7.8 mi west. Because of the distance separating the CSB from the PFP, the release would not adversely affect CSB operations and would not require evacuation of CSB personnel.

Low-Level Waste Disposal Site. The commercial low-level waste disposal site operated by U.S. Ecology, Inc., is the only non-DOE industrial facility within 5 mi of the CSB (Figure A1-1). The disposal site is on land leased from Washington State located 1 mi southwest of the CSB. The low-level waste is buried in lined containers. Monitoring of groundwater and vegetation is performed as required by the facility's NRC operating license and environmental impact statement. This facility is not likely to have a significant accidental airborne radioactive release that could adversely affect the CSB.

A1.7.1.2 Hazards to the Canister Storage Building from Nonnuclear Hanford Site Facilities. A number of nonnuclear industrial facilities operating in the 200 Areas pose the potential for accidental fires, explosions, or releases of toxic fumes. These include the Essential Materials Warehouse (Building 275-EA), oil and paint storage buildings, fabrication shops, gas cylinder storage buildings, the spare parts and electrical warehouse, B Plant storage buildings, maintenance facilities, gasoline service stations, and the powerhouse complexes in each area (284-E and 284-W). Considering its location, Building 275-EA may have the potential to pose a risk to CSB operations and personnel and is detailed below. The 2,000-lb chlorine bottles located at Building 283-E have been removed and are no longer considered a hazard to the CSB.
Building 275-EA. Building 275-EA, the Essential Materials Warehouse, was constructed in 1955 and is located 1.5 mi east-southeast of the CSB. It is classified as an unprotected wood frame structure and is susceptible to collapse as a result of an external event (e.g., earthquake, wind, snow, or ash loading) or an internal event (e.g., forklift collision with a bearing wall, or fire). Building 275-EA currently stores more than 100 different types of potentially hazardous solids and liquids including acids, bases, solvents, fluorides, pesticides, and herbicides. Radioactive materials are not stored in this building.

The worst-case chemical release postulated in the safety analysis occurs following a building collapse whereupon 2,450 kg of 1,1,1-trichloroethane evaporates under adverse atmospheric conditions. The maximum concentration at the PUREX Facility gatehouse and environs is calculated to be 187 ppm, which is below the time-weighted average threshold limit value of 350 ppm (i.e., the concentration for this chemical that an industrial worker may be repeatedly exposed to without adverse effects) as given in Threshold Limit Values and Biological Exposure Indices for 1989-1990 (ACGIH 1989). Concentration levels at the CSB would be significantly less than this because of the 1.5-mi separation.

A1.7.1.3 Hazards to the Canister Storage Building from Nuclear Reactors. Three recently shut down reactors, the N Reactor, Fast Flux Test Facility (FFTF), and the Critical Mass Laboratories, no longer pose a threat to the CSB. The N Reactor is undergoing decontamination and decommissioning, the FFTF is in standby mode and may operate again in the future, and the Critical Mass Laboratories in the 200 East Area north of the PUREX Facility are currently being used as tank farm office areas.

UNI-M-90, N-Reactor Updated Safety Analysis Report, describes the N Reactor as a 4,000 MW, dual-purpose, pressure tube, light-water cooled, graphite-moderated reactor. It is located in the 100 N Area and is about 5.5 mi from the nearest northwest Hanford Site boundary. The N Reactor began operating in 1964 producing plutonium for the defense program and steam for electrical power generation. It was shut down in 1987 for safety improvements and then subsequently defueled and placed in cold standby in 1988. It is currently being decontaminated and decommissioned.

It is planned to remove the reactor building structures for the production reactors down to the reactor block and then cocoon the reactor block for 75-year safe storage.

The FFTF is a 400 MW, sodium-cooled, mixed-oxide-fueled, reactor that is currently in standby status with the fuel removed from the core. Sodium is kept circulating in the loops at 400 °F until a decision is made to either restart the reactor for future missions or decommission it. The FFTF is located in the 400 Area and is approximately 4.5 mi from the nearest Hanford Site boundary, which is to the east of the facility (Figure A1-1). Spent FFTF fuel packaged in double-walled casks with an inert gas cover is stored in the Interim Storage Area at the 400 Area.

According to HEDL-TI-7500-FSAR, Fast Flux Test Facility (FFTF) Final Safety Analysis Report, the bounding accidents for the FFTF in its current status involve (1) a liquid sodium spill
and (2) damage to a cask and its contents in the Interim Storage Area. The sodium spill scenario postulates a spill of 180,000 lb of activated liquid sodium. The 2-hour dose at 1.5 mi from the FFTF is 0.015 mrem. The dose at 4.5 mi from the facility for a 30-day exposure is 0.26 mrem. The maximum credible cask release at the Interim Storage Area postulated cracking in 100% of the fuel pins of one cask, with crushing and exposure of 1% of the fuel material. The dose at 100 m from the facility was 4.5 rem, the maximum dose at the Site boundary was 4.0 mrem. Because of distance from the CSB, these accidents do not pose a hazard to CSB operations.

The only operating nuclear reactor on the Hanford Site is Washington Nuclear Plant (WNP)-2 operated by Energy Northwest. The location of this reactor is shown in Figure A1-1. WNP-2 is an operating commercial nuclear power plant using a boiling-water reactor steam supply system. According to Docket No. 50-397, Final Safety Analysis Report, Washington Nuclear Power Plant No. 2, the design power level was increased to 3,486 MW in 1995. The reactor was designed by the General Electric Company and is designated as a BWR/5 with a Mark II containment.

By the requirements of Title 10, Code of Federal Regulations, Part 100, "Reactor Site Criteria" (10 CFR 100), the following are the maximum allowable doses for WNP-2:

<table>
<thead>
<tr>
<th>Location</th>
<th>Duration</th>
<th>Whole body dose</th>
<th>Thyroid</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exclusion area boundary</td>
<td>2 hours</td>
<td>250 mSv (25 rem)</td>
<td>3,000 mSv (300 rem)</td>
</tr>
<tr>
<td>Low population zone</td>
<td>30 days</td>
<td>250 mSv (25 rem)</td>
<td>3,000 mSv (300 rem)</td>
</tr>
</tbody>
</table>

The exclusion area boundary for WNP-2 is 1,950 m and the low population zone distance is 3 mi. The CSB is located approximately 11 mi from WNP-2. Using the atmospheric diffusion guidance provided in NRC Regulatory Guide 1.3, Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss of Coolant Accident for Boiling Water Reactors, to estimate the dose reduction as a function of distance, it was determined that the 2-hour and 30-day doses at the CSB would be reduced by a factor of 20. Review of the site-specific meteorology provided in the WNP-2 Final Safety Analysis Report (Docket No. 50-397) shows there would be no significant reduction for the change in wind direction. The factor of 20 reduction for distance would result in a whole body dose of 12.5 mSv (1.25 rem) and a thyroid dose of 150 mSv (15 rem).

The expected dose that would be received at the CSB should a loss of coolant accident occur would be significantly less than this. NRC Regulatory Guide 1.3 requires an assumption that 25% of the radioactive iodine and all of the noble gases are released to the containment. In fact, the emergency core cooling system would prevent most of these releases as little fuel damage would occur as a result of the loss of coolant accident.
Energy Northwest plans to add an independent spent fuel storage installation on their leased property. The independent spent fuel storage installation would be licensed following the requirements in 10 CFR 72. According to 10 CFR 72.106, an individual located at the installation's controlled area boundary shall not receive a dose greater than 5 rem. At the CSB, this would result in a dose not exceeding 0.25 rem.

A1.7.1.4 Hazards to the Canister Storage Building from Industrial Facilities off the Hanford Site. There are no oil or gas pipelines in the vicinity of the CSB. The nearest major natural gas pipeline to the CSB site is about 29 mi away. A 20-in. gas transmission line of the Northwest Pipeline Corporation is located east and essentially parallel to U.S. Highway 395 between Pasco and Ritzville, Washington. According to Memo 042AGH.96, Contact with Local Organizations to Support CSB SAR Chapter I (Hosler 1996), a second pipeline system consisting of parallel 36-in. and 42-in. lines, owned by Pacific Gas Transmission Company, passes through Wallula, approximately 33 mi from the site. These distances eliminate any potential hazard to plant operations from a natural gas fire or explosion.

The nearest petroleum product storage tanks are located 38 mi from the site. These are 23-million-gallon capacity tanks at the Chevron Pipeline Company, and 21-million-gallon capacity tanks at the Tidewater Barge Lines. There are no plans to use a third petroleum storage facility at the Port of Pasco (Hosler 1996).

Located within the Richland city limits is the Siemens Power Corporation's Richland Engineering and Manufacturing Facility. All operational steps for the manufacture of nuclear fuel for light water reactors are conducted within the facility including the conversion of UF₆ to UO₂. According to Siemens Power Corporation Richland Engineering and Manufacturing Facility Emergency Plan (Siemens 1994), the most limiting postulated accident at this facility is a fire in the UF₆ cylinder storage area. Fusible plugs in twelve cylinders are assumed to melt causing the release of UF₆ that reacts with moisture in the air to form UO₂F₂ (solids in the form of uranyl fluoride hydrates) and 4HF (as hydrogen fluoride gas). UF₆ is a radiological hazard by inhalation. However, UF₆ is also a concern because of its chemical toxicity and the associated HF that can cause skin and eye burns and lung impairment. This accident results in a dose that exceeds 10 mSv (1 rem) out to 1.2 mi. The accident also exceeds the Emergency Response Planning Guideline-2 (ERPG) toxicology limits out to 8.8 mi (ACGIH 1989). The ERPG-2 is the maximum airborne concentration below which it is believed that nearly all individuals could be exposed for up to one hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair their abilities to take protective action. The CSB is located 19 mi from the Siemens facility. Therefore, CSB operators would not be placed at risk by an accident at the Siemens facility.

No other nonnuclear industrial facilities or operations have been identified that may impact CSB operations.

A1.7.1.5 Hazards to the Canister Storage Building from Military Facilities. The Yakima Training Center is a subinstallation under the command of Fort Lewis (Tacoma, Washington).
Further information is given in the Final Environmental Impact Statement — Ft. Lewis Military Installation (DOA 1979). The southeastern boundary of the Yakima Training Center is located about 23 km (14 mi) from the CSB (see Figure A1-16). The Yakima Training Center is used for military maneuvers and weapons training and is the only significant military activity in the vicinity of the Hanford Site.

The only weapon currently in use at the Yakima Training Center known to present a hazard to the Hanford Site is the Multiple Launch Rocket System (MLRS). With a range of approximately 16 mi, the MLRS could potentially impact the CSB site. However, the MLRS is only fired from the perimeter of the Yakima Training Center into a centrally located impact zone. The safety fan for the MLRS is shown in Figure A1-16. The MLRS is fired away from the Hanford Site and is only fired with dummy warheads. Given this information, additional safety features, and the administrative controls in place at the Yakima Training Center, a weapons accident having an impact on the Hanford Site is very improbable.

A more probable hazard to Hanford Site facilities is a scenario in which a fire started within the Yakima Training Center boundary spreads to the Hanford Site. Exploding artillery shells, sparks from tracked vehicles or other machines, and careless smoking by troops might start brush fires that, under adverse meteorological conditions, could spread rapidly beyond the Yakima Training Center boundaries. The hazards associated with range fires were considered with other hazards in the hazard analysis and in Chapter A3.0 and were found to not impact the CSB adversely.

A1.7.2 Potential Effects to Nearby Facilities

Potential CSB accidents are discussed in Section A3.4.2. CSB hazard assessments, as discussed in Section A15.4.2, will use the analyses of these potential accidents to help develop the CSB emergency response plan and procedures, as discussed in Section 15.4 of the SNF Project FSAR and Section A15.4.

The hazard assessments for emergency planning for the CSB will characterize the potential consequences to workers, the public, and the environment for each postulated accident. The hazard assessments will also determine the emergency planning zone as well as the emergency class, protective actions, and the observable indications and criteria (emergency action levels) corresponding to the range of potential accidents.

The hazard assessments will also include information to determine potential impacts to nearby facilities. This information will be made available to nearby facilities for determination of appropriate actions to be included in their emergency response plans and procedures. Information contained in CSB emergency response plans and procedures will also include notifications, evacuation potential, operations impacts, radiation threats to workers, and other information relevant to nearby facilities. Prompt and accurate emergency notifications will be performed in accordance with DOE O 151.1, Comprehensive Emergency Management System.
DOE O 232.1A, *Occurrence Reporting and Processing of Operations Information*; applicable federal, state, or local requirements; and special agreements with offsite agencies or tribal governments, to mitigate the consequences and to protect the health and safety of workers, the public, and the environment.

A2.0 FACILITY DESCRIPTION

A2.1 INTRODUCTION

This chapter provides facility and operating descriptions for the Canister Storage Building (CSB) (Building 212H) to support assumptions used in the hazard and accident analyses. These descriptions focus on all major facility features necessary to understand the hazard analysis and accident analysis, not just safety structures, systems, and components (SSCs). The level of detail used in this chapter is based on the significance of the preventive and mitigative features identified and the degree of complexity. The descriptions provide an understanding of the facility and processes in sufficient detail that a general understanding of the facility can be achieved without extensive consultation of the references cited. Chapter 2.0 of the Spent Nuclear Fuel (SNF) Project Final Safety Analysis Report (FSAR) provides an overview description of the SNF Project facilities and processes. This chapter provides a description of the CSB systems and processes but does not include information at the level of functional requirements and performance criteria because this information is provided in Chapter A4.0 for the CSB safety SSCs. The CSB systems and processes may be changed or modified as needed using the Unreviewed Safety Question process while protecting the key functions described in Chapter A4.0. Chapter A2.0 description changes of the systems and processes will be included in annual updates to the FSAR if not required to be submitted prior to implementation. This chapter reflects CSB design as of the date of this FSAR.

Chapter A3.0 describes the hazards, accident analyses, and safety classifications of the SSCs for the CSB, and Chapter A4.0 describes safety-class and safety-significant SSCs in greater detail and also identifies safety controls (the Technical Safety Requirements).

A2.2 REQUIREMENTS

The requirements that establish the basis for design are identified in Section 2.2 of the SNF Project FSAR. The following list describes how these requirements are applied to the CSB and includes additional requirements that apply to the CSB.

- Title 10, Code of Federal Regulations, Part 835, “Occupational Radiation Protection” (10 CFR 835). The shielding requirements for the CSB shall meet the ALARA (as low as reasonably achievable) guidelines established in this document. The overall source term is derived from the radionuclide composition of the SNF contained in a nominal multi-canister overpack (MCO); however, local shielding is provided for a single maximum MCO as described in HNF-S-0425, Performance Specification for the Spent Nuclear Fuel Canister Storage Building.

• DOE Order 5400.1, *General Environmental Protection Program*. This order establishes the U.S. Department of Energy (DOE) environmental protection program.

• DOE Order 5480.7A, *Fire Protection*. This order provides design criteria for fire protection systems for new DOE facilities. In particular, Section 9.b(3) of this order requires automatic fire suppression systems in all new structures with more than 5,000 ft² of floor area or with a maximum possible fire loss greater than $1.0 million. Because of the detrimental effects of inadvertent sprinkler activation on the SNF in the MCOs and the low quantities of combustible materials present, the contractor has requested and received an exemption from this order for the operating area over the vault, the load-in/load-out area, and the sampling/weld area. The exemption is documented in Letter 96-SFD-320, *Contract No. DE-AC06-96RL13200 — Project W-379, Spent Nuclear Fuel Canister Storage Building (CSB) Review and Approval of Exemption and Deviation Requests from Automatic Fire Sprinkler/Fire Suppression System Requirements* (Sellers 1996).

• DOE Order 5480.28, *Natural Phenomena Hazards Mitigation*. This order establishes mitigation requirements for natural phenomena hazards (NPHs) and target probabilistic performance goals based on the facility performance category. These requirements are identified in WHC-SD-SNF-DB-009, *Canister Storage Building Natural Phenomena Hazards*. Additional discussion of the NPH performance criteria is provided in Section 1.5 of the SNF Project FSAR.

• DOE Order 6430.1A, *General Design Criteria*. The main reference standards and guides for facility design are presented in Division 13, “Special Facilities.” DOE Order 6430.1A, Section 1320, “Irradiated Fissile Material Storage Facilities,” contains additional requirements for irradiated fissile material storage facilities (IFMSF). In particular, paragraph 1320-4, “Special Design Features,” requires a designed safety-class passive cooling air system that ensures an acceptable temperature for the stored material. HNF-4742, *Canister Storage Building Compliance Assessment DOE Order 6430.1A, General Design Criteria*, documents compliance to DOE Order 6430.1A. All future changes to the facility will be screened against the matrix using the Unreviewed Safety Question process to determine whether the proposed change affects any design aspect relied upon to show compliance to the order.

In Letter 95-SFD-167, *Implementation of K Basins Spent Nuclear Fuel Project (SNFP) Regulatory Policy* (Sellers 1995), DOE established the requirement for new SNF Project facilities to achieve “nuclear safety equivalency” to comparable U.S. Nuclear Regulatory Commission
(NRC)-licensed facilities. The SNF Project identified the NRC requirements that were to be met
during design and construction only in addition to existing applicable DOE requirements to
establish nuclear safety equivalency. These NRC requirements and the process used to identify
them are documented in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward,
Additional NRC Requirements*, and WHC-SD-SNF-DB-009.

Title 10, *Code of Federal Regulations*, Part 72, “Licensing Requirements for the
Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste” (10 CFR 72),
Subpart F, “General Design Criteria,” and Subpart H, “Physical Protection,” provide general
design criteria for a SNF storage facility. These criteria are identified in HNF-SD-SNF-DB-003
and are incorporated into the design criteria.

HNF-SD-SNF-DB-003 and WHC-SD-SNF-DB-009 established the design requirements to
be met for the CSB to achieve NRC equivalency based on 10 CFR 72. This rule is used for the
licensing of independent SNF storage installations. Section 72.3, “Definitions,” defines SSCs that
are considered “important to safety.” Section 72.122, “Overall Requirements,” requires that the
design bases for SSCs important to safety reflect appropriate combinations of the effects of
normal and accident conditions and the effects of natural phenomena.

Additional requirements are identified in the following documents:

- WHC-SD-SNF-DB-004, *Spent Nuclear Fuel Project Seismic Design Criteria, NRC
  Equivalency Evaluation Report*

- ANSI/ASME N509, *Nuclear Power Plant Air-Cleaning Units and Components*

- ANSI/ASME N510, *Testing of Nuclear Air Cleaning Systems*

  Storage Facilities at Nuclear Power Plants*

- NRC Regulatory Guide 8.8, *Information Relevant to Ensuring that Occupational
  Radiation Exposures at Nuclear Power Stations will be as Low as is Reasonably
  Achievable*

  Design Loads for Facilities*. Note: These requirements were applied only to the
  base sections constructed for the Hanford Waste Vitrification Plant (HWVP) facility.
  This document has been replaced by guidance in HNF-PRO-097, *Engineering
  Design and Evaluation*. 
For the CSB, important-to-safety SSCs have been identified in accordance with 10 CFR 72.3. Once SSCs have been identified as having a function meeting the definition of important to safety, the requirements for SSCs important to safety specified in 10 CFR 72 are imposed. The following graded approach is applied to SSCs important to safety using the guidance provided in NUREG/CR-6407, *Classification of Transportation Packaging and Dry Spent Fuel Storage Systems*, as modified by HNF-SD-SNF-DB-003.

- **A — Critical to Safe Operation**
  
  SSCs in this category include those whose failure or malfunction could directly result in a condition adverse to public health and safety. Important-to-safety SSCs in this category have been classified as safety class using the definition in DOE Order 6430.1A, with the additional requirements therein.

