Modeling done using the PHOENICS 2D Computational Fluid Dynamics model, described in PHOENICS Computer Program (CHAM 1991), shows that the temperature difference between the highest vault air temperature (hot spot) and the outlet air temperature is only 9 °F (CSB-HV-0001). According to Conceptual Design Report for Line Item Project Nuclear Materials Storage Facility Renovation at the Los Alamos National Laboratory, Technical Area 55, Building PF-41 (LANL 1995), a similar conclusion was obtained by the Los Alamos National Laboratory for their vault as a result of three-dimensional modeling using the CFX computer code. The range for MCO external surface temperatures is 241 °F to 252 °F for the four gases analyzed for the storage tubes: argon, helium, nitrogen, and air. The standard storage tubes contain air at atmospheric pressure. For air the estimated maximum MCO temperature is 251.4 °F. Helium was selected as the inert gas for the overpack storage tubes.

The design of the cooling system limits the MCO external temperature to a maximum 270 °F wall temperature to ensure the fuel centerline temperature limit of 1,112 °F and the concrete temperature limit of 150 °F are not exceeded. The thermal analysis (CSB-HV-0001) indicates that the maximum concrete temperature inside the vault is 121 °F. This temperature is below the ANSI/ACI 349-85 limit of 150 °F.

Temperature indicators are not needed in vault 1 because (1) the vault thermal analysis shows that air temperatures in the vault will not vary by more than 11 °F, (2) other approved DOE-managed sites (i.e., Fort St. Vrain) have been approved for operation without vault temperature indicators, and (3) even though air temperature monitoring is not required, the exhaust stack air temperature indicator will provide information that the vault temperatures are within temperatures predicted by the vault thermal analysis.

The passive cooling system contains no moving parts and no components likely to have significant deterioration during the design life of the CSB. The temperature of the vault depends on the outdoor temperature, which has a design range of -27 °F to 115 °F. The temperatures in a tube and in the MCOs contained in it depend on the temperature of the vault at that location and on the heat produced by the MCOs. The vault air temperature varies between 125 °F and 136 °F for a fully loaded vault with a maximum ambient inlet air temperature of 115 °F. If a heat wave occurs at the Hanford Site with an outside air temperature of 115 °F, the calculated maximum equivalent MCO surface temperature would be 230 °F for an MCO located in the fully loaded vault (CSB-HV-0001). The use of thermocouples to identify hot spots in the vault is not practical.
because the small 11 °F variability would not have a significant impact in predicting the MCO surface temperature. The exhaust stack is described in Section A2.4. The upper 57 ft of the stack is constructed of 7-ftouter diameter, 3/8-in.-thick steel plate. At an exhaust temperature of 134 °F, the estimated air flow rate through the exhaust stack is 31,700 ft³/min for the maximum vault loading of 161.2 kW and an inlet air temperature of 115 °F. Air inlet and exhaust temperatures and the flow rate are monitored using the DCS. A mass flowmeter and a temperature element are mounted in the vault cooling system intake stack to measure the flow rate and temperature of the incoming air. At the base of the intake stack, the air flows through the intake plenum into the storage vault and around the storage tubes, absorbing and removing heat from the stored fuel. As the air increases in temperature and expands, it flows through the outlet plenum (preferentially because the top of the exhaust stack is 90 ft higher than the intake stack) and out the exhaust stack, where a temperature monitor measures the temperature of the exhausted air. An exhaust flowmeter is not provided as there is no other airflow than through the intake, vault, and exhaust stack.

The thermal analysis for the CSB vault analyzed natural air convection flow due to nuclear decay heat of stored material inside the vault. Three computer programs based on conservation of mass, momentum, and energy were used to model airflow through the vault; T-DUCT, PHOENICS and LOTUS (CSB-HV-0001). The T-DUCT computer model creates numerical models of duct systems using two basic principles of ventilation; conservation of mass and conservation of energy. The T-DUCT simulated the changing cross-sections of the vault intake stack, inside the vault and the exhaust stack and estimated the pressure losses for airflow through the passive cooling system. The PHOENICS program simulated fluid flow, heat transfer, and turbulence based on the physical properties of air using the finite element approach. For vault flow, the flow is mostly turbulent and the problem is solved using the Navier-Stokes equations representing the conservation of mass, momentum, and energy. A LOTUS spreadsheet was used to model the "Hot Spot" in the vault, the area of the vault where, due to the buoyancy effect and air turbulence, the air temperatures are the highest. This spreadsheet solved a series of nonlinear simultaneous algebraic heat transfer equations using the matrix inversion method.

Design criteria are presented in the thermal analysis (CSB-HV-0001, page 8). The SNF MCO heat load for one vault is 161.2 kW. Thermal conditions in the vault are based on the following conservative assumptions:

- The highest outside air temperature, 115 °F
- The highest total heat load, 161.2 kW
- The highest tube heat load, 1.6 kW, surrounded by the tubes with the same highest heat load
- The worst location of the tube, in a "hot spot" area at the end of the vault
- No positive wind effect.
Although a three-dimensional vault thermal analysis was planned, the PHOENICS 2D Computational Fluid Dynamics model has been used showing that the temperature difference between the highest vault air temperature (hot spot) and the outlet air temperature is only 4 °F (CSB-HV-0001; note Figures A4-2 and A4-3 in Chapter A4.0). The Los Alamos National Laboratory obtained a similar conclusion for their vault using the three-dimensional CFX computer modeling code (LANL 1995).

A number of two-dimensional computational fluid dynamics studies were performed to explain the airflow patterns along the longitudinal side of the vault that resulted in such a low temperature difference. There are two major airflow streams in the vault: the primary stream at the bottom of the vault moving from the entry to the exit, and the secondary stream at the upper part of the vault moving in the opposite direction. The modeling shows that intensive airflow movement takes place in the vault zone where the tubes are located. Also, there is a passive airflow vortex with a central stagnant zone located in the corner below the outlet stack. However, this vortex occurs in the no-tube zone. The airflow pattern developed with two-dimensional computational fluid dynamics modeling was used to identify the free area for calculating pressure loss using the local resistance coefficient presented in Handbook of Hydraulic Resistance (Idelchik 1986, page 608, diagram 12-28). As shown in the thermal analysis (CSB-HV-0001), the pressure loss is negligible because of low air velocity in the vault. Three-dimensional modeling would be capable of creating the airflow pattern more accurately, but the results of that modeling would have to be applied to the C-coefficient developed by Idelchik (1986) for unknown and probably different airflow conditions and still negligible pressure loss. The two-dimensional computational models showed (1) a low temperature difference, (2) a vortex in the no-tube zone, and (3) a low air velocity in the vault. Therefore, the more accurate three-dimensional computational fluid dynamics modeling was not necessary.

The conservative assumption that the analyzed tube with the highest heat load is surrounded by tubes with the same heat load allows us to ignore the thermal radiation effect between tubes having the same surface temperatures. However, the thermal radiation effect between tubes and internal surfaces is calculated precisely. Under these conditions, the MCO external surface temperature is 230 °F. The design of the cooling system limits the MCO external temperature to a maximum 270 °F wall temperature to ensure the fuel centerline temperature limit of 1,112 °F is not exceeded. The thermal analysis (CSB-HV-0001) indicates that with the conservative assumptions noted above, the maximum concrete temperature inside the vault is 125 °F. This is below the ANSI/ACI 349-85 limit of 150 °F. The design of the cooling system does not include MCOs in overpack storage tubes.

The vault thermal analysis (CSB-HV-0001) was based on a total heat input of 161.2 kW. The heat load for each MCO is based on Basin data for the SNF loaded into an MCO (exposure, cooling time, and fuel weight). This analysis calculated a maximum surface temperature of 186 °F for an MCO. It is expected that MCOs in overpack storage tubes will likewise be at or below the maximum calculated MCO surface temperature. Placing MCOs in overpack storage tubes at the air entrance point and limiting them to one MCO per tube provide added assurance that the maximum surface temperature of an MCO will not be exceeded.
Because the overpack storage tubes will contain the heat input associated with only one MCO, the vault thermal analysis will not be invalidated as long as the total heat input for MCOs in standard storage tubes as well as overpack storage tubes does not exceed 161.2 kW.

The PHOENICS computer program simulates fluid flow, heat transfer, and other related phenomena. This simulation is based on mathematical derivation from established physical principles. The power and flexibility of PHOENICS has resulted in numerous applications in the aerospace, nuclear, process, defense, marine, environmental, turbo-machinery, and automotive industries. There are more than 350 installations of PHOENICS throughout the world. This program was selected as a result of a study of other existing codes. CHAM company, the author of PHOENICS, stated that the code “is very well validated and developed from over 10 years of commercial use” (CSB-HV-0001).

Safety Considerations. The intake stack, intake plenum/exhaust plenum, exhaust stack, and vault 1 are classified as safety class and important-to-safety Category A. The DCS is classified general service.

A2.5.3 Overpack Storage Tube Purge Operations

The following paragraphs summarize the recovery actions for MCOs and include the equipment and operations for monitoring and maintaining MCOs in overpack storage tubes. Overpack storage tube operations are designed to safely monitor a suspect leaking MCO or a damaged MCO. An MCO will be placed in an overpack storage tube for up to 1 year until monitoring activities determine the leak rate, if any, of gases escaping from the mechanically sealed MCO or from the damaged MCO. If the leak rate is determined to be acceptable based on the approved action plan developed for the MCO, the MCO will be transported to a sampling/weld pit and a canister cover assembly will be welded to the MCO. This MCO will then be placed in a standard storage tube. If overpack storage tube monitoring activities determine that the MCO leak rates are unacceptable (above $1 \times 10^{-5}$ standard cm$^3$/s·atm), the Unreviewed Safety Question recovery plan may recommend one of the following.

- The MCO may remain in the overpack storage tube for further monitoring.
- The MCO may be transported (with additional analysis) to a suitable location for reworking of the mechanical seals to reduce the leak rate.
- The MCO may be returned to the CVDF and the K Basins for MCO repackaging operations.

Using the overpack storage tube for more than 1 year requires performing an Unreviewed Safety Question evaluation. The overpack storage purge system is designed to monitor and maintain an inert gas environment around any MCO placed in the overpack storage tubes and may be used to
monitor the atmosphere in any of the standard storage tubes. A tube vent and purge cart (Figure A2-47) is used for the entire purging process.

Major Components. The following major components are included with the overpack tube purge equipment:

- Tube vent and purge cart
- Portable hoist
- Floor electrical sockets
- Helium fill station.

Equipment Description and Operational Considerations. Operation of the overpack storage tube purge system begins for an overpack storage tube when an abnormal or accident MCO has been identified and an MCO has been placed in the overpack storage tube by the MHM. The overpack storage tube purge system is designed for venting, purging, and refilling the atmosphere in an overpack storage tube containing an MCO. The primary equipment used for the purging process is the tube vent and purge cart described below. The tube vent and purge cart’s oxygen monitor alarms when the oxygen concentration in the airspace immediately around the cart is less than 19.5% to warn personnel of an oxygen-deficient atmosphere in the unlikely event of helium leaking from the purge system or helium exhausted from a purged overpack storage tube.

The overpack storage tube purge system has three main functions for overpack tubes: tube venting, tube pressure-purging, and tube refilling with inert gas.

- MCO overpack tube venting is required when an MCO stored in an overpack storage tube is to be moved to a standard storage tube.
- Purging of MCO overpack tubes is required after lowering an MCO into the overpack tube and the overpack tube plug has been replaced. Purging may also be required when the sampled gases in an overpack storage tube contain hydrogen.
- MCO overpack tube refilling operations are needed when the overpack tube gas pressure falls (caused by a slight gas leak) below 2 lb/in² gauge.

The tube vent and purge cart includes features to analyze gas from the overpack storage tube, purge generated gas (containing hydrogen) from the tube through a HEPA filter to the operating area atmosphere, and replace the purged gas with an inert gas (e.g., helium). The cart contains an inert gas supply (two gas cylinders), a flexible steel hose fitted for the overpack tube and another flexible steel hose for the standard storage tubes; a CAM unit; a radioactive gas monitor; a hydrogen gas monitor with associated alarms; a sampling connection; a HEPA filter; a gas monitor port heat exchanger; and an oxygen concentration monitor with associated alarms (Figure A2-48). The tube vent and purge cart interfaces with the overpack tube plug connector,
the floor electrical supply, the standard tube plug connector, and the helium filling station. The tube vent and purge cart also has the capability to sample standard storage tubes (Figure A2-14).

The tube vent and purge cart is a battery-powered, rechargeable, utility vehicle. The battery is maintenance free and attached to the cart inside a battery compartment designed to contain any acid that might leak from the battery. This battery design and configuration minimizes loss of battery acid and subsequent hydrogen generation caused by acid reaction with exposed metal components. The cart is designed with a rear bed and tow hitch. The rear bed, or cargo deck, is sized for a platform 4 ft, 7 in. by 9 ft, 7.5 in. The bed is fitted with all of the equipment and systems required to perform the tube venting and purging operations. A flexible steel hose connects the cart's piping header with the tube plug quick-disconnect coupling. The tube vent and purge cart's rated load capacity is specified to be not less than 3,000 lb. The cart can tow a portable floor crane. The floor crane is used for lifting the 425-lb center hatch of the standard or overpack tube plug cover. The portable floor crane is used to remove the standard or overpack tube plug covers in preparation for tube plug removal by the MHM. The standard tube plug cover weighs 1,475 lb, and the overpack tube plug cover weighs 1,805 lb. The portable crane's rated capacity is specified to be 2,000 lb. The cart receives electrical power for recharging its batteries and operating equipment by means of an on-board retractable cable reel (480 V, 3-phase, 4-wire cord with ground). The cord is plugged into the electrical distribution system outlets recessed into the operating deck.

During the time the cart is being used to perform venting and purging, the portion of the connected system that is between the cart-mounted HEPA filter and the tube atmosphere serves the same secondary confinement role as the overpack storage tubes. Under accident conditions, this confinement provides mitigation of radionuclide releases from the tubes. During purging operations, the purge cart is secured in place by wheel chocks adjacent to the storage tube being serviced. The portable crane is used to remove the center hatch and move it to a temporary location convenient to the tube. Removing the quick-disconnect cap on the MCO overpack tube plug, connecting the flexible steel hose from the cart to the plug, and opening the pressure-indicating valve on the cart shows the tube pressure. This pressure can be compared with the pressure indicated by the tube plug local pressure gauge. If these two pressure gauges differ by more than 0.5 lb/in² gauge, both instruments are recalibrated before continuing the purging operation.

The purge cart CAM, hydrogen monitor, and radioactive gas monitoring systems measure radioactivity, hydrogen concentration, and radioactive gas concentration of gases being evacuated or purged from the tube. Gas flow rate to the monitoring equipment is monitored, and if the flow rate to the CAM and radioactive gas monitor drops below the setpoint value (or if the flow to the hydrogen monitor drops below the setpoint value), a low-flow alarm activates alerting personnel that the gas monitoring equipment may not be operating properly. The hydrogen monitor alarms if the gas hydrogen concentration exceeds 1% by volume. The gas temperature is measured and an alarm is activated if the temperature exceeds 125 °F. A high gas temperature could cause thermal damage to the gas monitoring equipment. An inline gas cooler has been designed to cool
gases before they reach the CAM and gas monitors and prevent thermal damage to the gas monitoring equipment.

MCO overpack tube gases are vented through a HEPA filter to remove radioactive contamination before the gases pass into the operating area atmosphere. If there is a breach or leak in the MCO, SNF particulate may be suspended in the overpack tube atmosphere. An HPT will provide periodic radiation monitoring of the FH-3 HEPA filter to determine when filter changeout is needed. Venting continues until the pressure becomes atmospheric pressure (0.0 lb/in\(^2\) gauge). After the overpack tube is depressurized, tube plug seal integrity is checked by applying 35 lb/in\(^2\) gauge pressure to the plug seal space and monitoring the pressure for approximately 20 minutes. According to CSB-PR-0002, Plug Seal Leak Rate and Test, a plug seal pressure drop of greater than 0.5 lb/in\(^2\) gauge in that time means that the plug seals should be inspected and replaced if needed. The pressure gauge has increments of 0.5 lb/in\(^2\) gauge.

Overpack tube venting and purging (if required) includes final pressurization of the overpack tube with inert gas to 3 to 4 lb/in\(^2\). This slight gas pressure remaining in the overpack storage tube helps to prevent air from entering the overpack storage tube. After venting and purging the overpack tube, the flexible connection to the tube plug is disconnected, the quick-disconnect cap is replaced, the tube plug center hatch is replaced using the hoist, the cart is disconnected from the electrical outlet, and the cart is returned to the cart storage area. In the cart storage area, cart preparation activities for future storage tube purging or venting operations include recharging the cart battery, refilling the inert gas bottles, calibrating instruments (if needed), and general cart maintenance.

The overpack tube plugs have two interconnected pipe lines for inerting and purging the overpack tube. One line connects to a pressure gauge and the other to a quick-disconnect coupling. The standard storage tubes and preselected storage tubes will not need to be inerted. However, the tube vent and purge cart could be used to monitor the preselected tubes for hydrogen and helium.

Tables A2-6 and A2-7 list the operating conditions for which the tube vent and purge cart system and the overpack storage tubes have been designed.

Safety Considerations. The overpack storage tubes, bases, and embeds are classified as safety class and important-to-safety Category A. The overpack storage tube plug, lower flanges and the bottom impact absorbers are classified safety significant. All other components of the overpack storage tube assemblies are general service. The floor electrical plugs and helium fill station are general service. The hose, HEPA filter, and interconnecting equipment piping of the tube vent and purge cart are classified safety significant, and the remainder are general service (Figure A2-48).

A2.6 CONFINEMENT SYSTEMS

This section defines the confinement requirements, and identifies and describes the SSCs that perform confinement functions for the SNF stored in MCOs in the CSB. These confinement systems for sealed MCOs containing SNF meet the requirements of DOE Order 6430.1A, Sections 1300-7 “General Requirements: Confinement Systems,” and 1320-5 “Irradiated Fissile Material Storage Facilities: Confinement Systems.” A confinement system is “the barrier and its associated systems (including ventilation) between areas containing hazardous materials and the environment or other areas in the facility that are normally expected to have levels of hazardous materials lower than allowable concentration limits.” The following is a discussion of these confinement requirements.

A2.6.1 Requirements

DOE orders provide requirements and recommendations for the appropriate level of confinement needed for fuel storage. DOE Order 6430.1A, Section 1300-7, “General Requirements: Confinement Systems,” and 1320-5, “Irradiated Fissile Material Storage Facilities: Confinement Systems,” address the confinement appropriate for SNF fuel storage at the CSB. Section 1300-7 states:

“Confinement systems shall accomplish the following:

- Minimize the spread of radioactive and other hazardous materials within the unoccupied process areas
- Prevent, if possible, or else minimize the spread of radioactive and other hazardous materials to occupied areas
- Minimize the release of radioactive and other hazardous materials in facility effluents during normal operation and anticipated operational occurrences
- Limit the release of radioactive and other hazardous materials resulting from design basis accidents including severe natural phenomena and man-made events in compliance with the guidelines contained in Section 1300-1.4.2, Accidental Releases.”

Section 1300-7 are provides other general requirements.

- The HVAC system shall maintain a controlled continuous airflow pattern from the environment into the confinement building, from uncontaminated areas to potentially contaminated areas, and then to contaminated areas.
The number and arrangement of confinement barriers are determined on a case-by-case basis with the final objective being a practical design that achieves the confinement objectives.

The confinement systems shall perform their required functions for the design basis accidents they are required to withstand.

At least one confinement system remains fully functional following any credible design basis accident.

Section 1320-5 states: “The following provisions are typical for an Irradiated Fissile Material Storage Facilities (IFMSF) confinement system. The actual confinement system requirements for a specific IFMSF shall be determined on a case-by-case basis. In general, the primary confinement shall be the IFMSF cladding or canning. Secondary confinement shall be established by the facility buildings that enclose the dry storage area and/or the storage pool and auxiliary systems.”

Other general requirements from Section 1320-5 include the following.

- Special design features shall be considered for safe handling of irradiated fissile material to protect against dropping of shipping casks.
- Penetrations of the secondary confinement barrier shall have positive seals to prevent the migration of contamination.
- Ventilation systems shall provide for inlet air filtration, and the exhaust air shall have HEPA filters.

In summary, Section 1320-5 identifies the SSCs that accomplish the confinement objectives. In general the confinement barriers are identified on a case-by-case basis.

A2.6.2 Safety Classification of Confinement Systems

The hazard and accident analysis performed in Chapter A3.0 determines the safety classification for all SSCs in the CSB, including the confinement systems. The safety classification process uses guidance from HNF-PRO-704, Hazard and Accident Analysis Process, and applies the graded approach methodology of DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports. Classification of a confinement system as safety class, safety significant, or general service depends on the SSC’s preventive, mitigative, or worker safety functions for reducing adverse effects on the environment, the public, onsite workers, and facility workers. As shown in Chapter A3.0, there are no postulated releases with consequences exceeding offsite release limits. Therefore, no SSCs are required to have a safety-class confinement function. However, several SSCs have been
determined to have other safety-class functions and thus are classified as safety class. The one exception is the MCO sample station hood as described in Section A2.5.1.4.

A2.6.3 Confinement During Canister Storage Building Operations

The DOE Order 6430.1A requirements identified in Section A2.6.1 provide a flexible structure for determining the confinement requirements based upon the potential hazards and the propensity for radiological release. The SNF stored within the MCO does not have intact cladding so that no credit may be taken for the cladding as a confinement barrier. Therefore, the MCO provides the primary confinement barrier. The secondary confinement barrier during transportation cask–MCO handling in the trailer vestibule and the MCO service station is the transportation cask (Figure A2-49). For other operations within the CSB (Figure A2-50), the equipment encasing the MCO provides the secondary confinement barrier (Figure A2-49) as listed in Table A2-8. Finally, the building structure and ventilation system provides additional confinement, defense in depth, for the SNF. As explained in greater detail in the following sections, the confinement barriers for the CSB accomplish the confinement objectives required by DOE Order 6430.1A.

Operations involving MCOs containing SNF are conducted within the CSB operating shelter in five primary areas: the trailer vestibule, the MCO service station, the MHM, the sampling/weld stations, and the storage tubes. The design of the CSB provides primary and secondary confinement barriers during all normal operations. Figure A2-49 depicts the confinement barriers during normal CSB operations (Figure A2-50). The primary and secondary confinement barrier systems are listed in Table A2-8. These include receipt, handling, and interim storage of the MCOs containing SNF. The confinement systems in Table 2-8 include passive barriers, active barriers, and confinement protection features used by operations to assure that the confinement systems are functional.

A2.6.3.1 Multi-Canister Overpack Confinement Features. The MCO is a mechanically sealed pressure vessel before it is shipped to the CSB. The MCO is closed with a mechanical locking ring at the K Basins before the MCO is shipped to the CVDF. The CVDF processes the MCOs through process ports in the shield plug using a cold vacuum drying process. All four ports of the MCO are mechanically sealed with blind gasketed cover plates at the CVDF. This makes the process valves and pressure relief features of the MCO inactive while the MCO is being transported and during all phases of operation at the CSB. After a cap is welded to the MCO, the sealed welded MCO (cap and shell) provides the permanent primary confinement barrier for the SNF.

During all phases of normal CSB operations the MCO is credited with providing the primary confinement barrier against accidental releases of SNF or particulate. This barrier is designed to remain essentially leak tight during all normal and credible events except drops or shears from cranes and other handling equipment, as discussed in SNF-4042, Evaluation of Accident Frequencies at the Canister Storage Building. The leak rates for which the MCO is

designed are $\leq 1.0 \times 10^{-3}$ cm$^3$/s in the mechanically sealed configuration, and $\leq 1.0 \times 10^{-7}$ cm$^3$/s after welding the canister cover assembly.

A2.6.3.2 Confinement During Trailer Vestibule Operations. Trailer vestibule operations include off-loading the transportation cask/MCO from the transporter, and transferring the transportation cask–MCO from the trailer vestibule to the cask receiving pit. These operations are described in Section A2.5.1. For operations in the trailer vestibule area, the MCO shell provides the primary confinement barrier with the transportation cask providing secondary confinement functions.

A2.6.3.3 Confinement During Multi-Canister Overpack Service Station Operations. Operations in the MCO service station are related with preparing the transportation cask for MCO removal by the MHM. These operations include checking the internal pressure of the transportation cask on the transportation trailer or in the cask receiving pit before removing the cask lid. During operations in the cask receiving pit, primary confinement is provided by the MCO shell with the cask receiving pit and the shield hatch and MCO guide assembly, providing secondary confinement functions during preparation of the MCO for removal by the MHM.

Venting casks having "a higher than normal pressure" are considered for recovery operations from abnormal conditions. In addition to the confinement provided by the MCO shell and the MCO service station equipment (pit, shield hatch and MCO guide assembly, and tent for off-normal use), the cask servicing system provides secondary confinement functions during cask servicing operations.

A2.6.3.4 Confinement During Multi-Canister Overpack Handling Machine Operations. Once the transportation cask has been prepared for MCO removal by the MHM, the MHM's tube plug grapple is used to remove and replace the shield hatch and MCO guide assembly's center shield hatch plate (see Figure A2-17). The MCO hoist and grapple is used to withdraw the MCO from the transportation cask. The MHM can be used to transport the MCO to the sample station, weld station, or to a standard storage tube for staging. These travel paths are depicted on Figure A2-50.

During MCO transfers between the MHM and a storage tube, air from the operating area and from the storage tube is drawn through the MHM cask space and into the MHM's HEPA-filtered extract system. Control of potential incidental contamination from an MCO is maintained by the MHM's onboard, HEPA-filtered, extract system during MCO handling. Air from the MHM exhaust system discharges into the CSB operating area and is exhausted through the CSB HVAC system (Figure A2-51), which also contains HEPA filters. The MCO shell provides the primary confinement barrier with the MHM cask cavity and MHM extract system providing secondary confinement. The operating area shelter and the HVAC system provide additional confinement functions.

A2.6.3.5 Confinement During Sampling/Weld Station Operations. MCOs are transported by the MHM to a sampling/weld station where monitoring of MCO temperature and internal
pressure, and gas sampling occurs. After lowering an MCO into the sampling/weld station, a
sampling/weld station gantry crane removes the center shield plate and shield halves. A sample
hood is positioned over the MCO and sample lines attached to MCO process port 2. This MCO
process port connects to the MCO’s internal HEPA filter. A HEPA filtered sample hood exhaust
system provides secondary confinement to the MCO and sample lines. A sample cart connected
to the sample hood process HEPA filter provides the equipment for taking samples and
diluting/exhausting the internal MCO gases. The MCO and MCO internal HEPA filter provide
primary confinement for the SNF. The flexible line up to the HEPA filter, the sample hood HEPA
filter, the sample cart, sampling/weld pit, and sampling vent system provide secondary
confinement functions. The operating shelter and HVAC system also provide confinement
functions. For a short period of time between removal of the sampling/weld station shield plate
and installation of the sample hood, the secondary confinement function is provided by the
operating shelter and HVAC system.

A2.6.3.6 Confinement During Standard Storage Tube Operations. The MCO shell provides
primary confinement for SNF during storage in the standard storage tubes with the storage tube
and tube plug providing secondary confinement functions. An MCO that is to be monitored is
removed from its storage tube and transported by the MHM to a sampling/weld station for
sampling activities. The standard storage tubes are maintained at atmospheric pressure through a
filtered port in the tube plug, providing filtered inflow and outflow of air mixing with the facility’s
HEPA-filtered HVAC system. The tube plug design includes a tube plug filtered exhaust port, a
tube plug seal, and a valved port. The operating shelter and HVAC system also provide
confinement functions.

A2.6.4 Confinement During Storage Tube Surveillance

Operations described in Section A2.5 require long-term surveillance for the standard
storage tubes. These surveillance activities may include periodic radiation surveying of standard
tube-filtered exhaust ports and occasional monitoring of standard tube atmosphere using the tube
vent and purge cart. As mentioned in the previous section, the MCO shell provides the primary
confinement barrier for the SNF with the standard storage tube and standard tube plug providing
secondary confinement. The operating shelter and the HVAC system provide additional
confinement functions.

The operating shelter provides additional confinement for radioactive particulate and,
together with the shield wall and perimeter curb, provides additional shielding for radiation
control. The operating area shelter is a weatherproof structure having walls and a roofing system
that are resistant to wind-driven missiles and tornado wind loads. The operating shelter provides
additional confinement for radioactive particulate and, together with the shield wall and perimeter
curb, provides additional shielding for radiation control. However, it is not relied upon as a
mitigating feature against particulate releases caused by the postulated accident sequences.
In addition, the building ventilation system contains HEPA filters for removal of airborne
particulate. The operating area ventilation system filters would protect the public, environment,
and onsite workers by filtering radioactive particulate should a release occur from any of the
confinement systems. Therefore, the operating area shelter and the operating shelter HVAC
system provide additional confinement features for confinement of SNF and SNF particulate.

A2.6.5 Confinement During Overpack Storage Tube Operations

Overpack storage tube operations only occur when CSB operations detect an abnormal or
accident condition for an MCO. This may occur when the cask servicing system detects an
abnormal MCO. Recovery actions are determined, and the MCO subsequently is moved into an
overpack storage tube for monitored storage. The overpack storage tube operations include
checking the internal pressure of the overpack storage tube, checking the overpack tube plug
seals, monitoring the tube atmosphere for hydrogen concentration, purging the overpack storage
tube as needed to lower the hydrogen concentration, and adding inert gas. Venting, monitoring,
and reinerting the overpack storage tube is required when periodic checks indicate an abnormal
tube pressure. These actions also are required for an MCO that has vented hydrogen into the
overpack storage tube.

A2.7 SAFETY SUPPORT SYSTEMS

The principal safety support systems are identified and described in this section. The
descriptions include the purpose, an overview, principal components, operations, and control
functions.

A2.7.1 Fire Protection Features

The CSB structural system, roof, and exterior wall system are made of noncombustible
materials. This gives the building a construction type of Uniform Building Code (ICBO 1994),
Type II-N (nonrated). In any interior areas that have finishes, the finishes have a flame spread
index less than 25 when tested in accordance with ASTM E84, Test for Surface Burning
Analysis for the Canister Storage Building, by the Authority Having Jurisdiction (DOE, Richland
Operations Office) determined that an H-7 occupancy classification was more appropriate.
A deviation request, Letter 9655218, Project W-379, Spent Nuclear Fuel Canister Storage
Request for Deviation from the United States Department of Energy Order 6430.1A —
Automatic Sprinkler Protection Requirements (Williams 1996), was submitted to DOE, Richland
Operations Office, to allow the application of NFPA 101, Safety to Life from Fire in Buildings
and Structures, and NFPA 220, Standards on Types of Building Construction, in lieu of the
Uniform Building Code (ICBO 1994) requirements for definitions, occupancy classification, fire
ratings, and types of construction. Fluor Daniel Hanford, Incorporated has received approval of
the deviation request (Sellers 1996). The roof structural and steel column members in the truck
vestibule area and the two steel column members within the operations area (adjacent to the

A2-85 March 2000
Megadoor™) have a protective coating (minimum 3/4-in. thickness of spray-on coating on metal lath) providing a one-hour fire rating. The one-hour fire protective coating protects against the potential diesel spill fire that could cause structural failure of the roof supports and the steel column support members.

The administrative controls summarized below are based on analysis contained in the fire hazards analysis (HNF-SD-SNF-FHA-002).

- Combustible materials inherent to all equipment proposed for use within the operating area shall be ALARA. This includes limiting the use of materials with combustible components, and whenever possible, replacing them with either noncombustible or fire resistant or retardant components.

- Damage potential resulting from a vehicle fuel spill and resulting fire in the trailer vestibule shall be limited by restricting the receiving crane by administrative procedure or control from that area during those periods when a cask transportation truck and tractor is staged (located) within the trailer vestibule. A 3-in.-high dam in the receiving crane rail trenches prevents diesel flow into the load-in/load-out and operating areas.

- Transient combustible materials shall be limited to the minimum type and quantities required to perform the transient activity or operation and shall be removed upon completion of that activity or operation.

- Potential fire size resulting from a transient combustible fire shall be controlled by restricting the size and quantity of potentially combustible materials (i.e., MCOs wrapped in fire-retardant polyethylene or trash bags filled during normal operations) and maintaining the minimum separation distances identified in HNF-SD-SNF-FHA-002.

- The uncontrolled leakage of fluid (i.e., spray) from the receiving crane or MHM shall require the immediate safe shutdown of operations until corrective action to seal the leak is completed and the fire hazard inherent to the leak is eliminated.

The fire protection system for the CSB is designed to protect the support building from damage. A very early smoke detection alarm system draws air from the upper portion of the operating area through plastic piping and detects smoke. The fire alarm control panel is located in the entry hallway outside of the facility manager's office (room 28). The fire alarm features include transmission of signals to the Hanford Fire Department via a radio fire alarm reporter; annunciation of separate and distinct fire, supervisory, and trouble alarms; annunciation of local building fire alarms; and shutdown of appropriate HVAC units initiated upon receipt of any alarm.

The standard response to an alarm condition in the 200 East Area will be by the Hanford Fire Department from the 200 Area Fire Station. Response time to the CSB will be...
approximately 5 minutes. When manned, a crew from the 100 Area Fire Station will be
dispatched simultaneously with an estimated response time of 10 minutes. Vehicle access to the
facility will be provided by a paved access road that is included as part of the facility construction.
The Hanford Fire Department is fully staffed, trained, and equipped.

A pre-fire plan developed by the Hanford Fire Department will be issued before operation
of the facility. This plan will include special purpose systems for the operating area as the first
approach to fire suppression because of the restriction of using large quantities of water. Should
these special purpose systems fail to extinguish a fire, water hose streams may be used as a last
resort. Chapter A6.0 establishes the criticality safety fire fighting category and discusses any
restrictions for using water to extinguish a fire involving fissionable material.

The common wall section between the operations area and the support area building is
designed to provide a 2-hour Underwriters Laboratories-rated fire protection. One and one-half
hour rated fire dampers are provided at the exhaust and return registers of the operating area
(FD-1 and FD-2) and also at the supply to the utility rooms (FD-3 and FD-4). The fire control
panel is powered from the uninterruptible power supply (UPS).

The rooms of the CSB support area building are protected against fire damage by the fire
walls and the automatic, wet-pipe sprinkler system. The wet-pipe sprinkler system has been
designed to meet the requirements of DOE Order 6430.1A, Section 1530-3.1, and NFPA 13,
Installation of Sprinkler Systems. The design flow rate is 0.19 gal/min-sprinkler head (2,500 ft²),
ordinary hazard, Group 3. The fire alarm system may be activated by a manual alarm box.
Provisions have been included for future activation mechanisms as needed. The two utility rooms
are separated from the support area building and each other by a 2-hour rated fire wall. A space
heater in each utility room provides freeze protection for the sprinkler system. A 6-in. fire water
supply system begins at the north side of the CSB support area building using a connection to a
10-in. fire water main (Figure A2-4). DOE Order 6430.1A, Section 1530-99.0, requires a
minimum of two reliable, independent sources of water. The second source is provided by a
44,000-gal storage tank and pumping system dedicated to the fire water loop around the CSB and
Building 2704-HV. A post-indicating valve provides isolation of the 6-in. CSB fire water line
from the fire water main if required. Bollards, located adjacent to the post-indicating main shut-
off valve, protect the valve from accidental collision with off-road vehicle traffic. Other bollards
near the main shut-off valve protect the nearby cathodic test stations. A cathodic protection
system has been installed on the underground lines to prevent corrosion of the carbon steel water
lines (potable and sanitary). Other water mains include the 10-in. and 12-in. fire and raw water
lines to the north and east of the facility and smaller underground lines in the immediate area
around the facility. The routing of the sprinkler header is along the support area building corridor
ceiling. Runoff from sprinklers in uncontaminated areas goes to the outside of the building.
Runoff from fire sprinkler actuation in potentially contaminated areas (regulated change rooms) is
captured in the support area building in recessed floor sumps. Sleeves, pipes in a sleeve, and
conducts in the support area building pits are sealed to prevent runoff from leaving the sprinkled
areas. Water released by a rupture or actuation of the wet-pipe sprinkler fire system will be
collected in recessed floor sumps in the support area building (control, step-off pad, count,
monitoring and decontamination, and regulated change rooms).
Additional fire protection features include fire extinguishers located in the support area (electrical equipment, filter room, both air locks, and corridor), the trailer vestibule area, and the loading and staging area (Figure A2-3) that are mounted in accordance with NFPA 10. Also, manual pull boxes are mounted in accordance with NFPA 10 in the control room, at the east support area entrance, at the support area maintenance area, and the northeast operating area exit, and two are mounted in the sampling/weld station area (Figure A2-3).

Range fires do not present an exposure potential to the CSB. A clear space of at least 60 ft is provided on all sides of the CSB (HNF-SD-SNF-FHA-002). Unpaved areas around the CSB are overlaid with crushed rock surface.

Water leaking from the underground water supply lines could cause water accumulation, drainage problems, soil erosion, and CSB building foundation failure if the leak is not detected and the leaking line is not isolated from the water main. Periodically checking the soil level surrounding the facility and checking the soil level after an earthquake provide for early detection of water leaks and prevent significant soil erosion.

Table A2-9 lists the operating conditions for which the fire protection system has been designed.

**Safety Considerations.** The fire protection system is classified general service.

### A2.7.2 Heating, Ventilation, and Air Conditioning System

The HVAC system is designed to provide, along with physical barriers, part of the CSB contamination confinement system and contamination control within the CSB. The HVAC system provides a controlled pressure gradient flow of air from outside the CSB inward through uncontaminated areas to potentially contaminated areas of the building and out through HEPA filters and a monitored exhaust. The HVAC system also provides climate control to ensure that environmental conditions in the CSB are maintained in the required ranges for personnel and equipment. The HEPA-filtered service station enclosure discharges air into the operations area. The operations area air exchange rate is approximately 1.5 volume changes per hour.

The HVAC composite flow diagram can be seen on Figure A2-51. The HVAC system has its own programmable controller. The HVAC system is manually adjusted to achieve the operating area negative pressure. Dampers automatically compensate for changes in filter pressure drop or other sources of exhaust from the CSB. The setpoint for starting the second exhaust fan, in the event of failure of the lead fan, is 50% of normal flow or 4,500 ft³/min. The HVAC system comprises two subsystems, the operating area HVAC subsystem and the support area HVAC subsystem.

This table is for information only and does not provide operational controls.

NA = not applicable.
A2.7.2.1 Operating Area Heating, Ventilation, and Air Conditioning. The operating area HVAC subsystem provides ventilation and air conditioning for the CSB operating area and the HVAC equipment room. The operating area HVAC system is designed to maintain a negative pressure with regard to the outside environment to ensure airflow from areas of lower contamination potential to areas of higher contamination potential. The operating area HVAC system provides approximately 44,000 ft³/min of supply air and recirculates approximately 35,500 ft³/min of air through the operating area and HVAC equipment rooms. The HVAC system has continuous outside air makeup of 6,750 ft³/min and a HEPA-filtered exhaust of 8,970 ft³/min to 9,000 ft³/min that is continuously monitored for contamination. Outside air is drawn through roof-mounted intakes and an electric duct heater to air handling units where it is mixed with air recirculated from within the building. The exhaust air fans are equipped with backdraft dampers (BD-1 and BD-2) that are counterweighted to allow flow in only one direction to prevent backflow through the fan when it is not operating, damage to the fan, or possible spread of contamination.

During cold weather conditions, electric heating elements (present in the electric duct heater and in each operating area HVAC air handling unit) operate in a controlled, cascading fashion to maintain the operating area air temperature within the normal range above the low-temperature setpoint. For warm weather conditions, external, air-cooled condenser/compressor units that supply refrigerant to cooling vanes in the air handlers maintain the operating area air temperature in the normal range below the high-temperature setpoint. Inlet air coolers CU-001 and CU-002 are programmed using the LP-HV-001 HVAC panel board with one cooler designated as lead and the other as lag condensing unit. The controls turn on the first compressor of the lead condensing unit. A second compressor of the lead unit is started if the compressor is not providing adequate cooling after a set time delay. The lag condensing unit automatically starts if the lead condensing unit cannot satisfy adequate cooling after a given time delay.

Table A2-10 lists the operating conditions for which the operating area HVAC has been designed.

A2.7.2.2 Support Area Heating, Ventilation, and Air Conditioning. After passing through the operating area or the HVAC equipment room, air is exhausted from the support area HVAC through HEPA filters and an exhaust fan and out the main exhaust stack where continuous radiation monitoring records contamination, if any, in the air. Heater blankets in each exhaust HEPA filter housing prevent the accumulation of condensation on the filters. Ember screens upstream of the HEPA filters protect the filters from potential fire damage and meet the requirements of the *DOE Filter Plenum Fire Protection Standard* (DOE 1993).

The operating area HVAC airflow is balanced by setting manual airflow dampers in the operating area intake, recirculation, and HVAC equipment room ducts to achieve the desired differential pressure with a constant exhaust fan airflow. Manual damper MVD-1 maintains the balance of intake air to recirculating airflow for the operating area HVAC subsystem; manual damper MVD-2 maintains the balance of flows exiting the HVAC equipment room between that entering the exhaust flowpath and that recirculating to the operating area HVAC subsystem;

</table>

This table is for information only and does not provide operational controls.

HEPA = high-efficiency particulate air (filter).
manual damper MVD-3 sets the airflow entering the HVAC equipment room; and manual damper MVD-4 maintains the airflow to the "entry-related" rooms of the support area HVAC subsystem. The operating area HVAC controls the positions of the inlet vane damper of the operating area exhaust fan, varying the overall HVAC exhaust to maintain the desired constant exhaust fan discharge airflow. If both exhaust fans are shut down, the operating area HVAC air handlers shut down automatically (loss-of-flow controller FIC-281 50% exhaust flow permissive); if the operating exhaust fan is shut down, the other ("lag") exhaust fan automatically starts, followed by a restart of the air handlers when the 50% exhaust flow permissive is again met on loss-of-flow controller FIC-281. By shutting down the air handling units and allowing only an exhaust fan to operate in a low exhaust flow condition, an overpressurization of the operating area HVAC system and possible contamination spread is averted.

Automatic, fusible-link fire dampers and duct-mounted smoke detectors provide for worker safety and help prevent the fire from spreading to other areas of the facility. Fire dampers FD-1 and FD-2 are placed to automatically isolate the operating area from the rest of the operating area HVAC. An ember screen attached to FD-2 prevents airborne embers from entering the exhaust air plenum (Figure A2-51). Fire dampers FD-3 and FD-7 (room 018) and FD-4 and FD-8 (room 034) are placed to automatically isolate the utility rooms (room 1 and room 2, respectively) from the support area HVAC by blocking the room HVAC inlet flow ducting and return air dampers. Operation of the fire dampers in the operating area HVAC causes a loss of exhaust flow, with subsequent trip of the air handlers from the 50% exhaust flow permissive setpoint. The smoke detectors are mounted in the operating area HVAC return line and in the support area HVAC recirculation line. A trip of the operating area HVAC duct-mounted smoke detector shuts down the HVAC inlet air handlers (AH-001, AH-002, and AH-003); sounds an alarm within the facility; and transmits a fire alarm by radio from the fire control panel to the central fire alarm system, causing the fire department to respond. An exhaust fan (EF-001 or EF-002) continues to operate and maintains a negative pressure in the CSB. A trip of the support area HVAC duct-mounted smoke detector also performs these actions and sends a signal to the fire department. The fusible-link sprinklers in the support area release a water spray into the support area rooms when the air temperature melts the fusible link. Water flowing through the wet-pipe sprinkling system activates a flow switch in the sprinkler system and transmits a signal to the fire department indicating that the sprinklers have activated.

The support area HVAC subsystem uses forced-air ventilation to maintain desired support area temperatures and required contamination confinement for potentially contaminated rooms (also known as "entry-related rooms" [i.e., those rooms located between airlocks]) in the support area. The support area subsystem serves the control room, corridor, telephone and equipment room, effluent monitor room, utility rooms, electrical equipment room, regulated change room, HPT office, step-off pad and bag room, and the monitoring and decontamination room. Air is drawn from outside the building through roof-mounted intakes and an electric duct heater to an air-handling unit and passes through the support area rooms. Air from entry-related rooms is exhausted through a prefilter and another air-handling unit (AH-004) at a constant 920 ft³/min (nominal) flow rate and is discharged to the HVAC equipment room (where it joins the operating
area HVAC exhaust flow). Air supplied to the support area rooms shown in Figure A2-51 is recirculated.

The support area HVAC subsystem airflow is balanced by setting the manual airflow damper in the duct to the entry-related rooms. The relief damper (which relieves excess air pressure from the support area to the outside) is set to achieve the desired negative differential pressure balanced with the rest of the support area HVAC subsystem in the entry-related rooms. The relief damper relieves air only from the clean air system. Consequently, no air monitoring of air discharged from the relief damper is required. The desired airflow throughout the rest of the support area HVAC subsystem is balanced with a constant exhaust airflow (to the operating area HVAC subsystem). The support area HVAC maintains the desired differential pressures and flows by controlling the speed of the exhaust fan to maintain a constant discharge airflow. Support area HVAC air handler AH-003 will not start until support area HVAC exhaust fan AH-004 flow rate reaches the minimum 50% airflow. If exhaust fan AH-004 is shut down and low flow is sensed, the low-flow interlock automatically shuts down support area HVAC supply air handler AH-003 to prevent overpressurization. If the supply air handler is shut down, the exhaust fan continues to operate at a constant exhaust flow.

An air flow of 4,500 standard ft³/min is induced through the sampling/weld area stations by the operating area HVAC system. This airflow is exhausted through the sampling/weld area ducting to the operating area ventilation system after being HEPA-filtered and monitored.

The HVAC requirements in ANSI/ASME N509 and ANSI/ASME N510 were used in designing the CSB HVAC general-service and safety-significant systems. These design features provide onsite radiological doses that implement the principles of ALARA. Therefore, the NRC equivalency requirements, Item 12, for HVAC systems are met.

Table A2-11 lists the operating conditions for which the support area HVAC has been designed.

A2.7.2.3 Heating, Ventilation, and Air Conditioning Exhaust Stack. The HVAC exhaust stack is 75 ft tall; 2 ft, 4 in. in diameter; and is constructed of carbon steel plate and carbon steel pipe. The stack is formed from tubular sections of steel pipe joined with bolted flanges at two places along its height. The stack wall is a minimum of 0.375 in. thick. The uppermost 22-ft, 6-in. section has steel wind deflector vanes mounted around the outside of the stack. The stack has six capped test ports, 2 in. in diameter, used for airflow rate tests and air sample tests (Figure A2-52).

Safety Considerations. The HVAC system is classified general service.

A2.7.3 Health Protection System

The health protection system is designed to monitor and warn plant personnel of hazardous radioactive conditions that may occur as a result of malfunctions or accidents, provide contamination control, and provide limited computer-activated database management and status reporting. The health protection system employs radiation monitoring equipment and personnel contamination monitors.

The individual components of the health physics system are located throughout the CSB. Each instrument of the system has the ability to operate independently from the DCS. Not all of the health physics instruments are connected to the DCS. The data paths provided from the instruments to the DCS enable data collected by the instruments to be stored, compared, and displayed in one central location. The following is a list of the equipment designed for use in the CSB; and Figure A2-53, shows the locations of the monitoring equipment. The locations are based on radiation dose levels, operation occupancy factors, and egress pathways. These locations may change during facility operations if radiation protection determines that a different location will provide better protection for personnel.

- Multichannel Analyzer — One multichannel analyzer is located in the count room in the CSB. The multichannel analyzer is used for gamma spectrum analysis of radiological control swipes and air samples.

- Alpha/Beta Counter — Instruments in the countroom include a computer-controlled alpha/beta counting system that has a proportional detector and automatic sample changer. This system can simultaneously measure the alpha and beta activity on samples such as radiological control swipes and air samples, and print reports of the data.

- Germanium Detector — The germanium detector is used for gamma spectroscopy analysis of samples. The electronic signal from the germanium detector is analyzed by the multichannel analyzer indicating the gamma isotopes in the sample.

- Hand and Foot Monitor — One hand and foot monitor is located in the regulated change room (room 350). People place their feet in the foot slots and thrust their hands into the hand slots of the hand and foot monitor. The hands pressing in the hand slots activate the monitor, which measures radioactivity, if any, on the feet and hands. The chosen location ensures that personnel leaving the operating area can survey themselves before entering uncontaminated areas of the CSB.

- Area Radiation Monitors — Area radiation monitors, located throughout the CSB (Figure A2-53), monitor the general radiation level in the area surrounding their locations. A decade switch on the area radiation monitor provides for detection, indicating, and alarming for a range from 0.1 mrem/h to 10 rem/h (1 μSv/h to 100 mSv/h). All area radiation monitors have a microprocessor-based rate meter.
with readouts, including failure and high alarms with audible and visual annunciation. Area radiation monitors connect to the DCS through a remote terminal unit.

- Beta Continuous Air Monitors — Beta CAMs evaluate the amount of beta-emitting airborne radioactive material in sample air. Each beta monitor contains a Geiger-Muller detector and a count rate meter including failure and high radiation alarms. The beta CAMs are located in occupied areas having high potential for airborne contamination. For example, one is mounted on the MHM and another on the mobile containment service tent. Selected beta CAMs may be connected to the DCS. CAMs sample and monitor the air and are designed to provide early warning (local alarm bell and red rotating beacon light) of a significant release of radioactive material.

- Alpha Continuous Air Monitors — The alpha CAMs provide detecting, indicating, and alarming functions (local alarm bell and red rotating beacon light) for airborne alpha radioactive particulate. A pumped airflow is monitored and sampled for evidence of alpha airborne contamination. None of the alpha CAMs are connected to the DCS.

- Radioactive Gas Monitors — Radioactive gas monitors provide detection, indicating, and alarm functions for radioactive gases potentially released from MCOs. No radioactive gas monitors are connected to the DCS. These monitors are located on the MHM, tube vent and purge cart, and the mobile containment service tent.

- Body Frisker — A body frisker checks whole bodies for contamination. The body frisker monitors people for potential contamination as they exit the operating area airlock (room 25) and enter the uncontaminated areas of the support area.

- Record Air Samplers — Record air samplers, located throughout the CSB, provide a record of the work place air quality in high-occupancy and frequently traveled areas of the facility. A pumped airflow passing through high efficiency filters deposits particulate on the filter. These filters, counted using the alpha/beta counter and/or multichannel analyzer, can be used to sample room air for evaluation of potential inhalation hazards to personnel. The filters are exchanged by the Radiological Control personnel at a frequency specified by their management. These filters are exchanged if an incident involving airborne contamination occurs, because the filters provide an integrating sample over a period of time and CAMs provide immediate notification of a problem. These filters can be exchanged at the discretion of Radiological Control management to help evaluate an airborne contamination event. These data also can be used to support the concentrations recorded by a CAM alarm. The sample filter is counted by Radiological Control personnel and could be sent to the SNF Counting Facility for further analysis.
**Safety Considerations.** The health protection system is classified general service.

### A2.7.4 Airborne Emissions Monitoring System

The components of the CSB HVAC stack airborne emissions monitoring system include airflow rate and temperature measurements; a shrouded sampling probe for radioactive particulate and radionuclide monitoring; and two vacuum pumps (single redundancy), which draw the effluent sample at a flow rate that is nominally set at 2 standard ft³/min through a splitter. The sample splitter block and flow measurement and control components distribute, measure, and control the flow of the sample from the sample probe to the samplers. The splitter block is designed to provide a uniform representative sample to each sample collector assembly. There is a mass flow controller in each of the two flow streams that maintains 1 standard ft³/min of flow through each of the two streams. One stream contains a record air sampler and the other stream contains the alpha/beta detector. The system is designed to the following criteria:

- Monitor radionuclides that contribute 0.1 mrem/yr ($1.0 \times 10^{-3}$ mSv/yr) or more to the anticipated unabated offsite effective dose ($^{238}$Pu, $^{239}$Pu, $^{240}$Pu, $^{241}$Pu, $^{241}$Am, $^{137}$Cs, and $^{90}$Sr) (this criterion is based on WAC 246-247)

- Monitor radionuclides that contribute 25% or more of the anticipated abated offsite effective dose ($^{241}$Am) (this criterion is based on WAC 246-247)

- Provide constant air monitoring of alpha/beta particulate (this criterion is based on DOE Order 5400.1)

- Operate such that CAM downtime for scheduled maintenance does not exceed 8 hours in each 24-hour period; unscheduled downtime not greater than 72 hours in each 7-day period
• Provide for a minimum collection efficiency of 50% or more for 10 μm sized particles.

Figure A2-53 shows the layout of the monitoring equipment. Figure A2-52 shows the stack monitoring equipment. Each sample flow channel of the system is controlled by an independent microprocessor with a self-contained rate meter that will continue to operate even if the DCS or its communication lines fail. Local indications such as count rate data and radiation field intensities are available from each channel. If alarm conditions exist, local visual and audible annunciation occurs at the monitor panel independent of the DCS. Each monitoring channel is capable of self-testing using an independent radioactive check source. Testing can be initiated locally. The complete system provides monitoring, database management, and status reporting.

The remote stack sampler uses a shrouded probe located at an elevation of 25 ft, 9.25 in. The probe is installed with the nozzle at the cross-sectional center of the stack. The flow from this probe is piped to the in-line sample splitter and then to the detectors and record sampler located in the sampler skid. All piping is of seamless construction to reduce plateout of radioactive particulate and prevent hot spots. The alpha/beta and gamma record sampler collects a sample of particulate and gas exiting the stack for subsequent radionuclide analysis. The line loss and filter efficiency are such that the collected particle sample contains >50% of the 10 μm and larger (aerodynamic equivalent diameter) particles that are present in the free system. The alpha/beta scintillation detector, as described in NRC MD-345, *Iodine Detector*, monitors alpha activity from 239Pu and 241Am in stack effluent particulate. The detector also monitors for 90Sr beta emissions in stack particulate. The alpha/beta detector monitors for real-time early warning of an out-of-ordinary emission to facility personnel. The detector has circuitry for background subtraction of radon-thoron activity. Test ports have been installed on the exhaust stack (two near the base, two near the lower sample port, and two near the upper flow port) for manual monitoring of stack flow using portable flow measuring equipment and/or manual samplers.

The electronics console located in the CAEM room controls all functions of the HVAC stack monitoring system. A digital rate meter, bar code reader, pump control module, data storage, and transfer computer are included in this unit. All monitoring information that is provided and/or available to the CSB DCS comes from this unit, with the exception of the stack flow signal. The alarm setpoints can be set and changed from the console.

Item 25 of the NRC equivalency requirements (HNF-SD-SNF-DB-003) involves reviewing federal effluent monitoring requirements, for example, Title 10, *Code of Federal Regulations*, Part 20, “Standards for Protection against Radiation” (10 CFR 20); Title 10, *Code of Federal Regulations*, Part 70, “Domestic Licensing of Special Nuclear Material,” Section 70.59, “Effluent Monitoring Reporting Requirements” (10 CFR 70); and 10 CFR 835, to ensure the necessary monitoring instrumentation has been provided. The following is a summary of the review performed.
1. 10 CFR 20 provides standards for protection against radiation; Section 20.1501(b) discusses the need to calibrate equipment used for effluent monitoring. More prescriptive requirements on emission monitoring are found in 40 CFR 61 and in WAC 246-247. The radioactive airborne emission control system and monitoring system of CSB are in compliance with these requirements and have been approved by the Environmental Protection Agency, Region 10, and the Washington Department of Health (note the approved permit application, DOE/RL-98-30, describing the emissions control and monitoring system).

2. 10 CFR 70.59 provides for effluent monitoring reporting requirements. A review of 10 CFR 70.59 shows it requires the facility to provide NRC semiannual effluent reports. There are no liquid effluent streams for the CSB, so the only effluent stream is the airborne emissions stream. Annual emissions reporting to the Environmental Protection Agency is required by 40 CFR 61, Subpart H, and annual emissions reporting to the Washington Department of Health is required by WAC 246-247.

3. 10 CFR 835 does not apply because it has requirements for occupational radiation protection and not for environmental protection or monitoring of facility airborne emissions.

Safety Considerations. The airborne emissions monitoring system is classified general service.

A2.7.5 Inert Gas Supply System

The inert gas supply system (helium) interfaces with the cask servicing system (abnormal operations), the MCO tube vent and purge cart system, and sampling/weld stations. The inert gas supply system contains gas supply banks with an initial pressure of at least 2,000 lb/in² gauge. The gas bank is certified by the vendor upon shipment to ensure administrative control of gas content and purity. The gas supply pressure is reduced to a nominal pressure of 120 lb/in² gauge for distribution to the cask receiving pit and sampling/weld stations. Quick-disconnect fittings near the cask receiving pit and the sampling/weld stations provide a helium supply for purging casks and sampling MCOs. Flexible hoses from the MCO servicing system and the sampling/weld equipment are attached to these fittings when helium is needed.

The inert gas supply system is designed to provide four main functions for MCO servicing (abnormal operations): (1) high-pressure purging of an MCO cask in the cask receiving pit; (2) controlling dilution for gases vented from a cask in the cask receiving pit; (3) refilling an MCO at the sampling/weld station; and (4) controlling dilution for the gas vented from the MCO at the sampling/weld station to the HVAC exhaust duct to reduce the possibility of hydrogen combustion in accordance with NFPA 69, Explosion Prevention Systems. A pressure control valve automatically regulates the amount of inert gas used to dilute the concentration of hydrogen present in the MCO vent gas based on the pressure present in the MCO vent gas line.
The inert gas supply system is designed to provide inert gas to the tube vent and purge cart at the inert gas fill station. This fill station provides a minimum of 2,000 lb/in² gauge inert gas to refill the two inert gas cylinders present on the tube vent and purge cart. Helium is also supplied at reduced pressure to the sampling/weld station for refilling of monitored MCOs and for leak testing after welding cover cap assemblies to MCOs. The tube vent and purge cart bottles provide only enough capacity for one MCO storage tube volume of gas. The tube vent and purge inert gas fill station provides a quick and efficient method of refilling the tube vent and purge cart cylinders for reuse. The inert gas system piping and components located inside the CSB support and operations area are designed to ANSI/ASME B31.3, Process Piping, for the safety-significant portions that connect to the MCO servicing system and to ASME B31.1, Power Piping, for the general service portions that supply inert gas to the vent and purge cart refill station and to the helium let-down station. All pressurized gas cylinders received at the CSB have a cap screwed on the cylinder that prevents damage to the cylinder valve during shipment and handling. This cap remains on the cylinder until after the cylinder is chained to the cylinder rack and personnel are ready to attach the high-pressure discharge piping to the cylinder valve. All pressurized gas cylinders received at the CSB have a cylinder valve. According to ANSI/CSA/CGA, Standard V-1, Compressed Gas Cylinder Valve Outlet and Inlet Connections, a maximum hole size in the inlet to the butt of the cylinder valve restricts airflow through the valve and minimizes propulsion effects should the valve be accidentally severed at the top of the cylinder. Both the cylinder cap and the cylinder valve protect a pressurized gas cylinder from causing serious propulsion effects.

Figures A2-24, A2-42, and A2-45 show the inert gas supply system general service lines supplying inert gas to the load-in/load-out cask receiving pit, the tube vent and purge cart refill station, and to the helium let-down station in the sampling/weld area. A low pressure (125 lb/in² gauge) supply line is routed through the south side of the compressor area. There are two doorways separating this line from the control room (approximately 60 ft) where personnel are stationed. This is sufficient distance to protect personnel should a helium leak occur in the supply line. Also, the support area ventilation system will dilute and evacuate an accidental release of helium from this area. Pressure relief devices (valve and rupture disks) are located in the sampling/weld area and are mounted on the south wall. PSV-728 and PSE-1 provide pressure relief if the helium supply pressure exceeds 135 lb/in² gauge or 150 lb/in² gauge, respectively. Table A2-12 lists the operating conditions for which the inert gas supply system has been designed.

Safety Considerations. The helium supply system rupture disk (PSE-1) is classified safety significant and important-to-safety Category B. The remainder of the helium supply system is classified general service.

A2.7.6 Seismic Detection System

Redundant accelerometers are mounted on the northeast curb of the load-in/load-out area and are designed to detect building motion and dynamic response caused by a seismic event. The accelerometer control panel contains electrical connections to power sources for both the MHM and receiving crane. When excess seismic motion is detected by the accelerometers (the channel trip setting is 0.19 g peak ground acceleration, which is approximately 54% of the maximum horizontal or vertical spectra for the 0.35 g earthquake with 7% damping), a power disconnect switch for the receiving crane actuates causing loss of power. On loss of power, the receiving crane load is locked in the current position preventing further movement of the load or crane.

The accelerometers, upon detecting a seismic event, also activate a disconnect switch for the MHM power. The accelerometers are normally energized to hold closed the power supply contacts for the MHM. A seismic event will de-energize the accelerometers which in turn de-energizes the MHM. A loss of power for the MHM actuates seismic clamps for both sides of the bridge, stops turret rotation, and locks the shield plug hoist and the MCO hoist in the current positions. These clamps and locking features are designed to prevent further motion of the MHM, minimize damage to the MCO, and prevent a potential contamination spread.

The accelerometer panel and the accelerometer power panel are installed on an equipment rack that has been seismically qualified according to CSB-S-0064, *MHM and Receiving Crane Seismic Trip Supports*. Mounting on a seismically qualified equipment rack provides assurance that an earthquake can be detected with subsequent safe shutdown of the receiving crane and MHM.

Safety Considerations. The seismic detection system for the MHM, the receiving crane, and the power-disconnect system for the MHM are classified general service.

A2.8 UTILITY DISTRIBUTION SYSTEMS

This section provides a schematic outline of the basic utility distribution systems, including a description of the offsite power supplies and onsite components of the system. The CSB design relies on offsite power and road transport of bulk gases and supplies for normal operation. The CSB basic utility distribution systems, including the UPS, ensure continued operation of safety systems during NPHs or offsite emergencies.

A2.8.1 Normal Electrical Power

The normal electrical distribution system is shown in Figure A2-54. The figure shows the one-line connections between Hanford Site power, the CSB transformers, and switchgear for...
voltage and load control during normal operation of the CSB. The normal electrical distribution system comprises the following subsystems.

- The 13.8 kV, 3-phase Hanford Site overhead utility system brings power to a utility pole located northeast of the CSB through a cutout switch and fuses, and terminates at the primary circuit of the SNF CSB pad-mounted transformer.

- The pad-mounted transformer converts 13.8 kV to 480Y/277 V, which is then supplied through the utility metering cabinet to the low-voltage switchgear cabinet SG-32-202 (room 031) where it is distributed through circuit breakers to four MCCs.

- MCC-33-207, MCC-33-208, MCC-32-209, and MCC-32-210 distribute 480Y/277/208/120 V (ac) power to distribution panels A, B, D, G, H, and J. Each circuit is controlled by a circuit breaker designed to protect the circuit components if an electrical fault should occur. Distribution panels A, B, D, G, and H are located in the electrical equipment room (room 031): panels A, B, and D are on the west wall, and panels G and H are on the south wall. Distribution panel J receives power through MCC-32-210 and distributes power to the sampling/weld station equipment and distribution panel K, a 208/120 V (ac) panel. Panels J and K are located on the east wall of the sampling/weld station area.

- The UPS receives 480 V (ac), 3-phase, 60 Hz power from the dedicated MCC MCC-33-207. This MCC is part of the normal electrical distribution system and is considered the normal power supply for the UPS. If the normal power supply is unable to supply power, then the backup battery will automatically supply uninterrupted power until power from a portable diesel generator or normal power supplies are available. Distribution panels C and F receive 208/120 V (ac), 3-phase, 60 Hz power from the UPS. Power to distribution panels C and F may also be connected to either MCC-33-207 or MCC-32-210 by closing the appropriate circuit breaker on UPS-33-213. The UPS and panels C and F are located in the UPS room (room 020). Portable diesel-powered electrical generators are available onsite and can be brought to the CSB to supply electrical power.

Equipment support racks containing control panels, transfer switches, conduit supports, and circuit breakers have been designed using anchor bolts and unistrut construction to match the safety-class criteria of the equipment.

Cutout switch DD-32-101 is supplied electrical power from an existing 13.8 kV overhead utility circuit. The fused cutout switch provides electrical isolation during planned maintenance activities or circuit overloads. Each fuse installed in this switch assembly is rated for 50 amps. The cutout switch has ganged switching components that ensure all three phases are interrupted whenever the switch is placed in the open position. Power from the cutout switch is routed underground to the primary circuit of the pad-mounted transformer. Cable that has been pulled
through conduit meets the requirements in NFPA 70, *National Electrical Code*, for this type of
cable. Electrical conduit supports for safety significant and general service installations have been
designed and installed for the electrical cable trays.

Pad-mounted transformer XT-32-102 is energized by 13.8 kV through its 200 amp primary
disconnect switch and fuses. This transformer is rated for 1,000 kVA and steps 13.8 kV down to
480/277 V. It is a self-cooled unit with heat ratings of 65 °C (149 °F) temperature rise above
40 °C (104 °F) ambient. The transformer secondary circuit provides 480/277 V power to the
utility metering cabinet. Four grounding rings (loops) around this transformer ensure safe
grounding for the life of the facility. These grounding rings are electrically bonded to the
transformer and the CSB ground system.

Utility metering cabinet UC-32-201 houses circuit monitoring equipment and a three-phase
main circuit breaker. A solid-state, kilowatt-hour-meter/watt-hour-meter-with-demand meter
mounted on the door of the metering cubicle receives input from potential transformers and
current transformers housed in the metering compartment measuring power usage of the SNF
CSB. The utility metering cabinet circuit breaker isolates the pad-mounted transformer power
from the indoor switchgear. The circuit breaker is a 600 V, 1,200 amp frame with a 100,000 amp
interrupting capability. The 1,200 amp solid state trip unit has an adjustable long-time pickup,
long-time delay, short-time pickup, and short-time delay. Instantaneous override in conjunction
with the built-in ground fault protection is provided. When the main utility metering cabinet
circuit breaker is closed, it provides 480/277 V power to the low-voltage indoor switchgear.

Low-voltage switchgear cabinet SG-32-202 is constructed to house eight 3-phase circuit
breakers. Each breaker compartment is 92 in. high and 60 in. deep, and is isolated from other
breaker compartments with grounded metal barriers. The compartment doors are designed to
remain closed when racking the breakers to any of their three positions: disconnected, test, and
connected. A positive mechanical interlock is provided to prevent the breakers from being racked
in or out unless the breaker is tripped and to prevent the breaker from being closed while it is
being racked in or out. Each breaker compartment is provided with a pilot light for breaker open
or breaker closed. Four circuit breakers provide normal electrical power and circuit protection to
the four MCCs in the CSB. The remaining two circuit breakers and two empty cubicles are
spares for future use.

MCC-33-207, MCC-33-208, MCC-32-209, and MCC-32-210 are energized by the normal
electrical distribution system from low-voltage switchgear cabinet SG-32-202. All four MCCs are
part of the 480/277 V (ac), 3-phase, 4-wire, 60 Hz, grounded distribution system. MCC cabinets
are standard, prefabricated, vertical sections comprising individual control units arranged to
provide a completely dead-front, totally enclosed assembly. All motor starters are of the full-
voltage, nonreversing type. Each combination starter is housed in an individual compartment
removable from the front by disconnecting the necessary control and load leads. Each
compartment door is provided with an interlocking feature to prevent the opening of any door
when the unit it houses is energized. Each MCC is equipped with an ammeter to monitor total
MCC loads. Power distribution from the MCCs is divided into two basic groups. One group
supplies individual loads with optional control circuits, and the other group supplies the
distribution panels (A through H) where smaller loads are subdivided into single load groups.

Distribution panels A, C, D, F, and J receive 480/277 V (ac) 3-phase power from their
MCC and distribute it through individual molded case circuit breakers that are mounted in each
panel. Distribution panels B, E, G, H, and K are supplied power from their MCC through a
dedicated indoor dry transformer, which steps the voltage down to 208/120 V, 3-phase, 4-wire
for distribution through individual molded case circuit breakers. All panel assemblies are enclosed
in a surface-mounted steel cabinet. UPS distribution panels C and F have the ground bus
electrically isolated from the enclosure; all other assemblies have a ground bus bolted to the frame
and an isolated neutral bus. In compliance with 29 CFR 1910.306, the power supply
(DA-33-217, Figure A2-54, sheet 6) for the sampling/weld gantry crane can be viewed by
personnel, no fixed working platform can be attached to the crane for maintenance and the crane’s
power supply breaker is labeled on distribution panel J.

Lighting systems for the CSB comply with Illuminating Engineering Society of North
America’s Lighting Handbook (IES 1987) and ASHRAE 90-75R, Energy Conservation in New
Building Design. The lighting systems include exterior, interior, standby, and emergency lighting.
Exterior lighting illuminates the outside of the buildings using wall-mounted low-pressure sodium
light fixtures, which are controlled by light sensitive photocells in compliance with DOE
Order 5400.1, Section 1650-1. Interior lighting consists of normal lighting and standby lighting.
Illumination levels follow DOE Order 6430.1A, which recommends 50 footcandles for
workstation lighting, 30 for work area lighting, and 10 for non-work areas. Fluorescent light
fixtures with energy saving ballasts are used in the support building rooms. High intensity
discharge lighting fixtures are used in the operating area shelter. Standby lighting systems contain
rechargeable batteries providing power during power failures. The interior and standby lights are
controlled using manual light switches. Emergency lighting consists of individual lighting fixtures
powered by an integral battery and self-luminous exit signs which comply with NFPA 101 and the
life safety code, DOE Order 6430.1A, Section 1635-1. The emergency lighting fixtures are
installed in areas essential to life safety, ingress and egress routes from the equipment areas.
Portable lighting may be needed during inspection of the cask surface to meet the requirements of
ANSI/ANS-57.2-1992 (100 footcandles).

Table A2-13 shows the operating conditions for which the electrical systems have been
designed.

Safety Considerations. The normal electrical power system is classified as general service.

NA = not applicable.
A2.8.2 Backup Electrical Power System

The backup power system designed for the CSB will not be installed and connected at this time. No safety-class or safety-significant SSCs that would require a backup power system have been identified in Chapter A3.0. According to HNF-4776, Canister Storage Building Compliance Assessment, SNF Project NRC Equivalency Criteria — HNF-SD-SNF-DB-003, this meets the NRC equivalency requirement to evaluate loss of AC power to the facility (4). Two rooms in the support area building (rooms 18 and 34) are designated as utility rooms; and the two diesel supply tanks on the north sides of these rooms will not be used.

A2.8.3 Uninterruptible Power System

UPS UP-33-213 (Figure A2-54, sheet 7) is rated at 20 kVA, 208/120 V (ac), 3-phase, 4-wire, 60 Hz output and 480 V (ac), 3-phase, 60 Hz input. UP-33-213 functions to supply uninterrupted, reliable power to SNF CSB instrumentation distribution panels DA-33-304 (Panel F) and DA-33-303 (Panel C). MCC-32-207 is the normal power supply. If the normal power supply is unable to supply power, backup battery BA-33-301 automatically starts supplying power until a portable diesel generator or normal power is available, or until the backup battery power is depleted (about 30 minutes at full load). If the UPS should fail in such a manner that neither the normal power supply nor the UPS battery could supply power, the UPS maintenance bypass switch would be positioned to bypass the failed components and supply alternate power from MC-32-210 to the UPS.

The UPS is of a solid-state design, housed in a steel cabinet. The three-phase, four-wire system incorporates an ungrounded neutral bus and a ground bus that is electrically isolated from the enclosure. The major components comprise a rectifier-charger, battery and cabinet, inverter, static transfer switch, maintenance bypass switch, bypass transformer, synchronizing equipment, system control panel, metering, alarms, and protective devices. A UPS alarm is connected to the DCS and alerts personnel when a failure occurs in the UPS.

The rectifier-charger is a solid-state unit providing direct current to the inverter and to the battery for charging. The rectifier-charger unit has input current limiting set at the factory to 115%. An output filter is incorporated with the rectifier-charger unit to minimize ripple current into the battery. Under normal conditions, ripple current is limited to less than 2% root mean square. The charging rate of the rectifier-charger is sufficient to restore the battery from discharge to 95% charge within 8 hours.

The output frequency of the inverter is controlled by an oscillator that is temperature compensated, and is adjusted from 5% of the rated frequency to 0.1% for both steady state and transient conditions. The inverter output is designed to stay synchronized with the static bypass line provided the static bypass line remains within ±3 Hz of the nominal frequency. If the inverter frequency goes outside these limits, the inverter is designed to break synchronization with the lines and run on its internal frequency. The inverter is designed to sustain an overload across its...
output terminals up to 150% load, while supplying any load within its rating, without reducing the
output voltage. The efficiency of this unit is 85% at rated load. When the load is on the
maintenance bypass line, it is possible to check the operation of the rectifier-charger, inverter,
static transfer switch, and battery.

The battery cells are lead-calcium and contained in plastic vessels that have one vent for
each cell. The capacity of the battery is designed to supply direct current to the inverter for an
outage period of 30 minutes with the inverter operating at full rated output. A battery circuit
transfer breaker is provided.

**Safety Considerations.** The UPS is classified general service.

### A2.8.4 Distributed Control System

The DCS is designed to serve as the central monitoring and control system for CSB facility
conditions, systems (particularly the health physics monitoring system), and processes (specifically
the inert gas dilution of vented cask gases). Two central processing units provide redundant data
collection from instrumentation and monitoring systems located throughout the facility.

Components in the field (e.g., instruments, actuators, sensors) are connected to the DCS through
two remote termination unit cabinets that are located in rooms 019 and 030 in the facility. A data
highway links all components of the DCS together. A color printer in the control room permits
printing of hardcopy listings of alarms, control actions, and other reports by request. An audible
alarm in the control room alerts personnel when setpoints are exceeded. The DCS is shown on
Figure A2-55 and the instruments are listed in Table A2-14.

Two work stations provide monitoring of components connected to the DCS, control
functions, and the means for archiving mass data for safe storage. A programmable logic
controller accepts sensor inputs from field devices, accepts control inputs from the work stations,
processes these inputs through "ladder logic" algorithms in the programmable logic controller
processor, then generates and transmits control signals to field devices such as controllers or
alarms, and returns to the DCS for data recording or alarm annunciation. Programmable logic
controller remote input/output units concentrate and transmit data to another data processing
unit, which then acts as controller for the data processing unit represented by the input/output
unit. The DCS receives electrical power from the normal electrical distribution system through
battery-backed UPS DA-33-213.

The DCS provides monitoring capabilities for systems that provide for confinement of
incidental radioactive contamination to the CSB operating area by supporting key equipment
connected to health physics monitoring systems, the HVAC system, the MCO servicing system,
and the vault cooling system. For the vault cooling system, the air inlet and exhaust temperatures
and the flow rate are monitored using the DCS. The only control associated with the DCS is the
MCO vent inert gas dilution control valve in the cask servicing system. All other functions of the
DCS are monitoring functions of safety-significant equipment.

A2.8.5 Instrument and Plant Air System

The CSB instrument and plant air system comprises two 2-stage, oil-free, air-cooled, rotary screw compressors operating in alternating lead-starting fashion to deliver a minimum of 200 standard ft³/min of compressed air at 125 lb/in² gauge at the compressor discharge. The compressors have self-contained noise abatement features in compliance with DOE Order 6430.1A, Section 1300-12.4.3. Compressor operation is controlled by a separate microprocessor which senses pressure from instrument air receiver PT-248. When PT-248 senses a compressed air pressure drop to 90 lb/in² gauge, it signals the microprocessor to start a compressor. If pressure does not start rising, the second compressor also starts. The microprocessor is programmed to maintain the air receiver at a 100 ± 10 lb/in² gauge setpoint. The microprocessor will alternate the lead compressor based on a programmable time duration, presently set at 20 hours. The backup compressor will normally remain shut down in an "auto-start" mode, and start only if the lead compressor cannot supply the required air demand. Should that happen, both compressors will run. With no air demand, and after preset events, both compressors will stop and remain stopped in "auto-restart" mode. Subsequent air demand (PT-248 senses < 90 lb/in² gauge) will cause the current lead compressor to run. PIT-248 will signal the compressor selected as lag to start.

Compressed air from the compressors passes through a coalescing prefilter, a heatless desiccant air dryer, and a particulate after filter before it collects in a 340 ft³ air receiver to provide dry, oil- and particulate-free air on demand to the compressed air system, which supplies the instrument air subsystem and the service air subsystem. The instrument air subsystem distributes compressed air at 0 to 20 lb/in² gauge to HVAC equipment (pneumatic actuators, control valves, dampers, and instruments) throughout the CSB and the MCO service station area. The service air subsystem distributes compressed air at 100 to 110 lb/in² gauge to the MHM festoon supply, the weld stations, and for general use (e.g., for air tools) to utility stations in the north end of the CSB near the receiving area, as shown on Figure A2-56.