- **Category B — Major Impact on Safety**
  
  SSCs in this category include those whose failure or malfunction could result in a condition adversely affecting collocated worker health and safety. Note that from the definition of Category C, Category B is understood to include events that could significantly damage the MCO without severe impact to public health and safety. SSCs in this category are classified as safety significant.

- **Category C — Minor Impact on Safety**
  
  SSCs whose failure or malfunction would not significantly reduce containment and would not be likely to create a situation adversely affecting public or collocated workers' health and safety. SSCs in this category are unclassified and termed general service.

The SSCs identified as important to safety in accordance with 10 CFR 72.3 are listed in Tables A4-1 and A4-9. These lists also contain the important-to-safety classification for each SSC as determined by Chapter A3.0. The important-to-safety classification is directly incorporated into the tables of preventive and mitigative safety function features identified at the end of each design basis accident scenario in Section A3.4.2. External human-generated threats are discussed in Section A3.3.2.3. Three hoists, the tent gantry hoist and the two sampling/weld station hoists, are the only general service equipment items that are classified important-to-safety Category C because the hoists can potentially drop equipment that could cause minor damage to the top of an MCO.

### A2.3 FACILITY OVERVIEW

This section includes a brief overview of the CSB facility configuration, and the basic processes performed therein. The CSB provides a facility for receiving, sampling, monitoring,
welding, staging, and interim storage of MCOs. The CSB includes the partially constructed below-grade structures of the canceled HWVP in its design. According to HNF-SD-SNF-SP-012, Additional Guidance for Including Nuclear Safety Equivalency in the Canister Storage Building and Cold Vacuum Drying Facility Final Safety Analysis Report, the CSB design should consider evolving Hanford Site uses, public health and safety issues, and probable future uses of Hanford Site lands to assist in meeting NRC equivalency requirement Item 24 in HNF-SD-SNF-DB-003.

A2.3.1 Facility Description

The SNF CSB comprises a steel-frame building that encloses the operating area, the load-in/load-out area, the sampling/weld area, and three, equally sized, below-grade concrete vaults covered by a concrete operating area deck (Figure A2-1). Support functions and equipment are housed in a steel-frame support area on the north side of the operations building. Only the northernmost vault (vault 1) is equipped with steel tubes for staging of mechanically sealed MCOs and storage of the MCOs having welded caps (normally two in each storage tube). A mechanically sealed MCO can be safely staged for at least 40 years (see Chapter A3.0).

An MCO received at the CSB contains five or six baskets of SNF from the 100 K Reactor SNF storage basins stacked one on top of another (Figure A2-2). Figure A2-2 depicts an MCO containing Mark IV fuel baskets. The Mark IA fuel baskets are shorter, and an MCO is designed to contain six Mark IA fuel baskets. As discussed in HNF-SD-SNF-DR-003, Multi-Canister Overpack Design Report, the stainless steel outer shell and bottom of the MCO and the mechanically sealed top shield plug have been designed to meet the Boiler and Pressure Vessel Code (ASME 1995) and to provide the primary long-term containment and confinement for the enclosed SNF. The shield plug shields workers against radiological hazards from the SNF inside of the MCO. The shield plug also provides access to the interior of the MCO using four access ports on the top of the shield plug assembly. The access ports provide the means for sampling those selected MCOs to be monitored at the CSB. The four access ports will be sealed at the Cold Vacuum Drying Facility (CVDF) using bolted cover plates before the MCO is transported to the CSB. The shield plug features an integral axisymmetric lifting ring. The MCO handling machine (MHM) grapple uses the lifting ring to raise the MCO out of the transportation cask, transport the MCO to a storage tube location or MCO sampling/weld station, and lower the MCO into the storage tube or sampling/weld station.

The MCO storage vault (vault 1) contains 220 standard storage tubes, each capable of staging or storing two MCOs stacked one on top of the other. Vault 1 also contains six additional overpack storage tubes on the west side, each capable of accommodating one MCO. Vault 1 is designed to contain SNF currently being stored in the K East and K West Basins. According to HNF-SD-SNF-SARR-005, Multi-Canister Overpack Topical Report, the basins contain 2,271 metric tons (total mass) of SNF. The average MCO is projected to contain 5.96 metric tons of SNF (based on 70% Mark IV and 30% Mark IA fuel [HNF-SD-SNF-SARR-005]). Each MCO will contain either Mark IV or Mark IA fuel, consistent
with the criticality analysis. Based on these values, all of the K Basins SNF will be contained in
approximately 400 MCOs. Vault 1, at capacity, could store up to 440 MCOs plus 6 MCOs in
overpack storage tubes. Operational uses for vaults 2 and 3 are not authorized by this FSAR.

The storage tubes are supported from the foundation base slab of the vault and are
accessed through embedments in the operating deck, which are normally closed with removable
tube plugs. The standard tube plugs provide shielding, a filtered vent, and connections for
sampling of the storage tube atmosphere. Overpack storage tube plugs contain (1) connections
for sampling, purging, and relieving of tube atmosphere; (2) a pressure gauge for surveillance of
tube pressure; and (3) a lock-down device for the overpack tube plug.

The MCO storage vault (vault 1) is cooled by natural convection through the above-grade,
dedicated concrete and steel inlet structure and exhaust air stack and the below-grade reinforced
concrete plenums. The CSB floor plan and interior elevations are shown in Figure A2-3.

Each standard storage tube contains both a bottom impact absorber and an intermediate
impact absorber to mitigate the consequences of a concentric MCO drop. Only one MCO and a
bottom impact absorber are to be stored in an overpack storage tube. Intermediate impact
absorbers are not required for the overpack storage tubes. Bottom impact absorbers mitigate
damage to the storage tube and limit damage to the MCO in the event of a drop, as discussed in
Section A3.4.2.1. When placing a second MCO in a standard storage tube, the intermediate
impact absorbers protect the MCO cap lifting ring on the bottom MCO and protect the top MCO
from internal damage in the event of a drop.

The sampling/weld area, on the south end of the operating area, contains equipment for
pressure checking and sampling the MCOs, and welding equipment (future) for installing a welded
cap on the MCOs.

A2.3.2 Site Grading and Storm Drains

The CSB storm drain and flood control components have been designed to accommodate
the probable maximum precipitation (PMP) event, in accordance with WHC-SD-SNF-DB-009
requirements and Chapter A1.0. Culverts under roadways allow passage of runoff from storms of
less than a 25-year return frequency. The site civil grading and drainage plan is shown on
Figure A2-4. The CSB has been designed for a specific design basis storm event, a 25-year return
frequency storm, and takes into account storms larger than the one used for design by evaluating
the path that overflows (larger-than-design flows) will take when the system capacity is exceeded.

The CSB criterion for the overflow path assessment is to ensure that the PMP event, as
listed in Table A1-1, does not allow water flow into the CSB. WHC-SD-SNF-DB-009 specifies
that 9.2 in. over a 6-hour period be used for the CSB design. This PMP is estimated to be greater
than a “1 million-year average return period storm.”
The design storm used for culverts, drainage ditches, and general storm drainage is the 25-year, 6-hour storm. Letter FRP-112, *SNF Canister Storage Building* (Bedell 1996), specifies that “Culverts will be sized to flow with an unsubmerged inlet during the 25 year return 6 hour duration storm.” HNF-S-0425 states that the prevailing environmental condition for rain is “1.52 cm/hr (0.60 in/hr) maximum.” This corresponds to a 25-year storm, 1-hour duration.

The site and its surrounding tributary areas were analyzed and evaluated in CSB-C-0001, *SNF CSB Storm Drainage Calculation*, using the PMP criteria to determine the impact on the safety of the facility and facility workers. No non-CSB area contributed PMP drainage in a manner that would affect the CSB. Onsite, runoff water from the southern portion of the CSB site flows in an easterly direction in a drainage swale that is adjacent to the patrol road slope along the south edge of the CSB site. This water flows in an easterly direction around the south end of the site, then north along the east side of the site to the 36-in. culvert that passes under the ramp road immediately northeast of the CSB. This culvert is the only water pathway that have any impact on the CSB. In an extreme case, the culvert could be plugged with debris at the time the PMP storm occurred and pond up to the lowest elevation of the road immediately north of the CSB. This road ramps from an elevation of approximately 705 ft next to the CSB to an elevation of approximately 707 ft at the road’s intersection with the access road coming in from the north. The rest of the site drains away from the CSB, which has a floor elevation of 709 ft. Additional rainfall would increase the depth of flow about 1 ft over the ramped access road to an elevation of 706 ft, but at no time would the water level build up to the 709-ft elevation that would threaten the CSB, affect its structural integrity, or allow water into the building. Calculations documented in CSB-PR-0001, *Vault Moisture – SS by RO*, of potential maximum rainwater entering the vault area show that a build-up of water inside of the vault is not a concern. Inside the vault, the evaporation rate will be much greater and the amount of condensation will be much lower than outdoors, even before the storage tubes are loaded with MCOs. After the storage tubes are loaded, the floor will be warm and any water that could enter will evaporate within hours.

**A2.3.3 Historical Summary of the Canister Storage Building Vault Structure**

The SNF Project CSB incorporates portions of the design and the completed below-grade sections of the canceled HWVP CSB. All of the designs and completed sections of the HWVP CSB were reviewed and met or exceeded the requirements for the SNF Project CSB. Portions of the vault that were completed prior to suspension of the HWVP project in 1993, including the base slab and portions of the walls, were reviewed, approved, accepted, and incorporated into the present design by the architect-engineer.

Future use of the CSB may include receiving and storing glass log canisters shipped inside of a large, heavy, shielded canister transporter. Approval of a separate safety analysis addendum will be required for any activities outside the scope of this FSAR.
A2.3.4 Canister Storage Building Shielding Design

The MCOs are received at the CSB via truck shipment within a transportation cask. The transportation cask design provides about 7.6 in. of steel for the side thickness, resulting in a worst case dose rate of about 50 mrem/h on contact at the mid-height cask surface according to CSB-SH-1002, Bulk Shielding for the Vault Release (Phase I) of the Canister Storage Building (CSB). This higher than acceptable dose rate for the CSB has resulted in additional shielding requirements for the CSB. The following paragraphs outline the shielding analysis performed for detailed design of the CSB.

The code selected to perform shielding calculations on the CSB vault was the personal computer (PC) version of MCNP, version 4A, developed and supported by the Los Alamos National Laboratory LA-12625, MCNP - A General Monte Carlo N-Particle Transport Code, Version 4A. This code was selected because the complex geometry of the source region, and the CSB could be modeled with a high degree of confidence.

Running the test problems supplied with the code packages has validated all codes used in shielding and criticality calculations at Fluor Daniel, Incorporated. The test problem results are shown to be in agreement either with the published documentation supplied as part of the code package, or with the sample problem output, if supplied. This information is documented, dated, and retained on file. Any changes, such as upgrades, corrections, and modifications, are incorporated into the documentation following rerunning the verification problems. MCNP, Version 4A, described in LA-12625, is a widely used and well accepted radiation transport code employed for a wide variety of radiation analyses including neutron, photon and electron transport, and criticality. Los Alamos National Laboratory has performed extensive calculations with MCNP, duplicating a wide range of experimental results, to validate the models contained in this code. The results of these benchmark cases are documented in LA-12196, MCNP: Photon Benchmark Problems, and LA-12212, MCNP: Neutron Benchmark Problems. Exercising the 25 sample problems supplied by Los Alamos National Laboratory tested the version of MCNP-4A used at Fluor Daniel, Incorporated, and the results were found to be in agreement within reasonable statistical limits. These sample problems are designed to exercise a broad range of the code’s computational capabilities.

Fractional densities for common materials, radiation sources, fluence rate to dose rate conversion factors, and guidelines for statistically adequate results used in the calculations are documented in CSB-SH-1002. Source terms used in the shielding calculations are referenced in CSB-SH-1001, SNF CSB Shielding Source Terms. Monte Carlo shielding analyses codes (e.g., the MCNP-4A) rely on sampling a large number of particles and tracing them throughout the modeled geometry. Because the results are a function of the number of initial source particles sampled and the number of particles reaching the specified dose points, the resulting mean “detected” dose rates have an implied statistical uncertainty (relative error) associated with them. Depending on the degree of attenuation and the complexity of the sample space, achieving unrealistically low relative errors can be extremely time-consuming (e.g., days of PC computing time) and expensive (additional labor time and potential schedule impacts).
In order to place practical limits on relative errors (a statistical term meaning 1-sigma deviation from the mean), guidelines of acceptable uncertainty ranges were established (CSB-SH-1002). These uncertainty ranges provided practical limits on the relative error for each estimated dose rate. Table 4 in CSB-SH-1002 presents interpretations of the relative errors with regard to the quality of the results.

The shielding calculations noted in this chapter and Chapter A4.0 include estimated dose rates for the vault intake stack and vault exhaust stack (exterior walls), the CSB operating area shelter exterior, the operating area floor, the interior vault walls, the exterior vault walls, the cask receiving pit, and the sampling/weld stations. Shielding calculations were updated for the same equipment if subsequent design changes appeared to have an impact on the calculated doses. The radiation doses cited in this document reference the specific shielding calculations performed to estimate the doses. The shielding calculations contain the assumptions, geometry models, and equipment dimensions used.

A2.4 FACILITY STRUCTURE

This section provides an overview of the facility and auxiliary structures including construction details such as basic floor plans, equipment layout, construction materials, controlling dimensions, and dimensions significant to the hazard and accident analysis activity. This information supports an overall understanding of the facility structures and the general arrangement of the facility as it pertains to hazard and accident analyses. The following subsections describe the below-grade reinforced concrete structures (vault, basemat, inlet plenum and outlet plenum), the at-grade reinforced concrete structures (operating deck and perimeter curb), the steel structures (storage tubes, storage tube covers, tube plug covers, and impact absorbers), and the CSB above-grade structures (intake structure, exhaust stack, operating area shelter, and support area building).
A2.4.1 Canister Storage Building Subsurface Structure

The below-grade reinforced concrete portion of the CSB (basemat embeds, vaults, inlet plenums, and exhaust plenums shown in Figures A2-5 and A2-6) is approximately 181 ft long by 166 ft wide by 48 ft deep. The floor area encompassing the load-in/load-out area, operating area, and sampling/weld area is approximately 230 ft long by 136 ft wide. The operating floor is enclosed by a steel-framed building, the operating area shelter. The reference elevation of the facilities at the top of the operating deck is 709 ft above mean sea level.

**Basemat.** The CSB basemat (foundation) is constructed at an elevation of 661 ft, 3 in. above mean sea level, or approximately 46 ft, 9 in. below the grade elevation of 708 ft. The basemat is nominally 5 ft, 6 in. thick; its surface elevation is 666 ft, 10.5 in. The distance from the basemat floor to the underside of the operating deck is 37 ft, 3 in.

**Vaults.** Only vault 1, the northernmost vault, has carbon steel storage tubes and an individual intake structure and exhaust stack in order to expedite the receipt of MCOs containing SNF. The exterior walls and air intake and exhaust plenums are 4 ft, 6 in. thick. Interior partition walls between vaults are 3 ft thick. The intake structures and exhaust stacks for the other two vaults, except the intake and exhaust stack bases, have not been constructed and are outside the scope of this FSAR.

The below-grade walls and basemat carry the loads associated with handling and transporting the MCO (i.e., transporter with cask, receiving crane, and MHM).

**Air Intake and Exhaust Plenums.** The air intake and exhaust plenums are concrete ducts providing for airflow into and out of the vaults. The CSB below-grade structure provides shielding for the air intake and exhaust plenums. The subsurface structure with 3-ft-thick interior walls provides shielding from the source term associated with SNF storage. The exterior walls of the subsurface structure were designed to meet the criteria given in 10 CFR 835 for uncontrolled access. Shielding calculations have assumed that each MCO contains the maximum activity value associated with Mark IV fuel listed in HNF-S-0425. The shielding calculations indicate that the dose rate at the intake stack base will be less than the design requirements (0.05 mrem/h [5.0 x 10^-7 mSv/h]) (CSB-SH-1002), of which less than 10% is attributed to neutron scatter with SNF as the source term. Heating of the concrete by the radiation field inside the vault has been calculated (7 x 10^-8 W/m²). The value is insignificant compared with convection heat transfer according to CSB-HV-0001, *A Canister Storage Building Vault Thermal Analysis*. Neutron and gamma effects from the spontaneous fission of californium were not included in the shielding calculations or concrete heating calculations because their contribution is negligible.

**Safety Considerations.** The CSB subsurface structure (including the basemat embeds, vault, air intake plenum, and exhaust plenum) is classified as safety class and important-to-safety Category A.
A2.4.2 At-Grade Reinforced Concrete Structures

The at-grade concrete structure includes the operating deck, the intake structure, the exhaust structure (Figure A2-6), and the perimeter curb.

The operating deck is a 5-ft-thick reinforced concrete structure (Figure A2-6) that forms the at-grade portion of the CSB. The operating deck is shown in plan view on Figure A2-7. The dimensions of the operating deck are approximately 230 ft north-south by 137 ft east-west. The operating area deck floor is bounded to the north by the load-in/load-out area (trailer vestibule and MCO service station) and support area building foundations, and to the south by the sampling/weld area foundation. The operating deck structure contains numerous through-thickness steel sleeves (embeds) that receive the storage tubes and tube plugs for both the standard storage tube and overpack storage tube locations in vault 1, and that provide a location for the tube plug cover plates in vault 1 or deck embed cover plates in vaults 2 and 3. These embeds are offset and arranged at a center-to-center distance of 4 ft, 8 in. east-west and 4 ft, 6 in. north-south, as shown in Figure A2-7. This distance between MCOs has been evaluated for criticality prevention and found to be adequate (see Chapter A6.0).

Two hundred twenty standard and six overpack embeds are provided in vault 1. Details of the standard tube, embed, and plug at the deck level are shown on Figure A2-8, sheet 1. Overpack embeds, tubes, and plugs are of similar dimensions with the overpack embed 6 in. larger in diameter (Figure A2-8, sheet 2).

Each vault is provided with penetrations through the operating deck to accommodate a rectangular intake structure 10 ft, 8 in. by 16 ft by 2 ft thick and a circular exhaust stack structure 11 ft, 6 in. in diameter and 4 ft, 6 in. thick. Each of the three exhaust stack bases is furnished with 2.25-in.-diameter anchor bolts to which the steel exhaust stacks can be fastened. The vault 1 intake and exhaust stacks are fastened using these anchor bolts. The intake structure and exhaust stack structures are designed for the NPHs listed in Table A1-1.

The sampling/weld area is an extension to the south of the operating deck. Its foundation is a reinforced concrete structure that houses process module mounting plates and seven process pits for sampling and welding (future) equipment. The dimensions of the sampling/weld area foundation are 35 ft, 3 in. by 138 ft, 11 in. by 5 ft thick; the reinforced concrete slab is supported at grade. A loading/staging area is located on the west side of the sampling/weld area for egress and ingress of equipment. The dimensions of the loading/staging area foundation are 24 ft, 11 in. by 27 ft, 4 in. An outer and an inner door in the loading/staging area serve as an airlock for area ventilation confinement.

The load-in/load-out area is an extension to the north of the operating deck. This area houses a cask receiving pit and provides trenches and anchor bolts for the rails serving the receiving crane, service station enclosure, and tent gantry hoist. The load-in/load-out area reinforced concrete slab is 138 ft, 4 in. by 29 ft, 9.5 in. by 5 ft thick supported at grade. A trailer vestibule forms an extension to the west of the load-in/load-out area. The dimensions of the
trailer vestibule slab are 42 ft, 7 in. by 50 ft, 9.5 in. by 5 ft thick. The reinforced concrete slab is supported at grade. An outer door and an inner door in the trailer vestibule serve as an airlock for operating area ventilation confinement. Two additional service pits are provided in the CSB load-in/load-out area. The easternmost pit is for MHM maintenance, and the center pit was designed for future transloading removal of Fast Flux Test Facility (FFTF) fuels from a transportation cask. Details of these service pits can be seen on Figure A2-9. A 10-ton screw jack assembly, mounted on the floor at the west end of the MHM maintenance pit, supports, elevates, and lowers the MHM mounting ring assembly and retractable nose assembly during maintenance operations.

Surrounding the operating area on the south, east, and west is a 4-ft, 4-in.-thick by 3-ft-high concrete perimeter curb. The curb is 2 ft wide and 8 ft high at the north wall of the load-in/load-out area for shielding support area building personnel from the MCO transportation cask. Doors are provided for personnel traffic through this shield wall. The operating area steel superstructure is attached to anchor bolts set at column locations throughout this perimeter curb. Survey markers (shown in Figure A2-3, sheet 1) are attached flush with the concrete deck and will be used in the deck settlement monitoring program (see Section A4.3.3).

**Safety Considerations:** The at-grade reinforced concrete deck structure (operating area deck [includes load-in/load-out area and sampling/weld area], intake structure, and exhaust structure) is classified as safety class and important-to-safety Category A.

### A2.4.3 Steel Structures

**A2.4.3.1 Storage Tubes.** Storage tubes (Figure A2-10) are located under the operating floor, accessed through the top of the operating deck, and supported from the basemat by a tube base assembly. The storage tubes are used to provide a controlled environment to vertically store MCOs. There are two types of tube assemblies. A standard storage tube assembly has been installed through each of the 220 standard embed openings in the operating deck. An overpack storage tube assembly has been installed through each of the six overpack embed openings in the operating deck. The overpack storage tube assemblies provide a sealed confinement function in addition to a structural function. The upper end of each tube has a bellows with an upper flange. The upper bellows flange of each tube assembly is seal-welded to the deck embed.

Each of the 220 standard storage tube assemblies in vault 1 includes impact absorbers, a tube base, and a tube plug. Each storage tube location will receive a plug cover plate. Embed covers will be placed at the floor level in the embed openings for vaults 2 and 3 until a future mission is identified that requires utilization of these openings.

The storage tube assemblies are centered at the top, welded to the deck embed, and restrained from lateral movement at the basemat by the tube base assemblies into which the tubes are inserted (Figure A2-11). The assemblies are affixed to plates embedded in the basemat slab and are designed with cooling passages to ensure that the temperature at the basemat slab will not
The standard and overpack storage tubes are provided with stainless steel expansion bellows to complete the assembly. The bellows assembly (Figure A2-12) permits thermal displacement of the storage tube, accommodates differential movement of the operating deck in relation to the basemat slab, and seals the operating area from the vault. The standard bellows assembly is 37 in. in diameter and 21 in. tall with a free length of 9.4 in. The bellows are constructed of 0.036-in.-thick stainless steel Type 304 series.

The standard storage tubes are 39-ft-, 7-in.-long, 0.5-in.-thick ASTM A36 carbon steel pipes, 28 in. in diameter, are closed at the bottom, and are designed to meet the requirements of the Boiler and Pressure Vessel Code, Section III (ASME 1995). The storage tube assembly is 41 ft, 4 in. long when the bellows are in place at the top. The overpack storage tubes are SA-671 carbon steel plate pipes of the same length and thickness as the standard storage tubes, and are designed to meet the requirements of the Boiler and Pressure Vessel Code, Section III, Division 1, Subsection NC, Article NC-6300 (ASME 1995), for air at a pressure of 100 lb/in² gauge. Overpack storage tube assemblies are provided in vault 1 for potential future use to store and monitor suspect MCOs.

A stress analysis of the standard storage tube documented in CSB-RM-0011, *ASME VIII Evaluation of Storage Tubes*, shows that it will withstand an internal pressure of 100 lb/in² gauge at 104 °C (220 °F). The normal pressure is 0 lb/in² gauge (vented through a breather filter to the operating area). There is sufficient clearance between the tube wall and impact absorbers to allow easy removal and installation and to prevent lateral loads from impacting the tube wall during staging or storage in the event of an MCO drop.

Standard storage tubes are provided with impact absorbers at the bottom of the tubes (bottom impact absorber) and between MCOs (intermediate impact absorber). The bottom impact absorbers limit the deceleration (maximum force allowed on the MCO is 679,000 pounds-force) of a maximum weight MCO dropped from the maximum height of 44 ft (35 g loading) and limit the radial load on the storage tube. An intermediate impact absorber placed on top of the bottom MCO is between the MCOs and prevents local damage to the canister cover assembly of the bottom MCO. The intermediate impact absorber sits on the flat surface of the bottom MCO canister cover assembly (Figure A2-2). The bottom and intermediate impact absorbers are designed to limit their sideward thrust on the storage tube during deformation to that of the tube working pressure. The lower and intermediate impact absorbers are shown on Figure A2-13. An intermediate impact absorber is put in place before placing a second MCO in a standard storage tube. Overpack storage tubes do not require an intermediate impact absorber because only one MCO will be stored and monitored in an overpack tube.
The lower and intermediate impact absorber assemblies (Figure A2-13) consist of a top flange plate, a top plate bolted to the flange plate, a base plate, and 3.5-in.-diameter energy absorbing tubes between the plates. In addition, the lower impact absorber has an intermediate plate separating the upper energy absorbing tubes from the lower energy absorbing tubes. The top, intermediate, and base plates have 0.25-in.-deep grooves providing alignment and a piloting surface for each tube component. Carbon steel was selected as the tubing material because of its ductility and energy absorbing capabilities. According to PacTec ED-037, CSB Impact Absorber Analysis Report, the following three impact absorber design features avoid the high initial short-duration force spike: (1) approximately half of the tubes are shorter by a one-half crush wavelength, (2) each tube has three dents, or crimps, separated by 120° of circumference, and (3) the impact absorber, after assembly, is precrushed. The shorter tubes are fitted with guide sleeves at the opposite end from the crimps. These guide sleeves serve to guide the “free” end of the shorter tubes into the grooves on the plate. The effect of these three design features is to minimize the high initial force that starts crushing of the tubes and to produce a smoother force-deflection curve for the impact absorber, effectively minimizing the deceleration forces on the MCO during a dropping accident. The impact absorber assemblies are held together by galvanized steel cables fitted around the circumference of the impact absorber and tensioned. After a potential crush event, the cables remain undamaged and hold the components together during removal of the damaged impact absorber. The number of tubes for each impact absorber, ranging from 13 to 17, will be based on full-scale testing of a predetermined quantity of impact absorbers using tubing from a batch of tubes provided by a single tube manufacturer. The testing results will determine the number of tubes to be used in each impact absorber assembly.

A2.4.3.2 Storage Tube Plugs. The standard tube plug assembly has a breather filter, provides radiation shielding, and allows access to the tube interior for gas monitoring through a quick-disconnect fitting. The overpack tube plug assembly provides radiation shielding; holds gas pressure in the overpack storage tube; and allows access to the tube interior for gas inerting and gas pressure monitoring. The standard and overpack tube plugs provide confinement of the MCOs. The tube plug has a cast steel top and concrete-filled lower portion. The barrel of the concrete tube plug is constructed of SA-36 carbon steel material. A 0.125-in.-diameter vent hole ensures that pressure inside the concrete barrel is relieved. The tube interior is accessed through two 2-in. holes drilled into the casting that connect to two 1.5-in.-diameter tubes.

The 45° sealing surface of the tube plug is mated to the upper 45° sealing surface of the storage tube. The seal is made using an O-ring seal (one O-ring seal for the standard tube plug and two O-rings for the overpack tube plug) constructed of ethylene propylene. The O-ring is compressed by the weight of the plug, and the 45° surfaces make metal-to-metal contact. The O-ring helps to prevent escape of potential contamination from the MCO surface into the operating area and also aids in keeping dust, debris, and liquid spills from leaking into the storage tubes from the operating area. The overpack sealing requirement is that the leakage be less than $1.3 \times 10^{-5} \text{ft}^3/\text{h}$ (at established tube pressure) to maintain an inert pressurized atmosphere around a suspect integrity MCO. In addition to the two O-ring seals, the overpack tube plug has a spider lockdown mechanism (Figure A2-14, sheet 2) clamping the overpack tube plug in place. The spider lockdown mechanism is designed to maintain the overpack tube pressure and prevent gas...
leakage from the overpack storage tube into the operating area. The double O-ring seals and spider lockdown mechanism provide confinement for potential radioactivity leaking from a suspect integrity MCO. There are no other design differences between the overpack storage tube plugs and the standard storage tube plugs (Figure A2-14).

Tube plugs are shown on Figure A2-14. The dose rate estimate, based on the Monte Carlo, three-dimensional geometry, MCNP-4A code streaming and scattering calculations (LA-12625), is estimated at 200 mrem/h (2.0 mSv/h) near the top of the plug-tube gap (top of the bottom straight plug section). The O-ring seal manufacturer data sheet, Selecting Elastomer Seals #23B (Parker 1989), shows that ethylene propylene retains its elastomeric properties at temperatures up to 250 °F and accumulated dose up to $10^7$ R. The maximum concrete temperature near the seals has been estimated to be about 115 °F (Figure A4-3). At a dose rate of 200 mrem/h, the accumulated dose for 40 years would be approximately $0.3 \times 10^7$ R. These values show that the tube plug seals should retain their sealing properties for the life of the facility. Sections A4.4.2 and A4.4.3 provide a more complete description of the storage tube plugs. At the surface of the operating deck, the upper limit of the dose rate caused by the radiation from the plug-tube gap is less than 0.2 mrem/h (2.0 x $10^3$ mSv/h). The radiation fields will be confirmed by routine monitoring by a health physics technician (HPT) during operations and filling of the vault. The analysis was performed on the concrete and steel composite plug. Details of the shielding analysis can be found in calculation CSB-SH-2002, Floor Plug/Deck Interface Analysis. Overpack storage tube plugs were similarly analyzed.

**A2.4.3.3 Tube Plug Covers.** Tube plug covers protect the tube plug connections and devices and fit flush with the operating deck. In vault 1 the tube plug covers are 3-in.-thick carbon steel disks provided with lifting lugs and a concentric inspection port. The deck embed covers in vaults 2 and 3 are 0.5-in.-thick carbon steel plates designed with tube steel reinforcement and with gaskets at deck embed contact surfaces. The deck embed covers provide for personnel safety and maintain a level floor surface. Both the tube plug and embed covers are shown on Figures A2-15 and A2-16.

**A2.4.3.4 Cask Receiving Impact Absorber.** An impact absorber is located in the cask receiving pit in the load-in/load-out area to elevate the transportation cask, absorb the impact of a dropped cask, and align it with the top of the operating deck. The cask receiving impact absorber assembly (Figure A2-9, sheet 5) consists of a top plate, a base weldment, 12 energy absorbing tubes between the top plate and base weldment, and an outer 0.5-in.-thick tube enclosure around the tubes. The top plate and base weldment top plate have 0.375-in.-deep grooves providing alignment and a piloting surface for each tube component. Carbon steel was selected for the tube material because of its ductility and energy absorbing capabilities. The three receiving pit impact absorber design features selected to minimize deceleration forces of an accidentally dropped cask-MCO are identical to the three design features selected for the bottom and intermediate impact absorbers and discussed in Section A2.4.3.1. Six of the crush tubes are shorter and symmetrically arranged, as shown in Figure A2-9, sheet 5. The four rods mounted circumferentially around the base weldment serve the same purpose as the galvanized cables for the bottom and intermediate impact absorbers. The base weldment is composed of three rings of
welded steel plate and pipes designed to support a cask–MCO placed in the cask receiving pit.

Steel cask guides (Figure A2-9, sheet 2) are located inside the cask receiving pit to align the cask with the shield hatch and MCO guide assembly (Figure A2-17).

**Safety Considerations.** The standard storage tube and tube base assembly are classified as safety class and important-to-safety Category A. The standard storage tube plug, lower flange, bottom impact absorber, and standard storage tube intermediate impact absorber are classified safety significant.

The overpack storage tubes and tube base assemblies are classified as safety class and important-to-safety Category A. The overpack storage tube plug, lower flange, and bottom impact absorber are classified safety significant.

The cask receiving impact absorber is classified as safety significant.

A2.4.4 Canister Storage Building Above-Grade Structures (Intake Structure, Exhaust Stack, Operating Area Shelter, and Support Area Building)

A2.4.4.1 Intake Structure and Exhaust Stack. The CSB intake structure is a 17 ft by 18 ft by 22 ft high steel structure mounted on top of a 15 ft by 20 ft by 57 ft high reinforced concrete tower that is constructed monolithically with the CSB vault. The steel portion of the intake structure is a combination of a braced tubular steel frame with steel shear panels at the base. The tower is analyzed and designed as an integral part of the CSB vault structure according to CSB-S-0028A, **Intake Tower Analysis**. The intake structure contains an inlet that increases static wind pressure by reducing the wind velocity at the windward side. A canopy is provided for increased wind pressure efficiencies.

The exhaust stack is a self-supporting 156-ft-, 10.5-in.-tall cantilevered structure. The diameter at the base of the stack is 13 ft, and the diameter at the top of the stack is 7 ft. The bottom section of the 13-ft-diameter stack base rises 55 ft and is constructed of 0.63-in.-thick carbon steel plate. The middle section continues upward 33 ft and tapers from 13 ft to 7 ft in diameter and also is constructed of 0.63-in.-thick carbon steel plate. The 7-ft-diameter top section of the stack continues upward another 57 ft and is constructed of 0.38-in.-thick carbon steel plate. The upper 44-ft section of the stack is provided with vertical wind spoilers that are each 7 in. tall by 11 ft long, made of 0.38-in.-thick carbon steel plate and designed to ASCE-7-93, **Minimum Design Loads for Building and Other Structures** guidance. Thermal gradients across the stack are of minimal design concern for the materials and temperatures involved. The stack is topped by a wind deflector tip as shown on Figure A2-1.

**Safety Considerations.** The intake structure and exhaust stack are classified as safety class and important-to-safety Category A.
A2.4.4.2 Operating Area Shelter. The operating area shelter is a steel-frame enclosure that covers the vault operating deck, the load-in/load-out area on the north, and the sampling/weld area on the south. The structure is approximately 230 ft long, 137 ft wide, and 55 ft high and sits on a 3-ft-high concrete curb around the vault deck. The structural system comprises load-carrying roof trusses spanning the east-west dimension and supported by columns spaced typically at 20 ft, 4 in. centers.

The trailer vestibule and loading and staging areas extend out from the western edge of the operations area and provide controlled transfer of equipment and materials into and out of the operating area shelter. The sampling/weld area opens directly into the southern end of the operations area and uses the same MHM.

The standing seam welded roof system provides an impervious weatherproof barrier over the entire CSB structure. The structural steel deck and roof framing system are designed to resist tornado wind loads and other NPHs as discussed in Section A4.4.1.4. One weather-sealed penetration, a locked roof hatch, through the roof provides for outside crane access to the operating area. Future use of the roof hatch is not part of the authorization basis and will require using the Unreviewed Safety Question process.

The exterior siding encloses the CSB structure in a continuous, airtight, weatherproof shell, except for the doors. All areas of the CSB have the same siding design, comprising a 3-in.-deep metal liner panel screwed to structural girt framing. The metal siding resists extreme wind-driven missiles and tornado wind loads and pressure drop as required by WHC-SD-SNF-DB-009. Fasteners will resist both pull-out and pull-over stresses induced by the specified wind load, as well as seismic and other forces (e.g., construction loads, roof loading, thermal changes).

The operating area shelter contains a 4-ft-wide egress passageway that generally follows the perimeter walls. This passageway connects all of the emergency exits. A passageway also separates the vault operations area from the sampling/weld area. Personnel working in the deck area can directly access the exits through the dedicated egress passageway. The waterproofed, sealed (using a resinous coating), exposed concrete floors and horizontal surfaces of the load-in/load-out area resist liquid intrusion, aid in preventing contamination of the concrete surfaces, and reduce future decontamination and decommissioning labor by minimizing contamination of the concrete.

Two radiation shield doors allow ingress to and egress from the support area building from the operating area shelter. A third shield door allows access from the operating area into the filter room. These doors were chosen to meet space limitations and provide shielding characteristics equivalent to a labyrinth design. Special exit-only doors, spaced around the exterior walls, provide the only emergency exit from the operating area shelter. Emergency lighting and local alarms are provided at each emergency exit door. The trailer vestibule and loading and staging area also have exit-only doors. The operating area shelter has eight personnel emergency exits. All of the operating area emergency exits open to outside of the building onto either concrete door landings, concrete sidewalks or a paved area (see Figure A2-3).
Personnel enter and exit the main corridor in the support area building through one personnel entry door. Shielding calculation CSB-SH-3004, *Dose Rates through North Wall*, determined the shielding required to keep the dose rate to personnel in the support area building below 0.2 mrem/h (2.0 x 10^{-3} mSv/h) using the MCO transportation cask as a source term. The dose to unshielded personnel from the MCO transportation cask was calculated at 3.8 mrem/h (3.8 x 10^{-2} mSv/h) at 66.5 in. The 2-ft-thick concrete north wall of the load-in/load-out area and the 2.5-in.-thick steel doors reduce support area personnel exposure from the MCO transportation cask during offloading. With such shielding, the highest dose rate expected in the support area building is about 0.026 mrem/h (2.6 x 10^{-3} mSv/h), which is well below the 0.2 mrem/h (2.0 x 10^{-3} mSv/h) desired for full-time occupancy.

A large (37 ft by 38 ft), fabric panel Megadoor\(^1\) acts as an inner airlock door large enough for the receiving crane to pass through when traveling between the trailer vestibule and cask receiving pit load-in/load-out area. A fabric-type curtain door was chosen because of the large opening size to be closed and the air sealing capability needed. An overhead metal telescoping door (24 ft by 20 ft) encloses the outer opening of the trailer vestibule at the northwest entrance to the CSB. Two more telescoping doors (14 ft by 14 ft) serve as inner and outer airlock doors for receiving equipment at the southwest entrance to the CSB. Telescoping doors have multiple steel panels that telescope into the door as the door is raised. The trailer vestibule and southwest entrance exterior telescoping doors are protected from tornado damage and accidental truck crashes by rolling gates (Figure A2-18). Each hydraulic-driven gate is positioned by a drive train in front of the telescoping doors when the telescoping doors are in closed position to minimize penetration during the design basis tornado (Table A1-1) or from a runaway vehicle. Warning indicators (rotating beacons and alarm bells), located on the west building exterior near the telescoping doors, are activated when the doors are moving. Each gate and its telescoping door are interlocked so that both operate simultaneously from a single set of push buttons. Safety edges on both the gates and telescoping doors, when activated, stop the motion of either the door or the gate. When the gate and the telescoping door have been in the open position for 15 minutes, an audible alarm activates and continues alarming for 60 minutes or until the door-gate “Close” push button is pushed. The gate has a manual operation feature that provides for operation of the door during loss of power.

Each exterior telescoping door is interlocked with the airlock door (Megadoor\(^\text{TM}\)) or the interior telescoping door to maintain a negative pressure inside the operating area. The Megadoor\(^\text{TM}\) is also interlocked with the receiving crane to prevent movement of the crane into the Megadoor\(^\text{TM}\) when the door is closed. Megadoor\(^\text{TM}\) interlock switches allow the receiving crane bridge to travel through the door opening only when the Megadoor\(^\text{TM}\) is in the full open position. The outside and inside doors are interlocked so that one door is always closed. Whenever one door is open, the other door is interlocked to prevent that door from opening until the first door is closed. This is to ensure a negative air pressure between the operating area (zone IIIa) and the outside air. Both trailer vestibule doors are operated using identical control.