The two drying towers of air dryer DR-1 remove moisture from the air discharged from the instrument air compressors by passing it over an activated alumina desiccant material with one tower operating in drying mode while the other tower is in regeneration mode. When the desiccant is saturated, the active drying tower is automatically switched from a drying mode to regeneration mode. The other drying tower is switched from regeneration mode to drying mode. The dryer is a "heatless regenerative" dryer, meaning that regeneration of the desiccant is accomplished by routing a small amount of hot, dry, compressed air from the discharge of the active drying tower in a counter-current flow through the regenerating column to drive the moisture off the surface of the desiccant material rather than by using electric heating elements to provide the heat.
Instrument air receiver VX-1 is sized to provide up to 40 minutes of instrument air to normal instrument air loads in the event of a power loss to provide for shutdown of the systems using instrument air (e.g., HVAC, MHM). Receiver VX-1 is protected from overpressurization with pressure relief valves whose discharges are routed to safe areas away from any possible impingement on personnel. This compressed air is for plant uses only and is never to be used as breathing air. Table A2-15 lists the operating conditions for which the instrument air system has been designed.

Safety Considerations. The instrument and plant air system is classified general service.

A2.8.6 Liquid Waste Collection

The liquid waste collection system is designed to collect water condensate from HVAC air handling unit cooling coils and instrument air compressors, and provide for transfer of the condensate to approved containers for disposal. Water draining from these systems collects in sumps, and an air-operated pump transfers water from the sumps into the disposal container (Figure A2-57). Sumps collect the water because there are no floor drains in the facility. This system has been designated general service. The system is designed for a condensate collection rate of approximately 1 gal/h for 8 hours per day. The liquid waste collection system is not a floor drain or fire suppression water catchment. A concrete sealer has been applied to the walls and bottom of each sump that protects and waterproofs the concrete.

Sump SU-1 is a 4 ft by 2 ft by 2 ft deep recessed area in the support area building floor between the HVAC air handling units, as shown on Figure A2-53. A second sump (SU-2), 2 ft by 2 ft by 2 ft deep, is located between the instrument and plant air compressors, as shown on Figure A2-53. Both sumps are fall-protected with metal floor gratings.

HVAC condensate drains to the liquid collection sump SU-1 from drip pans located in the HVAC equipment room. Water separated by the air dryer system filters and compressed air system air-water separators drains into sump SU-2. An alarm is activated on the DCS when the level sensor in sump SU-1 indicates that the water level has reached the alarm setpoint (half full for the sump). When the alarm is received, personnel position a container and a portable pump at the sump, positions the pump suction and discharge hoses, connects the pump to a service air supply, and pumps the sump contents into the drum. According to DOE/RL-97-67, Pollution Prevention and Best Management Practices Plan for State Waste Discharge Permits ST4508 and ST4509, sampling and analysis of the drum contents will only be performed on the first few drums to document that the discharge meets Washington State Waste Discharge Permit ST 4509 for discharge to the ground. If it is suspected during normal operations that the condensate has been contaminated radiologically or chemically, it will be sampled and analyzed. When the contents are released for disposal, the container may be transported to a facility at which the contents can be transferred to the Treated Effluent Disposal Facility. If the contents meet the criteria for discharge under Washington State Waste Discharge Permit ST 4509 (DOE/RL-97-67) for cooling.

</table>

This table is for information only and does not provide operational controls.

RH = relative humidity.
water and condensate, the condensate may be used, as a best-management-practice, for lawn
irrigation or dust abatement. CSB Operations management is responsible for determining
disposition of container contents that are found to be in excess of Treated Effluent Disposal
Facility and/or State Waste Permit release limits.

Sumps in the FFTF pit and the MHM maintenance pit (one in each pit, 18 in. x 18 in. x
18 in. deep) collect fluids that drain from the equipment placed in these pits. The sumps may
contain organic fluids (crane lubricating oils or hydraulic fluids) or decontamination fluids. CSB
management will be responsible for fluid sampling, analysis, and disposal as described above.

Safety Considerations. The liquid waste collection system is classified general service.

A2.8.7 Sanitary Water

The 2-in. sanitary water line is blanked off underground approximately 5 ft north of the
support area building (Figure A2-4). The sanitary water system is designed and limited to
supplying clean water for possible future sanitary use (e.g., toilets, sinks, showers, drinking
fountains) if required. This line connects to the sanitary main 3-in. line located north of the
support area building.

Safety Considerations. The sanitary water system is classified general service.

A2.9 AUXILIARY SYSTEMS

This section includes information on the remaining portions of the CSB that have not been
covered by the preceding sections and that are necessary to provide information on the facility as
it pertains to the hazard and accident analyses.

A2.9.1 Communications System

The design of the plant communications system provides the cabling and/or raceway system
equipment for the telephone, public address, intercom, and radio communications systems within
the CSB to the communications equipment interface point. All communications system physical
interfaces are located in the communications equipment area of the CAEM and UPS room
(Figure A2-3). A door from the electrical equipment room provides access to the CAEM and
UPS room. Space is provided for telephone exchange equipment, paging equipment, wire
terminating frames, radio equipment, and coaxial and fiber-optic transmission equipment. Inside
cable design provides 50% spare cable and will provide spare raceway for inaccessible and/or
embedded areas.
Radio communications within the CSB include hand-held radios, a UHF station and base unit in the control room, an outside antenna mounted on the northeast corner of the operating shelter roof, and an interconnecting cable between the base unit and the antenna. The CSB UHF radio communication system provides for communications between the control room and personnel inside and outside of the operating area shelter and the support area building.

Telephone requirements are based on providing internal and external communications service to all office and operating areas within the CSB. The telephone system provides tie-ins to the Hanford Site crash alarm and the Hanford Site 911 emergency telephone system. An intercom system is incorporated into the telephone system.

Public address system coverage is required for all areas accessible to personnel, both interior and exterior. Public address systems within the CSB are accessed through specified telephone sets within the facility. Master overrides originate from the control room and the emergency response center. An evacuation alarm, complying with DOE Order 6430.1A, Section 1300-6.5.5, will be annunciated through the public address system speakers. The evacuation alarm can be activated from the control room or the emergency response center.

Area alarms are part of the 200 East alarm system, and plant alarms are incorporated into the DCS. Ringdown phones are installed for security use. Fire alarm and detection system signals (discussed in Section A2.7.1) are transmitted to the central fire alarm system by means of a radio system integral to the fire alarm control panel. Radiation and hazardous condition alarms are annunciated by means of the DCS. The Hanford Site crash alarm is annunciated through the general plant telephone system ringer and is directed to selected plant telephones.

**Safety Considerations.** The communications system is classified general service.

### A2.9.2 Security System

All areas of the building have locking Medeco doors and an alarm system. The operating area also has closed-circuit television cameras as part of security and safeguards protection.

Limited area entrances have special access hardware to control unauthorized entry. The large exterior openings have telescoping doors and heavy rolling shield gates (Figure A2-18) to minimize vehicle penetration during the design basis tornado at those locations. The concrete curb around the perimeter of the operations area shelter prevents vehicle penetration for the balance of the building. All vents, shafts, and ducts have intrusion barriers appropriate to their configuration. Limited area entrances have special outside access hardware for intrusion protection. All exit doors are equipped with crash bars for emergency exit.

---

3Medeco is a trademark of Medeco, Incorporated.
Security seals are installed between tube plug assemblies and the tube assemblies. This security measure helps to prevent inadvertent removal of a tube plug and also will indicate unauthorized tampering.

Safety Considerations. The security system is classified general service.

A2.9.3 Lightning Protection

The vault intake stack, vault exhaust stack, and ventilation exhaust stack each have lightning protection provided in accordance with NFPA 780. Two exposed cables located on opposite sides of the vault intake and vault exhaust stacks are attached to the stacks about 3 ft above the concrete base. The exposed cables are connected to the support building exhaust stack about 3 ft above roof level and connect to lightning protection ground rods (in the ground test well), which in turn are connected to the building ground grid. The stacks do not need separate air terminals (lightning rods) because they have an electrically continuous metal thickness greater than the 3/16 in. required by NFPA 780 (metal thickness varies for each stack, but no stack has a metal thickness less than 3/8 in.). Air terminals have been installed on the operating shelter roof and the support building roof to provide lightning protection for the buildings. Lightning protection ground conductors also connect these air terminals to the building ground grid. The stacks, air terminals, and ground conductors provide lightning protection for the CSB in accordance with NFPA 780.

Safety Considerations. The lightning protection system is classified general service.

A3.0 HAZARD AND ACCIDENT ANALYSES

A3.1 INTRODUCTION

This chapter presents a summary of the key methodology, assumptions, and results of the final safety hazard analysis and design basis accident (DBA) analyses that have been performed for the final design and operation of the Canister Storage Building (CSB). These analyses form a Safety Basis for the final safety analysis report (FSAR) and present a comprehensive evaluation of the CSB handling- and storage-related activities and natural phenomena and external hazards that can affect the public, workers, and environment. Single and multiple initiating events from equipment and human error failures in the facility, and human and natural events (i.e., common mode failure) outside of the facility have been considered. When the FSAR is approved by the U.S. Department of Energy (DOE), this Safety Basis will establish an Authorization Basis for the Spent Nuclear Fuel (SNF) Project. Changes to the facility during operations will be reviewed to ensure they do not affect the Authorization Basis and if necessary new analyses will be performed. This review process is described in Chapter 17.0 of the SNF Project FSAR and is termed the unreviewed safety question process.

This chapter has been prepared following the direction provided in Chapter 3.0 of the SNF Project FSAR. Where appropriate, this chapter references Chapter 3.0 of the SNF Project FSAR for additional details regarding the accident analysis evaluation guidelines and limits and analysis methodology. The contents of this chapter are as follows:

- The requirements for establishing the Safety Basis for the CSB are listed in Section A3.2. The requirements listed consist of DOE orders and standards and applicable U.S. Nuclear Regulatory Commission (NRC) rules and guidance.

- The CSB hazard analysis is summarized in Section A3.3. The complete hazard analysis is contained in HNF-SD-SNF-HIE-001, Canister Storage Building Hazard Analysis Report. The analysis identifies hazard sources, hazardous conditions, potential accident scenarios and their initiators, and assessments of event frequencies and consequences. Hazards are identified by form and location and represent a complete spectrum of events that could occur throughout the facility. An initial set of safety features that would serve to prevent or mitigate the postulated accident scenarios are identified in the hazard analysis, with a final set of safety features identified in the accident analyses in Section A3.4.2 and in Chapters A4.0 and A5.0. A safety feature that would prevent an accident scenario is defined as one that reduces the expected annual frequency of occurrence for the accident to beyond extremely unlikely (less than $10^{-6}$ per year). Hazard analysis methodology and evaluation criteria are discussed in further detail in Section 3.3 of the SNF Project FSAR.
The final facility hazard classification, determined in accordance with DOE-STD-1027-92, *Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports*, is addressed in Section A3.3.2.2. The CSB has been assigned a final designation of hazard category 2 facility based on material at risk (MAR).

Section A3.3.2.3 contains discussions of defense in depth, worker safety, and environmental protection, including a detailed tabulation of engineered and administrative features that have been identified as providing for worker safety.

The hazard evaluation ranking performed in the hazard analysis identifies hazards and associated events that pose a challenge to offsite and onsite radiological dose evaluation guidelines. This ranking serves as the basis for selecting unique and representative accidents for further detailed quantitative evaluation as DBAs. These are presented in Section A3.4.2. Each of the DBAs analyzed represents a bounding case for a category of hazards and accidents. SNF-4042, *Evaluation of Accident Frequencies at the Canister Storage Building*, documents the derivation of the DBA frequency range. The six major DBA categories are evaluated in the following sections:

- Section A3.4.2.1, "Mechanical Damage of Multi-Canister Overpack"
- Section A3.4.2.2, "Gaseous Release from the Multi-Canister Overpack"
- Section A3.4.2.3, "Multi-Canister Overpack Internal Hydrogen Deflagration"
- Section A3.4.2.4, "Multi-Canister Overpack External Hydrogen Deflagration"
- Section A3.4.2.5, "Thermal Runaway Reactions inside the Multi-Canister Overpack"
- Section A3.4.2.6, "Violations of Design Temperature Criteria."

Three receptor locations were used for the DBA analysis:

- Hanford Site boundary (17,390 m east of the CSB) — defined release limits; used for calculation of offsite doses and selection of safety-class features (Sellers 1997, Scott 1995)
- Onsite worker (100 m east from the CSB) — defined risk evaluation guidelines; used for calculation of onsite doses and selection of safety-significant features (Sellers 1997)
Highway 240 (onsite, approximately 9,280 m west of the CSB) — no defined evaluation guideline; doses calculated for informational purposes only (Scott 1995).

For the analyzed DBAs, safety-class and safety-significant features have been selected from the candidate features identified in the hazard analysis. When required by the SNF Project’s commitments to meet equivalent NRC requirements, candidate features have been identified as “important to safety” and designed, engineered, and procured consistent with safety-class or safety-significant classification requirements. Safety structures, systems, and components (SSCs) and controls are presented first in Section A3.4.2 with the discussion of each accident and described in more detail in Chapters A4.0 and A5.0.

Each of the six DBAs that have been quantitatively analyzed represents a bounding case for a category of hazards and accidents. An in-depth review was performed of all remaining significant accidents identified by the hazard analysis in each of the categories. The accidents reviewed typically represented the same accidents with different initiators, or a different accident bounded by the case presented. This review resulted in the selection of additional safety-class and safety-significant SSCs and technical safety requirements (TSRs) to ensure that all individual hazards and accidents within a category have been addressed. The table and text that accompany each DBA in Section A3.4.2 include the preventive and mitigative features and associated TSRs for the bounding case presented and for all other events within the accident category. Defense-in-depth features also are identified in these tables.

This chapter interfaces with several other SNF Project safety documents. This chapter identifies and evaluates material hazards associated with the CSB and analyzes bounding accident scenarios associated with multi-canister overpack (MCO) handling and storage activities that occur within the CSB. The planned scope and content of various other SNF Project safety reports, TSRs, and supporting safety documents are defined in HNF-SD-SNF-PLN-012, Spent Nuclear Fuel Project Integrated Safety Management Plan. The hazards associated with transport and accident scenarios that are postulated during shipment are analyzed in HNF-SD-TP-SARP-017, Safety Analysis Report for Packaging, Onsite, Multi-Canister Overpack Cask.

To protect the limiting values assumed in the hazard and DBA analyses, the interface between the Cold Vacuum Drying Facility (CVDF) and the CSB requires that an MCO delivered to the CSB contain less than 200 g of free water and provide confinement of the combustible hydrogen gases within the mechanically sealed MCOs. In addition, the CSB hazard and accident analysis relies on the SNF in an MCO to be clean (i.e., loose surface contaminants removed) and the fuel loading to be controlled (e.g., mass of fuel in a scrap basket, number of scrap baskets). The principal assumptions associated with K Basins and CVDF performance bounding limits are taken from HNF-SD-SNF-TI-059, A Discussion on the Methodology for Calculating Radiological and Toxicological Consequences for the Spent Nuclear Fuel Project at the Hanford Site, and they are identified in Section A3.4.2. Safety-related performance documentation from the K Basins and the CVDF is relied on to ensure that the as-received content and condition of...
the MCO are as required for the safety basis properties. The use of overpack tubes is related to recovery actions of short duration. The SNF Project will have direction in operating procedures that states the use of the overpack tubes is for recovery operations for potentially damaged MCOs or MCOs whose status or configuration is uncertain. A recovery team will convene in accordance with operational procedures. This team will determine recovery actions, including the conditions for use of overpack tubes. Actions using the overpack tubes will be for a short-term period, less than one year. Use of overpack tubes for other than recovery actions will be subject to the unreviewed safety question process.

In this chapter, there are references to the condition of the fuel in the MCO or the MCOs in the CSB facility as "safe and stable." In this context a "stable" condition is defined as either (1) an energy-balanced steady-state condition within temperature and pressure limits, or (2) a transient operating condition for which administrative controls are implemented to ensure the system can be placed into an energy-balanced steady-state condition before temperature or pressure limits are exceeded. A "safe" condition is defined as one in which one or more confinement barriers exist and are operative. This definition is consistent with HNF-SD-SNF-SARR-005, Multi-Canister Overpack Topical Report, Chapter 4.0.

A3.2 REQUIREMENTS

Chapter 3.0 of the SNF Project FSAR lists the design codes, standards, regulations, and DOE orders that contain requirements and guidance for establishing the safety basis for the SNF Project. The requirements for the CSB that pertain to the safety analysis are provided here.

- DOE Order 5480.23, Nuclear Safety Analysis Reports, in conjunction with its Attachment 1, "Interim Guidance for DOE Order 5480.23," sets the requirements for analysis. This chapter complies with these requirements by documenting performance of hazard and accident analyses. The methodology, assumptions, and criteria used to identify facility hazards, hazard rankings, candidate accidents, DBAs, preventive and mitigative features and controls and the classification of these features (along with the definition of safety functions, performance criteria, and applicability) are described in Chapter 3.0 of the SNF Project FSAR and documented in this chapter.

- DOE Order 5480.22, Technical Safety Requirements. This order sets the requirements for the development and preparation of a TSR document. This chapter complies with these requirements by documenting the performance of hazard and accident analyses in accordance with HNF-PRO-704, Hazard and Accident Analysis Process, and DOE Order 5480.23. The results of the analyses were used to identify specific SSC safety functions, performance requirements for the SSCs, and the times for application of the safety functions.
DOE Order 6430.1A, General Design Criteria. This order provides requirements for the identification of safety-class items. The analyses documented in this chapter used the SSC classification requirements of DOE Order 6430.1A in the identification of safety-function SSCs and their safety classification.

In Letter 95-SFD-167, Implementation of K Basins Spent Nuclear Fuel Project (SNFP) Regulatory Policy (Sellers 1995), DOE established the requirement for new SNF Project facilities to achieve “nuclear safety equivalency” to comparable NRC-licensed facilities. The SNF Project identified the NRC requirements that were to be met in addition to existing and applicable DOE requirements to establish nuclear safety equivalency. These NRC requirements and the process used to identify them are documented in HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements and in WHC-SD-SNF-DB-009, Canister Storage Building Natural Phenomena Hazards. These documents established the design requirements to be met for the CSB to achieve NRC equivalency and considered the following:

Title 10, Code of Federal Regulations, Part 72, “Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste” (10 CFR 72). This rule is used for the licensing of independent spent fuel storage installations. Section 72.122, “Overall Requirements,” requires that the design bases for SSCs important to safety reflect appropriate combinations of the effects of normal and accident conditions and the effects of natural phenomena. Section 72.24, “Content of Application: Technical Information,” provides requirements in Paragraph 72.24(m) for the analyses of accidents and natural phenomena events that could result in a dose at the controlled area boundary.

NRC Regulatory Guide 3.48, Standard Format and Content for the Safety Analysis Report for an Independent Spent Fuel Storage Installation or Monitored Retrievable Storage Installation (Dry Storage). This guide establishes the format and content for safety analysis reports for license applications for fuel storage facilities.

While these documents have particular significance to this chapter, they do not, by themselves, establish requirements for the CSB or the Chapter A3.0 accident analyses. Requirements identified in HNF-SD-SNF-DB-003 and WHC-SD-SNF-DB-009 address NRC safety equivalency. These requirements include safety documentation for (1) determining “important-to-safety” classifications for preventive and mitigative features; (2) identifying and resolving worker safety issues in DOE Order 6430.1A, DOE Order 5480.23, and DOE-STD-3009-94; and (3) evaluating nearby activities identified in Section A1.6, “External Human-Generated Threats,” that may represent a threat to the facility.
Important-to-safety SSCs have been identified in accordance with 10 CFR 72, Section 72.3, “Definitions.” Once SSCs have been identified as having a function meeting the definition of important to safety, the requirements for SSCs important to safety specified in 10 CFR 72 are imposed. A graded approach is applied to an SSC important to safety by using the guidance provided in NUREG/CR-6407, Classification of Transportation Packaging and Dry Spent Fuel Storage System Components According to Importance to Safety, as modified by Letter 98-SFD-172, Contract No. DE-AC06-96RL13200 — Approval of Spent Nuclear Fuel Project Path Forward, Additional Nuclear Regulatory Commission Requirements, HNF-SD-SNF-DB-003 (Sellers 1998):

- **Category A — Critical to Safe Operation**

  SSCs in this category include those whose failure or malfunction could directly result in a condition adverse to public health and safety. Important-to-safety SSCs in this category have been classified as safety class using the definition in DOE Order 6430.1A, with the additional requirements therein.

- **Category B — Major Impact on Safety**

  SSCs in this category include those whose failure or malfunction could result in a condition adversely affecting collocated worker health and safety. Note that from the definition of Category C, Category B is understood to include events that could significantly damage the MCO without severe impact to public health and safety. SSCs in this category are classified as safety significant.

- **Category C — Minor Impact on Safety**

  SSCs whose failure or malfunction would not significantly reduce confinement and would not be likely to create a situation adversely affecting public or collocated workers' health and safety. SSCs in this category are classified as non-safety related and may be credited as defense in depth.

The determination of important to safety is directly incorporated into the tables of identified preventive or mitigative safety function features at the end of each DBA scenario in Section A3.4.2, and external human-generated threats are discussed in Section A3.3.2.3. Requirements of WHC-SD-SNF-DB-009 are incorporated into natural phenomena hazard design criteria and considered in the hazard evaluation. Additional requirements for the MCO are identified in HNF-SD-SNF-SARR-005.

Letter 97-SFD-172, Risk Evaluation Guidelines (REGs) to Ensure Inherently Safer Designs (Sellers 1997), provides the onsite risk evaluation guidelines and offsite release limits that have been used in this chapter for comparison with DBA consequences.
A3.3 HAZARD ANALYSIS

The hazard identification and evaluation process provides a thorough, predominantly qualitative evaluation of the spectrum of risks to the public, workers, and the environment caused by accidents that involve the hazards identified in the hazard analysis. The hazard evaluation was a structured and systematic examination of the CSB facility and its operations using standard industry (American Institute of Chemical Engineers) hazard evaluation techniques. This process is further described in Section 3.3 of the SNF Project FSAR. An initial hazard analysis was prepared to support HNF-SD-SNF-RPT-004, Canister Storage Building Safety Analysis Report — Phase 3: Safety Analysis Documentation Supporting Building Construction, and to integrate all previous CSB hazard analyses. A final hazard analysis has been performed to support the accident analysis and is documented in HNF-SD-SNF-HIE-001. The final hazard analysis systematically reviewed the final CSB design, as described in Chapter A2.0, associated supporting design documentation, and design references to identify any additional hazardous materials or energy sources that have the potential to initiate an accident that could require further review or analysis. This process resulted in the selection of six candidate accidents for more comprehensive analysis in subsections of Section A3.4.2.

The hazard analysis (HNF-SD-SNF-HIE-001) was based on the design and operations described in Chapters A2.0 and A4.0. The analysis included review of the CSB design and reviews of operation flow diagrams and operating procedures. The following normal CSB operations were considered:

- Receiving the transporter containing the cask–MCO and moving it into the facility
- Moving the cask–MCO to the load-in/load-out area and removing the cask lid at the cask receiving pit
- Transporting the MCO from the load-in/load-out area to the storage tube or to the MCO sampling/weld station with the MCO handling machine (MHM)
- Transporting the MCO from the storage tube to the MCO sampling/weld station and returning it to the storage tube after sampling
- Conducting activities during sampling and welding
- Conducting activities during MCO staging and interim storage.

The following off-normal MCO storage operations also were considered in the hazard analysis.

- Completing recovery actions after the event or accident leading to MCO damage has been terminated.
- Placing the off-normal MCO in the overpack storage tube.
- Installing the overpack storage tube plug cover.
- Establishing an inert atmosphere in the overpack tube.

The following key sources of information were used during the hazard analysis to evaluate the hazards (HNF-SD-SNF-HIE-001):

- HNF-SD-TP-SARP-017, *Safety Analysis Report for Packaging, Onsite, Multi-Canister Overpack Cask*, for coverage of accidents involving the transporter and transportation cask and for definition of assumptions inherent in defining the transportation window

- HNF-SD-SNF-SARR-005, *Multi-Canister Overpack Topical Report*, for criteria and assumptions related to the MCO design

- Representatives from the design authority and from facility operations for details of design, operating modes, and procedures

**A3.3.1 Methodology**

The methodology used to identify and evaluate the SNF Project facility hazards is described in detail in Chapter 3.0, Section 3.3, of the SNF Project FSAR. This section discusses those areas of the methodology that are specific to the CSB. The hazard evaluation process identified hazardous conditions, determined causes and preventive and mitigative features, and qualitatively estimated the consequences and frequencies of occurrence. The results of the application of this methodology to the CSB are presented in Section A3.3.2. The hazard analysis was performed in accordance with DOE-STD-3009-94 and implements the requirements of DOE Order 5480.23.
A3.3.1.1 Hazard Identification. The CSB hazard analysis addressed normal CSB operations for handling and storing a sealed MCO (HNF-SD-SNF-HIE-001). In order to assist in unreviewed safety question determination for any future recovery plans, the hazard analysis also identified and analyzed potential hazards associated with storing an off-normal MCO in an overpack storage tube. The hazard analysis evaluated scenarios created by failures of SSCs, human errors, or other accidents leading to potential releases of hazardous material in the facility or other impacts on safety. The hazards associated with transport and the accident scenarios that are postulated to occur during shipment are analyzed in HNF-SD-TP-SARI'-017.

Hazard identification for the CSB was based on examination of seven major areas in the facility:

1. Trailer vestibule (TV)
2. Load-in/load-out area (formerly known as the service area) (SA)
3. Operating area (OA)
4. Sampling/weld station (formerly known as the weld station) (WS)
5. Vault (VL)
6. Support building (SB)
7. Outside (OU).

The hazard analysis included hazards in each area and the process through all areas. If a hazard affected another area, the hazard analysis evaluation either evaluated it in that area or evaluated it in the affected area.

The cask handling, MCO handling, and MCO storage activities that can take place within each area at the CSB were identified and the hazards identified by form (e.g., electrical, thermal, friction), type (e.g., motors, power tools, wiring), and building location. A standardized hazardous material/energy source checklist (see Section 3.3.1.1, Table 3-1 of the SNF Project FSAR) was used to group the potentially hazardous materials and energy sources in each of the seven major facility areas. The two-letter abbreviations shown for the seven areas were used as the checklist location designators in the hazard analysis. The methodology of the hazards identification process is described further in Section 3.3.1.1 of the SNF Project FSAR.

A3.3.1.2 Hazard Evaluation. As described in Section A3.3.1.1, hazards associated with abnormal, accident, or recovery conditions at the CSB were identified. The hazards identified were evaluated to determine the causes of the hazard, potential accidents that could result from the presence of each hazard, and consequences to the public offsite, the collocated and facility workers onsite, the environment, or the CSB. Safety features, segregated into preventive and mitigative features, were identified for each hazard based on the ability of the feature to prevent or mitigate the consequences. Qualitative estimates of the frequency and consequences of the hazardous condition also were assigned (see Section 3.3.1.2 of the SNF Project FSAR for the criteria used in assigning the consequence and frequency categories).
A3.3.2 Hazard Analysis Results

The hazard analysis process is described in HNF-SD-SNF-HIE-001 and summarized in Section 3.3.1 of the SNF Project FSAR and Section A3.3.1. The results of that process, in the order of progression, are as follows:

- A series of checklist-style tables describing hazardous materials and energy sources, organized by major areas of the CSB — These tables were used to develop hazard analysis accident scenarios.

- A series of tables describing standard industrial hazards considered, organized by major area of the CSB — These events were judged to have no contribution to uncontrolled radiological and/or hazardous materials releases and were not considered in the selection of DBAs, safety-class or safety-significant features, or TSRs. They were among the hazards considered and, therefore, are included for completeness.

- A series of tables describing potential hazard scenarios, organized by major area of the CSB — These tables included hazardous energy sources and materials, hazardous conditions, causes and initiators, potential accidents, qualitative determinations of event frequencies and consequences, safety features for prevention and/or mitigation of the consequences, and defense-in-depth or worker safety features.

- A table, organized by major building area of the CSB, assigning risk bins to causes associated with significant consequences to offsite and onsite receptors — Consistent with DOE-STD-3009-94, the events located in risk bins representing "situations of concern," or "situations of major concern," were evaluated as candidate DBAs.

- A final list of candidate DBAs sorted by risk ranking and energy change or release — This list formed the basis for selection of the DBAs presented in Section A3.4.2.

DBA selection is addressed in Section A3.3.2.3.5 and its accompanying Table A3-4. In terms of the risk binning process, the accidents chosen from the hazard analysis for further analysis as DBAs were all events identified in consequence categories S3 and S2. These categories indicate significant effects to offsite and onsite receptors. Some events were brought forward into Table A3-4 that were identified as S1 consequence category events in the hazard analysis. These events were brought into Table A3-4 because they were initially of particular concern and were to be evaluated in more detail. These events are represented in Table A3-4 with a dash (-) in the risk ranking column.

The final hazard analysis has been reconciled with the up-to-date CSB facility design described in Chapters A2.0, A4.0, and A5.0.
A3.3.2.1 Hazard Identification. The final CSB hazard analysis tables are shown in HNF-SD-SNF-HIE-001. The hazards are identified by form (e.g., electrical, thermal, friction), type (e.g., motors, power tools, wiring), and building location (e.g., trailer vestibule, load-in/load-out area, operating area, sampling/weld station, vault, support building). A checklist designator (originating in the CSB hazard analysis tables) associated with each hazard contains a two-letter facility location designation, a letter corresponding to the general type of hazardous energy or material source, and a final number (sometimes with an associated letter) that identifies the specific source of the hazardous energy or material source. The main inventory of hazardous material in the CSB is the radionuclide content of the MCOs. The toxicological hazards of the radionuclide inventory were reviewed. As described in Section 3.4.1.1 of the SNF Project FSAR, the radiological guidelines were found to be more limiting than the toxicological guidelines for the release of SNF particulate. Other hazardous material identified by the hazard identification process includes pyrophoric metals and hydrides, oxidizers, hydrogen, diesel fuel, and other flammable or combustible materials (see Table A3-1). As discussed in HNF-SD-SNF-HIE-001, no hazardous or toxicological materials were identified that are not routinely encountered by the public, thus no unique or specialized institutional controls are required. A specific and comprehensive analysis of all fire hazards associated with the CSB was completed to augment the standard hazard analysis (HNF-SD-SNF-FHA-002).

The CSB does not have an operating history, so major hazards resulting from facility operation cannot be identified or summarized as suggested by DOE-STD-3009-94. However, as described in Section 3.3.2.1 of the SNF Project FSAR, the CSB spent fuel handling and storage activities are similar to those used by the independent spent fuel storage installations that have been issued materials licenses under 10 CFR 72. Major hazards from similar independent spent fuel storage installations were considered when performing the hazard analysis for the CSB. These hazards include generation of combustible gases, failure of confinement barriers, defects in cask integrity, and the spread of external contamination. This was described in the preliminary safety evaluation and the preliminary hazard analysis.

A3.3.2.2 Hazard Classification. A final hazards categorization of the CSB facility was performed based on the final hazard analysis (HNF-SD-SNF-HIE-001) and on accident analysis documentation for the facility provided in SNF-3328, Canister Storage Building Design Basis Accident Analysis Documentation. Consistent with DOE-STD-1027-92, the final categorization was based on the unmitigated releases of the MAR, presented in Table A3-2, from the worst-case beyond design basis accident (BDBA) in Section A3.4.3.4.2. These CSB material quantities were compared against the DOE-STD-1027-92 threshold quantities. The CSB facility final hazard categorization found the CSB facility to be a hazard category 2 facility. This categorization level is consistent with the bases and guidance described in DOE-STD-1027-92.

The established safety basis radiological nuclide inventory per metric ton of uranium (HNF-SD-SNF-TI-015) was used to estimate the material quantities available for release by multiplying the MAR and the specific nuclide inventories per metric ton of uranium (see Table A3-2). These quantities were compared against the category 2 threshold values from DOE-STD-1027-92, Table A.1 (see Table A3-2). The inventories in Table A3-2 are based on 100 kg of UO$_2$, which is derived from the worst-case BDBA consequence in Section A3.4.3.1.

\(^a\) Sum of category 2 ratios (inventory material/threshold quantities): 1.85

Note: Radionuclide values are from HNF-SD-SNF-TI-015, 1998, Spent Nuclear Fuel Project Technical Databook, Rev. 6, Fluor Daniel Hanford, Incorporated, Richland, Washington.

*The material at risk used to calculate the final Canister Storage Building hazard category bounds the beyond design basis accident in Section A3.4.3.1.

Category threshold values are from Table A-1 of DOE-STD-1027-92, Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports, U.S. Department of Energy, Washington, D.C.

MTU = metric ton of uranium.
Using 100 kg (0.1 metric ton) UO₂ dispersible particulate as the MAR, the ratios of the constituents of the MAR to the category 2 threshold quantities were calculated and summed to compare with the summation of radionuclide ratios for category 2 threshold criteria. The sum of the ratios of material inventory to category 2 quantity thresholds is 1.85. Since the sum of ratios is greater than one when compared with category 2 threshold criteria, the CSB remains a category 2 facility as identified during the preliminary hazard classification.

A3.3.2.3 Hazard Evaluation. The final CSB facility hazard analysis identified hazards associated with MCO handling and storage operations to be used in the CSB. Standard industrial hazards were identified and removed from the list of facility hazards used to identify DBAs. The results of the hazard analysis identified hazard scenarios for each major area in the CSB. These were used to define the CSB DBAs selected for further analysis in Section A3.4.2.

The external hazards from human-generated threats to CSB operation identified in Section A1.6 involve only those from aircraft activity. Section A1.6 identifies nine active airports within a 24-mile radius of the CSB and defines a maximum credible evaluation basis aircraft impact for the CSB operating deck and the air intake structures. Based on a structural evaluation of this energy impact documented in Assessment of Aircraft Impact on the Canister Storage Building and Cold Vacuum Drying Facility (Beary 1997), the thickness of the operating deck floor and the air intake structure vertical walls are more than adequate to withstand the impact of the evaluation basis aircraft missile. Therefore, the CSB facility is adequately protected from this threat.

Evaluation of the hazards of nearby external human-generated activities that may represent a threat to the facility is an NRC equivalency requirement specified in HNF-SD-SNF-DB-003. Section A1.7 identifies and addresses the threats to the CSB from nearby external facilities.

HNF-SD-SNF-DB-003 does not require that threats from natural phenomena, fire hazards, and nearby facilities be evaluated in Chapter A3.0. Those threats are evaluated elsewhere in the FSAR and summarized here for completeness. As described in detail in Chapter A2.0, the design criteria for natural phenomena were defined based on applicable DOE orders and NRC equivalency requirements as documented in WHC-SD-SNF-DB-009. These design criteria were incorporated into the design and engineering of SSCs as described in Chapter A4.0 (Petersen 1998a). Therefore, credible natural phenomena hazards are addressed in the design of the facility. The CSB fire hazard analysis (HNF-SD-SNF-FHA-002) identified the fire hazards, fire loading criteria, and appropriate requirements for addressing fire hazards during CSB operation based on applicable DOE orders, regulations, and NRC equivalency requirements. The fire hazard analysis evaluated a diesel fire, and a fire from ordinary combustibles that required equipment and controls, fire protection features (i.e., fire detection equipment and sprinklers), and controls on combustibles. The findings of the CSB fire hazard analysis were incorporated into the design and engineering of CSB SSCs and controls (such as fire loads, inspections, and watches). Therefore, credible fire hazards are addressed in the design of the facility. Threats from nearby facilities are identified in Section A1.7 based on applicable DOE orders, regulations, and NRC...
equivalency requirements. Credible threats from nearby facilities are addressed as described in section A1.7.

A3.3.2.3.1 Planned Design and Operational Safety Improvements. This section discusses commitments for the planned major design, MCO handling, or MCO storage improvements for the facility not yet implemented. Because the facility design and accident analysis have been developing in parallel, feedback to the design process has been available. As the hazard evaluation and specific accident analyses progressed, cost-effective modifications that improve safety have been incorporated into the design. For the unrestrained seismic event, the MHM trolley seismic uplift restraints currently exceed the allowable limits in ASME-NOG-1, *Rules for Construction of Overhead and Gantry Cranes (Top Running Bridge, Multiple Girder).* The design of the MHM will be strengthened to meet ASME-NOG-1 requirements, and this modification will be incorporated before CSB FSAR implementation.

A3.3.2.3.2 Defense in Depth. A summary of fundamental points relevant to the concept of defense in depth is provided in Section 3.3.2.3.2 of the SNF Project FSAR.

Features Chosen to Provide Defense in Depth for the Canister Storage Building.
Defense-in-depth features for the CSB were selected based on a relative ranking of the hazards from the hazard identification process, followed by selection of the safety-class and safety-significant features and TSRs for the DBAs, which are described in Section A3.4.2. Preventive and mitigative features identified in the hazard analysis (HNF-SD-SNF-HIE-001) but not identified in the accident analysis as safety class, safety significant, or TSRs are identified as additional defense-in-depth features. The defense-in-depth features are presented in the tables that accompany each DBA in Section A3.4.2. Administrative features identified in these tables are in addition to those already identified in Chapters A4.0, A5.0, and the programmatic chapters of the SNF Project FSAR (e.g., Chapters 7.0, 8.0, and 11.0).

The first layer of defense in depth at the CSB is facility design. All SSCs are designed in accordance with applicable codes and standards with a high degree of reliability and simplicity. The design encompasses human factors considerations to ensure that operations can be conducted safely. Defense-in-depth features for preventing and mitigating hazards and accidents associated with recovery-related activities and SSCs also have been identified. The overpack storage tube assemblies and the tube vent and purge cart, described in Chapter A2.0, Section A2.5.3, are used in handling MCOs involved in accidents. The overpack storage tubes and the tube vent and purge cart are, therefore, defense-in-depth items for recovery purposes. Abnormal MCOs or MCOs associated with accidents are discussed in Sections A3.3.3 and A3.3.4 and include MCOs received from the CVDF that are out of receipt specifications and those that are dropped, impacted, or sheared at the CSB. The MCOs that are associated with abnormal events will be returned to normal operations as described in Section A3.3.3.

The MCOs associated with accidents will be handled within recovery operations under operations procedures, with the preferred approach being to move the MCO to an overpack storage tube for short-term observation and storage. Use of the overpack storage tube is an
option for recovery. Recovery will be based on analysis and the development of a recovery plan. The containment tent, described in Chapter A2.0, also is involved with potential recovery-related actions.

Safety-Significant Structures, Systems, and Components. Safety-significant SSCs are predominantly required to prevent or mitigate consequences of postulated accident events to the collocated onsite worker. DOE Letter 97-SFD-172 (Sellers 1997) provides a correlation of evaluation guidelines to identification of safety-significant SSCs. In addition, DOE-STD-3009-94 suggests that SSCs be designated as safety significant if they play a key role in defense in depth (or worker safety). The severity of the event being prevented or mitigated and the number of barriers present are provided in DOE-STD-3009-94 as guidance for the identification of defense-in-depth safety-significant SSCs.

Safety-significant defense-in-depth features are described in Chapter A4.0 and include the following:

- MHM hoist and grapple — Provide safe handling of the MCO
- MHM interlocks P2, P6, and P21 — Prevent damage to MCO or operating deck by structural failure of the MHM
- Sampling/weld station shield halves and impact absorber — Protect MCO from drop by crane into sampling/weld station
- Cask lifting yoke — Limit MCO lifting height
- Standard storage tube bottom and intermediate impact absorbers — Mitigate drop impact to MCO for drop into standard storage tube
- Cask receiving impact absorber — Mitigate drop impact to MCO for drop into the cask receiving pit
- MCO centering guide — Limit eccentricity of MCO drop
- Shield hatch and MCO guide assembly — Mitigate drop impact to MCO from drop at cask receiving pit
- Interface guide ring funnel — Mitigate drop impact to MCO from drop in the storage tube
- Standard storage tube lower flange — Mitigate drop impact to MCO from drop into the standard storage tube
MHM seismic restraints (trolley, turret, and bridge) — Prevent damage to operating
deck from MHM, prevent shear of MCO by MHM

MHM rail and rail frogs — Prevent damage to operating deck from MHM, prevent
shear of MCO by MHM.

**Technical Safety Requirements.** TSRs were identified for postulated accident events that
could challenge accident consequence release limits and evaluation guidelines for the offsite public
and collocated onsite worker. TSRs are identified in the individual DBA sections and further
explained in Chapter A5.0. Only when items are elevated to safety significant to provide
significant defense in depth or significant facility worker safety do they warrant TSR coverage.

**A3.3.2.3.3 Worker Safety.** Worker safety for the CSB is ensured by a combination of
design features that reduce exposure to radioactive (e.g., shielding), toxic (e.g., confinement), and
industrial hazards (e.g., auditory or visual warnings), and by institutional practices that, in total,
provide protection of workers from these hazards. Protection of the facility worker from standard
industrial hazards identified for the CSB is achieved through adherence to the institutional safety
programs described in Chapters 7.0, 8.0, 9.0, 11.0, 15.0, and 17.0 of the SNF Project FSAR and
documented in lower-tier documents, such as health and safety plans and job hazards analyses.

Such industrial hazards do not require specific safety-significant SSCs or TSR-level administrative
features. Therefore, in accordance with the guidance of DOE-STD-3009-94, the remainder of
this section deals with protecting workers from those hazards of facility operation that are
exclusive of standard industrial hazards.

The final CSB hazard analysis provides an overview of the major features protecting facility
workers at the CSB (see HNF-SD-SNF-HIE-001). Worker safety features are an integral part of
facility design and operation. The major features of worker protection are identified in
Table A3-3 and are categorized by hazard. The features presented in Table A3-3 are in addition
to those identified as safety-class or safety-significant features in the DBA sections. The features
in the DBA sections protect the facility worker in the same manner in which they protect the
onsite and offsite receptor. Only those hazards not addressed by DBA evaluations are examined
in this section. The hazard energy source or material and hazardous condition are identified in
Table A3-3 along with protective worker safety features, including passive, active, and
administrative features. SSCs or TSRs are identified as safety significant for the CSB based on
their prevention or mitigation of serious impacts to worker safety. These safety-significant
worker safety features are associated with radiation protection and shielding for facility workers
for activities close to the MCO or the cask. The operating deck also plays a significant shielding
role for personnel working in the operating area and is identified as a safety-class feature to
protect the assumptions in the criticality analysis.

ALARA = as low as reasonably achievable.
CSB = Canister Storage Building.
HEPA = high-efficiency particulate air (filter).
HVAC = heating, ventilation, and air conditioning.
MCO = multi-canister overpack.
MHM = multi-canister overpack handling machine.
Safety-significant worker safety features are described in Chapter A4.0 and include the following:

- Standard storage tube plugs — Provide shielding to reduce radiation dose to worker
- Overpack storage tube plug — Provide shielding to reduce radiation dose to worker
- Shield hatch and MCO guide assembly — Provide shielding to reduce radiation dose to worker
- Sampling/weld station shield halves — Provide shielding to reduce radiation dose to workers
- Sampling/weld station center shield plate — Provide shielding to reduce radiation dose to workers
- MCO shield plug shielding — Provide shielding to reduce radiation dose to workers
- Transportation cask shielding — Provide shielding to reduce radiation dose to workers
- MHM fixed shielding — Provide shielding to reduce radiation dose to workers
- MHM interlock P2 — Protect worker against direct radiation exposure
- Sampling hood exhaust system — Protect worker from injury caused by flammable mixtures
- Sampling piping confinement system — Protect worker from injury caused by flammable mixtures

The TSR controls identified in the analysis of the DBAs in Section A3.4.2, in conjunction with the safety features identified in the hazard analysis and institutional programs, are adequate to ensure worker safety. These worker safety TSR controls include the following:

- Standard and overpack storage tube plug placement for direct radiation shielding
- P2 interlock operability to limit personnel exposures
- Sampling/weld station temporary shielding (shield halves and center shield plate), operator insertion of shielding, or verification that shielding is in place
- Shield hatch and MCO guide assembly shielding placement for direct radiation shielding
A3.3.2.3.4 Environmental Protection. The hazard to the environment from CSB operations involves the potential release of contaminants. The release pathway for these contaminants is only via the air to the boundaries and receptors discussed in Section A1.3.1.3. No liquid release hazards or accidents have been identified and no contaminant releases to the ground or groundwater are involved for the CSB. In addition, where liquid releases (such as water from fire sprinkler system in the support building, battery acid used in carts) are possible, they are contained by the design of the facility.

Based on the CSB design and operating information, no use of toxic chemicals has been identified. The toxicological hazards of the radionuclide inventory have been reviewed. As described in Section 3.4.1.1 of the SNF Project FSAR, the radiological guidelines have been found to be more limiting than the toxicological guidelines for the release of SNF particulate. The SNF particulate is primarily oxides of uranium (with fission products), which are not expected to change under current accident conditions. Potential consequences, including offsite releases, and required prevention and mitigation features are discussed in Section A3.4.2. Implementation of the prevention and mitigation features will prevent large releases that could have significant environmental impact.

The project features that protect the onsite collocated worker and the offsite public against radiological exposure also serve to prevent and mitigate radiological release to the environment. In addition, sitewide programs for environmental monitoring provide for assessment of the impact of facility releases. Normal CSB MCO handling or storage activities are expected to have a minor impact on the local and regional environment, as noted in WHC-SD-SNF-TI-013, K Basins Environmental Impact Statement Technical Input Document.

A3.3.2.3.5 Accident Selection. The methodology for the selection of DBAs is specified in DOE-STD-3009-94. DBAs are to be selected so that the range of accident scenarios analyzed in the accident analysis represents a complete set of representative and bounding conditions. This is a common requirement among the SNF Project facilities and is described in Section 3.3.2.3.5 of the SNF Project FSAR. The list of six candidate accidents resulting from the hazards binning process for the CSB facility is presented in Table A3-4. The table also contains all identified category S3 and S2 events bounded by each candidate accident. All of these events, and the controls selected for their prevention and mitigation, are described in Sections A3.4.2.1 through A3.4.2.6.

<sup>a</sup>The risk ranking is derived from methodology found in DOE-STD-3009-94, *Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports*, which correlates the consequence–frequency pairs assigned by the hazard analysis (HNF-SD-SNF-HIE-001) to a single-scale risk ranking using a figure reproduced in Figure 3-1 of the SNF Project FSAR. Events identified by a dash (-) were considered SI events in the hazard analysis but were initially considered of particular concern to the SNF Project and therefore were to be evaluated in more detail.

<sup>b</sup>Definition and use of energy release categories (high, medium, low) are based on guidance and examples in DOE-STD-3009-94.

Energy was considered that could damage an MCO — falling onto the deck was viewed as higher energy than falling into the cask receiving or sampling/weld pit with impact absorbers present; falling into the tube with impact absorbers present was viewed as higher energy than falling into the cask receiving or sampling/weld pit with an impact absorber present.

Before detailed analysis was performed, the hazard evaluation identified WS-H-06b as a serious hazard to be evaluated. Subsequent detailed analysis has shown that thermal runaway reactions are not possible at the CSB given limitation of water and resulting temperature.

MCO = multi-canister overpack.
It should be noted that early in the SNF Project history, DOE and the SNF Project had decided that the functions of vault structural capability and vault cooling were important safety-class functions. These defined safety functions of the vault led to the classification of the vault and related supporting structures. The safety-class seismic response spectra, as defined in WHC-SD-SNF-DB-004, *Spent Nuclear Fuel Project Seismic Design Criteria, NRC Equivalency Evaluation Report*, were used for the design of the CSB structures.

From the relevant sections of Letter 97-SFD-227, *Contract No DE-AC06-96RL13200 — Conditional Acceptance of Phase Three, Canister Storage Building Safety Analysis Report* (SAR), WHC-SD-SNF-RPT-004, *Systems* (Hansen 1997), the bases for DOE, Richland Operations Office, authorization of construction of the CSB were established. This included identification of seismic criteria. DOE's review, as documented in Letter 97-SFD-227, focused on the technical accuracy and completeness of HNF-SD-SNF-RPT-004, Revision 7B, and supporting references. It was a specific intent of the DOE review to ensure that the design and construction of the structure and systems would meet applicable DOE criteria and NRC requirements.

To meet the aggressive completion schedule for the SNF Project, DOE decided to implement a “staged safety analysis report approach” that waived the requirement for a preliminary safety analysis report prior to construction. Instead, a single, staged FSAR was to be produced. To implement the staged safety analysis report approach, DOE determined the basis for authorizing the first phase of construction. As of the date of Letter 97-SFD-227 (Hansen 1997), DOE had performed a number of reviews that provided the basis for the authorization of construction. This authorization included the at-grade and below-grade portions of the CSB, including the load-in/load-out area, intakes, stack foundation, service building foundation, the superstructure, and the CSB systems, with the exception of the MHM.

Further, Letter 97-SFD-227 (Hansen 1997) identified the site characteristics necessary for understanding the SNF storage facility environs important to the safety basis of the facility. The letter found the sections in the safety analysis report related to hydrology, geology, and natural phenomena threats were acceptable.

Based on this phased approach to regulatory approvals, design bases, design, and construction, it is clear that the seismic design criteria approach was the basis for approval and construction. The details of these seismic design bases are described in Section 4.4 of Letter 97-SFD-227 (Hansen 1997). A technical basis was established for the geology and natural phenomena hazards. These hazards were used as the basis for seismic and natural phenomena criteria for the design and construction of the CSB structures and systems, except the MHM.

In regard to hazard and accident analyses, the methodology used and the analyses performed and documented in HNF-SD-SNF-RPT-004, Revision 7B, are consistent with the analysis reviewed in Letter 97-SFD-227 (Hansen 1997). In particular, the letter noted that “the results from the previous PHA [preliminary hazard analysis] were grouped into six accident types and a representative accident for each group was determined to be bounding. This is still the case
for the new HA, but the types of accident phenomena have changed.” None of the identified representative accidents is a seismic DBA. The letter concluded that “based on its judgement, the review team feels the proposed accident methodology is adequate for this phase of construction.”

As such, Letter 97-SFD-227 did not require the application of hazard and accident analysis methodology for the determination of the seismic performance of SSCs. Rather, Letter 97-SFD-227 accepted that these were defined by seismic design criteria set during the early phased FSAR approach.

A3.3.3 Abnormal Events for the Canister Storage Building Facility

Abnormal events are operating conditions resulting from situations outside of normal operations, where normal operations are defined by process flow diagram, system design descriptions, and operation and maintenance procedures. These abnormal events encompass malfunctions of systems, operating upset conditions, or operator error. Abnormal events are expected to occur annually or several times during the lifetime of the facility. Abnormal events may impact operational or programmatic schedules; however, the consequences of the events are near zero or are standard industrial hazards that may include worker radiation exposure.

This section addresses the identification and analysis of abnormal events having the potential to occur at the CSB. Using the process described in Chapter 3.0 of the SNF Project FSAR, hazardous conditions and associated accident conditions and events meeting the abnormal event profile were identified from the hazard analysis (HNF-SD-SNF-HIE-001). The hazardous conditions having common failures or impacts on facility operations were grouped into bins. Appendix A3A.0 presents the abnormal event bins, and lists events in each bin. Two bins, having distinct initiators and operational consequences, were identified at the CSB: (1) MCO 'suspect' condition and (2) loss of ability to normally handle or store cask-MCO. Bin 2 has the following four parts: 2A, electrical/mechanical failure; 2B, structural; 2C, fire; and 2D, errors. For each of these event bins, the descriptive information includes the event, the cause of the event, the consequence of the event, the means of detection for the event, and corrective actions.

The following sections provide a description of the CSB abnormal event analysis.

A3.3.3.1 Multi-Canister Overpack "Suspect" Condition. Events in bin 1 have an impact on CSB operations because of the uncertainty of the MCO structure or integrity, the internal geometry of the SNF within the MCO, or the chemical or thermal status of the SNF in the MCO. During the normal course of operations, if an event has occurred that raises uncertainty about the MCO condition, then an abnormal event has occurred and will be addressed as described below. However, it should be noted that the postulated causes of events in this bin can be the same as the postulated causes of some CSB DBAs. Consequences from these events, therefore, are prevented and/or mitigated as required by DOE orders. These events were included in the abnormal event analysis because they could occur during normal operations and not result in, or propagate, accident conditions.
Postulated Causes of the Event. Events in bin 1 involve:

- A higher than expected pressure or temperature
- An impact to the MCO during handling within the CSB
- Mishandling or misloading the MCO.

Receipt of an out-of-specification MCO could result from improper processing or shipping preparations at the K Basins or CVDF, and/or chemical reactions within the MCO occurring at a rate greater than anticipated. An MCO having a high pressure on receipt raises uncertainty as to proper handling, sampling, and storage procedures at the CSB.

Both an impact to the MCO during handling and mishandling an MCO within the CSB raise uncertainties regarding the MCO's structure and integrity, or the internal geometry of the SNF within the MCO. These events lead to uncertainty as to proper handling, sampling, and storage procedures at the CSB.

Means of Detection. Events in bin 1 are detected by indications or measurements of out-of-specification pressures in the cask-MCO, and direct operator observation of an impact to the MCO or the mishandling of an MCO.

Consequences. Events in bin 1 could impact the facility or project schedules and could result in an increase of facility occupational exposure totals. Receiving an out-of-specification MCO would result in facility delays caused by investigations to determine the reasons for the out-of-specification situation and special handling requirements for handling the cask or the MCO. Similarly, impacts, mishandling, and misloading of the MCO would require an investigation to determine the MCO condition and special handling requirements, if any, for continued MCO handling and storage. Special handling requirements could result in increased radiological exposure totals for the facility. Individual workers would not exceed radiological protection and ALARA (as low as reasonably achievable) program limits.

Corrective Actions and Return to Normal Operations. Immediate operational responses to bring events in bin 1 to safe and stable states are described in standard operating procedures, alarm response procedures, or emergency response procedures. Operating personnel are routinely trained in the use of these procedures. Once the event has been stabilized, further diagnosis will be required. Facility management, or a recovery team, will lead the investigation and develop a recovery plan following procedures written for anticipated abnormal events. Procedures addressing anticipated abnormal events specify MCO handling requirements and actions to return the facility to normal operations. Specific equipment operations during recovery are expected to be the same as those contained in the standard operating procedures. If necessary, the recovery team can specify additional MCO handling requirements normally not contained in the standard operating procedures. The important actions to be addressed by procedures and the recovery team are shown in Appendix A3A.0, Table A3A-1.
A3.3.3.2 Loss of Ability to Normally Handle or Store Cask–Multi-Canister Overpack.

Events in bin 2 impact CSB operations because of the inability of the MCO or the cask–MCO handling equipment to perform their handling functions. Bin 2 has four parts: electrical/mechanical failure; structural; fire; and errors. Until the equipment or structure is repaired or returned to operating status, MCO handling is halted within the CSB.

Postulated Causes of the Event. Events in bin 2 involve the functional loss of various MCO handling equipment within the CSB. Causes can include the following:

- Loss of power
- Mechanical failures in the MHM, receiving crane, or other handling systems
- Failure of vehicles associated with MCO handling
- Fires in the CSB
- Severe natural phenomena affecting MCO transport to the CSB or the CSB operating environment that will affect handling operations (e.g., extremely high or low temperatures in the operating area)
- Leakage of water into the facility that will violate the CSB requirements for the control of criticality
- Operator errors that would impact the functionality of the MCO handling equipment.

Means of Detection. Events in bin 2 are detected by instrumentation indications and direct operator observation of a failure of handling equipment to function, visual indications and audible soundings from alarms (including fire alarms or the sound of failed equipment), or notification by CSB maintenance personnel or other Hanford Site or offsite entities.

Consequences. Events in bin 2 primarily result in (1) schedule delays for placing the MCO into storage, (2) the potential for increased occupational radiological exposures to workers, and (3) the potential for programmatic delays to the SNF Project. Failures in handling equipment can lead to facility delays caused by investigations to resolve the reasons for the equipment failures and to determine the special requirements for handling the cask or the MCO. Special handling may be required, which could increase radiological exposure. In the event of a fire, equipment and personnel could be impacted by smoke, heat, and chemical vapors.

Corrective Actions and Return to Normal Operations. Immediate operational responses to bring events in bin 2 to safe and stable states are described in standard operating procedures, alarm response procedures, or emergency response procedures. Operating personnel are routinely trained in the use of these procedures. Once the event has been stabilized, further diagnosis could be required. Facility management, or a recovery team, will develop a recovery
plan following procedures written for anticipated abnormal events. Procedures addressing anticipated abnormal events specify MCO handling requirements and actions to return the facility to normal operations. The failed or damaged equipment would be repaired and tested before return to operation. For several of these events, the facility would need to be cleaned before resumption of normal operations. Specific equipment operations during recovery are expected to be the same as those contained in the standard operating procedures. If necessary, the recovery team can specify additional MCO handling requirements not normally described in the standard operating procedures. The important actions to be addressed by procedures and the recovery team are shown in Appendix A3A.0, Table A3A-1.

A3.4 ACCIDENT ANALYSIS

This section presents the methodology used to develop the DBAs identified in Section A3.3 and the quantified consequences of those events. It also presents the safety-class and safety-significant SSCs and TSRs necessary to protect the offsite public and onsite workers. For each DBA, the following standard topics are discussed:

- Scenario development
- Source term analysis
- Consequence analysis
- Comparison to guidelines
- Summary of safety SSCs and TSRs.

The hazard and accident analyses focused on addressing operational radiological related hazards and design basis events.

- Mechanical damage of MCO (Section A3.4.2.1)
- Gaseous release from the MCO (Section A3.4.2.2)
- MCO internal hydrogen deflagration (Section A3.4.2.3)
- MCO external hydrogen deflagration (Section A3.4.2.4)
- Thermal runaway reactions inside the MCO (Section A3.4.2.5)
- Violation of design temperature criteria (Section A3.4.2.6)

The consequences associated with each of these bounding DBAs are summarized in Table A3-5.

A3.4.1 Methodology

This section identifies methods, assumptions, or methodology used to quantify the consequences of the DBAs. Methods, assumptions, or methodology used to quantify the consequences of DBAs that are common or generic to all the SNF Project facilities at the CVDF, or CSB are described in Chapter 3.0 of the SNF Project FSAR.

MCO = multi-canister overpack.

A3.4.1.1 Scenario Development. Accident scenarios are developed for the bounding events in each accident category (see Table A3-5).

A3.4.1.2 Source Term. The common SNF Project methodology and assumptions used in developing the source term are described in Chapter 3.0 of the SNF Project FSAR. In addition, the CSB accident analyses have used the following methodology for dealing with the uncertainty associated with the source term.

In calculating consequences in safety analysis, a number of phenomenological uncertainties are usually associated with the calculation factors. While it is not appropriate to ignore these uncertainties and use only best estimates, it also is not appropriate or meaningful to compound all the uncertainties and use an ultraconservative result that has no real practical meaning. The following approach has been developed to acknowledge the individual uncertainties in the calculation factors and to combine them into an overall uncertainty factor that can be applied to the best-estimate results to arrive at a bounding value at a predetermined confidence level.
Uncertainty (or error) factors and best estimates that are conservative but credible can be developed for many of the variables used in accident analyses. Multiplying each best estimate by an error factor yields a bounding value for that factor. If the uncertainties in all these factors are multiplied together, however, the result is unrealistically high because it is exceedingly unlikely that all these factors would simultaneously be at their most pessimistic bounding value. Therefore, a better approach is to calculate a source term using nominal (or median) values of the uncertain parameters and apply an appropriate uncertainty or error factor to the result. The method for combining uncertainty factors to arrive at an overall upper bound value is developed in the following paragraphs.

Assume a Lognormal Distribution for Each Variable. An upper bound value for a variable derived as the product of a number of other parameters can be determined using a simple sum-of-the-products-of-the-factors model. By using lognormal distributions, error factors for each of the individual variables can be combined into an overall error factor to obtain an upper bound value (e.g., 95th percentile).

The usefulness of the lognormal distribution comes from the central limit theorem, which states that the product of \( n \) independent random variables is a lognormally distributed random variable for large \( n \) (Apostolakis 1974). For example, the MAR is treated as the product of a number of processing parameters, such as fuel surface area, reaction rate, and processing time. It is therefore reasonable to describe the MAR as a variable with a lognormal distribution.

The ratio of the upper bound value to the median value (i.e., 50th percentile) is the error factor. The application of this type of bounding error factor is sufficiently conservative for determining the bounding consequences for an accident analysis as well as for comparing with the radiological evaluation guidelines and release limits.

Identify Nominal and Bounding Values and Assign a Percentile to the Bounding Value. For each identified parameter of the product used in the calculation, an estimate of the nominal or median value, \( X_{50\%} \) (i.e., the value with 50% chance of being exceeded) is determined. An estimate of the upper bounding value, say \( X_{95\%} \) (i.e., the value with 5% chance of being exceeded) also is identified. An error factor is calculated by dividing the bounding value by the nominal value of the parameter (i.e., \( EF = \frac{X_{95\%}}{X_{50\%}} \)).

Calculate the Standard Normal Variable for Each Percentile. A confidence level is assigned to the bounding value for each identified parameter. The standard normal variable corresponding to the 95% confidence interval is 1.645. It would be 1.0 for the 84% confidence level, 1.28 for the 90% confidence level, and 2.32 for the 99% confidence level.

Estimate the Overall Median. The overall nominal value is the product of the individual nominal values.
Estimate the Overall Error Factor. The overall error factor for the 95% confidence level is the natural antilogarithm of the product of 1.645 times the square root of the sum of the squares of the natural logarithm of the individual error factors.

Estimate the Ninety-Fifth Percentile Upper Bound. The 95% upper bound value is the product of the overall nominal value times the overall error factor.

The use of this method to estimate the bounding value is a reasonable approximation for estimating uncertainty. This method is rigorously correct when (1) the consequence is a product of independent factors, (2) the factor uncertainties can be approximated by the lognormal distribution, and (3) the uncertainties in these factors are uncorrelated.

In the following example, this method is applied to determining the amount of particulate suspended inside an MCO by the shock impact of an MCO drop. The estimated amount of suspended material depends on the airborne release fraction (ARF), respirable fraction (RF), MAR, and the leak path factor (LPF) for the MCO. Statistical descriptors for each of these quantities are estimated from the literature or from SNF Project documentation as appropriate.

If an MCO were dropped, the impact of the drop would shock and suspend some amount of particulate matter within the MCO. Unless the MCO were also breached, none of this material would be released. However, for a breached MCO, the gas from the blowdown of the MCO would carry some fraction of the suspended material outside the MCO. The amount of respirable particulate released can be estimated using the following equation:

\[ M_{\text{released}} = \text{ARF} \times \text{RF} \times \text{MAR} \times \text{LPF}_{\text{MCO}} \]

where

- \( M_{\text{released}} \) = mass of material released
- ARF = airborne release fraction
- RF = respirable fraction
- MAR = material at risk
- LPF_{MCO} = leak path factor for MCO.

The ARF is the fraction of the particulate powder inside the MCO (UO\(_2\) particulate) that is suspended by the drop. The RF is the fraction of the suspended powder that is respirable. DOE-HDBK-3010-94, *Airborne Release Fractions/Rates and Respirable Fractions/Rates for Nonreactor Nuclear Facilities* (Section 4.4.3.3, "Impact"), provides a measured median ARF of \( 4 \times 10^{-4} \) and RF of 0.2 from the impact of structural debris on powder. The recommended ARF is \( 1.0 \times 10^{-3} \), used in conjunction with an RF of 1.0, as the bounding value (assumed to be the 95th percentile). The resuspension of material in the MCO, either by drop impact, MCO handling, or internal or external hydrogen deflagrations, is assumed to use these bounding values.
The amount of material available for release depends on the amount of particulate mass generated in the MCO during processing. This quantity is a function of processing times and temperatures as well as of the condition of the fuel in the MCO (e.g., exposed surface area of fuel). HNF-SD-SNF-TI-015, *Spent Nuclear Fuel Project Technical Databook*, provides two estimates of this quantity: one for the safety basis, which is considered the bounding value, and the other for the design basis, which is considered the nominal value. When the MCO is received at the CSB, the safety basis value is 26.3 kg UO$_2$ (23.1 kg uranium) and the design value is 0.613 kg UO$_2$ (0.54 kg uranium) (HNF-SD-SNF-TI-015). After 40 years of storage at the CSB, the safety basis value is 34 kg UO$_2$ (30 kg uranium) and the design basis is 2.1 kg UO$_2$ (1.85 kg uranium) (HNF-SD-SNF-TI-015). The 40-year design basis value is used as the nominal value and the 40-year safety basis value is assumed to be the 99th percentile value.

The pressure in the MCO at the start of the blowdown determines the fraction of the suspended particulate that is released. The initial pressure varies from 1.50 atm (corresponding to the helium fill pressure of 22 lb/in$^2$ absolute at the CVDF) to a maximum pressure of 5.2 atm (as defined in the Technical Databook [HNF-SD-SNF-TI-015]). To allow for some additional margin in the calculation, a pressure of 2.0 atm is considered nominal (50th percentile) and corresponds to an LPF of 0.5, while a pressure of 6.0 atm is considered bounding (95th percentile) and corresponds to an LPF of 0.83.

Table A3-6 shows factors used in calculating the overall bounding value of material suspended, 1.2 g. If the individual bounding values for each of the factors were to be multiplied together, the product of the individual bounding values is 25 g. This is equivalent to an uncertainty or error factor of over 330 (equivalent to a confidence level of 99.97%) compared with the calculated uncertainty factor of 15.7 (for the 95th percentile). This methodology is applied to the calculation of the source term for each of the DBAs as appropriate.

A3.4.1.3 Consequence Analysis. Radiological inhalation dose consequences for each accident analyzed are based on the following factors:

- Mass of respirable airborne material released (M)
- Material at risk (MAR)
- Respirable fraction (RF)
- Airborne release fraction (ARF) or airborne release rate (ARR)
- Leak path factor (LPF)
- Atmospheric transport factor ($\chi/Q'$)
- Breathing rate (BR)
- Dose per unit mass of uranium (UD)
- Duration of exposure.

Some of these parameters are CSB-specific and are discussed below; others are based on common methods, assumptions, or methodology for the SNF Project and are fully described in Chapter 3.0 of the SNF Project FSAR.

Square root \left\{\text{sum of} \ln(EF)/\text{SNV}\right\} = 1.673

Overall EF(95%) = \exp(1.645 \times \text{square root} \left\{\text{sum of} \ln(EF)/\text{SNV}\right\}^2) = 15.7

Overall median = \text{product of the individual median values} = 7.4 \times 10^{-2} \text{ g}

Overall bounding (95%) = EF(95\%) \times \text{overall median} = 1.2 \text{ g}

Product of individual bounding values = 25 \text{ g}

Percentile of product of individual bounding values = 99.97

Note: The 1.645 is the standard normal variable corresponding to the 95% upper confidence limit. For the 99% upper confidence limit, the corresponding value is 2.326.

\*LPF_{MCO} = (\text{MCO pressure} - 1 \text{ atm}) / (\text{MCO pressure}). At a nominal MCO pressure of 2.0 \text{ atm}, the LPF_{MCO} is 0.5, and at a bounding MCO pressure of 6.0 \text{ atm}, the LPF_{MCO} is 0.83.

ARF = airborne release fraction.
EF = error factor (i.e., bounding value divided by nominal value).
ln(EF) = natural log of EF.
LPF = leak path factor.
MAR = material at risk.
MCO = multi-canister overpack.
RF = respirable fraction.
SNV = standard normal variable.

The mass of respirable airborne material released (M) is determined by the specific CSB accident scenario. The quantity (M) is a function of the MAR and the RF, and the LPF of any passive structural enclosure that may cause deposition of an airborne release before the release enters the atmosphere. The LPF is based on a time-integrated calculation of aerosol deposition within and release from an enclosure of given dimensions with specified leakage area, pressure, and temperature differentials. The specific value of each parameter is determined in the individual DBA analysis and based on the physical phenomena of the accident; thus they are specific to CSB.

The atmospheric transport factor (\chi/Q') is based on specific release conditions (e.g., ground level or elevated, long or short duration) and the receptor's distance from the release.
While the methodology is common to the SNF Project, the atmospheric transport factor is the
time-integrated normalized air concentration at the receptor's location, which is a measured
distance from the CSB. The transport factor includes the dilution of an airborne contaminant
caused by atmospheric mixing and turbulence. The air transport values used in this report have
been generated using GXQ, which is described in WHC-SD-GN-SWD-30002, GXQ Program
User's Guide. GXQ is a FORTRAN program for calculating atmospheric dispersion using site-
specific wind data. It uses the Gaussian straight line model for both instantaneous and continuous
releases. Several models are available that modify parameters within the Gaussian plume model to
account for phenomena such as plume depletion, building wake, plume meander, gravitational
settling, and plume rise. The building wake model from NRC Regulatory Guide 1.145,
Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear
Power Plants, was used to model CSB building effects. The treatment of site wind data is also
subject to user controls to allow various frequencies of exceedance to be computed. GXQ is
intended to be used by individuals who understand the limits and applicability of the models
implemented. According to WHC-SD-GN-SWD-30003, GXQ Program Verification and
Validation, the program has been tested and verified to implement its calculational models
correctly. Table A3-7 contains the atmospheric transport values used to determine onsite and
offsite consequences.

a Units for these values are seconds per cubic meter. In all cases the releases are assumed to be point sources at ground level to maximize the dose consequences.
b No adjustment for plume meander (HNF-SD-SNF-TI-059, 1998, A Discussion on the
Methodology for Calculating Radiological and Toxicological Consequences for the Spent Nuclear
Fuel Project at the Hanford Site, Rev. 1, Fluor Daniel Hanford, Incorporated, Richland,
Washington.).

Atmospheric transport factors were calculated using methods found in NRC Regulatory
Guide 1.145. In each wind direction the observed frequencies of particular wind speed and
stability class combinations were used to compute $\chi/Q$. For the accident analysis, the higher of
either the 99.5% sector-dependent or the 95% overall value was used. This was repeated for all
16 compass directions to determine the worst-case location.

Exposures to the collocated worker onsite are calculated for the individual at the 100-m
location. The risk evaluation guidelines apply to this individual. For assessment purposes, DOE
has directed (Sellers 1996) that the Hanford Site boundary be considered the location of the
offsite receptor. Consequences for a receptor located on Highway 240 are included for
information only.

None of the accidents analyzed in this document adjusts the air transport factors for the
elevation of the release above ground level (the stack is not high enough relative to the operation
building to justify using elevated release). It is always conservative to ignore stack effects
because the stack effect serves to disperse the release such that the collocated worker and the
offsite receptor will receive a lower estimated dose if the effect is included. As an additional
conservatism, all accidents were evaluated using the air transport factors calculated for less than
1 hour (HNF-SD-SNF-TI-059). Section 1.4.1.2.8 of the SNF Project FSAR provides additional
information on the calculation of the air transport factors.

The breathing rate (BR) depends on individual activity factors and exposure duration. This
methodology is common to the SNF Project facilities and is described in Chapter 3.0 of the SNF
Project FSAR.

The dose per unit mass of uranium (UD) is the 50-year dose commitment for all relevant
exposure pathways per gram of uranium released (HNF-SD-SNF-TI-059). The major radiation
exposure pathway for the identified accidents is inhalation of radioactive material. This
methodology is common to the SNF Project facilities and is described in Chapter 3.0 of the SNF
Project FSAR.

A3.4.1.4 Comparison to Guidelines. The DOE-recommended radiological release limits and
risk evaluation guidelines (Sellers 1997) are applied across the SNF Project and are described in
Chapter 3.0 of the SNF Project FSAR. The guidelines are consequence (see Section A3.4.1.3)
and frequency based. The determination of frequency is based on methodology common to the
SNF Project facilities and is described in Chapter 3.0 of the SNF Project FSAR. SNF-4042
documents the accident frequencies and bases for determining accident frequencies for the CSB
DBAs.

A3.4.1.5 Safety Structures, Systems, and Components. "Safety class" and "safety
significant," as related to the SSCs, are defined consistently for the SNF Project in Chapter 3.0 of
the SNF Project FSAR.

For each accident scenario, the airborne radiological dose calculated using the methods
described here and in Chapter 3.0 of the SNF Project FSAR is compared with the appropriate
onsite evaluation guidelines and offsite limits from Letter 97-SFD-172 (Sellers 1997). If the
radiological dose for the unmitigated case exceeds the guideline, mitigative or preventive safety
features, with appropriate safety-class and/or safety-significant functional classifications, are identified. The dose consequences are recalculated taking appropriate credit for the mitigating safety features to verify that the mitigated doses satisfy the guidelines. If there is a potential for a loss of nuclear criticality control, the engineered features designed to prevent a nuclear criticality are designated safety-class SSCs.

Where appropriate, based on the accident scenario and the safety features or functions required to prevent the occurrence of an accident, specific interlocks have been identified and assigned safety designations. These interlocks have been identified based on safety function or feature required and the specific interlock functions identified in Table A2-4.

Tables associated with each accident scenario provide the safety SSCs for the evaluated accidents and other defense-in-depth features. The tables may be used in cost–benefit analyses to evaluate any future improvements in any of these features or safety systems in order to improve operations, maintenance, or design by using the tables’ general arrangement of most important systems and features to least important.

A3.4.2 Design Basis Accident Analysis

This section presents a summary of the key assumptions and results of the DBA analyses that have been performed for the CSB. The DBAs are summarized based on the guidelines provided in DOE-STD-3009-94 and include the following categories:

- Mechanical damage of MCO (Section A3.4.2.1)
- Gaseous release from the MCO (Section A3.4.2.2)
- MCO internal hydrogen deflagration (Section A3.4.2.3)
- MCO external hydrogen deflagration (Section A3.4.2.4)
- Thermal runaway reactions inside the MCO (Section A3.4.2.5)
- Violations of design temperature criteria (Section A3.4.2.6).

The DBAs have been analyzed to quantify consequences and compare them with release limits for offsite consequences and evaluation guidelines for onsite consequences. The process is iterative, starting by taking no credit for mitigative features and comparing the results to the limits or guidelines. Credit is then taken for safety SSCs that prevent or mitigate the consequences to show that the results are below the release limits and evaluation guidelines. The process continues after the release limits and evaluation guidelines are met by identifying other SSCs that, while not designated as safety class or safety significant, provide additional mitigative features as defense in depth. In addition, each individual DBA section references a supporting calculational note that provides more detail.
All analyses have been performed based on the following MCO initial conditions defined in HNF-SD-SNF-TI-015:

1. Maximum particulate mass of aluminum hydroxide less than or equal to 9.47 kg in an MCO with bounding total particulate delivered to the CSB

   The bounding value is based on statistical analysis of good quality film thickness data at a 99% confidence level. To obtain this confidence level, a thickness of 1.8 times the actual mean of the measurements was used. This value was multiplied by the total assumed surface area and the theoretical density of aluminum hydroxide to obtain the bounding value. Additional information is documented in HNF-1527, *Estimates of Particulate Mass in Multi-Canister Overpacks*.

2. Maximum mass of uranium oxide hydrates less than or equal to 10.8 kg in an MCO delivered to the CSB

   Over 90% of this value is from sources that are quantified by analysis. The bounding values for these sources are based on fuel characterization data combined with very conservative assumptions of the amount of damaged fuel in the MCO and on literature data on hydrate decomposition. Less than 10% of the value is from canister particulate. To obtain this value, credit is taken for fuel cleaning, which must be validated by examination of a test batch of cleaned fuel assemblies and confirmed by periodic examination of assemblies during the process. Additional information on the quantity of hydrates in a bounding MCO is provided in HNF-1527 and in HNF-1523, *K Basin Particulate Water Content, Behavior, and Impact* (Rev. 1).

3. Maximum of two scrap baskets in an MCO delivered to the CSB

   This condition is controlled by TSR commitments in HNF-SD-WM-SAR-062, *K Basins Final Safety Analysis Report*. The safety of two scrap baskets has been demonstrated relative to all credible accident scenarios.

4. Maximum (not strongly adherent) UO₂ particulate less than or equal to 34 kg in an MCO after 40 years of storage at the CSB

   This is particulate that is generated after fuel cleaning. The requirement is met by bounding analysis that relies on TSR commitments in HNF-SD-WM-SAR-062 that limit the amount of scrap and damaged fuel in an MCO. This value is based on very conservative assumptions for both oxidation rates and elapsed time at various process steps. Additional information regarding the values for these process steps is documented in HNF-1527.
5. Maximum free water less than 200 g in an MCO delivered to the CSB

This value is based on processing steps at the conclusion of cold vacuum drying with time, pressure, and temperature conditions that ensure sufficient water evaporation and removal even with very conservative assumptions of fuel cracking and trapped particulate. Analysis confirming the feasibility of limiting free water and the associated processing requirements at the CVDF is provided in HNF-1851, *Cold Vacuum Drying Residual Free Water Test Description* (Rev. 2). This analysis is supported by whole-element characterization data and bounds the free water present in the MCO.