\(^1\)Megadoor is a trademark of Megadoor Company.
systems. These doors are each controlled by a local control box. These controls initiate opening,
closing, and stopping of the door at any point in travel. Built-in adjustable limit controls are
provided to automatically disconnect power to the door operator control box at the full-open and
full-closed positions. Limit switches in the door header provide protection against damage in the
event of over-travel or a break in the lifting cable. This is used as a backup for the primary limit
control, which disconnects power from the operator control box. Each bottom door panel
contains various operating devices, including a pressure-sensitive bottom edge that automatically
reverses the door motion when an obstacle is met, and a special centering device that holds all
panels in proper lateral alignment to prevent side binding. A positive locking mechanism engages
automatically in both side guides when the door stops in the closed position and disengages
automatically when the opening action is initiated. An automatic load lock will hold the curtain in
a steady position whenever the curtain is stopped in vertical travel.

Hand-held fire extinguishers are provided in the operating area as defined by NFPA 10,
Portable Fire Extinguishers. A two-hour fire wall separates the operations area from the support
area building.

Seismic and tornado lateral forces are resisted through truss-column frame interaction in
the east-west direction and through a vertical bracing system along the east and west walls in the
north-south direction.

The CSB operating area shelter and supporting structures are protected from lightning
strikes in accordance with NFPA 780, Lightning Protection Systems. Air terminals are provided
along the perimeter of the operating area shelter roof. Section A2.9.3, “Lightning Protection,”
provides a description of the lightning strike protection features of the CSB operating area shelter.
Lightning arrestors are installed for 15 kV (nominal) systems. Lightning arrestors are spark-over
devices for overhead electrical distribution systems to protect their overhead electrical lines.
Grounding cables connect the lightning arrestors and the operating area shelter air terminals to the
CSB ground grid, an underground wire cable system that protects the CSB structures from
electrical hazards.

Safety Considerations. The operating area shelter is classified as safety significant and
important-to-safety Category B. The rolling shield gates are safety significant. The Megadoor™
and the telescoping doors are classified as general service.

A2.4.4.3 Support Area Building. The building that houses the CSB support area is a single-
story, steel-frame structure approximately 150 ft long, 53 ft wide, and 16 ft high. The support
area building is north of the CSB vaults and operating area shelter at the same 709-ft, 0-in.
elevation as the operating deck. The concrete slab is 8 in. thick constructed at grade. Below-
grade reinforced concrete footings are placed at equipment and column locations.

The support area building abuts the north edge of the operating area shelter and contains
several rooms: equipment spaces (including heating, ventilation, and air conditioning [HVAC],
filters; and instrument air); electrical room; two empty utility rooms with space heaters; control
room and security control space; HPT office; count room; regulated change room; operations office; and airlocks. The control room is essentially a monitoring station rather than a control room as defined by DOE conduct of operations standards. The equipment areas have dedicated access doors for equipment access and servicing. Exits from these areas are through the main corridor or, in the electrical and empty utility rooms, directly to the outside.

The support area building has a shed roof sloping down from the common wall adjoining the operating area. A structural steel deck is attached to the top of the roof-framing system. The support area building roof has an occasional-use access ladder, welded to brackets, that extends up the outside of the building, providing access to the ventilation exhaust stack and effluent-monitoring system probes.

Exterior siding and roofing for the support area building is of equal grade and finish appearance to the operating area shelter. The siding and exterior wall design for the support area building, including exterior joints and interface points, also is the same as described for the operating area shelter. A relatively small telescoping door on the west side (10 ft by 10 ft) opens to receive supplies into and discharge waste from the support area building. Warning indicators (rotating beacon and alarm bell) located on the west building exterior near the telescoping door are activated when the door is moving.

The primary personnel entrance for the CSB is at the northeast corner of the support area building near the HPT office, control room, and operations office. A main corridor crosses the entire support area building between the primary personnel entrance on the east and the loading dock on the west. This corridor provides an exit path to the primary support area building exits. Operating personnel enter the primary personnel entrance, don protective clothing in the change room, and enter the operating area shelter from an airlock in the support area building. The airlock ensures HVAC flow is from the support area building to the operating area. Personnel return from the operating area shelter by a similar path, passing through a portal contamination monitor, for clothing removal, decontamination, and egress. Personnel may access the HPT and operations offices, change and control rooms, and various other rooms through 12 single-wide interior personnel doors and 1 double-wide interior pair of doors. All doors (airlock and personnel) have air seals around the jambs. They are rated for at least 20 lb/ft² pressure and for 30 lb/ft² in the operating area. The HPT office has a view window to the personnel decontamination area.

Acoustical features provided for the control room in the support area include a suspended acoustical tile ceiling and sound board, which is installed on separate metal stud-framed wall partitions on both sides of the wall adjoining the empty utility room. The acoustical features are provided to comply with the requirements of DOE Order 6430.1A, Section 0950, “Acoustical Treatment.”

The personnel monitoring and decontamination room, count room, step-off pad, and regulated change room areas have a depressed floor level with an access floor aligned with the surrounding finished floor. The flooring in these access floor areas has perforations to allow
sprinkler discharge to accumulate in the depressed areas until the discharge can be
decontaminated and removed. Equipment areas have waterproofed, sealed, exposed concrete
floors and waterproofed, sealed, horizontal surfaces of the equipment pads. The sealed surfaces
resist liquid intrusion, aid in preventing contamination of the concrete surfaces, and reduce future
decontamination and decommissioning labor by minimizing contamination of the concrete. Sumps
are provided in the utility rooms, the HVAC equipment room, and mechanical equipment rooms.
Curbs and exterior access-only doors to the utility rooms ensure that liquids (fire sprinkler
actuation) will collect and drain away from the support area building.

Entry to the electrical room is through one tall exterior double door (6 ft by 9 ft) with a
removable top transom that allows equipment installation and servicing. Two similar, though
shorter, standard height (6 ft by 7 ft) pairs of exterior service doors provide access to the two
utility rooms. The utility rooms also have wall louvers. The room containing the continuous
airborne effluent monitor (CAEM) and the safeguards and security equipment is accessible from
inside.

The foundations and superstructure of the support area building are structurally isolated
from the CSB vaults and operating shelter. The building houses equipment for electrical, HVAC,
CAEMs, facility operations monitoring, and change rooms. A 28-in.-diameter, 75-ft-high steel
HVAC exhaust stack, supported at grade and guyed at the roof, penetrates through the building
roof. The structural system comprises roof beams that span the east-west dimension and are
supported by girders and columns. Seismic and tornado lateral force resistance is achieved by
girder-column frame interaction in the north-south direction and through a vertical bracing system
along the north and south walls. The building is brace-framed in the east-west direction. The
foundations for the building and equipment are spread footings located below the frost depth
according to CSB-S-0019, SNF Canister Storage Support Building.

Air terminals installed around the perimeter of the support area building roof provide
protection from lightning strikes in accordance with NFPA 780. The HVAC stack is provided
with two exposed cables located on opposite sides of the stack about 3 ft above the concrete
base. Grounding cables connect the support area building air terminals and HVAC exhaust stack
to the CSB ground grid, an underground wire cable system for protecting the CSB and its support
structures from electrical hazards. Section A2.9.3 provides a description of the lightning strike
protection features of the CSB support area building and HVAC exhaust stack.

Safety Considerations. The support area building is classified as general service, except the
foundation, which is classified as safety significant.

A2.5 PROCESS DESCRIPTION

Individual operations within the CSB are described in this section. The three major
operations are baseline operations, passive cooling, and overpack storage tube purge operations.
The details include basic parameters; summaries of types and quantities of hazardous materials;
equipment; instrumentation and control systems and equipment; basic flow diagrams; and
operational considerations of the individual processes and the entire facility, including major interfaces and relationships between SSCs. The intent of this information is to provide an understanding of the assessment of normal operations and insight into the types of operations for which a safety management program must be planned.

A2.5.1 Baseline Operations Involving Handling of Multi-Canister Overpacks

Baseline operations at the CSB include receiving operations, cask servicing operations, MCO operations, and MCO sampling operations. All operations in this subsection involve safe handling of sealed MCOs containing SNF. During normal operations, a maximum number of four MCOs would be in process in the operating area:

1. One MCO in the load-in/load-out area being prepared for receipt and transport by the MHM

2. One MCO in sampling/weld pit 2

3. One MCO in sampling/weld pit 7

4. One MCO being transported by the MHM.

A2.5.1.1 Receiving Operations. An MCO, loaded with SNF, is shipped from the CVDF to the CSB trailer vestibule (Figure A2-9) inside a transportation cask. The transportation cask is unloaded from the trailer, carried to the cask receiving pit, and preparations are made for cask servicing operations. The following sections describe the equipment and operations involved in receiving a cask and preparing for cask monitoring.

A2.5.1.1.1 Cask Receiving. The receiving crane is designed to offload an MCO transportation cask from a transport trailer and transfer the cask to the cask receiving pit. The receiving crane and appurtenances offload the MCO transportation cask from the transport trailer. After an MCO has been removed from the cask by the MHM, the receiving crane retrieves the cask, including an empty MCO, and places the cask back on the transport trailer.

Major Components. The following major components are used during the offloading of a transportation cask:

- Receiving crane
- Cask lifting yoke
- Rail frog assemblies
- Cask receiving impact absorber.

Equipment Description and Operational Considerations. The receiving crane is a 60-ton-capacity gantry crane with one 60-ton main and one 10-ton auxiliary wire rope hoist.
supported on a top-running trolley (Figure A2-19). The crane operates in a clean indoor
environment in the trailer vestibule and load-in/load-out areas of the CSB. The crane is equipped
with a shielded operator station and remote accessories, such as a powered rotating hook, local
control panels, and a radio-controlled operator station.

HNF-SD-TP-SARP-017, Safety Analysis Report for Packaging, Onsite, Multi-Canister
Overpack Cask, provides the safety basis for the cask–MCO during transportation activities. This
FSAR provides the safety basis for the cask–MCO during CSB activities after arrival of the
cask–MCO at the CSB. A cask transported to the CSB enters the trailer vestibule area on a
transport trailer (Figure A2-20). Trailer tire stops installed on the floor of the trailer vestibule
area prevent the transport trailer from backing too far. The overall length of the tractor-trailer is
approximately 54 ft, and the trailer length is approximately 40 ft. After the trailer is backed into
the trailer vestibule, the tractor leaves the area and the telescoping door is lowered. The cask
support and tie-down system hold the cask in an upright position surrounded on all sides by a
work platform. A stairway provides access for operations personnel to the elevated platform for
cASK inspection, radioactivity monitoring, loosening the cask tie-downs, and latching and
unlatching the cask-lifting yoke (Figure A2-21) and crane hook. The cask-lifting yoke has two
hooks used for lifting the cask (see Figure A2-21). The cask-lifting yoke and the receiving crane
main hook maintain the lifting height of the cask–MCO below 60 in. The receiving crane main
hook engages with the cask lifting yoke to lift the cask.

Trucks carrying empty MCOs enter the trailer vestibule and the empty MCOs are off-
loaded onto empty MCO transport dollies (Figure A2-22). The empty MCO cart is used to move
the empty MCO to the east end of the load-in/load-out area for storage until the empty MCO is
placed in the transportation cask.

Air/fuel dams (Figure A2-9, sheet 6) in the receiving crane rails, under the Megadoor™,
minimize air leakage paths so that the operating area HVAC can maintain a negative pressure.
The air/fuel dams also provide blockage against burning diesel fuel from entering the operating
area during the postulated fuel spill and fire accident in the trailer vestibule area.

The receiving crane gantry has a span of 27 ft, 6 in. and can travel 161 ft east-west. The
crane travels on runway rails that are recessed and flush with the operating floor. The runway
travel of the receiving crane intersects that of the MHM, which is also a gantry crane system. The
intersecting runway rails are coplanar and therefore have been provided with rail frogs that match
the bridge wheels on both cranes. The rail frog, with stop assembly (Figure A2-9), has been
designed with a rail stop and travel limit switches that prevent the cranes from colliding. An
emergency stop push button installed on the north wall, next to the receiving crane travel limit
floor marking, can be pushed by an individual to stop the receiving crane and prevent receiving
crane travel over the FFTF pit or the MHM maintenance pit. This push button is connected in
series with the shunt contact in the seismic trip panel and stops receiving crane travel when
pushed. In addition, solenoid-powered switch strikers (SPSSs, Figure A2-23, sheet 3) prevent the
receiving crane and the MHM from simultaneously occupying the overlap zone of the service
area. The SPSSs prevent the MHM and the receiving crane from colliding. This is particularly
important when the receiving crane is lowering an MCO cask into the cask receiving pit. As the receiving crane enters the overlap area where the MHM can collide with it, the receiving crane toggles two roller arm limit switches (RALs) that remove power from two SPSSs mounted on the east concrete curb of the CSB (Figure A2-23, sheet 4). The SPSSs are spring loaded and rotate striker arms to a position that will toggle the north slow and north stop limit switches (Figure A2-23, sheet 2) on the MHM. Actuation of the MHM limit switches, if the MHM attempts to enter the overlap zone, removes power from the MHM bridge drive motors and the MHM is prevented from entering the overlap zone. Similar MHM RALs and SPSSs for the receiving crane, activated by the MHM as it enters the load-in/load-out area, cut off power to the receiving crane if it approaches the load-in/load-out area, preventing the receiving crane from colliding with the MHM.

Jib cranes are provided for repositioning the rail frogs after one crane leaves the load-in/load-out area and before the other crane enters the load-in/load-out area. The rail frogs are expected to be repositioned twice for each MCO received. The south jib crane (Figure A2-9), equipped with a hoist and lifting device, has been designed to lift and rotate the rail frog and stop. The north jib crane (Figure A2-9), also equipped with a hoist and lifting device, has been designed to lift and rotate the north rail frog. Both jib cranes will be manually rotated into position as needed. When not in use, each jib crane will be secured in its storage position to prevent a collision with either of the cranes.

The limits of receiving crane gantry travel are established by bridge stops in the east and west building walls. These stops are designed to be contacted by bumpers mounted on the gantry trucks to absorb the energy of a kinetic impact. A positioning/interlock control system on the receiving crane indicates the location of the crane within any 6-in. increment of total crane travel. The resolver and limit switch dual channel interlock system limits crane travel over the FFTF pit and MHM maintenance pit. At a predetermined distance from the FFTF pit, the resolver controls will automatically stop movement of the receiving crane. A second function, controlled by a limit switch striker system mounted on the bus bar, prevents receiving crane travel over the FFTF pit or the MHM maintenance pit. If it is determined that the receiving crane is not carrying a cask, two different actions are required for the receiving crane to travel over the FFTF pit. The first action requires use of a control switch on the receiving crane control panel, and the second action requires personnel to use a supervisor-controlled fortress key (located remote from the receiving crane control panel). With the receiving crane emergency push button in the enable position and the control switches in the override mode, the receiving crane is permitted to travel over the FFTF pit. An interlock system on the crane prevents the crane from traveling east of the FFTF pit when the load suspended from the main hoist is identified as a transportation cask containing an MCO. These interlocks prevent the crane from hoisting the cask-MCO above the FFTF or MHM maintenance pits. A drop of the cask-MCO into either of these pits is prevented by an operator activating the receiving crane emergency stop push button and the receiving crane control interlocks.

Amber hazard lights mounted near the three doors providing entrance and exit from the support area building to the operating area (doors 008, 013, and 022) warn operating personnel
that the receiving crane is in the immediate vicinity. The lights (ceiling-mounted for doors 013
and 022 and wall-mounted for door 008) illuminate and shine on the doors whenever the receiving
crane is close to the door, and they remain lit until the receiving crane moves away from the
defined area close to the door. The hazard lights are a worker safety feature warning personnel to
be especially careful and to avoid injuries that might be caused by contact with the receiving
crane.

The receiving crane has a hook coverage capability that extends beyond the CSB SNF
requirements. The maximum hook elevation of 27 ft for the main hoist hook is needed to lift a
transportation cask containing FFTF fuel from the road truck. This hook elevation is
approximately 5 ft higher than the SNF cask transportation requirements. The main hoist of the
receiving crane is provided with height-limiting devices. These devices are a rotary hoist travel
limit switch and a weighted, lever-operated, up-limit switch. These devices are mounted on the
receiving crane's trolley floor. The switches are normally in closed position and in series with
other crane protective devices to provide a signal to the hoist-adjustable frequency drive. These
switches are activated when the receiving crane's main hoist hook block rises above the preset
height. When activated, the switches removed power from the main hoist motor and stop travel
of the hoist. These switches provide defense-in-depth safety features to prevent two-blocking the
hoist. The height of the cask lifting yoke is the safety feature for limiting the cask lift height to
60 in.

The receiving crane is expected to receive some radiation exposure when the transportation
cask is being moved. Based on an analysis of the side exposure to the receiving crane
documented in CAL-ME-007, Radiation Shield Requirements — Westinghouse Hanford
Company Receiving Crane, a maximum rate of about 11 mrem/h (0.11 mSv/h) is obtained (about
4 x 10^3 rad for a 40-year lifetime total integrated dose). This rate is a conservative value because
it is unlikely that the receiving crane will experience a 40-year continuous work schedule.
Therefore, the crane is expected to operate for the 40-year design life without significant
deterioration from radiation exposure.

The receiving crane has a shielded operator station mounted on the north bridge truck.
The shielding is 3.5-in.-thick carbon steel with viewing windows that have a shielding equivalency
of 3.5 in. of iron or 1 MeV photons reduced by a factor of 50. Shielding calculations performed
by the receiving crane supplier confirm that a shield thickness of 3.5 in. of steel results in an
individual dose rate of ≤0.2 mrem/h (≤2.0 x 10^3 mSv/h) (CAL-ME-007). In addition, the
specification requirement that 1 MeV gamma photons be reduced by at least a factor of 50 is met
by the lead glass shielding window when using a source based on 270 Mark IV fuel elements.
This source is more representative of the actual source to which personnel in the cab will be
exposed. The contact dose rate on the receiving crane is less than the specification requirement of
11 mrem/h (0.11 mSv/h). Dose measurements and shielding equivalency estimates will be
performed during startup and routine operations.

The receiving crane, including its load blocks, will not be exposed to temperatures,
pressures, or chemicals that would require special design considerations. The receiving crane
design provides for fail-safe features (e.g., load blocking and brakes) to be applied upon loss of power. Also, when an earthquake is detected, wall-mounted accelerometer channels in the northeast corner of the load-in/load-out area automatically disconnect the power source for the receiving crane. The seismic power disconnect eliminates potential failures resulting from seismic-initiated failures of the electrical interlock control system, which is not seismically qualified. The trip circuit is located in the power supply to the receiving crane and includes three tri-axial accelerometer seismic trip system channels connected to redundant power contactors in series. Any of nine sensors can cause both contactors to open. If only one contactor is functioning, the power circuit to the receiving crane will open. According to Report QA8685, *Commercial Grade Item Dedication*, the seismic trip system setting is 0.19 g peak ground acceleration based on guidance in ASME NOG-1-1995, *Rules for the Construction of Overhead and Gantry Cranes*, that the setpoint include the maximum horizontal and vertical spectra and 90% MHM weight participation at 7% damping. The estimated horizontal seismic spectral response acceleration values for CSB buildings (5% damping) and cranes (7% damping) are approximately two times the 0.35 g peak ground acceleration horizontal value. The trip setting, therefore, is approximately 54% of the building and crane response acceleration values to the design basis earthquake. This setpoint trips power to the receiving crane to protect the MCO from damage during the postulated design basis earthquake. The panels containing the accelerometers, signal conditioners, and trip units are rigidly mounted and seismically qualified.

The impact absorber in the cask receiving pit (Figure 2-9, sheet 5) is designed to reduce the likelihood of damage to an MCO inside the cask if the cask is accidentally dropped by the receiving crane.

**Safety Considerations.** The MHM rails and rail frogs, the MCO, and the transportation cask are classified as safety class and important-to-safety Category A. The receiving crane structure and hoist are classified as safety significant and important-to-safety Category B. The transportation cask shielding, the cask receiving impact absorber, the cask lifting yoke, and the MCO shield plug shielding are classified as safety-significant. The receiving crane positioning/interlock control system, the MHM collision avoidance system, and the receiving crane lift height limit switches are classified general service.

**A2.5.1.1.2 Preparation of Cask for Servicing.** The containment tent, tent gantry hoist (CRN-008), and auxiliary equipment are designed for preparing the cask for servicing operations and, after cask servicing operations (see Section A2.5.1.2), for safe handling of the transportation cask lid, and for preparing the cask for removal of the MCO by the MHM.

**Major Components.** The following major components are included in the process of preparing a cask for servicing:

- Cask receiving pit
- Tent gantry hoist
- Shield hatch and MCO guide assembly
- Cask lid automated torque tool
- Containment tent.
Equipment Description and Operational Considerations. The 5-ton motorized tent gantry hoist (also provided with manual hoist raise and lower capability) is used to remove the cask lid in the cask receiving pit and replace it after cask servicing operations are completed. The crane has an underhung electrical wire rope hoist. The crane does not exceed 8 ft in total height and has sufficient hoist capacity to effect a maximum lift of 5 ft. The underhung electrical wire rope hoist is equipped with brakes, end stops, and a free rotating hook. The wheels of the tent gantry hoist are designed to withstand a minimum loading of 5,000 lb each and are provided with locking devices to prevent movement while in use. The tent gantry hoist has an acceleration control, and its traveling speed does not exceed 35 ft/min. The wire rope hoist has a lift speed of 10 ft/min maximum, and the motorized trolley has a 25 ft/min maximum speed. After a power failure, the cask lid may be manually lowered.

The cask lid automated torque tool (Figure A2-9, sheet 7) provides automatic loosening, tightening, and torquing of the cask lid bolts. This tool uses pneumatically controlled torque wrenches mounted to a motor-driven, programmable-logic controlled, turntable fixture to torque the transportation cask bolts to prespecified torque values in a required bolting sequence. The cask lid automated torque tool has five main subassemblies: (1) frame and turntable assembly, (2) drive assembly, (3) pneumatic system, (4) control system, and (5) facility utilities. The frame and turntable assembly is self-aligning with the cask by means of guides that align to the lifting trunnions and tapered alignment pins on the cask lid. Personnel connect the tent gantry hoist hook to the frame and turntable assembly lifting yoke to lift the torque tool and places it on the transportation cask lid, aligning the guides with the tapered alignment pins. After disconnecting the tent gantry hoist lifting hook the following facility utilities are attached to connectors mounted on the lifting yoke: (1) an air supply, (2) a power cable, and (3) an umbilical cord (containing a power supply cable, an air line, and an interface cable) from the automatic torque wrench operator control panel. The drive assembly provides rotary motion for the turntable by means of an AC gear motor coupled through a 24 VDC electric clutch-brake to a chain drive and sprocket. The pneumatic system drives rotary operation of the torque wrenches, the Z-axis torque-wrench positioning system, and the index alignment pins. Personnel use the programmable-logic-control system to loosen the cask lid bolts (two at a time) for removal of the cask lid by the tent gantry hoist. After removing the MCO and inserting an empty MCO, the cask lid automated torque tool is again placed on the cask lid and personnel use the control system to tighten the cask lid bolts using the bolting sequence and prespecified torque value.

After cask servicing operations have been performed and the cask lid bolts have been loosened by the cask lid automated torque tool, the tent gantry hoist removes the cask lid, stores it on the cask lid stand, positions the MCO guide on the cask, and positions the shield hatch ring and shield hatch plate (shield hatch and MCO guide assembly, Figure A2-17) over the cask receiving pit. The 8-in.-thick MCO guide and the 10-in.-thick carbon steel shield hatch ring and shield hatch plate replace the cask lid function of shielding the MCO during MCO removal by the MHM. The radiation dose rate at the shield hatch and MCO guide assembly surface has been calculated at less than 0.5 mrem/h (5 x 10^{-3} mSv/h) in CSB-SH-3001, Service Pit Dose Rates. This hatch has double seals that mate to the MHM. The shield hatch and MCO guide assembly form an inverted cone opening, which mitigates accidental dropping of an MCO into the cask.
A containment tent has been designed to be used during off-normal operations to minimize potential contamination spread during servicing of a pressurized transportation cask received at the CSB. The containment tent, if needed, is a welded, carbon steel frame structure (material conforming to ASTM A36/A36M, Standard Specification for Carbon Structural Steel) with an inner attached flexible plastic polyvinyl chloride tent. The steel structure is 12 ft by 8 ft by 7 ft tall. The structure's height provides MHM bridge clearance (approximately 2 ft, 10 in.) when the MHM travels to the north end of the operating area. The containment tent is staged outside of the trailer vestibule area and is brought into the load-in/load-out area by a forklift and the receiving crane. If needed, the containment tent is placed over the cask receiving pit after a transportation cask loaded with an MCO is placed in the pit and cask servicing operations have determined that the cask is pressurized. The containment tent consists of three rooms separated by doors to provide entrance and egress of personnel while maintaining contamination control of the immediate area around the cask receiving pit. The primary purpose of the containment tent is to contain any contamination that may escape during cask sampling activities. A ceiling access sleeve is provided that allows for lowering a crane hook to lift the cask lid if required. The containment tent is removed from the cask receiving pit after cask servicing operations.

The containment tent is equipped with a high-efficiency particulate air (HEPA)-filtered exhaust unit (EF-005) with a built-in standby exhaust fan. One fan is in standby while the other is in operation. After the containment tent is moved into position, the flexible power cord for the containment tent exhausters is plugged into a power receptacle in the cask receiving service pit. The cask receiving service pit also provides helium and compressed air supply lines and connectors for use at the cask receiving pit. The exhaust system will maintain a negative pressure between the inside and the outside of the containment tent at a 1,000 ft³/min flow rate during the servicing operations. The exhaust unit discharges into the operating area where the air combines with the building ventilation system and discharges to the exhaust stack. On a loss of normal power, the containment tent exhaust system shuts down until power is restored.

The containment tent and the filtered exhaust system, when used, form the confinement envelope for the ventilation area around the cask receiving pit. To achieve and maintain a negative pressure the enclosure is sealed to the floor, and the openings and joints in the material of the enclosure are designed to efficiently maintain the seal.

The containment tent is made of a fire-retardant nuclear-grade polyvinyl chloride fabric in accordance with Chapter 12 of NFPA 701, Standard Methods of Fire Tests for Flame-Resistant Textiles and Films, and has a maximum tearing strength that is in accordance with ASTM D 2261, Standard Test Method for Tearing Strength of Woven Fabrics by the Tongue (Single Rip) Method (Constant-Rate-of-Extension Tensile Testing Machine); and ASTM D 2262, Standard Test Method for Tearing Strength of Woven Fabrics by the Tongue (Single Rip) Method (Constant-Rate-of-Traverse Tensile Testing Machine). The tent is large enough to house the cask lid and the shield hatch and MCO guide assembly. The tent is equipped with service sleeves, 3-in.-diameter minimum, to bring services into the enclosure as needed to support ventilation, to supply power, and to introduce tools.
HNF-3553 REV 0
Annex A — Canister Storage Building

HNF-SD-SNF-SARR-005 specifies a maximum time of 135 days that an MCO can remain sealed inside the transportation cask without venting after vacuum drying operations at the CVDF. The MCO should be removed from the transportation cask within this time limit or the cask–MCO annulus vented to prevent the potential for a flammable gas buildup in the cask cavity (HNF-SD-SNF-SARR-005).

Table A2-1 lists the operating conditions for which the cask receiving system has been designed.

Safety Considerations. The shield hatch and MCO guide assembly are classified as safety significant. The cask receiving pit is classified as safety significant. The containment tent, tent gantry hoist, and appurtenances are classified general service. The tent gantry hoist is important-to-safety Category C because it could potentially drop the cask lid causing minor damage to the top of an MCO.

A2.5.1.2 Cask Servicing Operations. The transportation cask servicing system is designed for checking the pressure of the transportation cask and, if necessary for recovery operations, taking a sample of the gases inside the cask and purging the gases from the cask. The cask servicing system can be used by personnel to check the pressure of the received cask. Gases inside the cask are purged or vented with helium to ensure that potential hydrogen concentrations are diluted below flammable concentrations.

Major Components. The following major components are part of the cask servicing operations:

- MCO servicing HEPA filter
- Flexible steel hose
- MCO servicing instruments
- Sampling equipment.

Equipment Description and Operational Considerations. Personnel connect the cask servicing system (Figures A2-24 and A2-25) flexible steel hose to the cask access port on the cask lid. The servicing system pressure gauge indicates the internal pressure of the cask space surrounding the MCO. A pressure increase up to 3 lb/in² gauge is possible in the transportation cask because the MCO and transportation cask may increase in temperature after the cask lid is bolted on and the transportation cask is transported to the CSB. The temperature increase causes the air pressure inside the transportation cask to increase. A cask pressure less than 3 lb/in² gauge indicates that the MCO can be handled using normal procedures. The normal operating steps include purging or venting gases from the cask through the cask servicing system's HEPA filter and into the operating area HEPA filter housing. These gases are mixed with helium to ensure that potential hydrogen concentrations that may be present are diluted to below flammable concentrations. The cask bolts are removed, cask lid is removed, and the shield hatch and MCO guide assembly is placed in the cask receiving pit opening using the tent gantry hoist. These steps prepare the MCO for lifting by the MHM.

This table is for information only and does not provide operational controls.

- MCO = multi-cask overpack.
- NA = not available.

March 2000
A pressure ≥3 lb/in² indicates that the MCO seals may have released gases into the cask and is considered an off-normal condition according to HNF-4509, *Evaluation of Canister Storage Building Cask Receipt Pressure*. If pressure in the cask is higher than 3 lb/in² gauge, the cask servicing system is designed for taking a sample of the gases, purging gas from the cask, and replacing it with an inert gas. This allows the cask lid to be removed to prepare the suspect MCO for placement in an overpack tube for monitoring (Section A2.5.3 summarizes overpack storage tube monitoring operations). The cask servicing system provides HEPA-filtered pathways to achieve the safety function of preventing or mitigating radiological releases during cask purging.

The cask servicing system provides inert gas to ensure that cask servicing activities prevent gases inside the cask from becoming flammable or explosive. Excluding oxygen from the cask, taking a gas sample from the cask, results of laboratory analysis of the sample for hydrogen, and purging hydrogen to safe concentration levels before release through the ventilation building system provide assurance that safe operating conditions are being maintained.

Venting of the internal cask atmosphere occurs through HEPA filter FH-2 into the load-in/load-out area where the gases mix with air circulating into the operating area exhaust system HEPA filter plenum and out of the CSB stack. These cask gases may contain suspended radioactive particulate that have leaked from the MCO into the cask. The cask may also contain residual particulate from the K Basin loading and cold vacuum drying unit operations. Radiation monitoring of the load-in/load-out area is provided by continuous air monitors (CAMs). Venting continues until cask pressure decreases to atmospheric pressure. During venting operations, a sample syringe may be used to collect a sample. A subsequent laboratory analysis measures for hydrogen concentration, water moisture, and other gaseous chemicals.

During venting operations, the servicing system automatically injects inert gas into the gas flow to dilute the hydrogen concentration to safe levels below the flammability limit. This dilution prevents a flammable mixture from reaching the operating area exhaust system. The servicing system proportionally controls the inert gas flow based on the pressure of the cask gases being vented to ensure efficient mixing and dilution. After reducing the cask pressure to atmospheric pressure, the cask can be pressure-purged with inert gas by pressurizing the cask with inert gas and venting through the cask servicing system to atmospheric pressure. This pressurizing and venting process may be repeated several times until the hydrogen concentrations within the cask are below the flammability level of hydrogen in air. After the pressure-purging and venting cycles, the hydrogen concentration within the cask will be low enough for safe removal of the MCO from the cask and placement in an overpack tube for monitored storage. If the preferred option is storing an MCO in the cask for a short time period (see Section A2.5.3) or shipping the MCO, the MCO cask may be repressurized with inert gas to ensure maintaining an inert atmosphere and preventing air in-leakage.

Table A2-2 lists the operating conditions for which the cask servicing operations equipment has been designed.

HEPA = high-efficiency particulate air (filter).
RH = relative humidity.
Safety Considerations. For the transportation cask servicing system, the flex connector, HEPA filter, piping between the filter and the cask, and PSV-102 are classified as safety significant. The remaining components are general service (Figure A2-24).

A2.5.1.3 Multi-Canister Overpack Handling Machine Operations. The MHM (Figure A2-26) is designed for safe handling of an MCO in the operations area of the CSB. The MHM removes an MCO from the cask in the cask receiving pit and carries the MCO to a standard storage tube for interim storage, to the sampling/weld station for sampling/weld operations, or to an overpack storage tube. The first step in placing an MCO into a storage tube is the removal of the storage tube cover. The MHM, containing the MCO retrieved from the cask receiving pit, moves on its gantry crane to a position above the storage tube. The seismic restraints are set. The MHM retractable shield skirt is lowered to meet the operating deck to form shielding. The MHM turret is rotated until the storage tube plug cavity is above the storage tube plug, and the tube plug is raised into the tube plug cavity. Once the tube plug is fully raised, the MHM turret rotates until the MCO cavity is aligned with the storage tube, the turret locking pins are set, and the MCO is lowered into the storage tube. When the MCO is on the bottom of the storage tube or on top of an intermediate impact absorber, the MHM grapple disengages and withdraws, the MHM barrel rotates to place the tube plug cavity over the storage tube, the tube plug is lowered into place, the turret is rotated to the camera position, the seismic restraints are released, and the MHM moves away. The storage tube cover is replaced, and staging operations are complete. In addition, the MHM retrieves intermediate impact absorbers from the MHM maintenance pit and lowers them into the standard storage tubes before retrieving MCOs from the cask receiving pit.

Major Components. The following major components are used during MCO operations:

- MHM bridge and trolley
- MHM cask and turret
- MHM retractable nose unit and shield skirt
- MHM ventilation and filtration system
- MHM power and compressed air supply.

Equipment Description and Operational Considerations. A bottom impact absorber is placed in each standard and overpack storage tube before placement of the MCO. Also, before the MHM can insert an MCO into a tube or remove an MCO from a storage tube, the storage tube cover is removed and an interface guide ring funnel (Figure A2-27), constructed of ASTM A36 carbon steel, is manually installed on the top flange of the storage tube. An HPT surveys the storage tube cover while it is being removed and surveys the top of the tube plug assembly. The storage tube cover will be decontaminated if excessive contamination is found. Table A2-3 lists the operating conditions for which the standard storage tube has been designed.

*NA* = not applicable.
The MHM is a fully shielded machine designed to safely transport an MCO within the CSB facility service and operating areas, including MCO retrieval from the cask receiving pit, the sampling/weld station pit, and the storage tubes. The MHM also removes and replaces storage tube plugs, the service station shield hatch plate, the sampling station shield plug, and impact absorbers.

The MHM is shown in Figure A2-26. The MHM comprises a bridge and trolley system and a shielded cask and turret system (Figure A2-28). The MHM weighs approximately 990,000 lb and is 17 ft high from the operating deck to the top of the trolley rails. The MHM turret and MCO hoist enclosure extend above this height. The MHM gantry bridge structure spans 126 ft, 6 in. from rail center to rail center. The wheel base is 23.5 ft center-to-center of the outside wheels, with two sets of 36-in.-diameter wheels on 60-in. centers. The MHM has a 2-in. nominal deck clearance below the nose of the cask with the shield skirt lifted above the deck, and a 9 ft, 0 in. minimum clearance between the deck surface and the bottom of the MHM gantry bridge box beams.

The SNF Project CSB uses the MHM to transport the MCOs. The MHM is designed to ride on steel rails that run north-south and are located at the 709 ft, 0 in. floor elevation. Anchor bolts are installed in the deck at the east and west sides of the operating floor for the installation of MHM rails. The MHM rails are installed in trenches that run north-south and cut across the receiving crane rails. The embedded MHM rails are provided with lateral restraints in addition to the anchor bolts. The lateral restraints and anchor bolts are designed to provide restraint of the MHM rails during the design basis earthquake. The receiving crane rails are installed in trenches that run east-west in the northernmost portion of the operating floor. The reinforced concrete construction of the northernmost portion of the operating floor includes the load-in/load-out area. Special rail crossover components called “frogs” are provided where the MHM rails and receiving crane rails intersect.

MHM operation is governed by a system of electrical interlocks. These interlocks (Table A2-4) provide permissives to the operator that allow the operator to perform MHM operations (e.g., actuate drives, motors) based on signals from a large number of sensors and switches. As can be seen in Table A2-4, many of the interlocks prevent or preclude MHM operational errors that may result in radiological consequences or facility damage. These interlocks are typically provided with two separate interlock protection channels (X- and Y-channel), thus providing single-failure-proof protection. Chapter A4.0 and the accident analysis sections in Chapter A3.0 identify MHM interlocks that perform safety-significant defense-in-depth functions. The operator station has indicator lamps, displays, and alarms that inform personnel about the state of the MHM. The operator will input commands to actuate drives via push buttons, switches, and joysticks.

This table is for information only and does not provide operational controls.

The previous safety function of this interlock is no longer needed.

MCO = multi-canister overpack.

MHM = multi-canister overpack handling machine.
The MHM is designed to prevent MHM lateral displacement that would shear an MCO as it is being raised or lowered inside the throughport. A system of MHM drive control interlocks provides for safe operation of the MHM. Interlocks prevent inadvertent activation of both bridge drive motors and the trolley drive motor unless the interlock sensors report that the state of the MHM is appropriate to allow safe operation for the motors. This interlock-permissive system greatly reduces the chance of (or in some cases prevents) damage to an MCO caused by personnel error, NPH, or failed protection channels.

**Bridge and Trolley System.** The MHM bridge and trolley system comprises a double-girder bridge with a top-running trolley supported on four end trucks that have two wheels each. The crane bridge rides on north-south runway rails recessed in the operating deck. The bridge drive truck system on each south girder (two motors, 7.5 hp each) is geared down to 244:1. Associated with each of the bridge trucks (four total) is braking from the flux vector-controlled brakes and end-of-travel switches. The trolley travels east-west on rails mounted on top of the bridge. The shielded cask and turret system is rigidly supported on the top-running trolley. This arrangement allows the cask to be positioned over all of the MCO storage and handling locations throughout the operating area. The 15 hp trolley drive system also has flux vector-controlled braking and end-of-travel switches. The trolley drive motor and the bridge drive motors have variable frequency motor controllers that allow operation of the motors at variable speeds. These variable frequency motor controllers have redundant contactors (X- and Y- channels), thus providing single-failure-proof protection.

The crane rails and two rail frogs (Figure A2-29) provide the interface surface for the four trucks and for the bridge seismic rail clamps. The rail frogs (Figure A2-9) are designed to bridge the gap at the rail intersections of the receiving crane and MHM rails. Each frog makes up the missing section of rail for one rail system (and corresponding machine) while placing a rail arm with a wedge stop along the rail in the direction of the other rail system (and corresponding machine). The wheels of the other machine (MHM or receiving crane) are stopped by the mechanical stop if they attempt to enter the overlap zone with the rail frog not aligned toward them. The rail frog at the southwest corner of the receiving area is equipped with a striker to actuate a limit switch on the MHM, which will monitor the orientation of the rail frog as the MHM attempts to cross into the receiving area. If the rail frog orientation is incorrect, a limit switch will interrupt power to the MHM bridge and stop MHM movement.