6. Leak rate of internal gas from MCO less than $10^{-5}$ standard cm$^3$/s

Before the MCO is shipped from the CVDF to the CSB, the MCO’s mechanical closure seal will have been demonstrated to meet a $10^{-5}$ standard cm$^3$/s total integrated leak test acceptance criterion as defined by ANSI N14.5-1987, *American National Standard for Radioactive Materials — Leakage Tests on Packages for Shipment*. The total integrated leakage criterion will be satisfied by a summation of test results for individual seals.

7. Maximum mass of uranium hydride (for heat and hydrogen generation) equal to 5.13 kg in an MCO delivered to the CSB and 9.08 kg after 40 years of storage at the CSB

Two methods were used to estimate bounding and nominal hydride inventories. The first method assumed particulate generated by in-basin corrosion is partially composed of uranium hydride, as found in literature experiments. The second method assumed an element contains uranium hydride equivalent to observations reported in single-element drying tests. Similar estimates were obtained from both methods, but the estimate based on element drying data was used to develop the bounding estimate of uranium hydride inventory. Additional information is provided in HNF-3372, *Uranium Hydride in Multi-Canister Overpacks*.

8. Maximum of 6,339 kg of uranium per MCO (based on five Mark IV fuel baskets)

The value is determined by the design of the MCO, which has room for five Mark IV fuel baskets. Each Mark IV fuel basket has positions for 54 fuel assemblies, and the maximum uranium mass in a Mark IV fuel assembly is 23.48 kg. The uranium mass in various fuel assemblies and the possible loading combinations are described in HNF-SD-SNF-TI-009, *105-K Basin Material Design Basis Feed Description for Spent Nuclear Fuel Project Facilities*.
Minimum inert gas pressure of 1.5 atm at 25 °C in an MCO delivered to the CSB.

Before the MCO is shipped from the CVDF to the CSB, it will have been chilled in accordance with SNF-2356, Spent Nuclear Fuel Project Cold Vacuum Drying Facility Operations Manual, and backfilled with helium to between 1.65 atm and 1.85 atm absolute.

Combustible loading controls are required to be in place to preserve the combustible loadings assumed in the fire hazard analysis (HNF-SD-SNF-FHA-002). The fire hazard analysis was prepared in accordance with DOE Order 5480.7A, Fire Protection, and HNF-PRO-350, Fire Hazard Analysis Requirements. The analysis evaluated potential fire risks at the CSB to determine whether any undue hazards required mitigation to protect workers, property, the public, or the environment. The conclusion of the analysis is that the fire risks present in the facility are being mitigated through engineering design and administration of control of fuel packages (HNF-SD-SNF-FHA-002). This conclusion is consistent with the results of the accident hazard analysis prepared for this chapter (HNF-SD-SNF-HIE-001). Consequently, the accident analysis in this chapter has only evaluated the potential for the DBAs associated with deflagrations caused by hydrogen generation resulting from radiolysis and fuel corrosion. The fire hazard analysis (HNF-SD-SNF-FHA-002) and its implementation plan define the facility requirements related to combustible loadings and necessitate TSR controls.

A3.4.2.1 Mechanical Damage of Multi-Canister Overpack. An MCO or the cask-MCO combination subjected to an accidental drop, impact, or shear force of sufficient magnitude could be damaged such that the MCO is breached or its internal geometry is substantially compromised. Several potential accidents at the CSB that could damage the MCO with mechanical forces are identified in HNF-SD-SNF-HIE-001 and are evaluated in SNF-3328. Three classifications of accidents have been selected for further evaluation: drop of the MCO or cask-MCO, shear of the MCO by the MHM, and impacts to the MCO other than drops and shears.

Drop of a Multi-Canister Overpack. An MCO or the cask-MCO combination subjected to an accidental drop of potentially sufficient magnitude could be damaged such that the MCO is breached or its internal geometry is substantially compromised. A number of potential drop accidents at the CSB have been identified for further discussion or evaluation. These accidents are listed in Section A3.4.2.1.1. Required controls for each accident are summarized in Section A3.4.2.1.5.

Drops that could lead to a ‘stuck’ MCO (with no loss of confinement or geometry) are all category 4 events as defined in NUREG-0612, Control of Heavy Loads at Nuclear Power Plants, Resolution of Generic Technical Activity A-36, and are therefore properly classified as accidents. The CSB has been designed to allow ready retrieval of SNF during normal and off-normal operation. Therefore, the CSB complies with the retrievability requirement for normal and off-normal conditions.
Having many different drop scenarios with different expected frequencies and consequences makes it difficult to plan detailed recovery actions for every eventuality. Therefore, a general recovery plan that maps out general approaches and thought processes will be used as guidance to develop a detailed, accident-specific recovery plan in the unlikely event an MCO is dropped.

Shear of a Multi-Canister Overpack. An MCO or the cask-MCO combination subjected to a shear force of sufficient magnitude could be damaged such that the MCO is breached or its internal geometry is substantially compromised. Several potential shear accidents at the CSB that could damage the MCO have been identified for further discussion or evaluation. These accidents are listed in Section A3.4.2.1.1.

Impacts to a Multi-Canister Overpack Other than Shears and Drops. An MCO or the cask-MCO combination subjected to a force of sufficient magnitude could be damaged such that the MCO is breached or its internal geometry is substantially compromised. Several accidents at the CSB that could potentially damage the MCO with mechanical forces have been identified. These accidents are listed in Section A3.4.2.1.1.

A3.4.2.1.1 Scenario Development.

Drop of a Multi-Canister Overpack. At the CSB the MCO is moved by both the receiving crane and the MHM. The MCO could be dropped, either when it is inside the transportation cask or when it is outside the cask. Several different scenarios that could cause an MCO drop have been considered. All of these drop scenarios are considered potentially serious hazards to the MCO in the CSB hazard analysis (HNF-SD-SNF-HIE-001):

D1 Cask-MCO drop from receiving crane onto receiving area
D2 Cask-MCO drop from receiving crane into cask receiving pit
D3 Cask-MCO drop from receiving crane into Fast Flux Test Facility (FFTF) pit or MHM maintenance pit
D4 Drop of MCO by MHM onto edge of cask receiving pit
D5 Drop of MCO by MHM back into cask
D6 Drop of MCO within MHM turret onto MHM turret deck
D7 Drop of MCO from MHM onto CSB operating area floor or onto storage tube covers of vault 2 or vault 3 in CSB
D8 Drop of MCO from MHM onto or into MHM maintenance pit or tube plug exchange facility
D9 Drop of MCO from MHM onto or into FFTF pit
D10 Drop of MCO by MHM into storage tube or sampling/weld station
D11 Drop of MCO by MHM onto another MCO located in the bottom of a storage tube
(no intermediate impact absorber involved)
D12 Drop of MCO by MHM onto storage tube plug because of inadvertent turret rotation
D13 Drop of MCO by MHM onto edge of storage tube
D14 Drop of MCO by MHM onto edge of sampling/weld station.

D1 — Cask-Multi-Canister Overpack Drop from Receiving Crane onto Receiving Area. The receiving crane is used to lift the cask-MCO from the transport trailer using a yoke. The crane is then translated to place the cask-MCO above the cask receiving pit, and the cask-MCO is lowered into the pit. The cask-MCO could be dropped from the receiving crane at any location through which the crane travels with the suspended cask-MCO. The CSB receiving crane has been designated a safety-significant and important-to-safety piece of equipment. The crane is not single-failure-proof but is rated for twice the load required for a safety-significant hoist.

Cask-MCO drops from the receiving crane could occur because of a failure in the lift system (e.g., the hook, hoist rope, cask yoke) or as a result of improper connection of the load to the hoist. Because the crane is designed to select criteria of ASME NOG-1, Type I, the crane load remains suspended during and after a design basis earthquake (DBE) event. The following five scenarios involving 60-in. drops from the receiving crane have been analyzed in WMTS-RPT-037, Canister Storage Building Multi-Canister Overpack Cask and Multi-Canister Overpack Impact Analyses.

1. **Cask-MCO Slapdown Drop onto the Concrete Deck.** In this case, two drop orientations of the cask-MCO are evaluated: a center-of-gravity over corner orientation and a shallow angle (15°) orientation. In both orientations, the cask-MCO is assumed to be suspended initially from the crane with the impacting corner of the cask-MCO 60 in. from the floor. The rigging then fails in a manner such that the cask-MCO is subjected to an oblique drop and slapdown onto the concrete deck of the CSB. For both orientations, the primary impacts are simulated as corner drops and the slapdowns are simulated separately as flat horizontal drops from heights that account for the additional rotational velocity of the cask center of gravity at impact.

2. **Cask-MCO End (Vertical) Drop onto the Concrete Deck.** In this case, the cask-MCO is assumed to be suspended initially from the crane with the bottom of
the cask-MCO 60 in. from the floor. The rigging then fails in a manner such that the
cask-MCO is subjected to a flat bottom-end drop onto the concrete deck and does
not tip over.

3. Cask-MCO Drop onto Edge of Cask Receiving Pit with Slapdown. This case is the
same as case 1 except the initial oblique drop is on the edge of the cask receiving pit
with slapdown (both shallow angle and center-of-gravity over corner orientations).
This slapdown is simulated by a horizontal side drop from an increased height that
accounts for the rotational velocity of the center of gravity of the cask.

4. Cask-MCO Drop Spanning Cask Receiving Pit. In this case, the cask-MCO is
assumed to drop from a height of 60 in. onto the cask receiving pit. The drop is
assumed to be a horizontal side drop with the center of gravity of the cask over the
geometric center of the pit.

5. Shallow Angle Cask-MCO Drop into the Cask Receiving Pit with Cask Impacting
on Opposite Edge of Vault Pit. In this case, the cask-MCO is assumed to drop into
the pit at a shallow angle off the horizontal (approximately 15°). Initially the
cask-MCO is assumed to be suspended from the crane with the impacting corner of
the cask-MCO 60 in. from the floor. The rigging then fails in a manner such that the
cask-MCO is subjected to a shallow angle drop into the pit and subsequent
slapdown onto the concrete deck near the edge of the vault pit. The primary impact
is simulated as a shallow angle drop impacting the opposite edges of the pit and the
slapdown is simulated separately as flat horizontal drops from heights that account
for the rotational velocity of the cask center of gravity at impact. The slapdown
sequence is that the cask initially impacts on its bottom corner in the pit and the top
end closure slaps down on the vault pit edge.

Using NRC and commercially accepted practices, the cask in these cases is considered to
be a rigid body impacting a yielding surface. The concrete and soil are considered real surfaces
that absorb the energy of impact. This is predicated on the shipping cask being much harder and
stiffer than a concrete surface. Consequently, the concrete and underlying soil act to decelerate
the cask.

Numerical simulations using the ABAQUS/Explicit computer program were used to
develop the average inertial load factors and inertial load factor time histories for the various
scenarios involving cask-MCO drops onto concrete surfaces at the CSB. Since the cask has a
natural frequency in excess of 33 Hz, the cask was modeled as a rigid body in the numerical
impact simulations. The impacted CSB concrete surfaces and soil subgrades were modeled as
real targets. The slope of the velocity time history profiles was used to determine the average
inertial load factors.

Quasi-static methods were used for structural evaluation of the cask-MCO closure. This
quasi-static method is based on D’Alembert’s principle of substituting an equivalent static force
for the inertial force created by impact. These inertial forces represented in the calculation as
equivalent static loads were determined by multiplying the weight of the cask by the average
inertial load factor of the cask. In addition, this average inertial load factor was multiplied by the
maximum dynamic load factor to account for the dynamic response of the cask.

Given the robustness of the cask and cask closure lid, the most vulnerable components of
the cask relative to loss of confinement during and after a free drop impact are the closure lid
bolts. The bolts were evaluated by classical linear elastic methods by the evaluation approach
specified in NUREG/CR-6007, Stress Analysis of Closure Bolts for Shipping Casks.
For conservatism, the closure system was considered a protected lid with the weight of the
closure lid applying a shear load to the bolts at the threads.

The loading evaluation for these cases (WMTS-RPT-037) shows that stresses in the bolts
are below the allowable limits specified in NUREG/CR-6007 for accident conditions. This is
demonstrated by the positive margins of safety based on the allowable stress intensity limits in all
cases. Results show that margins of safety on the reduced shank of the bolt are positive and the
margins of safety of the shear ring are large. During a flat bottom end drop, the only loading on
the closure lid bolts is the fixed edge moments and forces applied by the closure lid inertia. This
result in an average tensile load on the bolt that, when compared with the allowable stress
intensity limits, results in a margin of safety of 7.38. Initial oblique bottom impact loads on the
bolts were treated as axial and radial vector components of the impact force. In these cases, the
inertial load factors were relatively low compared with the horizontal side drop and bottom end
drop. As a result, the margins of safety on the closure bolts are large. Consequently, as
demonstrated by the positive margins of safety, the cask closure lid bolts, reduced bolt shank, and
shear ring remain elastic and maintain confinement in the various scenarios involving a drop of the
cask-MCO onto the CSB floor and floor structures.

To be conservative, a breach of the MCO as well as a breach of the cask following this
drop is assumed. Unmitigated, this event has been determined to be in the unlikely category
(SNF-4042). The gas leaving the MCO contains considerable hydrogen so a flammable mixture
of hydrogen, helium, and air forms in the space between the outside of the MCO and the inside of
the cask. This flammable mixture ignites, but the resulting pressure increase is not expected to
damage the cask (see Section A3.4.2.4).

D2 — Cask-Multi-Canister Overpack Drop from Receiving Crane into Cask
Receiving Pit. The cask receiving pit is fitted with an impact absorber designed to control the
dynamics of dropping an MCO cask containing an MCO into an empty cask (i.e., to limit the
deceleration). The impact absorber mitigates the damage to the MCO following the drop
accident. The impact absorber is required to limit the deceleration of a maximum weight MCO
dropped from the maximum height to less than 35 g. The MCO and internal baskets are designed
to maintain confinement under drops with decelerations limited below 35 g. The impact absorber
for the cask receiving pit is designed for a drop height of 281 in. The maximum height of the cask
receiving pit impact absorber is 45 in. The impact absorber design was developed through a
combination of both calculations and static and dynamic tests.
To be conservative, a breach of the MCO as well as a breach of the cask following this
drop is assumed. Unmitigated, this event has been determined to be in the unlikely category
(SNF-4042). Full-scale prototypic tests of the impact absorber were performed and are
documented in TR-003, Test Report for the CSB Prototypic Impact Absorbers. The tests used
video records to demonstrate acceptable deceleration. While a direct crush measurement of the
impact absorber indicated a deceleration load that was higher than expected and higher than the
design criteria, this was attributed to energy transferred to the ground upon impact.

HNF-SD-SNF-DR-003, Multi-Canister Overpack Design Report, demonstrates that the
MCO will meet design criteria. The design calculation shows that the Mark IA MCO’s internals
can withstand the design basis conditions of a 35 g vertical drop or a 101 g horizontal drop. The
MCO cask containing an MCO will not be damaged following a drop into the cask receiving pit.

D3 — Cask—Multi-Canister Overpack Drop from Receiving Crane into Fast Flux
Test Facility Pit or Multi-Canister Overpack Handling Machine Maintenance Pit. When
the receiving crane is moving the cask—MCO from the transport trailer to the cask receiving pit,
the cask—MCO is not to be moved over the FFTF or maintenance pits. The receiving crane
resolver tracks the east–west position of the receiving crane. Before the receiving crane reaches
the west side of the FFTF pit, the interlock removes power from the drive motors. Power may
only be restored to the crane by both the use of a supervisor-controlled fortress key at a remote
station and the operator depressing an override button on the crane. While this interlock does not
reduce the drop frequency, it does reduce the frequency of drops into the FFTF or maintenance
pits.

However, given certain errors, the cask—MCO could mistakenly be moved over the FFTF
or maintenance pits where it would be vulnerable to a potential drop into the pit. The
consequences of a cask—MCO drop by the receiving crane (from a height greater than 60 in.) into
the FFTF or maintenance pit with a slapdown have not been determined. While definitive
supporting calculations do not exist, no radiological releases or associated onsite or offsite dose
consequences are expected from such an accident because of the structural protection provided by
the cask. A breach of the MCO as well as a breach of the cask following this drop is assumed.
Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).
Radiological releases are presented in Section A3.4.2.1.3. The gas leaving the MCO contains
considerable hydrogen so a flammable mixture of hydrogen, helium, and air forms in the space
between the outside of the MCO and the inside of the cask. This flammable mixture ignites, but
the resulting pressure increase is not expected to damage the cask (see Section A3.4.2.4).

D4 — Drop of a Multi-Canister Overpack by the Multi-Canister Overpack Handling
Machine onto Edge of the Cask Receiving Pit. If the MHM were to drop an MCO, the MCO
would impact the slope of the shield hatch and MCO guide assembly because of the shield hatch
and MCO guide assembly design and the centering guide installed in the MHM. The shield hatch
has a 75° incline, which would greatly reduce the impact force. The centering guide would limit
MCO tilt, which would ensure the impact area was always on the shield hatch incline.
An engineering analysis using the ABAQUS/Explicit computer code has been performed to address dropping an MCO onto the edge of the cask receiving pit (eccentric drop); the analysis is documented in SNF-5204, *Analysis for Eccentric Multi-Canister Overpack Drops at the Canister Storage Building (CSB-S-0073)*. This analysis predicted accelerations, plastic strain, and stress distributions, and identifies failure modes. The structural numerical models addressed nonlinear material behavior as well as impact dynamics. The weight of the MCO used in the analysis was 20,000 lb, and the drop height was conservatively assumed to be 90 in. The maximum equivalent MCO strain was found to be 18% and occurred on the MCO bottom near the point of impact. Since the failure strain is above 80%, it is not likely that through-the-wall cracking would occur although removal of local surface metal may occur. The maximum predicted equivalent plastic strain at the MCO lower weld was 0.4% during a drop into the standard storage tube. This is well below a 13% failure strain. The maximum tensile principal strain was in a radial direction, so any failure would be by spalling or flaking rather than through-the-wall cracking.

The deceleration of the MCO baskets was shown to be about 20 g or less, well within the design allowable of 35 g.

To be conservative, a breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).

**D5 — Drop of Multi-Canister Overpack by the Multi-Canister Overpack Handling Machine Back into Cask.** An engineering analysis has been performed to address dropping an MCO back into the cask; the analysis is documented in SNF-5276, *Analysis for SNF MCO Drop into the Cask from the MHM with Air Cushion*. The MCO was assumed to drop from a height of 8.2 ft above the cask, enter the cask concentrically, and fall the additional 12.83 ft to the cask bottom. The MCO's fall would be slowed by air entrapment and the interface fit between the MCO and the cask. The shipping cask was assumed to be resting on the cask receiving impact absorber at the time of impact, and the energy absorbing properties of the cask receiving pit impact absorber were included in the analysis.

The engineering analysis (SNF-5276) showed that an MCO drop into the cask produces very large impact reactions on the MCO and its internals. Plastic strains were shown to occur in the bottom of the MCO, the sides of the MCO near the weld area, the basket support plates, the outside basket support posts, and the basket center support post. Large amounts of energy were absorbed during the impact by these components.

The maximum equivalent plastic strain in the bottom of the MCO was 2.0%. This is below the calculated effective failure strain of 15%. The effective failure strain value was calculated based on the multi-axial stress state (triaxiality factor), temperature, and strain rate. Breaching of the MCO pressure boundary by through-wall cracking is not expected.

Equivalent plastic strains in the weld area at the juncture of the MCO walls and the MCO bottom were 2.1%. This is below the calculated 12.5% effective failure strain. The maximum equivalent plastic strain occurred at the inside surface of the MCO in the weld area. Breaching of the MCO pressure boundary by through-wall cracking in the weld area is also not expected.
To be conservative, a breach of the MCO following this drop is assumed. Unmitigated this event has been determined to be in the unlikely category (SNF-4042).

**D6 — Drop of Multi-Canister Overpack within Multi-Canister Overpack Handling Machine Turret onto Multi-Canister Handling Machine Turret Deck.** When the MHM is traveling in the operating area with an MCO fully raised into the MCO cavity of the MHM turret, the MCO is vulnerable to a potential drop onto the MHM turret deck while partially rotated over the opening. Engineering analysis has been performed to evaluate an MCO drop onto the MHM turret deck (WMTS-RPT-037). As a worst case, it was assumed that the MCO dropped at a shallow angle of 1° off the vertical axis and onto a squared edge of the MHM turret base opening. The drop was assumed to result in an edge impact approximately one-eighth the diameter in from the edge of the MCO.

The results show that the most vulnerable areas of the MCO are not breached and the MCO maintains confinement even at a metal temperature of 270 °F. The maximum equivalent strain (which is a true strain) is 15.5% at the impact point on the MCO bottom plate outside surface. The maximum equivalent strain at the inside surface on the bottom-end-plate-to-shell weld joint is 3.72%. Based on the CSB Expert Panel criteria adjusted for true strain (SNF-5276), the failure strain value at 270 °F is 6.7%. The margin of safety at the impact point for the base metal is 2.1, and in the weld area, the margin of safety is 0.8 (SNF-5276). The margin of safety used is calculated as follows:

\[(\text{allowable value} / \text{calculated value}) - 1\]

The allowable values for the MCO are ASME Boiler and Pressure Vessel Code, Section III, class 1 allowables for Service Level D (ASME 1995).

The maximum strain energy density at the impact point on the MCO bottom plate outside surface is 7,317 in-lbf/in³, and the maximum strain energy density at the inside surface on the bottom-end-plate-to-shell weld joint is 1,258 in-lbf/in³. For Type 304L stainless steel at 270 °F, the minimum yield strength is 19.6 ksi, and the minimum ultimate strength is 62.5 ksi at 40% strain, equating to a minimum rupture toughness of 16,420 in-lbf/in³. Based on the material toughness criteria, the maximum allowable strain energy density of the base metal is 8,210 in-lbf/in³. The maximum allowable strain energy density in the weld region is 4,105 in-lbf/in³. The margin of safety of strain energy density is 0.12 at the impact point and 2.3 in the weld region.

The maximum equivalent plastic strain and strain energy density data show that at the contact locations, the outer surface of the bottom end closure of the MCO is dented. However, the data also show that this damage is only on the surface and does not extend into the inside surface of the bottom end closure plate. The maximum equivalent plastic strain at the weld joint between the MCO shell and bottom end closure plate is very low and well below the established limits for the material. In the weld joint region, the maximum equivalent plastic strain and strain energy density are on the inside surface of the confinement boundary.
To be conservative, a breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).

D7 — Drop of Multi-Canister Overpack from Multi-Canister Overpack Handling Machine onto Canister Storage Building Operating Area Floor or onto Storage Tube Covers of Vault 2 or Vault 3 in Canister Storage Building. If errors are made in failing to replace the storage tube plug (or cover plug or center plate) when the MHM has finished raising an MCO into the MCO cavity in the MHM turret, and the MHM is inadvertently moved a short distance over the operating floor, the MCO is vulnerable to a potential drop onto the operating area floor from the fully raised position in the MCO cavity in the MHM turret when no credit is taken for the MHM interlocks. Anytime an MHM is carrying an MCO in the MCO cavity in the MHM turret and stops anywhere on the operating area, the MCO is vulnerable to a potential drop onto the operating area floor from the fully raised position in the MCO cavity in the MHM turret when the MHM is rotated to the MCO cavity of the MHM turret position, providing no credit is taken for the MHM interlocks. Whenever an MHM is carrying an MCO in the MCO cavity in the MHM turret and stops over vaults 2 or 3, the MCO is vulnerable to a potential drop onto the vault covers from the fully raised position in the MCO cavity in the MHM turret when the MHM is rotated to the MCO cavity in the MHM turret position, providing no credit is taken for the MHM interlocks. A breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the extremely unlikely category (SNF-4042).

D8 — Drop of Multi-Canister Overpack from Multi-Canister Overpack Handling Machine onto or into Multi-Canister Overpack Handling Machine Maintenance Pit or Tube Plug Exchange Facility. When the MHM is moving an MCO in the operating area, the MHM is not to be moved over the MHM maintenance pit. However, given certain errors, the MHM containing an MCO could mistakenly be moved over the MHM maintenance pit or tube plug exchange facility, where the MCO would be vulnerable to a potential drop into the pit providing no credit is taken for the MHM interlocks. A breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the extremely unlikely category (SNF-4042).

D9 — Drop of Multi-Canister Overpack from Multi-Canister Overpack Handling Machine onto or into Fast Flux Test Facility Pit. When the MHM is moving an MCO in the operating area, the MHM is not to be moved over the FFTF pit. However, given certain errors, the MHM containing an MCO could mistakenly be moved over the FFTF pit providing no credit is taken for the MHM interlocks. A breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the extremely unlikely category (SNF-4042).

D10 — Drop of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine into Storage Tube or Sampling/Weld Station. Each storage tube bottom is fitted with a bottom impact absorber of stainless steel tubes that has been designed to control the dynamics of dropping a single MCO into an empty storage tube. The bottom impact absorber will mitigate damage to an MCO following such a drop. These bottom impact absorbers are required...
to limit the deceleration of a maximum weight MCO dropped from the maximum height to less than 35 g. The MCO and its internal baskets are designed to maintain confinement under drops with decelerations limited below 35 g as specified in HNF-S-0426, *Performance Specification for Spent Nuclear Fuel Project, Multi-Canister Overpack*. Therefore, the MCO will not be damaged following a drop into the storage tube. The adequacy of the bottom impact absorber has been demonstrated by a full-scale test. To be conservative, a breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).

An intermediate impact absorber is placed between two MCOs stacked in a storage tube. The intermediate impact absorber is designed to mitigate damage to both MCOs if the top MCO is accidentally dropped during storage tube loading. These intermediate impact absorbers are required to limit the deceleration of an MCO dropped on top of another MCO to less than 35 g. The MCOs will not be damaged following a drop on top of another MCO in the storage tube. The adequacy of the intermediate impact absorber has been demonstrated by a full-scale test.

Each sampling/weld station pit is fitted with an impact absorber of stainless steel tubes that has been designed to control the dynamics of dropping an MCO into the sampling/weld station rotating shield. The sampling/weld station impact absorber will mitigate damage to the MCO after such a drop. These impact absorbers are required to limit the deceleration of a maximum weight MCO dropped from the maximum height to less than 35 g. The MCO and its internal baskets are designed to maintain confinement under drops with decelerations limited below 35 g (HNF-S-0426). Therefore, the MCO will not be damaged following a drop into the sampling/weld station rotating shield. The design adequacy of the impact absorber has been demonstrated by a full-scale drop test.

**D11 — Drop of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine onto Another Multi-Canister Overpack Located in the Bottom of a Storage Tube (No Intermediate Impact Absorber Involved).** When the MHM is placing an MCO into a storage tube that contains one MCO but which has no intermediate impact absorber, each MCO would be vulnerable to a potential drop of the MCO hanging from the MHM.

A drop of an MCO onto another MCO already loaded into the storage tube would cause plastic deformation to the bottom of the dropped MCO and the top of the impacted shield plug, but the confinement functions of either MCO would not be jeopardized. The deceleration associated with such a drop would not damage the MCO internals. HNF-SD-SNF-DP-007, *Multi-Canister Overpack Analysis File Documentation*, Appendix D, "Multi-Canister Overpack to Multi-Canister Overpack Drop Analysis," documents the simulation of a 31-ft drop of a loaded MCO onto another MCO. A bottom impact absorber is in place under the first MCO, but no intermediate impact absorber is in place between them. The analysis indicates that plastic deformation of the impacted shield plug seal and shoulder would be a maximum of 0.030 in. The impact absorber under the bottom MCO would be compressed 6 to 9 in. To be conservative, a breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).
D12 — Drop of Multi-Canister Overpack by the Multi-Canister Overpack Handling Machine onto the Storage Tube Plug because of Inadvertent Turret Rotation. Anytime an MHM is carrying an MCO in the MCO cavity in the MHM turret and stops over a storage tube plug, the MCO is vulnerable to a potential drop onto the storage tube plug pintle from the fully raised position in the MCO cavity in the MHM turret when the MHM is rotated to the MCO cavity in the MHM turret position providing no credit is taken for the MHM interlocks. A breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the extremely unlikely category (SNF-4042).

D13 — Drop of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine onto Edge of Storage Tube. The storage tube is supported off the floor. The lower flange of the tube is 4.5 in. thick and has a 45° incline to reduce any direct impact between a dropped MCO and the edge of the storage tube following an eccentric drop event. An engineering analysis (SNF-5204) has been performed to address dropping an MCO onto the edge of a storage tube (eccentric drop). The drop was conservatively assumed to hit the lower flange of the storage tube (which has a 45° incline) not the guide funnel (which has a 75° incline). The weight of the MCO used in the analysis was 20,000 lb, and the drop height was conservatively assumed to be 90 in. The MCO was assumed to be tilted by no more than 2°21' from vertical because of the MCO centering guide installed in the MHM. If a drop tilted more than 2°21', the MCO would most likely hit the funnel placed above the upper flange. The funnel has a 75° entrance angle, and the impact would be less severe than an impact on the lower flange. The engineering analysis predicted accelerations, plastic strain, and stress distributions, and identified MCO failure modes. The structural numerical models address nonlinear material behavior as well as impact dynamics. The tube bellows, which has an insignificant effect, was not included in the model.

According to the analysis, the maximum equivalent MCO strain was 40% to 45% and occurred on the MCO bottom near the point of impact (SNF-5204). Since the failure strain is above 80%, it is not likely that through-the-wall cracking will occur although removal of local surface metal may occur. The maximum predicted equivalent plastic strain at the MCO lower weld was 2% during the drop into the standard storage tube. This is well below a 13% failure strain. The maximum tensile principal strain was in a radial direction, so any failure would be by spalling or flaking rather than through-the-wall cracking. The deceleration of the MCO baskets was shown to be about 20 g or less, well within the design allowable of 35 g. The deformations of the MCO and standard storage tube were less than the tube clearance, so no wedging of the MCO in the tube is expected. To be conservative, a breach of the MCO following this drop is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).

D14 — Drop of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine onto Edge of a Sampling/Weld Station. The MCO impacts a 75° inclined surface on the shield hatch ring at the cask receiving pit. The impact at the sampling/weld station is on a similar 75° inclined surface on the shield halves. The shield halves at the sampling/weld station is less massive and held in place less securely than the shield hatch ring of the cask receiving pit and...
will cause less damage to the MCO. Therefore, the results of an MCO drop onto the edge of the
cask receiving pit bound those for a drop onto the edge of the sampling/weld station.

The MCO will impact the incline of the shield halves because of the design of the shield
halves and the MCO centering guide installed in the MHM. The shield halves have a 75° incline,
which will greatly reduce the impact force. The MCO centering guide will limit the MCO tilt,
which ensures that the impact area is always on the incline of the shield halves. To be
conservative, a breach of the MCO following this drop is assumed. Unmitigated, this event has
been determined to be in the unlikely category (SNF-4042).

Shear of a Multi-Canister Overpack. At the CSB the MCO is hoisted by both the
receiving crane and the MHM. The MCO could be sheared, either when it is inside the
transportation cask or when it is outside the cask. Several different scenarios that could cause an
MCO shear (which would be a localized breach or tear and not complete severance of the MCO)
have been considered. All of these shear scenarios are considered potentially serious hazards to
the MCO in the CSB hazard analysis (HNF-SD-SNF-HIE-001):

S1  Shear of cask–MCO by moving receiving crane while cask–MCO is partially
     lowered into cask receiving pit, or shear of cask–MCO because of collision between
     MHM and receiving crane as receiving crane lowers cask–MCO into cask receiving
     pit

S2  Shear of MCO by MHM turret rotation with MCO partially retrieved into MHM at
cask receiving pit, storage tube, or sampling/weld station

S3  Shear of MCO by MHM translational movement with MCO only partially retrieved
     into MHM at cask receiving pit

S4  Shear of MCO while MCO is partially retrieved from or inserted into cask receiving
     pit, storage tube, or sampling/weld station during significant seismic event

S5  Shear of MCO by MHM translational movement with MCO only partially retrieved
     into MHM turret at storage tube or sampling/weld station.

S1 — Shear of Cask–Multi-Canister Overpack by Moving Receiving Crane while
Cask–Multi-Canister Overpack is Partially Lowered into Cask Receiving Pit, or Shear of
Cask–Multi-Canister Overpack because of Collision between Multi-Canister Overpack
Handling Machine and Receiving Crane as Receiving Crane Lowers Cask–Multi-Canister
Overpack into Cask Receiving Pit. When the receiving crane is lowering the cask–MCO into
the cask receiving pit and the cask–MCO is partially inserted into the cask receiving pit, the
cask–MCO is vulnerable to a potential shear of the cask between the pit wall and the cask wall if
the receiving crane were to be moved at this time. The shear forces from accidental movement of
the receiving crane are bounded by those from collision of the MHM with the receiving crane and
are therefore insufficient to breach the cask–MCO. No breach of the MCO following this
collision is predicted by analysis. Unmitigated, this event has been determined to be in the anticipated category (SNF-4042).

When the receiving crane is lowering the cask–MCO into the cask receiving pit and the cask–MCO is partially inserted into the cask receiving pit, design features preclude the MHM from colliding with the crane. It is conservative to assume that the cask–MCO is vulnerable to a potential shear of the cask from the MHM colliding with the receiving crane and subsequently with the cask; the cask provides confinement. Analysis documented in FDT-137, *MHM Impact with Cask/MCO during Insertion into CSB Transfer Pit* (Petersen 1998b), has shown that a collision would not breach the cask–MCO. MHM interlock P5, which inhibits receiving crane and MHM interaction, was not credited in the frequency calculation (SNF-4042); it is considered part of the defense-in-depth measures.

S2 — Shear of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine Turret Rotation with Multi-Canister Overpack Partially Retrieved into Multi-Canister Overpack Handling Machine at Cask Receiving Pit, Storage Tube, or Sampling/Weld Station. When the MHM is raising the MCO into the MHM turret and the MCO is partially removed from the transportation cask, the storage tube, or sampling/weld station, the MCO is vulnerable to a potential shear from premature MHM turret rotation.

Analysis documented in SNF-5930, *Structural Analysis of Multi-Canister Overpack for Accidental Movement of Multi-Canister Overpack Handling Machine during Multi-Canister Overpack Lifting Operations*, demonstrates that a shear of the MCO is not possible using the turret rotation motor. For a turret rotational speed of 2 rpm, the kinetic energy is 1,300 ft-lbf. A locked rotor torque of 63 lb-ft results in a force on the MCO of 10,000 lbf. This force applied over a distance of 0.2 in. (penetration to fracture) increases the total energy to 1,470 ft-lbf. The energy required to initiate puncture of the MCO shell is 3,000 ft-lbf; therefore, the shell will not puncture from the inertial effects of the rotating turret combined with the drive motor effects. The peak force required to initiate puncture is 270,000 lbf. This value is roughly 27 times the 10,000 lbf the motor and gearing are capable of applying to the MCO at a locked rotor torque of 63 lb-ft. No breach of the MCO following turret rotation is predicted by analysis. Unmitigated, this event has been determined to be in the anticipated category (SNF-4042).

S3 — Shear of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine Translational Movement with Multi-Canister Overpack only Partially Retrieved into Multi-Canister Handling Machine at Cask Receiving Pit. When the MHM is raising the MCO into the MHM turret and the MCO is partially removed from the transportation cask, the MCO is vulnerable to a potential shear from premature MHM translational motion. A breach of the MCO following the shear forces from MHM translational movement is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042). Analysis documented in SNF-5930 shows that the internal geometry of the Mark IA baskets remain intact (no rearrangement of internal geometry).
S4 — Shear of Multi-Canister Overpack while Multi-Canister Overpack is Partially Retrieved from or Inserted into Cask Receiving Pit, Storage Tube, or Sampling/Weld Station during Significant Seismic Event. When the MHM is raising the MCO into the MHM turret and the MCO is partially removed from the shipping cask, the MCO is vulnerable to a potential shear from a seismic event. This shear event includes the potential shear caused by turret rotation or the potential shear caused by translational movement of the MHM. This shear event is prevented by the bridge and trolley seismic restraints as well as by the turret locking pin and base locking pin. Calculations have been performed to demonstrate the design adequacy of the seismic restraints and locking pins for seismic events with forces up to those of the DBE. To be conservative, a breach of the MCO following the shear forces from MHM translational movement during a significant seismic event is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).

S5 — Shear of Multi-Canister Overpack by Multi-Canister Overpack Handling Machine Translational Movement with Multi-Canister Overpack only Partially Retrieved into Multi-Canister Overpack Handling Machine Turret at Storage Tube or Sampling/Weld Station. When the MHM is raising the MCO into or lowering the MCO from the MHM turret and the MCO is partially removed from the storage tube or sampling/weld station pit, the MCO is vulnerable to a potential shear from premature MHM translational motion.

Analysis shows that the internal geometry of the Mark IA baskets remain intact (SNF-5930). To be conservative, a breach of the MCO following the shear forces from MHM translational movement is assumed. Unmitigated, this event has been determined to be in the unlikely category (SNF-4042).

Impacts Other than Shears and Drops of a Multi-Canister Overpack. At the CSB impacts to the MCO or to the cask–MCO could also be caused by events other than shears and drops. Several different scenarios that could cause an impact to the MCO have been considered. All of these impact scenarios are considered potentially serious hazards to the MCO in the CSB hazard analysis (HNF-SD-SNF-HIE-001):

O1 Drop of receiving crane yoke onto cask lid, or drop of cask lid onto MCO

O2 Collapse of CSB structure and impact to MCO during seismic event

O3 Drop of cask receiving pit shield hatch and MCO guide assembly’s shield hatch plate by MHM onto MCO, or drop of storage tube plug or sampling/weld station enter shield plate by MHM onto MCO in storage tube or sampling/weld station

O4 MHM fall or damage caused by a seismic event

O5 Drop of intermediate impact absorber onto MCO.
O1 — Drop of Receiving Crane Yoke onto Cask Lid, or Drop of Cask Lid onto Multi-Canister Overpack. When the receiving crane is raising the cask-MCO yoke away from the cask-MCO in the cask receiving pit, the cask lid is vulnerable to a potential drop of the yoke. In the case of the lifting yoke and crane rigging falling onto the MCO cask lid, the acceptable performance criterion is the cask lid not being punctured. Acceptable performance of the MCO cask lid is demonstrated by a quantitative comparative analysis based on a cask puncture test (WMTS-RPT-037).

For this scenario, the impact energy of the lifting yoke, crane rigging, and hook dropping onto the cask-MCO lid was compared with the cask-MCO puncture resistance analysis documented in Design Analysis Report for the TN-WHC Cask and Transportation System (TN 1996). The following assumptions were made in the comparative energy evaluation:

- Crane two-blocking causes the lifting yoke and crane hook and rigging to drop onto the cask-MCO lid while the cask is in the cask receiving pit.
- The total weight of the lifting yoke and crane hook and rigging is 6,200 lb.
- The cask-MCO is elevated to a working height, therefore the closure bolts are at CSB floor level.
- For conservatism, the protection provided by the lifting brackets and trunnions is not considered.
- The crane hook impacts the cask lid.

Based on the above assumptions, the drop height of the lifting yoke, crane hook, and rigging is 28 ft. The top of the cask closure lid, excluding the trunnion brackets, is 11 in. off the floor. This results in a drop height of 27 ft, 1 in. onto the closure lid. The potential energy from such a drop is 168 kip-ft.

The top end cask puncture evaluation (TN 1996) was performed in accordance with Title 10, Code of Federal Regulations, Part 71, “Packaging and Transportation of Radioactive Materials,” Section 71.73, “Hypothetical Accident Conditions” (10 CFR 71). The evaluation (TN 1996) determined that the loaded cask-MCO could survive a 40-in. drop onto a 6-in. solid vertical cylinder (puncture bar) mounted on an unyielding surface.

The impact energy of the lifting yoke and crane hook and rigging was calculated as being approximately 19% less than the impact energy evaluated in the Transnuclear (TN 1996) design analysis report. Therefore, there is margin of safety of 19% based on the cask puncture bar test. This is in addition to cask-MCO margin of safety in resisting puncture of 6.07 shown in the Transnuclear (TN 1996) evaluation.
The tent gantry hoist in the load-in/load-out area will be used to remove the cask lid from the cask-MCO. When the tent gantry hoist is raising the cask lid away from the cask-MCO in the cask receiving pit, the MCO is vulnerable to a potential drop of the cask lid. An analysis has been performed to evaluate cask lid drops (HNF-SD-SNF-DP-007). The analysis concluded that the MCO maintains confinement of all SNF during and after a 1.5-m (approximately 60 in.) drop of a cask lid. A drop of the cask lid from the tent gantry hoist onto the MCO would cause only local cosmetic damage at the point of impact, but the MCO would maintain its confinement functions. Local plastic damage would only be found by close inspection of the hardware after the event. If the receiving crane were used to remove the cask lid from the cask, the reliability of the receiving crane makes the consequences of the cask lid drop acceptable for the likelihood of a receiving crane drop. No breach of the MCO following drop of the cask lid by the tent gantry hoist is predicted by analysis. A breach of the MCO following drop of the cask lid by the receiving crane is assumed. Unmitigated, this breach event has been determined to be in the unlikely category (SNF-4042).

O2 — Collapse of Canister Storage Building Structure and Impact to Multi-Canister Overpack during Seismic Event. Given a seismic event occurs, there is potential for the CSB facility to structurally fail and fall to the operating area deck and to strike an MCO exposed at the cask receiving pit or the sampling/weld station pit. The CSB has been designed to withstand the DBE.

O3 — Drop of Cask Receiving Pit Shield Hatch and MCO Guide Assembly’s Shield Hatch Plate by Multi-Canister Overpack Handling Machine onto Multi-Canister Overpack, or Drop of Storage Tube Plug or Sampling/Weld Station Center Shield Plate by Multi-Canister Overpack Handling Machine onto Multi-Canister Overpack in Storage Tube or Sampling/Weld Station. When the MHM is raising the cask receiving pit shield hatch and MCO guide assembly’s shield hatch plate, it is possible that the MHM could drop the shield hatch plate toward the MCO in the cask. However, it is physically impossible for a dropped shield hatch plate to make contact with the top of an MCO because of the dimensions of the shield hatch plate and depth of the top of the MCO below the shield hatch and MCO guide assembly.

When the MHM is raising or lowering a storage tube plug or sampling/weld station center shield plate with the tube plug grapple, it is possible that the MHM could drop the storage tube plug or sampling/weld station center shield plate toward the MCO in the storage tube or the sampling/weld station pit. However, it is physically impossible for a dropped tube plug or cover plug to make contact with the top of an MCO because of the dimensions of the plug and depth of the top of the MCO below the storage tube embed or the sampling/weld station shielding.

O4 — Multi-Canister Overpack Handling Machine Fall or Damage Caused by a Seismic Event. Evaluations documented in SNF-5984, Multi-Canister Overpack Handling Machine Trolley Seismic Uplift Constraint Design Loads, were performed to study the behavior of the MHM during a DBE. These evaluations considered the effects on the MHM both with and without the seismic restraints and without the rail stops. All cases studied demonstrate that the
MHM will not tip over or collapse during a DBE. For the unrestrained seismic event, the MHM trolley seismic uplift restraints exceed the ASME-NOG-1 allowables. The design of the MHM will be strengthened to meet ASME-NOG-1 requirements, and this modification will be incorporated before CSB FSAR implementation. A potential MHM tip-over caused by the rail stops (if the MHM is near the rail stops without seismic restraints) during a DBE was not analyzed. The postulated scenario was judged to have very low likelihood because the MHM is rarely located close to the rail stops without the seismic restraints applied.

**O5 — Drop of Intermediate Impact Absorber onto Multi-Canister Overpack.** The acceptable performance criterion for the intermediate impact absorber impacting the top of an MCO is that the critical confinement boundaries of the MCO remain below yield under the impact loading.

A comparative qualitative analysis of an intermediate impact absorber drop onto the top of an MCO was performed based on HNF-SD-SNF-DP-007, the impact energy, and the design and weight of the intermediate impact absorber (WMTS-RPT-037).

The evaluation demonstrates that the MCO after a free drop impact of the intermediate impact absorber onto the MCO maintains confinement. Analysis documented in HNF-SD-SNF-DP-007 shows the MCO maintains confinement after the impact from a 31-ft free fall of another fully loaded MCO onto the top of a stationary MCO in the CSB storage tube. It was assumed that the MCO canister cover was not installed and the MCO shield plug area was exposed to the impact (HNF-SD-SNF-DP-007). The comparative analysis shows that based on the difference in weight of the MCO (20,000 lb) and the intermediate impact absorber (630 lb), the impact energy of the intermediate impact absorber is significantly less than the impact of a fully loaded MCO (620 kip-ft versus 19.5 kip-ft) (WMTS-RPT-037). Consequently, the MCO, with or without the cover cap, will maintain confinement after a free fall drop of the intermediate impact absorber onto a stationary MCO in the CSB storage tube.

**A3.4.2.1.2 Source Term Analysis.** The quantity of particulate released following an MCO breach caused by mechanical damage depends on the initial aerosol concentration, which includes that generated by the mechanical accident forces, and subsequent particulate entrainment. The potential sources of particulate entrainment come from venting of pressurized powder and aerodynamic entrainment. Both of these sources represent the effects of local gas velocities to entrain particles. The key difference between two entrainment sources is that the powder venting source is intended to represent a situation in which the gas flow field is predominantly through the particle bed, while the aerodynamic entrainment source is intended to represent a situation in which the gas flow field is predominantly outside the bed.

The amount of material available for release depends on the amount of particulate mass generated in the MCO during processing. This quantity is a function of processing times and temperatures as well as of the condition of the fuel in the MCO (e.g., exposed surface area of fuel). HNF-SD-SNF-TI-015 provides two estimates of this quantity: one for the safety basis, which is considered the bounding value, and the other for the design basis, which is considered the
nominal value. When the MCO is received at the CSB, the safety basis value is 23.1 kg uranium
and the design value is 0.54 kg uranium (HNF-SD-SNF-TI-015). After 40 years of storage at the
CSB, the safety basis, or bounding, value is 30 kg uranium and the design basis, or nominal, value
is 1.85 kg uranium (HNF-SD-SNF-TI-015). Because of the conservative methodology used to
calculate the bounding value, 30 kg is considered representative of the 99th percentile.

The MCO blowdown scenario features films of particles, not deep powder beds. While it is
true that there is some gas flow through particle layers during a blowdown, experiments
documented in Technical Report 11.6: Resuspension of Deposited Aerosols Following Primary
System or Containment Failure (IDCOR 1984) clearly show that this is a trivial effect.
Experiments that underlie the powder venting source term feature a pressurized cylinder packed
with powder. During depressurization, the flow velocity is zero at the bottom of the particle bed
when there is no underlying gas plenum, and the velocity increases to its maximum at the exit,
which is at the top. The gas velocity at the top of the bed must be enough to fluidize the bed
locally and to entrain the particles. When the particle bed height was decreased in these
experiments, the velocity at the top of the bed decreased in linear proportion to the distance, and
there was a bed height at which little or no entrainment could occur. In such a situation, there
was gas flow through the bed during depressurization, but the local velocity was simply not
sufficient for entrainment (IDCOR 1984). Therefore, for application to the MCO blowdown
accident scenarios, in which particle layers are thin and relatively well-distributed throughout the
MCO, the pressurized powder venting source term is not applicable, and a source term based
upon aerodynamic entrainment should be used.

DOE-HDBK-3010-94 documents ARRs and RFs. Based on the data reported in
DOE-HDBK-3010-94, a bounding (95th percentile) ARR of $4 \times 10^4$/h and an RF of 1.0 were
selected. The contents of the MCO are intact fuel elements tightly packed in fuel baskets and
pieces of fuel elements housed in scrap baskets. Particulate matter swept upward by streams of
flowing gas within the MCO must take a tortuous path through the MCO to exit the MCO. For
shielded powder, where the aerodynamic stresses are reduced by debris or exposure to static
conditions, DOE-HDBK-3010-94 recommends an ARR of $4 \times 10^4$/h and an RF of 0.2. These
values were selected as nominal (50th percentile).

The duration of the blowdown depends on the flow area of the leak and the initial MCO
pressure. The MCO depressurizes to atmospheric pressure in less than 1 minute, even for an
MCO pressure of about 150 lb/in² gauge and a 0.25-in. hole. The MCO depressurizes in a much
shorter time for lower pressures and larger leak paths. For the calculation of the source term, a
nominal (50th percentile) value of 10 seconds and a bounding (95th percentile) time of 60 seconds
were selected.

Using the methodology described in Section A3.4.1.3 and the bounding and nominal values
identified above, the bounding (95th percentile) value for the material released through
aerodynamic entrainment is calculated to be $2.0 \times 10^4$ g, as shown in Table A3-8.
The aerosol concentration inside the MCO at the time of the release depends on prior MCO handling conditions and the mechanical forces exerted on the MCO structure by the accident. The powder in the MCO at rest could be ejected into the gas volume by the response of the underlying solid MCO and fuel substrate to vibration or jolting induced by impact or falling debris. According to DOE-HDBK-3010-94, the value of the ARF under such circumstances should exceed the value of the ARF for aerodynamic suspension alone but be less than the ARF for the free fall of powder. The powder undergoing vibration shock is bounced into the gas while subject to the same gas velocities as those for aerodynamic entrainment. Based on the discussion in DOE-HDBK-3010-94, a bounding (95th percentile) ARF of $1 \times 10^{-3}$ and an RF of 1.0 were chosen for the suspension of powder-like surface contamination by shock vibration. A nominal (50th percentile) value of $4 \times 10^{-4}$ was chosen for the ARF and a nominal (50th percentile) value of 0.2 was chosen for the RF based on evaluation of the discussion in DOE-HDBK-3010-94. The pressure in the MCO at the start of the blowdown determines the fraction of the suspended particulate that is released. The initial pressure varies from 1.50 atm (corresponding to the helium fill pressure of 22 lb/in² absolute at the CVDF) to a maximum pressure of 5.2 atm (as defined in
the Technical Databook [HNF-SD-SNF-TI-015]). To allow for some additional margin in the
calculation, a pressure of 2.0 atm is considered nominal (50th percentile) and corresponds to an
LPF of 0.5, while a pressure of 6.0 atm is considered bounding (95th percentile) and corresponds
to an LPF of 0.83.

Using the methodology described in Section A3.4.1.3 and the bounding and nominal values
identified above, the bounding (95th percentile) value for the material released by impact is
calculated to be 1.2 g, as seen in Table A3-9.

| Table A3-9. Initial Aerosol Concentration Source Term for
| Mechanical Damage of the Multi-Canister Overpack. |
| Nominal | Bounding | EF | Percentile | SNV | ln(EF)/SNV |
| MAR     | 1.85 kg  | 30 kg | 16.22 | 99 | 2.326 | 1.198 |
| ARF     | 4.00 E-04 | 1.00 E-03 | 2.50 | 95 | 1.645 | 0.557 |
| RF      | 0.20     | 1.00  | 5.00  | 95 | 1.645 | 0.978 |
| LPF_{MCO} | 0.50   | 0.83  | 1.67  | 95 | 1.645 | 0.311 |

Note: The 1.645 is the standard normal variable corresponding to the 95% upper confidence limit. For the 99% upper
confidence limit, the corresponding value is 2.326.

\*LPF_{MCO} = (MCO pressure - 1 atm) / (MCO pressure). At a nominal MCO pressure of 2.0 atm, the LPF_{MCO} is
0.5, and at a bounding MCO pressure of 6.0 atm, the LPF_{MCO} is 0.83.

\*Nominal_{overall} M = MAR_{nominal} \times ARF_{nominal} \times RF_{nominal} \times LPF_{MCO}.

\*Bounding_{overall} M = (EF_{overall}) (nominal_{overall} M).

\*EF_{overall} = \exp \left( SNV_{95\%} \left( \sum_i \left[ \frac{\ln(EF_i)}{SNV_i} \right]^2 \right)^{1/2} \right)

ARF = airborne release fraction.
EF = error factor (i.e., bounding value divided by nominal value).
ln(EF) = natural log of EF.
LPF = leak path factor.
M = mass of material released.
MAR = material at risk.
MCO = multi-canister overpack.
RF = respirable fraction.
SNV = standard normal variable.
The bounding source term for the gaseous release is 1.2 g, which is the sum of $2.0 \times 10^4$ g from the aerodynamic entrainment of particulate and 1.2 g from vibration and shock.

### A3.4.2.1.3 Consequence Analysis

The dose calculation equation and data from Section 3.4.1 of the SNF Project FSAR are used to calculate the dose to the onsite receptor.

$$D_{\text{onsite}} = M \times \frac{\chi}{Q} \times BR \times UD \times LPF_{\text{building}}$$

$$= (1.2 \text{ g U})(1.14 \times 10^{-2} \text{ s/m}^3)(3.33 \times 10^{-4} \text{ m}^3/\text{s})(4.38 \times 10^5 \text{ rem/g U})(1.0)$$

$$= 1.9 \text{ rem (1.9 } \times 10^{-2} \text{ Sv)}.$$  

where

- $D_{\text{onsite}}$ = committed effective dose equivalent (rem)
- $M$ = mass of respirable airborne material released (g U)
- $\chi/Q$ = time-integrated atmospheric transport factor (s/m$^3$)
- $BR$ = breathing rate (m$^3$/s)
- $UD$ = dose per unit mass of uranium (rem/g U)
- $LPF_{\text{building}} = 1.0.$

The dose consequences at the remaining receptor sites are calculated in the same manner and are shown in Table A3-10.

### Table A3-10. Dose Calculation Summary for Mechanical Damage of a Multi-Canister Overpack.

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

$^a$Fifty-year committed effective dose equivalent.

$^b$Evaluation guideline for onsite (100 m) receptor only.

$^c$Unmitigated frequency for these events is unlikely ($>10^{-4}$ to $\leq 10^{-2}$ per year) or less.

$^d$Provided for information only.
Because the consequences of the unmitigated accident do not exceed offsite release limits, no mitigated consequences were calculated for the offsite doses. No mitigated dose calculation was performed for the onsite receptor because the onsite consequences are within the evaluation guidelines for an unlikely event.

A3.4.2.1.4 Comparison to Guidelines. The unmitigated radiological offsite dose for all mechanical damage events is below offsite release limits while the unmitigated onsite dose is within evaluation guidelines for unlikely events.

A3.4.2.1.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. This section identifies the safety SSCs and provides a brief description of their safety functions.

Drop of a Multi-Canister Overpack.

D1 Cask–MCO drop from receiving crane onto receiving area
- Safety-significant SSCs
  - MCO transportation cask — Provide structural protection for confinement capability (note that the MCO transportation cask has been designated safety class at other SNF Project facilities)
  - Receiving crane structure and hoist — Provides design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

D2 Cask–MCO drop from receiving crane into cask receiving pit
- Safety-significant SSCs
  - MCO transportation cask — Provide structural protection for confinement capability (note that the MCO transportation cask has been designated safety class at other SNF Project facilities)
  - Receiving crane structure and hoist — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

D3 Cask–MCO drop from receiving crane into FFTF pit or MHM maintenance pit
- Safety-significant SSCs
HNF-3553 REV 0
Annex A — Canister Storage Building

D4 Drop of MCO by MHM onto edge of cask receiving pit

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

D5 Drop of MCO by MHM back into cask

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

D6 Drop of MCO within MHM turret onto MHM turret deck

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation...
required, as well, by NRC equivalency important-to-safety Category B for
SSCs that handle SNF.

D7 Drop of MCO from MHM onto CSB operating area floor or onto storage tube covers of
vault 2 or vault 3 of CSB

- Safety-significant SSCs
  - MHM structural components and MHM MCO hoist and grapple — Provide
design features to protect assumptions for MCO drop frequencies; designation
required, as well, by NRC equivalency important-to-safety Category B for
SSCs that handle SNF.

D8 Drop of MCO from MHM onto or into MHM maintenance pit or tube plug exchange
facility

- Safety-significant SSCs
  - MHM structural components and MHM MCO hoist and grapple — Provide
design features to protect assumptions for MCO drop frequencies; designation
required, as well, by NRC equivalency important-to-safety Category B for
SSCs that handle SNF.

D9 Drop of MCO from MHM onto or into FFTF pit

- Safety-significant SSCs
  - MHM structural components and MHM MCO hoist and grapple — Provide
design features to protect assumptions for MCO drop frequencies; designation
required, as well, by NRC equivalency important-to-safety Category B for
SSCs that handle SNF.

D10 Drop of MCO by MHM into storage tube or sampling/weld station

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for
confinement capability (note that the MCO shell has been designated safety-
class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide
design features to protect assumptions for MCO drop frequencies; designation
required, as well, by NRC equivalency important-to-safety Category B for
SSCs that handle SNF.
Drop of MCO by MHM onto another MCO located in the bottom of a storage tube (no intermediate impact absorber involved)

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

Drop of MCO by MHM onto storage tube plug because of inadvertent turret rotation

- Safety-significant SSCs
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

Drop of MCO by MHM onto edge of storage tube

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

Drop of MCO by MHM onto edge of sampling/weld station

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities).
MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

**Shear of a Multi-Canister Overpack.**

S1 Shear of cask–MCO by moving receiving crane while cask–MCO is partially lowered into cask receiving pit, or shear of cask–MCO because of collision between MHM and receiving crane as receiving crane lowers cask–MCO into cask receiving pit

- Safety-significant SSCs
  - MCO transportation cask — Provide structural protection for confinement capability (note that the MCO transportation cask has been designated safety class at other SNF Project facilities).

S2 Shear of MCO by MHM turret rotation with MCO partially retrieved into MHM at cask receiving pit

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)

S3 Shear of MCO by MHM translational movement with MCO only partially retrieved into MHM at the cask receiving pit

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities).

S4 Shear of MCO while MCO is partially retrieved from or inserted into cask receiving pit, storage tube, or sampling/weld station during a seismic event

No safety SSCs or TSRs are required to prevent or mitigate this accident.
S5 Shear of MCO by MHM translational movement with MCO only partially retrieved into MHM turret at storage tube or sampling/weld station

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities).

Impacts to a Multi-Canister Overpack Other than Drops or Shears.

O1 Drop of cask lifting yoke onto the cask lid, or drop of the cask lid onto MCO

- Safety-significant SSCs
  - MCO transportation cask — Provide structural protection for confinement capability (note that the MCO transportation cask has been designated safety-class at other SNF Project facilities)
  - MCO shell, locking ring, and shield plug — Provide structural protection for confinement capability (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - Receiving crane structure and hoist — Provides design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

O2 Collapse of CSB structure and impact to MCO during seismic event

- Safety-class SSCs
  - Standard and overpack storage tubes, carbon steel basemat embeds, tube base assemblies, operating deck, and vault — Prevent collapse of CSB during seismic event

O3 Drop of cask receiving pit shield hatch assembly's center plate by MHM onto MCO, or drop of storage tube plug or sampling/weld station cover plug by MHM onto MCO in the storage tube or sampling/weld station pit

No safety SSCs or TSRs are required to prevent or mitigate this accident.
O4  MHM fall onto operating deck resulting in major structural damage to deck

- Safety-class SSCs
  - Standard and overpack storage tubes, carbon steel basemat embeds, tube base assemblies, operating deck, and vault — Prevent collapse of CSB during seismic events up to the DBE.
  - Rail frogs, rails, and MHM seismic restraints

- Safety-significant SSCs
  - Operating area shelter (waiver 1 to HNF-PRO-704)
  - MHM (structural components) (waiver 2 to HNF-PRO-704).

O5  Drop of intermediate impact absorber onto MCO

- Safety-significant SSCs
  - MCO shell, locking ring, and shield plug — Provide structural protection for criticality geometry control under normal operating conditions (note that the MCO shell has been designated safety-class at other SNF Project facilities)
  - MHM structural components and MHM MCO hoist and grapple — Provide design features to protect assumptions for MCO drop frequencies; designation required, as well, by NRC equivalency important-to-safety Category B for SSCs that handle SNF.

The SSCs, TSR controls, and defense-in-depth features designated to mitigate mechanical damage to an MCO from a drop event are summarized in Table A3-11. The SSCs, TSR controls, and defense-in-depth features designated to mitigate mechanical damage to an MCO from a shear event or other impact are summarized in Table A3-12. NRC important-to-safety category SSCs and defense-in-depth features also are included for each specific accident in Tables 3-11 and 3-12.

bSSCs are classified per their function in mitigating or preventing specific accidents. SSCs may have other classifications based on their functions in other events.

CSB = Canister Storage Building.
FFTF = Fast Flux Test Facility.
ITS = important to safety.
MCO = multi-canister overpack.
MHM = multi-canister overpack handling machine.
NA = not applicable.
NRC = U.S. Nuclear Regulatory Commission.
SSC = structure, system, and component.
TSR = technical safety requirement.

#### Defense in Depth:
- The MHM grapple is designed with a mechanical lock such that it should not be able to open while a load is suspended from it.
- MHM interlocks (P57, P61, P62, P63, P65, and P66)
- MHM grapple is designed to handle the loads they will carry.
- Personnel are trained in facility-specific procedures in the proper handling of the MCO and MHM.
- Qualified operators.
- Regular maintenance of the MHM is performed to ensure it is in good working order.
- The hoist design includes:
  - Interlocks to preclude lift and horizontal motion at the same time.
  - Dual brakes.
  - No free fall capacity.

Note: Defense-in-depth features and safety-significant defense-in-depth features are not designated as NRC ITS.

2. SSCs are classified per their function in mitigating or preventing specific accidents. SSCs may have other classifications based on their functions in other events.

CSB = Canister Storage Building.
ITS = Important to safety.
MCO = Multi-canister overpack.
MHM = Multi-canister overpack handling machine.
NPH = Natural phenomena hazard.
NRC = U.S. Nuclear Regulatory Commission.
SSC = Structure, system, and component.
TSR = Technical safety requirement.
A3.4.2.2 Gaseous Release from the Multi-Canister Overpack. This accident evaluates events that may result in releases of radioactive materials to the CSB facility caused by loss of the MCO confinement pressure boundary. The potential for hydrogen deflagrations caused by loss of confinement is discussed in Section A3.4.2.4. MCOs are backfilled with helium to a prescribed pressure just before being sealed for shipment from the CVDF to the CSB. The integrity of the mechanical seal also is checked and verified at the CVDF before the MCO is shipped to the CSB. The uncontrolled release of the MCO internal gas pressure, referred to as a pressurized gaseous release accident, results from failure of the MCO pressure boundary to confine the MCO gases at the CSB. A pressurized gaseous release would lead to the entrainment and release of fuel particulate from the MCO and the creation of a radiological hazard. The gases released from the MCO in this event are those in the MCO after it is processed at CVDF and those generated in the MCO at the CSB. These gases include helium, hydrogen, water vapor, and possibly some small concentration of oxygen.

Based on the results of the hazards analysis (HNF-SD-SNF-HIE-001) and shown in Table A3-1, the potential for gaseous releases from an MCO can be the result of operations at the CSB, chemical properties of the SNF, and a breach of confinement caused by drops or impacts. The bounding accidents selected for further evaluation include (1) overpressurization caused by radiolytic decomposition of water and aluminum hydroxide, and the generation of hydrogen from the chemical reaction of water with fuel inside the MCO; (2) sampling system equipment failures or operator error during sampling and backfilling operations at the CSB; and (3) breach of MCO confinement caused by drops or impacts of objects onto the MCO at the sampling/weld station. The potential for a drop of the MCO or cask-MCO and MCO or cask-MCO impacts has been addressed in Section A3.4.2.1. The scenarios considered in this accident analysis are assumed to not result in a deflagration of the gases within the MCO. Therefore, the bounding accident scenarios addressed in this section include overpressurization due to radiolytic decomposition and gaseous releases due to sampling system equipment failures or operator error during sampling and backfilling operations at the CSB. Internal and external deflagrations are addressed in subsequent DBA sections.

As discussed in the HNF-SD-SNF-TI-059, the radiological guidelines associated with the release of SNF are more limiting than the toxicological guidelines, thus, the toxicological consequences associated with the gases released in this event do not require mitigating features beyond those required by the radiological consequences. Additional information about the MCO gaseous release accidents can be found in SNF-3328.

A3.4.2.2.1 Scenario Development. The following describes the scenario development for each of the cases evaluated.

Overpressurization Due to Radiolytic Decomposition. MCOs arrive at the CSB from the CVDF in a mechanically sealed configuration with no pressure relief. Following operations at the CVDF the MCO is transported to the CSB. During the period encompassing closure at CVDF and awaiting transport to the CSB, transport to the CSB, and receipt at the CSB awaiting closure, there is the potential for the MCO to pressurize from radiolytic decomposition. This scenario
assumes that the MCO overpressurizes (i.e., pressure caused by radiolytic decomposition is sufficient to fail the mechanical seal) and releases gases and particulate to the CSB facility.

As discussed in Chapter A2.0, the mechanical seal is designed to withstand pressures up to 150 lb/in² (18.3 atm). The initial pressure within an MCO is 22 lb/in² absolute (1.5 atm). According to HNF-SD-SNF-TI-040, MCO Internal Gas Composition and Pressure during Interim Storage, internal MCO pressures following 40 years of storage could be as high as 76 lb/in² absolute (5.2 atm), which is well below the design pressure of the MCO. Therefore, insufficient pressures will be generated within the MCO to fail the mechanical seal (receipt conditions or conditions during sampling operations) or the welded seal (long-term or 40-year storage condition). Thus it can be concluded that insufficient pressures will be generated within an MCO from radiolytic decomposition to overpressurize an MCO and result in a release upon receipt at the CSB.

Gaseous Release During Sampling Operations. A gaseous release could occur at the CSB because of operator error during sampling and backfilling operations. This scenario assumes the incorrect installation or removal of the sampling and backfill equipment or a failure of the equipment resulting in a direct path for leakage into the CSB facility. Dropping of an object onto the sampling/weld station components is another potential initiator for a leak from the sampling system. A drop could shear the sampling system piping or otherwise fail the confinement capability of the sampling system pressure boundary. A confinement failure could also result from the sampling/weld station gantry crane, the MHM, or some other equipment moving horizontally into the sampling/weld station components and shearing the piping.

The sampling process begins when the MHM lowers the selected MCO into the sampling/weld station pit. The surface temperature of the MCO is monitored. If the surface of the top of the MCO is not sufficiently cool, the MCO is cooled using the sampling/weld station cooling cap to reduce the exposed portions of the MCO to a temperature consistent with standard industrial safety regulations. After removing temporary radiation shields and guard rails, the sampling hood is installed on the MCO to confine possible airborne contamination generated by an accidental release during sampling. The MCO sampling cart is connected to the local distributed control system and inert gas system. Piping on the sample cart connects to the sample gas accumulator through the sampling hood high-efficiency particulate air (HEPA) filter outlet using a quick-disconnect attachment. The flexible hose of the sample cart vent is connected to the sampling hood discharge, which dumps to the exhauster. This exhaust system fan establishes negative pressure within the hood relative to the operating area pressure to maintain air contamination control and air flow around the top of the MCO.

For MCO sampling, an MCO process valve operator is installed on the short tube port (port 2) of the MCO after the cover plate is removed. The process valve operator is connected with a quick-disconnect coupling to a flexible hose that connects to the inlet of the sample line HEPA filter. The remainder of the sample system piping is the flexible piping that connects the outlet of the sample line HEPA filter to the sample cart and the rigid piping in the sample cart that goes to the sample valve and the sample accumulator. This piping is used to draw a sample of gas
from the MCO and to pressurize the MCO using helium from the 120 lb/in² gauge CSB helium supply system. The sampling system piping between the refill valve and the MCO is pressurized during the MCO refill operation. The entire sampling process is a manual operation; the technician taking the sample is present at all times during sampling.

After completion of the sampling activities, the MCO is backfilled with helium if necessary to maintain internal pressure. The same equipment and process lines used during sampling are used to backfill the MCO. However, the sample valve is closed and the helium backfill valve is opened (see Figure A2-42).

The following scenario involves a failure of this process line while it is connected to the MCO with the MCO process valve open, leading to a blowdown of the gases inside the MCO. With only one process line connected to the MCO, no flow path through the MCO can exist to continuously remove particulate from the MCO for an extended period of time. To get a release, the break in a section of process piping must be upstream of the sample line HEPA filter. A release from a piping failure downstream of the sample line HEPA filter requires failure of the sample system HEPA filter as well. A release also is possible if the MCO valve operator is inadvertently removed before the process port is closed.

A leak within the confines of the sample hood would be quickly exhausted through the sampling/weld station HEPA filter to the CSB exhaust system plenum and out to the environment through the CSB stack. Leaks from the sample system outside of the sample hood would be to the CSB operating air.

The effective leak flow area is bounded by the flow area of the path through the MCO shield plug (1.0-in.-diameter). All of the sampling system piping outside of the sampling hood is less than 0.75-in. inside diameter except the sample line to the cart, which is 1 in. in diameter. The flexible hose inside the sample hood and the associated fittings have inside diameters less than 1.0 in. If the valve operator body is improperly secured to the top of the MCO, then the leak path flow area around the valve could be large enough to make the flow area of the shield plug the limiting flow area. Therefore, the largest leak path flow area possible would be for a leak into the sample hood. Sampling system leaks outside of the sample hood would have smaller flow area paths and would have traveled through the sample line HEPA filter.

Gaseous Release from Overpressurization Due to Equipment Failure. In addition to the gaseous release accident at the sampling/weld station, the overpressurization of the MCO by the inert gas system during reinerting of a monitored MCO after sampling also is considered. This accident is initiated by failure of the pressure regulator on the helium supply system while an MCO is in the sampling/weld station undergoing the MCO helium backfill operation. This scenario assumes the helium supply pressure is sufficient to breach the MCO shield plug seal. As with the sampling process, the entire backfilling process is a manual operation and the technician is present at all times.
A3.4.2.2 Source Term Analysis. For the gaseous release accident, the MAR (particulate available for release) depends on the amount of particulate generated between the time the fuel is washed at the K Basins and the time of the accident. The MCO gaseous release accident could only occur during the time the MCO sampling program is being conducted. The Technical Databook (HNF-SD-SNF-TI-015) states that the safety basis or bounding value for the mass of particulate in the MCO is 34.0 kg of uranium dioxide, which contain 30.0 kg of uranium. Because of the conservative methodology used to calculate the bounding value, 30 kg is considered representative of the 99th percentile. The Technical Databook (HNF-SD-SNF-TI-015) also states that the design or nominal value is 2.1 kg of uranium dioxide, which contain 1.85 kg of uranium.

The quantity of particulate actually released during a gaseous release accident depends on the initial aerosol concentration and subsequent particulate entrainment. The pressurized powder venting source term is not applicable, and a source term based upon aerodynamic entrainment, as described in Section A3.4.2.1.2, is used.

Based on the data reported in DOE-HDBK-3010-94, a bounding (95th percentile) ARR of $4 \times 10^{-5}$/h and an RF of 1.0 were selected. The contents of the MCO are intact fuel elements tightly packed in fuel baskets and pieces of fuel elements housed in scrap baskets. Particulate matter swept upward by streams of flowing gas within the MCO must take a tortuous path through the MCO and through the MCO shield plug to exit the MCO. For shielded powder, where the aerodynamic stresses are reduced by debris or exposure to static conditions, DOE-HDBK-3010-94 recommends an ARR of $4 \times 10^{-6}$/h and an RF of 0.2. These values were selected as nominal (50th percentile).

The pressurized gaseous release from the MCO occurs close to the MCO through a leak path with a flow area greater than or equal to the flow area through the MCO shield plug. Such a leak could be caused by complete severance of the pipe or flexible tubing within the sampling/weld station sample hood or by failure to tighten the hold down bolts on the MCO port valve operator. The duration of the blowdown depends on the flow area of the leak and the initial MCO pressure. The MCO depressurizes to atmospheric pressure in less than 1 minute, even for an MCO pressure of about 150 lb/in$^2$ gauge and a 0.25-in. hole. The MCO depressurizes in a much shorter time for lower pressures and larger leak paths. For the calculation of the source term, a nominal (50th percentile) value of 10 seconds and a bounding (95th percentile) time of 60 seconds were selected.

Using the methodology described in Section A3.4.1.3 and the bounding and nominal values identified above, the bounding (95th percentile) value for the material released through aerodynamic entrainment is calculated to be $2 \times 10^4$ g, as shown in Table A3-13.

Note: The 1.645 is the standard normal variable corresponding to the 95% upper confidence limit. For the 99% upper confidence limit, the corresponding value is 2.326.

\[^{a}\text{Nominal}_{\text{overall}}M = \text{MAR}_{\text{nominal}} \times \text{ARR}_{\text{nominal}} \times \text{RF}_{\text{nominal}} \times \text{time}_{\text{nominal}}\]

\[^{b}\text{Bounding}_{\text{overall}}M = (\text{EF}_{\text{overall}})(\text{nominal}_{\text{overall}}M)\]

\[^{c}\text{EF}_{\text{overall}} = \exp \left( \text{SNV}_{95\%} \left[ \sum_i \left[ \frac{\text{In}(\text{EF}_i)}{\text{SNV}_i} \right]^2 \right]^{\frac{1}{2}} \right)\]

ARR = airborne release rate.

EF = error factor (i.e., bounding value divided by nominal value).

ln(EF) = natural log of EF.

M = mass of material released.

MAR = material at risk.

RF = respirable fraction.

SNV = standard normal variable.

The aerosol concentration inside the MCO at the time of the release depends on prior MCO handling conditions. The powder in the MCO at rest could be ejected into the gas volume and suspended by the response of the underlying solid MCO and fuel substrate to vibration or jolting induced by impact or falling debris. According to DOE-HDBK-3010-94, the value of the ARF under such circumstances should exceed the value of the ARF for aerodynamic suspension alone but be less than the ARF for the free fall of powder. The powder undergoing vibration shock is bounced into the gas while subject to the same gas velocities as those for aerodynamic entrainment. Based on the discussion in DOE-HDBK-3010-94, a bounding (95th percentile) ARF of $1 \times 10^3$ and an RF of 1.0 were chosen for the suspension of powder-like surface contamination by shock vibration. A nominal (50th percentile) value of $4 \times 10^4$ was chosen for the ARF and a nominal value of 0.2 was chosen for the RF based on evaluation of the discussion in DOE-HDBK-3010-94. The pressure in the MCO at the start of the blowdown determines the fraction of the suspended particulate that is released. The range in initial pressure varies from 1.50 atm (corresponding to the helium fill pressure of 22 lb/in\(^2\) absolute at the CVDF) to a maximum pressure of 5.2 atm (as defined in the Technical Databook [HNF-SD-SNF-TI-015]).
To allow for some additional margin in the calculation, a pressure of 2.0 atm is considered
nominal (50th percentile) and corresponds to an LPF of 0.5, while a pressure of 6.0 atm is
considered bounding (95th percentile) and corresponds to an LPF of 0.83.

Unlike in a drop event, there is no clear mechanism identified in this accident to provide the
impact to suspend particulate within the MCO. However, normal handling of the MCO by the
MHM during transport from the storage tube to the sampling/weld station will produce some
vibration and jostling of the fuel and suspend some material. For the purposes of this analysis, it
is assumed that nominally 1% of the impact suspension concentration exists within the MCO at
the start of sampling. Therefore a value of 1% is assumed for the 50th percentile. In addition, a
value of 10% is assumed for the 95th percentile.

Using the methodology described in Section A3.4.1.3 and the bounding and nominal values
identified above, the bounding (95th percentile) value for the material released by impact is
calculated to be $2.7 \times 10^{-2}$ g, as shown in Table A3-14.

The bounding source term for the gaseous release is $2.7 \times 10^{-2}$ g, which is the sum of
$2.0 \times 10^{-4}$ g from the aerodynamic entrainment of particulate and $2.7 \times 10^{-2}$ g from vibration and
shock.

A3.4.2.2.3 Consequence Analysis. The radiological dose is calculated using the dose
calculation equation and data from Section 3.4.1 of the SNF Project FSAR.

The dose to the onsite receptor is calculated as follows:

$$D_{on site} = M \times \frac{X}{Q'} \times BR \times UD \times LPF_{building}$$

$$= (0.027 \text{ g U})(1.14 \times 10^{-2} \text{ s/m}^3)(3.33 \times 10^{-4} \text{ m}^3/\text{s})(4.38 \times 10^5 \text{ rem/g U})(1.0)$$

$$= 4.5 \times 10^{-2} \text{ rem (4.5 \times 10^{-4} Sv)}.$$
Table A3-14. Initial Suspended Material Source Term for the Gaseous Release from the Multi-Canister Overpack.

Note: The 1.645 is the standard normal variable corresponding to the 95% upper confidence limit. For the 99% upper confidence limit, the corresponding value is 2.326.

\[
\text{LPF}_{MCO} = \frac{(\text{MCO pressure} - 1 \text{ atm})}{(\text{MCO pressure})}.
\]

At a nominal MCO pressure of 2.0 atm, the \( \text{LPF}_{MCO} \) is 0.5, and at a bounding MCO pressure of 6.0 atm, the \( \text{LPF}_{MCO} \) is 0.83.

\[\text{ARF}_{\text{overall}} = \exp\left(\text{SNV}_{95\%} \left( \sum_i \left[ \frac{\ln\left[E\left(E_{i}\right)\right]}{\text{SNV}_{i}} \right]^2 \right)^{1/2}\right)\]

ARF = airborne release fraction.
EF = error factor (i.e., bounding value divided by nominal value).
\( \ln(EF) \) = natural log of EF.
LPF = leak path factor.
M = mass of material released.
MAR = material at risk.
MCO = multi-canister overpack.
RF = respirable fraction.
SNV = standard normal variable.

The actual duration of the release is expected to be less than 1 hour for all receptors, therefore the applied \( \chi/Q \) value is conservatively chosen for a 1-hour duration. The estimated bounding doses to receptors at several locations have been calculated and the results summarized in Table A3-15.
### A3.4.2.2.4 Comparison to Guidelines

The annual frequency of a gaseous release from the sampling system is estimated to be the sum of the frequency of a leak from the MCO sampling system pressure boundary configuration that exists during sampling. This includes (1) a leak resulting from failure to properly seal the MCO valve operator at the sampling/weld station, (2) leaks from the process line inside the sample hood, and (3) leaks from the process line outside the sample hood, which includes the piping in the sample cart. The number of MCOs processed per year, the probability of an operator error in properly installing the MCO valve operator, and the chance of a sampling line failure due to internal or external forces (SNF-4042) combine to place the annual frequency of this event into the anticipated category.

The unmitigated radiological dose to the onsite worker from the gaseous release accident is calculated to be less than the onsite risk evaluation guidelines for anticipated events and, therefore, no additional mitigative or preventive features are required.

The dominant defense-in-depth features of the CSB design to reduce doses associated with sampling system leak accidents are the HEPA filter train of the sample hood air system, which discharges to the CSB general exhaust system, and the HEPA filter on the sample line located on the sample hood. These filters will mitigate releases associated with breaches of the sample line inside and outside of the sample hood.

### A3.4.2.2.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls

The following safety SSCs and TSR controls are designated to mitigate the dose consequences of the bounding gaseous release accidents:

#### G1. Gaseous Release during MCO Sampling Operations

The release of MCO gases during the MCO sampling operation is due to a leak from the sampling system. Such a leak could result from operator error, the drop of objects onto the sampling/weld station, or the
sampling/weld station gantry crane, the MHM, or some other equipment moving horizontally into the sampling/weld station components and causing a shear of the piping or otherwise failing the sampling system pressure boundary. No specific safety features and controls are required to prevent or mitigate this event.

G2. Gaseous Release from Overpressurization. The release of MCO gases resulting from overpressurization of the MCO is caused by the inert gas system during reinerting of a monitored MCO after sampling. This accident is initiated by failure of the pressure regulator on the helium supply system while an MCO is in the sampling/weld station undergoing the MCO helium backfill operation. The following is the specific safety feature that prevents or mitigates this event:

- Safety-significant SSCs
  - Pressure relief device (rupture disk) — The rupture disk is provided to prevent releases from the sampling system when sampling the MCO. This pressure safety device will maintain pressure to less than design value (150 lb/in² gauge) when sampling the MCO.

In addition, the maintenance of gas cylinders is assumed to be controlled by the site/project maintenance program. This program will verify that the gas cylinders have cylinder valves that prevent excessive gas flow from the cylinders. As such, a TSR is not required.

The SSCs, controls, and defense-in-depth features designated to mitigate gaseous release accidents are summarized in Table A3-16. NRC important-to-safety category SSCs and defense-in-depth features also are included for each specific accident in Table 3-16.

G3. Gas Cylinder Impacts. A high-pressure gas cylinder is not expected to be propelled and impact the sample system and shear the piping because the gas cylinders used for MCO sampling and welding operations will be located outside the CSB. The only bottles available to create this hazard are those on the tube vent and purge cart and those brought into the facility for maintenance welding activities. Accidentally shearing the valve body from the cylinder, by dropping the cylinder or crashing something into the cylinder, would not result in the cylinder causing serious propulsion effects because the cylinder valve butt that remains in the neck of the bottle severely limits the flow rate of gas from the cylinder. Limiting the flow rate limits the thrust generated by the escaping gas such that the cylinder will not accelerate to a dangerous velocity. Removal of the valve in the neck of the pressurized cylinder is an extremely difficult task that could not be accomplished by one person without special equipment. The following is the specific safety feature that prevents or mitigates this event:

- Design feature
  - Maximum hole diameter in the butt of the valve on all gas cylinders — Limits the thrust produced by escaping gas to an amount that cannot accelerate the cylinder to dangerous velocity; this feature protects against cylinder propulsion caused by accidentally breaking off the cylinder valve.

Note: Defense-in-depth features and safety-significant defense-in-depth features are not designated as NRC ITS.

*bSSCs are classified per their function in mitigating or preventing specific accidents. SSCs may have other classifications based on their functions in other events.

*There is only an impact to the MCO vessel in this accident — no offsite dose greater than 5 rem occurs and there is no criticality problem.

CSB = Canister Storage Building.
HEPA = high-efficiency particulate air (filter).
ITS = important to safety.
MCO = multi-canister overpack.
MHM = multi-canister overpack handling machine.
NA = not applicable to ITS category classification.
NRC = U.S. Nuclear Regulatory Commission.
SSC = structure, system, and component.
TSR = technical safety requirement.
A3.4.2.3 Multi-Canister Overpack Internal Hydrogen Deflagration. Three design basis events could result in the formation of flammable mixtures of hydrogen and oxygen within an MCO, which, if ignited, could result in a deflagration. The events are (1) radiolytic decomposition of the oxygen containing compounds, (2) introducing oxygen into the MCO during charging, and (3) ingress of oxygen following an MCO breach. The first two events, radiolytic decomposition and introduction of oxygen, have been evaluated further. The third event, ingress of oxygen, is similar to the second event; however, when comparing accident frequencies and consequences, the introduction of oxygen during charging is considered to present a substantially greater risk.

A3.4.2.3.1 Scenario Development. The following paragraphs describes the scenario development for each of the cases evaluated.

Radiolytic Decomposition. This scenario involves the radiolytic decomposition of the aluminum hydroxide, aluminum and iron hydrates, free water and water bound as hydrates in the uranium oxide and the potential for flammable mixtures of hydrogen and oxygen in an MCO. Of particular interest is the concentration of oxygen within the MCO. The detailed analysis of the potential for a flammable mixture within the MCO, and the minimum concentration of oxygen required, is contained in HNF-SD-SNF-TI-040.

To determine the potential for a flammable mixture within an MCO (i.e., oxygen concentration exceeding 4% [HNF-SNF-SD-TI-040]) two mechanisms were evaluated. The mechanisms included thermal decomposition, and radiolysis of aluminum hydroxide and uranium oxide hydrates. HNF-SD-SNF-TI-040 concludes that the aluminum hydroxide will only decompose by radiolysis based on CSB storage conditions (temperature). Over a 40-year period, only 4% of the aluminum hydroxide cladding material will decompose and about 10% of the particulate will decompose because of radiolysis. Uranium oxide hydrates will decompose thermally; however, the presence of water vapor limits thermal decomposition. The analysis contained in HNF-SNF-SD-TI-040 considers only radiolytic decomposition because radiolytic decomposition will generate more moles of gas (including oxygen) per mole of solid. Approximately 50% of the uranium oxide hydrate will decompose by radiolysis in a 40-year period.

Using the reference g(O2) values from HNF-SD-SNF-TI-015, the MCO oxygen concentration in the MCO remains below 4% after 40 years. The analysis of a zero scrap basket configuration (i.e., low reactive area) at various MCO power and water contents with nominal helium backfill does not result in oxygen concentrations above 4% over 40 years. All one and two scrap basket configurations also do not exceed 4% oxygen concentration over a 40-year period.

The conclusions reached in HNF-SNF-SD-TI-040 regarding radiolytic decomposition and the production of oxygen have been validated through literature reviews. From the data reviewed, approximately 50% of the uranium hydrate is expected to decompose over the 40-year storage time. Much of this decomposition results from alpha and beta radiolysis, which has been
projected to produce stoichiometric evolution of oxygen. The overall stoichiometry of radiolysis
does not produce a large increase in oxygen that must be incorporated in the crystal structure.
Therefore, it is concluded that the nonstoichiometric G-values for hydrated oxides can be
sustained throughout the 40-year storage period (SNF-3328).

The potential for a flammable mixture (i.e., oxygen concentration greater than 4%) using
reference \( g(O_2) \) values is considered beyond extremely unlikely because of the ability of the solid
materials to incorporate excess oxygen. Thus an internal deflagration and possible detonation
during the 40-year interim storage period are also considered beyond extremely unlikely.

Introduction of Oxygen into a Multi-Canister Overpack. This accident involves
insertion of inert gas contaminated with oxygen into an MCO being sampled. The cover cap
welding on selected MCOs will be delayed to allow for gas sampling. An MCO to be sampled is
moved to the sampling/weld station and a sample hood is placed over the MCO. Connections are
made to the MCO sample port and MCO gas is collected using the positive pressure of the MCO.
Inert gas is added to raise the pressure if necessary. Flammable mixtures of hydrogen and oxygen
can form in the MCO if the inert gas is contaminated with oxygen.

The following process conditions were inputs to the accident analysis:

- The MCO contains the maximum hydrogen inventory corresponding to reaction of all
  200 g of free water and half of the water bound as hydrates. The radiolytic
decomposition of water and aluminum hydroxide adds very little gas during the first
year after sealing and is not considered. The bounding MCO, which contains the
maximum hydrogen inventory, contains two scrap baskets and three fuel baskets.

- The pressure in the MCO after hydrogen combustion can be estimated from the
  adiabatic flame temperature of the reacting gases. Basically, an assumption is made
that 100% of the oxygen reacts to form water vapor. The heat of formation and the
specific heat capacity of the post-combustion gases determine the final temperature of
the gas mixture. The ideal gas law is then used to estimate the pressure due to the
combustion.

- An MCO helium inerting pressure of 1.1 atm is used in the analysis to maximize the
hydrogen concentration. The helium pressure is normally about 1.5 atm or more. A
contaminated helium supply at either pressure would lead to flammable mixtures.

The unmitigated scenario is brought to a stable state by allowing the MCO to depressurize
to atmospheric pressure. If the MCO is inside the cask, MHM, or the storage tube, these also are
allowed to depressurize to atmospheric pressure. The MCO is handled within recovery
operations under operational related procedures, with the preferred approach being to move the
MCO to the overpack storage tube for long-term observation and storage.
Mixtures of hydrogen in air are flammable in the range of 4% to 75% hydrogen by volume. The minimum oxygen concentration required for combustion is 4%. According to NUREG/CR-2726, *Light Water Reactor Hydrogen Manual*, high-pressure shock waves can be produced if the hydrogen concentration is between 18 vol% and 58 vol% in air.

The oxygen concentration in the MCO at the time of the accident depends on the oxygen concentration in the CSB helium system and on the amount of helium and hydrogen in the MCO before sampling. The helium inventory in the MCO can be estimated from the ideal gas law and the filling pressure at the CVDF, assuming a conservatively low MCO gas temperature due to the operation of the tempered water system.

Over a period of weeks, the available water in the MCO would react with uranium metal and uranium hydride to form uranium oxide and hydrogen provided there is no oxygen in the MCO. This assumption is realistic because oxygen reacts with uranium metal more readily than water. The water inventory has two parts: (1) the 200 g of free water found in cracks and crevices and (2) the water contained as a hydrate in the oxide films and aluminum hydroxide. For an MCO with two scrap baskets and three fuel baskets, the maximum hydrate water is 1,190 g (HNF-SD-SNF-TI-015). Because the uranium hydrate water loss is temperature dependent (HNF-1523 [Rev. 1]), it is assumed that half of this hydrate is available to become vapor and reacts with the uranium fuel to form hydrogen (see discussion and table in Section A3.4.2.5.1). The total water available to form hydrogen for temperatures less than 100 °C is 800 g, leading to the production of 124 g of hydrogen. This includes the production of hydrogen from hydride decomposition. To maximize the hydrogen concentration, the helium fill pressure at the CVDF is assumed to be 1.1 atm instead of 1.5 atm. This yields a concentration of 73% hydrogen and 27% helium in the MCO on receipt at the CSB. The MCO gas temperature at the CSB is assumed to be 50 °C (122 °F).

When the MCO is moved from the storage tube to the sampling station for analysis, a sampling hood is placed over it. The hood is connected to a HEPA-filtered exhaust system. A sampling line is connected to the MCO, and a gas sample is collected using the pressure of the MCO. If the MCO were inadvertently depressurized, a recharge sequence would be initiated by the operator to add helium and restore the MCO pressure.

When the MCO is depressurized, the relative amounts of helium and hydrogen remain unchanged. The gas mixture is still 27% helium and 73% hydrogen. At a pressure of 1.0 atm and a temperature of 50 °C (122 °F), the MCO inventory is 18.9 gmoles total, or 13.9 gmoles hydrogen and 5.0 gmoles helium.

The action of adding a helium-oxygen mixture to the MCO increases the pressure in the MCO to 1.27 atm. The amount of gas added is calculated from the ideal gas law to be 5.1 gmoles. The final total number of moles of gas in the MCO is 24.0 gmoles. The hydrogen concentration in the MCO is diluted from 73% to 58%. The oxygen concentration in the MCO depends on the oxygen concentration in the added gas. From the ideal gas law, the final oxygen concentration in the MCO is 21.3% of its concentration in the added helium-oxygen mixture.
If the added mixture were 60% oxygen, then the final oxygen concentration in the MCO would be 12.8%.

For a flammable mixture to occur at atmospheric pressure, the oxygen concentration must exceed 4% in the MCO. Thus, the contaminated inert gas has an oxygen concentration greater than 23%. For a mixture in the MCO to support a detonation with shock waves, the oxygen concentration in the MCO must be at least 9%. The flammable mixture in the MCO does not support damaging shock waves until the oxygen concentration in the added gas exceeds 42%.

If the contaminated inert gas added to the MCO is 60% oxygen, then the final composition of the MCO gas is 7.1 gmoles helium, 13.9 gmoles hydrogen, and 3.0 gmoles oxygen. The MCO pressure at this time is 1.27 atm. The MCO gas temperature is 50 °C (122 °F). The complete combustion of this mixture yields an energy release of 355,000 calories with a final theoretical temperature of the gas mixture of about 2,790 °C (5,054 °F). The corresponding pressure in the MCO is 10.5 atm. The oxygen concentration of the contaminated gas is high enough that there is a potential for detonation shock waves to form. The pressure from a detonation could be as much as two times higher in localized areas than the pressure from the burn alone. Before welding, the MCO rated pressure is 150 lb/in² (SNF-3328); the MCO is not expected to be damaged by the worst-case deflagration. An MCO with mechanical closure is stable to an internal loading of 340 lb/in², and after welding, rated pressure is 450 lb/in² (HNF-SD-SNF-SARR-005). In addition, the sample line and connection are expected to withstand these pressures. However, the sample line is assumed to fail and release gas and particulate from the MCO into the environment.

A3.4.2.3.2 Source Term Analysis. For the internal hydrogen deflagration, the MAR (particulate available for release) depends on the amount of particulate generated between the time the fuel is washed at the K Basins and the time of the accident. The Technical Databook (HNF-SD-SNF-TI-015) provides a bounding estimate of the MAR for any time during the 40-year life of the facility. The Technical Databook (HNF-SD-SNF-TI-015) identifies the safety basis or bounding value for the mass of particulate as 34.0 kg UO₂, which contains 30.0 kg of uranium. Because of the conservative methodology used to calculate the bounding value, 30 kg is considered representative of the 99th percentile. The Technical Databook also identifies a design or nominal value of 2.1 kg UO₂, which contains 1.85 kg of uranium.

The quantity of particulate actually released during an accident depends on the initial aerosol concentration, which includes that generated by accident forces, and subsequent particulate entrainment. This blowdown scenario would feature films of particles rather than deep powder beds. In such a situation, there would still be gas flow through the bed during depressurization, but the local velocity is simply not sufficient for entrainment (IDCOR 1984). The pressurized powder venting source term is not applicable, and a source term based upon aerodynamic entrainment, as described in Section A3.4.2.1.2, is used.

Based on the data reported in DOE-HDBK-3010-94, a bounding (95th percentile) ARR of $4 \times 10^5$/h and an RF of 1.0 were selected as bounding for the blowdown. The contents of the MCO are intact fuel elements tightly packed in fuel baskets and pieces of fuel elements housed in...
the scrap baskets. Particulate matter swept upward by streams of flowing gas within the MCO
must take a tortuous path through the MCO and through the MCO shield plug to exit the MCO.
For shielded powder, where the aerodynamic stresses are reduced by debris or exposure to static
conditions, DOE-HDBK-3010-94 recommends an ARR of $4 \times 10^6$/h and an RF of 0.2 for
powder under debris. These values were selected as nominal (50th percentile).

The initial pressure in the MCO at the start of the blowdown determines the fraction of the
suspended particulate that is released. The range of pressure for an internal hydrogen deflagration
varies with the composition of the initial flammable mixture. According to NUREG/CR-2726, the
range of pressure from a hydrogen burn would be from 3 to 12 times the initial pressure. For the
calculation of the source term, 5 atm is assumed to be the nominal pressure (50th percentile) with
12 atm used as the 95th percentile pressure. This results in a nominal (50th percentile) LPF of 0.8
for the MCO and a 95th percentile LPF of 0.92.

The pressurized release from the MCO following the internal deflagration would flow most
likely through a leak path with a flow area greater than or equal to the flow area through an MCO
shield plug port. The duration of the blowdown depends on the flow area of the leak and the
resultant pressure following the burn. The MCO depressurizes to atmospheric pressure in less
than 1 minute, even for an MCO pressure of about 150 lb/in$^2$ gauge and a 0.25-in. hole. The
MCO depressurizes in a much shorter time for lower pressures and larger leak paths. For the
calculation of the source term, a nominal (50th percentile) value of 10 seconds and a bounding
(95th percentile) time of 60 seconds were selected.

The material released by aerosol entrainment can be calculated using the methodology
described in Section A3.4.1.3 and the bounding and nominal values identified above. The
bounding (95th percentile) value for the material released by aerodynamic entrainment is
$2.0 \times 10^3$ g, as shown in Table A3-17.

The blast and shock from the hydrogen deflagration would suspend some of the particulate
within the MCO. The powder at rest in the MCO could be ejected into the gas volume by the
response of the underlying solid MCO and fuel substrate to the vibration and jolting induced by
deflagration. According to DOE-HDBK-3010-94, the value of the ARF under such
circumstances should exceed the value of the ARF for aerodynamic suspension alone but be less
than the value of the ARF for the free-fall of powder. The powder undergoing vibration shock is
bounced into the gas while subject to the same gas velocities as those for aerodynamic
entrainment. Based on the discussion in DOE-HDBK-3010-94, a bounding (95th percentile) ARF
of $1 \times 10^3$ and an RF of 1.0 were chosen for the suspension of powder-like surface contamination
by blast and shock vibration. A nominal (50th percentile) value of $4 \times 10^4$ was chosen for the
ARF and a nominal (50th percentile) value of 0.2 was chosen for the RF based on the evaluation
of the discussion in DOE-HDBK-3010-94.

\(^d\)Provided for information only.

A3.4.2.3.4 Comparison to Guidelines. The unmitigated radiological offsite dose for this event is below offsite release limits, and the unmitigated onsite dose does not exceed onsite evaluation guidelines for an unlikely event.

A3.4.2.3.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. No safety-class SSCs are required to prevent the hydrogen deflagration DBA or to mitigate its dose consequences. Under normal operating conditions, there is no anticipated internal accumulation of flammable mixtures of hydrogen and oxygen.

11. Oxygen Buildup from Radiolysis. A hydrogen deflagration (SA-J-06a, OA-J-06a, WS-J-06a) during cask handling follows from excessive gas buildup in the MCO caused by radiolysis. It has been shown that the bounding case MCO will not be able to generate flammable gas mixtures even after 40 years of storage. Somewhat larger inventories of aluminum hydroxide
remaining in the MCO after washing at K Basins could lead to flammable mixtures after many
years of storage. For short durations (i.e., prior to welding), the MCO design pressure
(150 lb/in²) will not be exceeded in the worst-case deflagration or gas buildup. The MCO with a
mechanical seal will not fail (i.e., is stable) up to a pressure of 340 lb/in²
(HNF-SD-SNF-SARR-005). During long-term storage, combustion of these mixtures will not
exceed the 450 lb/in² design pressure of the welded MCO. To exceed this pressure limit, the key
interface performance assumptions identified in Section A3.4.3.1 must be exceeded. Exceeding
these key assumptions is discussed in Section A3.4.1. The following control prevents this event:

- TSR

  - Verify the proper processing steps and conditions have been carried out at
    CVDF and K Basins before accepting an MCO at CSB.

12. **Oxygen Used as a Purge Gas.** Good operating practices during the sampling process
will not significantly depressurize the MCO. As little sample gas as possible should be taken from
the MCO during sampling. Using a sampling operation that minimizes the need to refill the MCO
with inert gas reduces the frequency with which this accident could occur. This sampling
operation should be considered defense in depth for prevention of flammable gas mixtures within
the MCO at the sampling station.

The SSCs and TSR controls designated to protect the assumptions of the analysis for MCO
internal hydrogen deflagration accidents are summarized in Table A3-20. Defense-in-depth
features also are included in Table A3-20.

</tbody>
</table>

Note: Defense-in-depth features and safety-significant defense-in-depth features are not designated as NRC ITS.

*SSCs are classified per their function in mitigating or preventing specific accidents. SSCs may have other classifications based on their functions in other events.

CSB = Canister Storage Building.
CVDF = Cold Vacuum Drying Facility.
ITS = important to safety.
MCO = multi-canister overpack.
NRC = U.S. Nuclear Regulatory Commission.
SSC = structure, system, and component.
TSR = technical safety requirement.
A3.4.2.4 Multi-Canister Overpack External Hydrogen Deflagration. Based on the transport
time restrictions identified in HNF-SD-TP-SARP-017, insufficient pressure will be generated
during the transport of the MCO from the CVDF to the CSB to fail the mechanical seal and
release gases to the internals of the shipping cask. In addition, HNF-SD-TP-SARP-017 requires
the cask to be vented to the CSB facility if the cask–MCO is stored at the CSB for an extended
period. Therefore, the event of concern is a hydrogen release during sampling activities because
of (1) releases from an MCO during sampling activities and (2) an inadequately sealed MCO
shipped from the CVDF to the CSB.

Particulate releases from an MCO during sampling activities have been previously
evaluated (see Section A3.4.2.3). However, the release of hydrogen during sampling activities
assumes that a gaseous release (primarily hydrogen) occurs and that the hydrogen mixes with the
oxygen in the CSB facility creating a flammable mixture that is ignited. External hydrogen events
in the MHM and the storage tube have the same risk ranking as the external hydrogen
deflagration at the sampling/weld station (HNF-SD-SNF-HIE-001), but the deflagration at the
sampling/weld station was chosen as the DBA because it has a higher potential to impact worker
safety than an external hydrogen event in the MHM or storage tube. Storage of the MCO in a
cask at the CSB is discussed in SNF-3328, including consideration of a hydrogen deflagration.

A3.4.2.4.1 Scenario Development. The DBA scenario identified is the release of
flammable gases from an MCO during sampling activities. The cover cap welding on selected
MCOs will be delayed for approximately one year to allow for gas sampling at the CSB. An
MCO to be sampled is moved to the sampling/weld station, and a sample hood is placed over the
MCO. Connections are made to the MCO sample port, and MCO gas is collected using the
positive pressure of the MCO. If the connection to the MCO fails and discharges MCO gas into
the sample hood, a flammable mixture of hydrogen and air could be formed in the hood.
Personnel are normally near the hood during this time, and it is possible that a deflagration in the
sample hood would cause a serious injury to the nearby operator opening the MCO port valve. In
addition, the deflagration in the sample hood causes additional damage to the sample line and
connector, so a gaseous release of particulate from the MCO also may occur.

The following planned process conditions and assumptions are used in the accident analysis
calculations.

- The MCO contains the maximum hydrogen inventory corresponding to reaction of
  all the residual free water and half of the water bound as hydrates. The radiolytic
decomposition of water and aluminum hydroxide adds very little gas and will not be
  considered. The MCO yielding the maximum hydrogen inventory contains two
  scrap baskets and three fuel baskets.

- The approximate volume of the sample hood is 600 L. The dimensions and volume
  of the sample hood are not critical to the accident analysis conclusions. Larger or
  smaller volumes can be used to give the same flammable concentration by adjusting
  the assumed MCO leak rate.
The sample hood exhaust heating, ventilation, and air conditioning (HVAC) system is operating normally, but at its lowest flow rate, 100 ft³/min. The pressure in the MCO is relieved at the rate of 42 ft³/min due to a failure of the sample line connection.

The bounding pressure in the sample hood can be estimated from the adiabatic flame temperature of the reacting gases. Basically, one assumes 100% of the hydrogen reacts to form water vapor. The heat of formation and the heat capacity of the post-combustion gases determine the final temperature of the gas mixture. The ideal gas law is then used to estimate the pressure due to the combustion.

The MCO helium inerting pressure before it is sealed at the CVDF is 1.5 atm.

An ignition source is present in the sample hood and causes a deflagration of the hydrogen, helium, and air mixture in the hood.

The sample line connection is not properly made, so MCO gases leak from the connection and the resulting deflagration leads to a pressurized release of gas and particulate in the MCO.

The particulate not removed from the fuel by washing at the K Basins will not be dislodged and released by the pressurized gas release.

The unmitigated scenario is brought to a stable state by allowing the MCO to vent any gas continuing to be generated. If the MCO is inside the cask, MHM, or the storage tube, these also are allowed to continue venting. A confinement service tent is used to cover the MCO and its vehicle, if appropriate, until the continued gas generation subsides to low levels a few hours after the event. Any contamination is cleaned consistent with radiation control procedures. The MCO is handled within recovery operations under emergency response procedures, with the preferred approach being to move the MCO to the overpack storage tube for short-term observation and storage.

The analysis of the hydrogen deflagration at the sampling/weld station focuses on the hydrogen concentration in the sample hood. Mixtures of hydrogen in air are flammable in the range of 4% to 75% hydrogen by volume. High-pressure shock waves can be produced if the hydrogen concentration is between 18 vol% and 58 vol% in air (NUREG/CR-2726).

The hydrogen concentration in the sample hood at the time of the accident depends on the hydrogen concentration in the MCO, the sample line leak rate, and the hood ventilation rate. The helium inventory in the MCO can be estimated from the ideal gas law and the filling pressure at the CVDF, assuming a conservatively low MCO gas temperature due to the operation of the tempered water system.
Over a period of weeks, the available water in the MCO reacts with uranium metal and uranium hydride to form uranium oxide and hydrogen, provided there is no oxygen in the MCO. Typical exposed fuel surface areas are large enough to keep the oxygen content low. The bounding water inventory has two parts: (1) the 200 g of free water found in cracks and crevices and (2) the water contained in the oxide films as a hydrate and aluminum hydroxide. For an MCO with two scrap baskets and three fuel baskets, the maximum hydrate water is 1,190 g (HNF-SD-SNF-TI-015). Because the uranium hydrate can lose water rapidly (HNF-1523 [Rev. 1]), it will be assumed that half of this hydrate is available to become vapor and will react with the uranium fuel to form hydrogen. The total water available to form hydrogen at temperatures of less than 100 °C is 800 g, leading to the production of 124 g of hydrogen.

At the time of the accident, the gas mixture in the MCO is 67% hydrogen and 33% helium (initial condition assuming a fill pressure of 1.5 atm at the CVDF). At an MCO gas temperature of 75 °C (167 °F), the pressure of the helium and hydrogen mixture in the MCO is 63 lb/in² gauge.

When the MCO is moved from the storage tube to the sampling/weld station for analysis, a sampling hood is placed over it. The hood is connected to a HEPA-filtered exhaust system, and the flow rate through the hood is between 100 and 250 ft³/min. A sampling line is connected to the MCO with a port valve operator, and a gas sample is collected using the internal gas pressure of the MCO. If the sample connection fails or the valve operator is not fully installed, hydrogen and helium in the MCO would leak into the sample hood and its exhaust system.

Assuming a sample line failure occurs and the MCO discharges gas into the sample hood at the rate of 42 ft³/min, the hydrogen concentration quickly becomes flammable inside the sampling hood. Assuming the MCO gas mixes thoroughly with the air in the hood, only 2 seconds are needed for the hydrogen concentration to exceed the 4% hydrogen lower flammability limit. The peak concentration is 17% hydrogen after 27 seconds.

If the hydrogen concentration in the sample hood is 10% at the time of the deflagration, the sample hood would contain 4.9 g hydrogen. The adiabatic flame temperature would be 1,370 K, which leads to a maximum pressure of 49 lb/in² gauge. This pressure is large enough to damage the hood and injure any personnel nearby. The potential for significant personnel injury exists because an operator is normally located in front of the sample hood when opening and closing the MCO port valve.

A3.4.2.4.2 Source Term Analysis. In addition to causing personnel injury, the hydrogen deflagration in the sample hood can damage the sample line, resulting in depressurization of the MCO. Radioactive contamination in the MCO and the sample hood HEPA filter can be released to the environment. The primary sources of radioactivity are (1) the HEPA filter near the sample hood, (2) the particulate matter suspended inside the MCO by the deflagration, and (3) the entrained particulate matter resuspended and carried out with the gases leaving the MCO.
The MAR (particulate available for release) depends on the amount of particulate generated between the time the fuel is washed at the K Basins and the time of the accident. The Technical Databook (HNF-SD-SNF-TI-015) provides a bounding estimate of the MAR for any time during the 40-year life of the facility. The Technical Databook (HNF-SD-SNF-TI-015) identifies the safety basis or bounding value for the mass of particulate as 34.0 kg UO₂, which contains 30.0 kg of uranium. Because of the conservative methodology used to calculate the bounding value, 30 kg is considered representative of the 99th percentile. The Technical Databook (HNF-SD-SNF-TI-015) also identifies a design or nominal (50th percentile) value of 2.1 kg UO₂, which contains 1.85 kg of uranium.

In this accident, the MCO would blow down through the damaged sample line to relieve the pressure inside the MCO. However, such a blowdown scenario would feature films of particles rather than deep powder beds. In such a situation, there would still be gas flow through the bed during depressurization, but the local velocity is simply not sufficient for entrainment (IDCOR 1984). The pressurized powder venting source term is not applicable, and a source term based upon aerodynamic entrainment, as described in Section A3.4.2.1.2, is used.

Based on the data reported in DOE-HDBK-3010-94, a bounding (95th percentile) ARR of $4 \times 10^9$/h and an RF of 1.0 were selected. The contents of the MCO are intact fuel elements tightly packed in fuel baskets and pieces of fuel elements housed in the scrap baskets. Particulate matter swept upward by streams of flowing gas within the MCO must take a tortuous path through the MCO and through the MCO shield plug to exit the MCO. For shielded powder, where the aerodynamic stresses are reduced by debris or exposure to static conditions, DOE-HDBK-3010-94 recommends an ARR of $4 \times 10^{-6}$/h and an RF of 0.2 for powder under debris. These values were selected as nominal (50th percentile).

The pressurized release from the MCO following the external deflagration would flow mostly likely through a leak path with a flow area greater than or equal to the flow area through an MCO shield plug port. The duration of the blowdown depends on the flow area of the leak and the resultant pressure following the burn. The MCO depressurizes to atmospheric pressure in less than 1 minute, even for an MCO pressure of about 150 lb/in² gauge and a 0.25-in. hole. The MCO depressurizes in a much shorter time for lower pressures and larger leak paths. For the calculation of the source term, a nominal (50th percentile) value of 10 seconds and a bounding (95th percentile) time of 60 seconds were selected.

The material released by aerosol entrainment can be calculated using the methodology described in Section A3.4.1.3 and the bounding and nominal values identified above. The bounding (95th percentile) value for the material released by aerodynamic entrainment is $2 \times 10^4$ g, as shown in Table A3-21.

$\text{RF} = \text{respirable fraction.}$

$\text{SNV} = \text{standard normal variable.}$

A blast and shock could suspend some of the particulate within the MCO. The powder at rest in the MCO could be ejected into the gas volume by the response of the underlying solid MCO and fuel substrate to the vibration and jolting induced by deflagration. According to DOE-HDBK-3010-94, the value of the ARF under such circumstances should exceed the value of the ARF for aerodynamic suspension alone but be less than the value of the ARF for the free-fall of powder. The powder undergoing vibration shock is bounced into the gas while subject to the same gas velocities as those for aerodynamic entrainment. Based on the discussion in DOE-HDBK-3010-94, a bounding (95th percentile) ARF of $1 \times 10^3$ and an RF of 1.0 were chosen for the suspension of powder-like surface contamination by blast and shock vibration. A nominal (50th percentile) value of $1 \times 10^4$ was chosen for the ARF and a nominal (50th percentile) value of 0.2 was chosen for the RF based on the evaluation of the discussion in DOE-HDBK-3010-94.

As in the case of the gaseous release event, there is no clear dominating mechanism identified in this accident to provide the shock and impact to suspend particulate within the MCO.
However, normal handling of the MCO by the MHM during transport from the storage tube to
the sampling/weld station will produce some vibration and jostling of the fuel and suspend some
material. For the purposes of this analysis, it is assumed that nominally 1% of the impact
suspension concentration exists within the MCO at the start of sampling. Therefore a value of 1%
is assumed for the 50th percentile. In addition, a value of 10% is assumed for the 95th percentile.
The initial pressure in the MCO at the start of the blowdown determines the fraction of the
suspended particulate that is released from the MCO. The range of MCO pressure for this
scenario varies from a nominal (50th percentile) pressure of 2.0 atm to a maximum pressure of
6.0 atm, which is assumed to be the 95th percentile pressure. These pressures equate to a
nominal (50th percentile) LPF of 0.5 for the MCO and a 95th percentile LPF of 0.83.

The material released by shock impact can be calculated using the methodology described
in Section A3.4.1.3 and the bounding and nominal values identified above. The bounding
(95th percentile) value for the material released by shock impact is $2.7 \times 10^{-2}$ g, as shown in
Table A3-22.

The external hydrogen deflagration also has the potential to damage the HEPA filters in the
sample line and sample hood exhaust system. For the HEPA filter blasts, the bounding release
fraction is 0.01 with an RF of 1.0 (DOE-HDBK-3010-94, Section 5.2.2.2). The canister HEPA
filter attached to the sample hood is assumed to contain 20 g of fuel (SNF-3328). The amount of
fuel released from the HEPA filter by the blast of the hydrogen deflagration is 0.2 g.

The bounding (95th percentile) source term for the external hydrogen deflagration is
$0.23$ g, which is the sum of $2.0 \times 10^{-2}$ g from vibration and shock and $2.0 \times 10^{-4}$ g from
aerodynamic entrainment, plus an additional 0.2 g from the damage to the HEPA filter.

**A3.4.2.4.3 Consequence Analysis.** The dose calculation equation and data from
Section 3.4.1 of the SNF Project FSAR are used to calculate the dose to the onsite receptor.

\[
D_{\text{onsite}} = (M_{\text{MCO}} + M_{\text{HEPA}}) \times \frac{\chi}{Q'} \times BR \times UD \times LPF_{\text{building}}
\]

\[
= (0.23 \text{ g U})(1.14 \times 10^{-2} \text{ s/m}^{3})(3.33 \times 10^{-4} \text{ m}^{3}/\text{s})(4.38 \times 10^{5} \text{ rem/g U})(1.0)
\]

\[
= 0.38 \text{ rem (3.8 } \times 10^{-3} \text{ Sv)} .
\]

where

- $D_{\text{onsite}}$ = committed effective dose equivalent (rem)
- $M$ = mass of respirable airborne material released (g U)
- $\chi/Q'$ = time-integrated atmospheric transport factor (s/m$^3$)
- $BR$ = breathing rate (m$^3$/s)
- $UD$ = dose per unit mass of uranium (rem/g U)
- $LPF_{\text{building}}$ = leak path factor from building.

A3.4.2.4.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. No safety-class SSCs are required to prevent hydrogen deflagration DBA accident (WS-L-11) outside of the MCO. Under normal operating conditions, there is no external accumulation of flammable concentrations of hydrogen.

E1. Sample Line Disconnection. The MCO leaves the CVDF with a leak rate less than \(10^{-5}\) cm\(^3\)/s and the sample line leakage also is very low. Under abnormal or accident conditions, safety-significant equipment is required in order to ensure flammable concentrations of hydrogen external to the MCO and CSB systems are precluded. To prevent the bounding external hydrogen deflagration in the sample hood, it is necessary to check the leak rate of the sample line before the MCO port valve is opened. The maximum allowable leak rate is based upon the bounding hydrogen concentration and air flow rate in the sample hood. If the air flow rate is greater than or equal to 5 ft\(^3\)/min in the sample hood and assuming a sample line leak rate up to 40 cm\(^3\)/s, the hydrogen concentration in the hood will not exceed 1%. The 5 ft\(^3\)/min flow rate represents an easily detected minimum, and the 40 cm\(^3\)/s is derived from it (SNF-3328). The following are the specific TSR controls that ensure worker safety:

- TSRs
  - Verify minimum air flow rate for hydrogen gas dilution (5 ft\(^3\)/min) in the hood exhaust for worker safety.

The TSR controls designated to prevent the MCO external hydrogen deflagration are summarized in Table A3-24. Defense-in-depth features also are included in Table A3-24.

<td></td>
</tr>
</tbody>
</table>
### E2. Hydrogen Leakage from MCO inside MHM

The hydrogen deflagration in the MHM (OA-J-06b) caused by hydrogen leakage from the MCO occurs during MCO handling. This accident scenario assumes that the MHM contains an MCO with a small leak (10,000 times the criteria). If the MHM is immobilized by a power failure or some other event and the ventilation system is off, the gas mixture in the MHM will become flammable in less than a day (SNF-3328). Combustion of this hydrogen mixture would at most release activity accumulated on the MHM HEPA filters into the environment. Using the bounding release factor for deflagrations on HEPA filters, the onsite dose guidelines are met if the HEPA filter loading is less than 20 g of SNF. Because the corresponding exposure rate near the filter exceeds 600 mR/h, ALARA considerations will ensure the filter loading is well below 20 g. The following specific control that prevent this event:

- **TSR**

  - Verify the proper processing steps and conditions have been carried out at CVDF and K Basins before accepting an MCO at CSB.

### E3. Hydrogen Leakage from MCO inside Cask

The cask–MCO is dropped while being removed from the transportation trailer. The cask is not damaged by this drop, but the MCO may be damaged if the cask falls more than 5 ft. It is assumed that the MCO is breached and loses pressure. The gas leaving the MCO contains considerable hydrogen, so a flammable mixture of

Note: Defense-in-depth features and safety-significant defense-in-depth features are not designated as NRC ITS.

**SSCs** are classified per their function in mitigating and/or preventing specific accidents. **SSCs** may have other classifications based on their functions in other events.

CSB = Canister Storage Building.
CVDF = Cold Vacuum Drying Facility.
HEPA = high-efficiency particulate air (filter).
HVAC = heating, ventilation, and air conditioning.
ITS = important to safety.
MCO = multi-canister overpack.
MHM = multi-canister overpack handling machine.
NA = not applicable to ITS category classification.
NRC = U.S. Nuclear Regulatory Commission.
SSC = structure, system, and component.
SNF = spent nuclear fuel.
TSR = technical safety requirement.
hydrogen, helium, and air forms in the space between the outside of the MCO and the inside of
the cask. This flammable mixture ignites, and the resulting pressure increase may breach the cask.

Calculations have been performed to determine the cask internal pressure following a
combustion event within the cask (SNF-3328). The resulting pressure (about 280 lb/in² gauge)
exceeds the design pressure (150 lb/in² gauge) of the cask. According to WMTS-ECAL-010,
Maximum Pressure Load Determination for MCO Cask, the cask-MCO could sustain a pressure
load up to 345 lb/in² gauge without losing confinement (WMTS-ECAL-010). Therefore, damage
to the cask from combustion is not expected. No additional safety features and controls are
needed to prevent or mitigate this event.

A3.4.2.5 Thermal Runaway Reactions inside the Multi-Canister Overpack. A thermal
runaway reaction is only possible in an MCO containing extremely high temperature fuel and
excessive amounts of water or oxygen. With increasing fuel temperature, the chemical reaction
rates increase and produce more gases (primarily hydrogen) and heat, which increases the
pressure inside the MCO. If pressure inside the MCO continues to increase to the point that the
MCO pressure boundary is challenged, the MCO could fail and release radioactive particulate and
hydrogen gas into the surrounding environment.

The calculations summarized in this subsection demonstrate that a thermal runaway fuel
reaction accident is not credible at the CSB provided the MCOs satisfy the dryness tests
(i.e., < 200 g water) (HNF-1851 [Rev. 1]) at the CVDF and if the aluminum hydroxide thermal
decomposition data based on an initial quantity of 9.47 kg (HNF-SD-SNF-TI-015) and
decomposition rate (SNF-3328) are maintained.

A3.4.2.5.1 Scenario Development. Two primary chemical reactions could lead to a
thermal runaway event in an MCO at the CSB:

T1 — Reaction of water with uranium fuel and uranium hydride (UH₃).
T2 — Reaction of oxygen with uranium fuel and uranium hydride.

T1 — Reaction of Water with Uranium Fuel and Uranium Hydride. The design
pressure of an MCO is 150 lb/in² gauge (HNF-SD-SNF-DR-003) before the cover cap is welded
in place. According to HNF-3312, MCO Monitoring Activity Description, and HNF-3354, MCO
Monitoring Issue Closure Package, a number (around six) of MCOs will be sampled and
monitored after arrival at the CSB. The MCOs reserved for sampling could have time to
pressurize before the MCO cover cap is welded in place. Before welding, an MCO with
mechanical closure is stable to an internal loading of 340 lb/in² (HNF-SD-SNF-SARR-005).
After welding rated pressure is 450 lb/in².

Each MCO is pressurized to approximately 1.5 atm with helium before leaving the CVDF
(SNF-2356). The average temperature of this helium is conservatively assumed to be 25 °C
because the MCO skin is cooled to 25 °C or lower at the CVDF before being shipped to the CSB
(the actual gas and fuel temperatures will be higher). Using the ideal gas law, the initial helium
inventory in an MCO is estimated to be about 33 gmoles (SNF-3328). The number of moles of
gas required to increase the MCO pressure to 150 lb/in² gauge and to 450 lb/in² gauge can be
computed from the ideal gas law. For an MCO gas temperature of 150 °C, which is greater than
the bounding value of 125 °C (HNF-SD-SNF-TI-015), 173 moles of gas would have to be
present in the MCO to achieve a pressure of 150 lb/in² gauge.

At a rate dependent on temperature and steam pressure, water (liquid or vapor) reacts with
uranium to form uranium dioxide particulate and hydrogen gas, liberating heat in the process.
Water also reacts with uranium hydride (UH₃) to form uranium dioxide and hydrogen, again
liberating heat during the reaction. About 33 moles of helium are contained in an MCO at the
time of arrival at the CSB. An additional 140 moles of additional gases would need to be created
to reach 150 lb/in² gauge for an MCO gas temperature of 150 °C.

The amount of water needed to generate this additional quantity of hydrogen depends on
whether uranium or uranium hydride is reacting. Table A3-25 summarizes the total free water
required to react in order for the MCO to reach pressures of 150 lb/in² and 450 lb/in² gauge.

Table A3-25. Water Mass Required to Pressurize Multi-Canister
Overpack by Chemical Reaction.

*Weighted combination based on bounding uranium hydride inventory and reaction surface area
from HNF-SD-SNF-TI-015, 1998, Spent Nuclear Fuel Project Technical Databook, Rev. 6, Fluor Daniel
Hanford, Incorporated, Richland, Washington.

After successful processing at the CVDF, the bounding inventory of free water in an MCO
received at the CSB is 200 g. The bounding MCO is assumed to be dried at the CVDF, with less
than 200 g of free water remaining in cracks after the dryness tests at the CVDF (HNF-1851
[Rev. 1], HNF-SD-SNF-TI-015). In addition to the 200 g of free water, there is a bounding value
of about 1.19 kg of water in the uranium hydrate that is part of the uranium oxide particulate
matter (HNF-1523 [Rev. 1], HNF-SD-SNF-TI-015) for an MCO with two scrap baskets and
three fuel baskets. However, according to HNF-SD-SNF-CN-023, Thermal Analysis of Cold
Vacuum Drying of Spent Nuclear Fuel, this water would not be initially available for hydrogen
gas-producing reactions, and some of the hydrate water is expected to be removed at the CVDF.
The bounding water content MCO is one with two scrap baskets and three fuel baskets with fuel from aluminum canisters at the K Basins. For this MCO, up to 3.32 kg of water is contributed by both the bounding quantity of aluminum hydroxide, Al(OH)$_3$, on the fuel cladding and by an additional 0.13 kg of water in aluminum and iron hydrates in the canister sludge (HNF-1523 [Rev. 1], HNF-SD-SNF-TI-015). This bound water, like the uranium hydrate water, would not initially be available for reactions. Very little of the hydroxide water is expected to be freed from the thermal decomposition of the hydroxide based on previous and current data (HNF-1523 [Rev. 0 and Rev. 1]) at fuel temperatures below 150 °C. The data set provided in SNF-3328 and HNF-1523 (Rev. 0), is used because it is more conservative at lower temperatures (<150 °C) than the recent data (HNF-1523 [Rev. 1]). Both data sets are similar at high temperatures around 300 °C.

The expected bounding sources of water in an MCO on arrival at the CSB and the availability of the water for reactions are shown in Table A3-26. If the MCO temperatures reach very high values (approximately 200°C), the thermal decomposition of aluminum hydroxide, along with hydrate decomposition and initial free water, could supply about 1.91 kg of water. This total is based on 15% thermal decomposition of the water in aluminum hydroxide and the water in Al+Fe hydrate, 100% thermal decomposition of the uranium hydrate, and the 0.2 kg of free water.

The water required (Table A3-25) is combined with the water available (Table A3-26) to determine the additional free water needed to pressurize the MCO to 150 lb/in² gauge and 450 lb/in² gauge. It is assumed in Table A3-27 that the fuel temperatures are not more than 50 °C higher than the gas temperatures, which has been shown to be true for most conditions (HNF-SD-SNF-CN-023).

<td>0.24 kg</td>
</tr>
</tbody>
</table>

CSB = Canister Storage Building.

In summary, Table A3-27 shows that for bounding conditions, at least 6.29 kg of additional free water would need to be available at the CSB for the MCO pressure to reach 450 lb/in² gauge. However, the MCO design pressure is 150 lb/in² gauge before welding, therefore the additional water margin for the unwelded MCO is much smaller, as shown in Table A3-27. In fact, only 0.24 kg of additional water is needed to pressurize the MCO to 150 lb/in² gauge at the CSB under severe conditions. However, the unwelded MCO is not expected to leak at 150 lb/in² gauge.

HNF-SD-SNF-SARR-005 states that based on the codes used in the MCO design, the mechanically closed MCO (before welding at the CSB) would not suffer any damage at internal pressures up to 340 lb/in² gauge. At some pressure in excess of 340 lb/in² gauge, the thread root of the collar would begin to yield, and at some pressure very much greater than 340 lb/in gauge, leakage around the Helicoflex seal would result. An MCO has been built and tested to an internal pressure of 562.5 lb/in² gauge to match the test requirement to be placed on MCO procurement. In that test, no leakage and no permanent damage were observed.

Because the additional water margin is small for the 150 lb/in² gauge pressure and the calculations in Table A3-27 are only approximate, the HANSF code was used to simulate a very hot MCO in the sampling/weld station under severe conditions. The software verification and validation documentation for version 1.2 of the HANSF code may be found in FAI/98-40, *Hanford Spent Nuclear Fuel Safety Analysis Model HANSF 1.2: User's Manual*. HNF-SD-SNF-CN-023 also documents that the HANSF code has been benchmarked for code version 1.2 using the benchmark data in FAI/98-40. The key input parameters are given in Appendix D of SNF-3328 based on HNF-SD-SNF-TI-015. The newer HANSF version 1.3.2, described in SNF-3650, *HANSF 1.3.2: User's Manual*, is compared with HANSF version 1.2 in SNF-5226, *Comparison Cases Simulated with HANSF 1.3.2 that Supplement the Thermal...*
Analyses Documented in HNF-SD-SNF-CN-023. The comparison shows that the results from HANSF version 1.2 are more conservative than the results from HANSF version 1.3.2 for the cases in this analysis.

To maximize the results and minimize the number of simulations, a hypothetical MCO that had the decay heat of an MCO with one scrap basket and the water content of an MCO with two scrap baskets was simulated. Although five fuel baskets may have more decay power (~35 W) than four fuel baskets and one scrap basket, the scrap basket has more reactive surface area and will contribute more chemical heat when oxidants are present (SNF-3328).

In the first case, a bounding MCO is left in the sampling/weld station for at least 40 days without active cooling (e.g., because of MHM failure). The calculated fuel temperatures are consistent with the 132 °C boundary (MCO wall) temperature. The simulations were started with fuel temperatures at 125 °C and calculated the temperatures for 2 days. Water was assumed to be 2% (saturated steam at 25 °C) of the 1.5 atm of helium injected at the CVDF, or about 9 g of water mass. In this simulation, steady-state temperatures for this case are attained in less than a day (SNF-3328).

The highest fuel temperature for this scenario occurs on the inner fuel elements (six total) nearest the center post of the MCO and has a value of about 145 °C. The highest temperature for the scrap fuel is about 140 °C, with a steady-state value of 135 °C, which is cooler than the hotter fuel elements because the copper fins on the scrap basket effectively conduct heat toward the MCO. This simulation uses the maximum decay power for fuel from aluminum canisters. According to HNF-3035, MCO Gas Composition for Low Reactive Surface Areas, the bounding decay power for fuel from aluminum canisters is 528 W per five fuel baskets.

The MCO gas temperature reaches about 140 °C in the fuel baskets and about 132 °C in the scrap basket. The initial gas temperature is 25 °C when helium is injected into the MCO at a pressure of about 1.5 atm at the CVDF. This cool gas heats up very quickly in the simulation and causes a rapid pressure increase. It is anticipated that the MCO wall temperatures will be well below the 132 °C limit.

In another case, the final results of the previous case were used for all initial conditions. This simulation adds 0.52 kg of water, which is about 15% of the water contained in aluminum hydroxide and the aluminum and iron hydrates in the canister sludge (HNF-SD-SNF-TI-015). ALCOA data (SNF-3328) indicates that as much as 15% of the hydroxide water (or about 5% of total hydroxide mass) can be freed by thermal decomposition for temperatures up to 200 °C and about 57% for temperatures up to 300 °C. Since the maximum fuel temperature in the previous case was 145 °C, indicating that less than 15% of the water in aluminum hydroxide is expected to be freed. Because thermal decomposition of aluminum hydroxide is not included in the HANSF code, additional water vapor (steam) was added as a source to simulate its effect on temperatures and pressure. To be conservative, 15% or 0.52 kg of hydroxide water was added to this case over a short 10,000-second interval. The Alcoa data set used in SNF-3328 is more conservative at lower temperatures than recent data (HNF-1523 [Rev. 1]). One reason for the lower
decomposition rate found in the data set used in SNF-3328 may be that thermal equilibrium was not achieved.

In the simulation, the freed hydroxide water was added only to the fuel baskets, which is more conservative than spreading the water into all of the baskets. The added hydroxide water causes the maximum fuel temperature to increase to about 155 °C in less than three hours. The fuel and gas temperatures decrease after 3 hours because no more water is available to continue the chemical reactions. In less than 2 days, the maximum fuel temperature reaches a new steady-state value of 145 °C, which is lower than the temperature before the additional water was added. The additional water created hydrogen gas, which has a high thermal conductivity, so heat is removed faster from the MCO. The MCO pressure rises to 10.0 atm (132 lb/in² gauge) (SNF-3328). This is below the MCO design pressure of 11.2 atm (150 lb/in² gauge). The pre-welded (i.e., mechanically sealed) MCO can withstand pressure up to 340 lb/in² (HNF-SD-SNF-SARR-005). The maximum fuel temperature does not rise above 155 °C, and the gas temperature does not rise above 140 °C, indicating that the helium and hydrogen provide good thermal conductivity, thereby keeping the temperatures stable in the MCO at the CSB.

Conclusions and Conservatisms for Water Reaction Cases. MCO temperatures have been shown to be stable even under very severe external thermal conditions, and the maximum gas pressure has been shown to stay below 150 lb/in² gauge, which is far below the 450 lb/in² gauge MCO design pressure after the cover cap is welded in place. The main conservatisms and/or margins over bounding parameter values in the computer simulations are itemized in the following list:

- No hydrate water is removed at the CVDF, so all hydrate water is available for thermal decomposition at the CSB.
- No hydride mass is consumed at the CVDF and a hydride reaction rate multiplier of 12 is used for all simulations at all times (this is documented in HNF-SD-SNF-TI-015).
- MCO wall temperature is 132 °C because of being located in the sampling/weld station pit without active cooling for 40 days (this is documented in CSB-HV-0014).
- Steam (water vapor) mass of 9 g is added to the MCO to account for the CVDF helium supply possibly being contaminated with 2% steam.
- Fifteen percent of aluminum hydroxide water is released at a lower temperature (<150 °C) instead of at a higher temperature of 200 °C (this is documented in HNF-1523 [Rev. 0]), and this water is added only to the fuel baskets instead of being spread among the fuel and scrap baskets.
- No hydrogen gettering takes place, which maximizes the gas pressure; if hydrogen gettering were allowed to take place, the hydrogen fraction in the MCO would get
very small and reduce the pressure by a large amount. Hydrogen gettering is expected to occur after all of the free water has been depleted, which could lower the MCO pressure by as much as 80%.

T2 — Reaction of Oxygen with Uranium Fuel and Uranium Hydride. Another way to generate heat in an MCO is for oxygen (or air) to enter as the result of an accident event or to be created by radiolysis. Section A3.4.2.3 examines the long-term effects of radiolysis and flammability issues.

Any oxygen that enters the MCO will react with uranium hydride and uranium to liberate heat, depending on the temperature (HNF-SD-SNF-TI-015). Reactions with oxygen liberate heat and increase the fuel and gas temperatures so that additional water would be available from the decomposition of the uranium hydrate and aluminum hydroxide, which would increase the pressure and temperature in the MCO. The reactions with oxygen are followed by the reactions with water after the oxygen is consumed. Because all of these reactions are coupled and interrelated, the HANSF code (FAI/98-40) was used to simulate air ingress.

In one case, an MCO is charged with pure oxygen instead of helium during gas sampling at the CSB sampling/weld station (i.e., helium bottles accidentally filled with oxygen or oxygen bottles accidentally used in place of helium). In obtaining a gas sample from one of the monitored MCOs, the helium pressure in the MCO is accidentally reduced to 1.0 atm. Hence, when oxygen, instead of helium, is accidentally injected into the MCO to get the pressure back up to 1.5 atm, 0.5 atm (about 33%) of the total pressure is due to oxygen. Heat removal is assumed to be limited in the sampling/weld station by a cooling failure of the shield, such that the air temperature and MCO wall temperature are both 132 °C, the maximum possible with complete cooling failure (CSB-HV-0014). This maximum steady-state temperature is only reached after 40 days in the sampling/weld station with no active cooling. All fuel temperatures are conservatively assumed to be at 153 °C in the HANSF simulation.

A very high fuel temperature was assumed to demonstrate margin. If oxygen reactions starting at high temperatures do not cause thermal excursion, then oxygen reactions starting at lower temperatures will not cause thermal excursion. This scenario is expected to bound all air entry cases and cases with helium bottles contaminated with air or oxygen because 100% oxygen is postulated to be injected and air has an oxygen content of only 21%. Also, no natural circulation with air ingress is expected at the CSB because natural circulation requires two openings, one for air entry and one for gas exit, and two openings are not available in the MCO at the CSB.

Therefore, oxygen, instead of helium, is assumed to be injected into the MCO at the gas sampling station. The innermost fine scrap fuel has a thermal increase up to about 440 °C before the oxygen is depleted in the scrap basket and cools off. This temperature increase occurs because the fine scrap fuel has a high surface-area-to-volume ratio and is initially hot enough (153 °C) to rapidly oxidize the uranium hydride in the scrap fuel and increase the fine scrap temperature dramatically. The oxygen-hydride reaction at this high temperature rapidly consumes
the oxygen and is depleted within an hour. Because the scrap basket is dry, except for the thermal
decomposition of the hydrate mass, there is not enough water available to continue the chemical
reactions. If aluminum hydroxide were included, only a small amount of water would be freed by
thermal decomposition because the elevated temperature lasts for less than an hour and is
restricted to only the innermost fine scrap in the fine scrap portion of the scrap basket
(SNF-3328).

The maximum MCO pressure of about 6.2 atm in 1 day is far below the MCO design
pressure of 150 lb/in² gauge before the cover cap is welded in place. The peak pressure is lower
than the previous cases (with water) because oxygen reactions do not produce as much gas as
water reactions. Also, the temperatures in this case are not as high, except for the sharp peak, as
in the previous cases, so the hydrates do not completely decompose for this case, which means
less water reacts in this case than in the previous two cases.

Conclusions and Conservatisms for Oxygen Reaction Case. Temperatures remain stable in
an MCO even under very severe external thermal conditions. The following conservatisms and/or
margins over bounding parameter values in the computer simulations ensure that the MCO will
not exceed its design pressure limit.

- No hydrate water is removed at the CVDF, so all hydrate water is available for
  thermal decomposition at the CSB.

- No hydride mass is consumed at the CVDF and the hydride reaction rate multiplier is
  kept at 12 (HNF-SD-SNF-TI-015) for all times, which keeps the hydride-oxygen
  reaction going. In reality, much of the hydride would be consumed at the CVDF and
  not be available for reaction at the CSB.

- The wall temperature of the MCO is 132 °C because of failure of the MHM and of
  the cooling shield in the sampling/weld station for 40 days.

A3.4.2.5.2 Source Term Analysis. Because there is no release expected even under
severe conditions, no source term was estimated.

A3.4.2.5.3 Consequence Analysis. Because there is no release expected, even under
severe conditions, the inhalation dose consequences are zero.

A3.4.2.5.4 Comparison to Guidelines. Because the dose consequences are zero for
thermal runaway reaction events at the CSB, all dose guidelines are met. These results assume
that the MCOs pass the dryness tests at the CVDF and that the tests are accurate in ensuring that
less than 200 g of free water is present in the MCO after leaving the CVDF. The results depend
on the amount of hydride in the MCO and the amount of aluminum hydroxide, as well as its
thermal decomposition rate as a function of temperature. If the MCO design pressure were
lowered to 150 lb/in² gauge, there would still be no dose consequences, but the margin of safety
would be significantly reduced.
The equivalent cases involving MCOs with two scrap baskets, analyzed and presented here, maximize the amount of water and hydrides in the MCO. These cases are expected to bound the thermal and high-pressure estimates and associated consequences when compared with events involving an MCO with one scrap basket or a MCO with no scrap baskets.

A3.4.2.5.5 Summary of Safety Structures, Systems, and Components and Technical Safety Requirement Controls. All of the hazards related to fuel reactions that could cause a release are shown in Table A3-28. Detailed analyses in Section A3.4.2.5.1 showed that there was not enough heat, air, or water in the MCO for any of these initiators to cause thermal runaway events. Therefore, no safety-class or safety-significant SSCs are required to prevent the consequences of this accident.

T1. Thermal Runaway Reaction Due to Fuel Reaction with Water. The fuel reactions with water hazards were identified with zero-release consequences in the CSB hazard analysis because of insufficient free water (HNF-SD-SNF-HIE-001). The following TSR protects the assumptions used in the analysis:

- TSR
  - Verify the proper processing steps and conditions have been carried out at CVDF and K Basins before accepting an MCO at CSB.

T2. Thermal Runaway Reaction Due to Fuel Reaction with Oxygen or Contaminated Gas. Temperatures are shown to remain stable in an MCO even when the MCO is presumed to be inerted with pure oxygen or an air ingress occurs.

No SSCs are required to prevent the MCO thermal runaway accident. The TSR and defense-in-depth features are summarized for each specific accident in Table A3-28.
Table A3-28. Summary of Safety Features Required to Prevent a Multi-Canister Overpack Thermal Runaway.

Note: Defense-in-depth features and safety-significant defense-in-depth features are not designated as NRC ITS.

SSCs are classified per their function in mitigating or preventing specific accidents. SSCs may have other classifications based on their functions in other events.

CSB = Canister Storage Building.
CVDF = Cold Vacuum Drying Facility.
ITS = important to safety.
MCO = multi-canister overpack.
NA = not applicable to ITS category classification.
NRC = U.S. Nuclear Regulatory Commission.

A3.4.2.6 Violation of Design Temperature Criteria. Heat is produced in an MCO from energy released by radioactive decay and by chemical reactions occurring between the fuel and water or gases. MCOs and the CSB have been designed to provide for sufficient heat transfer from the MCO so that unacceptably high temperatures will not be reached during normal handling and storage of the MCO at the CSB. This analysis investigates situations in which a reduction in normal heat conduction causes overheating of an MCO and surrounding structures. Preventive measures are required to preclude this overheating because it could compromise the safety function of safety components. Required controls to prevent the potential consequences of each overheating condition are summarized in Section A3.4.2.6.5. Additional information about the violation of design temperature criteria accidents can be found in SNF-3328.

A3.4.2.6.1 Scenario Development. Radioactive decay reactions and chemical reactions within the MCO generate heat. The situation in which heat transfer from the MCO to the outside environment is disrupted enough to lead to violation of the temperature criteria was identified in...
the CSB hazard analysis (HNF-SD-SNF-HIE-001). In this case, the natural convective cooling airflow to the vault is disrupted. This bounds effects due to convective heat transfer at other locations in the CSB. The hazard is exceeding the design temperature for the concrete vault structure. See HNF-SD-SNF-SARR-005, Chapter 4.0, for thermal design limits of the MCO.

If the passive cooling air flow of the CSB vault is significantly reduced, either the MCO wall temperature or the CSB vault concrete temperature could exceed its respective design temperature. The natural convection of air through the vault will be reduced for blockage (full or partial) of vault intake and/or exhaust stacks. Significant blockage of the flow occurring from causes including debris trapped in the inlet or frost formation over the inlet is very unlikely. Without the vault convective air cooling, temperatures in the vault would rise above the design temperature criteria for the vault walls and operating deck, thereby reducing the strength of the concrete and compromising their safety functions. Loss of the structural integrity of the vault concrete could make it more susceptible to failure during a seismic event.

ACI-349, Code Requirements for Nuclear Safety Related Concrete Structures, Appendix A.4, provides limitations for concrete temperatures during normal operation or any long-term period. The temperatures shall not exceed 66 °C (150 °F), except for local areas (e.g., around penetrations), which are allowed to have increased temperatures not to exceed 93 °C (200 °F). The concrete surface temperature shall not exceed 177 °C (350 °F) for an accident duration or any short-term period.

Bounding calculations for the effect of loss or partial loss of vault convective cooling flow on the MCO wall and the vault concrete temperatures have been performed and are documented in CSB-HV-0003, Spent Nuclear Fuel Vault Loss of Cooling Analysis. These calculations assume that the vault is full of MCOs with a corresponding total heat load of 191.6 kW (HNF-SD-SNF-TI-015). The outside air temperature available to cool the vault is assumed to be 46 °C (115 °F), and the surrounding ground temperature is assumed to be 16 °C (60 °F). With these conditions, the maximum initial temperature of the MCO wall (no blockage of vault air flow) is about 122 °C (252 °F), and the maximum vault concrete ceiling surface temperature is 56 °C (132 °F). CSB-HV-0003 calculations show that for an intake stack cross-sectional area reduction of 25% of normal flow (i.e., is 75% blocked), the MCO wall temperature reaches 131 °C (268 °F), and the operating deck temperature reaches 66 °C (151 °F) in 72 hours. For a complete vault inlet stack blockage, the MCO wall temperature reaches 132 °C (270 °F) in about 15 hours with the temperature continuing to rise at a rate of about one degree per hour. For 50% or less of the inlet area blocked, the vault air flow rate and the MCO and vault concrete temperatures would be nearly equal to those expected for zero blockage.

The bottom of the inlet area of the vault intake structure is more than 62 ft above the surrounding grade. A vertical grating surrounds the opening to the intake stack on four sides. The grating consists of a heavy gauge (0.13-in. wire diameter) interwoven stainless steel screen with 0.75-in. square openings supported by more widely spaced steel cross members. The overall dimensions of this grating are about 15 ft by 17 ft on two sides and 15 ft by 18 ft on two sides, giving a total flow area for all four vertical inlet grates of more than 1,000 ft². Inlet air flows
through this grating and down the inlet stack to a second horizontal grate inside the inlet stack. The horizontal grating is composed of a metal lattice with perpendicular members spaced 6 in. apart. The intake stack horizontal cross-section is rectangular with minimum interior dimensions of about 16 ft by 11 ft and has a flow area of more than 170 ft². Blowing debris (e.g., tumbleweeds or garbage) may occasionally be lifted to the height of the upper vertical grating and become lodged but by design, significant (>50% blockage) accumulation of debris on either grating is not considered possible for the following reasons.

- The intake outer grating is open on all sides and the opening is quite large, it is not probable that a significant portion of the intake could become blocked.
- The openings in the vertical inlet grate are significantly smaller than those of the horizontal grate, it is not considered possible for significant debris to accumulate on the horizontal grate.
- The vertical inlet grating has a total flow area that is more than 6 times that of the horizontal cross-section of the inlet, about 92% of the vertical grating area must become fully blocked before more than 50% of the inlet cross-section area will be blocked.
- Both the intake and exhaust are significantly above grade.

In summary, the bounding scenario for this accident category describes conditions in which CSB safety classified concrete structures could exceed their design temperatures because of a lack of cooling. The unmitigated scenario is brought to a stable state by restoring cooling to bring the vault to a stable thermal condition. If the MCOs are in the vault of the CSB, any debris is removed to restore air flow to the air intake and exhaust structures. Once a stable thermal condition is attained, the MCO is handled in accordance with recovery procedures or the vault is returned to operational status.

**A3.4.2.6.2 Source Term Analysis.** The scenario described above could potentially damage safety-class structures (in this case, the vault) and result in compromise of their safety function. This accident also leads to the potential loss of structural capability for the concrete vault structures. Controls as defined in DOE Order 6430.1A are required to prevent conditions that would lead to the damage of safety-class equipment or structures that would impede their ability to perform their safety function. Because these accidents are prevented, no source terms are developed.

**A3.4.2.6.3 Consequence Analysis.** The potential unmitigated impact is a reduction in the structural integrity of the concrete. However, the maximum expected vault temperatures are not sufficient to cause loss of structural capacity.

Temperature increases in the vault over a long period of time result in gradual damage to the vault and operating deck concrete. Damage to the concrete would slowly continue once it
began. A structurally impaired operating deck may not survive the DBE. The collapse or
significant failure of the deck could potentially lead to the breach of MCOs stored in the vault.
Ample time would be available to identify and correct any loss of air flow condition in the vault.
Because the outer vertical inlet screens are so large and are located so far above the existing
grade, it is not considered credible for sufficient blockage of the inlet to occur and result in a
temperature violation. These temperature criteria violation scenarios will be prevented so that no
safety-class structures or equipment will be damaged.

Calculation CSB-S-0043C, *HCSA Deck Design — Confirmation*, evaluates the thermal
effects on a concrete structure of an MCO left in the sampling/weld pit for 40 days. Using the
thermal gradients shown in CSB-HV-0014, *Long Term MCO Temperature Without Cooling in
the Sampling Station*, the deck and the pit meet all design criteria (worst-case demand—capacity
ratio is 0.99 [vertical reinforcing on inside face of the tubular portion of the pit]). The calculation
considered concrete strength degradation from thermal exposure by reducing the concrete
strength from 4,000 lb/in² to 3,000 lb/in². This approach is conservative and has been used in
other CSB structural calculations to account for concrete degradation.

**A3.4.2.6.4 Comparison to Guidelines.** Safety-class SSCs are identified to keep vault
temperatures from exceeding the maximum expected values, thus no comparisons to dose
consequence guidelines are made to identify additional SSCs.

**A3.4.2.6.5 Summary of Safety Structures, Systems, and Components and Technical
Safety Requirement Controls**

**VI. Loss of Vault Cooling.** The safety-class structural components that are required to
ensure that passive cooling is sufficient to prevent the MCOs or safety-class facility concrete
structures from being exposed to temperatures in excess of design criteria are summarized in
Table A3-29 and listed below:

- Safety-class SSCs
  - Vault (concrete) — Maintains geometry to provide for passive convective
    cooling air flow past the storage tubes
  - Vault intake structure — Provides inlet for passive cooling air to the vault, is
    above grade, and has screened entrances that provide assurance that the inlet
    will not become significantly obstructed
  - Vault exhaust stack — Provides exit for passive cooling of vault, is above
    grade, and is designed such that it will not become significantly obstructed
  - Storage tubes, tube base assemblies, and carbon steel base slab embeds —
    Provide spacing of MCOs within the vault to ensure that each will be cooled
    by passive airflow.

A3.4.3 Beyond Design Basis Accidents

DOE Order 5480.23 requires the evaluation of accidents beyond the design basis to provide a perspective of the residual risk associated with the operation of the facility. The BDBAs are not analyzed to the same level of detail as DBAs, but rather simply provide insight into the magnitude of consequences of BDBAs. This insight from BDBA analysis has the potential for identifying additional facility features that could prevent or reduce severe BDBA consequences. Only BDBAs of significance (for internal events and natural phenomena hazards) are identified and assessed for their importance.

This section presents a summary of the key assumptions and results of the BDBA analyses that have been performed for the CSB. As such, the evaluation associated with each BDBA provides insight into the magnitude of the consequences of BDBAs.

Identified CSB BDBAs include the following:

- Failure of MCO confinement because of internal overpressurization
- Hydrogen combustion events
• Collapse of the building’s superstructure

• Failure of multiple MCOs

• Failure of identified safety-class accident prevention and mitigation features, including those that control drops, collisions or impacts.

The DBA analyses in Section A3.4.2 envelop the scenarios and consequences of failure of MCO confinement because of internal overpressurization, and hydrogen combustion events. The analyses demonstrate that these events are limited in their potential hazardous material quantities and energy sources because of limited reactants in the MCO. The analyses assume that the safety basis properties and facility features are in place to ensure the reactants are limited. An MCO received out of these specifications is a BDBA discussed in Section A3.4.3.1.

Collapse of the CSB superstructure could be caused by human-generated external events (e.g., crash of a light airplane) or natural phenomena (e.g., tornado and tornado-generated missiles, high winds, earthquake, or snow or ashfall loading of the roof). DOE-STD-3009-94 specifically excludes evaluation of human-generated events as BDBAs. The consequences of beyond design basis natural phenomena events are generally bounded by a beyond design basis seismic event, which is discussed in Section A3.4.3.2. An exception would be a beyond basis natural phenomena event that leads to flooding of the CSB underground vaults. Flooding of the vaults is discussed in Section A3.4.3.3.

Failure of multiple MCOs (e.g., as a result of a seismic event) is considered in the discussion of common mode initiators in Section A3.4.4. The failure of identified safety class accident prevention and mitigation features (including those that control drops, collisions, or impacts) is discussed in Section A3.4.3.4.

The results of the BDBA evaluations did not identify additional mitigative or preventive barriers beyond those required for the DBAs.

A3.4.3.1 Failure of Multi-Canister Overpack Confinement Because of Internal Overpressurization. As discussed in HNF-SD-SNF-OCD-001, *Spent Nuclear Fuel Project Product Specification*, receipt of MCOs with properties outside of safety basis assumptions is beyond the design basis of the SNF Project. As such, this is a BDBA occurrence that could lead to consequences at the CSB beyond those described in the DBAs in Section A3.4.2. Key properties relied on to ensure that the as-received content and condition of the mechanically sealed MCO (150 lb/in²) are as required for safety basis properties include the following values (see Section A3.4.2):

1. Maximum particulate mass of aluminum hydroxide in an MCO delivered to the CSB less than or equal to 9.47 kg
2. Maximum mass of uranium hydrates in an MCO delivered to the CSB less than or equal to 10.8 kg

3. Maximum of two scrap baskets in an MCO delivered to the CSB

4. Maximum removable, not strongly adherent, UO₂ particulate in an MCO at the CSB is 34 kg

5. Maximum free water in an MCO delivered to the CSB less than 200 g

6. Leak rate of internal gas from MCO less than 10⁻⁵ standard cm³/s

7. Maximum mass of uranium hydride (for heat and hydrogen generation) of 5.13 kg on receipt at CSB and 9.08 kg after 40 years storage at CSB

8. Maximum of 6,339 kg of uranium per MCO (five Mark IV fuel baskets)

9. Minimum MCO inert gas pressure on receipt at CSB of 1.5 atm at 25 °C.

An overpressurization is the most significant consequence of excess free and bound water inside the MCO. Such an occurrence is related to exceeding limits 1, 2, 3, and 5, individually or in combination. Because the uranium reaction with water is exothermic, heat released by the reaction could raise the temperature of the fuel to the point of a thermal runaway if the MCO contained excess amounts of water available for reaction. Additional scrap baskets mean more fuel surface is available for reaction, leading to potentially more severe fuel oxide exothermic reactions.

Exceeding limits 1, 2, and 5, individually or in combination, could also result in internal hydrogen deflagrations because the increased water available for radiolysis allows increased production of hydrogen gas. Exceeding limit 6 by increasing the leak rate could increase the probability of occurrence and consequence of external hydrogen deflagration events.

The integrated facility dose resulting from an out-of-specification MCO caused by overpressurization can be estimated from the DBA for a gaseous release from the MCO, Section A3.4.2.2. The MAR from the overpressurization would be three to four times the MAR for the gaseous release DBA because the generation of the high pressure required to fail the MCO also creates additional amounts of UO₂ during the reaction. For example, 450 lb/in² of H₂ pressure requires the reaction of water with approximately 90 kg of UO₂ compared with the 35 kg of UO₂ available for the gaseous release DBA.

An increase of three to four times in the MAR would essentially result in an increase of three to four times in the radiological dose consequences at both the onsite and offsite receptors. However, three to four times the radiological dose consequences calculated for the gaseous release DBA still represents a relatively small dose to receptors of interest. Finally, although not
credited for the DBA, the MHM extract system and the building exhaust, and their associated
HEPA filters, provide additional mitigation of some portion of the release.

A3.4.3.2 Beyond Design Basis Seismic Event. Beyond design basis forces from seismic events
could affect the performance of systems and structures in the CSB during MCO handling and
placement operations and during interim storage. The impact of a beyond DBE on structures is
discussed in Section A3.4.4.1. The CSB has been designed to withstand seismic forces greater
than the Hanford Site DBE with the functions of the structure, including spent fuel cooling,
remaining intact. As discussed in Section A3.4.4.1, seismically induced failures of the
sampling/weld systems at CSB would have only significant onsite consequences.

When the MCOs are in their storage tubes, the facility structures, storage tube assemblies,
and MCO are passive structural barriers that are all designed for the DBE. In the beyond DBE
event, failures of above-grade structures (e.g., the operating area shelter, support area building,
and intake and exhaust stacks) would not significantly affect the structural integrity of the
below-grade storage tubes and MCOs. If the flow of air through the vault were impeded,
affecting the cooling capability of the vault, the MCO skin and fuel temperature criteria could be
exceeded over a long period of time. Significant blockage, more than 50% of the intake structure
cross-sectional area, could result in thermal conditions approaching the thermal criteria in a few
days, which is sufficient time for recovery actions. Failures of the above-grade structures with
below-grade structures intact would allow the below-grade structures to continue to provide a
reasonably stable and safe condition for the SNF with sufficient time to recover adequate passive
cooling capability before the MCO thermal criteria are exceeded. Thus, source terms and dose
consequences in the short term could be expected to be minimal at the facility and at the Site
boundary.