Seismic clamps located in the bridge wheel trucks grip the MHM crane rail flanges when deenergized. The crane bridge and trolley restraints ensure that the bridge is held in place on the runway rails and the trolley stays in its location on the trolley rails on the bridge girders during a seismic event. Several interlocks depend on the seismic clamps being engaged with the rails before permitting various functions of the MHM to take place. The fail-safe bridge truck clamps have shoes that are applied by coil springs and hydraulic motors that are energized to disengage the clamps. The redundant seismic clamp position indication is interlocked with the MCO hoist limit switches and inhibits power to the clamp hydraulic pump if the hoist is not at its top position. Interlocks also prevent the trolley brakes from being applied when the trolley bridge is moving. A hydraulic flow orifice prevents a rapid depressurization of the hydraulic system on the bridge.
truck seismic restraint clamps, and thus clamp engagement, before the MHM has coasted to a stop on loss of electrical power.

Two seismic X-restraint pins (Figure A2-30) lock the trolley to the bridge rails, preventing east-west motion of the trolley and turret. When activated, trolley pins are inserted into pockets welded onto the bridge beam. Personnel visually verify that the trolley seismic restraint pins (Figure A2-30) are fully inserted before using the MCO hoist. The trolley south seismic pin can be seen by standing on the trolley ladder. The trolley north seismic pin can be seen using a mirror mounted near the MHM control cabinets on the operating platform. These locking pins have the shear strength to safely withstand seismic forces during a design basis earthquake. Restraints for the trolley in the north-south direction are passive restraints formed by the wheel flanges. Uplift restraint is provided by four fixtures that hook beneath the top flange of the girders. The seismic pin power is interlocked with the MCO hoist limit switches and inhibits power to the locking pin drive motor to disengage the pin if the hoist is not at its top position. These locking pin drive systems have position switches that permit power to the MCO hoist only on redundant indication of full insertion.

A collision-avoidance system is provided to stop the MHM when it collides with objects on the deck of the CSB that could interfere with the movement of the MHM. Interlock P10 stops trolley travel when the east-west bumpers are activated and stops bridge travel when the north-south bumpers are activated. The MHM collision-avoidance system uses an octagonal arrangement of pressure-sensitive bumpers with redundant sensors surrounding the retractable shield skirt at the bottom to detect by contact objects that are in the path of the MHM. The MHM collision-avoidance system actuates a signal to the MHM control system once the object is detected (bumped), and the P10 interlock prevents movement of the MHM toward the detected object. The P10 interlock inhibits crane bridge travel and prevents crane trolley travel collision with the sample station gantry crane, the service tent, or an object greater than 2 in. high standing on the operating deck.

The receiving crane and MHM anti-collision systems prevents the MHM and the receiving crane from colliding when they operate at the north end of the CSB operating area. When one crane or the other is in the overlap zone where a collision could occur, SPSSs (Figure A2-23, sheet 3) are tripped (de-energized) to restrict operation of the other crane so that it cannot travel into the same area. When the MHM enters the overlap zone, the MHM toggles two RALSs, (Figure A2-23, sheet 4) which removes power from the two SPSSs mounted on the receiving crane's power strip structural support. The SPSSs are spring loaded and rotate striker arms to a position that will toggle RALSs on the receiving crane. Actuation of the receiving cranes RALSs, if the receiving crane attempts to enter the overlap zone, removes power to the receiving crane bridge drive motors and the receiving crane is prevented from entering the overlap zone. The P5 MHM interlock removes power to the bridge drive motor of the MHM if it attempts to enter the receiving area when it is already occupied by the receiving crane. As noted earlier, the rail frog mechanical stop also prevents the MHM and receiving crane from colliding.
The MHM travel limit switches include features that prevent the MHM from traveling too far north or south and a safety system for preventing the MHM turret from rotating to the MCO position while at the MHM maintenance pit or sampling/weld station area. Limit switches mounted on the east MHM tie beam deck (Figure A2-23, sheet 2) are toggled by the MHM north slow and stop limit switch striker arm (Figure A2-23, sheet 4) if the MHM travels too far north. The striker arm first toggles the north slow limit switch, slowing the MHM speed, and then, if the MHM continues to travel north, toggles the north stop switch to remove power from the MHM bridge drive motors. Similarly, the south slow and stop switch striker arm slows and stops MHM travel if the MHM attempts to travel too far south. The MHM maintenance pit limit switch system consists of RALSs mounted on the east MHM tie beam deck (Figure A2-23, sheet 4) and ramps mounted on supports (Figure A2-23, sheet 4). As the MHM travels north, the upper RALSs are toggled by the exchange facility ramps that inhibit turret rotation when the trolley travels over the MHM maintenance pit. This system reduces the risk of dropping an MCO into the MHM maintenance pit. A similar single RALS and ramp system at the south end of the operation area warns the MHM operator if the sampling/weld station covers are not in place before operating the MHM in the area.

**Cask and Turret System.** The integrated cask and turret system allows the MHM to:

1. locate the cask receiving station, a storage tube, or a sampling/weld station;
2. remove the shield hatch plate, the tube plug, or the sampling/weld station center shield plate;
3. retrieve and transport an MCO from the transport cask; 
4. place an MCO in, or remove and transport an MCO from, a tube or sampling/weld station; 
5. replace the tube plug, shield hatch plate, or center shield plate; and 
6. place an intermediate impact absorber in the tube (note Figures A2-31 and A2-32). The cask and turret system comprises a stack of interconnected components that is rigidly suspended from the trolley. The trolley supports a rotating upper turntable, which supports the upper turret and hoist assembly. A stationary lower turntable and retractable shield skirt are fixed below the rotating turret by the base torsion link arm from below the trolley. The two rotating points use large concentric slewing bearings and a large ring gear that are mounted concentrically. The upper turret and the turntable can spin freely around the vertical centerline established by the two bearings. Rotation of both components is controlled with operational interlocks and seismic restraints, especially during MCO raising and lowering operations. The turret rotate drive motor and the MCO hoist motor have variable frequency motor controllers that allow operation of the motors at variable speeds.

The upper turret has three main cavities:

- An MCO cavity inside the main cask body, with an MCO hoist and grapple that is used for raising and lowering an MCO or an impact absorber and, using a plug adapter grapple, replacing a tube plug
- A plug cavity, with a hoist and grapple system to accommodate routine plug handling, to facilitate replacement of damaged plugs, and to raise and lower the shield hatch plate and center shield plate
A radiation-hardened television camera with a zoom lens for viewing down a storage tube via the television monitoring system, and sufficient lighting for accurately positioning the MHM on the appropriate targets over the cask receiving station, above a storage tube, or at a sampling/weld station, and for viewing down a storage tube.

These three cavities each have a vertical centerline spaced equidistant from the vertical centerline of turret rotation in such a way that each may be indexed to precisely coincide with the single throughport in the lower nonrotating turntable. The main cask body represents the largest mass in the upper turret. Placement of the cask body and plug cavity housing means that the upper turret has a heavy mass center of gravity eccentrically located to the vertical line of rotation. Figure A2-33 provides a cross-sectional view of the MHM turret showing the MCO and tube plug cavities.

The upper turret can be rotated into the following three index positions: (1) MCO cavity, (2) tube plug cavity, and (3) television camera. The upper turntable and drive motor are used to rotate the MHM turret to the desired orientation. The lower turntable has a single throughport for passage of an MCO, tube plug, or impact absorber. The throughport is on the same radius as the three cavities eccentrically located with respect to the rotation centerline of the two slewing bearings. This arrangement allows the turret to rotate with respect to the base such that one of three turret compartments may be aligned with the throughport. The lower ends of the MCO and tube plug cavities, which are “open” when MCOs or plugs are being transferred into or out of the MHM, are automatically closed whenever the upper turret is rotated away from the “MCO cavity” or “tube plug cavity” index positions.

The turret-locking pin (Figure A2-34) is a powered, 5-in.-diameter horizontal steel pin that fits into any of three pockets in the turret support turntable (Figure A2-35). When the pin is engaged in one of these three pockets, it serves to precisely align the turret with one of its three positions (MCO cavity, tube plug cavity, or television camera) and to prevent it from rotating by securing it to the trolley. Personnel visually verify that the turret-locking seismic pin, located on the same level as the MHM operating platform, is fully inserted before using the MCO hoist. This locking pin has the shear strength to safely withstand the seismic forces of a design basis earthquake. The single failure-proof interlock with the MCO hoist limit switches inhibits power to the locking pin drive motors to disengage the pin if the hoist is not at its top position. This locking pin drive system has a position switch that permits power to the MCO hoist only on satisfactory engagement of the locking pin.

A powered, base-locking pin (Figure A2-36) secures the rotating turret base to the stationary lower turntable at each turret index position. On the operating deck, an individual, while monitoring the MHM visually verifies that the base-locking pin seismic restraint is inserted before the MHM operator uses the MCO hoist. The base-locking pin has the shear strength to safely withstand seismic forces during a design basis earthquake. The locking pin drive has position indication switches that are interlocked with the MCO hoist and with the bridge, trolley,
and turret drives. The base-locking pin drive systems have switches that will permit power to the MCO hoist only on satisfactory engagement of the locking pins.

A television camera within the MHM camera cavity on the turret assembly is used to position the MHM and view inside the storage tubes. A single zoom-lens camera is mounted within the camera cavity along with six tungsten halogen lamps and a coarse fixed-lens backup camera. When the turret is rotated to the television camera, the main camera is aligned with the machine axis so that precise alignment between this axis and the desired MHM location may be achieved. The signal from either camera can be displayed on a 12-in. video monitor at the operator station console in the operator station on the MHM trolley. Using the image on the monitor, personnel can recognize when the MHM is properly aligned with the appropriate target. The camera also provides personnel with a means to read the unique alphanumeric identifier on the top face of each tube plug.

A tube plug hoist and grapple system (Figure A2-37) is used to raise and lower the storage tube plug. The MHM has the ability to lift the tube plug, or other similar plug (i.e., shield hatch plate or center shield plate), with the plug hoist, and to place it back into its fitted opening. During MCO retrieval or placement operations, the tube plug cavity temporarily houses the tube plug or other similar plug. Redundant optical sensors in the tube plug cavity detect the presence of a tube plug suspended by the tube plug hoist and close contacts which allow the turret to rotate to the MCO hoist position. The tube plug hoist is a screw jack driven by a single-speed AC motor that is vertically mounted. The interface is between the MHM plug grapple and the lifting pintle of the tube plug or other similar plug. MHM controls ensure that the grapple and hoist are able to hold the plug securely, without the ability to release it, except when the weight of the tube plug is supported. Mechanical roller cams engage the grapple jaws before raising the tube plug or until the tube plug is seated in the tube when lowering it. A mechanical torque limiter ensures that the force exerted by the jack cannot exceed design limits in any faulted condition. In the event of motor failure, a shoe brake prevents reverse drive and plug drop.

The MCO hoist and grapple system (Figure A2-38), located in the MCO cask within the turret (Figure A2-33), raises and lowers an MCO, a replacement storage tube plug, or an intermediate impact absorber. The MCO hoist and grapple system has a rated capacity of 12 tons and meets single failure criteria (HNF-S-0425). The upper limit of hoist travel is set by a limit switch (the high limit switch), which is tripped by the top of the MCO grapple. The elevation of the grapple is of utmost importance because it represents the only elevation at which the MCO can be considered safe from being accidentally impacted or trapped by inadvertent operation of the bridge, trolley, and/or turret drives. In addition to interrupting power to the hoist motor, tripping the high limit switch also permits the disengagement of the base and turret locking pins. This in turn permits rotation of the upper turret to the television camera, thereby automatically closing off the bottom opening of the MCO cavity. The high limit switch has a redundant backup, which is labeled the high-high limit switch. The MCO hoist has a resolver to indicate the instantaneous grapple height. An MCO centering guide mounted in the MCO cavity (Figure A2-33) helps to align the MCO when an MCO is lowered into a storage tube or a
The grapple is suspended by a redundant, two-part wire rope system. The MCO grapple (shown in Figure A2-38) is a self-centering, self-aligning, six-jaw grapple. The grapple is designed to engage and lift, and lower and release, the MCOs, impact absorbers, and tube plugs fitted with a lifting adaptor. The grapple uses its own weight to align the six jaws with the MCO lifting feature at all offset positions within the storage tube. An air-operated cylinder releases the jaws, allowing them to close under their own weight once the grapple is fully engaged and positioned. A positive mechanical lock on the locking plate ensures the jaws cannot be opened when the grapple is carrying a load. A manual, compressed air-actuated release mechanism for the jaws is available if normal-supply compressed air is unavailable. The manual connection for the air cylinder is located inside the hoist enclosure and accessible through hand holes at the intermediate platform.

Control and interface of the grapple is through duplicate limit switches. Two sets of limit switches are used to indicate the position of the probe. The first set of limit switches is set to operate once the control probe has been depressed approximately 0.375 in. (load contacted) to stop the hoist and initiate the jaws-open sequence to center the grapple. The second set of limit switches operates when the proximity probe is fully depressed by the locking plate, indicating the grapple is seated. This second set of switches enables discrimination between an MCO and an impact absorber or tube plug because each impact absorber and tube plug adaptor has a recessed center that can be sensed by the central probe in the MCO grapple.

Both the MCO and plug grapples are equipped with electrical and mechanical interlocks that prevent them from opening unless they are in the correct location and orientation. This is intended to eliminate the possibility of inadvertently releasing and dropping the MCO or the plug. The interlocks also prevent the hoists from raising or lowering unless the grapple position and status are as required for safe handling of the MCO and plug.

A festoon connects the CSB facility's service air system to the MHM. Valves in the grapple air supply system include a manual isolation valve to isolate the grapple air supply from the balance of the air supply system on the MHM. A pressure regulator controls the supply pressure to the grapple air supply system. A pressure switch provides pressure indication for the system and actuates and annunciates on low pressure. A check valve is provided to prevent back contamination of the air supply. A solenoid-actuated valve directs air to the grapple actuation cylinder to open the grapple jaws or relieves the pressure within the grapple actuation cylinder to close the grapple jaws. The solenoid-actuated valve is spring-fail to relieve pressure within the grapple actuation cylinder on loss of power. A backup air supply reservoir and valves are provided on top of the hoist enclosure (Figure A2-39).

The MCO hoist consists of dual rope systems, each capable of supporting the full load on a twin-groove drum that is connected to a primary and secondary planetary right angle gearbox, one on each side of the drum. The primary electric shoe brake is positioned between the motor...
and right angle gearbox and provides the main load-holding brake. A second brake provides dual
backup load-holding capability. Two handwinds and a height resolver and indicator are
connected via a bevel gearbox. The handwinds provide a means for raising or lowering the load
in the event of motor failure. The resolver provides a signal to the control system indicating
current grapple height. A dial indicator on the drum handwinds provides a rough mechanical
position indication of the grapple height.

The two hoist ropes travel from the drum up to twin head pulleys, down to the load block,
and back up to a balancing beam where they are fixed (Figure A2-38, sheet 2). Load cells on the
hoist, two per rope, indicate the load suspended from the grapple. Limit switches on the balance
beam detect whether its position is level, thereby maintaining balanced loads between the support
ropes. This arrangement detects any unbalanced loading or spooled length discrepancy between
the two ropes. A hydraulic cylinder connected to a strongback mounted on the floor of the FFTF
pit (Figure A2-9, sheet 3) will be connected to the MHM hoist periodically to provide verification
testing and calibration for the MHM MCO hoist weight system.

The hoist holding brakes support the MCO when hoisting is halted with the MCO
suspended. Each holding brake has a capacity to hold a load equal to 125% of the MCO hoist
rated load. The holding brakes are automatically applied on interruption of power to the hoist
motor by loss of brake power and spring-close shoes on the drum. For controlled lowering of the
MCO, the hoist is equipped with a flux-vector motor drive that provides normal braking to
control the descent at any speed within the specified speed range.

Retractable Nose Unit and Shield Skirt. The MHM shield skirt and the nose unit is a
suspended assembly that is raised when the MHM moves and is lowered when the MHM
performs MCO transfer operations. The shield skirt is a concrete slab resting on top of a steel
ring that suspends four rows of annular steel segmented floating blocks. Airflow to provide air
sweep of any contamination is drawn through the nose unit and shield skirt by the MHM extract
ventilation system. The MHM retractable shield skirt is lowered to rest on the deck and the nose
unit is lowered against an interface ring or pit cover that encircles the access opening. Interlocks
are provided to constrain the raising and lowering of the skirt and the nose to the proper
sequence. The shield skirt position is interlocked with bridge, trolley, and turret drives to
maintain shielding integrity and to prevent damage to the MCO, deck, or the MHM. The shield
skirt provides radiation shielding for the operating area during MCO raising, lowering, and
transferring operations.

Ventilation and Filtration System. To support ALARA goals, the MHM onboard filtration
(extraction) system (Figure A2-39) removes any unexpected incidental contamination that may be
present on an MCO. This system also helps to minimize contamination spread and cleanup costs
in a radiological release scenario. The MHM maintains an airflow up through the MCO turret
cavity (around the MCO) and out through a HEPA filter that exhausts to the operating area. An
alpha CAM, beta CAM, and a radioactive gas monitor can be mounted on the MHM trolley
exhaust or work area if radiation monitoring is necessary. A negative pressure within the MHM is
maintained relative to the operating area. The airflow provides cooling. Passive natural
convection cooling to the massive steel casting of the MCO cavity (a heat sink) will provide supplemental cooling of the MCO. The operating area has been designed to be maintained by the operating area exhaust system at a negative pressure relative to the outdoors and the support building. Therefore, any airborne contamination from the MHM will be exhausted through the operating area HEPA filters before reaching the environment.

**Electrical Power and Compressed Air Supply.** The MHM festoon system provides electrical power and a compressed air supply for the MHM. The part of the festoon system that accommodates bridge movement is suspended from a support rail mounted on the CSB wall columns. Electrical power for the MHM is provided from the northeast corner of the CSB through a 480 V main disconnect switch that is fed by motor control center (MCC) MC-32-209. Power is routed to the MHM bridge and trolley via the bridge festoon and the trolley festoon. The disconnect switch provides power to the MHM power loads.

Electrical service to the cask mechanisms is provided via the turret rotate festoon and a flexible connection between the trolley and rotating upper turret. One end of the flexible connection is suspended from the hoist platform and the other end is attached to the turret rotate festoon mounted on the trolley. The MHM power supply connection includes dual seismic contactors mounted to the northeast deck curb in the receiving area and actuated by two of three accelerometers in any one of three channels. The seismic power disconnect eliminates potential spurious operation resulting from seismic initiated spurious operation of the non-seismically qualified MHM electrical control system. The 480 V redundant power line contactors are located in a separate panel next to the accelerometer trip circuit panel. The power line contactors are fed by a signal from the accelerometer trip circuits based on a two-of-three trip signal polling circuit. If any contactor operates, the power circuit to the MHM will open. The trip setting for the seismic trip system is 0.19 g peak ground acceleration (Report QA8685) based on guidance in ASME NOG-1-1995 that the setpoint include the maximum horizontal and vertical spectra and 90% MHM weight participation at 7% damping. The estimated horizontal seismic spectral response acceleration values for CSB structures (5% damping) and cranes (7% damping) are approximately two times the 0.35 g peak ground acceleration horizontal value. The trip setting, therefore, is approximately 54% of the building and crane response acceleration values to the design basis earthquake. This setpoint trips power to the MHM to protect the MCO from damage during the postulated design basis earthquake. The panel containing the accelerometers is rigidly mounted and seismically qualified.