In the event of the beyond DBE occurring during the period of MCO handling, sampling,
and placement into the storage tubes, the MCOs being handled would be located outside of the
vault. These MCOs would be vulnerable to structural failure caused by the impact of falling
structures, cranes, and other SSCs located in the operating area. In general, at any one time, only
a limited number of MCOs are located at the CSB outside of the storage tubes. As discussed in
Section A3.4.4.1, it is possible to have up to four MCOs outside the storage tubes at the CSB.
These four MCOs would provide the source material for airborne releases and immediate doses to
the public beyond the Site boundary. However, such damaged MCOs would likely have limited
internal pressure with which to cause release of their radioactive particulate inventory, and they
would likely be covered by steel debris from the collapsed operating area shelter, which would
provide limited shielding and airborne pathway disruption. The dose from the facility for this
event is based on the combined airborne particulate released from damaged MCOs. Assuming
four damaged MCOs above the operating deck during the BDBE, the radiological dose to the
onsite receptor would be 1 to 10 rem, which is on the order of four times the consequences of the
mechanical damage to the MCO accident (Section A3.4.2.1).

If the below-grade structures (e.g., operating deck, storage tube assemblies, intake and
exhaust plenums, and MCOs) structurally failed, the SNF would be buried below massive
quantities of concrete and steel debris. There likely would be minimal immediate and short-term
radiological releases and doses from such a catastrophic event. Longer term radiological releases
and doses would depend on the airborne and other release pathways and mechanisms. It is
unlikely that airborne release pathways and airborne dose consequences would be unimpeded and
free flowing over the longer term because the SNF would be contained within steel MCOs and
storage tubes covered by steel and concrete debris.

A3.4.3.3 Beyond Design Basis Flooding of the Underground Vaults. The CSB is at an
elevation of about 700 ft above mean sea level. The MCOs are stored in metal tubes in the CSB
underground vaults approximately 40 ft below grade. The Columbia River is closest to the CSB
at river mile 370 where the normal level is at approximately 375 ft and the estimated flood level,
at an annual probability of $1 \times 10^{-4}$, is 435 ft above mean sea level (WHC-SD-SNF-DB-009).
This is about 265 ft below the CSB. The CSB site is a flood-dry site with respect to river
flooding, so only flooding caused by precipitation runoff need be considered. The probable
maximum precipitation (PMP) for the local storm for CSB is a one-square-mile, 6-hour storm
with 9.2 in. of rainfall for the surrounding watershed runoff (WHC-SD-SNF-DB-009).

The CSB storm drain and flood control components have been designed to accommodate
the PMP event and contain provisions for culverts to allow passage under roadways of runoff
from storms smaller than the PMP. The site civil grading and drainage plan is for the PMP event
and to accommodate for storms larger than the PMP by overflows (larger-than-design flows)
using drain and flood control over the site plan when the system capacity is exceeded. The CSB
criterion for the culverts, drainage ditches, and general storm drainage overflow path is to
maintain safety of the property by ensuring that the PMP event of 9.2 in. of rainfall in 6 hours
does not allow water flow into the CSB. Onsite, runoff water flows to a culvert that passes under
the ramp road immediately northeast of the CSB. This culvert is the only water pathway that
could have any impact on the CSB. In an extreme case, the culvert could be plugged with debris
at the time the PMP storm occurred, backing up rain water and making a pond that would rise up
to the lowest elevation of the road immediately north of the CSB. Other parts of the site drain
away from the CSB. Additional rainfall would increase the depth of flow over the ramped access
road, but the site is designed such that the water level does not build up to a height that would
threaten the CSB, affect its structural integrity, or allow water into the building. The steel cover
over the north intake stack prevents rain from entering the vault through the intake stack.

In a BDBA rainfall or other flooding event, such as a fire main break, water could flow into
the building via doorways, cracks, and other inlets to the building. Water could also enter the
building or the underground vaults via covers to the underground structure adjacent to the intake
stacks on the west side of the building. Water in the vaults should not have structural implications
to the structural integrity of the building nor negative thermal effects on the building structure,
tubes or the MCO shell. Current structural analyses, including CSB-S-0025, HCSA/SNF Vault
Design, and CSB-S-0023, HCSA/SNF Gravity Load Analysis, indicate margins of safety without
seismic loads on the order of 20% to 30%. As an indicative measure, one foot of standing water
imposes a 0.5 lb/in$^2$ load. A catastrophic flood would yield a load on the basemat on the order of
40 lb/in$^2$. This is judged a minimal load on the basemat. For the exterior walls, the soil loads

a-csb03.sar A3-131 March 2000
imposed on these walls, where the stresses in the walls may change direction, would balance the water loads. For the interior walls, in a catastrophic flood, the loads on the other side of the wall would balance the water loads on one side of the wall by the water in vaults 2 and 3. The N-S end walls would also sustain differential directional loading. In general, the catastrophic flood has minimal structural impact within the existing margins of safety. It is also noted that the heat from the storage tubes and the passive airflow through the vault facilitate vault dryout.

A3.4.4 Common Cause Initiators

The hazard and accident analysis process identified several common cause initiators that have the potential to impact the CSB (HNF-SD-SNF-HIE-001). These initiators have been addressed individually as discrete accidents but are discussed collectively here to address the risks of common cause failure at the CSB.

A3.4.4.1 Seismic Forces. Forces from seismic events could affect the performance of safety SSCs at the CSB during the handling and placement of MCOs or during interim storage of MCOs. Typically, only three MCOs (no more than four) would be handled or processed concurrently in the CSB: one in the receiving pit and two in sampling/weld stations or any two of these locations plus one in the MHM. Equipment handling the MCOs is designed to maintain structural integrity during seismic events and to not fail in such a way as to adversely impact the MCO or to affect other safety function SSCs.

Without controls, a seismic event could lead to handling upsets by cranes, the MHM, and other handling equipment that result primarily in physical impacts to the MCO. In this event, passive features (e.g., cask lifting yoke, limited MHM hoist height, impact absorbers) limit drop heights and provide passive energy absorption and passive barrier protection to the MCO.

A seismic detection system at the CSB disconnects power to the receiving crane and the MHM in the event of a DBE (see Section A2.7.6). On a disconnect of power, the receiving crane load is locked in its current position and the wheel brakes lock, preventing further movement of the load or crane. A disconnect of power to the MHM activates seismic clamps for both sides of the bridge and for both sides of the trolley, stops turret rotation, and locks the shield plug hoist and the MCO hoist in their current positions. The clamps and locking features are designed to prevent further motion of the MHM, minimize damage to the MCO, and prevent potential contamination spread. These actions comply with ASME NOG-1 requirements for power disconnects during a safe-shutdown earthquake.

The sampling equipment and connectors are designed to safety-significant criteria. The sampling/weld station gantry hoist has seismic restraints, and the sampling lines and connectors are designed to withstand the DBE.

The facility structures (vaults, intake structure and exhaust stack, at-grade structures, tube base assemblies, and carbon steel basemat embeds) and storage tube assemblies are passive
safety-class features designed to protect MCOs during the DBE. Thus, releases are not
anticipated during interim storage operations at the CSB, and the controls identified in the DBA
analyses in Section A3.4.2 are sufficient to prevent a release following a DBE.

The CSB has been designed to meet the seismic criteria in WHC-SD-SNF-DB-004 and
DOE-STD-1020-94, Natural Phenomena Hazards Design and Evaluation Criteria for
Department of Energy Facilities, which require that the effects of a 50% greater seismic loading
be no greater than the following (the functions of the structure, including spent fuel cooling,
remain intact).

- Concrete barriers can be cracked, but cracks should be small enough to maintain
  pressure differential with normal HVAC systems. Cracks should not be expected to
  exceed 0.125 in.

- Metal liners and metal pressure-retaining components should remain leak-tight.

- Components should remain anchored in place and be functional.

- Visible local damage occurs, but permanent distortion will not be immediately
  apparent to the naked eye.

A3.4.4.2 Loss of Facility Power. Natural phenomena events (e.g., rain, lightning, freezing
weather) can cause the temporary loss of facility power. In addition, certain external events (e.g.,
vehicle impacts with critical components outside the facility) could also cause a loss of facility
power. There were no loss of power events identified requiring further evaluation (see
HNF-SD-SNF-HIE-001). The facility has a fail-safe design for loss of power to all the SSCs at
the CSB (e.g., MHM [see Chapters A2.0 and A4.0 for details]); and no identified need for active
safety function performance during and after a loss-of-power event. Thus, no releases are
anticipated to occur in the event of a loss of power (see HNF-SD-SNF-HIE-001), and the
features and controls identified in the DBA analyses and discussed in Section A3.4.2 are sufficient
to prevent a release following a loss of power.

A3.4.4.3 High Vault Temperatures. High vault temperatures could lead to a violation of
thermal design criteria for multiple MCOs. High vault temperatures have been analyzed for single
MCOs under unmitigated and mitigated conditions as a DBA in Section A3.4.2.6. The features
identified in the DBA analyses are sufficient to prevent excessive vault temperatures, and
therefore, no releases are expected from such an event.

Furthermore, the effects of volcanic ash that may tend to cling to tube surfaces during a
volcanic eruption have been studied and are documented in Appendix J of CSB-HV-0001,
A Canister Storage Building Vault Thermal Analysis. A conservative condition was assumed:
(1) a 0.25-in. coating of ash with a conductivity coefficient of 0.25 Btu/h-ft-°F adhered to the
vertical tube surfaces and (2) a vault fully loaded with MCOs. This study found that the reduction
in heat transfer led to minor increases in temperatures (on the order of 1 °F to 3 °F in MCO and
concrete temperatures). Thus minimal thermal impacts are expected on peak MCO and concrete
temperatures in the vault. Such volcanic ash conditions should bound the expected impacts from
ash resulting from a range fire because volcanic ash should have larger thermal resistance
properties and densities than ash from a range fire.

A3.4.4.4 Loss of Facility Support Systems. A loss of facility support systems (e.g., HVAC,
power, and inert gas supply) could impact CSB sampling activities if the loss occurred during
sampling of monitored MCOs. Other operational activities are not adversely affected by the loss
of support systems because of the uninterruptible power supply available for monitoring
instrumentation; the fail-safe design of the safety function MHM interlocks at the CSB; and the
lack of need for active safety function performance during and after a loss of HVAC, power, or
inert gas supply. The receiving crane and the MHM do not require power to maintain safe control
of an MCO, do not interface with the HVAC system, and do not utilize inert gas. On a loss of
power, the receiving crane and the MHM stop motion.

The facility HVAC system is not credited to mitigate any radiological releases. However,
the sampling/weld station HVAC system is expected to dilute hydrogen or filter radiological
releases during an MCO sampling accident. In the event of the loss of the inert gas system during
sampling activities, simple operator actions (i.e., closing the sample line valve) put the sampling
configuration into a safe and stable mode. MCO cooling is either designed to be passive or its
absence does not lead to a condition exceeding design criteria for a long time period (months).
Thus, ample time exists for support systems to be reestablished. No releases are anticipated to
occur, and therefore, the features and controls identified in the hazard and DBA analyses are
sufficient to prevent a release caused by the loss of facility support systems.

A3.4.4.5 Facility Fire. The fire hazard analysis (HNF-SD-SNF-FHA-002) identified the CSB
fire-related hazards, preventive and mitigating actions, fire protection features, and damage
potentials from fire. The findings of the fire hazard analysis were incorporated into the design and
engineering of the CSB SSCs and controls. A fire involving a transport vehicle with 100 gal of
fuel had the highest loss. This loss included damage to the trailer vestibule area, damage to
installed equipment, and cleanup of the products of combustion from the operating area. No
specific fire considerations were required for dealing with hydrogen deflagration in the fire hazard
analysis because those considerations are addressed in Sections A3.4.2.3 and A3.4.2.4.

The maximum possible fire loss for the facility was from a support area building fire.
However, this section of the CSB facility has sprinklers to protect it from such damage. The
conclusion of the analysis is that the fire risks present in the CSB facility are acceptable with
regard to protecting employees, property, the public, and the environment from any undue
hazards and that the objectives of DOE Order 5480.7A are met based on the fire protection
features in the CSB (HNF-SD-SNF-FHA-002).

A3.4.4.6 Emergency Evacuation Caused by External Events. If the CSB is evacuated
because of external events at other facilities, a loss of operator control over MCO handling and
monitored MCO sampling could occur. Emergency response procedures will be used to respond to these events; however, the inherent risk is assessed without taking credit for such procedures.

- The cask-MCO can be left unattended on the transporter without risk of radiological consequences because of the passive cooling of the cask-MCO and the structural protection provided to the MCO by the cask.

- Lack of operator control for MHM handling of the MCOs is not a safety concern because of the fail-safe design of the MHM, which, on loss of power or without an operator, will not satisfy permissives and will shut down with no ability for motion.

- During sampling operations, the sampling operator has the simple action of closing the MCO valve operator or the sampling valve before evacuation.

Consequently, evacuation due to external events is not anticipated to lead to events with radiological releases and is not a safety concern. A facility evacuation due to internal events is adequately protected against with the existing features and controls identified within the DBAs. Therefore, the facility SSCs and controls are adequate to passively maintain safe conditions for all MCOs during and after an evacuation.

CHAPTER A4.0

SAFETY STRUCTURES, SYSTEMS, AND COMPONENTS
NOTE: If this information is being provided for the purposes of evaluating the multi-canister overpack handling machine (MHM) and its components under the realm of the Spent Nuclear Fuel Project, limited use restrictions apply to the documents prepared by GEC Alsthom Engineering Systems Ltd. that are referenced in this appendix. “Limited rights data” requirements and use are explained below.

Further disclosure or use of GEC Alsthom Engineering Systems’ technical data may be made for the following purposes.

1. The “limited rights data” may be disclosed for evaluation purposes under the restriction that the “limited rights data” be retained in confidence and not be further disclosed.

2. The “limited rights data” may be disclosed to other Contractors participating in the Government’s program of which the MHM contract is a part for information or use in connection with the work performed under a government contract and under the restriction that the “limited rights data” be retained in confidence and not be further disclosed.

3. The “limited rights data” may be used by the Government or others on its behalf for emergency repair or overhaul work under the restriction that the “limited rights data” be retained in confidence and not be further disclosed.

A4.0 SAFETY STRUCTURES, SYSTEMS, AND COMPONENTS

A4.1 INTRODUCTION

This chapter provides details on those facility structures, systems, and components (SSCs) that are necessary for the facility to satisfy evaluation guidelines, provide defense in depth, contribute to worker safety, or meet important-to-safety criteria. Descriptions of the attributes (i.e., functional requirements and performance criteria) required to support the safety functions identified in the hazard and accident analyses and to support subsequent derivation of technical safety requirements (TSRs) are provided. This chapter meets the requirements of DOE Order 5480.23, Nuclear Safety Analysis Reports, follows the format guidance in DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, and includes the following information.

- A list of the safety-class SSCs and subsections containing details of safety functions, a system description, functional requirements, a system evaluation, and a list of assumptions requiring TSRs to ensure performance of the safety function.

- A list of the safety-significant SSCs and subsections containing details of safety functions, a system description, functional requirements, a system evaluation, and a list of assumptions requiring TSRs to ensure performance of the safety function.

The Canister Storage Building (CSB) [Building 212H] has been designed using an SSC safety classification based on Letter 97-SFD-172, Risk Evaluation Guidelines (REGs) to Ensure Inherently Safer Designs (Sellers 1997), and on HNF-PRO-704, Hazard and Accident Analysis Process. HNF-PRO-704 implements the safety classification methodology presented in DOE Order 6430.1A, General Design Criteria, for safety-class SSCs and in Letter 97-SFD-172 (Sellers 1997) for safety-significant SSCs. A graded approach has been used based on the unmitigated consequences of potential accidents. SSCs are designated as safety class or safety significant based on their safety function for the prevention or mitigation of potential accidents or to ensure that the assumptions made in safety analyses remain valid.

In general, safety-class SSCs are those items required for protection of the offsite public. Safety-class SSCs include those items designated as safety class in accordance with DOE Order 6430.1A. Safety-class SSCs also encompass items that are designated as “important to safety” (ITS) in accordance with Title 10, Code of Federal Regulations, Part 72, “Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste,” Section 72.3, “Definitions” (10 CFR 72), and have been classified as Category A as defined in Item 29 of HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements.

Safety-significant items are those SSCs required for the protection of onsite personnel not directly involved in facility operations. Safety-significant SSCs also encompass those items that
have been designated ITS Category B in accordance with Item 29 of HNF-SD-SNF-DB-003. SSCs that would prevent a fatality or protect multiple facility workers from serious injury (not standard industrial hazards), or those SSCs that would prevent or mitigate toxic chemical exposures, also are designated safety significant. Those SSCs whose failure could impact or impair the function of safety SSCs are designated as the same level of importance as the potentially affected SSCs, except for the operating shelter, receiving crane, and the multi-canister overpack handling machine (MHM). Although the operating shelter, receiving crane, and the MHM are designated as safety-significant, they have been designed to safety-class design basis earthquake (DBE) loads and analyzed to this higher loading to ensure adequate margins of safety to prevent collapse of these structures onto the safety-class operating deck during a DBE. Both safety-class and safety-significant SSCs are subject to higher control levels and reviews than general service SSCs during design, fabrication, procurement, and installation.

All SSCs that are not classified as safety class or safety significant are general service SSCs. Those SSCs that have been designated as ITS Category C also are included in the general service SSCs. These SSCs protect workers from standard industrial hazards or are controlled by site safety programs. Items that do not perform a safety function other than industrial safety or that have a minor impact on safety are designated general service SSCs following the guidance in HNF-PRO-704.

### A4.2 REQUIREMENTS

This section provides a summary list of the U.S. Department of Energy (DOE) orders and standards, U.S. Nuclear Regulatory Commission (NRC) rules and guidance, industry standards and design codes, and Hanford Site requirements used in establishing the facility safety basis. The intent is to provide only the requirements that are specific to this chapter and pertinent to the safety basis.

#### A4.2.1 U.S. Department of Energy Orders and Standards

The following DOE orders and standards are applicable to the facility safety basis.

- **DOE Order 6430.1A, General Design Criteria.** Compliance to this order is documented in FDH-9951266, *Canister Storage Building 6430.1A and Nuclear Regulatory Commission Equivalency Compliance Matrix* (Williams 1999), which provides a requirement-by-requirement evaluation of the compliance of the CSB design to DOE Order 6430.1A. Attachment 3 of FDH-9951266 contains a list of areas where further action is needed to demonstrate compliance. These areas are primarily in startup and test, and acceptance testing.
• DOE Order 5480.24, Nuclear Criticality Safety. This order establishes nuclear
criticality standards and criteria for nuclear facilities. Additional discussion of the
CSB nuclear criticality safety criteria is provided in Chapter A6.0.

• DOE Order 5480.28, Natural Phenomena Hazards Mitigation. This order
establishes mitigation requirements for natural phenomena hazards (NPHs) and
targets probabilistic performance goals based on the facility performance category.
Additional discussion of the NPH performance criteria is provided in Section A1.5.
DOE Order 5480.28 is implemented via WHC-SD-SNF-DB-009, Canister Storage
Building Natural Phenomena Hazards.

• DOE-STD-1020-94, Natural Phenomena Hazards Design and Evaluation Criteria
for Department of Energy Facilities. This standard provides the methodology
applicable to design of nuclear facilities for NPH events.

A4.2.2 U.S. Nuclear Regulatory Commission Rules and Guidance

The following NRC rules and guides are applicable to the facility safety basis.

• Title 10, Code of Federal Regulations, Part 72, “Licensing Requirements for the
Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste”
(10 CFR 72). The design bases for items identified as ITS must reflect appropriate
combinations of the effects of normal and accident conditions and the effects of
natural phenomena. This is implemented by the application of the design criteria for
safety-class items, as provided in DOE Order 6430.1A, to those items identified as
ITS. Applying NRC equivalency requires that SSCs ITS be identified in accordance
with the definition in 10 CFR 72.3. Once SSCs ITS have been identified, a graded
approach is applied using the definitions in HNF-SD-SNF-DB-003. ITS is
subdivided into the categories defined in HNF-SD-SNF-DB-003. SSCs found to
belong in categories A or B must also meet 10 CFR 72, Subparts F and G, using a
graded approach.

  – Category A — Critical to Safe Operation

  SSCs in this category include those whose failure or malfunction could
directly result in a condition adverse to public health and safety. ITS SSCs in
this category have been classified as safety class using the definition in DOE
Order 6430.1A, with the additional requirements therein.

  – Category B — Major Impact on Safety

  SSCs in this category include those whose failure or malfunction could result
in a condition adversely affecting collocated worker health and safety.
Note that from the definition of Category C, Category B is understood to include events that could significantly damage the multi-canister overpack (MCO) without severe impact to public health and safety. SSCs in this category are classified as safety significant.

- **Category C — Minor Impact on Safety**

SSCs whose failure or malfunction would not significantly reduce containment and would not be likely to create a situation adversely affecting public or collocated workers’ health and safety. SSCs in this category are classified as general service (safety class 3 [nonsafety] in DOE Order 6430.1A).

The SSCs identified as ITS in accordance with 10 CFR 72.3 are listed in Tables A4-1 and A4-9. These lists also contain the ITS classification for each SSC as determined by Chapter A3.0. The ITS classification is directly incorporated into the tables of preventive and mitigative safety function features identified at the end of each design basis accident (DBA) scenario in Section A3.4.2. Three hoists, the tent gantry hoist and the two sampling/weld station hoists, are the only general service equipment items that are classified as ITS Category C because the hoists can potentially drop equipment that could cause minor damage to the top of an MCO.

Additional discussion of the NRC criteria for mitigation of natural phenomena is provided in Section A1.2.

- **NRC Regulatory Guide 1.26, Quality Group Classifications and Standards for Water-, Steam-, and Radioactive-Waste-Containing Components of Nuclear Power Plants.** This regulatory guide is invoked by HNF-SD-SNF-DB-003. For the CSB, the guide is used to assist in assigning the appropriate code class to systems and components designed to the Boiler and Pressure Vessel Code (ASME 1995), Section III. This guidance was used in selecting the Boiler and Pressure Vessel Code (ASME 1995), Section III, Subsection NC, as the appropriate code for the overpack storage tubes and the overpack storage tube plugs.

- **NUREG-0800, Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants.** This plan provides guidance that is used in WHC-SD-SNF-DB-009 to establish probabilistic risk assessment techniques for tornado-generated missile protection of specific targets.
A4.2.3 Industry Consensus Standards and Other Documentation

The following industry standards are applicable to the safety basis for the facility.

- ANSI N14.6-1993, Radioactive Materials — Special Lifting Devices for Shipping Containers Weighing 10,000 Pounds (4,500 kg) or More. This standard provides design criteria for special lifting devices for critical loads and is used in the design of the MHM MCO grapple, the standard and overpack tube plug pintle, and the receiving crane lifting yoke. Compliance with the added safety margins required by this standard provides a high degree of assurance against inadvertently dropped loads.

- ANSI/ANS-57.9-1992, Design Criteria for an Independent Spent Fuel Storage Installation (Dry Type). This standard includes requirements for the design of major buildings and structures, including physical security and safety features for independent spent fuel storage installations. An application evaluation against the requirements of ANSI/ANS-57.9-1992 was included in Addendum 3 of Attachment 1 to FDH-9761261 R4, Safety Classification of Cranes and Handling Equipment (Williams 1998b). The information included a listing of those items cited in ANSI/ANS-57.9-1992 as relevant to nuclear safety that are not in the CSB design, justification for not including them, and a listing of the items cited in ANSI/ANS-57.9-1992 that were included as criteria independent of ANSI/ANS-57.9-1992. An earlier review of ANSI/ANS-57.9-1992 identified an additional requirement from Section 6.17.1.1(1) to increase the dead load of structures by 5%. The 5% dead load contingency has been included in the design of the CSB. In Letter FDH-9755210 R1, Response to Issues Associated with Fabrication Release for the Spent Nuclear Fuel Project Multi-Canister Overpack Handling Machine (Mahaffey 1997), the MHM design was found to be consistent with the requirements of ANSI/ANS-57.9-1992. An updated ANSI/ANS-57.9-1992 compliance matrix, Attachment 5 of SNF-5790, Design Compliance Matrices to ANSI and OSHA, was prepared and provides justification that the CSB complies with the criteria in ANSI/ANS-57.9-1992. Design compliance statements for the receiving crane and the MHM were provided for all issues and additional requirements identified in the earlier evaluation.

- ANSI/ACI 349-85, Code Requirements for Nuclear Safety Related Concrete Structures. The requirements of ANSI/ACI 349-85 were applied to the design of safety-class and safety-significant reinforced concrete structures following the guidance in HNF-PRO-097, Engineering Design and Evaluation, and FRP-112, SNF Canister Storage Building (Bedell 1996a; this is the architect-engineer's Design Basis Document).

- ANSI/AISC N690-94, Specification for the Design, Fabrication, and Erection of Steel Safety-Related Structures for Nuclear Facilities. The requirements of
ANSI/AISC N690-94 were applied to the design of safety-class and safety-significant steel structures following the guidance provided in HNF-PRO-097 and the architect-engineer's Design Basis Document (Bedell 1996a).

- ASME N509-1989, Nuclear Power Plant Air-Cleaning Units and Components New Construction and Modification Only, and ASME N510-1989, Testing of Nuclear Air-Cleaning Systems. These two standards were used in the design of the CSB high-efficiency particulate air (HEPA) filter enclosures.

- ANSI/ANS-57.1-1992, Design Requirements for Light Water Reactor Fuel Handling System. According to HNF-SD-SNF-DB-003, the requirements in ANSI/ANS-57.1-1992 for cranes and lifting devices used in fuel handling operations are to be incorporated into the design of the CSB. A review of the MHM and receiving crane design packages concluded that some of the NRC requirements identified already were included as features in the vendor designs either because they were included in the procurement documents or were required by ASME NOG-1-1995, Rules for the Construction of Overhead and Gantry Cranes.

- ANSI/ANS-57.2-1992, Design Requirements for Light Water Reactor Spent Fuel Storage Facilities at Nuclear Power Plants. According to HNF-SD-SNF-DB-003, the requirements in ANSI/ANS-57.2-1992 for cranes and lifting devices used in spent fuel handling operations are required to be incorporated into the design of the CSB. FDH-9855462 (Williams 1998a) evaluates compliance with and deviations from the requirements of ANSI/ANS-57.1-1992, Section 5.0, “System Functional Description,” and Section 6.0, “Design Requirements.” Certain of these requirements apply to the design of the CSB. A later evaluation (Williams 1998b) identified applicable requirements from this standard for the MHM and receiving crane. Part of the requirements was already in the designs, and the remainder was added using the Design Change Notice process. The evaluation concluded that additional modifications of the project cranes are not necessary and that the NRC equivalency requirement, Item 13, is met.
• ASCE-4-86, *Seismic Analysis of Safety-Related Nuclear Structures and Commentary on Standard for Seismic Analysis of Safety-Related Nuclear Structures*. ASCE-4-86 provides acceptable methods for seismic analyses, which were used for analysis of safety-class and safety-significant structures. Application of this standard conforms with the guidance provided in DOE-STD-1020-94, HNF-PRO-097, and the architect-engineer's Design Basis Document (Bedell 1996a).

• ASCE-7-93, *Minimum Design Loads for Building and Other Structures*. ASCE-7-93 provides for snow and wind loads to be applied to the design of structures. This standard is used in the Design Basis Document (Bedell 1996a) for load combinations with wind and snow loads following the guidance in HNF-PRO-097 and Table A1-1.

• ASME B30.20-1993, *Below-the-Hook Lifting Devices*. ASME B30.20-1993 provides requirements for the design and fabrication of lifting devices that attach to a crane lifting hook. This specification is used to establish the requirements for the receiving crane transport cask lifting yoke and the MHM tube and shield plug grapples.

• ASME *Boiler and Pressure Vessel Code* (ASME 1995). Safety-class vessels are designed in accordance with the requirements of Section III, Class 2, of the *Boiler and Pressure Vessel Code*. Pressure vessels designated safety significant and general service are designed in accordance with the requirements of Section VIII, Division 1. Application of the *Boiler and Pressure Vessel Code* is required by HNF-SD-SNF-DB-003, in conjunction with NRC Regulatory Guide 1.26.

• ASME NOG-1-1995, *Rules for the Construction of Overhead and Gantry Cranes*. ASME NOG-1-1995 provides requirements for the design, fabrication, and erection of overhead cranes used in nuclear facilities. The ASME NOG-1-1995 design requirements for Type I cranes are imposed on the receiving crane and the MHM crane gantry and hoists by their respective performance specifications. This specification also is used for seismic analysis and design of the MHM and receiving crane.

• NRC Regulatory Guide 1.84, *Design and Fabrication Code Case Acceptability — ASME Section III, Division 1*, and NRC Regulatory Guide 1.85, *Materials Code Case Acceptability — ASME Section III, Division 1*, were reviewed to determine NRC positions on the *Boiler and Pressure Vessel Code* (ASME 1995), Section III code cases for safety class I applications. After reading the titles and brief descriptions, four code cases were investigated. These cases involved alternate rules for examination of welds (Regulatory Guide 1.85), a certified design report summary for component standard supports (Regulatory Guide 1.84), tack welds for major components and piping supports (Regulatory Guide 1.84) and major component
material requirements (Regulatory Guide 1.85). No additional requirements applicable to the CSB were identified from this review of Regulatory Guides 1.84 and 1.85. These code cases were not used in the design of the Boiler and Pressure Vessel Code (ASME 1995), Section III components because the design requirements for the components are adequate and provide similar safety functions. Therefore, the NRC equivalency requirements, Item 11, for the Boiler and Pressure Vessel Code, Section III (ASME 1995), are met.

A4.2.4 Hanford Site Requirements

The following Hanford Site standards are applicable to the safety basis for the facility. Implementation of these standards ensures consistent compliance with DOE orders and implementing standards.

- WHC-CM-4-46, Safety Analysis Manual, Revision 1, as modified by Letter 96-SFD-318, Contract No. DE-AC06-96RL13200: Proposed Spent Nuclear Fuel Project Division (SFD) Risk Acceptance Guidelines (RAGs) (Sellers 1996). Chapter 9.0 of WHC-CM-4-46 identifies the methodology for determining the safety classification of SSCs and the applicable design criteria. The safety-class requirements in Chapter 9.0 of WHC-CM-4-46 implement the criteria established in DOE Order 6430.1A for safety-class items and the requirements for 10 CFR 72 ITS SSCs. Design criteria for safety-significant SSCs also are provided in Chapter 9.0 of WHC-CM-4-46.

The previous versions of the CSB safety analysis report were originally written under a waiver to Chapter 9.0, Revision 2, of WHC-CM-4-46; and the last revision of the phased safety analysis report began incorporating the safety-class/safety-significant terminology of Revision 2. Both sets of terminology were used in the text of this chapter in the last phased safety analysis report revision. This final safety analysis report (FSAR) is written using the guidance of HNF-PRO-704.

- HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements. This document provides guidance on demonstration of NRC equivalency. The major NRC equivalency items related to the CSB design and construction are the seismic criteria contained in WHC-SD-SNF-DB-004, Spent Nuclear Fuel Project Seismic Design Criteria, NRC Equivalency Evaluation Report. Other NPHs required for consideration by HNF-SD-SNF-DB-003 are
described in WHC-SD-SNF-DB-009 and included in Table A1-1. Other impacts to
the design caused by NRC requirements are the use of ANSI/ANS-57.9-1992 for the
application of 5% dead load contingency and the use of ANSI/ANS-57.1-1992 for
lifting requirements for the receiving crane and MHM.

- WHC-SD-SNF-DB-004, 1996, Spent Nuclear Fuel Project Seismic Design Criteria,
  NRC Equivalency Evaluation Report. WHC-SD-SNF-DB-004 provides the basis
  for the Spent Nuclear Fuel (SNF) Project decision and justification that the criteria
  of DOE Order 5480.28 and its implementing standards, and the resulting
  performance category 3, provide adequate seismic design safety. Safety-class SSCs
  are designed to the seismic spectra curves contained in this document and included
  in Figure A4-1.

- WHC-SD-SNF-DB-009, 1996, Canister Storage Building Natural Phenomena
  Hazards. WHC-SD-SNF-DB-009 supplements the Performance Category-3 loads
  in DOE-STD-1020-94 and HNF-PRO-097 for use in the design and construction of
  the CSB. Compliance to both NRC and DOE requirements is accomplished by
designing the CSB to the higher loads recommended by this document. Applicable
  loads of WHC-SD-SNF-DB-009 for safety-class SSCs are contained in Table A1-1.

- HNF-S-0425, Performance Specification for the Spent Nuclear Fuel Canister
  Storage Building. HNF-S-0425 requires that the CSB implement the spectra given
  in DOE-RL-HPS-SDC-4.1, Standard Architectural-Civil Design Criteria: Design
  Loads for Facilities, in designing the facility for a DBE. Earthquake time histories
  for the DBE may be used to satisfy these loading requirements for design and
  analysis of safety-class nonreactor nuclear systems and components as defined in
  DOE-RL-HPS-SDC-4.1.

These loading requirements are supplemented by WHC-SD-SNF-DB-004 as
required by WHC-SD-SNF-DB-009 to comply with NRC equivalency criteria.
Safety-significant items shall be designed to withstand wind loading and
wind-generated missiles according to HNF-PRO-097. Features necessary to protect
the offsite and onsite personnel shall be designed to withstand design basis wind and
missiles, with the criteria for high-hazard usage applicable to safety-class items and
moderate hazard usage applicable to safety-significant items.

- HNF-PRO-097, Engineering Design and Evaluation. This procedure provides
criteria for the design of the CSB. This document is invoked by HNF-S-0425 and
HNF-PRO-704. Section 5.0 of this procedure provides structural design criteria
loads and load combinations for SSCs in Performance Category-4, 3, 2, 1 facilities.
These include dead, live, snow, and soil loads; normal operating loads; and natural
phenomena loading of extreme wind, earthquake, ashfall, and flood. The facility
design has been evaluated for applicable natural phenomena loads listed on
Table A1-1 of Section A1.5, “Natural Phenomena Threats,” for the SSCs impacted.
These loads are higher than HNF-PRO-097 loads, particularly those associated with tornado wind and probable maximum precipitation effects. For example, the tornado wind speed from Table A1-1 is given as 200 mi/h total, versus no tornado wind speed in HNF-PRO-097. This higher wind speed on the operating area shelter transmits higher loads to the below-grade portion of the CSB. The design of the CSB takes into account other NPH loads from Table A1-1. For example, a ground snow load of 20 lb/ft² in Table A1-1 is in excess of the HNF-PRO-097 loading of 15 lb/ft².

A4.2.5 Fluor Daniel, Incorporated, Requirements

- FRP-112, SNF Canister Storage Building (Bedell 1996a). FRP-112 provides information on the design intent, the design methods, and the functions to be performed by SSCs within the CSB. This Design Basis Document (Bedell 1996a) supplements the SNF CSB Performance Specification and provides more detail but does not subtract from the DOE or additional NRC equivalency requirements (HNF-SD-SNF-DB-003). Design of safety-class and safety-significant SSCs is performed to the criteria contained in this document.

A4.3 SAFETY-CLASS STRUCTURES, SYSTEMS, AND COMPONENTS

The safety-class SSCs are summarized in Table A4-1. The table also presents the ITS classification of the SSCs. These safety-class SSCs are designed to the criteria of DOE Order 6430.1A and HNF-PRO-097, applying NPH loads from Section A1.5 for the postulated accident criteria. The subsections of Section A4.3 provide details expanding on the summary descriptions in Table A4-1. The safety significant-functions of safety-class equipment are also shown in Table A4-1.

Nuclear safety equivalency to comparable NRC-licensed facilities is implemented by compliance with existing and applicable DOE requirements coupled with the additional requirement items documented in HNF-SD-SNF-DB-003 that are applicable to the CSB. Compliance with the additional HNF-SD-SNF-DB-003 requirements is documented in a compliance matrix (HNF-4776) and summarized in Table A4-2.

A4.3.1 Canister Storage Building Subsurface Structure

A4.3.1.1 Safety Function. The safety function of the CSB subsurface structure is to prevent damage to MCOs caused by structural failure and provide for natural convective cooling of MCOs that contain SNF until their final disposition has been determined. This forms the design life of the CSB including the subsurface structures as 40 years. The CSB subsurface structure consists of the vault’s concrete basemat, exterior perimeter and interior partition walls, and air

ALARA = as low as reasonably achievable.
CSB = Canister Storage Building.
DOE = U.S. Department of Energy.
FSAR = final safety analysis report.
HEPA = high-efficiency particulate air (filter).
I&C = instrumentation and control.
MCO = multi-canister overpack.
NRC = U.S. Nuclear Regulatory Commission.
SNF = spent nuclear fuel.
intake and exhaust plena. The subsurface structure is classified safety class in accordance with DOE Order 6430.1A because it is required to prevent failure of MCOs from the design criteria NPHs and DBA events described in Section A1.5 (Table A1-1) and Chapter A3.0 and to maintain the MCOs below the design fuel centerline temperature. The air intake and exhaust plena are integral features of natural convection cooling that prevent the violation of concrete design temperature criteria described in Section A4.3.1.3. The plena are structurally integral with the reinforced concrete below-grade exterior walls. The CSB subsurface structure is also classified ITS in accordance with 10 CFR 72, and Category A in accordance with the graded approach outlined in HNF-SD-SNF-DB-003.

A4.3.1.2 System Description. The CSB subsurface structure is described in Section A2.4.1 and shown on Figures A2-5, A2-6, and A2-7. The CSB subsurface is composed of reinforced concrete structures that divide the below-grade vault into three separate storage vaults and dedicated intake and exhaust plena. The design and construction of these structures provide protection from all applicable NPH and DBA events for the 220 storage tubes containing MCOs in vault 1 and for the 6 overpack tubes that may contain MCOs. These structures also are an integral part of the convective cooling system needed to maintain the MCOs below the design SNF centerline temperature, provided in HNF-SD-SNF-SARR-005, Multi-Canister Overpack Topical Report, and the concrete below ANSI/ACI 349-85 temperature limits for long-term normal operation. Vaults 2 and 3 are reserved for future missions. All three vaults provide means to anchor storage tube assemblies to embedded plates located in strips on the basemat directly below the operating deck embeds (see Section A4.3.2).

A4.3.1.3 Functional Requirements. The reinforced concrete subsurface structure is required to withstand all applicable NPH and DBA events to ensure that the MCOs and the storage tubes are not damaged. Maintaining the vault concrete temperature below 150 °F protects the vault’s concrete from long-term thermal degradation (HNF-SD-SNF-SARR-005) and maintains the MCO wall temperature below 270 °F. The air intake and exhaust plena are required to withstand all applicable NPHs to ensure that cooling is maintained to the vault and MCOs. The NPH events applicable to the CSB subsurface structure are discussed in Section A1.5. The NPH design requirements bound all DBAs identified in Chapter A3.0 for the reinforced concrete vault.

The design basis structural analysis of the CSB vault 1 demonstrates that the structure will be capable of withstanding the following load conditions:

- Reinforced concrete dead load
- Continuous live load on deck (100 lb/ft² plus tube vent and purge cart loads)
- Dead weight of the vault 1 exhaust stack
- Loadings associated with all three air-intake structures, steel and concrete portions (includes amplification of top steel canopy structure)
- Loadings associated with 220 standard and 6 overpack steel and concrete tube plugs (dead load supported by tube, seismic horizontal forces at deck, vertical at basemat)
- Loadings associated with 220 standard and 6 overpack steel storage tubes (dead load supported by tube base assemblies located in basemat embeds)
- Dead weight of 440 MCOs including impact absorbers
- Dead weight and live loads associated with MHM, 1,000,000 lb
- Dead weight and live loads associated with MCO cask transporter (live load in load-in/load-out trailer vestibule), 104,000 lb
- Dead weight and lifting loads associated with receiving crane (in load-in/load-out area), 330,000 lb
- Loading associated with the MCO sampling/weld area with seven pits and related equipment; two gantry cranes, sample cart, weld equipment, exhaust equipment
- Operating shelter structure weight (dead load, live load, tornado wind, snowfall and ashfall, seismic loads), 2,160,000 lb
- Side pressure on vault due to soil pressure (at rest) and surcharge load (200 lb/ft²)
- Thermal operating loads, based on Calculations CSB-S-0002, Vault Heat Transfer Analysis, and CSB-S-0003, Thermal Stress Analysis
- MCO concentric drop, 44 ft into storage tube, impact absorber (26 in. diameter)
- MCO eccentric drop, approximately 8 ft onto tube sealing flange, impact on deck
- Dead load of cask and MCO in cask receiving pit and associated gantry crane and tent enclosure in load-in/load-out area
- Loading associated with the Fast Flux Test Facility (FFTF) and MHM maintenance pits in load-in/load-out area
- DBE response spectral analysis with input motion at top of competent layer (8 ft below surface) and dynamic soil shear modulus variation of 1.5 and 1-over-1.5 times the best estimate value with confirmatory analysis using C_v = 1.0
- Tornado wind loads on stacks and intake structures that are transferred to the deck and vault.
A4.3.1.4 System Evaluation. The CSB below-grade structures are designed to withstand the natural phenomena specified in Section A1.5. The CSB basement foundation coincides with a soil profile identified as stratum 3 in Section 3.6.1.9 of WHC-SD-HWV-PSAR-001, Hanford Waste Vitrification Plant Preliminary Safety Analysis Report. This layer exhibits light cementation and is typically in a dense to very dense condition. The formation extends to a depth of approximately 250 ft below grade. Geotechnical investigations reported in WHC-SD-HWV-PSAR-001 characterized the soil properties at the elevation of interest as having high strength and low compressibility. Stratum 3 has a vertical static subgrade modulus value of 518 kip/ft$^2$ based on a 1 ft$^2$ plate. This value is adjusted for the actual foundation size by the equation in Report 10805-385-016, Report of Geotechnical Investigations for the Proposed Hanford Waste Vitrification Plant, Hanford Washington (Dames and Moore 1989).

The structural loading to the foundation, assuming all vaults are fully loaded with SNF, is well within the allowable soil bearing values. Details of the analysis of the adequacy of the soil to carry the anticipated foundation loading are documented in Calculation CSB-S-0023, HCSA/SNF Gravity Load Analysis (W/Tornado). The soil bearing pressures beneath the vault are less than 8 kip/ft$^2$, which is well within the allowable bearing capacity of 14 kip/ft$^2$. The factor of safety against sliding during a DBE is approximately 1.8 as determined in Calculation CSB-S-0024, Vault Seismic Load Analysis. Further soil compaction and settling and vault sliding analyses were performed because of the cantilever effect of the sampling/weld area. Transmittal FRT-011, Deck Cantilever Settlement and Vault Sliding Estimates (Bedell 1996b), concludes that only negligible settlement will occur in the compacted soils around the CSB and under the sampling/weld area and that vault wall pressures during a DBE are adequately considered.

HNF-PRO-097 provides criteria that apply to the design of the portion of the CSB requiring mitigation against NPH loads. Additional natural phenomena requirements associated with NRC equivalency, notably, tornado hazards, ashfall, and increased probable maximum precipitation amounts, are listed on Table A1-1. These loads take into account the seismic criteria of Item 2 of HNF-SD-SNF-DB-003. The facility design has been evaluated for applicable natural phenomena loads listed on Table A1-1 for the SSCs impacted. These loads are higher than loads in HNF-PRO-097, particularly those associated with tornado wind and probable maximum precipitation effects. For example, the tornado wind speed from Table A1-1 is given as 200 mi/h total, while the HNF-PRO-097 tornado wind speed is given as 175 mi/h for reactors. Higher wind speed on the superstructure transmits higher loads to the below-grade portion of the CSB. The design of the CSB takes into account the NPH loads from Section A1.5. The analysis of the subsurface structure design is contained in CSB-S-0042, Vault Design — Confirmation. A summary of the results (demand-to-capacity ratios) of structural analysis and design for the operating area deck, load-in/load-out area, sampling/weld station, and support area building foundation is provided in the structural analyses (Bedell 1996a). Table A4-3 summarizes the demand-to-capacity ratios and the governing load combinations from the structural analysis calculations. The demand-to-capacity ratios for many of the other calculated loads not shown in Table A4-3 are much lower than the demand-to-capacity ratios shown in this table. For all governing load combinations, structural demands are within structural capabilities.

*The design basis extreme temperature maximum and minimum are assumed to occur for a duration of 6 hours.

To = Normal operating temperature.

Toh = Internal forces as a result of normal high operating temperature. They are assumed equal to the forces determined for the extreme high ambient temperature of 115°F.

Tol = Internal forces as a result of normal low operating temperature. They are assumed equal to the forces determined for the extreme low ambient temperature of -27°F.

The thermal loads are negligible since the ambient temperature inside and outside is same.

*Only Vault 1 tower will be constructed for the Spent Nuclear Fuel project.

'1. Assumes two MCOs at 18,100 lb each.

2. Tube assembly weight is 5,450 lb.

3. Assumes two impact absorbers at 500 lb each.

FFT = Fast Flux Test Facility.

MCO = multi-canister overpack.

MHM = multi-canister overpack handling machine.

C = Compression.

D = Dead load.

Ed = Design basis earthquake.

ED = Dead load, vaults empty with MCOs.

FD = Dead load, vaults full with MCOs.

Fu = Inelastic energy absorption capacity factor.

H = At-rest soil pressure load.

L = Live load (floor, roof, snow, ashfall).

S = Snow load.

T = Tension.

Wt = Tornado wind load.

The following referenced calculations were prepared by Fluor Daniel, Incorporated, Richland, Washington:

- CSB-S-0042, 1996, *Vault Design — Confirmation, Rev. 0*.
- CSB-S-0043, 1996, *HCSA Deck Design — Confirmation, Rev. 0*.
- CSB-S-0046, 1997, *Air-Intake Concrete Structure — Confirmation, Rev. 0*.
- CSB-S-0047, 1997, *Air-Intake Steel Structure — Confirmation, Rev. 0*.
The subsurface concrete structure forms the major portion of the natural convection cooling design for the CSB. Design of the natural convection cooling features is based upon two-dimensional thermal analysis using two-dimensional modeling software and assuming the maximum design air inlet temperature of 115 °F. Results of the vault thermal analysis are documented in Calculation CSB-HV-0001, *A Canister Storage Building Vault Thermal Analysis*. The results indicate that the maximum air temperature inside the vault is less than the 150 °F concrete limitation in ANSI/ACI 349-85, Appendix A. Figures A4-2 and A4-3 represent the results of the thermal analyses and should be referred to for temperature profiles. The results of calculation CSB-S-0042 are based on the assumption that the design basis extreme temperature maximum occurs for a duration of 6 hours. For conservatism, the reinforced concrete strength values used in the analysis were decreased by 1,000 lb/in² to account for long term concrete temperature effects. The specified reinforced concrete 90-day compressive strength (Class MC1P) for the subsurface concrete structures (below elevation 704 ft) is 5,000 lb/in² in accordance with ANSI/ACI 349-85. Steel reinforcement is specified as 60,000 lb/in² tensile strength in accordance with ASTM A615/A615M-96a, *Standard Specification for Deformed and Plain Billet-Steel Bars for Concrete Reinforcement*. For shielding purposes, the density of the subsurface concrete is assumed to be 2.24 g/cm³.

Detailed design calculations have not addressed solar heat gain and wind effects because those effects are of minor importance. The underground storage vault is not directly affected by solar heat. The exhaust stack and the air intake are exposed to the same incidence of instantaneous solar exposure, which has a negligible effect on the thermal analysis because of the slight increase in density differential created by the stack effect. The thermal analysis does not include this effect and has considered the effect to be a part of the safety factor in the calculation. The above-grade structures that rest on the below-grade intake and exhaust plena are designed to prevent plugging caused by ice, snow, ashfall, and windborne debris. Evaluations of flow blockage contained in CSB-HV-0003, *Spent Nuclear Fuel Vault Loss of Cooling Analysis* (see Section A3.4.2.6), demonstrate that the increased temperatures due to blockage do not challenge the structural integrity of the CSB vault.

**A4.3.1.4.1 Soil-Structure Interaction.** Several steps were used to determine the effects of soil-structure interaction (SSI) on the seismic response of the SNF CSB. Initially, parametric studies were conducted to evaluate the seismic response of the site soils and to determine the level of the soil stress-strain properties for the given level of input ground motion. This was accomplished by finite element methods using the SHAKE computer code analysis. One-dimensional models of the soil properties were developed and equivalent linear soil properties compatible with the strains developed in each layer. These properties were then used in the next step as an initial estimate of soil properties used in the SSI analysis. The SSI was defined by finite element methods using the FLUSH computer code analysis, which is described in *FLUSH: A Computer Program for Approximate 3-D Analysis of Soil–Structure Interaction Problems* (Lysmer et al. 1975).

Two-dimensional models of the soil and structure were developed and gross motion SSI responses for the structure and loads in the below-grade walls and basemat were assessed.
These results served as verification of the three-dimensional dynamic model created using the
SAP90 computer program documented in *SAP90, A Series of Computer Programs for Finite
Element Analysis of Structures* (CSI 1995). The model included the SNF CSB underground vault
with surrounding soil and a massive soil column representing "free field." The outer perimeter
nodes of the soil elements surrounding the vault were slaved to the elements of the massive soil
column thus simulating the transmitting boundary as in the FLUSH (Lysmer et al. 1975) analysis.
This forced the outer perimeter boundaries of the soil surrounding the vault to move with the free
field. This analysis approach provided a one-step method to account for SSI effects and yielded
three-dimensional shear and moment force distributions over the underground vault structure.
The three-dimensional analysis used input (response spectra and time histories) at the bottom of
the vault generated from the free field ground motions acting at the top of the competent layer,
deconvoluted to the bottom of the vault using the SHAKE program.

Uncertainty in the accurate prediction of dynamic soil properties was accounted for by
employing a parametric analysis using a range of soil dynamic shear moduli values. The range of
soil dynamic shear moduli was bounded by the best estimate dynamic shear modulus multiplied by
1.5, the best estimate dynamic modulus divided by 1.5, and the best estimate shear modulus
multiplied by 1.0 (ASCE-4-86). Confirmatory analyses for soil dynamic shear moduli ranging
from 2 and 0.5 times the best estimate were also done. Strain-dependent soil shear modulus and
damping values were used in the SSI analysis.

The SAP90 computer program (CSI 1995) is not normally used to account for SSI.
However, applying the boundaries of soil elements, using the appropriate properties and applying
the free-field motion for the surface and below-surface soil pressures, the resultant response
spectra were shown to be consistent with the FLUSH (Lysmer et al. 1975) analysis values. It is
on this basis that the SAP90 computer model is reasonable and the analysis results are
appropriate. The comparison results were documented in Letter FRF-092, *DOE SAR Team

A4.3.1.4.2 Time Histories. ABB Impell Corporation was a subcontractor to the
architect-engineer on the Hanford Waste Vitrification Plant Project. They provided the artificial
earthquake time history that was used in the design of the Hanford Waste Vitrification Plant CSB
and is being used in the SNF CSB Project. *Seismic Acceleration Time Histories in Support of
Fluor Daniel, Inc. Project HWVP-845734* (Salmon et al. 1990) indicates that a single synthetic
time history was created to simulate the DBE. The resulting time history is shown to meet NRC
acceptance criteria for a single design time history (NUREG-0800). All important ground motion
characteristics, including check for power spectral density content, were included in the developed
time history.

A4.3.1.4.3 Asymmetric Loading Effects on the Substructure. The seismic analysis
considered all three vaults to be filled with MCOs and all three intake structures and exhaust
stacks to be in place. In addition to all the actual above-grade eccentricities (e.g., MHM,
superstructure, and receiving crane), the model included a 5% accidental eccentricity.
A dominant feature of these below-grade vaults is the participation of the soil mass in the wall
flexure and in-plane shears. Since the stored SNF, intake structures, and exhaust stacks account
for less than 1% of the total seismic model mass (soil, structure, and stored fuel) and
approximately 32% of the vault structure and stored fuel system, it was judged that the effective
eccentricity was small and that the governing configuration for seismic analysis would be the
condition in which all three vaults are full and all three intake and exhaust structures in place.
A two-dimensional, 1-ft strip model of the vault-deck section was evaluated for the asymmetric
gravity and temperature loads. The results of the analysis confirmed that the demand in moments
and shears did not exceed the capacity (Jacobs 1996).

The design of the basemat and below-grade walls is in accordance with ANSI/ACI 349-85.
In general the governing design condition for the concrete deck, below-grade walls, and basemat
was based on thermal and seismic rather than tornado loads. The extreme high-temperature
condition only occurs when the vault is completely full and the extreme low-temperature
condition occurs only when the vault is completely empty. Any asymmetric loading of the vault
(e.g., all tubes in one or two vaults full of heat-source material, but not all three vaults loaded)
relaxes the self-straining thermal stresses in the vault structure and reduces thermal demand.
Based on this reasoning, it was judged that the governing condition for the design of the basemat
and below-grade walls was either all the vaults full with high temperature inlet air or all vaults
empty with low temperature inlet air. Therefore, the designs of the basemat and below-grade
walls are bounded by the two extreme conditions and are not governed by a checkerboard loading
pattern because of the dominance of thermal loads.

The internal forces due to temperature used in the design are based on the design basis
extreme ambient temperature of 115 °F maximum and -27 °F minimum (Bedell 1996a) occurring
for a duration of 6 hours at any time during the service life of the CSB based on site
meteorological data. Therefore the demand-capacity ratios with the temperature load $T_a$ include
conservatism as loads caused by extreme temperature conditions have been used in lieu of normal
operating temperatures as required by ANSI/ACI 349-85. The demand-capacity ratios given are
for seismic confirmatory analysis done with seismic input at the top of the competent layer (8 ft
below the surface) and using soil shear modulus variations between best estimate values multiplied
by $(1 + C_v)$ and best estimate values divided by $(1 + C_v)$, where $C_v$ is a factor that accounts for
uncertainties in the SSI analysis and soil properties. The minimum value of $C_v$ according to
ASCE-4-86 is 0.5; however, for confirmatory analysis, $C_v = 1.0$ was used.

The high mass of the generally box-like configuration formed by the below-grade concrete
CSB structure, the deck, and the above-grade concrete features (the concrete portion of the inlet
structure and the exhaust stack bases) makes it susceptible to DBE forces. When combined with
thermal stresses, governing load combinations result for many of these components.

The deck has been designed to provide an adequate safety margin for combined thermal
and tornado wind loading to prevent a 200 mi/h tornado wind load from creating unacceptable
loads on areas where the bending moment is transmitted from the above-grade structures to the
deck. Tornado wind loading by itself is governing for some features of the operating area shelter
as well as for the support building.
A4.3.1.4.4 Modeling of the Deck, Superstructure, Ventilation Stacks, and the Multi-Canister Overpack Handling Machine — Effects on the Substructure. As severe as tornado loading may be, the forces transmitted to the below-grade structure are well below the forces transmitted by seismic forces. Calculations indicate that the below-grade design controlling values of soil pressures, member stresses, displacements, or other parameters are not affected by tornado wind (Wt) loads. None of the governing conditions for below-grade items (the substructure) were based on tornado wind loads. The weight of the MHM is included in the seismic calculation that affects the seismic response of the CSB below-grade and at-grade structures. The design also includes evaluations of the deck and related structures, such as the stacks and inlets for tornado wind effects as well as the 5% dead load increases required by ANSI/ANS-57.9-1992 and Item 28 of HNF-SD-SNF-DB-003. The designs were modified as appropriate to accommodate those loads before releases for construction of the below-grade and at-grade reinforced concrete structures.

A4.3.1.4.5 Vault Sliding Resistance and Passive Wall Pressures. Analysis to determine the level of strain required to slide (see Bedell 1996a), as compared with calculated strain values, was performed to demonstrate that relevant passive wall pressures were used in the design of the below-grade walls (see CSB-S-0024). The analysis contained in the Design Basis Document (Bedell 1996a) estimates that full frictional resistance of the vault basemat-soil interface occurs at a displacement of only 0.15 in., whereas full passive soil pressures on the wall are activated at a movement of approximately 14 in. for a 47-ft-deep vault wall.

The FLUSH analysis documented in CSB-S-0032, FLUSH Analysis — MEAN 1.5 and MEAN/1.5, indicates that the maximum shear strain and shear modulus in the soil elements below the vault basemat result in a DBE shear stress at the soil basemat interface of 1.54 kip/ft². Obtaining the frictional resistance of the mass concrete on coarse sand and gravel (2.38 kip/ft²) results in a factor of safety against sliding of 1.55. The 0.15-in. displacement for full frictional resistance to be activated and the ratio of shear stress to frictional resistance of 0.65 results in a displacement of 0.10 in. due to DBE shear. For shear deformation of 0.15 in. or less, the passive pressure coefficient is given as 0.50 (Bedell 1996a). The CSB walls were designed for a passive pressure coefficient of 0.62, which is greater than the passive pressure occurring from vault displacement during a DBE. In summary, the CSB vault walls have been designed for larger soil pressures than the passive pressures developed during a DBE.

A4.3.1.5 Controls (Technical Safety Requirements). The CSB subsurface structure is a design feature (see Section A5.6), and its safety function is managed by the configuration control process.

A4.3.2 Carbon Steel Basemat Embeds

A4.3.2.1 Safety Function. The 220 tubes (and 6 overpack tubes) of vault 1 are seismically restrained through the use of tube base assemblies that bolt to carbon steel embeds in the basemat of the CSB. In vault 1 these embeds are safety class in accordance with DOE Order 6430.1A and
ITS Category A in accordance with the graded approach in HNF-SD-SNF-DB-003 because they serve the safety function to maintain horizontal stability of standard and overpack storage tubes, provide for natural convective cooling, and prevent damage to MCOs caused by structural failure.

A4.3.2.2 System Description. Two rows of carbon steel embed strips are located under each row of tubes, as shown in Figure A2-5. The embeds serve as the welding plates for the threaded weld studs to which the tube base assemblies are bolted. The tube base assemblies are not affixed to the tubes but will restrain the tubes. Each tube base assembly comprises a 1-in. carbon steel plate bolted to the embed strips in four places and a short (about 6 in. tall), right-circular cylinder of 0.5-in.-thick carbon steel, of a diameter slightly larger than that of the tube, welded to the top of the plate. The tubes rest on top of the carbon steel plates and are seismically restrained within the 6-in.-tall cylindrical band.

A4.3.2.3 Functional Requirements. The embeds in vault 1 must remain in place during the DBE to provide horizontal stabilization of the tubes. Horizontal stability of the storage tubes is required during the DBE to maintain cooling.

A4.3.2.4 System Evaluation. The carbon steel embeds for vault 1 have been evaluated for the DBE specified in Section A1.5 based on the seismic loading from the storage tubes, impact absorbers, and the MCOs, which contain SNF and weigh up to 20,200 lb. Embed–tube interface design accommodates the DBE for tubes loaded with MCOs and impact absorbers. The embeds and tube base assemblies work in concert to restrain the storage tubes at the basemat elevation. Seismic analysis and design of the embeds was performed to ANSI/ACI 349-85 standards in calculation CSB-S-0007A, Storage Tube Analysis, and included the seismic interaction loads from two MCOs.

A4.3.2.5 Controls (Technical Safety Requirements). The carbon steel basemat embeds are a design feature (see Section A5.6), and their safety function is managed by the configuration control process. Design features for the carbon steel basemat embeds ensure that their safety function can be relied upon.

A4.3.3 Canister Storage Building At-Grade Structures

A4.3.3.1 Safety Function. The at-grade reinforced concrete structures of the operating area deck (including the sampling/weld area, the load-in/load-out area, and the intake structure and exhaust stack bases) are an integral part of the CSB vault and are classified as safety class in accordance with DOE Order 6430.1A. The CSB at-grade structures share the design functions of the vault to prevent damage to MCOs caused by structural failure and provide for natural convective cooling. The CSB at-grade structures are classified ITS in accordance with 10 CFR 72, and Category A in accordance with the graded approach outlined in HNF-SD-SNF-DB-003.
A4.3.3.2 System Description. The at-grade reinforced concrete structures are shown on Figures A2-3 and A2-7. The at-grade reinforced concrete structures have overall dimensions of 285 ft, 0.5 in. by 189 ft, 5.5 in. The operating area deck is a 5-ft-thick reinforced concrete structure. The deck is 181 ft, 2 in. by 165 ft, 9 in. Deck embeds in the operating area deck locate the openings for the 220 standard and 6 overpack storage tube locations. The deck embeds for vault 1 are fitted with tube plugs and covers designed to provide shielding and to provide access to service connections on the tube plugs (see Section A4.4.2). The deck embeds for vaults 2 and 3 are fitted with embed covers to protect personnel from falls (see Section A2.4.3.3). The deck embed sleeves in the operating area deck provide a finished surface on which to rest the storage tube bellows assembly (see Sections A4.3.4 and A4.3.5).

A 4 ft, 4 in. wide by 3 ft high curb borders the operating floor area (operating deck, sampling/weld area, and load-in/load-out area) on the east, west, and south. The curb height is increased to 8 ft at the north end to meet shielding requirements for the transportation cask while allowing unlimited occupancy in the support area building.

The intake structure and exhaust stack are described in Section A2.4.4.1.

The sampling/weld area is an extension to the south of the operating deck with overall dimensions of 138 ft, 11 in. by 35 ft, 3 in. A loading–staging area is provided at the west side of the sampling/weld area. The loading–staging area dimensions are 27 ft, 4 in. by 24 ft, 11 in.

The load-in/load-out area is located at the north end of the operating deck. The dimensions of the load-in/load-out area are 189 ft, 5.5 in. by 42 ft, 7 in. at the trailer vestibule and 189 ft, 5.5 in. by 29 ft, 9.5 in. at the MCO service station.

The at-grade structure of the CSB is designed to carry the loads associated with the MHM transporting an MCO. The MHM, a large, heavy crane, weighs approximately 990,000 lb, and the heaviest MCO weighs approximately 20,200 lb. The MHM rides on steel rails running north and south and embedded in the operating deck concrete. Anchor bolts and lateral restraints secure the rails within the trenches and are designed to provide restraint of the MHM rails, including the MHM bound to the rails by the MHM bridge seismic clamps, during a DBE (see Section A4.3.10 for a discussion of the MHM rails).

A4.3.3.3 Functional Requirements. The operating deck is designed to move with the vault walls and basemat to support the loads associated with the CSB. The operating deck, support area building foundation, load-in/load-out area, and sampling/weld area are designed to the same safety-class criteria and NPH events as the below-grade vault. The NPH events are those discussed in Section A1.5. The NPH design requirements bound all identified DBAs.
To meet these requirements, the operating area deck (including the sampling/weld areas and load-in/load-out area) is designed for the following loading conditions:

- Roof dead load (17 lb/ft² used in design, 15.44 lb/ft² estimated including a 5% contingency [0.74 lb/ft²] per ANSI/ANS 57.9-1992)
- Snow load at ground level; roof snow load (considering drifts at low roofs)
- Roof live load (20 lb/ft²)
- Volcanic ashfall load at ground level and ashfall roof drift
- Siding dead load
- Wind loads (90 mi/h; wind-driven missile 2 in. by 4 in. wood plank, 15 lb at 50 mi/h)
- Seismic load, horizontal response spectra anchored at 0.35 g (“free field” used in Calculation CSB-S-0029, CSB Operating Shelter); vertical is two-thirds of horizontal spectra; confirmatory analysis Calculation CSB-S-0048, Operating Shelter Confirmation Analysis, used in-structure response spectra at deck level based on seismic input at top of competent layer and soil properties at mean, two times mean, and one-half mean

A4.3.3.4 System Evaluation. The operating area deck has been designed to provide an adequate safety margin for combined thermal and tornado wind loading to prevent a 200 mi/h tornado wind load from creating unacceptable loads on areas where the bending moment is transmitted from the above-grade structures to the deck. Tornado wind loading by itself is governing for some features of the operating area shelter. The CSB at-grade reinforced concrete structures have been designed for all applicable loads and load combinations required by Table A1-1. These are further defined in the architect-engineer’s Design Basis Document (Bedell 1996a), Section 10. The loads include normal loads, severe and extreme environmental loads, and natural phenomena loads. The NPH loads bound all identified DBAs. A summary of the results (demand-to-capacity ratios) of structural analysis and design for the operating area deck, load-in/load-out area, sampling/weld station, and support area building foundation is provided in the structural analyses (Bedell 1996a). For all governing load combinations, structural demands are within structural capabilities.

The operating area deck has been designed using an isotropic plate model with a reduced modulus of elasticity derived from a comparison of the natural frequencies of a beam (grillage) model and a plate-element model. Demand capacity ratios derived from Calculation CSB-S-0041, SNF Deck Design and Exhaust Stack — Confirmation, indicate that the governing load combinations are those of dead and live load with a soil pressure load in combination with
extreme temperatures ($T_{el}$ and $T_{oh}$), and seismic loads (modified using $F_u > 1.0$ per
DOE-STD-1020-94). Demand/capacity ratios in excess of 90% during these conditions are
present in the operating floor at the crane rails (N–S flexural shear; 0.99), at the intake plenum
(E–W flexural shear; 0.98, E–W top reinforcing; 0.99, and N–S bottom reinforcing; 0.99), and at
the exhaust plenum (E–W flexural shear; 0.95, E–W bottom reinforcing; 0.95, and N–S top
reinforcing; 0.99). Highest demand/capacity ratios for the operating floor at the tubes were at the
E–W top reinforcing; 0.88, and E–W bottom reinforcing; 0.86 (Table A4-3).

Structural concrete mix classes for the operating area deck structures (above elevation
704 ft, 0 in.) have a specified 90-day compressive strength of 6,000 lb/in² (Class MC2P) in
accordance with ANSI/ACI 349-85. Those structures that are slab-on-grade (north and south
cantilevers), i.e., the load-in/load-out area, support building foundation and sampling/weld station,
have a specified 28-day compressive strength of 4,000 lb/in² in accordance with
ANSI/ACI 349-85. For conservatism, the reinforced concrete strength values of the operating
area deck structures used in the analysis were decreased by 1,000 lb/in² to account for long term
concrete temperature effects. Steel reinforcement for all at-grade structures is specified as
60,000 lb/in² tensile strength in accordance with ASTM A615/A615M-96a. For shielding
purposes the density of the operating area deck concrete is assumed to be 2.24 g/cm³.

The operating area deck has been designed to perform at the temperatures expected from
the below-grade storage of MCOs. The design analysis results, as shown on Figure A4-3,
indicate that for a fully loaded vault, the highest calculated concrete temperature on the operating
deck floor surface is 105 °F, coincident with a site ambient temperature of 115 °F. The results of
calculation CSB-S-0041 are based on the assumption that the design basis extreme temperature
maximum occurs for a duration of 6 hours. The highest calculated temperature for the operating
area deck slab on the vault side is 121 °F except for slightly higher temperatures in the local areas
adjacent to the storage tubes. This temperature occurs at the underside of the deck slab next to
the storage tube. These temperature values were obtained from CSB-HV-0001.

The geotechnical predicted-settlement values (Bedell 1996a) were compared with the
settlement values computed by the structural analysis for the sampling/weld station, which is
documented in Calculation CSB-S-0026A, HCSA/SNF Deck Design. The differential settlements
computed by the structural analysis were found to be generally larger than in the geotechnical
analysis. The maximum anticipated differential settlement is on the order of 0.10 in. across the
30 to 35 ft of the south cantilevered deck. Although the predicted differential settlements are
small, a crack control joint at the interface with the vault's north and south walls has been included
in the design.

The quality of backfill material being used and the field compaction tests conducted to date
have been reviewed and found to meet or exceed the project specification requirements
(Bedell 1996a). To account for uncertainty in the execution of construction and to confirm the
design agent's predicted settlement assumptions, settlement measurements using the survey
markers shown in Figure A2-3, sheet 1, at the north and south vault walls and at the edges of the
north and south deck cantilevers will be taken and evaluated after construction and during
operation.

Specific tornado wind loads were developed for the intake and exhaust stacks to evaluate
their impact on the vault deck. Structural evaluations are documented in Calculation
CSB-S-0012, Vault Exhaust Stack, for the exhaust stack (including exhaust stack base);
Calculations CSB-S-0028, Intake Structure, Steel (Tornado Loading); and CSB-S-0028A, Intake
Structure, Concrete (W/Tornado), for the intake structure; and Calculation CSB-S-0026, Deck
Design, for the operating area deck (CSB-S-0026A for the sampling/weld area). The change
from hot conditioning pits to sampling/weld stations is documented in Calculation CSB-S-0043,
HCSA Deck Design — Confirmation. The governing load combination with tornado wind for the
operating area floor is at the exhaust plenum (E–W top reinforcing, 0.42).

The columns of the operating area shelter are pin-connected to base plates located along
the curbs. Anchor bolts for these base plates are in accordance with ANSI/ACI 349-85. Moment
loadings associated with the partial fixity of these columns are carried by these curbs into the
operating deck and subsurface structure. Evaluations of the partial plate fixity condition are
included in CSB-S-0048, Supplement A, and determined that the anchor bolts can accommodate
moments varying between 20% for the 8-bolt pattern and 40-50% for the 12-bolt pattern, of the
fully fixed moments. These capacities are based on the 100-40-40 rule (as permitted by
DOE-STD-1020-94 for seismic component loadings) and also considered 17 lb/ft² dead load and
5 lb/ft² for the snow as additional effective mass for seismic analysis. The capability of the
operating deck and subsurface structures to withstand the added base plate fixity was evaluated
(see CSB-S-0041), and it was determined that the deck has the necessary capacity to carry the
added moment fixity load (Table A4-3).

Using NRC-accepted tornado missile probability methodology provided by the design
authority in Letter 9652531, Spent Nuclear Fuel/Canister Storage Building — Tornado Strategy
Implementation Plan (Bazinet 1996), the architect-engineer completed a probabilistic risk
analysis of tornado wind-driven missiles becoming credible impact loads for the CSB assuming no
resistance provided by the superstructure. Further adjustments to the probabilistic risk analyses
were made using a survey of the site for potential missiles and documented in
Letter 96-0133.MMB, Task Order 07, WHC Contract No. MRV-SBW-482901. Analysis of
Tornado/Tornado Missile Risk to New SNFP Facility; Initial Report (Beary 1996b), and in Letter
075MMB.96, Errata: Table 4. Analysis of Tornado/Tornado Missile Risk to New SNFP Facility
(Beary 1996a). The revised estimated annual frequency of 4 × 10⁻⁶ for a missile strike on the CSB
is well below the NRC criterion of 1 × 10⁻⁶ per year (Jacobs 1996). Therefore, the CSB is not
subject to missile impacts, and the structures are designed for the tornado wind and atmospheric
pressure change.

A4.3.3.5 Controls (Technical Safety Requirements). The CSB at-grade structures are design
features (see Section A5.6), and their safety functions are managed by the configuration control
process. Design features of the CSB at-grade structures ensure that their safety function can be
relied upon.
A4.3.4 Standard Storage Tubes and Tube Base Assemblies

A4.3.4.1 Safety Function. The standard storage tubes and tube base assemblies are classified as safety class in accordance with DOE Order 6430.1A and ITS Category A, using the graded approach of HNF-SD-SNF-DB-003. These components perform the safety functions of preventing damage to MCOs caused by structural failures and providing for natural convective cooling. These components are designated safety class and ITS Category A as derived in Section A3.4.2.1 and Section A3.4.4.1. Safety features of the storage tube design limit potential damage to an MCO and ensure that an MCO is “readily retrievable” before and after an accidental drop. This meets the NRC equivalency requirement in Item 2 of HNF-SD-SNF-DB-003 that the MCO be readily retrievable.

A4.3.4.2 System Description. The standard storage tubes are 0.5-in.-thick, 41-ft, 4-in.-long carbon steel pipes. The 220 standard tubes have outside diameters of 28 in. The standard storage tube assemblies, including standard tube plug covers, are described in Section A2.4.3 and shown on Figures A2-10 through A2-15.

Tube base assemblies (see Figure A2-11) locate and attach the base of the storage tubes to the vault basemat. The tube base assemblies attach to basemat embeds as described in Section A4.3.2. Standard storage tube center-to-center distances are the same as the basemat embed center-to-center distances, which are provided in Section A2.4.2.

A4.3.4.3 Functional Requirements. The storage tube and tube base assembly (which is attached to a basemat embed) are required to provide lateral restraint of the MCO during a seismic event. The seismic event is represented by the free field response spectra found on Figure A4-1 and described in WHC-SD-SNF-DB-004 amplified by the response of the building’s attachment points.

The safety function of the standard tubes, which must be maintained during and after a seismic event, is to provide and maintain structural support and the required geometry for cooling. HNF-PRO-097 provides a consistent approach for implementing requirements for design of SSCs designated safety class in accordance with DOE Order 6430.1A.

A4.3.4.4 System Evaluation. The standard storage tubes and base assemblies, attached to the slab embeds, are designed to provide adequate restraint of the MCOs during all NPHs, including seismic events. The restraint provided by the storage tubes maintains the geometric spacing modeled by criticality analyses and required for cooling.

All aspects of the design, fabrication, and installation of the standard storage tube assemblies and tube base assemblies meet Section III of the Boiler and Pressure Vessel Code (ASME 1995), or ANSI/AISC N690-94, or have been demonstrated to be equivalent to Section III (ASME 1995).
The design of the tube body, the tube bottom plate, and the bellows assembly has been shown to meet the requirements of the *Boiler and Pressure Vessel Code*, Section III (ASME 1995). Structural calculations supporting the design, including seismic analysis, predict stresses within allowables.

The tubes were fabricated by rolling plate, joining the plate edges by a longitudinal weld, and attaching the base plate at the bottom and the bellows at the top by a circumferential weld. In Letter 97-SFD-135, *Request for Independent Review Panel (IRP) Concurreance with Nonconformances in the Application of ASME Section III to the Canister Storage Building (CSB) Tube Assemblies to Achieve NRC Nuclear Safety Equivalency* (Hiegel 1997), the tube material and the welds were judged to be equivalent to the *Boiler and Pressure Vessel Code*, Section III (ASME 1995), requirements. The longitudinal weld was inspected by ultrasonic examination in accordance with recommendations resulting from the analysis supporting equivalency. The storage tube bottom plate attachment weld to the storage tube pipe was performed to ANSI/AISC N690-94.

The fabrication requirements of Section III of *Boiler and Pressure Vessel Code* (ASME 1995) were applied to the tube base assemblies (ASME A36 carbon steel). The tube base assemblies provide lateral restraint, which is a structural function. They are bolted to the basemat embeds using ASME SA-307 studs and ASME SA-563 nuts. The structural and thermal functional requirements of Section III, Division 1, Subsection NE, Class MC, of the *Boiler and Pressure Vessel Code* (ASME 1995) have been applied to the standard storage tubes. The exceptions to the application of the *Boiler and Pressure Vessel Code* (ASME 1995) were identified and dispositioned by Letter 97-SFD-135 (Hiegel 1997). The storage tube bellows are fabricated to Section III, Division 1, Article NE-4800 (ASME 1995), for high reliability.

According to WHC-SD-WM-ER-525, *Thermal Hydraulic Feasibility Assessment for the Spent Nuclear Fuel Project*, the vault was designed to ensure that the fuel centerline temperature never exceeds 400 °F under steady-state conditions. This value is substantially less than the 1,112 °F design limit (HNF-SD-SNF-SARR-005). The highest calculated storage tube temperature is 186 °F (Figure A4-3), coincident with a site ambient temperature of 115 °F (Figure A4-2) and a flow rate through the vault of 31,700 ft³/min. These values are from information contained in the addendum to Calculation CSB-HV-0001. The cooling passages in the tube base assemblies provide thermal isolation of the concrete vault basemat and of the steel embeds from the storage tube to ensure that the concrete's temperature limit of 150 °F is not exceeded. In Calculation CSB-SH-1001, *SNF CSB Shielding Source Terms*, radiation levels in the vault are estimated at 200 rem/h for a total integrated dose to the impact absorbers of $7 \times 10^7$ rad. These maximum temperatures and radiation levels are not detrimental to the materials of construction for the standard storage tube assemblies.

The storage tube assembly was investigated for compliance with requirements for operational conditions only without seismic forces. These calculations are included as a reference in Calculation CSB-S-0007A, Appendix K. Modifications to the storage tube assembly design as identified in this investigation were incorporated and form the basis for the design used in this...
current analysis. This analysis supplements the previous one by incorporating the effects of seismic forces.

Operational conditions of the storage tube assembly present during the seismic event included an elevated operating temperature of 220 °F, an operating pressure of 100 lb/in² gauge, plug weight, and gravity. This maximum combined loading condition resulted in a maximum combined stress in the storage tube assembly of 13,400 lb/in². The governing condition included seismic + thermal + gravity forces (no internal pressure). This resulted in a maximum compression stress for design of approximately 12,000 lb/in² (Calculation CSB-S-0007A, Appendix K). The allowable for compression is 17,000 lb/in² according to the requirements of the Boiler and Pressure Vessel Code (ASME 1995), Section III. As addressed in Letter 97-SFD-135 (Hiegel 1997), the maximum combined stress is less than the allowable stress, therefore the standard storage tube assembly design is in compliance with the requirements of the Boiler and Pressure Vessel Code, Section III (ASME 1995).

A4.3.4.5 Controls (Technical Safety Requirements). The standard storage tube and the tube base assemblies are design features, and their safety function is managed by the configuration control process (see Section A5.6).

A4.3.5 Overpack Storage Tubes and Tube Base Assemblies

A4.3.5.1 Safety Function. The overpack storage tubes and tube base assemblies provide the safety functions of preventing damage to MCOs caused by structural failure and providing for natural convective cooling. Confinement of suspect MCOs is a recovery action and is designated safety significant. The overpack storage tubes and tube base assemblies are designated safety class in accordance with DOE Order 6430.1A and ITS Category A using the graded approach of HNF-SD-SNF-DB-003 per the requirements of Sections A3.4.2.1 and A3.4.4.1. The overpack storage tubes and the tube base assemblies provide structural support for the MCOs during NPHs to maintain the geometric array for cooling. A nominal 1-in. clearance between the lower bellows flange and the lower deck embed step (see Figure A2-8) helps to maintain overpack storage tube integrity during a potential MCO eccentric drop accident and to limit the impact damage to the MCO from the drop to ensure that the dropped MCO is retrievable. Safety features of the storage tube design limit potential damage to an MCO and achieve “readily retrievable” for an MCO before and after an accidental drop. This meets the requirements for ready retrievability as defined by NRC equivalency Item 2 of HNF-SD-SNF-DB-003. The overpack storage tubes provide the additional function of containing inert gas and of forming the secondary confinement for the SNF-containing accident-damaged or suspect MCOs. This function is considered a corrective action to an abnormal event.
A4.3.5.2 System Description. The six overpack storage tubes are fabricated from carbon steel rolled plate conforming to ASME SA576 (ASTM A576) or pipe conforming to ASME SA671 (ASTM A671) Gr. CC-70 (ASME 1995, Section II) and are 41 ft, 4 in. long. The overpack storage tubes have an outside diameter of 28 in. Overpack storage tube base assemblies locate and attach the base of the overpack storage tubes to the vault basemat. Overpack storage tube center-to-center distances are the same as the basemat embed center-to-center distances, which are provided in Section A2.4.2. Overpack storage tube base assemblies are constructed of carbon steel plate sections conforming to ASTM A36/A36M, Standard Specification for Carbon Structural Steel. Bottom closure plates on the overpack storage tubes conforming to ASME SA516 (ASTM A516), Grade 70 (ASME 1995, Section II), are 30 in. in diameter to fit snugly into the overpack tube base assemblies. Bellows assemblies consist of a stainless steel, convoluted, thin gauge sheet plate formed into a cylinder conforming to ASME SA-240 (ASTM A240) Type 304 or 321 with stub ends conforming to ASME SA36 (ASTM A36/A36M) or SA516 (ASTM A516/A516M) welded to upper and lower carbon steel flanges conforming to ASME SA516 (ASTM A516/A516M). The lower bellows flange is provided with hold-down bolts to restrain the plug from lifting off the flange surface and releasing radioactive gas or particulate. A separate hold down bolt locking assembly ensures that the plug will not lift. Redundant O-ring seals in the tube plug contain the inert gas and confine the radioactive gas and particulate from the suspect MCO (see Section A2.4.3 and Figures A2-10 through A2-15). Overpack tube plugs are described in Section A4.4.3.

A4.3.5.3 Functional Requirements. The overpack storage tubes and tube base assemblies, which are attached to the basemat embeds, are required to provide lateral restraint of the MCOs during NPHs including seismic events. The seismic event is the free-field response spectra found on Figure A4-1 and described in WHC-SD-SNF-DB-004 amplified by the response of the building's attachment points. The overpack storage tube assemblies are designed to contain the inert gas atmosphere and confine the radioactive gas or particulate that may escape from an off-normal MCO placed in the tube. The design pressure for the overpack tube is 75 lb/in² gauge at a temperature of 220 °F. The pressure vessel safety-class code used for the analysis, design, and fabrication of the overpack storage tube components is the Boiler and Pressure Vessel Code, Section III, Class 2 (ASME 1995). HNF-SD-SNF-DB-003, Item 10, requires that systems and components designated to comply with Section III of the Boiler and Pressure Vessel Code implement NRC Regulatory Guide 1.26 in assigning the appropriate code class. Subsection NC has been selected for the overpack storage tube assemblies because Subsection NC provides more stringent quality requirements and is generally applied to containment vessels. Similarly, the other components of the overpack storage tube assemblies also are assigned Subsection NC based on using Category B from NRC Regulatory Guide 1.26. Quality Category B is based on the overpack storage tube providing postaccident containment and heat removal in accordance with NRC Regulatory Guide 1.26. The structural safety-class code used for the analysis, design, and fabrication of the overpack storage tube base assembly is ANSI/AISC N690-94. For continuity of design and future operational flexibility, the safety-significant overpack tube plugs are designed to the Boiler and Pressure Vessel Code, Section III, Class 2, Subsection NC requirements (ASME 1995), as are the safety-class overpack storage tube assemblies.
A4.3.5.4 System Evaluation. The overpack storage tubes and tube base assemblies, attached to the basemat embeds, are required to provide adequate restraint of the MCOs during all NPHs, including seismic events. The overpack storage tubes are designed to the *Boiler and Pressure Vessel Code*, Section III, Division 1, Subsection NC (ASME 1995). CSB-S-0007, *Storage Tube Analysis and MCO Drop*, documents a structural analysis of the overpack storage tube base assembly. The analysis results show that the overpack tube base assembly design provides adequate support for the overpack tube assembly and MCO during accident drop conditions and postulated DBE and NPH events.

The interaction of the MCO with the standard storage tube during a DBE has been analyzed to determine the maximum forces generated by the MCO storage tube on the vault's operating deck and basemat and to determine the maximum stresses developed in the storage tube (see Section A4.3.4). Because the design of the overpack storage tube assemblies is similar to the standard storage tube assemblies, the design of the overpack storage tube assembly is in compliance with the seismic requirements of the *Boiler and Pressure Vessel Code*, Section VIII (ASME 1995). *Boiler and Pressure Vessel Code*, Section VIII, allows are lower than the allowables in Section III, Class 2, Subsection NC. Therefore the overpack storage tube assemblies exceed the seismic requirements of the *Boiler and Pressure Vessel Code*, Section III (ASME 1995).

Overpack storage tube assemblies are required to be pneumatically pressure tested by the fabricator in accordance with the requirements of *Boiler and Pressure Vessel Code*, Section III, Division 1, Subsection NC, Article NC-6300 (ASME 1995), using air or inert gas at a pressure of 94 lb/in² gauge.

The vault is designed to ensure that the fuel centerline temperature never exceeds 400 °F under steady-state conditions (WHC-SD-WM-ER-525). This value is substantially less than the 1,112 °F design limit (HNF-SD-SNF-SARR-005). The highest calculated storage tube temperature is 186 °F (Figure A4-3), coincident with a site ambient temperature of 115 °F (Figure A4-2) and a flow rate through the vault of 31,700 ft³/min. These values are from information contained in the addendum to Calculation CSB-HV-0001 and are conservative given that only one MCO is in an overpack storage tube assembly. The cooling passages in the tube base assemblies provide thermal isolation of the concrete vault basemat and of the steel basemat embeds from the storage tube to ensure that the concrete's temperature limit of 150 °F is not exceeded.

A4.3.5.5 Controls (Technical Safety Requirements). The overpack storage tube and the tube base assemblies are design features, and their safety function is managed by the configuration control process (see Section A5.6). There are no TSR controls for this SSC because its safety function is related to recovery actions, not to accidents during normal operations. Controls related to specific recovery actions must be developed on a case-by-case basis depending on current conditions and recovery evaluation results.
A4.3.6 Canister Storage Building Intake Structure and Exhaust Stack

A4.3.6.1 Safety Function. The safety function of the CSB intake and exhaust stack is to provide passive cooling for MCOs. The intake structure and exhaust stack are classified as safety class in accordance with DOE Order 6430.1A and ITS Category A using the graded approach of HNF-SD-SNF-DB-003 per the requirements of Section A3.4.2.6. They are integral parts of the CSB passive cooling system and, as such, are designed for the DBE and design basis tornado wind loads.

A4.3.6.2 System Description. The CSB intake structure is a 17 ft by 18 ft by 22 ft high welded steel structure weighing 867,000 lb that is mounted on top of a 15 ft by 20 ft by 57 ft high reinforced concrete tower constructed monolithically with the CSB vault's intake plenum. The steel portion of the intake structure (tower) is constructed as a braced tubular steel frame with steel shear panels at the base. Tubular steel members conform to ASTM-A588/A588M, Standard Specification for High-Strength Low-Alloy Structural Steel with 150 Ksi (345 MP), Grade A with a minimum yield strength of 50,000 lb/in². Space cloth Type 304 stainless steel covers the intake structure and acts as a debris barrier for the CSB vault's convective cooling system. Reinforced concrete is specified to have a 28-day compressive strength of 4,000 lb/in² in accordance with ANSI/ACI 349-85. Reinforcing steel is in accordance with ASTM A615/A615M-96a Grade 60.

The exhaust stack is a self-supporting, 169-ft-tall, cantilevered structure. The diameter at the base of the stack is 13 ft, and the diameter at the top of the stack is 7 ft. The bottom section of the 13-ft-diameter stack base rises 67 ft above floor level and is constructed of 0.63-in.-thick steel plate. The bottom section of the exhaust stack is attached to a reinforced concrete foundation 20 ft, 9 in. in diameter and 12 ft, 1.5 in. thick. The middle section of the exhaust stack continues upward 33 ft and tapers from 13 ft to 7 ft in diameter. The middle section is constructed of 0.63-in.-thick steel plate. The 7-ft-diameter top section of the exhaust stack continues upward another 57 ft and is constructed of 0.38-in.-thick steel plate. The upper 44 ft of the top section of the stack are provided with a series of vertical wind spoilers that protrude 7 in. from the stack and are each 11 ft long. The spoilers are made of 0.38-in.-thick steel plate and are designed to the guidance in ASCE-7-93. Stack material meets the specifications in ASTM A847, Standard Specification for Cold-Formed Welded and Seamless High Strength, Low Alloy Structural Tubing with Improved Atmospheric Corrosion Resistance, ASTM A606, Standard Specification for Steel, Sheet and Strip, High-Strength, Low-Alloy, Hot-Rolled and Cold-Rolled, with Improved Atmospheric Corrosion Resistance, or ASTM A588/A588M Grade A (50,000 lb/in² yield). The stack is topped by a 12-ft-tall wind deflector as shown on Figure A2-1.

A4.3.6.3 Functional Requirements. The intake structure and exhaust stack for the CSB vault must provide airflow adequate to prevent overheating of the SNF. This overheating could be caused by damage to the structure from the DBE, tornado winds, or other NPHs such as ashfall. A summary of loads considered in the design of the intake structure and exhaust stack is given below.
Annex A — Canister Storage Building

- **Intake structure**
  - Roof and structure dead load
  - Roof live load (20 lb/ft²)
  - Snow load at ground level
  - Extreme wind (90 mi/h)
  - Tornado wind (200 mi/h)
  - DBE seismic free-field response spectra applied at base of supporting tower analyzed as part of the vault-CSB model
  - Volcanic ashfall ground load

- **Exhaust stack**
  - Structure dead load
  - Extreme wind (100 mi/h)
  - Tornado wind (200 mi/h)
  - DBE free-field response spectra applied at base of stack.

The structural safety-class code used for the analysis, design, and fabrication of the intake structure and exhaust stack components is ANSI/AISC N690-94 for the structural steel intake and exhaust stack portions, and ANSI/ACI 349-85 for the reinforced concrete intake towers.

**A4.3.6.4 System Evaluation.** The intake structure and exhaust stack are designed to survive the DBE and tornado wind loads given in Table A1-1.

The intake structure (tower) has been designed and analyzed as an integral part of the CSB vault structure (Calculation CSB-S-0028A). In the vault gravity and seismic analysis, the intake housings were modeled as lumped masses located at the proper elevation on top of the concrete towers, which were modeled using plate elements. The reinforced concrete towers were designed based on the loads from the vault gravity and seismic load models. In-structure response spectra at the base of the towers enveloping one-half mean, mean, and two times mean soil properties were developed using the vault seismic model. To design the steel housing, a single model was created that included a detailed model of the steel housing on top of a stick model of the intake tower. The enveloped response spectra at the base of the towers developed from the vault model
Post-construction measurements and analysis of the intake structure and operating structure are documented in Calculation CSB-S-0048, Supplement H, *Operating Shelter Roof Dead Load Confirmatory*. The analysis confirms that it is possible for the CSB operating shelter structure to impact the intake structure during a DBE. The estimated intake structure top deflection added to the estimated operating structure deflection at the same height is 5 in., and the as-built gap between the siding and the intake structure varies from 4.75 in. to 5.375 in. Analysis of the impact of the roof deck with the concrete intake structure has determined that no permanent effect on the intake structure results. The roof deck is estimated to buckle locally where it impacts the intake structure, and the damage is estimated to be slight and should not compromise the safety-significant function of the operating area structure (see Section A4.4). The estimated deflections in Table A4-4 are derived using conservative assumptions. Use of actual values in the estimates would probably preclude impact during a seismic event. Actual values were not used in the estimates because the analysis showed that the slight buckling effect in the conservative analysis does not compromise the safety-significant function of the operating area structure.

SRSS = square root of the sum of the squares.

The exhaust stack was analyzed for tornado loading in Calculation CSB-S-0012. The internal loads and moments for the 200 mi/h tornado load were developed, and the stack design was modified as required. A confirmatory analysis of the exhaust stack was performed in Calculation CSB-S-0045, *Exhaust Stack Pedestal Analysis*. The general procedure was to compare shears and moments for the exhaust stack that were obtained from the three-dimensional SAP90 vault model (CSI 1995) with the design shears and moments for tornado from Calculation.
CSB-S-0012. The exhaust stack results for the one-half mean, mean, and two times mean soil property analyses of the vault were compared with the tornado design loads from Calculation CSB-S-0012. It was found that the tornado loads were 55% higher at the base of the stack and 14% higher at the bottom of the 7-ft-diameter section. Based on these results, the stack was deemed adequate for the revised seismic loads. Thermal gradients across the stack are of minimal design concern for the materials and temperatures involved.

To design the steel housing, a single model was created that included a detailed model of the steel housing on top of a stick model of the intake tower. The estimated response spectra at the base of the towers developed from the vault model were used as input motion for the intake structure-tower model. Gravity and tornado loads were applied as static loads in the design of the steel structure. The estimated deflections representative of tornado wind and seismic loads are listed in Table A4-4.

A heat transfer evaluation of the air intake structure, the underground vault airflow paths, and the exhaust stack concluded that the CSB natural convection cooling design provides adequate cooling of the MCOs and maintains the MCO surface temperatures and concrete temperatures within the allowable limits (Calculation CSB-HV-0001). This heat transfer analysis is based on vault 1 having a total heat load of 161.2 kW. This is the heat load associated with the current inventory of SNF in the K Basins. The heat transfer calculations used three computer codes for the analysis.

- The T-Duct\(^1\) simulation program allowed the analyst to model the airflow system (inlet screen, inlet stack, ducts, duct changes in size, the vault inlet plenum, the staggered tube bank in the vault, the vault exhaust plenum, and the stack size and height) and provide airflow rates and system pressures using the two basic principles, conservation of mass and conservation of energy.

- The PHOENICS\(^2\) program analyzed the temperature and velocity profiles within the storage vault by solving equations for flows, turbulence, mass, and heat transfer using a controlled volume method based on the finite element approach.

- A LOTUS spreadsheet was used to model the “hot spot” in the vault, the area of the vault where, because of the buoyancy effect and air turbulence, the air temperatures are the highest. This spreadsheet solved a series of nonlinear simultaneous algebraic heat transfer equations using the matrix inversion method. The computer code analyzed the surface temperature of the MCO and the resultant maximum concrete temperature.

\(^{1}\)T-Method Duct Design computer code, Fluor Daniel, Incorporated, Irvine, California.
\(^{2}\)PHOENICS computer code, CHAM of North America, Huntsville, Alabama.
Considered in these analyses were important factors that influence the design of the cooling system in limiting the MCO surface temperature (e.g., ashfall, hoarfrost, wind effect, and loading scenario). Loss of natural convective ventilation as a result of “intake blockage” is not considered credible because the building has a safety-class elevated air intake structure. The following statements summarize the heat transfer analysis.

- The air intake structure using the cruciform and canopy design creates a positive pressure at the intake under all wind directions. In addition, the deflector at the top of the exhaust stack enhances exhaust airflow by increasing the wind suction pressure for all wind directions.

- The MCO maximum external temperature will be maintained below 270 °F as long as the total decay heat generated by the stored SNF is limited to 161.2 kW and the maximum heat released by an MCO is 800 W.

- The elevated 7-ft-diameter vault exhaust stack at 169 ft above the operating deck provides adequate buoyancy forces (the stack effect) for inducing airflow.

- The sequence of MCO loading into the vault tubes is optional, however the preferred loading is that the storage tubes near the exhaust stack be loaded first.

- When vault 1 is fully loaded, the long-term concrete temperature has been calculated to remain well below the allowable maximum concrete temperature (150 °F) required by ANSI/ACI 349-85, Appendix A, for long-term normal operation.

CHAM of North America, the author of the PHOENICS computer program, stated in *PHOENICS Computer Program* (CHAM 1991), that the code “is very well validated and developed from over 10 years of commercial use.” Monitoring and verification of the results of the CSB heat transfer and flow calculations using PHOENICS were performed using the Design Control Procedures Manual (Section 4, “Calculations”, and Section 9, “Computer Code Validation and Verification”). The following steps were included: (1) available commercial computer programs were studied and the most efficient, PHOENICS, was selected; (2) the PHOENICS introductory course, given by CHAM of North America, was completed by the heat transfer analyst; (3) the Computer Code Summary sheet has been completed and verified; (4) sample test problems were run by the heat transfer analyst before using the program; (5) a study of the publications where the PHOENICS program was verified by tests was conducted; (6) a complete description of the model was included in the report (CHAM 1991); and (7) an independent reviewer checked and verified that the model used is a reasonable representation of the CSB physical constraints and the outputs are reasonable.

Although a three-dimensional vault thermal analysis was planned, the PHOENICS 2D Computational Fluid Dynamics model has been used showing that the temperature difference between highest value (hot spot) and the outlet air temperature is only 4 °F (CSB-HV-0001, page 41, Figure 6A). The Los Alamos National Laboratory obtained a similar conclusion for their
vault as a result of three-dimensional modeling using the CFX computer code. Their conclusion is documented in "Conceptual Design Report for Line Item Project Nuclear Materials Storage Facility Renovation at the Los Alamos National Laboratory, Technical Area 55, Building PF-41" (LANL 1995).

Validation of the T-Duct computer calculations was performed by comparing the results of manual calculations with computer output for duct systems including five-section and nineteen-section systems. The five-section comparison provided verification of the airflows, air velocities, friction factors, pressure losses, and mass flow rates balancing. The nineteen-section comparison verified C-coefficients selection. The comparisons revealed insignificant differences, demonstrating the validity of the T-Duct code.

The computer calculations using LOTUS were verified by comparison with hand calculations to determine the maximum MCO and concrete temperatures in the vault hot spot. All equations used in the matrix were verified.

The vault cooling system is an entirely passive system. No mechanical or electrical equipment is required for it to perform its function. There are no identifiable hazards related to operation of the vault cooling system. Airflow through the vault is enhanced by the structure of the exhaust plenum because the top of the exhaust plenum is 7 ft higher than the top of the inlet plenum.

BNFL Inc. performed an independent review of the natural convection cooling calculations provided by Fluor Daniel, Incorporated. The BNFL Inc. report (see CSB-HV-0001, Appendix H) agreed with the basic conclusions of the Fluor Daniel, Incorporated, heat transfer analysis and also offered some constructive comments on issues associated with the design of the CSB as follows.

- The extreme ambient temperature of 115 °F used in the analysis has been recorded at the Hanford Site once in the past 50 years for a 2-hour duration. Modeling the CSB using this high temperature provides a safety margin of about 3 °F to 5 °F for the maximum temperatures calculated.

- The one-dimensional heat balance analysis used to calculate the maximum temperature (MCO, tube, and concrete) uses a heat balance of a tube located in the hottest part of the vault and loaded with two MCOs at 800 W each. The calculation shows the maximum concrete temperature (121 °F) is substantially lower than the 150 °F concrete temperature limit.

- The heat transfer analysis used a two-dimensional model (PHOENICS computer code) of the vault from which the predominant hot spots were determined. It is expected that the results of a three-dimensional model (which would include eddy current airflow patterns within the vault) would show lower temperatures, providing additional margins of conservatism.
The CSB model used in the heat transfer analysis assumed that the vault walls were smooth with no obstructions impeding airflow around the storage tubes. This flow pattern increases the tube temperature because some of the air would bypass the tubes and not provide direct cooling of the tubes. As Figure A2-5 indicates, 10 air foil baffles have been installed on the walls of vault 1 to impede airflow that would bypass the storage tubes. These baffles direct air in a cross flow pattern around the storage tubes and thus increase heat transfer from the storage tubes to the air. This provides an additional measure of conservatism to the maximum temperatures calculated for the heat transfer analysis.

Wind tunnel tests at Colorado State University, Fluid Dynamics and Diffusion Laboratory, demonstrated that wind flow direction can affect the performance of the CSB passive cooling system. The laboratory simulated airflow patterns around the CSB using a scale model of the CSB, including surrounding structures, in their laboratory wind tunnel. The results of the tests showed that for all wind directions, a net positive pressure occurs at the capped cruciform/screen inlet structure of the CSB inlet stack. The results also showed that for all wind directions, a net negative pressure occurs at the deflector mounted on top of the CSB exhaust stack. Thus, for the CSB intake cruciform and exhaust stack deflector designs, wind from any direction enhances the pressure gradient caused by the passive natural convective cooling system, increases the airflow rate through vault 1, and provides further conservatism to the maximum temperatures calculated for the heat transfer analysis.

A4.3.6.5 Controls (Technical Safety Requirements). The CSB above-grade structures (intake structure and exhaust stack) are design features (see Section A5.6), and their safety function is managed by the configuration control process.

A4.3.7 Multi-Canister Overpack

A4.3.7.1 through A4.3.7.4 The MCO has been classified as safety class in accordance with DOE Order 6430.1A and ITS Category A using the graded approach of HNF-SD-SNF-DB-003. The safety functions for the MCO are providing confinement of SNF and maintaining geometrical arrangements assumed in criticality analyses. See the MCO Topical Report (HNF-SD-SNF-SARR-005) for the safety functions, system description, functional requirements, and system evaluation of the MCO.

The MCO is a single-use container consisting of the following components:

- Stainless steel shell
- Five or six fuel baskets containing SNF
- None, one, or two scrap baskets containing SNF
- Stainless steel center post (Mark IA baskets only)
- Stainless steel shield plug
- Stainless steel locking ring.
These components and configurations are shown on Figure A2-2 and described in the MCO Topical Report (HNF-SD-SNF-SARR-005).

The interface between the MCO and the MHM grapple is at the MCO ring collar and canister cover assembly. As described in the MCO Topical Report (HNF-SD-SNF-SARR-005), the design of the MCO ring collar uses the guidance of ANSI N14.6-1993 of a factor of safety of three on material yield and five on material ultimate strength. The canister cover assembly design uses the normal (Service Level A) criteria of Subsection NB of Section III of the Boiler and Pressure Vessel Code (ASME 1995). A mechanically sealed MCO may have a leakage rate of no greater than $10^{-5}$ cm$^3$/s as defined by the MCO Topical Report (HNF-SD-SNF-SARR-005).

The canister cover assembly must support the total weight of the MCO and contents for lifting, which equates to a conservative total lifting capacity of 12 tons. A lifting grapple with six gripping shoes will be used to lift the MCO and its contents by the canister cover assembly. Figure A2-38 displays the gripping shoe configuration for the lifting grapple-canister cover assembly interface. The stress through the MCO shell resulting from the lifting load is 615 lb/in$^2$. The thinnest point in the shell is located at the thread relief in the canister collar. Since it will also see the lifting load through its section, the thread relief was analyzed and found to have a stress of 866 lb/in$^2$.

The canister cover assembly must be able to withstand an internal pressure of 450 lb/in$^2$ gauge. The MCO shell has a thickness of 0.5 in., and its inside diameter is 23 in. The stress through the shell due to the pressure load was found to be 10,575 lb/in$^2$. The stress for the thinnest section through the canister collar buttress thread (0.354 in. thick) is 15,840 lb/in$^2$.

When both lifting and pressure loads are applied together, the stress through the thinned portion of the canister cover assembly shell due to these loads then becomes:

- Axial stress = 39,200 lb/in$^2$
- Axial stress ratio = 0.88
- Hoop stress = 8,300 lb/in$^2$
- Hoop stress ratio = 0.19.

A4.3.7.5 Controls (Technical Safety Requirements). The MCO is a design feature (see Section A5.6) and its safety function is managed by the configuration control process.

A4.3.8 Transportation Cask

A4.3.8.1 Safety Function. The transportation cask is a safety-class equipment item as defined at other facilities and provides a safety-significant function for the CSB. The transportation cask has the safety function of providing a confinement barrier and structural protection to the MCO from drops from the receiving crane.
A4.3.8.2 System Description. The transportation cask consists of a body fabricated from stainless steel forgings conforming to ASME SA-336 (ASTM A336/A336M) Type F304, and a bolted-on stainless steel lid conforming to ASME SA-336 Type F304 with two welded-on trunnions conforming to ASME SA-336 Type F304 or SA-240 Type 304. The overall dimensions of the cask are 170.5 in. long and 39.81 in. in diameter. The cask cavity is 160.5 in. long and has an inner diameter of 25.19 in. Other dimensions and details of the transportation cask can be found in HNF-SD-TP-SARP-017, Safety Analysis Report for Packaging (Onsite) Multi-Canister Overpack. The SNF FSAR CSB Annex assumes the design and configuration shown in Revision 1 of HNF-SD-TP-SARP-017. The transportation cask is designed to be transported in the vertical position by a dedicated semitrailer. This arrangement is shown on Figure A2-20.

A4.3.8.3 Functional Requirements. The transportation cask is required to provide a confinement barrier and structural protection from drops from the receiving crane.

A4.3.8.4 System Evaluation. The transportation cask has been analyzed for its capability to provide the necessary protection of the MCO during cask lowering by the receiving crane and a collision of the MHM with the receiving crane. The analysis conservatively eliminated any energy absorption contribution by the receiving crane or MHM. In the analysis the MHM was modeled as a rigid body. Upon contact with the cask, the MHM was further driven into the cask at the maximum drive wheel torque, resulting in additional loading on the cask wall of 6,000 lb. The cask was conservatively positioned, impacting the rigid cask receiving pit edge at its midpoint. The transportation cask, MCO, Mark IA baskets, lifting fixture, simplified MHM, and rigid transfer pit were modeled dynamically by finite element analysis.

Analysis of the impact at the cask receiving pit was broken up into two dynamic simulations: the first simulated the MHM impacting the static cask–MCO suspended by the lifting fixture, and the second simulated the MHM and cask–MCO moving sideways at 40 ft/min and impacting the edge of the cask receiving pit. The results of the first simulation indicate that the cask, MCO, and all six Mark IA baskets remain linearly elastic; there is no plastic damage. The results of the MHM and cask–MCO impacting the cask receiving pit edge indicate that the MHM is stopped and rebounds. The maximum equivalent plastic strain was in the bottom basket with a value of approximately 0.3% strain. There was no significant plastic damage. These results are contained in analyses documented in transmittal FDT-137, MHM Collision with Cask/MCO (Peterson 1998).

A4.3.8.5 Controls (Technical Safety Requirements). The transportation cask is a design feature and requires no TSR controls to ensure performance of its safety function (see Section A5.6.1).
A4.3.9 Multi-Canister Overpack Handling Machine Seismic Restraint System

A4.3.9.1 Safety Function. The safety function of the MHM seismic restraint system is to prevent shearing of an MCO by the MHM during a DBE and during all MCO handling activities so that the MHM cannot apply significant shearing stress to an MCO that is partially lowered from the MHM’s MCO cavity. The seismic restraint system has a related safety function of ensuring that the MHM will not impact or structurally collapse and cause damage to the safety-class operating deck. The MHM seismic restraint system is designated safety class in accordance with DOE Order 6430.1A and ITS Category A in accordance with the graded approach in HNF-SD-SNF-DB-003.

A4.3.9.2 System Description. The MHM seismic restraint system consists of four subsystems: the bridge seismic restraint system, the trolley seismic restraint system, the turret locking pin system, and the base locking pin system. These systems restrain movement of the MHM turret with respect to the trolley and nose assembly and translational movement of the MHM trolley and bridge with respect to the facility.

The MHM bridge seismic restraint system comprises spring-applied rail clamps, bridge wheels, shaped hooks that are located under the railhead, and a motor and hydraulic components that release the rail clamps. The bridge seismic clamps physically interface with the MHM bridge rails installed on the CSB operating deck. The rail clamps have fail-safe features in which the shoes are applied by coil springs and the hydraulic motors are energized to disengage the clamps. The rail clamps provide Y (north-south) direction seismic restraint. The wheel flanges provide X (east-west) direction seismic restraint. The Z (vertical) direction seismic restraint is provided by the shaped hooks positioned under the railhead to prevent vertical uplift.

The trolley seismic restraint system is composed of X-restraint pins, pin actuation motors, screw jacks and jack drive, steel pockets on the bridge beams, trolley wheels, and lugs that hook beneath the bridge beam top flange. Two X-restraint pins lock the trolley to the bridge rails, preventing east–west motion of the trolley and turret. The trolley pins are inserted by the pin actuation motors into pockets welded onto the top of each bridge beam. The screw jacks and jack drive allow the exact positioning of the pins to be adjusted so that the pins line up with the corresponding bridge beam pockets. Restraints for the trolley in the Y direction are passive restraints formed by the trolley wheel flanges that mate to the trolley rails. Passive restraints for the Z direction are provided by four lugs that hook beneath the top flange of each beam.

The turret locking pin system consists of the turret locking pin, an actuation screw jack and motor, and three steel pockets installed on the turret support turntable. The actuation screw jack and motor are installed on the MHM trolley. The turret locking pin is a 5.1-in.-diameter steel pin that fits into any of three pockets on the turret support turntable. When the pin is engaged in one of these three pockets, it serves to precisely align the turret with one of its three positions (tube plug, MCO, or camera) and to prevent the turret from moving by securing it to the trolley.

a-csb04.sar  A4-48  March 2000
A powered, base locking pin system consists of the base locking pin, an actuation screw jack and motor, and three steel pockets in the base nose block. This system is similar to the turret locking pin system except that it secures the turret base plate to the machine base nose block at each turret index position. A base locking pin locks the turntable to the lower turret.

Visual verification of the four seismic restraint subsystems ensures that they are properly positioned and capable of performing their designed seismic restraint functions. Verification that the seismic restraints are in position is procedurally required and will be surveyed before MCO hoist operation.

A4.3.9.3 Functional Requirements. The MHM seismic restraint system, when applied, is required to limit the translational movement of the bridge, trolley, and turret that could cause significant physical damage to an MCO within or partially within the MHM. All of the components that provide restraint in the Z direction are always engaged (trolley uplift hooks, bridge hooks). The bridge X direction (wheel flanges) and the trolley Y direction restraints are passive and always effective. If not engaged, the bridge seismic rail clamps slowly actuate after a loss of power. All of the seismic structural components are required to safely withstand seismic forces during a DBE and prevent the MHM from collapsing onto the operating deck. The seismic input is based on the response spectra included in Figure A4-4.

A4.3.9.4 System Evaluation. All of the seismic structural components have the strength to safely withstand seismic forces during a DBE. The MHM bridge seismic clamps (four total) are each capable of applying a 200,000 lb holding force to the 175 lb per yard crane rails. Loading conditions used to generate the seismic analyses were evaluated in accordance with the requirements of ASME NOG-1-1995. Analyses documented in ESL/R(96)083, Hanford MHM Seismic Analysis of the Hanford MCO Handling Machine, demonstrate that the MCO will not be trapped while being lowered or retrieved by the MHM during the DBE. The seismic analysis report [ESL/R(96)083] provides the results of seismic analysis for the MHM bridge wheel and trolley wheel seismic restraints (Table A4-5).

A4.3.9.5 Controls (Technical Safety Requirements). The MHM seismic restraint system is a design feature of the MHM (see Section A5.6), and its safety function is managed by the configuration control process. The MHM vendor has not established any special maintenance or surveillance requirements. The following TSR is required to ensure that the seismic restraint system will perform its safety function.

- Visual verification that the east and west bridge clamps engage the rails (hydraulic pressure gauges indicate a low pressure), the seismic locking pins for the North and South trolley rails are inserted, the turret locking pin is inserted, and the base locking pin is inserted must be performed before MCO hoist operation (see Chapter A5.0, Section A5.5.3.3).

A4.3.10 Multi-Canister Overpack Handling Machine Rails and Rail Frogs

A4.3.10.1 Safety Function. The safety function of the MHM rails and rail frogs is to prevent shearing of an MCO by restraining movement of the MHM. Failure to withstand the seismic loads could lead to inadvertent movement and collapse of the MHM, which could damage CSB facility structures designated safety class. Because they function to ensure operation of the MHM seismic restraints during the DBE, the MHM rails and rail frogs are designated safety class in accordance with DOE Order 6430.1A and ITS Category A in accordance with the graded approach in HNF-SD-SNF-DB-003.

A4.3.10.2 System Description. The MHM rails and rail frogs provide for safe movement of the MHM and facilitate safe transport of the MCOs throughout the CSB facility. Seismic rail clamps lock the MHM wheel trucks to the rails whenever the MHM is not in transport MCO mode, and they are locked automatically by a signal from the seismic detection and MHM power-disconnect actuation system.

The MHM rails are located at the east and west edges of the operating area deck directly over the thick vault walls. The two parallel rails run in a north-to-south direction from the load-in/load-out area in the north to the sampling/weld station in the south. The rails are recessed into trenches to maintain the top of the rail at deck level. The trenches are wide enough to permit clamping of the MHM rail clamps.
The MHM rails transmit their loads to the operating area deck through a system of bearing plates, rail clips, lateral restraints, and anchor bolts. The bearing plates are provided with threaded holes. Anchor bolts installed into the reinforced concrete of the operating area deck secure the bearing plates. Bolted connections through the rail clips secure the rails to the bearing plates. Lateral restraint is provided by keeper bars placed alongside the toe of the rail between rail clips. The keeper bars are welded to the bearing plate.

Rail frogs are a welded fabrication of rails and base plates that bolt directly to the rail bearing plate. The rail frogs provide a means for the MHM and receiving crane to alternately access the cask receiving pit. The rail frogs incorporate design features to activate trip sensors for the MHM and hard stops for both cranes. The rail frogs are aligned, positioned, and secured manually to administratively limit the load-in/load-out area to one crane at a time.

MHM and rail frog rails are constructed of 175 lb/yd rails conforming to American Institute of Steel Construction configuration; the continuous-welded material conforms to ASTM A759-85, Standard Specification for Carbon Steel Crane Rails. Bearing plates are constructed of 1-in.-thick plate material conforming to ASTM A36/A36M. Rail clips are constructed of 1.5-in.-thick material conforming to ASTM A572/A572M, Standard Specification for High-Strength Low-Alloy Columbium-Vanadium Structural Steel, Grade 70. Anchor bolts are 1.25-in.-diameter threaded stud anchors conforming to ASTM A449-93, Standard Specification for Quenched and Tempered Steel Bolts and Studs, with an embedment length of approximately 24 in. Keeper bars are constructed of 0.75-in.-thick, long carbon steel conforming to ASTM A572/A572M Grade 50. Fabrication and manufacturing of the rail frogs are in accordance with AWS D14.1, Specifications for Welding of Industrial and Mill Cranes and Other Material Handling Equipment. Rail runways are flashbutt welded at the job site using procedures developed in accordance with AWS D14.1.

A4.3.10.3 Functional Requirements. Nominal and seismic loads are imposed on the rails and rail frogs. Live, dead weight, and seismic loads caused by the MHM response are transmitted to the reinforced concrete of the operating deck for dissipation into the below-grade vault walls. Acceptable analytical results are required in order to demonstrate that the rails and rail frogs withstand and transmit these load combinations.

DOE Order 6430.1A provides criteria that SSCs designated safety class be designed in accordance with the Boiler and Pressure Vessel Code, Section III, Class 2 (ASME 1995), or other applicable nuclear safety code. HNF-PRO-704 refers to HNF-PRO-097 for design codes and standards to safety-class structural SSCs. HNF-PRO-097 provides a consistent method for implementing these codes and standards. HNF-PRO-704 requires that safety-class structural SSCs be designed and constructed in accordance with ANSI/AISC N690-94. In order to demonstrate MHM rail and rail frog structural availability, independent checks of hold-down bolt torque must be performed each time the rail frogs are repositioned.

A4.3.10.4 System Evaluation. The governing loads were used to calculate the MHM rail and rail frog component loads and to determine material properties, thicknesses, and spacing for the...
rails, anchor bolts, bearing plates, base plates, rail clips, keeper bars, and hold down bolts. 

Governing MHM crane rail loads were obtained from the MHM modeling using ANSYS 
BEAM44 and BEAM44 elements for the trolley at the mid-span, quarter span, and mid position 
following the requirements of ASME NOG-1-1995, Section NOG-4151. The seismic analysis 
report [ESL/R(96)083] provided the results of these analyses. These results are included in 
Table A4-5. The demand/capacity ratios for various MHM components associated with the 
seismic restraints are shown in Table A4-6.

These results were obtained applying the seismic response spectra for accelerations acting at the MHM runway level resulting from a DBE having an NPH of 0.35 g horizontally and 0.23 g vertically above 33.33 Hz. Similarly, the receiving crane confirmatory analysis documented in Calculation CSB-S-0031, Rail System Calculations, provided rail loads due to seismic loading on the rails. These results are contained in Table A4-7. Structural analyses were performed for the rails and rail frogs in accordance with the Manual of Steel Construction Ninth Edition (AISC 1989), and ACI 318-89, Building Code Requirements for Reinforced Concrete. The results of these analyses for the MHM rails and frogs under the above loading conditions are contained in CSB-S-0031. A summary of the demand/capacity ratios is provided in Table A4-8.

Load combinations for steel components are:

\[ 1.7A_s = D + L \pm Ed/F_{\mu} \]
\[ 1.7A_s = 0.85D \pm Ed/F_{\mu} \]

and load combinations for concrete are:

\[ U = D + L \pm Ed/F_{\mu} \]
\[ U = D \pm Ed/F_{\mu} \]

where

- \( A_s \) = allowable stress
- \( U \) = ultimate concrete stress
- \( D \) = dead load
- \( L \) = live load
- \( Ed \) = design basis earthquake load
- \( F_{\mu} \) = allowable seismic inelastic demand capacity ratio.

A4.3.10.5 Controls (Technical Safety Requirements). The MHM rails and rail frogs are design features and their safety function is managed by the configuration control process (see Section A5.6). The following assumption associated with the MHM rails and rail frogs requires TSRs to ensure performance of the safety function.

- Periodic surveillance of the rail clip hold-down bolts will verify that the bolts have sufficient torque as defined in AISC (1989). Verification of the rail frog's hold-down bolt torque must be performed each time the rail frogs are repositioned (see Chapter A5.0, Section A5.5.3.3) and before the MHM's seismic clamps are positioned over them to ensure consistency with the analysis results in CSB-S-0031.

### A4.4 SAFETY-SIGNIFICANT STRUCTURES, SYSTEMS, AND COMPONENTS

The CSB safety-significant SSCs are described in Sections A4.4.1 through A4.4.21 and are summarized in Table A4-9. These items are designated safety significant in accordance with DOE-STD-3009-94, Letter 97-SFD-172 (Sellers 1997), and where applicable, ITS using the graded approach in HNF-SD-SNF-DB-003. Safety-significant SSCs provide design features and controls for safe handling of an MCO and for worker safety and also provide defense-in-depth safety features as defined in HNF-PRO-097. Where the design, construction, or procurement preceded HNF-PRO-704 implementation, waivers to safety-class designation of SSCs were documented. The safety-class designation would have been required due to their role in protecting safety-class SSCs, and from physical interaction. Previous procedures allowed a "3 over 1" designation for SSCs performing in that role. These SSCs are included herein as safety-significant SSCs.

The industry codes and standards used for the design, fabrication, and procurement of safety-significant SSCs are shown in Table A4-10. Safety-significant SSCs and services are procured from vendors whose quality assurance programs have been evaluated against the applicable quality assurance program requirement, such as ASME NQA-1-1994, *Quality Assurance Program Requirements for Nuclear Facilities*, or Title 10, *Code of Federal Regulations*, Part 830, “Nuclear Safety Management,” Section 120, “Quality Assurance Requirements” (10 CFR 830), and who have been placed on the Fluor Hanford Evaluated Suppliers List. In all cases, safety-significant SSCs are required to withstand NPH loads except for seismic criteria. Safety-significant SSCs may selectively be required to meet safety-class or industry standards for seismic events.
Table A4-9. Summary of Safety-Significant Structures, Systems, and Components. (5 sheets)

</table>

ALARA = as low as reasonably achievable.
DBA = design basis accident.
DBE = design basis earthquake.
HEPA = high-efficiency particulate air (filter).
ITS = important to safety.
LCO = Limiting Conditions for Operation.
MCO = multi-canister overpack.
MHD = multi-canister overpack handling machine.
NA = not applicable (this SSC does not have an ITS category).
NPH = natural phenomena hazard.
NRC = U.S. Nuclear Regulatory Commission.
SSC = structure, system, or component.
TSR = technical safety requirement.

A4.4.1 Operating Area Shelter and Support Area Building Foundation

A4.4.1.1 Safety Function. The safety function of the operating area shelter is to protect the operating area deck from structural failure of the operating area shelter. The safety function of the support area building foundation is to protect the operating area shelter from structural failure of the support area building. The operating area shelter is designed so that its failure will not result in failure of the safety-class deck below. Therefore, the operating area shelter is designed for NPH events listed in Table A1-1 including DBE and tornado wind loads. Because of the proximity of the support area building to the operating area shelter, the main frame of the support area building also is subjected to design basis loading for DBE and tornado wind. Tornado and DBE loads are transmitted to the support area building foundation. The support area building is designed to not fail and cause failure of any CSB SSC. HNF-PRO-704 would have required that the support building and operating area shelter be designated safety class after the completion of construction. The project prepared and obtained a waiver to HNF-PRO-704, Table 5, Note 4 (Waiver). The operating area shelter, including the rolling shield gates, and support area building foundation are designated as safety significant in accordance with Letter 97-SFD-172 (Sellers 1997) and as identified in Section A3.4.2.1.

A4.4.1.2 System Description. The operating area shelter is a steel-framed enclosure that covers the operating area deck, the load-in/load-out area on the north, and the sampling/weld area on the south. The building structural system is steel ordinary moment resisting frame (columns/truss) in the east-west direction, and steel concentric diagonal braced frame in the north-south direction (see Section A2.4.4.2 and Figure A2-1). The building is approximately 230 ft long, 136 ft wide, and 55 ft high and is supported on a 3-ft-high concrete curb that surrounds the operating area deck. The structural system consists of load-carrying roof trusses spanning east–west and supported by columns. Seismic and tornado lateral forces are resisted through truss-column frame interaction in the east–west direction and through a vertical bracing system along the east and west walls in the north–south direction. Rolling shield gates at the north trailer vestibule and south load-in/staging area (see Figure A2-18) protect the telescoping doors components from wind forces, including tornado missiles, and serve as security barriers. The telescoping doors are general service. However, without the protection provided by the gates, the telescoping doors would fail and permit missiles inside the operating shelter. For this reason, the rolling shield gates are classified safety significant and designed to withstand the same loads from Table A1-1 as the operating area shelter.

The support area building is an extension to the north of the operating deck and the MCO load-in/load-out area. The support area building’s foundation dimensions are 150 ft by 54 ft, 3 in. The foundation system consists of reinforced concrete spread footings. The support area building is a steel-framed structure approximately 150 ft by 54 ft by 16 ft high enclosed by insulated metal siding and roof deck. A heating, ventilation, and air conditioning (HVAC) exhaust stack projects upwards from the support building roof (see Section A2.4.4.3 and Figure A2-1).

A4.4.1.3 Functional Requirements. The operating area shelter must not be damaged by the DBE or other NPH loads listed in Table A1-1 so that safety-class items under the shelter (e.g., the...
operating area deck) can maintain their safety functions. For continuity of design and to eliminate interaction effects, the support area building must not be damaged by the DBE and other NPH loads listed in Table A1-1 to prevent damage to the nearby operating area shelter. The standing seam architectural cladding is able to sustain the 90 mi/h design basis wind load. The support building's exhaust stack is required to withstand the design basis tornado and DBE loads listed in Table A1-1. The support area building foundation is designed for the following design basis loading conditions:

- Roof dead load
- Roof live load (20 lb/ft²)
- Floor live load (100 lb/ft²)
- Roof snow load based on ground-level snow load plus drift
- Siding dead load
- Equipment weight (consideration for vibration and/or overturning accounted for in the foundation design)
- DBE seismic for free-field response spectra for interaction with operating deck
- Tornado loads (wind 200 mi/h)
- Extreme wind (90 mi/h, including 2 in. by 4 in. wood plank, 15 lb missile at 50 mi/h).

A4.4.1.4 System Evaluation. A three-dimensional model of the operating area shelter was subjected to the basic static load cases, including the 200 mi/h tornado load with atmospheric pressure change, and to response spectra dynamic analysis. The horizontal response applied was developed using a vault model, with the control motion being applied at the competent soil layer, and the soil properties were varied using one-half mean, mean, and two times mean values. For vertical response, the building was subjected to two-thirds of the free-field control motion. Loads were combined and the demand-to-capacity ratios for the structure were developed. One weather-sealed penetration (roof hatch) through the roof (5 ft, 3 in. by 5 ft, 3 in. clear opening), installed between the existing purlins and roof beams, provides for outside crane access to the operating area. Installing the roof hatch between the existing roof support structures has minimal effect on the calculated demand-to-capacity ratios.

\( F_\mu \) values > 1.0 per DOE-STD-1020-94, Table 2-4, were used for member evaluation in combination with snow and other loads, but the connection designs are based on \( F_\mu = 1.0 \). The recommendations of the Uniform Building Code (UBC 1994) pertaining to good seismic detailing were used in the design of the CSB operating area shelter and support building. Analysis for 25% of the design basis snow load of 20 lb/ft², with the 20 lb/ft² roof live load and 17 lb/ft² roof dead
load combined with DBE for the controlling members was performed with appropriate $F_p$ factors
greater than 1.00 as allowed by DOE-STD-1020-94, Table 2-4, based on governing tensile, shear,
or compressive loads. $F_p$ values of 1.00 were used in calculations CSB-S-0029 and CSB-S-0048,
which resulted in demand capacity ratios less than 1.0. A post-construction check of the
operating shelter roof dead load estimated that the actual dead load is 15.8 lb/ft² (CSB-S-0048,
Supplement H). This post-construction analysis confirms that the 17 lb/ft² used in the DBE
analysis is conservative.

The demand-to-capacity ratios calculated include the tornado and seismic loads. The
combination of dead-plus-live load with tornado wind results in demand-to-capacity ratios for the
operating area shelter that are lower than dead load plus tornado wind. Calculated
demand-to-capacity ratios of load combinations for dead-plus-live load with tornado wind are
acceptable. Demand-to-capacity ratios of dead load plus earthquake (free field and at top of
competent layer with $C_v = 1.0$), dead load plus tornado wind, and dead load plus snow with
ashfall loads also are acceptable.

Seismic and tornado wind analysis of the HVAC exhaust was conservatively carried out
for the design basis loads in Table A1-1 using RISA-3D per the load combinations required by
AISC (1989). The results indicate that tornado wind with dead load ($1.05D + W_t$) governs the
design demand/capacity ratio of 0.84 for flexure and is the most limiting.

Seismic motions of the operating area shelter and intake structure were evaluated in
CSB-S-0048, Supplement H (see Section A4.3.6.4). Motions up to 5.0 in. are predicted across
the 4.75-5.375 in. gap (see Table A4-4). Damage to the building's roof line from the seismic
movement of the exhaust stack and operating area building is predicted for the eave and gutter
and the architectural standing seam roofing; some buckling of the structural roof deck is also
expected. These items are either sacrificial or easily repaired and pose no restrictions to
continued operation following a seismic event. No energy-absorbent materials are warranted.
The standing seam architectural cladding is required only to sustain the 90-mi/h design basis wind
load, not the tornado wind load.

The wind missile specified in Letter FRP-112 (Bedell 1996a) (15 lb, 2 in. by 4 in. board
with a horizontal velocity of 73.5 ft/s and a maximum height of 50 ft) is consistent with
DOE-STD-1020-94 and HNF-PRO-097. The steel barrier thickness required to prevent
penetration from this missile is one sheet of 13-gauge or two sheets of 18-gauge material
(Bedell 1996a, Section 10B, page 26). The siding provided for the operating shelter is two sheets
of 18-gauge material.

The siding and structural framing for the operating shelter were evaluated for impact from
the wind-generated missile in Calculation CSB-S-0010, Operating Shelter Design/Analysis,
Sheets 107 through 109. The siding and girts (the lightest framing members) were evaluated
directly and found to be adequate for the missile impact. Based on the ratio of the missile mass to
the effective mass of the main framing members, the effect of the missile loads on the main
framing members was deemed to be insignificant. Subsequent to this analysis, the main framing
members for the operating area shelter were increased in size because of the imposition of the
tornado loading; therefore, no further consideration of wind-generated missiles was necessary.

The support area building structure is designed and analyzed as a moment frame in the
north-south direction and as a braced frame in the east-west direction. The steel framing, roof
deck, and siding are designed to resist wind pressures from a 200 mi/h tornado, and the primary
framing also is designed for a DBE. The calculated demand-to-capacity ratios of the primary
structural elements are acceptable. The limiting loading condition for the columns is the
combination of dead load and snow load with tornado wind \(1.05D+S+W_t\).

A4.4.1.5 Controls (Technical Safety Requirements). The operating area shelter and the
support area building foundation are design features (see Section A5.6), and their safety function
is managed by the configuration control process.

A4.4.2 Standard Storage Tube Plug

A4.4.2.1 Safety Function. The standard storage tube plugs are classified safety significant in
accordance with DOE-STD-3009-94 and provide the safety function to protect workers from
radiation dose in vault I (see Chapter A3.0, Section A3.3.2.3.3).

A4.4.2.2 System Description. The standard storage tube plugs are a composite cast steel upper
section with a carbon steel, cast-in-place concrete-filled cylindrical lower section. The composite
cast steel upper section meets the specifications in ASTM A27/A27M, Standard Specification for
Steel Castings; Casting for General Application, and the carbon steel in the lower section meets
the specifications in ASTM A36/A36M for rolled plate or pipe. The weight of a standard storage
tube plug is approximately 5,300 lb. A 4-in.-diameter lifting pintle shown on Figure A2-14,
Sheet 1, is used for removal and installation of the standard storage tube plug. The carbon steel
pintle material conforms to ASTM A108, Standard Specification for Steel Bars, Carbon, Cold-
Finished, Standard Quality, Grade AISI 1040 or 1045. The three jaws of the MHM tube plug
hoist and grapple close and lock on the 2-in.-diameter machined “neck” of the pintle during
movement of the standard storage tube plug. The standard storage tube plug fiber filter media
(90% efficiency) are contained within metal canisters. The breather filter with a quick-connect
coupler is shown on Figure A2-14. The filter media housing and quick connect coupler are
attached to a quick connect nipple which screws into an ASTM A106, Standard Specification for
Seamless Carbon Steel Pipe for High Temperature Service, pipe coupling. The coupling is
screwed onto an ASTM A53, Standard Specification for Pipe, Steel, Black and Hot Dipped
Zinc-Coated (Galvanized) Welded and Seamless, pipe nipple. The other opening in the standard
tube plug assembly has a quick connect screwed into a ball valve which is screwed on the
ASTM A53 pipe nipple (Figure A2-14, sheet 1). Pressure in the standard storage tube is
maintained at atmospheric pressure as air from the operating area flows in and out of the breather
filter. The tube temperature is expected to range from 70 °F to 150 °F. The standard storage
tube plug has one O-ring seal.
A4.4.2.3 Functional Requirements. The requirement for shielding protection of the facility worker by the standard storage tube plugs is governed by the ALARA (as low as reasonably achievable) goal and related principles and practices for radiation protection. The plug's concrete-filled barrel (standard structural un-reinforced) and heavy cast steel top composition are provided to achieve this goal.

A4.4.2.4 System Evaluation. The standard storage tube plugs provide radiation shielding for personnel working above the standard storage tubes that contain MCOs. Calculations for standard storage tube plugs (CSB-SH-2002) estimate the dose at the surface of the operating deck to be about 0.2 mrem/h (2.0 × 10^-3 mSv/h). This value excludes any shielding contribution from the standard tube plug cover to provide shielding. An extremity dose of about 0.4 mrem/h (4.0 × 10^-3 mSv/h) is estimated for surveillance operations on the storage tube plugs below the tube plug covers. The standard storage tube plug design (Figure A2-8) meets the requirements for personnel shielding safety in accordance with HNF-SD-SNF-DB-003 (Items 20 and 23) and minimizes the spread of contamination. Standard storage tube plugs have a seal to provide a physical barrier and a breather filter to contain particulate and maintain atmospheric pressure within the standard storage tube. Standard tube plugs are filled with concrete at the job site. Typical concrete mix densities range from 2.33 g/cm³ to 2.40 g/cm³. Concrete density used in the shielding analysis was 2.24 g/cm³.

The initial stress analysis documented in Calculation CSB-RM-0002, Plug Lifting Lug Stress, was performed to ASME B30.20-1993 safety factors of 3 on yield and 5 on tensile strength, assuming a test weight of 1.5 times the all steel overpack tube plug weight of 12,300 lb. This is 2.3 times the estimated 5,300 lb. weight of a composite steel-concrete standard storage tube plug. The analysis examined the critical areas for the plug load path; the plug female threads and the plug lifting attachment top transition from 4 in. to 2 in. The analysis determined safety factors of 4.2 and 6.5, respectively, for the top transition 4 in. lifting attachment point. The stress analysis demonstrates that the design of the pintle exceeds the yield and tensile safety factor requirements of ASME B30.20-1993.

A4.4.2.5 Controls (Technical Safety Requirements). The following assumptions associated with the standard storage tube plugs require TSRs to ensure performance of the safety function.

- Tube plugs are in place over every storage tube unless that tube is being accessed by the MHM.
- MHM safety features ensure that the MHM will not leave a storage tube location before replacing the tube plug. Operability of interlock P2 is discussed under Limiting Condition for Operation (LCO) 3.1.1 in Chapter A5.0.
A4.4.3 Overpack Storage Tube Plug

A4.4.3.1 Safety Function. Overpack storage tube plugs are designated safety significant because of their safety function to protect workers from radiation dose in vault 1.

A4.4.3.2 System Description. Section A2.4.3 contains a description of the overpack storage tube assemblies including the overpack storage tube plug and the overpack tube plug covers. These components are shown on Figures A2-14 and A2-15. The plugs are a composite cast steel upper section (ASTM A27/A27M) with a carbon steel (ASTM A36/A36M), cast-in-place concrete-filled cylindrical lower section. The concrete has a compressive strength of 3,000 lb/in² in accordance with ASTM C94, Standard Specification for Ready Mixed Concrete, and ACI 301, Specification for Structural Concrete. The weight of an overpack storage tube plug is approximately 6,200 lb. A 4-in.-diameter lifting pintle shown on Figure A2-14, sheet 2, is used for removal and installation of the overpack tube plug assembly. The carbon steel pintle material conforms to ASTM A108, Grade AISI 1040 or 1045. The three jaws of the MHM tube plug hoist and grapple close and lock on the 2-in.-diameter machined “neck” of the pintle during movement of the overpack storage tube plug. A pressure gauge connected to a quick connect coupler is shown on Figure A2-14, sheet 2. The quick-connect coupler is attached to a quick-connect nipple, which screws into an ASTM A106 pipe coupling, which is screwed on an ASTM A53 pipe nipple. Another opening in the overpack tube plug assembly has a quick connect screwed into a ball valve which is screwed on an ASTM A53 pipe nipple. The overpack storage tube plug has two O-ring seals in the 45° mating surface. The double O-ring seal pressure check connection assembly is a quick connect screwed on a 1/4 in. ASME SA213 (ASTM A213/A213M) 304 stainless steel tube, which has been welded to a side opening drilled through the steel shield and opening between the O-ring seals. Pressure in the overpack storage tube will be approximately 7 lb/in² gauge during MCO storage to prevent air from entering and mixing with gases potentially emitted from an off-normal MCO. A spider lock-down device holds the overpack storage tube plug in place (Figure A2-14). The tube temperature is expected to range from 70 °F to 150 °F. Other than sharing the same shielding approach of a composite steel with concrete-filled barrel plug, overpack tube plugs differ from the standard tube plugs in size, configuration, and function. The pressure-retaining function of the overpack storage tubes requires that the overpack tube plugs be provided with features that interface with the plug hold-down bolts and the spider lock down mechanism. Redundant seals and no overpressurization relief ensure containment of the inert gas and confinement of any released MCO gases (see Section A4.3.5 and Figure A2-8).

A4.4.3.3 Functional Requirements. Overpack storage tube plugs provide shielding for the operators from the SNF contained in the MCOs in vault 1 and are in compliance with Items 20 and 23 of HNF-SD-SNF-DB-003. Standard structural un-reinforced concrete and heavy cast steel top composition are provided to achieved this goal. Shielding analyses assume a concrete density of 2.24 g/cm³.

A4.4.3.4 System Evaluation. HNF-PRO-704, Table 2, lists design codes and standards for design of SSCs based on their safety designation. Process equipment (e.g., vessels and tanks)
designated safety significant can be designed in accordance with the *Boiler and Pressure Vessel Code*, Section VIII (ASME 1995). Item 10 of HNF-SD-SNF-DB-003 requires that NRC Regulatory Guide 1.26 be used in assigning the appropriate code class to systems and components designed to the *Boiler and Pressure Vessel Code*, Section III (ASME 1995). The Category C quality level from NRC Regulatory Guide 1.26 has been assigned to the overpack storage tube assemblies because of the safety-class mitigative features described in Section A4.3.5. The overpack storage tube assemblies, including the overpack storage tube plug, are designed and fabricated in accordance with the *Boiler and Pressure Vessel Code*, Section III, Class NC (ASME 1995). For continuity of design, the bellows (Figure A2-8, sheet 2), although outside of the pressure boundary for the overpack storage tube assembly, also is designed and fabricated to the requirements of *Boiler and Pressure Vessel Code*, Section III, Class NC.

The overpack storage tube plugs provide shielding for the facility operators from the SNF contained in the MCOs below the deck in vault 1. Results of calculations for standard storage tube plugs estimate the dose at the surface of the operating deck to be about 0.2 mrem/h (2.0 \times 10^{-3} \text{ mSv/h}). An extremity dose of about 0.4 mrem/h (4.0 \times 10^{-3} \text{ mSv/h}) is estimated for surveillance operations on the overpack storage tube plugs below the deck (see CSB-SH-2002 and Section A4.4.2.4 above). The overpack storage tube plug design and the spider hold-down device meet the requirements for personnel shielding safety in accordance with HNF-SD-SNF-DB-003 (Items 20 and 23).

A stress analysis (CSB-RM-0002) was performed to ASME B30.20-1993 safety factors of 3 on yield and 5 on tensile strength, assuming a test weight of 1.5 times the all steel overpack tube plug weight of 12,300 lb (2 times the estimated 6,200 lb. weight of a composite steel-concrete overpack storage tube plug). The analysis examined the critical areas for the plug load path: the plug female threads and the plug lifting attachment top transition from 4 in. to 2 in. The analysis determined safety factors of 5.2 and 8.1 (respectively, yield and tensile) for the female plug threads and safety factors of 4.2 and 6.5, respectively, for the top transition 4 in. lifting attachment point. The stress analysis demonstrates that the design of the pintle exceeds the yield and tensile safety factor requirements of ASME B30.20-1993.

**A4.4.3.5 Controls (Technical Safety Requirements)**. The following assumptions associated with the overpack storage tube plugs, overpack tube plug covers, and overpack tube deck embed covers require TSRs to ensure performance of the safety function.

- Overpack tube plugs are in place over every overpack storage tube unless that tube is being accessed by the MHM.

- MHM safety features ensure that the MHM will not leave an overpack storage tube location before replacing the overpack tube plug. This interlock (P2) is described in Sections A4.4.4 and A4.4.12 and operability is discussed under LCO 3.1.1 in Chapter A5.0.
A4.4.4 Multi-Canister Overpack Handling Machine Structural Components; Multi-Canister Overpack Hoist and Grapple; and Multi-Canister Overpack Handling Machine Interlocks P2, P6, and P21

A4.4.4.1 Safety Function. Structural failure of the MHM could cause damage to the safety-class MCO or to the safety-class CSB operating deck. The safety function of these SSCs is to prevent damage to an MCO or the operating deck caused by structural failure of the MHM and to provide safe handling of the MCOs. The MHM is structurally classified as safety significant in accordance with Letter 97-SFD-172 (Sellers 1997) and DOE-STD-3009-94, and consistent with waiver 1 to HNF-PRO-704. The MHM MCO grapple and hoist assembly also is classified safety significant (Williams 1998a) and ITS Category B in accordance with the graded approach in HNF-SD-SNF-DB-003. The safety functions of the MHM structural components and MCO hoisting components are to provide a robust system to safely handle the MCO, to reduce the frequency and risk that the MCO will be dropped from or damaged by the MHM, and to reduce the frequency and risk that the operating deck will be damaged by the MHM during normal operations and during the DBE.

MHM operation is governed by a system of electrical interlocks. These interlocks provide permissives that allow the operator to perform MHM operations (e.g., actuate drives or motors) based on signals from a large number of sensors and switches. Interlocks P2, P6, and P21 have been designated safety significant for their safety function of protecting the MCO from drop and shear accidents and for providing worker radiation protection. In addition, MHM interlocks P3, P5, P8, P9, P26, P57, P61, P62, P63, P65, P66, P80, and P85 have been designated as defense-in-depth features for their safety function of providing additional design features and controls to prevent MCO drop and shear accidents.

A4.4.4.2 System Description. The MHM primarily consists of the bridge, trolley, and turret and turntable assemblies. The bridge is comprised primarily of bridge girders, wheel trucks, and a related drive system. The bridge is comprised primarily of a central deck, two outer box beams that carry the wheel and bearing assemblies, and a drive system. The turret and turntable assembly is comprised primarily of the MCO cavity, the tube plug cavity, the camera cavity, the shield skirt, two large slewing bearings, and a nose unit. The MCO hoist and grapple are located on the upper turret above and within the MCO cavity and consist of a drum and external drive assembly, an upper hoist assembly, and the grapple.

The grapple is a self-centering, self-aligning, six-jaw grapple designed to engage and lift, and lower and release MCOs and impact absorbers. The grapple configuration is designed to ensure that all the jaws can achieve the fully closed position without contacting the MCO. Each of the six jaws is operated via two pairs of pinned linkage arms. The jaws are mounted via pivot pins at one end of the linkage arms while the other end of the arms are attached to the jaw operating weight by a roller and bearing arrangement. The operating weight operates vertically with respect to the jaw carriers. When the jaws are to be opened, pressurized air is admitted to the cylinder to extend the piston, allowing the operating weight to lower under its own weight and open the jaws.
The crane’s bridge girders are plate box sections (6 ft wide by 8 ft high) with all-welded construction and stiffening diaphragms at proper intervals. The girders have plates for fastening to equalizing sills with large fitted bolts. Rails for trolley travel are fitted to the top of the girders and secured by bolted rail clips. The crane is carried on box sections, all-welded, pin-equalized trucks that are diaphragmed and plated for attaching to sills. Trucks are in-line machine bored with interface surfaces machined for accurate bolting of renewable wheel bearing cartridges. The bridge drive has two motors located at the trucks.

The trolley rides on the crane bridge girder rails and supports the MHM turret assembly, enabling it to traverse the east–west direction along the girders. The main trolley deck surrounds the turret and has the MHM operator station and the turret rotation drive and lock assembly mounted to it. The outer wheel beams are welded box sections with machined seatings formed at each end to receive the rail wheel bearing housings. All load points are stiffened with internal diaphragms. The trolley drive consists of a motor, brake, reduction gearbox, and twin cardan shaft driving two of the four trolley wheels.

The turret and turntable assembly is designed to ASME NOG-1-1995, Type I, crane requirements for permissible materials and stresses. The expected stresses for the turret and turntable assembly have been demonstrated to be within code allowable values. The turret consists of a rotating upper assembly and a nonrotating bottom nose unit. The upper turret assembly is supported from the trolley by a slewing bearing and the turntable. The upper turret is bolted to the turntable with a segmented packer at the interface that helps to provide a natural convection air passage for the MCO cavity. The nose unit consists of the lower turntable and retractable shield skirt. The nose unit is suspended from the underside of the upper turret by a slewing bearing. The nose unit is tied to the trolley via the base torsion linkage. The upper turret can be rotated relative to the trolley and the nose unit. The nose unit has one cavity or throughport that is eccentric to the center of the turntable slewing bearing. The upper turret has three cavity positions — MCO cavity, tube plug cavity, and television camera — any one of which may be placed over the nose throughport by rotating the upper turret to the proper location. The retractable shield skirt is mounted concentrically with and suspended from the nose unit and can be lowered to contact the deck to complete the MHM shielding during MCO hoisting or storage tube operations.

The MCO hoist is designed to CMAA 70-94, Specifications for Top Running Bridge and Gantry Type Multiple Girder Electric Overhead Traveling Cranes, class D, for permissible materials and stresses. A failure modes and effects analysis of the hoist and grapple system has been completed consistent with MIL-STD-1629A, Procedures for Performing a Failure Modes, Effects and Criticality Analysis. The results of the analysis are provided in ESL/R(97)36, Failure Modes and Effects Analysis of Hanford MCO Hoist and Grapple. A stress analysis of the load path components for the MHM MCO grapple and hoist assembly is documented in ESL/R(96)099, Multi-canister Overpack Handling Machine Turret Design Calculations. The analysis confirms that the normal and seismic loads can be lifted in accordance with ASME NOG-1-1995 requirements and the Grapple Design Code ANSI N14.6-1993. These two references confirm that the MCO grapple and hoist are single-failure proof for lifting. The load
The load path components for the MCO grapple include the jaws, jaw pins, grapple body, link arms, pins, bolts and nuts, and flange ring shown on Figure A2-38, sheet 1. The load path components for the hoist assembly (Figure A2-38, sheet 2) include the load block, pulleys and pins, rope, balance beam, hoist support enclosure, main beam, pulley brackets, clevis, trunnions, and connectors. The hoist drum and external drive assembly are bolted to the top of the upper turret shield body, and the hoist upper assembly is bolted to the top of the drum structure. The hoist design uses a dual rope system with a twin-grooved drum (Figure A2-38, sheet 2). The two rope grooves in the drum are opposite-handed, helical grooves to ensure that both rope lengths remain identical throughout the MCO lift. The hoist drum is driven by a motor and primary drive train with a secondary drive train connected to the opposite end of the drum. An electric shoe brake provides the main load-holding brake for the drum. The secondary drive incorporates a second shoe brake and ensures that no credible single failure will result in the loss of ability to stop and hold the MCO load. The upper hoist assembly contains the reeving system for the two hoist ropes and the load block for attaching the grapple to the hoist system (Figure A2-38, sheet 2). The two hoist ropes are 0.75-in.-diameter, nonrotating ropes, each with a minimum breaking strength of 39 tons. The ropes travel from the drum up to twin head pulleys, down to the load block, and back up to the balancing beam where they are securely fixed. Guards on all pulleys ensure that the ropes remain within the pulley grooves. The load block clevis is mounted to the top of the MCO grapple lifting body and is suspended from the hoist ropes via two pulleys that are mounted such that either rope can perform a vertical lift if the other rope should fail. In the event that one rope should fail, the load on the remaining rope will overbalance the balancing beam, and damping cylinders ensure that the overbalancing motion will not lead to a shock loading on the rope and hoist and grapple mechanism that exceed allowable values from ASME NOG-1-1995, Section NOG-5425.

The MCO grapple is designed as a special lifting device for critical loads in accordance with Section 7 of ANSI N14.6-1993 for permissible materials, lower stresses, and higher proof load requirements. This results in high safety factors for the rated load. The expected stresses for the MCO grapple have been demonstrated to be within code allowable values. The MCO grapple is connected to the main hoist load block by the grapple lifting body, which lifts the grapple through the top plate. The grapple is a self-centering, self-aligning, six-jaw grapple designed to engage, lift, lower, and release MCOs and impact absorbers. Each of the six jaws is operated via two pairs of pinned linkage arms (bell cranks). Each set of linkage arms is pivot mounted on either side of a plate jaw carrier, and the six jaw carriers are welded to a top plate and a base guide plate to make up the main body fabrication. The jaws are mounted via pivot pins at one end of the linkage arms while the other end of the arms is attached to the jaw-operating weight by a roller and bearing arrangement. The operating weight moves vertically with respect to the jaw carriers. This vertical movement is translated through the linkage arms to operate the jaws in such a way that an upward motion of the weight causes the jaws to move downward and inward, closing the jaws. The operating weight is held raised by a single-acting, spring-return, operating cylinder mounted on the top plate. To close the jaws, the air pressure is removed from the cylinder, allowing the cylinder spring to retract the cylinder piston and raise the operating weight. The jaws are opened (Figure A2-38) before full engagement with the MCO. If the MCO is offset within the storage tube, the weight of the grapple is used to force the jaws partially closed as the
base guide plate guides the grapple assembly into alignment with the MCO lift feature. The locking plate is located beneath the base plate and is connected to the lifting cap by three operating rods that are mounted in a way that ensures that the locking plate will be raised before the main grapple body. A mechanical lock on the locking plate is designed to ensure that the jaws physically may not be opened if the lock is engaged and the grapple is supporting a load.

The MHM MCO shear and drop prevention interlock system channels consist of interlocks and the sensors, relays, and associated electrical power contactors. The sensors (limit switches, resolvers, photoelectric switches, proximity sensors, or load cells) associated with a given interlock measure or detect a parameter associated with the physical state of the MHM, such as the position of one of its mechanical components. The electrical power control contactor controls whether or not power is made available to the motor or drive associated with the interlock upon demand by the operator. The power contactor forms an open circuit when the interlock logic is not satisfied and a closed circuit whenever the interlock permissive logic is met. All of the MCO shear and drop prevention interlocks are dual-channel interlocks whose power contactors are in series so that power will not be supplied unless the interlock logic of both channels has been satisfied. The two interlock channels are electrically independent and physically separate to satisfy the single failure-proof criterion.

The interlock logic is described below for each safety-significant interlock.

P2 X channel

INHIBIT: Crane bridge travel motors operating and crane trolley travel motors operating and shield skirt jack raising

UNLESS: IF MHM is in MCO mode OR impact-absorber-exchange mode, the tube plug hoist is fully raised and the tube plug grapple jaws are fully open and the plug cavity is empty

AND

IF MHM is in tube-plug-exchange mode, and the tube plug hoist is fully raised and tube plug grapple jaws are fully open and the plug cavity is empty and the MCO grapple is in contact with a load and the MCO weight is above minimum grapple-plus-tube plug weight limit

OR

IF MHM is in tube-plug-exchange mode, and the tube plug hoist is fully raised and tube plug grapple jaws are fully closed and locked and the plug cavity is occupied and the MCO grapple is not in
contact with a load and the MCO weight is below the maximum grapple-only weight limit.

Y channel

INHIBIT: Crane bridge travel motors operating and crane trolley travel motors operating and shield skirt jack raising

UNLESS: IF MHM is in MCO mode OR impact-absorber-exchange mode, the tube plug hoist is fully raised and the tube plug grapple jaws are fully open and the plug cavity is empty

AND

IF MHM is in tube-plug-exchange mode, and the tube plug hoist is fully raised and tube plug grapple jaws are fully open and the plug cavity is empty and the MCO grapple is in contact with a load and the MCO grapple jaws are closed and locked and the MCO grapple load is not an MCO

OR

IF MHM is in tube-plug-exchange mode, and the tube plug hoist is fully raised and tube plug grapple jaws are fully closed and locked and the plug cavity is occupied and the MCO grapple is not in contact with a load and the MCO grapple jaws are not closed.

P6 INHIBIT: Turret rotation, turret locking pin disengagement, and base locking pin disengagement

UNLESS: IF in MCO mode or impact absorber exchange mode, the MCO grapple is fully raised

OR

IF in tube plug exchange mode, the MCO hoist is at the tube plug raise limit.

P21 INHIBIT: Shield skirt jack lowering, turret rotation, turret locking pin disengagement, base locking pin disengagement, tube plug hoist operation, and MCO hoist operation

UNLESS: The crane bridge clamps are fully applied and trolley restraint pins fully inserted.
Interlock P2 consists of the MCO-operating-mode-select switch, two tube-plug-hoist-fully-raised limit switches (LFPFRX and LFPFRY); two tube-plug-grapple-jaws-fully-open limit switches (LFPGOX and LFPGOY); two plug-cavity-empty photoelectric switches (PESSPX and PESSPY); two MCO-grapple-in-contact-with-a-load limit switches (LFMOCX and LFMOCY); two tube-plug-grapple-jaws-fully-closed limit switches (LFPGLX and LFPGLY); two tube-plug-grapple-jaws-locked limit switches (LFPGLX and LFPGLY); one MCO-grapple-jaws-not-closed limit switch (LFMJC); two MCO-hoist load cells (LCMHR1X and LCMHR2X); a trip-point unit connected to the output of the load cells; logic relays; and three sets of power contactors — one to the bridge travel motors, one to the crane trolley travel motors, and one to the shield skirt jack raise motors. The tube-plug-hoist-fully-raised limit switches are located inside and near the top of the tube plug hoist screw jack bellows assembly. The tube-plug-jaws-fully-open limit switches are positioned on a cam near the top of the actuator shaft assembly that rotates to open or close the tube plug jaws. The plug-cavity-empty photoelectric switches are located in the side wall of the tube plug cavity. The MCO-grapple-in-contact-with-a-load limit switches also are located on the MCO grapple assembly and are actuated when the grapple is seated on an MCO and the proximity probe is fully depressed. The tube-plug-grapple-jaws-fully-closed limit switches are positioned on a cam near the top of the actuator shaft assembly that rotates to open or close the tube plug jaws. The tube-plug-grapple-jaws-locked limit switches are positioned on a cam that rotates to open or close the tube plug jaws. The MCO-grapple-jaws-not-closed limit switch is located on the MCO grapple assembly and actuated by the position of the grapple central post. The two MCO hoist load cells are mounted on rope 1 and rope 2 of the MCO hoist. The sensors provide electrical input to the logic relays. If all required logic is satisfied, power is made available through pairs of power contactors, upon demand, to the bridge drive motors, the trolley drive motors, and the shield skirt jack motors for raising.

Interlock P6 (MCO hoist raise limit) is comprised of the following components: a limit switch (LFMGUDX) and associated push rod, a resolver (RSVMGHY and PLS2), logic relays, and three pairs of electrical power contactors. The P6 interlock limit switch is located in the MCO hoist compartment. A push rod that extends from the hoist compartment below into the MCO cavity activates the limit switch when the fully raised MCO grapple contacts the push rod. The resolver is mounted on the MCO hoist drive unit. The resolver constantly measures the height of the MCO grapple by measuring the angle through which the MCO hoist drive has rotated. The limit switch and the resolver provide separate electrical input to the two channels of logic relays. If required two-channel logic is satisfied, then power is made available, upon demand, through pairs of power contactors to the turret rotate motor, the turret locking pin motor, and the base locking pin motor.

Interlock P21 (bridge seismic clamps and trolley seismic restraints fully applied) is comprised of the following components: two sets of trolley dual limit switches (LFTSLP1AX and LFTSLP1AY, LFTSLP2AX and LFTSLP2AY), two sets of bridge limit switches (PSLTSC1AY and PSLTSC1AX, PSLTSC2AY and PSLTSC2AX), relays, and six pairs of electrical power contactors. The interlock P21 trolley seismic restraint pin limit switches are mounted on the trolley seismic restraint assembly. The bridge seismic clamp detection limit switches are mounted
inside the rail Johnson clamps. All of the limit switches provide separate electrical input to the
two-channel logic relays. If interlock P21 and all other required two-channel logic are satisfied,
then power is made available, upon demand, through pairs of power contactors to the shield skirt
jack motors for lowering, the turret rotation motor, the turret locking pin motor, the base locking
pin motor, the tube plug hoist motor, and the MCO hoist motor.