The CSB compressed-air supply line provides plant air to the MHM festoon cable line connection at approximately 100 lb/in² gauge. The compressed-air supply system provides air for gas cylinder actuation (opening) of the MCO grapple and also for cooling the MCO camera lights. The cooling airflow is sized to maintain ambient air temperature around the cameras while cooling the lights provided for the cameras. An onboard air receiver (Figure A2-39) is required to function as a backup compressed-air source to the manually actuated MCO grapple opening valve. This arrangement ensures that the manual opening function is always available. The air receiver is provided with an extra connection to facilitate pressurization using a portable air compressor in the event that plant air is unavailable.
System Operation. The MHM retrieves an MCO after the transportation cask containing
the MCO has been lowered into the cask receiving pit by the receiving crane. The sides of the
cask receiving pit are equipped with guides to align the cask so the MCO can be removed from
the cask by the MHM's MCO grapple and hoist. An impact absorber at the bottom of the pit
supports the cask at the correct elevation so the grapple and hoist will encounter the MCO at an
accessible height. The cask impact absorber also mitigates any damage to an MCO caused by a
cask drop.

The shield hatch and MCO guide assembly covers the cask receiving pit and provides
shielding. It consists of a shield hatch ring and a shield hatch plate. It serves as the physical
interface with the MHM retractable nose and shield skirt during MCO transfer operations
between the MHM and the transport cask. The center opening in the shield hatch ring is sized to
allow passage of an MCO. The diameter and design of the shield hatch plate are such that the
plate may be handled by the MHM in a way that is similar to handling the tube plug. A recessed
lift pintle is provided on the top center of the shield hatch plate for lifting by the MHM plug
grapple. The top of the pintle is flush with or below the surface of the operating deck. The lift
pintle is marked with a sighting target for interface with the MHM television camera to assist in
positioning the MHM. The shield hatch plate is stowed in the MHM plug chamber during MCO
raising operations. The MHM nose unit lowers to contact the shield hatch ring. The MHM
retractable shield skirt lowers to make up the shielding interface, contacting the concrete area
around the cask receiving pit, and protecting personnel from radiation exposure. The MHM
MCO grapple couples with the lifting flange at the top of the MCO, and the hoist raises the MCO
within the MCO cavity until the upper limit switch interlock is activated. The MHM then replaces
the center shield hatch plate and moves the MCO to the appropriate tube location or
sampling/weld station.

The tube plug cover plate must be separately removed from the deck embed before a
storage tube can be accessed. A small hoist attached to the tube vent and purge cart lifts the tube
plug cover plate and stows the plate temporarily in a safe, out-of-the-way location. If a storage
tube already is being used to store SNF, the material balance area custodian removes the tamper-
indicating device from the storage tube plug prior to access.

After removing the tube plug cover plate, personnel install a standard interface guide ring
funnel (Figure A2-27) using the tube vent and purge cart hoist. The standard interface guide ring
funnel (Figure A2-27) is a spacer placed between the storage tube and the MHM nose unit. The
standard interface guide ring funnel fits snugly into the top of the storage tube embed, resting on
the bellows assembly top flange. It fills the gap between the top of the bellows assembly and the
deck level. The standard interface guide ring funnel is lifted and handled using the tube vent and
purge cart hoist.

After preparing the storage tube for an MCO transfer operation, the operator drives the
MHM over the tube opening. Before moving the MHM, the MHM operator rotates the turret
and positions the television camera over the center of the throughport. The operator positions the
MHM over the tube and uses the television camera to accurately position the MHM's nose and
throughport directly over the tube centerline. The camera lighting system allows the operator to
clearly view the surfaces below the camera on a view screen located at the MHM console. The
camera view screen has a crosshair on it to aid the operator in centering the MHM over the tube.
The crosshair is lined up with a marking on the top center of the tube plug lift pintle. The
operator also views the tube plug number to verify that the proper tube is being accessed. The
MHM shield skirt is lowered to the operating deck so that adequate shielding is available before
tube plug removal.

With the MHM properly aligned over the tube, the operator sets the seismic restraints,
rotates the MHM turret, and aligns the tube plug cavity with the throughport. The tube plug
grapple is lowered and engages the tube plug pintle. Once properly engaged, the tube plug is
lifted into the MHM tube plug cavity, and the turret is rotated back to the television camera
position. The camera can be used to inspect the interior of the tube using a variable zoom lens
and supplemental lighting to view the MCO that is to be removed or to verify that an impact
absorber, bottom or intermediate, is in place before an MCO is lowered into the tube.

With the tube plug removed, the MHM performs one of three general tasks: place or
remove an MCO, place or remove an impact absorber, or replace the existing tube plug with a
new one. All of these tasks are performed using the MCO grapple and hoist. First the MHM
turret is rotated to the MCO cavity position. If an MCO, an impact absorber, or a new tube plug
is to be lowered into place, it will already be attached to the MCO grapple. The MHM operator
positions the console switches to automatically lower the MCO, impact absorber, or new plug to
the proper height. When the load has been relieved, the MCO grapple can be unlocked, opened,
and retrieved from the storage tube into the MCO cavity. If an impact absorber or MCO is to be
retrieved from the tube, the empty grapple is lowered into the tube. The hoist stops after a sensor
on the grapple has made solid contact with the MCO or impact absorber. The grapple opens and
self-centers itself in the tube as rollers on the outer jaw surface contact the inner wall of the tube.
The grapple is lowered until sensors indicate that it has fully engaged the object to be lifted. The
grapple is then closed, the jaws locked, and the MCO or impact absorber is removed from the
storage tube by the hoist. Unless the MHM is in the tube plug exchange mode, the tube plug in
the MHM tube plug chamber must be replaced in the tube before the shield skirt can be raised and
the MHM relocated.

If a tube plug is found to be damaged or faulty, the tube plug is exchanged with the aid of
the MHM. After the MCO centering guide is removed, a grapple adapter is installed on a
replacement tube plug at the plug exchange facility in the MHM maintenance pit and is picked up
by the MCO grapple and stowed in the lower part of the MCO cavity. The MHM moves to the
storage tube location, where it removes the faulty tube plug with the plug grapple, places the tube
plug in the MHM plug cavity, rotates to the MCO cavity, and lowers the replacement tube plug
into the storage tube using the MCO grapple.

Intermediate impact absorbers protect the first MCO in a standard storage tube from
damage caused by accidental dropping of the second MCO onto it. Intermediate impact
absorbers are required between the MCOs in the standard storage tubes. The intermediate impact
absorbers are designed for placement using the MCO grapple. The intermediate impact absorber
is retrieved from its storage place (an overpack tube or the exchange facility) and placed on top of
the bottom MCO in the storage tube before a second MCO is inserted into the tube. All
conditions that are required for placing an MCO into the storage tube must be met to place the
intermediate impact absorber. The impact absorbers are provided with a central recess that allows
the MCO grapple to recognize an impact absorber. The recess also provides a sighting target for
interface with the MHM television camera to assist in positioning the MHM for attaching the
grapple to the impact absorber.

The sampling/weld stations, located in pits at the south end of the CSB, are used to weld
the canister cover assemblies to the MCOs. The sampling/weld station located in the easternmost
pit (pit 7) will serve initially as a sampling station for monitoring of MCOs. The sampling/weld
station pit and trench shields are designed for docking with the MHM when the MCO transfers
are made between the MHM and the sampling/weld stations. The MHM moves over the
sampling/weld station pits and centers precisely over the shielding assembly for MCO transfer
operations. Precise alignment with the shielding assembly is accomplished by using the MHM
television camera and locating the target on the center shield plate pintle. The center shield plate
pintle is designed to be handled by the MHM plug grapple, and the center shield plate is stowed in
the plug cavity of the MHM during MCO lowering and raising operations. All equipment that
may be placed in the coverage area of the MHM, including the sampling/weld station gantry crane
and hoist, is less than 8 ft, 10 in. high to avoid interference with the MHM bridge.

MCO transfer at the sampling/weld stations is accomplished after lowering the MHM nose
unit onto the sampling/weld station shielding assembly and the shielding skirt against the deck
around the sampling/weld station pits. The MCO grapple and hoist raise or lower the MCO,
subject to restrictions by the MHM interlocks.

Shielding. The MHM shielding is part of the cask and turret system and is designed in
accordance with the requirements of W-379-C-CSB-13091, CSB MCO Radiation Source, Dose
Rate and Material Properties for Shielding Analysis. The dose rate criterion for the MHM is
0.2 mrem/h (2.0 × 10^{-3} mSv/h) at contact. The design objective is based on 10 CFR 835 for
controlling personnel exposure from external sources of radiation in areas of continuous
occupational occupancy (2,000 h/yr). This design objective is to maintain exposure levels below
an average of 0.5 mrem/h (5.0 × 10^{-3} mSv/h) and as far below this average as is reasonably
achievable. The 0.2 mrem/h (2.0 × 10^{-3} mSv/h) at contact criterion considers the possibility of
multiple other sources associated with the CSB and is based on ALARA program evaluations.
Shielding calculations documented in CSB-SH-1004, Bulk Shielding for the MHM and Portable
Shield Gate, demonstrate that shielding for the MHM satisfies these criteria.

Gamma and neutron shielding are integral to the MHM design. The cask and turret system
has full gamma and neutron shielding. The gamma shielding of the cask and turret body is made
from cast steel (ASTM A36/A36M) sections (10-3/4 in. thick) and is rigidly bolted together with
face-to-face contact joints. The horizontal rotating interface gap between the base of the rotating
turret and the top face of the stationary turntable is kept to a practical minimum of 0.0625 in. and
is stepped to provide a minimum metal thickness in any direction comparable to that of the cask and turret body. A 4-in.-thick outer layer of boron-infused, densified wood (Jabroc N\(^2\)) provides neutron shielding where required. Neutron shielding is needed because approximately 30% of the estimated dose is from neutron radiation.

An alpha-beta CAM can monitor the MHM's cask and turret cavity at the ventilation system's HEPA filter.

The slant-angle concrete path and the gap between the MHM and the deck surface need to be taken into account when estimating the dose rate at the floor surface of the operating deck. The dose rate, including streaming, should be less than the 0.2 mrem/h \((2.0 \times 10^{-3} \text{ mSv/h})\) criterion. The dose rate is reduced by a shield skirt that extends at least 36 in. beyond the edge of the floor embed that surrounds the storage tube. Based on calculation CSB-SH-2002 this distance is judged to be adequate. To complete the gamma shielding at charge face level, the retractable shield skirt is lowered to rest on the deck. The lower turntable at the bottom end of the rotating turret provides protection from gamma radiation coming from the MCOs in the storage tube. (Approximately 5 in. of steel effectively blocks the path, in addition to the very narrow and extended gap based on the extended skirt.)

The nonrotating lower turntable also is manufactured from cast steel and, in conjunction with the components of the retractable shield skirt, has a net shielding thickness comparable to that of the cask and turret body. At the turntable and around the retractable shield skirt, the neutron shielding is provided by cast concrete. Elsewhere, neutron shielding is boron-infused densified wood. A circular slab forming part of the retractable shield skirt functions as a gamma gate when the cask and turret system is rotated to the "camera" index position during intermediate operations and during traveling operations. The thickness of the MCO hoist enclosure and the top plate is governed by the gamma shielding required.

A retractable shield skirt attached around the lower end of the MHM base can be lowered to the operating deck to provide continuous shielding whenever an MCO is engaged. The body of the skirt is designed to provide radiation shielding at the interface. With the skirt raised, there is a 2-in. nominal clearance between the bottom of the skirt and the operating deck. The retractable shield skirt is raised and lowered with motor-driven screw jacks. The mode of suspension has sufficient freedom of motion to ensure that vertical potential seismic displacements are accommodated and that the shielded cask and turret system does not hammer the operating deck. Torque limiters and associated interlocks are provided to avoid overtorquing the drive motors if the skirt-deck interface malfunctions.

**Maintenance.** After supervisory approval, the MHM will move to the MHM maintenance pit, where the maintenance pit equipment frame is located, for supporting the retractable shield skirt and retractable nose for maintenance. The MHM will be positioned over the MHM

---

\(^2\)Jabroc N is a product of Permalli Gloucester Limited, Gloucester, England.
maintenance pit equipment frame and aligned with the assistance of a spotter in the pit providing
direction to the operator. The maintenance pit equipment frame has the necessary interface
components to remove the MHM retractable nose assembly.

The MHM maintenance trolley sets on the concrete operations area deck during assembly
and maintenance disassembly operations. The maintenance trolley enables disassembly of the
MHM and provides tooling and fixtures for major repairs. The MHM maintenance trolley is a
rigid structure with dual casters in each corner. It is rolled into position over the maintenance pit
and centered on the maintenance pit equipment frame. As components are removed, the
maintenance trolley supports and maintains stability for the equipment above. Additional frames
and structures are provided with the MHM maintenance trolley to perform different tasks as
needed.

Also located in the MHM maintenance pit is the tube plug and impact absorber exchange
station (Figure A2-9, sheet 8). This station provides a below-floor-level area where the MHM
can deposit or retrieve a tube plug or an impact absorber for changeout, inspection, maintenance,
repair, or surveillance. The top of the tube plug and impact absorber exchange station consists of
flat steel deck plates flush with the load-in/load-out area deck. Beneath the steel deck plates is
the support steel framework, which supports the steel deck plates. The support framework also
supports the MHM shield skirt when the MHM is in position for exchanging a tube plug or an
impact absorber. The tube plug and impact absorber exchange fixture is positioned below the
steel deck plates and rests on the MHM maintenance pit floor station (Figure A2-9, sheet 8).
The tube plug and impact absorber exchange fixture is independent of the support steel
framework and steel deck plates. The steel deck plates are connected to the support steel
framework and anchored to the MHM maintenance pit walls. A removable steel hatch plate
covering the access opening in the deck plates allows the MHM to gain access to the tube plug
and impact absorber exchange fixture. A tube plug support ring for a tube plug or an impact
absorber insert subassembly for an impact absorber is mounted on the tube plug and impact
absorber fixture as needed. The support ring or insert subassembly holds the tube plug or impact
absorber in place during MHM depositing and retrieving operations.

Safety Considerations. The MHM seismic restraints and the MHM rails and rail frogs are
classified as safety class and important-to-safety Category A. The lower flanges of the standard
and overpack storage tubes, the interface guide ring funnel, and the MHM MCO centering guide
are classified as safety significant. The MHM interlock that prevents radiation exposure and
translational shear (P2); the MHM interlock that prevents turret rotation when the MCO hoist is
not fully raised (P6); the MHM interlock that prevents hoist operation and turret rotation unless
the seismic clamps are applied (P21); the MCO hoist and grapple design; and MHM fixed
shielding are safety significant defense in depth. The MHM structural components and the MCO
hoist and grapple are safety significant and important-to-safety Category B. The remaining
components of the MHM, the collision avoidance system, the seismic detection and MHM power-
disconnect system, and the anticollision system are classified general service.
A2.5.1.4 Multi-Canister Overpack Sampling/Weld Operations. The MCO sampling system (Figures A2-40 through A2-46) is used for withdrawing a sample of gases from the monitored MCOs according to a predetermined schedule. Weld equipment will provide additional sealing of the MCO by welding a cap on the MCO.

A2.5.1.4.1 Sampling Operations. MCOs designated as monitored MCOs are sampled periodically at a sampling/weld station to provide data on interim storage of MCOs containing SNF. The sampling procedure (based on HNF-SD-SNF-CN-027, SNF Process Validation Requirements) provides a process for monitoring MCO storage of SNF at the CSB. Several (one to six) MCOs, with and without scrap baskets, will be selected from each K Basin for the MCO monitoring program. The monitoring program will attempt to provide as much information as possible from monitoring selected MCOs. For this reason, the monitored MCOs may include SNF with high and/or low aluminum hydroxide concentrations, and MCO's loaded for specific plutonium blending and single pass reactor fuel. The analytical data and MCO pressurization models indicate that the maximum MCO pressure expected after a 40-year storage period would be approximately 62 lb/in² gauge. The data from the monitoring program will be evaluated. If the monitoring program detects a higher pressurization rate, an engineering evaluation will be organized to review the data, make recommendations, and develop an action plan. A record will be maintained identifying the monitored MCOs and will include data on the SNF stored in the MCO, data from the vacuum drying operations, preselected storage tube location, and data collected from pressure and sampling activities during interim storage in a preselected storage tube. Only one MCO will be placed in each preselected storage tube. Upon receipt at the CSB, an MCO selected for monitoring will be placed in a preselected storage tube. The MCO will be transported using the MHM to the sampling station in the sampling/weld area for measurements of temperature, internal pressure, and gas composition. The MCO pressure will be checked and the MCO will be inerted to approximately 7 lb/in² gauge if needed, and the MCO will be replaced into the preselected storage tube. The monitored MCOs will again be pulled from the preselected storage tubes and checked and sampled during the winter months and summer months. These sampling checks will provide a history (approximately 2 years) of internal gas generation rates and pressure buildup. After sampling has been completed, the MCO cap will be welded on the MCO, and the MCO will be placed in a standard storage tube for interim storage. The SNF Project is considering implementing a long-term MCO pressure monitoring program (port penetration is not required) to detect pressure in excess of the MCO design pressure. The MCO pressure will be transmitted by an internal device to an external receiving device.

Major Components. The major components of the MCO sampling operations are as follows:

- Sampling/weld station impact absorber
- Sampling/weld gantry cranes and hoists
- Sample cart
- Sample hood
- Sampling station cooling cap
- Sampling station chiller
Sampling station HEPA filter and exhauster
Center shield plate
Shield halves
Sampling/weld station MCO support structure
Trench cover shields
Drive assembly cover shields.

Equipment Description and Operational Considerations. The sampling process begins when the MHM lowers a monitored MCO into the sampling/weld pit. The sampling/weld station shielding (shield halves, trench cover shields, drive assembly cover shields, and center shield plate) are used whenever a monitored MCO is raised or lowered into the sampling station to reduce the radiological streaming coming from the MCO to within ALARA limits. The shield halves also form an inverted truncated cone opening, which mitigates accidental dropping of an MCO into the sampling/weld pit. The rotating shielding and fixed shielding in the sampling/weld pits (Figure A2-40) are a composite steel and borated-polyethylene laminate designed to limit gamma and neutron radiation from the MCO to less than 10 mrem/h according to CSB-SH-3005, Sample Station Shielding Calculation. An MCO placed in the sampling/weld pit is supported by the impact absorber on the bottom of the rotating shield which rotates on bearings retained in the stationary shielding (Figure A2-40). The weight of the rotating shield and the MCO is supported by the stationary shielding. The weight of the stationary shielding is supported by six 6-in. diameter pipes which are supported by a carbon steel plate on the sampling/weld station pit floor. A shear ring, which reduces radiation streaming from the MCO, is attached to the rotating shield using 12 screws. The shear ring is designed to shear if an MCO is accidentally dropped into the sampling/weld station. Damage to an MCO is mitigated by the impact absorber. The sampling/weld station features that could be challenged, and whose failure could lead to MCO damage, are designed to safety-class seismic (0.35 g) spectra. The fixed optical pyrometer senses and measures, and the distributed control system (DCS) records, the MCO profile skin temperature as the MCO is lowered into the sampling station. An impact absorber in the bottom of the rotating shield will cushion the MCO if it is dropped and prevent breach of the MCO. The DCS skin temperature data can be used to indicate possible heatup problems from the SNF fuel in the MCO. After placing the MCO in the pit, an optical pyrometer (hand-held) is used to measure the MCO cover surface temperature. An MCO cover surface temperature exceeding a predetermined range will require cooling of the cover before sampling operations begin and protects personnel from skin burns. A chilled cooling cap will be placed on the MCO cover to cool the top surface to a safe temperature range (typically less than 120 °F). Cooling the MCO also maintains MCO temperatures within the safe limits of less than 180 °F delta between the MCO shield plug assembly and the MCO shell temperature, and less than 180 °F/h heat-up/cool-down rate (HNF-SD-SNF-SARR-005).