A4.4.4.3 Functional Requirements. The MHM structure and MCO hoist are designed to
prevent overstress or failure that could result in damage to the MCO or the CSB operating deck
during normal operation or during the DBE. The DBE seismic response spectra curves are shown
on Figure A4-4. The MHM safety-significant interlocks are designed to prevent an accidental
drop or shear of an MCO and provide radiation protection for workers in the CSB operating area.

A4.4.4.4 System Evaluation. The main structural components of the MHM will withstand the
DBE loading without the stress levels exceeding the allowable stresses permitted by
ASME NOG-1-1995. The turret and turntable assembly are designed to ASME NOG-1-1995,
Type I, crane requirements for permissible materials and stresses. The expected stresses for the
turret and turntable assembly have been demonstrated to be within code allowable values.

A dynamic analysis using the Response Spectrum Method was employed for the seismic analysis
of the MHM. This seismic analysis included the MHM grapple system. The response spectra for
accelerations acting on the MHM runway level were evaluated for a DBE having a zero period
acceleration 0.35 g horizontally and 0.23 g vertically above 33.33 Hz (see Figure A4-1). The
response spectrum method assumes the MHM responds as a linear elastic system. Results of the
seismic analysis are contained in report ESL/R(96)083.

The tube plug hoist and grapple have been designed to ASME NOG-1 Type-II crane
requirements for permissible materials and stresses. The calculated results of the stresses induced
in the load path components are contained in ESL/R(96)099. The MCO grapple is designed as a
special lifting device in accordance with ANSI N14.6-1993 for permissible materials, lower stress
allowables, and higher proof load requirements. This results in high safety factors for the rated
load. The ANSI N14.6-1993 safety margins require that analyzed stresses be below material yield
strength when multiplied by 6, or below material ultimate tensile strength when multiplied by 10.
See Table A4-6 for grapple load path components. The expected stresses for the MCO grapple
have been demonstrated to be within code allowable values. Proof testing of the grapple was
performed at 3 times the rated load of 12 tons (72,000 lb) in accordance with ANSI N14.6-1993.

The MCO hoist and grapple designs have been shown to be single-failure-proof against a
load drop event. The hoist is equipped with two brakes, redundant ropes and one drive train. The
interlocks discussed previously also terminate some events, which could lead to a load drop event
such as overspeed or hoist operation above upper limit. The MHM vendor performed failure
mode and effects analyses on both the MCO hoist and grapple and the MCO hoist and grapple
control system. The analyses are documented in ESL/R(97)36 and ESL/R(97)43, Failure Modes
and Effects and Hazard Analysis of Hanford MCO Hoist and Grapple Control System. These
failure mode and effects analyses were carried out to the format of MIL-STD-1629A and
considered failures at the component level. The failure mode and effects analyses revealed the
components whose failures give rise to a dropped MCO. The results indicate that with implementation of strict setting-up and maintenance programs, the design meets the single-failure criterion.

Evaluation of the MHM contained in the seismic analysis report [ESL/R(96)083] also has determined that during a DBE, MHM movement is within the design tolerance, the MCO will not become trapped, and the MHM will not hammer or collapse on the operating deck.

The MCO shear and drop prevention interlock system is comprised of a number of sensors (resolvers, limit switches, photoelectric switches, load cells, proximity sensors), relays, power contactors, and other electrical components. The devices are initially set during preoperational acceptance testing and are subject to surveillance checks at regular maintenance intervals as recommended by the MHM vendor.

Figure A4-5 is a single-line power distribution diagram that depicts the arrangement of the MHM power and control interlock system. Facility power is provided to the MHM at 480 V/3 ph. AC. The power passes through the seismic trip panel, through a main disconnect, and delivered through the trolley festoon cable to control cabinets located on the MHM trolley. The power is provided through fused 480/120 VAC transformers to separate power and interlock panels for the X and Y channels. The X-channel cabinets also include control circuitry from the operator’s console. Relay logic is powered by 120 VAC. When control power is lost to one or both channels, any single failure will not defeat both the X and Y channel. If all power is lost, none of the drives will operate.

The MHM interlocks protecting against an MCO drop are active interlocks in that they perform an action. They are designed to interrupt MCO hoist operation when unfavorable conditions are encountered or prevent MCO grapple operation. A generic interlock is shown in Figure A4-6. It consists of an X-channel and a Y-channel. Each channel consists of sensors, logic relays and a power contactor to the hoist drive motor. All components in the channel have an active safety function to perform when control and drive power are available. There is no safety function to perform when drive power is removed.

In general, two sets of redundant and independent sensors are used, one for each channel. The X and Y channel control power devices, relay logic and power contactors are located in separate panels dedicated to the X and Y channels as shown on Figure A4-5. These panels and the control console are mounted around the periphery of the trolley. A fire in one panel or failure in a panel cannot propagate to another panel. The panel supports are designed to ensure that the panels stay attached to the trolley frame and flooring during the DBE. There will be no missiles or falling components from the MHM that could sever the conduit and wiring between the panels or between the panels and the turret, trolley or bridge. The X-channel cabinets include part of the command circuitry for the drives coupled with the interlock logic. A command signal and satisfied interlock logic are necessary to satisfy the X-channel permissive. The command circuitry is powered by X-channel 120 VAC power and interfaces with the interlock logic through
energized relays. Closure failure of these relays has no effect on the remainder of the interlock logic and therefore the safety function is not compromised.

The MHM elementary control schematics will delineate the safety significant portions of the system. Periodic surveillance testing will ensure that the sensors, relays or power contactors have not failed closed. The operator panel is also equipped with status lights to show when the MCO hoist or MCO grapple are energized. There are no shared systems associated with the interlocks. In most cases, multiple interlocks will need to be satisfied before a power contactor to the MCO hoist drive motor or MCO grapple solenoid will be energized. The hoist interlocks are somewhat different than the passive permissive interlocks. In some cases, one channel will allow hoist motion in one direction for recovery operation when the second channel is manually overridden. A failure of the manual override only affects the one channel and has no impact on the other channel retaining the safety function.

A loss of electrical power or a seismic event exceeding the setpoint trips all control and drive power to the machine. The MHM is not required to perform any operation in the event of loss of electrical power or after the DBE. Regardless of MCO position, there is adequate natural convection cooling to prevent MCO temperature limits from being exceeded. Any of the drives can be manually actuated to rotate the turret, raise or lower the MCO, etc, should this become desirable. When power is restored, the machine power must be manually reset and a startup sequence performed before any drive can be actuated; therefore, the machine will not spontaneously resume hoist operation when power is restored. The behavior of the system for earthquakes less than one half the DBE is discussed in Section A2.5.1.3 under the seismic trip system evaluation.

The following paragraphs describe the various safety-significant interlocks associated with the MCO.

The sensors that are part of interlock P2 must be functionally evaluated to ensure that the MHM cannot remove a storage tube plug from a storage tube without replacing it with the same or another plug before raising the shield skirt to relocate.

- The pair of tube-plug-hoist-fully-raised limit switches are positioned near the top of the tube plug hoist screw jack bellows assembly and directly contact the top of the hoist when activated.

- The two tube-plug-grapple-jaws-fully-open limit switches are set to indicate that the jaws are closed only when the cam that opens the jaws is within 5° of the fully open rotational position.

- The pair of plug-cavity-empty photoelectric switches simply indicate whether or not a tube plug is in the tube plug cavity.
The pair of MCO-grapple-in-contact-with-a-load limit switches are set so that the grapple proximity probe must be essentially fully extended for no contact to be sensed. The X channel makes contact when the proximity probe has been depressed 4 mm or more, and the Y channel detects a load if the proximity probe has been depressed 3 mm or more from its fully extended position.

The fully closed jaw position will have a maximum separation between opposing jaw tips of 2.5 in.

The two MCO hoist load cells circuitry must be calibrated so that when the weight suspended from the MHM grapple is between zero and 24,000 lb, the reported weight indication has a minimum accuracy of 5% of rated load (HNF-S-0468).

All of the preceding checks on components ensure that they are calibrated or set and are not malfunctioning in a way that could bypass the intent of interlock P2.

Interlock P6 (MCO hoist at raise limit) requires that both a limit switch and the MCO hoist interlock resolver and programmable limit switch indicate that the MCO hoist is fully raised. The push rod that activates the limit switch has an adjustable beveled sleeve that contacts the limit switch. The switch will not be actuated unless the top of the MCO grapple assembly is less than 5.5 in. below the outside bottom of the MCO hoist and drive assembly box. The MCO hoist resolver is set such that it will not indicate that the MCO hoist is fully raised unless the grapple is less than 5.5 in. below the outside bottom of the MCO hoist and drive assembly box.

Interlock P21 (bridge seismic clamps and trolley seismic restraints fully applied) requires that two sets of dual limit switches on the trolley seismic restraint pin indicate that the restraint is fully applied. Interlock P21 also requires that four sets of dual pressure switches on the bridge seismic clamps indicate that the clamps are fully applied. These switches are adjusted so that they do not indicate that the clamps have been fully applied until both sides of the rail clamps are simultaneously in contact with the sides of the rail (under the railhead).

A4.4.4.5 Controls (Technical Safety Requirements). The following assumptions associated with the MHM require TSRs to ensure performance of the safety functions.

- MHM interlocks prevent shearing an MCO from translational movement. Interlocks P6 and P21 are operable.
- Configuration control of the MHM is maintained to ensure its continued structural integrity.
- To ensure that the MHM radiation protection interlock system is operable, operational checks of interlock P2 must be performed consistent with the frequency recommended by the MHM supplier.
A4.4.5 Tube Vent and Purge Cart

A4.4.5.1 Safety Function. The safety function of the pressure boundary portions of the tube vent and purge cart is to maintain confinement when connected to an overpack storage tube plug and minimize releases of particulate from overpack storage tubes to the environment. The tube vent and purge cart is provided for use in recovery operations involving MCOs should the recovery operations team deem its use appropriate. The tube vent and purge cart (see Figure A2-47) provides a means to periodically purge the overpack storage tubes of hydrogen and to sample the gas stream for concentrations of radioactivity. The cart contains a helium gas supply to install and maintain an inert atmosphere around the MCOs staged in the overpack tubes. The tube vent and purge cart also provides confinement when connected to the overpack storage tube plug (see Figure A2-14). Confinement is ensured by providing a HEPA-filtered pathway for controlled venting of gases that may have built up in the overpack storage tubes from relief of pressure from MCOs. To minimize the potential for release of particulate to the operating area, the cart contains HEPA filtration equipment to remove particulate released into the overpack storage tube and pushed into the cart.

Other non-safety related functions of the tube vent and purge carts associated with preparing the standard and/or overpack storage tube for removal or placement of an MCO are removal of the tube plug cover assemblies and placement of the interface guide ring funnel to comply with TSRs in Sections A4.3.15 and A4.3.16. These operations are considered non-safety related and are further described in Section A2.5.1.3.

A4.4.5.2 System Description. The tube vent and purge cart is designed to monitor the gas concentration in the overpack storage tube, pressure purge the tube with helium while maintaining confinement (gases are vented through HEPA filters), and refill the tube with helium. The tube vent and purge cart is shown in Figure A2-47. A towable hoist is provided to remove the center access plate in the overpack tube plug. Figure A2-48 represents a diagram of piping, instruments, and equipment required by the tube vent and purge cart to service the storage tubes.

The tube vent and purge cart connects to the overpack storage tube plug by means of a 1.5-in., flexible metal hose. The pressure in the overpack storage tube, or the pressure introduced by the cart's onboard helium supply, pushes the tube atmosphere through the HEPA filter for removal of particulate exhausted from the storage tube. The metallic filter medium is rated for 175 °F, a flow rate of 20 standard ft³/min at a pressure drop of 1 in. w.g. The gas in the overpack storage tube is monitored by means of a 0.75-in. line from the 1.5-in. piping header through a 21 W heat exchanger, an in-line continuous air monitor, radioactive-gas monitor, and hydrogen monitor. Instruments on the tube vent and purge cart detect airborne radioactivity and hydrogen concentrations in an overpack storage tube.

A 0.75-in. manifold feeds inert gas to the 1.5-in. cart header at 5 lb/in² gauge from two 2,000 lb/in² cart-mounted gas bottles. The inert atmosphere is initially supplied from these high-pressure inert gas bottles after the overpack storage tube has been vented. A pressure regulator and relief valve prevent overpressurization of the overpack storage tube.
The tube vent and purge cart is battery powered for motion. The equipment on the cart is powered through cables inserted into electrical outlets in the deck. The tube vent and purge cart equipment is operated using manually operated valves that are located on the cart. The operator has to make and break connections to the overpack storage tube plug. The overpack storage tube plug is designed to provide shielding, confine radioactive particulate, and minimize hydrogen fire hazards (see Sections A4.4.3 and A4.3.5).

The safety-significant components of the tube vent and purge cart include all lines, fittings, valves, components, and instruments between the overpack storage tube plug connection and the outlet from the tube vent and purge cart HEPA filter. These items ensure that the overpack storage tube atmosphere remains inert by excluding air ingress during all tube vent and purge cart operations.

**A4.4.5.3 Functional Requirements.** The tube vent and purge cart is used to install, maintain, and replenish the inert gas atmosphere in the overpack storage tubes. The cart facilitates controlled venting of gases that may have built up in the overpack storage tubes from relief of pressure from the accident or suspect MCOs (these MCOs may be leaking through the gasketed cover plates bolted to the four ports of the cover assembly). Gases from the overpack storage tube are monitored and vented to the operating area through a HEPA filter on the tube vent and purge cart. The cart interfaces with a connection on each overpack storage tube plug that allows monitoring and purging of the tube atmosphere without interfering with the sealing surfaces of the plug. The cart’s flexible hose and cart piping and equipment must be designed to withstand the expected maximum overpack storage tube atmosphere temperature and pressure. Overpack storage tube design pressure is 75 lb/in² gauge (see Section A4.3.5). Figure A4-3 indicates a tube exterior temperature of 186 °F for the standard storage tube containing two MCOs. Overpack storage tubes are designed to contain only one MCO. Gas temperatures are expected to be lower for the overpack storage tubes.

The tube vent and purge cart vents, purges, and refills an overpack storage tube to maintain a slightly positive pressure. Equipment on the tube vent and purge cart can detect airborne radioactivity and hydrogen concentrations and provide HEPA filtration of the sampled volume before release to the operating area atmosphere. The cart equipment takes a sample of the overpack tube’s atmosphere (the gas temperature could range from 125 °F to 186 °F as shown in Figure A4-3), passes it through the monitors, and vents it to the operating area through two stages of HEPA filters. Connections to the overpack storage tube are made using quick-disconnect fittings atop the storage tube plug.

**A4.4.5.4 System Evaluation.** Piping and the external surfaces of other equipment (e.g., gauges, valves, HEPA filters) are adequate to provide confinement of gases from the overpack storage tubes under any potential venting conditions. Components not required to ensure confinement or to minimize the potential for ingress of air during tube servicing are considered general service features.
The tube vent and purge cart will fulfill its safety function of maintaining safe conditions in overpack storage tubes in the following way. After initial inerting, the pressure in an overpack storage tube is slightly positive (4 lb/in² gauge). If hydrogen is relieved from the MCO, the pressure in the overpack storage tube increases. The hydrogen concentration and pressure are measured each time the tube vent and purge cart makes a scheduled visit to an overpack storage tube. If an MCO relief has occurred, the hydrogen concentration could exceed 4%; in this event, the hydrogen concentration in the overpack storage tube will be diluted to below 4% by adding inert gas before the release is vented to the operating area. This process also accomplishes the safety function of preventing oxygen ingress into the overpack storage tubes.

The pressure rating of the tube vent and purge cart components of 150 lb/in² gauge and 400 °F as listed in Table A2-6 are adequate to ensure that the overpack storage tube inert gas atmosphere operation does not exceed the purge cart temperature ratings and is accomplished in a safe manner.

A4.4.5.5 Controls (Technical Safety Requirements). There are no TSR controls for this SSC because its safety function is related to recovery actions. Controls related to specific recovery actions must be developed on a case-by-case basis depending on current conditions and recovery evaluation results.

A4.4.6 Receiving Crane Structure and Hoist

A4.4.6.1 Safety Function. The safety function of the receiving crane structure and hoist is to provide safe handling of the transportation cask and MCOs. The receiving crane and hoist are designed to safely handle transport casks loaded with MCOs. The receiving crane and hoist are designated safety significant in accordance with Letter 97-SFD-172 (Sellers 1997) and DOE-STD-3009-94 and ITS Category B per NRC equivalency requirements using the graded approach in HNF-SD-SNF-DB-003. The safety functions for which the receiving crane is credited are described in Section A3.4.2.1.

After removing an MCO from the transportation cask (as described in Section A2.5.1.3 and shown in Figure A2-32) an empty MCO shell (without baskets or shield plug) is placed into the empty transportation cask, the cask lid is put back on and the completed assembly repositioned onto the transport trailer. The receiving crane is used for placing the cask containing an empty MCO onto the transport trailer. This operation is analyzed in HNF-SD-SNF-HIE-001, Canister Storage Building Hazard Analysis Report, Table 19, checklist designator SA-G-03a.

A4.4.6.2 System Description. The receiving crane is a 60-ton capacity, equal-leg gantry crane with two wire-rope hoists (a main and an auxiliary) supported on a top-running trolley. The receiving crane is designed in accordance with ASME NOG-1-1995 Type I, and Crane Manufacturer’s Association of America class D for indoor service. The receiving crane gantry spans 27 ft, 6 in., and it can travel 164 ft east–west. The receiving crane includes a 10-ton auxiliary hoist, a shielded operator station, remote operating equipment including a powered
rotating hook and local control. Both the bridge and trolley speeds are variable up to 40 ft/min.

Hoist speed for both the main and auxiliary hoists is variable up to 10 ft/min. The trolley weight is 43,000 lb, and the bridge weight is 156,000 lb. Maximum wheel load is 135,000 lb. The NEMA 12 control enclosure is designed in accordance with NEMA 250, Enclosures for Electrical Equipment (1000 Volt Maximum). The power supply is 460 VAC, 3 ph, 60 Hz.

The receiving crane is used to off-load transportation casks from their vertical position on the transport vehicle and to place them into the cask receiving pit. After the MCO has been removed from the transportation cask, the receiving crane is used to place a new (empty) MCO into the transportation cask, remove the transportation cask from the cask receiving pit, and return it to the transport trailer. The transport trailer is loaded and unloaded while it is located in the trailer vestibule. The trailer vestibule is an extension of the CSB that provides an air-locked transition area for the transport trailer and receiving crane to off-load the transportation cask (see Figures A2-19 through A2-21, and A2-31).

The receiving crane is equipped with a shielded operating station located on the outboard side of the north gantry leg. This station is necessary to implement ALARA considerations. Crane control is available either from the operating station or by radio. The receiving crane is expected to receive a total integrated dose of $4.0 \times 10^3$ rad over its 40-year design life. The shielded operating station is 3.5-in.-thick carbon steel with viewing windows at least 12 in. by 6 in. in size providing a normal viewing angle of 50° in the horizontal and vertical direction and an extreme viewing angle of 90° in the horizontal and 80° in the vertical direction.

A4.4.6.3 Functional Requirements. The receiving crane operates over the cask receiving pit, which may contain an MCO and a containment tent. The receiving crane features that prevent dropping loads or components onto the MCO are designated safety significant. DOE Order 6430.1A, Section 1320-5, requires systems and equipment that “ensure safe loading, removal, and handling” of SNF to be designed as “safety class items.” The receiving crane does not handle unconfined SNF nor carry loads over unconfined SNF. Therefore, the features of the receiving crane that prevent crane collapse, dropped loads, or falling components from breaching the MCO are designed to safety-significant criteria (Williams 1998b). Features of the receiving crane that provide protection against tipping over and potentially impacting the safety-class operating area deck structures are designated safety class and required to be designed to withstand the DBE with factors of safety per ASME NOG-1-1995.

Not all receiving crane components need to be operational after a seismic event. If a suspended transportation cask remained inaccessible for sufficient time, overheating of and/or hydrogen buildup in the contained MCO could result in a release of radionuclides to the interior of the transportation cask. The transportation cask is designed to prevent damage to the MCO and to prevent the release of radioactive material if a drop were to occur. Analyses referred to in SNF-3328, Canister Storage Building Design Basis Accident Analysis Documentation, address the consequences of a dropped transportation cask in the CSB.
Receiving crane load rating of 60 tons (120,000 lb) is based on the expected future mission of servicing FFTF fuel casks (see HNF-S-0425). The required rating for the SNF mission is approximately half of this value. The transportation cask containing a full MCO weighs less than 60,000 lb (see HNF-SD-TP-SARP-017). The shielded operator viewing window is required to reduce 1 MeV gamma radiation by a factor of 50.

**A4.4.6.4 System Evaluation.** During normal operations or a DBA, receiving crane components are designed to prevent the drop of a transportation cask containing an MCO, thus preventing severe damage to the transport vehicle, the reinforced concrete floor, and/or the cask receiving pit structure.

The receiving crane is designed to resist tipping over and provide protection against a DBE. The receiving crane is considered decoupled from the runway rails (e.g., no mechanical rail clamps). Lateral displacement is restrained by the wheel flanges and longitudinal displacement is restrained by the crane wheel brakes during a seismic occurrence. The receiving crane is stable against overturning during a seismic occurrence with a safety factor of 1.1, in accordance with ASME NOG-1-1995. Results of the stability analysis performed by the manufacturer of the receiving crane are provided in WRC1-AC-0014, *Seismic Analysis and Design of the 60/10 Ton Receiving Crane with the Credible Critical Load*. The results indicate that the minimum safety factor against overturning for the extreme environmental load conditions is 1.64 about the x axis (transverse horizontal) and 1.1 about the z axis (transverse longitudinal). Static and dynamic analyses of the receiving crane have been performed to verify that the receiving crane will not tip over or collapse during a seismic event (WRC1-AC-0014). The seismic design ensures that the crane will not tip over and impact the safety-class MCO located in the cask receiving pit, or other safety-class or safety-significant SSCs, or cause injuries or fatalities to facility workers.

The receiving crane was also evaluated for the extreme environmental load combination considering dead, live, and seismic loads. The load path components (Figure A2-19) used in the stress analysis for the receiving crane include the trolley, bridge, legs, end trucks, hoist drums, girders, and beams. The live load is the credible critical load of 60 tons. The seismic analysis of the crane is based upon the provisions of ASME NOG-1-1995, Section NOG-4150. A linear response spectrum analysis is used for the evaluation, which is documented in WRC1-AC-0027, *Seismic Analysis and Evaluation of the 60/10 Ton Receiving Crane with the Credible Critical Load*. The static and dynamic analyses of the receiving crane are performed with the STARDYNE computer program. Four STARDYNE models represent the receiving crane and trolley in order to satisfy the requirements of ASME NOG-1-1995, Section NOG-4153.7. At each trolley position, an analysis is performed considering the credible critical load in the raised and the lowered position. The seismic input is based upon the response spectra included in Figure A4-7. The modal responses are combined based upon the Ten Percent Method permitted by ASME NOG-1-1995, Section NOG-4153.10(b)(2). The percentage of critical damping is not required by this modal combination method. The three-directional components of the structural response to earthquake motion are combined by taking the square root of the sum of the squares of the responses caused by each component of earthquake motion as described in ASME NOG-1-1995, Section NOG-4153.10(c). As indicated in the seismic analysis report (see
WRC1-AC-0027), the demand capacity factors for combined bending and axial load for the
girders, endties, legs, bridge endtrucks, and trolley endtrucks are less than 1.0. The maximum
demand-to-capacity ratio for the trolley rail is 0.81 based upon the requirements of ASME
NOG-1-1995, Section NOG-4423.4. The demand-to-capacity ratio for the trolley main load girt
is 0.66 based upon the requirements of ASME NOG-1-1995, Sections NOG-4312, NOG-4313,
NOG-4321, and NOG-4322. The design of bolted connections is based upon the Research
Council on Riveted and Bolted Structural Joints of the Engineering Foundation’s “Structural
Joints Using ASTM A 325 or A 490 Bolts.” The allowable stresses for bearing type joints are
increased by a factor of 1.50 for extreme environmental (DBE) load conditions. The allowable
stresses in welds are based upon AWS D1.1, Structural Welding Code — Steel, for operating load
conditions. The allowable weld stress may be increased by a factor of 1.5 for extreme
environmental conditions. The bolts associated with the connections at the top of the legs are
stressed to capacity for the extreme environmental load conditions. The maximum demand-to-
capacity ratio for these bolts is 1.029. This is acceptable because the compression is
conservatively included in the bolt force. The 0.625-in. welds located between the leg and the
connection plate and the connection plate thickness are adequate for the extreme environmental
load conditions. The bolts associated with the connection of the legs to the bridge endtruck have
a demand-to-capacity ratio of 0.970 (see WRC1-AC-0027).

The receiving crane hoist brake and the seismic accelerometer power-disconnect switch
provide safe shutdown of the receiving crane during a postulated seismic event. This provision is
a requirement of ASME NOG-1-1995 and not driven by safety analysis. If the accelerometer
detects a seismic event in excess of the seismic trip point, the power-disconnect switch
automatically causes loss of power to the receiving crane. On loss of power, the receiving crane
stops, and the load brake is applied preventing motion of either the receiving crane or a suspended
cask. Any suspended load remains in a safe position until power is restored and the operator
restarts load movement. These safety features prevent dropping of the cask if it is suspended
during a seismic event.

HNF-SD-SNF-FHA-002, Final Fire Hazard Analysis for the Canister Storage Building,
determined that a fire, in the load-in/load-out area or elsewhere, will not result in the loss of safe
handling of the cask-MCO by the receiving crane. Collision prevention switches are designed to
prevent the possible collision of the receiving crane with the MHM crane, as these cranes travel
on intersecting rails.

Bridge stops and over-travel limit switches prevent the receiving crane trolleys from
impacting the ends of the rails. Over-travel limit switches cause the trolley motors to slow down
and stop before impact with the bridge stops. The bridge stops are designed to absorb whatever
momentum is left after the over-travel limit switches have engaged. Collision prevention switches
prevent a possible collision between the crane and the trailer vestibule inner door.

The receiving crane system is designed, fabricated, manufactured, inspected, and tested in
accordance with the requirements of CMAA 70-94; ASME B30.20; and ASME NOG-1-1995,
Type I, with the exception of Section NOG-5420(a) (receiving is in accordance with

a-csb04.sar

A4-88

March 2000
CMAA 70-94) and Section NOG-5428.1 (a single hook is used rather than a double hook). The crane's main and auxiliary hoists were tested to 125% of rated load for the entire operating range, as documented in W379-012, Cask Receiving Crane PAT. An analysis and review of the cask and trunnion in HNF-SD-SNF-FDR-003, Design Analysis for the NT and WHC Cask and Transportation System, and an analysis of the cask lifting yoke in HNF-SD-SNF-DA-022, Report on Canister Storage Building (CSB) Crane Hook Structural Analysis, demonstrate that the cask lifting equipment complies with ANSI N14.6-1993 requirements.

The receiving crane design requirements also satisfy the additional NRC equivalency requirements of ANSI/ANS-57.1-1992 and ANSI/ANS-57.2-1992. Design features meeting the additional ANSI/ANS-57.1-1992 requirements include provisions for control manipulation with gloved hands, an interlock that prevents simultaneous hoisting and translational movement (except when manually actuated), and a conveniently located manual disconnect for emergency shutdown of the electrical power supply. Design features meeting the additional ANSI/ANS-57.2-1992 requirements include provisions for safe access to all components for the purposes of testing, inspection, and maintenance; a positive braking or holding mechanism (stop blocks) for the trailer vehicle in the facility; and limiting the potential height of a cask drop by electrical or mechanical controls. Results contained in Calculation CALC-ME-007, Shielding, demonstrate the adequacy of the shielded operator's console and viewing window.

A4.4.6.5 Controls (Technical Safety Requirements). There are no TSR controls for the safety-significant receiving crane structure and hoist for this safety function because the credited features are design features (see Section A5.6) and their safety function is managed by the configuration control process.

A4.4.7 Cask Receiving Pit

A4.4.7.1 Safety Function. The safety function of the cask receiving pit is to protect the facility worker from excessive doses of radiation during the time that the MCO transportation cask is in the cask receiving pit with the cask lid removed and while the MCO is being removed from the transportation cask by the MHM.

A4.4.7.2 System Description. The cask receiving pit is a reinforced concrete structure integral with the 5-ft-thick load-in/load-out concrete floor described in Section A2.4.2. The concrete floor is supported at grade. The cask receiving pit is a 56-in.-diameter, 18.5-ft-deep cylinder. The top 4 ft of the pit contain a 1-in.-thick carbon steel liner embed assembly welded to concrete embedded weld studs. The liner embed assembly carbon steel plate conforms to ASTM A36/A36M. Cask guides mounted in the cask receiving pit center the transportation cask as it is lowered into the pit.

A4.4.7.3 Functional Requirements. The cask receiving pit is designated safety significant. This pit and the shield hatch and MCO assembly prevent radiation exposure by sealing to the MHM while an MCO is being removed from the transportation cask and lifted into the MHM.
The shielding goal for the cask receiving pit and the shield hatch and MCO guide assembly is to meet the ALARA guidelines of Title 10, *Code of Federal Regulations*, Part 835, “Occupational Radiation Protection (10 CFR 835). The cask receiving pit is designed to meet the requirements for personnel shielding safety in accordance with HNF-SD-SNF-DB-003 (Items 20 and 23).

### A4.4.7.4 System Evaluation

The cask receiving pit and the safety-significant shield hatch and MCO guide assembly provide a radiologically safe area for operators to conduct cask receiving and MCO retrieval operations. With the shield hatch and MCO guide assembly in place, radiation dose rate to the facility operator is less than the 0.05 mrem/h calculated value for the operating deck over vault 1 (CSB-SH-2002). The pit is adequate to protect the facility worker and complies with Items 20 and 23 of HNF-SD-SNF-DB-003.

### A4.4.7.5 Controls (Technical Safety Requirements)

The cask receiving pit is a design feature (see Section A5.6), and its safety function is managed by the configuration control process. Design features of the CSB structures ensure that their safety function can be relied upon.

### A4.4.8 Transportation Cask Servicing System

#### A4.4.8.1 Safety Function

The safety functions for the transportation cask servicing system are to protect an MCO from exceeding external design pressures, maintain confinement when connected to the transportation cask, minimize releases of particulate from the transportation cask, and prevent buildup of flammable gases in the transportation cask. The transportation cask servicing system prevents or mitigates a radiological release by purging generated gas (primarily hydrogen generated from the MCO) from the cask and replacing the purged gas with helium. Subsequently, if required, the suspect MCO can be removed from the cask and placed in an overpack storage tube for monitoring by the MCO tube vent and purge cart. Servicing of normal shipping casks and MCOs arriving from the Cold Vacuum Drying Facility is not required (i.e., whenever the internal cask pressure is less than 3.0 lb/in² gauge). Refer to HNF-4509, *Evaluation of Canister Storage Building Cask Receipt Pressure*, for additional details.

The majority of the items in the transportation cask servicing system are classified as safety significant because of their role in providing confinement and worker safety. The transportation cask servicing system is designated safety significant in accordance with DOE-STD-3009-94 and implements the guidance of HNF-PRO-704 for design codes and standards. This system has not been identified in Chapter A3.0 as mitigating or preventing an accident or DBA. It is provided for use during recovery from an accident or suspect MCO shipping cask should the facility recovery team deem it appropriate.

Overpressurization protection is provided by pressure safety valve PSV-102 located outside the west wall of the support building (see Figure A2-24). This valve is set to relieve at 150 lb/in² gauge.
A4.4.8.2 System Description. The transportation cask servicing system comprises an inert gas supply, flexible steel hose, a canister HEPA filter (FH-2), piping, valving, and control system interfaces. The transportation cask servicing system is designed to vent the cask to a safe condition by removing excessive amounts of hydrogen and replacing a high-hydrogen cask atmosphere with inert gas. This replacement is accomplished by repeatedly venting and pressure purging any cask that has been determined to be abnormally pressurized (>3 lb/in² gauge). The cask is vented and purged while located inside the cask receiving pit. The piping and instrumentation are depicted on Figure A2-24. The containment tent is available for control of radioactive contamination during recovery operations, if needed.

The designed flow path for servicing system operations begins with aligning the system for venting (confinement of gases vented from a transportation cask containing an abnormal MCO is controlled to safety-significant criteria). The quick-disconnect fitting is connected to the appropriate fitting on the transportation cask. The gas from the transportation cask is vented through a HEPA filter. Equipment provided for the venting operation downstream of the HEPA filter includes piping, valves and fittings, a sampling connection with a flow orifice, and an inert gas (helium) dilution control system. The sampling connection provides a means of pulling a sample from the transportation cask and is designed for the potentially high temperature of the gas coming from the transportation cask. The addition of inert gas to the transportation cask off-gas stream is controlled via a pressure controller combined with the flow orifice to promote mixing and dilution before venting the potentially high-hydrogen gases into the operating area and through the exhaust stack.

The designed flow path for the cask servicing system ends with aligning the system for the purging operation. Purging is performed by providing pressurized inert gas directly to the transportation cask. A combination of special-connection hardware specific to the inert gas and operation of the transportation cask servicing system at atmospheric pressure and above minimizes the potential for inadvertently adding air to the transportation cask. Upon completion of venting and purging operations, the transportation cask is returned to atmospheric pressure. Hydrogen monitoring can be performed using the tube vent and purge cart if necessary. The quick-disconnect fitting is disconnected from the appropriate fitting on the transportation cask before the cask lid is removed and the MCO removed from the service station by the MHM for transport to the sampling/weld area or a standard storage tube.

A4.4.8.3 Functional Requirements. Transportation cask purging and inerting operations must not create a flammable atmosphere inside the transportation cask. Using a closed (air-free) system to purge the transportation cask of hydrogen, and to return the transportation cask to atmospheric pressure, prevents the creation of a flammable atmosphere.

HNF-SD-SNF-DB-003, Item 12, requires that the FH-2 HEPA filter be in accordance with ASME N509-1989 and ASME N510-1989 to implement the principles of ALARA.

A4.4.8.4 System Evaluation. The transportation cask servicing system is designed as a closed system that operates at atmospheric pressure and above. Special connections unique to
pressurized helium gas bottles prevent inadvertent attachment of the wrong gas (oxygen or air) thus minimizing the potential for hydrogen deflagration resulting from use of the cask servicing system. Since the transportation cask is initially un-inerted, the consequences of accidentally introducing air into the cask are minimal. All system components that connect to the abnormal or accident transportation cask and that filter released gases are designed to 150 lb/in² gauge and 400 °F. The cask servicing system components that provide filtration and dilution of cask atmosphere are located in the support area building. See Table A2-2 for design and operating conditions of the cask servicing system.

During venting operations, the transportation cask is depressurized to atmospheric pressure. The offgas is vented to the HVAC exhaust stack through a filtered pathway, first passing through the sintered metal canister-type HEPA filter (FH-2) and then through a secondary nonmetal HEPA filter, as discussed in Calculation CSB-PR-0012, Tube Plug HEPA Filter Particulate Loading, eventually joining the HVAC exhaust airflow just upstream of the HVAC exhaust fans (see Figure A2-51). The FH-2 HEPA filter is 99.97% efficient and allows only 0.3 μm or smaller particle penetration with a design pressure range of full vacuum to 150 lb/in² gauge and a maximum design temperature of 400 °F. The FH-2 HEPA filter is in accordance with ASME N509-1989 and ASME N510-1989. The normal operating range of the HEPA filters is 0.1 lb/in³ absolute to 80 lb/in³ gauge with a maximum temperature of 150 °F. A 1.5-in. temperature element with a design temperature range of 50 °F to 400 °F and a maximum design pressure of 150 lb/in² gauge is used in the flow path to monitor and record the transportation cask gas temperature as the cask depressurizes. The design pressure for the vent piping is in accordance with ANSI/ASME B31.1, Power Piping, for the safety significant portion and ANSI/ASME B31.3, Process Piping, for the general service portion. The design temperature range is -27 °F to 400 °F. According to Calculation CSB-P-0001, Pipe Stress Calc for LN-MOC-038, 041, 042, the transportation cask servicing system components are designed to seismic ground acceleration of 0.21 g, which is appropriate for safety-significant items.

The inert gas system also plays a role in diluting the transportation cask exhaust gas to minimize the potential for a flammable gas mixture to occur in the 3-in. piping upstream of the secondary HEPA filter. This is accomplished by using a flow orifice and an inert gas pressure control system to ensure enough inert gas is mixed with the gas venting from the transportation cask to minimize the potential for a flammable concentration of hydrogen to enter the operating area exhaust system and exhaust stack. This system also is used to assist the vent system in providing an atmospheric pressure vent path (0.0 lb/in² gauge) and inert gas purge (80 lb/in² gauge). The venting and purging operations are repeated until the residual atmosphere in the transportation cask is below flammability limits. The helium system supplies the inert gas required to purge the transportation cask to safe hydrogen concentration levels and to mix and dilute gases as they are vented. Servicing an abnormal or accident transportation cask containing the maximum credible amount of hydrogen may require up to three vent-and-purge cycles to ensure that the residual concentration of hydrogen in the serviced transportation cask is not hazardous. This value is conservative considering the smaller freeboard volume of the transportation cask as compared to the MCO. Calculation CSB-PR-0013, Number of Pressure Purges Required, estimated the number of purges for an MCO at three. After purging operations are complete, the
transportation cask is returned to atmospheric pressure and monitored for acceptability before the
cask lid is removed and the MCO is removed with the MHM.

A4.4.8.5 Controls (Technical Safety Requirements). There are no TSR controls for this SSC
because its safety function is related to recovery actions, not to accidents during normal
operations. Controls related to specific recovery actions must be developed on a case-by-case
basis depending on current conditions and recovery evaluation results. The HEPA filter testing
and system component surveillances are performed by operations.

A4.4.9 Multi-Canister Overpack Sampling System

A4.4.9.1 Safety Function. The safety function of the MCO sampling system is to maintain
confinement when connected to an MCO, prevent a flammable mixture in an MCO or in the
sampling equipment, protect workers from radiation dose, protect the MCO from NPH and load
drop events. A bumper protects the sampling system from damage caused by equipment moving
horizontally. The MCO sampling system provides data for an engineering evaluation of SNF
stored in MCOs. This is accomplished by a program of sampling the gas inside MCOs selected
for monitoring and accumulating information from that sampling program. The safety-significant
features of the MCO sampling system are the sampling/weld station MCO support structure
(which includes the rotating shield, the stationary shielding, the shear ring and shear screws, and
the stationary shield support pipes), the sample hood and HEPA filter, the exhaust system from
the sample hood to and including exhaust fan HEPA filter, the sample hood flow indicator, shield
halves, center shield plate, and MCO valve operator. These features are designed to maintain the
confinement barrier for gases from an MCO during sampling operations to prevent the buildup of
flammable gases in the MCO or in the sampling/weld station equipment. Another safety function
related to the MCO sampling system includes shielding (shield halves, center shield plate, rotating
shield, and stationary shielding) to protect personnel from radiation exposure.

A4.4.9.2 System Description. The MCO sampling system, located in pit 7 in the sampling/weld
area of the CSB, is designed to sample and monitor selected MCOs. See Figure A2-3 for a
location in plan view. Duplicate support equipment at pit 2 is also available for sampling. The
major components of the MCO sampling system are the impact absorber used to cushion the
MCO if it is dropped by the MHM as it is being lowered into a sampling/weld station, a gantry
crane system for positioning the sample hood and temporary shielding components, shield halves
to guide a dropped MCO into the sampling/weld pit and protect operating personnel against
radiation streaming during MCO transfer, fixed shielding with MCO cooling capability, a cooling
cap to cool any high-temperature MCO shield plug assembly, a sample hood with a glove box to
confine airborne radiological emissions accidentally released during sampling operations, a
filter–exhauster to ventilate the hood, an infrared pyrometer to measure MCO skin temperature
when the MCO is lowered into the pit, an MCO valve operator for the process valve in the MCO
that provides gas sample access, an MCO sample cart for sampling and reinserting the MCO, a
sample syringe to extract a gas sample for analysis, tools for MCO process port removal and
cover plate removal and installation operations, and leak-test equipment to test the MCO cover plate seals.

MCOs are received at the sampling/weld station from either their preselected storage tubes or directly from the CSB load-in/load-out area. The MCOs are transported to the sampling/weld station by the MHM. The MCO sampling/weld station cart is used during all MCO sampling operations and is designed to provide a mobile storage location for the components required to (1) determine MCO internal pressure and gas temperature, (2) obtain a sample of the MCO internal atmosphere for laboratory analysis, and (3) refill the MCO with inert gas, if needed, following the sampling operations to ensure a positive pressure (nominally at 7 lb/in² gauge) during MCO storage.

The sampling process begins when the MHM brings an MCO to the sampling/weld station and lowers the MCO into the sampling/weld station pit until the MCO is resting on the safety-significant impact absorber with the MCO collar slightly above the shear ring on the rotating shield (see Figure A2-40). An infrared pyrometer scans the MCO while the MCO is being lowered into the pit, and the temperature readings are recorded and tracked by the distributed control system. A 7.5-ton gantry crane is used to remove the shield halves and center shield plate; the sampling/weld station trench cover shield is removed; and temporary handrails are placed around the trench. An operator enters the trench and uses a hand-held pyrometer to measure the MCO shield plug temperature. Based on these temperature readings, a cooling cap may be placed on the MCO shield plug to reduce the temperature to a value safe for operations.

The sampling hood is lowered over the MCO, and connections are made to the vent system and the sample cart. The sample cart’s flexible lines are connected to the electrical outlet and the helium supply line. Using the sampling procedure, the lines are purged, a sample is taken, and the MCO is reinerted with helium if needed. After sampling, the operator checks for leaks, and purges the sample cart lines. The vent system is shut down, the cart is disconnected, the vent system is disconnected, and the sample hood is lifted from the MCO. The removable guard rails are removed, the trench cover shield is reinstalled, the shield halves and center shield plate are reinstalled, and the MHM retrieves the MCO and returns it to the preselected storage tube or to a standard storage tube. This procedure for MCO sampling is designed for collecting data.

### A4.4.9.3 Functional Requirements

The MCO sampling system is required to prevent ingress of air to the MCO during sampling operations to prevent the formation of flammable concentrations of hydrogen outside the MCO around the process port connections under the sample hood. The lower shield support columns are required to maintain their structural integrity, including during a seismic event. The sampling/weld station impact absorber (IMP-005) is designated safety significant for its role in protecting the MCO and is described in Section A4.4.20.

The sample cart can be used to refill the MCO with helium to ensure a positive pressure during storage. The helium backfill pressure must be controlled to acceptable limits so as to not damage sampling/weld station components or cause an unmitigated release of particulate from the
MCO. The sampling equipment must be able to perform its safety function during normal and postulated NPHs and DBA conditions. Any features required to maintain the confinement barrier for the MCO during the sampling and pressure checking are safety significant.

The MCO sampling/weld station gantry crane is classified as general service (HNF-PRO-704) and ITS Category C in accordance with the definitions in HNF-SD-SNF-DB-003 because of the potential damage to the MCO process port covers that could be caused by dropping a shield half onto them. Once the MCO is placed in the sampling/weld station pit and the center shield plate is replaced, the MCO is protected from damage from falling objects. The MCO sampling/weld station gantry crane crash shield guard protects the MCO sample lines from a shear by the MHM by activating the MHM's collision avoidance system. The seismic input is based on the response spectra included in Figure A4-8.

The MCO sample hood is classified as safety significant because the hood is designed to maintain a confinement barrier around the top of the MCO during sampling operations and under certain design basis events that could allow detonation of hydrogen from a broken sample line. Other safety-significant designations are assigned to equipment credited in protecting the facility worker from serious injury or death as a result of radiation exposure. These components are the stationary and rotating shielding, the trench cover shields, the drive assembly cover shields, and the shield halves. The inverted cone shape of the shield halves opening guides an accidentally dropped MCO into the sampling/weld station pit and mitigates the effects of the fall.

A4.4.9.4 System Evaluation. The sampling/weld station hood is designed to protect operating personnel from gases that might escape from the MCO process port connection during sampling operations and form a flammable mixture with air. The exhaust system is designed to provide a minimum flow of 100 ft³/min through the sampling/weld station hood. The sampling/weld station hood inlet slots provide a maximum flow area of 0.35 ft². This results in a flow velocity of 286 ft/min into the hood. According to Calculation CSB-HV-0013, Sample Station and Future Weld Station Exhaust Ventilation System Pressure Drop Calc, with one glove missing out of the port, the flow velocity would be 182 ft/min, which is greater than the 100 ft/min required by ERDA 76-21, Nuclear Air Cleaning Handbook, for glovebox design.

The rupture disk associated with the helium supply system protects the MCO from pressurization to greater than 150 lb/in² gauge and is classified as safety significant. The MCO sampling system piping is of at least 150 lb/in² gauge design rating and meets ANSI/ASME B31.1 requirements for safety-significant portions, and ANSI/ASME B31.3 piping code requirements for general service portions.

The shield halves, the center shield plate, and the shear ring are used to reduce radiation streaming coming from the MCO. These components maintain radiation exposures within facility limits and ALARA principles during lowering and raising of the MCO within the sampling/weld station pit and while performing sampling operations. Shielding analyses documented in CSB-SH-3005, CSB Sample Station Shielding Calculation, and ALARA analyses documented in ALARA 09, SNF Canister Storage Building, that were performed for the sampling/weld station...
estimate the dose to the worker at 0.40 mrem/h to 0.60 mrem/h depending on fuel type. These shielding components are control features that prevent exposure of personnel to the high radiation of the MCO. This equipment meets the requirements for shielding as referenced in NRC equivalency criteria given in Items 20 and 23 of HNF-SD-SNF-DB-003. The carbon steel shield halves, trench cover shield, drive assembly cover shield, and center shield plate conform to ASTM A36/A36M standards.

With the shield halves in place and the center shield plate removed by the MHM, the inverted cone shape of the opening into the sampling/weld pit provides for mitigation of an accidentally dropped MCO. The thickness of the steel shield halves and the cone angle provide assurance that a dropped MCO will be guided into the sampling/weld pit, where the sampling/weld station impact absorber absorbs the energy of the dropped MCO, protecting the MCO.

A pressurized release could cause significant onsite consequences (see Chapter A3.0). The sampling/weld station design includes a pressure safety valve located on the south wall downstream of the pressure control valve and a rupture disk (PSE-1) located next to the pressure safety valve. These devices protect the sampling system and the MCO from overpressurization. The pressure safety valve is set to relieve at 135 lb/in² gauge with a tolerance of ±10%. The helium supply system rupture disk is described in Section A4.4.11. The 0.75-in. pressure safety valve is capable of discharging 20 standard ft³/min through a 10-ft-long tail piece back into the sample hood. This additional feature is provided for worker protection from high-pressure, high-temperature gas impingement in accordance with 29 CFR 1910.103 (b)(1)(ii) (29 CFR 1910).

With the MCO process valve open, a direct path exists through the MCO internal HEPA filter to the internal regions of the MCO. Actual release of contamination from the MCO is likely to be very small, and the sample hood HEPA filter (FH-009) should not become contaminated rapidly. The sample hood HEPA filter constitutes the safety-significant barrier to prevent air inleakage that would mix with the MCO gases. This filter is a sintered metal filter (316L stainless steel) contained in a stainless steel housing (304L stainless steel) and has a design pressure of 150 lb/in² with a design temperature of 400 °F. The safety-significant sample hood is designed to receive gases vented from the MCO and diluted with helium through the sample cart as well as air that enters the hood at its slotted interface with the MCO. The sample hood is a specially constructed stainless steel box with viewing windows, external lighting, and a flexible hose connection to the vent piping that leads, via the sampling/weld station gantry cranes, to the exhaust unit. The hood is suspended from the gantry crane during movement and remains connected to the crane during use. The hood incorporates code features from the following sources:

- ANSI B18.2.1, Square and Hex Bolts and Screws (Inch Series)
- ASME B30.20-1993, Below-the-Hook Lifting Devices
The hood is designed and fabricated in compliance with AWS D1.1; NFPA 70, National Electrical Code, Article 410, "Lighting Fixtures, Lampholders, Lamps and Receptacles;" NEMA 250; NFPA 255, Standard Method of Test of Surface Burning Characteristics of Building Materials; SAE J429, Mechanical and Material Requirements for Externally Threaded Fasteners; and UL 181, Factory-Made Air Ducts and Air Connectors.

The major components of the sampling/weld station MCO support structure are the rotating shield, the stationary shielding, the shear ring and shear screws, and the stationary shield support pipes (Figure A2-40). The sampling/weld station MCO support structure provides support for an MCO placed in the sampling/weld station and radiation protection for the operators. The rotating shielding carbon steel conforms to ASTM A36/A36M standards. The stationary shielding material is a laminate of borated polyethylene with carbon steel conforming to ASTM 36/A36M standards. The shear ring is made from 0.875-in.-thick ASTM A36/A36M carbon steel plate, and the alloy steel shear screws conform to ASTM F835-98, Standard Specification for Alloy Steel Socket Button and Flat Countersunk Head Cap Screws. The 6-in.-diameter, schedule 80, black carbon steel support pipes conform to ASTM A53, Grade B standards. The remainder of the sampling/weld station MCO support structure is fabricated using materials that conform to ASTM A36/A36M standards.

The sampling/weld station exhaust unit consists of a filter housing and a prefilter and is provided with a HEPA filter. The HEPA filter is a stainless steel, bag-in/bag-out style sized for a flow rate of 500 ft³/min and a face velocity of 250 ft/min. The prefilter is also a bag-in/bag-out style. The prefilter is rated at a minimum of 30% removal efficiency when tested in accordance with ASHRAE 52.1, Gravimetric and Dust-Spot Procedures for Testing Air-Cleaning Devices Used in General Ventilation for Removing Particulate Matter. The HEPA filter housing and ducting from the sample hood to the filter provide confinement of gases released from an MCO and radioactive particulate and contamination spread in accordance with ASME N509-1989 and ASME N510-1989 and meet the NRC equivalency requirement, Item 12, for HVAC systems.
The HEPA filter housing is of Type 304 stainless steel, all-welded construction in accordance with ASME N509-1989. The sampling/weld station exhaust unit is designed to meet AMCA 99, *Standards Handbook*, and AMCA 210, *Laboratory Methods of Testing Fans for Rating*, standards and is tested to ASHRAE 52.1. There is no requirement for the sampling/weld station exhaust unit to incorporate explosion-proof electrical design features because the small amount of hydrogen that could reach the fan is already diluted with helium and air. A flow indicator is included to ensure that sampling does not start if exhaust unit flow is insufficient.

The sampling/weld station stationary shielding and cooling cap are designed for removing heat from the body and top of the MCO. Insulated lines provide coolant (chilled water and propylene glycol) from the sampling/weld station chiller through pipe sleeves below the sampling/weld station operating deck to channels in the stationary shielding and to disconnect fittings and valves for the cooling cap. This system may be used if necessary to ensure that exposed MCO surfaces are sufficiently cool to permit hands-on operations such as removing the process port cover and placing the MCO process valve operator. This feature is provided for worker protection from high surface temperatures in accordance with 29 CFR 1910 and ASTM C1055-92, *Standard Guide for Heated System Surface Conditions that Produce Contact Burn Injuries*. Calculation CSB-HV-0014, *Long Term MCO Temperature Without Cooling in the Sampling Station*, assumed a steady-state outside temperature of 115 °F and a corresponding indoor temperature of 85 °F. Calculation CSB-HV-0014 determined that the performance specification surface temperature limit (270 °F) for the MCO would not be exceeded until after 30 days if an MCO were stranded in the sampling/weld station because of MIM operational problems. Therefore the cooling system is designated general service. The MCO sampling/weld station cooling system has a limited function in postrecovery cooling of the stationary shielding if an MCO is stranded. The sampling/weld station chiller is a commercially manufactured air-cooled unit sized to match the cooling needs of the sampling/weld station. It meets the requirements of ANSI/ARI 590, *Positive Displacement Compressor Water Chilling Package*; ANSI/ASHRAE 15, *Safety Code for Mechanical Refrigeration*; ANSI/ASHRAE 30, *Methods of Testing for Liquid Chilling Package*; and other appropriate standards of the American Society of Mechanical Engineers, American Society for Testing and Materials, Manufacturing Standardization Society, and the National Electrical Manufacturers Association; the unit is required to meet UL 109, *Tube Fittings for Flammable and Combustible Fluids, Refrigeration Service, and Marine Use*. The cooling cap is a custom designed and fabricated device that matches the configuration of the MCO top and cools the personnel contacted region of the MCO. Together with the piping that connects the cooling cap to the chiller unit, it is designed to meet the requirements of ANSI/ASME B31.3.

The impact to the MCO from dropped sampling/weld station shield half sections was evaluated and compared with the impact from a dropped cask lid. The analysis results are documented in Calculation CSB-RM-0016, *MCO Sampling Station—Shield Components*, and Calculation CSB-RM-0019, *Temporary Shielding Components*, and they indicate that damage to the MCO rupture disk process port cover is not sufficient to cause a release when credit is taken for the bounding MCO internal pressure of 5.2 atm. The sampling/weld station gantry crane has
the identified safety role of staying intact during a seismic event. Because the sampling/weld station hood remains connected to the sampling/weld station gantry crane during sampling operations, failure of the gantry crane could result in damage to the sampling equipment and the MCO. For this reason the gantry crane and hoist is designated ITS Category C. The seismic clamps are attached to the gantry crane and are manually engaged to the rails whenever the crane is in use over the MCO in the sampling/weld station. The seismic clamps are designed to a seismic response spectra based on 0.35 g zero-period acceleration with 5% damping for crane stability evaluation (see Figures A4-8 and A4-9).

The MCO sampling station crane is designed (and anchored as described below) to withstand the effects of a seismic event without overturning or failure. The seismic effects include the crane weight and lifted loads that result in the worst case design conditions for the crane and crane support restraint. The restraint capacity is capable of resisting the effects of an equivalent seismic acceleration acting through the center of gravity of the crane and lifted load. This equivalent acceleration is given as 1.25 g in any two orthogonal directions and 1.00 g in any vertical direction, acting simultaneously. These values were derived from peak values with 5% damping for the sampling/weld area as given in Calculation CSB-S-0040, ISRS Generation, MHM, Operating Shelter, Air Intake. The peak values, derived by SAP 90 analysis, were scaled by the ratio of 0.21/0.35 for the gantry crane and multiplied by 1.50 for equivalent static analysis per Section 10A.3.4 of the architect-engineer's Design Basis Document (Bedell 1996a).

The gantry crane is equipped with seismic restraints for the gantry in four locations; with the main hoist over the center of the pit, with the main hoist over the center of gravity of each of two sections of temporary shielding, and with the rail beam that supports the 1-ton hoists over the pit.

The gantry crane is equipped with seismic restraints for the 7.5-ton trolley at a single location when the 7.5-ton hoist is over the center of the pit. The gantry crane is designed in accordance with ANSI/ASME B30.17-1998, Overhead and Gantry Cranes (Top Running Bridge, Single Girder, Underhung Hoist), and CMAA 74-94, Specifications for Running and Underrunning Single Girder Electric Overhead Traveling Cranes Utilizing Underrunning Trolley Hoist. The underhung hoists are designed in accordance with ANSI/ASME B30.16-1998, Overhead Hoists (Underhung).

The only identified potential accidents at the sampling/weld station with the potential for significant onsite consequences are hydrogen deflagration, which is protected against by maintaining confinement of gases released from an MCO during sampling operations, and overpressurization of the MCO, which is protected against by the helium supply rupture disk (see Section A4.4.11). The sampling/weld station area steel-reinforced concrete and the adjacent walls and roof structure are contiguous with the operating deck and the operating area shelter and are designed to safety-class criteria to protect the MCOs in the storage tubes. Sampling/weld station features (including seismic restraints on the crane, and the carbon steel lower shield support columns in the sampling/weld station pits) whose failure would lead to MCO damage are designed to the seismic spectra based on 0.35 g zero-period acceleration. Structural calculations
(CSB-S-0043 and CSB-S-0026A) show that these sampling/weld station components will survive the DBE loads. The sampling/weld station support stand design has been analyzed to verify its structural adequacy for the design loads (CSB-RM-0016). The design loads for the sampling/weld station support stand include vertical loads from the stationary shield, the rotating shield, and MCO weights; vertical seismic loads; and a dropped MCO. Vertical seismic loads were not included in the analysis because a dropped MCO load is much greater. The analysis concluded that the sampling/weld station support stand design, including the rotating shield, supports the loads during normal operations and the components have adequate strength to support an MCO during a drop accident. The analysis also shows that the shear screws holding the shear ring in place have adequate strength to support an MCO and will shear when an MCO is accidentally dropped and cushioned by the sampling/weld station impact absorber. The support columns are structural features composed of 0.5-in. ASTM A36/A36M carbon steel plate and 6-in.-diameter Schedule 80 black carbon steel pipe (ASTM A53 Grade B) that provide support for the fixed shielding in the sampling/weld station pits (Figure A2-40). They are designed to ANSI/AISC N690-94, and they are welded to AWS D1.1. Pipe sleeve material and impact absorber stand are composed of carbon steel plate and shapes conforming to ASTM A36/A36M.

The sampling cart is classified general service because there are no anticipated accidents in the sampling/weld station involving the cart that are expected to have significant onsite consequences. No analyzed accidents from a DBE have been identified that would have onsite or offsite consequences.

A4.4.9.5 Controls (Technical Safety Requirements). The sampling/weld station support structure, center shield plate, trench cover shield, and drive assembly cover shield are design features (see Section A5.6), and their safety function is managed by the configuration control process.

The following assumptions associated with the MCO sampling system require TSRs to ensure performance of the safety functions.

- Overpressurization of the monitored MCOs could result in gas and particulate released to the operating area in excess of onsite guidelines. This event is precluded by having a safety-significant rupture disk in the helium supply system at the let-down station. Rupture disk PSE-1, designed to relieve at 150 lb/in², on the helium supply system to the sampling/weld station cart is credited with providing protection of the MCO from overpressurization and subsequent gaseous release. The pressure safety valves PSV-720 and PSV-728, set at 135 lb/in² gauge with a tolerance of ±10%, provide additional protection and protect the sampling/weld station components from high MCO pressure.

- The sampling/weld station shield halves are credited with mitigating the consequences of an accidentally dropped MCO and providing worker protection from excessive radiation dose. The shield halves are required to be in place for the center shield plate to be at the MHM plug grapple height. The MHM interlocks
discussed in Section A4.4.4 prevent placement of the MCO unless the shielding surface is in place. To provide significant worker safety and significant defense in depth, Administrative Control (AC) 5.9, described in Chapter A5.0, contains requirements to verify that the sampling/weld station shield halves have been installed before sampling operations are begun. After the MHM has placed an MCO into the sampling/weld station and has returned to its staging position, the sampling/weld station gantry crane removes the center shield plate and the shield halves and places the sample hood on the rotating shield.

- The sample hood and the sampling/weld station exhaust system are designed to dilute the potential hydrogen releases to below concentrations that would be flammable. Just before sampling operations are begun, the following inspections are performed:

  - Sample hood glove ports for degradation
  - Flexible hose and connections for integrity
  - Balance and isolation dampers MD-5, MD-6, and MD-8 full open; MD-7 and MD-9 partially open.

Support systems required for sampling operations include 480 V power to the combination starter for the exhaust fan, to the disconnect switch for the sampling/weld station cooler, to the motorized gantry and hoist, and to the sampling/weld station rotation motor; 120 V power to the pyrometer panel and receptacles.

After placing the sample hood and establishing that all equipment is operable, verify flow rate through the hood of 100 ft³/min minimum by observing the sampling/weld station HVAC flow indicator and the sample hood pressure differential indicator.

- Leak testing of the MCO process valve operator and connection to the sample cart is credited with preventing releases of potentially flammable MCO gases into the sample hood space. During a loss of power, this combination of MCO gas leak and loss of dilution airflow through the hood could result in the accumulation of a flammable concentration of hydrogen gas. Before sampling operations are begun, the MCO process port connection and attached flexible hose piping for the sample system are leak tested to ensure that no flammable atmosphere could be created inside the sample hood. Leak test of the sample line to the MCO process port valve operator shall be shown to be less than 40 cm³/s at 75 lb/in² gauge (as confirmed by a pressure decay rate). Verification of this test is required according to Chapter A5.0, LCO 3.2.2.
A4.4.10 Standard Storage Tube Intermediate Impact Absorber

A4.4.10.1 Safety Function. The safety function of the intermediate impact absorber is to protect both the bottom MCO and the accidentally dropped MCO from damage exceeding the design requirements. In the absence of an intermediate impact absorber, the dropped MCO causes the welded cap on the MCO to bulge downwards and outwards. This could make it difficult to retrieve the bottom MCO and could cause significant damage to the dropped MCO (see Figure A4-10).

A4.4.10.2 System Description. The intermediate impact absorbers are described in Section A2.4.3 and are shown on Figure A2-13, sheet 2. The intermediate impact absorbers (see Figure A2-13) consist of the following components: a flange plate with a top plate bolted to the flange plate, the base plate, and energy-absorbing tube components in the middle. The flange plate with the top plate is 3.01-in.-thick carbon steel material conforming to ASTM A36/A36M. The base plate is constructed of 1.5-in. carbon steel plate conforming to ASTM A36/A36M. Carbon steel material conforming to ASTM A513, Standard Specification for Electric-Resistance-Welded Carbon and Alloy Steel Mechanical Tubing, is selected for the tube sections. The maximum diameter of the lower impact absorbers is 26 in. The overall height is 25.35 in. after factory precrush of the assembled intermediate impact absorber. The top and bottom plates serve to maintain the impact absorber centered in the storage tube. Galvanized steel cables spaced equidistantly around the absorber circumference maintain the pipe components in place.

A4.4.10.3 Functional Requirements. Limiting the energy imparted by the dropped MCO to the bottom MCO to below 35 g has been specified as a criterion for the intermediate impact absorbers. This value is provided in HNF-S-0426, Performance Specification for Spent Nuclear Fuel Project, Multi-Canister Overpack, for the MCO. The MCO has been designed to withstand the stresses associated with a 35 g loading (HNF-SD-SNF-SARR-005).

A4.4.10.4 System Evaluation. Intermediate impact absorbers are designed to protect the MCO during the accidental drop event. The vendor is required to perform testing on samples of the materials before fabricating each lot of intermediate impact absorbers. The test results will be used to confirm that the intermediate impact absorber will mitigate damage to an accidentally dropped MCO and to a lower capped MCO. A drop analysis for an MCO accidentally falling onto an MCO stored in a standard storage tube estimates values of 28 g and 16 g, respectively, for the falling MCO without an intermediate impact absorber and with an intermediate impact absorber. See SNF-4042, Evaluation of Accident Frequencies at the Canister Storage Building, and SNF-3328 for additional details. The analysis shows that damage to the falling MCO and the bottom MCO also is mitigated by the bottom impact absorber. Both of these values are within the design limits for an MCO. Without an intermediate impact absorber in place, an MCO dropped on top of the bottom MCO (Figure A4-10) would deform the canister cover assembly of the bottom MCO and impair retrievability. With an intermediate impact absorber in place, deformation of the bottom MCO canister cover assembly would not occur because the bottom impact absorber and the intermediate impact absorber are designed to protect the bottom and top MCOs.
A4.4.10.5 Controls (Technical Safety Requirements). The following assumption associated
with the intermediate impact absorber requires TSRs to ensure performance of the safety function.
This is controlled by administrative procedures discussed in Chapter A5.0 under AC 5.10.

- The intermediate impact absorber must be verified to be in place by the MHM
  television camera before a second MCO is put into the tube.

A4.4.11 Helium Supply System Rupture Disk

A4.4.11.1 Safety Function. The safety function of the rupture disk (PSE-1) on the helium
supply system to the sampling/weld station is to prevent damage to MCOs caused by
overpressurization with helium. Design pressure limits for the MCO are given in the MCO
Topical Report (HNF-SD-SNF-SARR-005). Helium supply system is designed for a pressure of
150 lb/in² gauge and temperatures up to 270 °F. Exceeding this design pressure limit could result
in internal changes severe enough to prevent MCO process functions, exceed load limits specified
in the MCO performance specifications, or possibly fail confinement (see Section A4.3.7).

Overpressurization of the MCO through inadvertent charging with high-pressure helium
(2,000 lb/in² gauge) has been identified as a potential accident that must be precluded by safety-
significant design features as determined by Section A3.4.2.2, “Gaseous Release from the
Multi-Canister Overpack.” This event is precluded by a rupture disk (PSE-1) on the helium
supply let-down station. This device (PSE-1) is designated safety significant in accordance with
DOE-STD-3009-94 and Letter 97-SFD-172 (Sellers 1997) and ITS Category B using the graded
approach of HNF-SD-SNF-DB-003. If a helium overpressurization condition occurs, PSE-1
vents into the operating area. The helium mixes with the large air volume being circulated by the
ventilation system and does not create an oxygen-deficiency problem for the operations personnel.
Pressure safety valves on the sample line designated general service (PSV-720 and PSV-728)
provide overpressurization protection for sampling/weld station equipment whose unmitigated
failure would result in releases.

A4.4.11.2 System Description. The helium supply to the sampling/weld station is provided by
an extension of the 2-in. line supplying the helium refill station to the south and east of the helium
let-down station (see Section A2.7.5 and Figure A2-42). Pressure control valve PCV-733
reduces the helium supply line pressure from 2,000 lb/in² gauge to 120 lb/in² gauge. Line size for
PCV-733 is 0.5 in. Line size for PSE-1 is 1.0 in. The reduced pressure helium supply is delivered
to the sampling/weld station via 0.75-in. lines that are routed below the deck to connection boxes
in pits 3 and 6, which adjoin the sampling/weld station pits 2 and 7. Overpressurization
protection of the sampling/weld station supply line and sample cart components is also provided
by PSV-728. Protection of sampling/weld station components from excessive MCO pressures is
provided by PSV-720 located downstream of the canister filter as part of the sampling/weld
station hood.
A4.4.11.3 Functional Requirements. The helium rupture disk must be adequately sized to prevent the 2,000 lb/in² gauge helium supply from pressurizing the MCO beyond its 150 lb/in² gauge design limit. PSV-720 is subject to the temperatures and gas composition from the MCO interior and must be designed to function in that temperature environment. The likelihood of a seismic event occurring in concert with sampling operations has been determined to be beyond extremely unlikely. Therefore, failure of pressure relief devices in the closed position during a seismic event has been excluded as a design requirement.

A4.4.11.4 System Evaluation. Pressure safety devices PSV-728 and PSE-1 are mounted on the south wall of the sampling/weld station above the curb at elevation 714 ft and are designed to relieve helium overpressurization through a 10-ft-long tail piece sized by the valve vendor. This ensures that workers would not be exposed to high noise levels in the unlikely event of a valve or rupture disk actuation. Pressure safety relief device PSE-1 is specified to relieve at 150 lb/in² gauge. PSV-728 is sized for the case in which pressure control valve PCV-733 fails wide open with pressures of 2,000 lb/in² gauge upstream and 150 lb/in² gauge downstream of PCV-733. Pressure safety device PSV-720 is sized to relieve 20 standard ft³/min at temperatures up to 400 °F. Discharge from PSV-720 is routed back to the sampling/weld station hood for worker protection. Pressure safety device PSV-728 setpoint for overpressurization is 135 lb/in² gauge ±10% to allow for margin below the MCO design pressure. Pressure safety devices PSV-728 and PSE-1 are also specified to be furnished in accordance with ASME B16.34-1996, *Valves—Flanged, Threaded, and Welding End*. They have carbon steel bodies and 316 stainless steel trim.

A4.4.11.5 Controls (Technical Safety Requirements). The rupture disk PSE-1 is a design feature (see Section A5.6) and its safety function is managed by the configuration control process.

A4.4.12 Multi-Canister Overpack Handling Machine Fixed Shielding System

A4.4.12.1 Safety Function. The safety function of the MHM fixed shielding system (including the shield skirt) is to protect workers from radiation exposure from the MCO. This criterion is met by reducing the maximum total dose rate at a 30-cm distance from any exterior location on the MHM to less than 0.5 mrem/h. The MHM fixed shielding system provides significant worker safety for personnel located in the operating area and is therefore designated a safety-significant design feature of the MHM.

A4.4.12.2 System Description. The MHM is fully shielded for gamma and neutron radiation emitted from an MCO. The gamma shielding of the main cask body, which encloses the MCO while in transit, is manufactured from cast steel. This cask body was manufactured in sections that are rigidly bolted together using high tensile studs and face-to-face contact joints. The horizontal interface gap between the base of the rotating turret and the top face of the stationary nose casting is 0.08 in. thick and is stepped to prevent direct radiation streaming from the gap. Above the level of the MCO in the cask, a steel slab integral with the grapple assembly and the
MCO hoist confinement chamber walls provide gamma protection. The neutron shielding around the turret is provided primarily by 4-in.-thick Jabroc N, a densified wood product.

The nonrotating nose also is manufactured from cast steel and, in conjunction with the components of the retractable nose, has a net shielding thickness comparable to that of the main cask body. A circular slab forming part of the nose section provides gamma attenuation when the cask is rotated from the "nose aligned" condition during intermediate operations and when the television camera is aligned over the nose cavity. A circular steel slab at the bottom end of the rotating turret provides protection from gamma radiation from an MCO in the vault when the MHM is located over an open storage tube. At the turntable fabrication and around the fixed nose and retractable shield skirt, the neutron shielding is provided by cast concrete sections.

**A4.4.12.3 Functional Requirements.** The MHM is provided with interlocks to prevent the MCO from being lowered if the MHM shield skirt is not in proper position to shield the worker. The shield skirt and the MHM fixed shielding constitute control devices that ensure exposure to the worker from the MCO (which emits radiation from its lateral surfaces at greater than 100 mrem/h at 30 cm) is in compliance with the requirements of Title 10, *Code of Federal Regulations*, Part 20, "Standards for Protection Against Radiation," Section 20.1601, "Control of Access to High Radiation Areas" (10 CFR 20), as referenced in HNF-SD-SNF-DB-003, Item 20. The fixed and moveable MHM shielding protects the operator or other facility worker from excessive doses of radiation in keeping with guidance from NRC Regulatory Guide 8.8, *Information Relevant to Ensuring that Occupational Radiation Exposures at Nuclear Power Stations will be as Low as Reasonably Achievable*, as referenced in HNF-SD-SNF-DB-003, Item 23. The MHM service pit provides a location with equipment that can be used without resulting in excessive exposure. Maintenance activities at the MHM service pit are not planned to be conducted when an MCO is contained within the MHM. HNF-SD-SNF-DB-003, Item 20, also imposes the requirement of 10 CFR 20, Section 1301, "Dose Limits for Individual Members of the Public," that the dose rate to the public is limited to 2 mrem/h for any unrestricted area from external sources during normal operations.

**A4.4.12.4 System Evaluation.** Interlock P2 is considered safety significant due to the possible dose impact on the facility worker of not replacing a tube plug in the storage tube before moving the MHM. The MHM fixed shielding system has been shown to adequately reduce the maximum total dose rates around the MHM when carrying a bounding radiation-emitting MCO. The maximum calculated dose rate 30 cm from an outer MHM surface was 0.28 mrem/h (0.0028 mSv/h) [ESL/R(96)085]. This maximum dose rate permits personnel to work around the MHM 40 hours a week all year without exceeding any Hanford Site total dose administrative limits. During normal operations and anticipated events in the CSB, the 2 mrem/h criterion of 10 CFR 20.1301 will not be exceeded.

The MHM shield skirt, when fully lowered, has been shown to adequately reduce the maximum total dose rate around the MHM as a bounding radiation-emitting MCO is being lowered from the MHM. In ESL/R(96)085, *Hanford MHM Phase III Shielding Assessment*, the
maximum dose rate 30 cm from an outer MHM surface was calculated to be 0.28 mrem/h, which
was less than the target value of 0.5 mrem/h.

A4.4.12.5 Controls (Technical Safety Requirements). The MHM fixed shielding system is a
design feature of the MHM (see Section A5.6), and its safety function is managed by the
configuration control process.

A4.4.13 Transportation Cask Shielding

A4.4.13.1 through A4.4.13.4. The safety function of transportation cask shielding is to protect
the facility operator from excessive radiation dose. The MCO transportation cask shielding has
been classified safety significant. The MCO transportation cask safety analysis report for
packaging (HNF-SD-TP-SARP-017) demonstrates that the MCO transportation cask meets the
onsite transportation safety criteria. The cask shielding is an integral part of the MCO
transportation cask, is required for worker safety protection, and is classified as safety significant
in Chapter A3.0. The transportation cask shielding is a control device that protects the CSB
facility worker from radiation doses from the high radiation area internal to the cask containing an
MCO in compliance with the requirements of 10 CFR 20.1601 as cited in HNF-SD-SNF-DB-003,
Item 20. At the CSB there are no normal or anticipated events involving the shielded cask that
result in exposure to the public in excess of the 10 CFR 20.1301 dose limit of 2 mrem/h, also
cited in HNF-SD-SNF-DB-003, Item 20.

A4.4.13.5 Controls (Technical Safety Requirements). Transportation cask shielding is a design
feature (see Section A5.6), and its safety function is managed by the configuration control
process.

A4.4.14 Multi-Canister Overpack Shield Plug Shielding

A4.4.14.1 through A4.4.14.4. The safety function of the MCO shield plug shielding is to protect
the facility operator from excessive radiation dose. This is done by reducing the maximum dose
rate at contact (<10 cm distance) from the top of the MCO shield plug to an average of 2 mrem/h
and not greater than 8 mrem/h. See the MCO Topical Report (HNF-SD-SNF-SARR-005) for the
safety functions, system description, functional requirements, and system evaluation of the MCO
shield plug shielding. The MCO shield plug is an integral part of the MCO, is required for worker
safety protection, and is classified as safety significant in Chapter A3.0. The MCO shield plug
provides protection of the worker from excessive dose in compliance with the requirements of
10 CFR 20.1601 that control devices be in place for all high radiation areas (the inside of the
MCO is a high radiation area). There are no requirements to remove the MCO shield plug after it
is mated to the rest of the MCO. Workers will attach the sample hood to the process valve port 2
on the MCO top when taking a sample from a monitored MCO. Additional shielding is in place at
that time to protect them from excessive exposure. It should also be noted that only very small
amounts of radioactive material are expected to travel from the MCO into the sample cart piping.
because of the HEPA filter FH-009 in the sample hood and the internal HEPA filter inside the MCO shield plug at port 2. Therefore, the requirements of NRC Regulatory Guide 8.8 as referenced in HNF-SD-SNF-DB-003 are met in that features are provided to minimize personnel doses associated with the MCO shield plug.

At the CSB there are no normal or anticipated events involving the MCO shield plug that result in exposure to the public in excess of the 10 CFR 20.1301 dose limit of 2 mrem/h, also cited in HNF-SD-SNF-DB-003, Item 20.

A4.4.14.5 Controls (Technical Safety Requirements). MCO shield plug shielding is a design feature (see Section A5.6), and its safety function is managed by the configuration control process.

A4.4.15 Standard Interface Guide Ring Funnel, Storage Tube Lower Flanges, and Bottom Impact Absorbers

A4.4.15.1 Safety Function. The standard interface guide ring funnel, storage tube lower flanges, and bottom impact absorbers perform the safety function of protecting the MCO during the potential drop accident. The standard interface guide ring funnel and storage tube lower flange mitigate the effects of a potentially dropped MCO by guiding the MCO into the storage tube where it is cushioned by the bottom impact absorber. Bottom impact absorbers serve to reduce the deceleration forces on a dropped MCO to below the 35 g limit found in the MCO Topical Report (HNF-SD-SNF-SARR-005).

A4.4.15.2 System Description. The standard interface guide ring funnel, storage tube lower flange, and bottom impact absorber are shown in Figures A2-8, A2-12, A2-13, and A2-27. The lower flange is part of the standard storage tube assembly welded between the bellows and the tube. The lower flange is made from 4.5-in.-thick steel plate conforming to ASTM A36/A36M with an inverted cone opening having a 45° seating surface, matching the seating surface of the standard storage tube plug. The lower flange outer diameter is 39 in. with an inner diameter opening of 27 in.