The sampling/weld station impact absorber assembly (Figure A2-40, sheet 4) consists of a top plate, a base plate, and 13 to 17 energy absorbing tubes between the top plate and base plate. The top plate and base plate have 0.25-in.-deep grooves providing alignment and a piloting surface for each tube component. Carbon steel was selected for the tube material because of its ductility and energy absorbing capabilities. The three sampling/weld station impact absorber
design features selected to minimize deceleration forces of an accidentally dropped MCO are identical to the three design features selected for the bottom and intermediate impact absorbers discussed in Section A2.4.3.1. Approximately half of the crush tubes are shorter by half a crush wave length and symmetrically arranged as shown in Figure A2-40, sheet 4. The three galvanized steel cables mounted circumferentially around the assembly hold the components together and, in case of an accidentally dropped MCO, remain undamaged and hold the components together during removal of the damaged impact absorber. The number of tubes selected for each sampling/weld station impact absorber will be based on full-scale impact absorber tests as discussed in Section A2.4.3.1.

The MCO temperature and pressure are recorded; and gases in the MCO are sampled using the MCO sample cart. An analysis of the gases determines the hydrogen, oxygen, radioactive particulate, and radioactive gas concentrations. After monitoring and sampling operations are complete, the MCO pressure is reestablished with inert gas. The MCO mechanical seal and cover plate may be leak tested to confirm seal integrity. These monitored MCOs will eventually be transferred to a weld station for the cover cap welding operation. If required, the sampling station chilled cooling cap is connected to the chilled supply and return lines to cool the MCO cover. The stationary shielding and cooling cap are designed to cool the MCO by removing heat from the MCO body and top (Figure A2-40, sheet 2).

The sampling/weld station shield halves, trench cover shield, trench grates, and center shield plate are removed and stored, and guard rails are installed to prevent workers from falling into the open trench and the sampling/weld station pit. A ventilation supply system has not been provided for the sampling/weld trenches because the trenches are shallow. If the MHM inadvertently moves near the sampling/weld gantry crane, a crash shield guard attached to the sampling/weld gantry crane (Figure A2-41) will activate the MHM collision avoidance system to prevent a collision of the MHM with the sampling/weld station sample hood. The gantry crane also has seismic restraints to prevent horizontal motion of the crane and the hood. Personnel use the rotating shielding, driven by a worm-gear drive motor (Figure A2-40), to rotate the MCO sample port to an accessible position for sampling operations. Rotating the MCO reduces the radiation dose received by personnel leaning over the MCO. The MCO port cover plate is removed, and the MCO valve operator (Figure A2-40, sheet 3) is bolted to the MCO. The 1.0-ton crane hoist is used to lower the sampling hood over the sampling pit. The sampling hood is used to confine potential airborne contamination coming from an accidental MCO release during sampling operations and dilute any hydrogen released.

The sampling cart is moved near to the sampling pit, and connections are made to the utilities in sampling/weld pit. The quick-disconnect lines from the sampling cart are attached to the inert gas supply, the sampling hood filter, and the discharge line of the sampling hood. The sampling hood flexible exhaust line is connected to the sampling station HEPA filter and exhauster (CSB-AH-006). The exhauster provides a negative sampling hood pressure relative to the sampling/weld area, maintains air contamination control around the sampling pit, dilutes the gases released, and protects operating personnel from any MCO gases that might escape during sampling operations. A negative pressure in the sampling hood and pressure testing of the
sampling lines connected to the MCO provide for safe sampling operations and prevent
contamination of the sampling/weld area and a potential hydrogen deflagration. The exhauster
airflow ensures that any openings in the sampling hood have an air velocity of greater than
100 linear ft/min into the hood to prevent contamination in the hood from escaping into the
operating area. Flow rate and pressure are controlled using load and duct dampers.

Once the sample hood exhaust is functioning, the sample cart lines are purged with inert
gas to remove air, which has the potential for mixing with MCO gases and forming a flammable
mixture. The sample cart is connected, pressure checked, and ready to sample the MCO.

Personnel use the MCO process valve operator to open the MCO process valve. Gases
from inside the MCO flow to the sample cart pressure gauge. The MCO pressure is read and
recorded. The MCO's internal pressure reading is taken through the sample cart system; if it falls
within a specific pressure range, it is sampled and re-inerted. The collected gas sample is sent to
the laboratory for gas analysis. The recorded temperature and pressure readings and gas analysis
sample results provide the data to accurately calculate the gaseous contents of the MCO and
develop a gas composition history for each monitored MCO.

The sampling hood and HEPA filter (FH-9) provide a confinement barrier preventing the
release of particulate contamination to the operating area environment.

After sampling operations, the sample cart pipelines are vented and purged. The purge
allows inert gases to mix with the exhausted MCO gases and dilute the MCO gases before
discharging through the sampling station HEPA filter and exhauster and into the exhaust vent
ducting to the support area exhaust stack. The purge flow is designed to prevent a potentially
flammable gas mixture from entering the sampling station HEPA filter and exhauster.

Opening the MCO process valve, the surge valve, and the refill valve reinerts the MCO
(Figure A2-42). A pressure relief valve located downstream of the MCO vent gas connection
prevents overpressurization of the MCO sampling system. The MCO pressure can be verified by
opening the PI-736 toggle valve, reading the pressure on PI-736, and comparing with PIT-721.
Opening the refill valve during pressure release of the MCO ensures that inert gas dilutes the
released hydrogen to safe concentrations below the flammability limits. The refill valve is allowed
to remain open for a few more seconds to purge the vent line. The MCO process valve operator
is closed and removed, and the remaining sample cart lines are purged by opening the refill valve
and the surge valve to allow inert gases to flow into the sample hood. Closing the surge valve
prevents air from entering the sample cart lines and accumulator. The sampling station HEPA
filtered exhauster may be shut down, the sampling cart lines are disconnected, and the sample
hood flexible line to the HEPA filter and exhauster is removed. The sample hood can now be
lifted off of the sampling station pit using one of the 1.0-ton hoists.
The MCO process port cover leak testing equipment comprises a cover that self-seals around the MCO cover, a vacuum pump that pulls a vacuum on the MCO dome cover, and a mass spectrometer for determining the helium leakage rate. The examiner uses this equipment to sense and record the leak rate for the MCO upper seal.

The guard rails are removed and the sampling/weld station shielding is reinstalled. The sample station chiller is shut down. The MHM then removes the monitored MCO from the sampling station and places it in the assigned preselected storage tube. The sampling pit cover plate is placed over the sampling/weld pit if no other monitored MCOs are to be placed in the sampling/weld pit.

Table A2-5 lists the equipment and operating conditions for which the sampling/weld station has been designed.

Safety Considerations. The sampling/weld station impact absorber, shield halves, and helium rupture disk PSE-1 are classified as safety significant. The helium rupture disk is important-to-safety Category B. Some components of the MCO sampling equipment (the sampling/weld station MCO support structure [which includes the rotating shield, the stationary shielding, the shear ring and shear screws, and the stationary shield support pipes], sample hood and HEPA filter, exhaust system [HEPA filter], sample hood exhaust flow indicator, center shield plate, and MCO valve operator) are classified safety significant. Because a potential drop of a shield half or sampling hood could cause minor damage to the top of an MCO, the sampling/weld gantry crane structure and hoist are classified important-to-safety Category C (Figure A2-41).

A2.5.1.4.2 Canister Cover Assembly Welding Operations. MCOs received at the CSB have a canister cover assembly welded to them before being placed for interim storage in the standard storage tubes. Monitored MCOs received at the CSB are placed in a standard storage tube and periodically sampled at a sampling/weld station. At the completion of monitoring activities, a canister cover assembly is welded to the MCO, and the MCO is placed in a standard storage tube. The canister cover assembly together with the stainless steel shell and bottom provide a container for the SNF (Figure A2-2) that meets all regulatory requirements for SNF dry storage (HNF-SD-SNF-SARR-005). The canister cover assemblies are welded using the welding equipment in pit numbers 2 and 7 in the sampling/weld area of the operating area shelter (Figure A2-43). MCOs received from the CVDF are transported by the MHM to these pits, and welding equipment, attached to the cover assembly, welds the canister cover assembly to the MCO. A connector installed on the south wall provides inert weld cover gases through a hose to the welding equipment.

MCO = multi-canister overpack.
NA = not applicable.
**Major Components.** The following major components are part of the canister cover assembly welding operations (in addition to the equipment provided for sampling operations):

- East sampling/weld station gantry crane and hoists
- West sampling/weld station gantry crane and hoists
- Weld hood
- Welding equipment
- Inert gas manifold.

**Equipment Description and Operational Considerations.** Before welding operations begin, the following preliminary steps are completed: (1) verify that the sampling/weld station impact absorber is in place and in good condition, (2) verify that the sampling/weld station shield halves, trench cover shield, and drive assembly cover shield are in place, (3) verify that the center shield plate is in place, and (4) verify that the sampling/weld station gantry crane and auxiliary equipment have been moved away from the sampling/weld station pit where the canister cover assembly will be welded to the MCO. These steps prepare the sampling/weld station for access by the MHM for lowering of an MCO into the sampling/weld station pit.

The sampling/weld area has seven pits with pits 2 and 7 each equipped with a sampling/weld gantry crane, as described in Section A2.5.1.4.1. Both pits 2 and 7 are equipped for welding operations, and pit 7 is equipped for MCO monitoring operations. Pits 2 and 7 are approximately 40 ft apart. The east and west sampling/weld gantry cranes use the same east–west wheel tracks. Anticollision devices prevent the east and west sampling/weld gantry cranes from colliding. Travel for the east sampling/weld gantry crane is physically limited to pits 4 through 7, and travel for the west sampling/weld gantry crane is limited to pits 1 through 4. If an inadvertent collision between these two cranes occurred, there would be no adverse consequences because the collision would occur over pit 4, which would not contain an MCO, and the cranes would not have hoods connected to MCOs in pits 2 or 7. Each gantry crane has a crash shield guard to prevent a collision with the MHM.

The MHM transports the MCO to the sampling/weld station from the cask receiving pit or transports a monitored MCO from a storage tube. After centering the MHM over the sampling/weld pit, the retractable nose unit and shield skirt are lowered, the center shield plate is retrieved into the MHM plug cavity, and the MHM lowers an MCO into the sampling/weld station and replaces the center shield plate. The sampling/weld station shield halves, trench cover shield, and drive assembly cover shield in contact with the MHM retractable nose unit and shield skirt provide shielding for personnel from the MCO while it is being lowered. As the MCO is lowered into the sampling/weld station pit, an infrared pyrometer, TI-723, monitors the MCO surface temperature. These temperature readings are recorded and tracked on the DCS.

After the MHM has moved away from the sampling/weld station, personnel use the sampling/weld station gantry crane hoist (Figure A2-44) to remove the center shield plate and the shield halves and place them in their temporary storage places. Personnel then install the removable handrails and removes the sampling/weld station pit covers. These covers are also
placed in their temporary storage locations as shown in Figure A2-43. The removable guard rails, after being installed into position, provide protection for personnel from an accidental fall into the sampling/weld station pit or into the pit trench.

Removal of the shield halves, trench cover shield, and trench grates exposes the top of the MCO's canister collar for welding operations. Personnel descend into the pit trench and use a hand-held infrared pyrometer to measure the temperature of the MCO. At MCO shield plug temperatures within the predetermined safe range (typically less than 120 °F), personnel can work safely near the MCO. If the MCO temperature is higher than the safe range, personnel place a portable cooling cap on the MCO, and a chilled water flow circulating around the sampling/weld station stationary shielding and through the portable cooling cap cools the MCO. Both the portable cooling cap and the stationary shielding have supply and return lines connected to the sampling/weld station chiller unit. The sampling/weld station chiller is mounted on a concrete pad outside of the operating shelter on the south side (Figure A2-45). The sampling/weld gantry crane's 1-ton hoist will be used to place the portable cooling cap on the MCO shield plug assembly if it is needed.

After ensuring that the MCO shield plug temperature is within a safe operating temperature range, a canister cover assembly is retrieved from storage, affixed to the MCO weld hood lifting clamps, and positioned over the MCO using the 1-ton auxiliary hoist of the sampling/weld station gantry crane. Welder set-up time can be reduced by placing the welder assembly on the canister cover assembly in the storage area, positioning the welding track to circumvent the weld area, and clamping the welder to the canister cover assembly. After the canister cover assembly with the attached welder assembly has been placed on the MCO, only minor welder assembly adjustments should be required before the automatic welding process begins. Once the canister cover assembly is in place, the ventilation fan for the weld hood is turned on, the ventilation flow dampers are positioned to provide an adequate airflow rate, and the HEPA filter differential pressure is checked. These steps provide assurance that only gases generated by the weld process (radioactive or hazardous) will be extracted by the ventilation system from the weld area. The gas tungsten arc welding process only emits trace amounts of noxious gases mixed with the inert gas; however, minute amounts of residual contamination may adhere to the outer surface of the MCO and become airborne during the welding process.

The canister cover assembly weighs approximately 500 lb. The weld area on the MCO is examined for cleanliness before the canister cover assembly is placed on the MCO. The procedures for attaching, lifting, and moving the canister cover assembly contain safety precautions for personnel. A weld technician correctly positions the canister cover assembly and checks the weld area for alignment and cleanliness. The weld technician checks that the utility supply lines (argon, and electrical power and instrument cables) are connected to the welding equipment, the welding head is positioned correctly, and the welding wire supply is adequate, and also checks the controls at the welding machine remote operating terminal (Figure A2-46). The weld head is used to temporarily attach the canister cover assembly to the MCO using several tack welds. After the tack welding operations are completed, the canister cover assembly is welded to the MCO using a number of passes. Two video cameras mounted on the weld head
monitor and record the welding process. A television monitor next to the welding machine’s remote-operating terminal allows the weld technician to view and control the welding process. The video recording can be used as part of the verification process used to certify weld quality. The weld area is allowed to cool before checking for weld quality. Weld verification and certification also includes a visual examination of the cooled weld area for flaws and other weld quality examination procedures (i.e., liquid-penetrant examination and helium leak checking). The inert gas supply system summarized in Section A2.7.5 provides helium for leak testing of the canister cover assembly. The welding and examination procedures ensure that the MCO canister cover assembly weld meets the requirements of the ASME Boiler and Pressure Vessel Code, Section III, subsection NB (ASME 1995).

After a successful welding operation, the ventilation damper is closed shutting off airflow. The welding equipment is disengaged from the canister cover assembly, the sampling/weld station chiller valves are closed, and the weld hood is lifted off of the MCO and returned to its storage location. The trench cover shield and trench grates are replaced, and the removable guardrails are removed. The sampling/weld station gantry crane’s 5-ton hoist is used to reinstall the shield halves and the center shield plate. The affected gantry crane is moved away from the sampling/weld station pit, and the MHM retrieves the capped MCO and transfers it to a storage tube. Simultaneous welding operations can occur in both pits 2 and 7, or simultaneous welding and sampling operations can occur in pits 2 and 7.

The air-cooled chiller is a factory-assembled refrigeration unit designed to provide and circulate a 40% to 50% propylene glycol mixture for both pits. The unit is pad mounted outside of the operating shelter on the south side. Insulated pipelines enter the operating shelter at just above ground level and extend into sampling/weld station pits 2 and 7 through encased pipes under the deck (see Figure A2-44). The chilled water cools the sampling/weld station stationary shielding by flowing through pipes in contact with the outer surface of the shielding. Flexible and insulated connecting hoses can also be connected to the portable cooling cap if separate cooling of the MCO top is needed.

Components of the air-cooled chiller unit include an evaporator, storage or expansion tank, circulating pump, controls, refrigerant piping, and accessories. The unit has been designed with weatherproof protection for outdoor use. A fence surrounding the chiller unit protects the chiller components from passing traffic. The chiller has been designed to have a net cooling capacity of 60,000 BTU/h and to meet the standards, rating, and testing requirements of ANSI/ARI 590, Positive Displacement Compressor Water Chilling Package.

An inert gas manifold assembly, installed in the argon gas manifold building, provides cover gases for the welding process to prevent oxidation of the welded area. The argon gas manifold building, located outside and adjacent to the chiller unit (Figure A2-45), contains a gas manifold cylinder rack and a cabinet providing storage for spare and used argon high-pressure gas cylinders. The argon gas manifold building is a steel-frame building with corrosion-resistant metal siding and roof. The roof is attached using corrosion-resistant fasteners. The cylinders are maintained in an upright position by chaining them to the cylinder racks. All pressurized gas
cylinders received at the CSB have a cylinder cap that remains on the cylinder until after the
cylinder is chained to the cylinder rack. All cylinders have a cylinder valve. A maximum hole size
in the inlet to the butt of the cylinder valve restricts airflow through the valve and minimizes
propulsion effects should the valve be accidentally severed at the top of the cylinder. Both the
cylinder cap and the cylinder valve protect the cylinder from causing serious propulsion accidents.

Pipelines from the argon gas manifold building enter the south side of the operating shelter above
floor level and terminate just inside the south wall with valves and quick-disconnect couplings
(Figure A2-45 is a flow diagram of the chilled glycol system). The valves and quick disconnect
couplings are located in the sampling/weld area opposite sampling/weld station pits 2 and 7.

Safety Considerations. The sampling/weld station impact absorber and shield halves are
classified as safety significant. Some components of the canister cover assembly welding
equipment (the sampling/weld station MCO support structure and center shield plate) are
classified safety significant, and the remainder of the components are general service. The
sampling/weld gantry crane structure and hoist are important-to-safety Category C because the
crane could potentially drop a shield half or sampling hood causing minor damage to the top of an
MCO.

A2.5.2 Passive Cooling of the Canister Storage Building Storage Vault

The CSB contains an array of storage tubes that are cooled using passive, naturally
circulating air to remove the decay heat from the SNF (CSB-HV-0001, Table 3) contained in
MCOs in the storage vault. According to HNF-SD-SNF-CN-005, Bounding Temperatures and
Gas Generation Rates during CSB Staging, this system is designed to ensure that the fuel
centerline temperature limit of 600 °C (1,112 °F) and the concrete temperature limit of 65 °C
(150 °F) per the requirements of ANSI/ACI 349-85 are not exceeded.

Major Components. The following major components are part of the passive cooling
system:

- Intake plenum
- Outlet plenum
- Intake stack
- Exhaust stack
- Vault 1
- DCS.

Equipment Description and Operational Considerations. The storage vault is passively
cooled using the "stack effect" to promote ventilation flow. Natural convection occurs when a
heated surface is in contact with fluid (air) of a different temperature than the surface. Density
differences provide the motive energy to move the air. The height difference between the
operating vault deck and the air exhaust stack (169 ft above the operating vault deck) increases
the motive force for airflow (stack effect). Also, the top of the inlet plenum opening is 7 ft lower
than the top of the exit plenum, causing heated air to preferentially expand into the exit plenum and exhaust up the stack. Air passes down through the air intake stack, where its temperature and flow rate are monitored, to an inlet plenum. From the inlet plenum the air flows into the enclosed volume of the vault where it removes heat from the MCO storage tubes. The heated air flows out of the vault into the outlet plenum, up the exhaust stack, where the temperature is monitored, and discharges into the atmosphere. The air intake cruciform and canopy improves airflow efficiencies by reducing wind velocity from any direction to positive pressure. A wind deflector on top of the exhaust stack improves airflow efficiencies for the exiting hot air by creating a negative pressure.