The interface guide ring funnel is a spacer placed between the storage tube plug and the MHM nose piece (Figure A2-27). The interface guide ring funnel is moved and placed using the tube vent and purge cart hoist. The interface guide ring funnel fits snugly into the top of the deck embed, resting on the bellows assembly top flange (note operations described in Section A2.5.1.3). The interface guide ring funnel provides a resting surface for the MHM nose piece’s machined surfaces. The interface guide ring funnel is fabricated from ASTM A36/A36M carbon steel using AWS D1.1 as the welding code and 100% visual examination in accordance with Paragraph 6.9 of D1.1-96. The extension piece consists of 0.5-in.-thick plate sections constructed of carbon steel conforming to ASTM A36/A36M. Lateral movement of the interface guide ring funnel is restricted by the deck embed and the tube assembly.
Bottom impact absorbers are provided at the base of all standard storage tubes. The bottom impact absorbers mitigate the effects of an MCO drop to limit MCO impact forces and prevent possible rearrangement of the MCO internals. The bottom impact absorbers (see Figure A2-13) consist of the top flange plate, a top plate bolted to the flange plate, an intermediate plate, the base plate cable assemblies, and energy-absorbing pipe components between the plates. The flange plate is 2.13-in.-thick carbon steel material conforming to ASTM A36/A36M. The top, base, and intermediate plates are constructed of 0.88, 0.5, and 0.88-in. carbon steel plates, respectively, conforming to ASTM A36/A36M. Carbon steel material conforming to ASTM A513, Type 5, is selected for the tube sections. The maximum diameter of the lower impact absorbers is 26 in. The overall height is about 34.65 in. after factory precrush of the assembled bottom impact absorber. The top and bottom plates serve to maintain the impact absorber centered in the storage tube. Galvanized steel cables spaced equidistantly around the absorber circumference maintain the tube components in place.

The impact absorbers are designed to preclude overstressing the MCO by absorbing the kinetic energy of a free-falling MCO and safely decelerating it. That is, the tube components between the top, intermediate, and bottom plates are crushed by the MCO, absorb the kinetic energy, and prevent the MCO from striking the bottom and becoming overstressed. Preliminary testing has demonstrated that material strength, operating temperature, number of tubes, tube thickness, precrimping the lower part of the tube (precrushing, installing short and long tubes), and crush stroke length are important parameters in designing the impact absorbers (PacTec 1999). These parameters provide for predictable results and a smooth force-deflection curve, and under impact conditions, the drop testing results provide assurance that the impact absorbers will preclude overstressing the MCO. After receipt of the tube stock, a preselected number of impact absorbers will be assembled. Full-scale testing of a preselected number of assembled bottom impact absorbers and cask receiving impact absorbers will determine the number of tubes needed in each impact absorber to prevent overstressing of the MCO. This method of receiving a batch of tubes, assembling the test impact absorbers, and full-scale testing will determine the number of tubes required for the bottom impact absorbers, the intermediate impact absorbers, the cask receiving impact absorber, and the sampling/weld station impact absorbers.

**A4.4.15.3 Functional Requirements.** A drop of an MCO onto the edge of a storage tube is mitigated by the 45° angle of the lower flange of the standard storage tube. The bottom impact absorber protects the MCO from exceeding its specified design limits during an accidental drop from heights up to 44 ft by limiting the total force (maximum imposed force on the MCO is 679,000 lb-force) transmitted to the MCO. The total force transmitted is not to exceed 680,000 lb-force for an MCO weighing 20,000 lb dropped from a height of 44 ft. The bottom impact absorber also protects the storage tube from exceeding the pipe wall material working strength of 750 lb/in² during an MCO drop. Design life of the bottom impact absorber with the weight of two MCOs and an intermediate impact absorber is specified to be 40 years (with an expected extension to 75 years) at the design temperatures and radiation levels anticipated without settling. Design temperature for the standard storage tubes is 220 °F.
The interface guide ring funnel is required to withstand the eccentric drop of an MCO while guiding the MCO into the storage tube. Damage or deformation to the interface guide ring funnel is acceptable as long as the MCO is guided from the eccentric drop position to the analyzed configuration of MCO contact with the lower flange.

A4.4.15.4 System Evaluation. The thickness of the lower flange and the angle of the sealing surface provide assurance that a dropped MCO will be guided into the storage tube and cushioned by the impact absorber. A preselected number of storage tube bottom impact absorbers and cask receiving impact absorbers will be drop-tested to determine the number of tubes needed to protect the MCO during a drop accident and to ensure that neither MCO loading due to deceleration nor any tube wall contact pressures exceed the design limits. The impact absorbers are custom-designed by the supplier to specified crush strength and dimensional envelope requirements. The structural safety-class code for the analysis, design, and fabrication of the storage tube components including impact absorber is ANSI/AISC N690-94. Final design configuration for each tube batch will be based on the drop test results. Loads on the supporting structure for the storage tube bottom impact absorber were considered in calculation CSB-S-0007, Appendix 6. The results indicate that a concentric drop of an MCO with no impact absorber in place will not crush or damage the base assembly or the basemat embeds or exceed the basemat's punching shear capacity.

Calculation CSB-S-0062, MCO Drop on Guide Ring Flange, evaluated the accidental eccentric drop of an MCO from the MHM onto the storage tube and the effect of the drop on the interface guide ring funnel. The analysis assumed that the interface guide ring funnel would be in position and deflect the dropped MCO onto the lower bellows flange. The results of the analysis for impact indicate that the dropped MCO is guided into the storage tube without much contact with the bellows lower flange. The MCO transmits approximately 15% of its kinetic energy into the interface guide ring funnel. The interface guide ring funnel sustains some damage (about 46% limited to a very small area), but it is able to perform its safety function during the postulated accident event. Impact to the concrete reinforced deck was about 2,720 lb/in², and impact to the carbon steel deck embed flange upon which the interface guide ring funnel rests was about 17,500 lb/in².

A4.4.15.5 Controls (Technical Safety Requirements). The standard storage tube lower flange is a design feature and its safety function is managed by the configuration control process (see Section A5.6). The following assumptions associated with the standard storage tubes, interface guide ring funnel, bottom impact absorbers, and tube base assemblies require TSRs to ensure performance of the safety functions.

- The bottom impact absorber is in place in each standard tube before positioning the first MCO (see AC 5.10).
- Verify that the standard interface guide ring funnel is in place before placing an MCO or removing an MCO from a storage tube.
A4.4.16 Overpack Interface Guide Ring Funnel, Storage Tube Lower Flanges, and Bottom Impact Absorbers

A4.4.16.1 Safety Function. The overpack interface guide ring funnel, storage tube lower flanges, and bottom impact absorbers perform the safety function of protecting the MCO during the potential drop accident. The overpack interface guide ring funnel and storage tube lower flange mitigate the effects of a potentially dropped MCO by guiding the MCO into the overpack storage tube where it is cushioned by the bottom impact absorber. The overpack storage tube is provided with an impact absorber similar to the standard storage tube impact absorber (see Section A4.4.15). Bottom impact absorbers serve to reduce the deceleration forces on a dropped MCO to below the 35 g limit found in the MCO Topical Report (see HNF-SD-SNF-SARR-005).

A4.4.16.2 System Description. The overpack interface guide ring funnel, storage tube lower flange, and bottom impact absorber are shown in Figures A2-8, A2-12, A2-13, and A2-27. The lower flange is part of the overpack storage tube assembly welded between the bellows and the tube. The lower flange is made from 5.5-in.-thick steel plate conforming to ASME SA516 (ASTM A516/A516M), GR-70, with an inverted cone opening having a 45° seating surface, matching the seating surface of the overpack storage tube plug. The lower flange outer diameter is about 45.25 in. with an inner diameter opening of 27 in. The overpack interface guide ring funnel is nearly identical to the standard interface guide ring funnel described in Section A4.4.15. The overpack storage tube bottom impact absorber is identical to the impact absorber described in Section A4.4.15.

A4.4.16.3 Functional Requirements. A drop of an MCO onto the edge of an overpack storage tube is mitigated by the 45° angle of the lower flange of the overpack storage tube. The overpack interface guide ring funnel and bottom impact absorber protect the MCO from exceeding its specified design limits during an accidental drop as described in Section A4.4.15.

A4.4.16.4 System Evaluation. The thickness of the lower flange and the angle of the sealing surface provide assurance that a dropped MCO will be guided into the overpack storage tube and cushioned by the impact absorber. The results of the analysis of an eccentric drop of the tube plug from the MHM (an 87.75-in. maximum drop height) are documented in Calculation CSB-S-0061, MCO and Plug Drop Effects Analysis, Section 6.2. The results indicate that a significant amount of local damage occurs to the contacted portion of the standard tube flange. The results indicate that the tube plug can be reinserted and the MCO placed or removed following appropriate recovery actions to restore the MHM’s functionality. The reinstalled plug may not completely seal along the flange-to-plug sealing surface because of residual flange deformations. As a minimum, the overpack storage tube plug should be exchanged for one with undamaged sealing surfaces. An eccentric dropped plug onto an overpack storage tube assembly removes this storage tube from consideration as a suspect MCO storage tube. The tube’s flange sealing surface is expected to be damaged, and its ability to seal is questionable. As a minimum, the plug could be exchanged for one with undamaged sealing surfaces. Preferably, the MCO could be placed in an adjoining overpack storage tube.
Calculation CSB-S-0062 evaluated the accidental eccentric drop of an MCO from the MHM onto the storage tube (see Section A4.4.15). Results of the analysis of a concentric drop of a tube plug onto the standard tube lower bellows flange (a 126-in. maximum drop height) are documented in Calculation CSB-S-0050, MCO and Plug Drop Effects of the Shimmed Storage Tube Assembly and Related Components, Appendix D. The results indicate that negligible permanent damage occurs. The resultant net decrease in the inner diameter of the standard tube was determined to be negligible. It is expected that the concentric drop of a tube plug onto the overpack storage tube’s lower bellows flange will not affect tube plug or MCO placement. As a minimum, the dropped tube plug will be tested to ensure that the seals can contain an inert gas pressure in the overpack storage tube and the locking mechanism can lock an overpack storage tube plug into position. The overpack storage tube plug will be replaced or repaired if the tests show that the overpack storage tube plug cannot hold an inert gas pressure in the overpack storage tube.

A4.4.16.5 Controls (Technical Safety Requirements). The overpack storage tube lower flange is a design feature and its safety function is managed by the configuration control process (see Section A5.6). There are no TSR controls for this SSC because its safety function is related to recovery actions, not to accidents during normal operations. Controls related to specific recovery actions must be developed on a case-by-case basis depending on the current conditions and recovery evaluation results.

A4.4.17 Cask Lifting Yoke

A4.4.17.1 Safety Function. The receiving crane is used each time a transportation cask containing an MCO is removed from the transporter and placed in the cask receiving pit in the load-in/load-out area of the CSB. The safety-significant safety function of the cask lifting yoke is to prevent lifting a cask-MCO to a height from which it would sustain unacceptable damage if dropped. The cask lifting yoke is a design feature that is credited with preventing the drop height from being exceeded. The cask lifting yoke is designated safety significant in accordance with DOE-STD-3009-94 and Letter 97-SFD-172 (Sellers 1997).

A4.4.17.2 System Description. Chapter A2.0, Section A2.5.1.1.1, and Figure A2-21 contain a description of the cask lifting yoke. The cask lifting yoke, conforming to ASTM A36/A36M, has two lower hooks that interface with the transportation cask trunnions and an upper bar that interfaces with the receiving crane hook. An emergency stop push button installed near the receiving crane can be used to stop the receiving crane to prevent travel over the FFTF pit or the MHM maintenance pit. This push button is in series with the shunt activation contact in the interface panel.

A4.4.17.3 Functional Requirements. Safe handling of the MCO transportation cask is achieved by ensuring that the receiving crane will not raise the cask above 60 in. from the floor.
The safety-significant protective feature provided by the cask lifting yoke is required to provide a high level of assurance that the receiving crane main hoist will not raise the transportation cask above the 60-in.-height limit required by Section A3.4.2.1. Safe handling of the cask-MCO ensures that the cask-MCO will not be dropped and damaged.

**A4.4.17.4 System Evaluation.** Analysis and review of the cask and trunnion in HNF-SD-SNF-FDR-003 and an analysis of the receiving crane lifting yoke in HNF-SD-SNF-DA-022 demonstrate that the cask lifting equipment complies with ANSI N14.6-1993 requirements.

In HNF-3243, *Detailed Simulation of Cask and Multi-Canister Overpack Vertical Drop onto the Canister Storage Building Receiving Area Floor*, a drop of the cask-MCO from a height of 60 in. onto the concrete floor of the CSB receiving area is shown to result in no releases of radioactivity.

**A4.4.17.5 Controls (Technical Safety Requirements).** The following assumptions associated with the cask lifting yoke require TSRs to ensure performance of the safety function.

- Verify, before using the receiving crane to lift a transportation cask, that the correct lifting yoke for the cask is used to ensure that the 60-in. height limit is not violated (see Section A5.5.3.3 and A5.6.15).

- Perform routine and recommended surveillance and nondestructive examination on the stressed components of the lifting yoke as recommended by the vendor or ANSI N14.6-1993, whichever is more restrictive. ANSI N14.6-1993 requires initial and annual acceptance testing at 150% of the maximum service load. These tests are followed by visual examination. Alternatively, in areas where surface cleanliness and conditions permit, dimensional testing, visual inspection, and nondestructive testing shall suffice.

**A4.4.18 Multi-Canister Overpack Centering Guide**

**A4.4.18.1 Safety Function.** The safety function of the MCO centering guide, located in the MHM MCO cavity, is to ensure that an accidentally dropped MCO will always impact on the inclined surfaces of the cask receiving pit shield hatch and MCO guide assembly, the standard or overpack storage tube lower flange, or the sampling/weld station shield halves. This MCO cavity feature protects the MCO from damage. The MCO centering guide is designated safety significant in accordance with DOE-STD-3009-94 and 97-SFD-172 (Sellers 1997).

**A4.4.18.2 System Description.** The MCO centering guide is a spacer attached to the inner wall of the MHM MCO cavity (Figure A2-33). The MCO centering guide fits snugly inside the MHM MCO cavity and is bolted to the cavity wall. The MCO centering guide is fabricated of carbon steel conforming to ASTM A36/A36M. The MCO centering guide positions an MCO suspended...
by the MCO grapple in the middle of the MCO cavity and prevents the MCO from drifting too far from the center of the MCO cavity.

A4.4.18.3 Functional Requirements. The MCO centering guide is required to position the MCO in the center of the MHM MCO cavity to prevent a dropped MCO from hitting the edge of shields or flanges when the MCO is lowered. The MCO centering guide prevents an eccentric drop from striking an edge of the shield hatch and MCO guide assembly, the storage tube lower flange, or a sampling/weld shield half. Damage or deformation of an MCO is minimized when an MCO strikes the inclined surfaces of these shields or flanges.

A4.4.18.4 System Evaluation. The accidental eccentric drop of an MCO from the MHM has been evaluated and is summarized in Sections A4.4.15, A4.4.16, A4.4.19, and A4.4.20. The results of the analyses show some damage to the inverted cone surfaces leading into the storage tube, the sampling/weld station pit, the cask receiving pit with deflection of the dropped MCO into the cavity and absorption of the fall by the impact absorbers. The MCO centering guide prevents the dropped MCO from striking the edges of the inverted cone surfaces.

A4.4.18.5 Controls (Technical Safety Requirements). The MCO centering guide is a design feature of the MHM (see Section A5.5.3.3), and its safety function is managed by the configuration control process. There are no special maintenance or surveillance requirements.

- Verify that the MCO centering guide is in place before the MHM leaves the maintenance pit in the MCO mode.

A4.4.19 Cask Receiving Impact Absorber

A4.4.19.1 Safety Function. The cask receiving impact absorber has the safety function to protect the cask–MCO dropped by the receiving crane into the cask receiving pit from unacceptable damage. The cask receiving pit impact absorber is designated safety significant because of its role in limiting the deceleration forces to the MCO.

A4.4.19.2 System Description. The cask receiving impact absorber, placed in the cask receiving pit, cushions the cask–MCO if it is accidentally dropped and supports the cask–MCO at floor level making the cask lid accessible for cask lid bolt loosening and cask lid removal operations. The impact absorber positions the top of the MCO at the proper height for the MHM to retrieve it from the transportation cask. A shield hatch and MCO guide assembly (Figure A2-17) placed over the cask receiving pit at deck level provide radiation protection for the facility worker (see Section A4.4.7) and interfaces with the MHM (see Figure A2-32).

The cask receiving impact absorber (see Figure A2-9, sheet 5) consists of the following components: the top plate, the base weldment, and energy absorbing tube components between the top plate and base weldment. The top plate is 1.5-in.-thick carbon steel material conforming to ASTM A36/A36M. The base weldment is constructed of carbon steel pipes and plates.
conforming to ASTM A53 and ASTM A36/A36M. Carbon steel material conforming to
ASTM A513, Type 5, is selected for the tube sections. The maximum diameter of the cask
receiving impact absorber is 53 in. The overall height is approximately 44 in. after factory
precush of the assembled cask receiving impact absorber. The base weldment serves to maintain
the impact absorber centered in the cask receiving pit. Alloy steel rods spaced equidistantly
around the absorber circumference maintain the pipe components in place. These rods conform to
ASTM A193/A193M, Standard Specification for Alloy-Steel Stainless Steel Bolting Materials
for High-Temperature Service.

A4.4.19.3 Functional Requirements. The cask receiving impact absorber must absorb the
energy from a dropped cask-MCO to the extent that deceleration forces to the MCO are below
the specified design limits. The MCO’s DBA loading limits are provided in the MCO Topical
Report (HNF-SD-SNF-SARR-005). The MCO is required to survive deceleration loads up to
35 g. According to HNF-SD-SNF-DP-007, Multi-Canister Overpack/Cask Drop Analysis File
Documentation, Appendix O, the dropped cask-MCO has been found to exceed the 35 g
specification limits of the MCO without an impact absorber in the cask receiving pit. The cask
receiving impact absorber is specified to limit the dropped cask-MCO forces to the MCO from
the maximum drop height of 60 in. above the operating deck into the cask receiving pit to less
than 35 g. The specified loaded cask weight is 59,000 lb. The loaded cask can be dropped from a
maximum height of 23 ft, 5 in. onto the cask receiving impact absorber without exceeding the
35 g specification limit.

A4.4.19.4 System Evaluation. Analyses of a dropped loaded cask-MCO into the cask receiving
pit without an impact absorber are documented in Calculation CSB-S-0014, Deck Cantilever/
Load-In/Load-Out Design. The analyses show that the drop penetration depth using the
Modified National Defense Research Committee Formula requires a slab thickness greater than
that provided. For a 19-ft unmitigated drop, the pit foundation base slab required is 29.3 in. as
compared to the 24 in. provided. No structural consequences other than damage to the pit are
caused by this unmitigated drop scenario. The functional requirements listed above are provided
in performance specifications to the supplier. The specification requirements include conformance
with ANSI/AISC N690-94 for design and fabrication. Specification requirements include that a
prototypical drop test be performed. Before the cask receiving impact absorber is installed in the
cask receiving pit, vendor testing will confirm that the cask receiving impact absorber will
mitigate damage to an accidentally dropped cask-MCO.

A4.4.19.5 Controls (Technical Safety Requirements). The cask receiving pit guides are a
design feature of the MCO cask receiving pit, and their safety function is managed by the
configuration control process (see Section A5.6).

The following assumption associated with the cask receiving impact absorber requires a
TSR to ensure performance of the safety functions (see Section A5.5.3.4).

- Verification that the cask receiving impact absorber is in place before facility startup
  and following any required maintenance on the cask receiving impact absorber.
A4.4.20 Sampling/Weld Station Impact Absorber and Shield Halves

A4.4.20.1 Safety Function. The shield halves and impact absorber at the sampling/weld station have the safety function to protect an MCO dropped by the receiving crane into the sampling/weld station from unacceptable damage. The sampling/weld station shield halves, and impact absorber are designated safety significant because of their role in reducing the impact force and limiting the deceleration forces to the MCO.

A4.4.20.2 System Description. The rotating shield supports the MCO below the operating deck at the sampling/weld station. A sampling/weld station impact absorber is located below the MCO. The shield halves and center shield plate (Figure A2-40) placed over the sampling/weld station at deck level provide radiation protection for the facility worker (see Section A4.4.9) and interface with the MHM.

The sampling/weld station shielding consists of the center shield plate and two shield halves (Figure A2-40). The sampling/weld station shielding forms an inverted cone with a removable center shield plate. The center shield plate and shield halves are fabricated from 6-in.-thick carbon steel plate conforming to ASTM A36/A36M requirements. Before sampling or welding operations begin, the grating covers over the sampling/weld pit are removed and the sampling/weld station shielding is lowered into place by the sampling/weld station gantry crane. The shield halves are designed to provide closure of the sampling/weld pit, isolating it from the grade-level sampling/weld area concrete floor. The sampling/weld station shielding provides radiation protection for operating personnel. After sampling/weld station shielding is in place, the MHM aligns the MHM turret over the center shield plate, the center shield plate is retrieved into the MHM plug cavity, and the turret rotates and lowers the MCO into the sampling/weld station pit with the MCO supported by the sampling/weld station impact absorber inside the rotating shield. The center shield plate is then replaced by the MHM; the MHM moves away from the sampling/weld station; and the sampling/weld station shielding is removed by the sampling/weld station gantry crane to expose the top of the MCO for sampling and welding activities.

A sampling/weld station impact absorber (see Figure A2-40) consists of the following components: the top plate, the base plate, and energy-absorbing tube components in the middle. The top plate is 1.0-in.-thick carbon steel material conforming to ASTM A36/A36M. The base plate is constructed of a 0.5-in. carbon steel plate conforming to ASTM A36/A36M. Carbon steel material conforming to ASTM A513 is selected for the tube sections. The maximum diameter of the sampling/weld station impact absorber is 25.5 in. The overall height is about 18 in. after factory precrush of the assembled sampling/weld station impact absorber. The top and base plates serve to maintain the impact absorber centered in the sampling/weld station rotating shield. Galvanized steel cables spaced equidistantly around the absorber circumference maintain the tube components in place. Shear pins (12 total) at the rotating shield section below the MCO's canister collar will shear when impacted by an accidentally dropped MCO and allow the dropped MCO to impart the load to the absorber and rotating shield support structure, thus limiting the impact loads on the dropped MCO.
A4.4.20.3 Functional Requirements. The shield halves form an inverted cone with 75° angle of incline to the horizontal sampling/weld area surface. This angle effectively deflects an MCO that has been inadvertently, eccentrically dropped by the MHM into the sampling/weld rotating shield. The force of a dropped MCO is cushioned by the sampling/weld station impact absorber. Significant damage to the dropped MCO is prevented by compressing the impact absorber.

A sampling/weld station impact absorber must absorb the energy from a dropped MCO to the extent that deceleration forces to the MCO are below the specified design limits. The MCO’s DBA loading limits are provided in the MCO Topical Report (HNF-SD-SNF-SARR-005). The MCO is required to survive deceleration loads not to exceed 35 g. Without an impact absorber in the sampling/weld station pit, the dropped MCO is expected to exceed the 35 g specification limits of the MCO, similar to the cask receiving pit dropped MCO event (HNF-SD-SNF-DP-007, Appendix O). The sampling/weld station impact absorber is specified to limit the forces to the MCO from the maximum drop height above the operating deck to less than 35 g. The shear ring screws are required to shear and allow the dropped MCO to engage the impact absorber yet hold the MCO in place.

A4.4.20.4 System Evaluation. With the shield halves in place and the center shield plate removed by the MHM, the inverted cone shape of the opening into the rotating shielding mitigates the consequences of an accidentally dropped MCO. The thickness of the steel assemblies and the cone angle provide assurance that a dropped MCO will be guided into the rotating shielding cavity and cushioned by the sampling/weld station impact absorber.

The functional requirements listed above are provided in performance specifications to the supplier. The specified loaded MCO weight is 20,200 lb; the loaded MCO can be dropped from a maximum height of 20 ft, 3 in. without exceeding the 35 g specification limit or 679,000 lb force. The specification requirements include conformance with ANSI/AISC N690-94 for design and fabrication. Results of prototypical testing will demonstrate compliance with the functional requirements.

Analyses performed for the shear ring collar behavior during MCO drop conditions are documented in CSB-RM-0016. The results indicate that the dropped MCO energy will shear the screws at the scored reduced thickness points yet support the MCO in the sampling/weld station. The shear screws are furnished in accordance with ASTM F835 with a cut groove to 0.312 in. diameter, and provide a factor of safety of 2.7 to ensure that the ring does not break away during MCO placement.

A4.4.20.5 Controls (Technical Safety Requirements). The shield halves and sampling/weld station impact absorber are design features, and their safety function is managed by the configuration control process (see Section A5.6).
The following assumption associated with the sampling/weld station impact absorber requires TSRs to ensure performance of the safety functions.

- The sampling/weld station impact absorber provides protection of the MCO internals should an accidental drop of the MCO occur during lowering or raising of an MCO by the MHM. The presence of the sampling/weld station impact absorber is confirmed as part of initial construction acceptance. The sampling/weld station impact absorber needs verification of being in place before facility startup (see Sections A5.5.3.3 and A5.5.3.4).

- The shield halves need to be verified as being in place before the MHM lowers an MCO into the sampling/weld station pit for sampling or welding operations (see Section A5.5.3.3).

A4.4.21 Shield Hatch and Multi-Canister Overpack Guide Assembly

A4.4.21.1 Safety Function. The safety function of the shield hatch and MCO guide assembly is to deflect the MCO back into the cask receiving pit in the unlikely event the MHM drops the MCO onto the edge of the cask receiving pit. The shield hatch and MCO guide assembly protect the MCO from significant damage and provide radiation shielding for workers during cask lid removal and MCO removal operations.

A4.4.21.2 System Description. The shield hatch and MCO guide assembly unit consists of three parts: the shield hatch plate, the shield hatch ring, and the MCO guide assembly (Figure A2-17). The shield hatch and MCO guide assembly form an inverted cone plug with a removable shield plate. The shield hatch and MCO guide assembly are 66.25 in. in diameter. The MCO guide (fabricated of 8-in.-thick carbon steel) and the shield hatch ring and shield hatch plate (fabricated of 10-in.-thick carbon steel plate) conform to ASTM A36/A36M requirements. The MCO guide assembly has two drilled holes for alignment with the cask lid guide pins. The shield hatch and MCO guide assembly provide closure of the cask receiving pit, isolating it from the grade-level load-in/load-out area. The cask receiving pit is shown on Figure A2-9.

The tent gantry hoist is used to place the MCO guide assembly on the transportation cask after removal of the cask lid. The two centering holes of the MCO guide assembly align the MCO guide assembly over the center of the transportation cask. Next the shield hatch ring and shield hatch plate are lowered to floor level using the tent gantry hoist. This operation takes place after a transportation cask has been lowered into the cask receiving pit by the receiving crane and after the transportation cask lid has been removed. The shield hatch ring provides an interfacing surface for the MHM. The shield hatch ring has been designed to form a seal with the MHM's retractable nose. The shield hatch plate is designed to be removed by the MHM plug grapple. MHM interlocks prevent lifting the MCO unless the MHM is properly positioned over the shield hatch plate. The MHM's retractable nose in contact with the troweled concrete surface of the cask receiving pit provides shielding continuity during MCO retrieval operations.
A4.4.21.3 Functional Requirements. The shield hatch ring and MCO guide assembly form an inverted cone with a 75° and 71°, respectively, angle of incline to the horizontal load-in/load-out area surface. This angle effectively deflects an MCO, which has been inadvertently, eccentrically dropped by the MHM, back into the transportation cask. Significant damage to the dropped MCO is prevented by the MCO striking the bottom of the transportation cask with energy absorption by the cask and the cask receiving impact absorber.

The shield hatch and MCO guide assembly also perform a radiation shielding function for workers by sealing with the MHM’s retractable nose. The shielding goal for the cask receiving pit and the shield hatch and MCO guide assembly is to meet the ALARA principles of 10 CFR 835. The cask receiving pit and shield hatch and MCO guide assembly meet the requirements for personnel shielding safety provided in HNF-SD-SNF-DB-003 (Items 20 and 23).

A4.4.21.4 System Evaluation. With the shield hatch and MCO guide assembly in place and the shield hatch plate removed by the MHM, the inverted cone shape of the opening into the cask mitigates the consequences of an accidentally dropped MCO. The thickness of the steel assemblies and the cone angle provide assurance that a dropped MCO will be guided into the transportation cask cavity.

The shielding function of the shield hatch and MCO guide assembly ensures a safe area for operators to conduct cask receiving and MCO removal activities. Calculation CSB SH-2002, Floor Plug/Deck Interface Analysis, concluded that with the 10-in.-thick shield plate in place, the dose rate to the facility operator is less than the 0.05 mrem/h value calculated for the operating floor deck over vault 1. The design thicknesses of the shield hatch and MCO guide assembly are adequate to protect the facility worker and complies with Items 20 and 23 of HNF-SD-SNF-DB-003.

A4.4.21.5 Controls (Technical Safety Requirements). The following assumption associated with the shield hatch and MCO guide assembly requires TSRs to ensure performance of the safety functions.

- The shield hatch and MCO guide assembly are in place before the MCO is removed by the MHM. This is an MHM interface requirement, a dropped MCO mitigating requirement, and a worker protection requirement (Section A5.5.3.3).

A5.0 DERIVATION OF TECHNICAL SAFETY REQUIREMENTS

A5.1 INTRODUCTION

A description of the essential features of Spent Nuclear Fuel (SNF) Project derivation of Technical Safety Requirements (TSRs) is provided in Section 5.1 of the SNF Project Final Safety Analysis Report (FSAR).

A5.2 REQUIREMENTS

The requirements that form the basis for the SNF Project derivation of TSRs are identified in Section 5.2 of the SNF Project FSAR.

A5.3 TECHNICAL SAFETY REQUIREMENTS COVERAGE

The suite of TSRs for analyzed hazards and accidents is summarized in Table A5-1. This table lists TSR controls in accordance with the accident analyses in Chapter A3.0. Table A5-1 is written to provide a road map from the respective accident analysis section to the relevant subheadings within Section A5.5, where derivation details are arranged by TSR control.

The necessary and sufficient TSR controls are established based upon consideration for public safety, significant defense in depth, significant worker safety, and for maintaining radiological consequences below release limits and risk evaluation guidelines. Section 5.3 of the SNF Project FSAR contains details applicable to all SNF Project facilities. Section A5.3.2 contains information specific to the Canister Storage Building (CSB) in addition to that provided in Section 5.3.2.

A5.3.1 Criteria

The control selection criteria used for the SNF Project are described in Section 5.3.1 of the SNF Project FSAR.

LCO = Limiting Condition for Operation.
MCO = Multi-canister overpack.
MHM = Multi-canister overpack handling machine.
A5.3.2 Safety Structures, Systems, and Components not Provided
with Technical Safety Requirement Coverage

The safety-class and safety-significant structures, systems, and components (SSCs) that
have not been provided with TSR coverage are identified below. All other safety SSCs are
provided with TSR coverage with a Limiting Condition for Operation (LCO) or are included in an
Administrative Control (AC) program. The bases for not providing TSR coverage are provided
in the following paragraphs.

A5.3.2.1 Transportation Cask. The transportation cask is a safety-class SSC. There are no
TSR controls for this safety SSC because it is a Design Feature (refer to Section A5.6, “Design
Features”) and its safety function is managed by the configuration control process. In
Chapter A3.0 this SSC was classified as providing significant defense in depth by maintaining its
structural integrity.

A5.3.2.2 Multi-Canister Overpack. The multi-canister overpack (MCO) is a safety-class SSC.
There are no TSR controls for this safety SSC because it is a Design Feature (refer to
Section A5.6) and its safety function is managed by the configuration control process. In
Chapter A3.0 this SSC was classified as providing significant defense in depth by maintaining its
structural integrity. It also was credited in Chapter A6.0 as having certain geometrically favorable
design characteristics.

A5.3.2.3 Canister Storage Building Subsurface Structures. The CSB subsurface structures
(vault 1, air intake and exhaust plenums) are classified as safety-class SSCs. There are no TSR
controls for these safety SSCs because they are Design Features (refer to Section A5.6) and their
safety functions are managed by the configuration control process. These SSCs were identified as
maintaining structural integrity throughout all design basis natural phenomena hazard (NPH)
events.

A5.3.2.4 Carbon Steel Basemat Embeds. The carbon steel basemat embeds are classified as
safety-class SSCs. There are no TSR controls for these safety SSCs because they are Design
Features (refer to Section A5.6) and their safety functions are managed by the configuration
control process. These SSCs were identified as maintaining structural integrity throughout all
design basis NPH events.

A5.3.2.5 Canister Storage Building At-Grade Structures. The operating area deck,
sampling/weld area, load-in/load-out area, intake structure, and exhaust stack are classified as
safety-class SSCs. The operating area shelter, support area foundation, cask receiving pit, and
sampling/weld station MCO support structure are classified as safety-significant SSCs. There are
no TSR controls for these safety SSCs because they are Design Features (refer to Section A5.6)
and their safety functions are managed by the configuration control process. The safety-class
SSCs were identified as maintaining structural integrity throughout all design basis NPH events,
and the safety-significant SSCs were identified as not failing in such a way as to cause the failure
of any safety-class SSC.
A5.3.2.6 Standard Storage Tubes, Lower Flanges, Tube Base Assemblies, and Tube Plugs. The standard storage tubes and tube base assemblies are classified as safety-class SSCs, and the lower flanges and tube plugs are classified as safety-significant SSCs. There are no TSR controls for these safety SSCs because they are Design Features (refer to Section A5.6) and their safety functions are managed by the configuration control process. These SSCs were identified as maintaining structural integrity throughout all design basis NPH events.

A5.3.2.7 Overpack Storage Tubes, Lower Flanges, Tube Base Assemblies, and Overpack Tube Plugs. The overpack storage tubes and tube base assemblies are classified as safety-class SSCs, and the lower flanges and overpack tube plugs are classified as safety-significant SSCs. There are no TSR controls for these SSCs because they are Design Features (refer to Section A5.6) and their safety functions are related to recovery actions, not to accidents during normal operations. Controls related to specific recovery actions must be developed on a case-by-case basis depending on current conditions and recovery evaluation results.

A5.3.2.8 Helium Rupture Disk. The helium rupture disk PSE-1 is classified as a safety-significant SSC. There are no TSR controls for this SSC because it is a Design Feature (refer to Section A5.6) and its safety function is managed by the configuration control process. This SSC was identified as relieving pressures at the sampling/weld station.

A5.3.2.9 Receiving Crane Structure and Hoist. The receiving crane structure and hoist are classified as safety-significant SSCs. There are no TSR controls for these safety SSCs because they are Design Features (refer to Section A5.6) and their safety functions are related to recovery actions, not to accidents during normal operations. Controls related to specific recovery actions must be developed on a case-by-case basis depending on current conditions and recovery evaluation results.

A5.3.2.10 Multi-Canister Overpack Handling Machine Structural Components and Multi-Canister Overpack Hoist and Grapple. The MCO handling machine (MHM) structural components and MCO hoist and grapple are classified as safety-significant SSCs. There are no TSR controls for these safety SSCs because they are Design Features (refer to Section A5.6) and their safety functions are managed by the configuration control process. These SSCs are credited in the accident analyses because of their contribution to reducing drop frequencies.

A5.3.2.11 Shielding Features of the Transportation Cask, Multi-Canister Overpack Shield Plug, Multi-Canister Overpack Handling Machine, and Operating Deck. The shielding features of the transportation cask, MCO shield plug, MHM, and operating deck that protect workers from direct radiation from the MCO contents are classified as safety-significant. There are no TSR controls for these safety SSCs because they are fixed Design Features (refer to Section A5.6) and their safety functions are managed by the configuration control process. These SSCs were identified as providing significant worker safety in Chapter A3.0.

A5.3.2.12 Tube Vent and Purge Cart. The tube vent and purge cart is used in support of recovery actions, and the pressure boundary in the sampling path is classified as safety significant in this role. There are no TSR controls for this SSC because its safety function is related to
recovery actions, not to accidents during normal operations. Controls related to specific recovery actions must be developed on a case-by-case basis depending on current conditions and recovery evaluation results.

A5.3.2.13 Transportation Cask Servicing System. The transportation cask servicing system is used in support of recovery actions and the flex connector, high-efficiency particulate air filter, piping between the filter and the cask, and pressure safety valve PSV-102 are classified as safety-significant in this role. There are no TSR controls for this SSC because its safety function is related to recovery actions, not to accidents during normal operations. Controls related to specific recovery actions must be developed on a case-by-case basis depending on current conditions and recovery evaluation results.

A5.4 DERIVATION OF FACILITY MODES

A5.4.1 Operational Modes

The facility operational modes (Operation and Standby) for the CSB were identified to indicate overall facility status so that conditions can be clearly highlighted to CSB personnel.

The facility modes for the CSB are defined as follows.

Operation — The facility is capable of receiving MCOs or transferring MCOs between locations within the facility. Routine operational and maintenance activities may be performed (e.g., surveillances, equipment checks). Major planned maintenance activities (e.g., work requiring the replacement or temporary disassembly of major components such as MHM interlock controls) are not allowed. Corrective maintenance to restore operability as part of an LCO-required action is allowed. Any other operational evolutions (e.g., sampling, welding) already in progress must be completed, or terminated in accordance with procedures to return to a stable condition, before moving to Standby mode.

Standby — The facility contains MCOs. Receipt of new MCOs, transfers of MCOs between locations within the facility, and MCO welding or sampling activities are not allowed, except as part of an approved recovery plan. (Note: The facility may not enter the Standby mode while an MCO is located within the MHM.) Routine operational and maintenance activities may be performed (e.g., surveillances, equipment checks). Major maintenance activities (e.g., work requiring the replacement or temporary disassembly of major components such as MHM interlock controls) may be performed.

The facility may be manned or unmanned in either mode. To be unmanned, all MCOs within the facility must be within a standard storage tube, the sampling/weld station, or the cask receiving pit. When the CSB is unmanned, MCOs are not allowed to be attached to CSB lifting
devices, and welding or sampling activities are not allowed to be in progress (i.e., they must have been completed or terminated).

A5.4.2 Minimum Staffing Levels

When the CSB is manned, the minimum operations shift complement for both the Operation and Standby modes is one shift manager (or designee) and two nuclear operators. In Standby mode, the required minimum CSB staff can be composed of any SNF Project shift managers or nuclear operators who have had the appropriate CSB-specific training, regardless of whether those staff members are physically located at the CSB or at another SNF Project facility. This minimum staff in each mode is considered adequate to perform the minimum safety functions necessary to protect the health and safety of the public, onsite workers, and the environment during normal operations, and abnormal and emergency conditions. The shift manager (or designee) is required to be Building Emergency Director (BED)-qualified.

Qualification training for the minimum staff (managers and nuclear operators) is addressed in Chapter 12.0, “Procedures and Training,” of the SNF Project FSAR. The program for TSR, emergency, and alarm response administrative procedures also is addressed in Chapter 12.0 of the SNF Project FSAR. Emergency response is addressed in Chapter 15.0, “Emergency Preparedness Program,” of the SNF Project FSAR. The general considerations for determining the minimum staff are provided in Section 5.4.2 of the SNF Project FSAR, while CSB-specific considerations are identified below.

Normal operations. Staffing requirements for the minimum operations shift complement during normal operations is based on accomplishment of the routine surveillances required for TSR compliance. A surveillance is considered a low-difficulty task. The surveillances that must be performed during normal operations include the following:

- Verifications that systems are operable
- Verifications that equipment is in place prior to beginning specific operational tasks
- Instrument calibrations
- Functional tests of systems to demonstrate operability.

The minimum operations shift complement is adequate during normal operations to perform necessary job functions.

Abnormal conditions. The minimum operations shift complement during abnormal conditions is necessary to ensure compliance with required actions specified in LCO action statements with completion times of less than 8 hours or that include the term “immediately.” Hanford Site experience has shown that additional staff could be provided within 8 hours, if needed (considering the most adverse weather and travel conditions), to ensure all LCO completion times are met. LCO completion times of “immediately” imply the highest sense of
urgency and are given top priority over all other activities. The minimum staff is not given tasks that could interfere with meeting TSR requirements.

The minimum operations shift complement is the same in either Operation or Standby mode. Specific LCO-required actions that would need to be performed immediately within a specified completion time, or prior to resuming operation (in this case a completion time is not specified), include the following:

- Shutdown of MHM operation
- Verify operating conditions (e.g., change of component status such as valve closure)
- Restore system operability.

The minimum operations shift complement is adequate during abnormal conditions to perform necessary job functions.

Emergency conditions. The minimum operations shift complement during emergency conditions is necessary to ensure response to the spectrum of accidents analyzed in Chapter A3.0 (hazardous and nonhazardous). The minimum operations shift complement must make prompt initial notifications and implement initial protective actions to preclude or reduce the exposure of individuals affected by hazards or unsafe conditions during an emergency.

The shift manager (or designee) is the BED. The BED is primarily responsible for assessment of the event and protective actions at the CSB. The BED also makes onsite notifications, implements emergency management procedures, implements facility emergency plans, classifies events, and controls event response. Two nuclear operators are considered adequate to respond to an event scene and support actions requested by the BED. The BED requests support services, as necessary, to perform administrative functions and the minimum functions required to ensure the health and safety of the public, onsite workers, and the environment.

The minimum operations shift complement is adequate to meet applicable emergency preparedness requirements.

A5.5 TECHNICAL SAFETY REQUIREMENT DERIVATION

A5.5.1 Multi-Canister Overpack Handling Machine

A5.5.1.1 LCO 3.1.1 — Multi-Canister Overpack Handling Machine Shear and Drop Prevention Interlock System.

Purpose. This control, to ensure MHM shear and drop prevention interlock system operability, is derived from the mechanical damage of MCO accident in Section A3.4.2.1.
Shearing the MCO or dropping it from an excessive height potentially results in a loss of SNF confinement. The P2 interlock is relied on as a significant defense-in-depth feature to limit the susceptibility of an MCO to breach caused by inadvertent MHM movement and as significant worker safety protection to limit personnel exposure to direct radiation from MCOs stored in the storage tubes. In addition, the P6 and P21 interlocks provide safety-significant defense-in-depth protection against shears caused by seismic events. The remaining interlocks in this system that are identified in Chapter A3.0 (P3, P5, P8, P9, P26, P57, P61, P62, P63, P65, P66, P80, and P85) provide additional defense in depth (non-TSR) for their role in contributing to the low likelihood of drops and shears throughout the facility. A summary of the interlocks addressed by this LCO follows:

- The P2 interlock to ensure that the storage tube plug has been placed in a storage tube before allowing shield skirt raising and bridge and trolley travel.
- The P6 interlock to ensure that the limit switch is not actuated and the resolver and programmable limit switch do not indicate a fully raised position unless the top of the MCO grapple assembly is less than the required distance below the outside bottom of the MCO hoist and drive assembly box.
- The P21 interlock to ensure that the switches are not actuated unless the right hand face of the trolley seismic restraint pin is within its acceptance distance below the lower face of the mounting plate and the bridge seismic clamps are fully disengaged.

This LCO applies in the Operation mode. The LCO requires operability of each interlock, including sensors, relays, and contactors, that is identified in Chapter A3.0 to reduce the likelihood of MCO shear. Operability requirements include the following:

- Prior to MHM operation after startup, a channel check of the P6 and P21 interlocks will be performed to give assurance that the MHM-supported subsystem equipment functions as intended.
- A quarterly channel test will be performed to demonstrate the proper response of the interlock to an injected signal (simulated or actual) to verify the correct channel response.
- Annual calibration and functional test of each interlock to ensure that all required inputs and their expected responses are adequate to verify operability.

**Derivation Criteria.** These controls were selected because they prevent, rather than mitigate, the associated accidents and use engineered controls rather than administrative programs to achieve their safety functions.
A5.5.2 Confinement Systems

A5.5.2.1 LCO 3.2.1 — Sampling Hood Exhaust System.

**Purpose.** This control, to ensure sampling hood exhaust system operability, is derived from the MCO external hydrogen deflagration accident in Section A3.4.2.4. The release of radioactive material without controls is below risk evaluation guidelines. However, the worker safety considerations of an external deflagration warrant the elevation of the sampling hood exhaust system to safety significant. Ensuring the operability of this system reduces the inherent risk to worker safety.

The sample hood confinement system controls consist of operability requirements that include:

- Instrumentation necessary to determine that sample hood flow rates are adequate
- Integrity of the ducting up to and including exhaust fans.

This LCO applies in the Operation mode when the MCO process port valve is open to the sampling/weld station equipment. Surveillance requirements associated with this LCO include the following:

- Calibration of the flow instrumentation as established by the SNF Project Preventive Maintenance/Testing Program
- An operability inspection before MCO sampling operations are begun — This inspection includes sample hood glove ports for degradation, flexible hose and connections for integrity, proper balance damper and isolation damper positioning. Part of the operability inspection includes verification of a 100 ft³/min flow rate through the sample hood prior to MCO sampling. This verification ensures that the hood exhaust system flow is operating before opening the MCO process port. Although the safety analyses in Chapter A3.0 show that flow on the order of 5 ft³/min is sufficient, 100 ft³/min was chosen as the minimum value because it represents the minimum design flow value. Flow rates below this value are indicative of problems with the hood exhaust and bring into question the reliability of the system to perform its safety function throughout the sampling operations.

**Derivation Criteria.** This control was selected based on significant worker safety considerations in Chapter A3.0.

A5.5.2.2 LCO 3.2.2 — Sampling Piping Confinement System.

**Purpose.** This control, to ensure sampling piping confinement system operability, is derived from the MCO external hydrogen deflagration accident in Section A3.4.2.4. The release
of radioactive material without controls is below risk evaluation guidelines. However, the worker safety considerations of an external deflagration warrant the elevation of the sampling piping confinement system to safety significant. Ensuring the operability of this system reduces the inherent risk to worker safety.

The sampling piping confinement system controls consist of operability requirements to ensure the integrity of the sampling piping. Surveillance requirements associated with this LCO include the following:

- A pressure check of the sampling piping and MCO connection to verify that the system leakage rate is less than 40 cm³/s at 75 lb/in² gauge (as confirmed by a pressure decay rate) before taking an MCO sample.

This LCO applies in the Operation mode when the MCO process port valve is open to the sampling/weld station equipment.

**Derivation Criteria.** This control was selected based on significant worker safety considerations in Chapter A3.0.

### A5.5.3 Administrative Controls

AC 5.1 through AC 5.6 are addressed in Chapter 5.0 of the SNF Project FSAR.

### A5.5.3.1 AC 5.7 — Nuclear Criticality Safety

**Purpose.** This control protects the assumptions of the nuclear criticality evaluation in Chapter A6.0 to ensure that CSB operations minimize the risk of nuclear criticality. The purpose of this AC is to protect double contingency features that are relied upon to preclude a criticality event at the CSB. Key elements of this programmatic AC are derived from contractor procedures that include requirements for criticality safety evaluations, criticality prevention specifications, pre-fire plans, and criticality training. The criticality controls identified in Chapter A6.0 are derived from HNF-SD-SNF-CSER-005, *Criticality Safety Evaluation Report for the Multi-Canister Overpack*.

**Derivation Criterion.** A nuclear criticality program is required according to DOE Order 5480.22, *Technical Safety Requirements*, Section 9.e.(5).

### A5.5.3.2 AC 5.8 — Measurement and Test Equipment

**Purpose.** This control provides a support control for the measuring and test equipment used to verify process parameters to comply with the TSRs when specific instrumentation and associated surveillances are not included in the TSR. This control applies to (1) optional instrument systems allowable in accordance with the LCO bases, and (2) instrumentation used to
verify parameters for the ACs in the TSR. This control on the measuring and test equipment ensures that process parameters are properly monitored.

The key elements of the program include maintaining identification and traceability of TSR-related instrumentation and equipment, periodic testing of the instrumentation and equipment used, and maintaining records that demonstrate that the instrumentation and equipment were used while in calibration.

The program applies to installed and portable measuring and test equipment when used to verify parameters specified in the TSRs where specific instrumentation and associated surveillances are not already identified in the TSR. This program does not apply to equipment such as rulers, tape measures, levels, and other measurement devices if commercial equipment provides accuracy adequate to meet the measurement specifications.

**Derivation Criteria.** This control was included because for some parameters in the TSR, it is not essential to specify the particular instrumentation or measuring equipment used to demonstrate compliance with the parameter involved provided the instrumentation or equipment used to monitor the parameter is maintained. This support control was selected because it provides operational flexibility to use various instrumentation and equipment to measure TSR parameters provided it complies with this AC while ensuring the safety functions assumed in the accident analysis are met.

**A5.5.3.3 AC 5.9 — Canister Storage Building Operational Controls.**

**Purpose.** This AC focuses on the importance of those planned operational steps that were identified as critical assumptions in the accident analyses in Chapter A3.0 or that provided significant defense in depth. The key elements of the AC include the following.

- Requirement to use the proper yoke (the cask lifting yoke) when moving the cask-MCO with the receiving crane — This provides significant defense in depth by protecting the lift height of the bottom of the cask-MCO to a maximum of 60 in. above the load-in/load-out area floor.

- Visual verification that the MHM seismic restraints (bridge, trolley, and turret) are applied before MCO raising or lowering operations begin — This ensures that the MHM is capable of performing properly during a seismic event to provide significant defense in depth to reduce the likelihood of MCO shearing as well as to maintain initial condition assumptions used to demonstrate that the MHM is not susceptible to catastrophic failure.

- Verification that rail frog hold-down bolts are snug when the rail frog is repositioned — This ensures that the rail frog is capable of performing properly during a seismic event to provide significant defense in depth to reduce the likelihood of MCO
shearing as well as to maintain initial condition assumptions used to demonstrate that
the MHM is not susceptible to catastrophic failure.

- Surveillance of the rail clip hold-down bolts for relaxation in accordance with
  recommendations from the designer — Maintenance ensures the proper configuration
  of the rail clips as a structural Design Feature to provide significant defense in depth
to reduce the likelihood of MCO shearing as well as to maintain initial condition
assumptions used to demonstrate that the MHM is not susceptible to catastrophic
failure.

- Verification that the sampling/weld station shield halves are in place before placing an
MCO in or removing an MCO from the sampling/weld station — This ensures the
proper configuration of the shielding as a Design Feature to provide significant
defense-in-depth protection against eccentric MCO drops and to provide worker
safety from direct radiation doses during MCO placement and removal.

- Verification that the interface guide ring funnel is in place before placing an MCO in
or removing an MCO from a storage tube — This ensures the proper configuration
of the interface guide ring funnel as defense in depth against eccentric MCO drops.

- Verification that the shield hatch and MCO guide assembly is in place before the
MCO is removed from the cask receiving pit by the MHM — This ensures the proper
configuration of the shielding as a Design Feature to provide significant defense-in-
depth protection against eccentric MCO drops and to provide worker safety from
direct radiation doses during MCO removal.

- Verification that the MCO centering guide is properly installed in the MHM before
the MHM leaves the maintenance pit in the MCO mode — This ensures the proper
configuration of the MCO centering guide as a Design Feature to provide significant
defense-in-depth protection against eccentric MCO drops.

This AC heightens attention to the need for CSB compliance with these planned operational steps.

Derivation Criterion. These controls are necessary to support the assumptions made
within the safety analysis. These assumptions rely upon operator actions to ensure that they are
valid.

A5.5.3.4 AC 5.10 — Impact Absorber Availability.

Purpose. The impact absorber availability control is derived from the accident analyses for
mechanical damage of MCO in Section A3.4.2.1. The impact absorbers in the cask receiving pit,
storage tube, and sampling/weld station play a significant defense-in-depth role to prevent damage
to MCOs handled at the CSB.
This control requires that a program be established and maintained to ensure that the following key elements occur.

- Verify that impact absorbers are installed in the sampling/weld station, cask receiving pit, and storage tubes (bottom impact absorbers only) before facility startup.
- Verify that intermediate impact absorbers are placed in any storage tube that is to be used to store a second MCO.
- Establish procedures to ensure prompt replacement of damaged impact absorbers.

**Derivation Criterion.** This control is necessary to support the safety analysis regarding mitigation of MCO drops. Placement of impact absorbers within these locations is an administrative feature and best handled through an AC.

**A5.5.3.5 AC 5.11 — Storage Tube Plug Placement.**

**Purpose.** This control is derived from the evaluation of significant worker safety in Section A3.3.2.3.2 of Chapter A3.0. Direct radiation doses from the MCO are significant and shielding is required at all times. This shielding is provided by the tube plugs during MCO storage.

This control requires that a program be established and maintained to ensure that standard storage tube plugs and overpack storage tube plugs are properly placed at all times during facility operation, and are in good working condition. This involves verification of placement before facility startup and procedures to deal promptly with tube plugs that may need replacement. The only acceptable method of removal of the tube plugs is with the MHM, which provides shielding during this operation. Replacement of a tube plug is necessary before the MHM moves from the tube location affected.

**Derivation Criterion.** This control was selected to protect the facility worker from significant direct radiation exposure during operations. Proper placement of all tube plugs at the start of operations is assumed within the safety analysis report to protect facility workers from shine effects from storage tubes that may be near the otherwise open storage tubes.

**A5.5.3.6 AC 5.12 — Receipt Acceptance Criteria.**

**Purpose.** This control protects the accident analysis assumptions in all the evaluated accidents. The safety analysis assumes that all MCOs received meet the minimum requirements for acceptance.

This AC requires a program to verify the acceptability of an MCO before receipt by CSB personnel. A key element of this program is verification before acceptance of each MCO delivery to ensure that the proper processing steps and conditions have been carried out for each MCO.
The program also must address recovery planning activities for out-of-specification MCOs that arrive at the CSB.

**Derivation Criteria.** This control was selected to protect major analysis assumptions (e.g., maximum particulate content, maximum leakage rate, maximum water content) that, if altered, could significantly affect consequences.

A5.5.3.7 AC 5.13 — Combustible Loading Limits.

**Purpose.** The combustible loading limits control is established based on Chapter A3.0 assumptions made regarding combustible loading limits determined in HNF-SD-SNF-FHA-002, *Final Fire Hazard Analysis for the Canister Storage Building*, and in its implementation plan.

This control applies in the Operation and Standby modes. A program shall be established and maintained to limit the combustible loadings as determined by the fire hazard analysis (HNF-SD-SNF-FHA-002) and implementation plan.

**Derivation Criteria.** This control was selected to protect Chapter A3.0 assumptions relating to fire hazards that, if altered, could significantly affect consequences.

A5.5.3.8 AC 5.14 — Configuration Management of Design Features.

**Purpose.** This configuration management AC was deemed necessary to protect the safe operation of the facility against uncontrolled changes to Design Features. A sitewide institutional safety program for configuration management is in place to control such changes. In addition, the SNF Project has developed its own plan, HNF-SD-SNF-CM-001, *Spent Nuclear Fuel Project Configuration Management Plan*, to handle configuration management at the SNF Project facilities. The plan defines the process that the SNF Project has approved to secure configuration management, and it is formatted to include the elements and functions established in DOE-STD-1073-93, *Guide for Operational Configuration Management Program*. The plan includes compliance requirements with the overall Site configuration management system and criteria for change control, document control, configuration management implementation, and periodic assessments. This AC heightens attention to the need for CSB compliance with these configuration management plans.

**Derivation Criteria.** This control was deemed necessary to protect the safe operation of the facility against uncontrolled changes to Design Features. HNF-PRO-700, *Safety Analysis and Technical Safety Requirements*, states that configuration management is a candidate AC when Design Features have been identified for a facility.
A5.6 DESIGN FEATURES

Design Features for the CSB that, if altered or modified, would have a significant effect on safe operation are listed below. Descriptions of these Design Features are provided in Chapter A2.0, "Facility Description." The safety functions they perform are provided in Chapter A4.0, "Safety Structures, Systems, and Components." Chapters A2.0 and A4.0 should be consulted for details.

A5.6.1 Transportation Cask

Design Features for the transportation cask include the following.

- The cask structure provides protection to the MCO from shearing forces while being lowered into the cask receiving pit.
- The cask shielding, in conjunction with the receiving crane shielded operator station, provides attenuation of gamma and neutron radiation to limit facility worker exposure to levels consistent with site administrative limits and ALARA (as low as reasonably achievable) practices.
- Under normal conditions, the cask is leaktight and capable of maintaining confinement as identified in Chapter A3.0.

A5.6.2 Multi-Canister Overpack

Design Features for the MCO include the following.

- The MCO shell, filter guard plate, shield plug, Mark IA fuel and scrap baskets' center posts, and baseplates provide a geometrically favorable SNF configuration in regard to criticality issues.
- Under normal conditions, the MCO is capable of maintaining confinement with a leakage rate of no greater than $10^{-4}$ cm$^3$/s, as required by HNF-SD-SNF-SARR-005, *Multi-Canister Overpack Topical Report*.
- The MCO shield plug shielding provides attenuation of gamma and neutron radiation to limit facility worker exposure to levels consistent with site administrative limits and ALARA practices.
A5.6.3 Canister Storage Building Subsurface Structures

Design Features for the CSB subsurface structures (vault 1, air intake and exhaust plenums) include the following.

- The structural features maintain structural integrity throughout all design basis NPH events.

A5.6.4 Carbon Steel Basemat Embeds

Design Features for the carbon steel basemat embeds include the following.

- The structural features maintain structural integrity throughout all design basis NPH events.

A5.6.5 Canister Storage Building At-Grade Structures

Design Features for the CSB at-grade structures (operating area deck, sampling/weld area, sampling/weld station MCO support structure, load-in/load-out area, cask receiving pit, support area building foundation, intake structure, exhaust stack, and operating area shelter) include the following.

- The structural features of the operating deck, sampling/weld area, load-in/load-out area, intake structure, and exhaust stack maintain structural integrity throughout all design basis NPH events.

- The operating area shelter, support area building foundation, sampling/weld station MCO support structure, and cask receiving pit will not fail during a design basis NPH event in such a way as to cause the failure of any safety-class SSC.

A5.6.6 Standard Storage Tubes, Lower Flanges, Tube Base Assemblies, and Tube Plugs

Design Features for the standard storage tubes, lower flanges, tube base assemblies, and tube plugs include the following.

- The structural features maintain structural integrity throughout all design basis NPH events.

- The lower flange of the storage tube has a 45° incline.
The tube plug geometry is such that the plug is incapable of passing through the lower flange and impacting an MCO.

A5.6.7 Overpack Storage Tubes, Lower Flanges, Tube Base Assemblies, and Overpack Tube Plugs

Design Features for the overpack storage tubes, lower flanges, tube base assemblies, and overpack tube plugs include the following.

- The structural features maintain structural integrity throughout all design basis NPH events.
- The lower flange of the storage tube has a 45° incline.

A5.6.8 Shielding Features of the Shield Hatch and Multi-Canister Overpack Guide Assembly, Multi-Canister Overpack Handling Machine, Operating Deck, Tube Plugs, and Sampling/Weld Station Shield Halves and Center Shield Plate

Design Features for the shield hatch and MCO guide assembly, MHM, operating deck, tube plugs, and sampling/weld station shield halves and center shield plate include the following.

- The shielding provides attenuation of gamma and neutron radiation to limit facility worker exposure to levels consistent with site administrative limits and ALARA practices.

A5.6.9 Receiving Crane Structure and Hoist

No individual Design Feature of the receiving crane is more important than another to protect its safety function. Therefore no individual features are listed here.

A5.6.10 Multi-Canister Overpack Handling Machine

Design Features for the MHM include the following.

- The MHM seismic restraints maintain structural integrity throughout a design basis seismic event.
- The MHM rails and rail frogs maintain structural integrity throughout a design basis seismic event.
• The MHM MCO grapple is designed to preclude releasing an MCO (disengaging) unless the load is no longer supported by the grapple.

A5.6.11 Sampling/Weld Station

Design Features of the sampling/weld station include the following.

• Pressure safety relief device PSE-1 is specified to relieve at 150 lb/in² gauge.
• The sampling/weld station shield halves have a 75° incline.
• The center shield plate geometry is designed such that the center shield plate is incapable of passing through the shield halves and impacting an MCO.

A5.6.12 Shield Hatch and Multi-Canister Overpack Guide Assembly

Design Features of the shield hatch and MCO guide assembly include the following.

• The shield hatch geometry is designed such that the shield hatch is incapable of passing through the MCO guide assembly and impacting an MCO.
• The shield hatch and MCO guide assembly have a 75° incline.

A5.6.13 Gas Cylinder Valves

Design Features of all gas cylinders valves include the following:

• A maximum hole size in the inlet to the butt of the cylinder valve limits the thrust produced by escaping gas to an amount that cannot accelerate the cylinders to dangerous velocities.

A5.6.14 Site Grading

Design Features for site grading include the following.

• Site grading is maintained such that the probable maximum precipitation event (9.2 in. in 6 hours) does not allow water to flow into the CSB operating area.
• Site grading is maintained such that the accumulation of runoff water cannot result in the flow of significant water into the CSB operating area.
A5.6.15 Cask Lifting Yoke

Design Features for the cask lifting yoke include the following.

- The length of the cask lifting yoke limits the lift height of the cask-MCO such that the receiving crane cannot lift the bottom of the cask more than 60 in. above the floor.

A5.7 INTERFACES WITH TECHNICAL SAFETY REQUIREMENTS FROM OTHER FACILITIES

The TSRs of other facilities that affect the SNF Project facilities safety basis are summarized in Section 5.7 of the SNF Project FSAR. TSRs of other facilities that affect the CSB are summarized in the following subsections.

A5.7.5 Receipt of Spent Nuclear Fuel

The CSB interfaces with other facilities through the receipt of SNF from the Cold Vacuum Drying Facility (CVDF). Chapter A3.0 identifies facility interfaces that are key to protecting the CSB safety basis. As discussed in Section 5.7.5.2 of the SNF Project FSAR, SNF shipments from the CVDF must meet the criteria and assumptions identified in Chapter A3.0.

The CVDF sends SNF to the CSB based upon dryness testing. HNF-3673, *Cold Vacuum Drying Facility Technical Safety Requirements*, requires that proper testing be conducted to establish that the MCO water content is within acceptable levels to ensure that key parameters assumed in the CSB safety analysis are protected. In addition, the CVDF process for mechanically sealing the MCO before transport to the CSB must ensure that the CSB assumptions are valid.

The K Basins safety analysis report must similarly protect the key interfaces identified relative to K Basin processes in Chapter A3.0. HNF-SD-WM-SAR-062, *K Basins Safety Analysis Report*, establishes MCO basket loading controls and overall MCO loading controls to ensure that the initial conditions and assumptions used in the CSB safety analyses are valid.

A6.0 PREVENTION OF INADVERTENT CRITICALITY

A6.1 INTRODUCTION

This chapter evaluates the potential for criticality of spent nuclear fuel (SNF) during normal, abnormal, and accident conditions in the Canister Storage Building (CSB). It further describes the engineered features and administrative controls that give added assurance that a criticality event during handling and storage of SNF at the CSB is incredible. Chapter 6.0 of the SNF Project Final Safety Analysis Report (FSAR) provides an overall description of the SNF Project criticality prevention program.

The SNF received at the CSB is contained in baskets tiered vertically inside a multi-canister overpack (MCO). The MCO is moved to the CSB in a transportation cask from the Cold Vacuum Drying Facility (CVDF) in a nominally dry condition, except for a small amount of water or hydrogen chemically bound in the fuel matrix. MCOs will be stored at the CSB in an array of vertical tubes, two MCOs per tube, in a below ground vault that is designed for interim dry storage. The CSB facility design is described in detail in Chapters A2.0 and A4.0. CSB facility design aspects pertinent to criticality prevention are summarized in Section A6.4, which also specifies administrative controls.

Many SNF geometries, events, and conditions have been hypothesized for all operating and storage functions in the CSB under normal and accident conditions. The quantification of the approach to criticality for all of these actual and hypothesized conditions is described in HNF-SD-SNF-CSER-005, *Criticality Safety Evaluation Report for the Multi-Canister Overpack*. Many of the scenarios analyzed in HNF-SD-SNF-CSER-005 involving the MCOs and the fuel baskets are the same or similar for various facilities. A selected set of analyses of the bounding and credible conditions applicable to the CSB are described. These analyses establish the criticality safety design limits, their bases, and the parameters to be applied for prevention of a criticality in the CSB.

The scope of the analysis presented in this chapter includes only the SNF received at the CSB that has been loaded into MCOs at the K Basins and cold vacuum dried at the CVDF. Other fuels stored in the Interim Storage Area at the CSB are addressed in Annex D, “200 Area Interim Storage Area Final Safety Analysis Report.” The scope does not include handling of the SNF assemblies and the MCOs at the K Basins and the CVDF, or the transportation of the MCOs from the K Basins. Criticality concerns associated with loading and handling MCOs at the K Basins are addressed in HNF-SD-WM-SAR-062, *K Basins Safety Analysis Report*, while criticality issues associated with transporting the MCOs to the CSB are covered in HNF-SD-TP-SARP-017, *Safety Analysis Report for Packaging (Onsite) Multicanister Overpack Cask*. Unloading of the MCOs from the transportation cask and movement of the MCOs within the CSB are within the scope of this chapter. This chapter addresses the administrative controls at the K Basins to the extent that the failure of those administrative controls could affect criticality safety at the CSB.
The K Basins administrative controls and their failure modes are described in detail in HNF-2032, *SNF Fuel Retrieval Subproject Safety Assessment Document*.

This chapter also addresses implementation of requirements to achieve U.S. Nuclear Regulatory Commission equivalency in the design of the CSB with respect to criticality prevention based on the double contingency principle. The double contingency principle is stated in DOE Order 5480.24, *Nuclear Criticality Safety*, as follows: “Process designs shall incorporate sufficient factors of safety to require at least two unlikely, independent and concurrent changes in process conditions before a criticality accident is possible.” As described in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements*, a system is considered acceptably subcritical if it has an effective neutron multiplication factor ($k_{eff}$) less than or equal to 0.95. The criteria used to determine whether $k_{eff}$ meets the 0.95 limit are described in Section 6.3.3.1 of the SNF Project FSAR. As applied in this chapter, criticality is a beyond double contingency event and is incredible.

The normal condition for the SNF at the CSB is in dry, sealed MCOs. The criticality calculations for normal conditions result in very low $k_{eff}$ values — less than 0.4. All credible conditions have calculated $k_{eff}$ values less than the limit of 0.95. It should be noted that although only a very small fraction of the fuel is unburned (<0.14%), all criticality analyses have been performed using fresh fuel compositions, which is conservative.

A bounding scenario was hypothesized to determine the maximum $k_{eff}$ values computed for Mark IA and Mark IV fuel in an MCO. This scenario involves a drop accident that results in the following:

- The shipping cask breaches
- The MCO breaches
- Hydrogen is released
- An ignition source is present
- Hydrogen ignites and the Hanford Fire Department responds
- The geometry is distorted
- All fuel rubblizes to optimally sized and optimally spaced pieces
- Moderator is added to the interior of the MCO during fire fighting.

Furthermore, the MCO was assumed to contain a mass distribution of unirradiated fuel that maximizes the calculated $k_{eff}$. Even under these hypothetical conditions, the system was still not critical. The maximum $k_{eff}$ computed was approximately 0.97 for a Mark IA MCO and approximately 0.93 for a Mark IV MCO.

For $k_{eff}$ of an MCO or an array of MCOs to exceed 0.95 independent of controls requires not only the failure of design features and the failure of administrative controls but also a sequence of hypothetical conditions that must occur concurrently. These conditions are incredible, as discussed below.
Fuel rubblization into optimally sized particles is judged to be incredible because when discharged from the N Reactor, the individual fuel elements survived vertical drops of more than 40 feet with only minor damage, and the elements also will have been processed by the primary clean machine in the K Basins without rubblizing.

Optimization of the fuel requires that it form pieces that are approximately twice the diameter of the thickness of the original fuel elements, which is judged to be incredible.

Rubblized fuel and scrap achieving and maintaining optimum spacing is judged to be incredible because there is nothing to support the fuel particles in an optimum matrix.

In conclusion, the $k_{eff}$ for all credible scenarios is considerably less than 0.95 (HNF-SD-SNF-CSER-005).

**A6.2 REQUIREMENTS**

The requirements that form the basis of criticality prevention are identified in Section 6.2 of the SNF Project FSAR. Technical safety requirements for nuclear criticality safety at the CSB specify that a program will be established, implemented, and maintained to prevent an accidental criticality at the CSB. Criticality limits and controls will be documented in criticality safety evaluation reports and implemented in criticality prevention specifications.

**A6.3 CRITICALITY CONCERNS**

**A6.3.1 Criticality Hazards**

See Section 6.3.1 for identification of the fissile material available in SNF Project facilities and loaded into MCOs. The CSB is classified as a limited control facility because it contains greater than one-third of a minimum critical mass.

**A6.3.2 Criticality Analysis**

The criticality analyses for the CSB consider only fissionable material contained in MCOs.

**A6.3.2.1 Multi-Canister Overpack Loadings.** Baskets containing fuel or scrap are loaded into MCOs at the K Basins. An MCO can contain either six Mark IA fuel and scrap baskets or five Mark IV fuel and scrap baskets. Normal MCO loadings and limits are described in HNF-SD-WM-SAR-062. Each MCO may be loaded in one of three normal configurations:

- All fuel baskets
- One scrap basket and four or five fuel baskets
Two scrap baskets and three or four fuel baskets.

Mark IA and Mark IV baskets are not loaded into the same MCO. It is permissible to mix Mark IV fuel or scrap with Mark IA fuel or scrap in Mark IA baskets. As described in HNF-SD-WM-SAR-062, the only situation in which Mark IA fuel would be loaded into Mark IV baskets occur when the long-length (26-in.) Mark IA fuel assemblies in the K West Basin are loaded into Mark IV fuel baskets.

A6.3.2.2 Description of the Canister Storage Building. The CSB is composed of an operating area and a below grade SNF storage area consisting of three vaults. Storage tubes for MCOs are located in vault 1 only. There are 220 tubes arranged in a 10 (north-south) by 22 (east-west) hexagonal array. The tube center-to-center distance is 4 ft, 8 in. in the east-west direction and 4 ft, 6 in. in the north-south direction. Two normal MCOs are placed in each storage tube in a vertical column, as shown in Figure A6-1. There is an impact absorber at the bottom of each tube and between the two MCOs in a tube. The bottom impact absorber is 36 in. long, and the intermediate impact absorber is 24 in. long (see Figure A2-13). Further details are provided in Chapters A2.0 and A4.0.

Six additional overpack storage tubes are also available in vault 1 for storing damaged MCOs or MCOs suspected of leakage. The overpack storage tubes are located along the west edge of the 10-by-22 array of normal MCO storage tubes as shown in Figure A2-7. There are no provisions for storing more than one MCO in an overpack storage tube. Thus, there is only one impact absorber at the bottom of each overpack storage tube.

The vault walls, vault basemat, and operating deck are constructed of reinforced, high-density concrete (see Chapter A2.0 for details). The exterior vault walls are 4.5 ft thick and the walls between vaults are 3 ft thick. The vault basemat is 5.5 ft thick and the operating deck is 5 ft thick. The thick concrete walls between the vaults neutronically isolate the fissile material in one vault from that in adjacent vaults. Therefore, reactivity of the CSB may be assessed by analyzing a single vault.

As described in Chapter A4.0, the CSB substructure consists of safety-class components designed to prevent failure of MCOs during the natural phenomena hazards listed in Chapter A3.0, and to maintain the SNF in a subcritical geometry. Therefore, complete collapse of the vault storage tubes, resulting in rearrangement of the MCOs in the vault, is considered a beyond design basis contingency and was not analyzed.

While at the CSB, an MCO is in its transportation cask; in the MCO handling machine (MHM); in a sampling/weld station; or in a storage tube. The MHM, which has a bell-shaped configuration with 10-in.-thick stainless steel walls, is used to remove the MCO from its cask and to move the MCO to and from process pits in the sampling/weld area and storage tubes in the vault. There is a row of seven process pits in the sampling/weld area, but only two of the pits are needed. However, there are no criticality concerns with using more than two pits. Two of the
remaining pits provide utilities for the sampling/weld stations. The other three pits are to be used for future projects.

A6.3.2.3 Criticality Hazard Configurations. Table A6-1 identifies the normal operating conditions considered, and for each, the hypothetical criticality hazards that could be created by abnormal occurrences during MCO handling and storage at the CSB. Also listed are the features that prevent or mitigate the consequences of each abnormal occurrence. The identified criticality hazards are based primarily on the hazard analysis, HNF-SD-SNF-HIE-001, Canister Storage Building Hazard Analysis, which is summarized in Chapter A3.0. Table A6-1 provides information for selecting credible criticality scenarios and for determining the scope of the required criticality ($k_{\text{eff}}$) analyses.

A6.3.3 Criticality Models and Calculations

A complete description of the models used and calculations completed for the criticality analyses is given in HNF-SD-SNF-CSER-005. A description of the codes used to perform the criticality analyses, their modeling assumptions, and their validation is also provided in HNF-SD-SNF-CSER-005. A variety of models was used in the criticality analyses, due in large part to the fact that the analyses were in progress while MCO and CSB designs were still evolving. Not all calculations were redone to incorporate the latest design parameters. Typically, a calculation was not redone if it was still bounding or if it was used only in a sensitivity study and was still adequate for that purpose. Also, calculations were not rerun for highly subcritical conditions if the design changes were not major. In such cases, representative results were deemed sufficient.

The effect of uncertainties such as moisture content, fuel length selections, and corrosion were investigated by performing calculations over the range of possible variations for the individual parameters (HNF-SD-SNF-CSER-005). These calculations showed that $k_{\text{eff}}$ typically increases with water addition. Both corrosion and fuel relocation (e.g., settling) reduce $k_{\text{eff}}$ by reducing the amount of either fuel or water or by producing a less optimal geometry. The longest elements for the Mark IV fuel assemblies and the 20.9-in.-long elements for the Mark IA fuel assemblies were chosen to represent “normal conditions.” A study of fuel length versus the $k_{\text{eff}}$ of a flooded MCO concluded that there is a modest sensitivity in $k_{\text{eff}}$ due to changes in fuel length (HNF-SD-SNF-CSER-005, Appendix B). However, use of this length to represent normal conditions is justified because about 88% of the Mark IA fuel is 20.9 in. long and use of the optimal length (19.6 in.) increases $k_{\text{eff}}$ by only 0.006.

MCOs at the operating deck level of the CSB are handled as single units located inside the MHM. There is no credible mechanism for placing two MCOs side-by-side outside their transportation casks on the CSB operating deck. As described in Chapter A2.0, an MCO is in its transportation cask, in the MHM, in a sampling/weld station, or in a storage tube. Therefore, all criticality scenarios on the operating deck were analyzed for a solitary MCO.

**Note 1:** "Dry" means only a minimal quantity of water.

**Note 2:** Abnormal or accident events involving CSB and MCO flooding, MCO misloading and overloading, and earthquakes are common to all five configurations. In general, they are listed only once, for configuration 1, but apply to the other configurations as well.

CSB = Canister Storage Building.
CVDF = Cold Vacuum Drying Facility.
MCO = multi-canister overpack.
MHIM = multi-canister overpack handling machine.
SSC = structure, system, and component.
Six calculational models were employed in the criticality analyses. The first three models simulate various locations for the MCO outside the storage vault. The other three models simulate the CSB vault area where the SNF will be stored. The MCOs in all models can be either water-flooded or dry. MCOs are normally dry at the CSB; however, flooded MCOs were analyzed as a contingency.

1. Figure A6-2 shows the first model, which represents an MCO inside the MHM on the operating deck. The operating deck's concrete floor acts as a neutron reflector. This model bounds the transportation cask-MCO configuration, which has a maximum of 8 in. of steel shielding.

2. Figure A6-3 shows the second model, which depicts an MCO surrounded by concrete. This model was used to evaluate a normal configuration in which an MCO is lowered through the concrete operating deck into a storage tube.

3. The third model represents an MCO in a sampling/weld station where there is steel shielding around the MCO and an impact absorber and concrete below it. To be conservative, the impact absorber was omitted from this model. As shown in Figure A6-4, there is an annulus filled with coolant (a propylene glycol and water mixture) in the steel surrounding the MCO. The annulus is 1.75 in. thick and is 2.75 in. outside the MCO. The steel between the MCO and the coolant represents the wall of the sampling/weld station pit, and the steel outside the coolant represents the rotating shield (see Chapter A2.0 for details of the sampling/weld station design). The weld cap that also contains coolant was not included in the model. However, the MCO shield plug isolates the coolant from the fissionable material inside the MCO.

4. The fourth model, shown in Figure A6-5, represents a 10-by-22 array of normal storage tubes with two MCOs per tube. The impact absorbers in the tubes are modeled as cylinders containing steel at 50% density. The bottom impact absorbers are 36 in. long, while the intermediate impact absorbers are 24 in. long. The MCO basket loadings in this model, which are based on the latest design specifications, are described in Section 6.3.2 of the SNF Project FSAR. The six overpack storage tubes for MCOs are not included in this model, however this modeling simplification has a negligible effect on reactivity. There is only one MCO per overpack tube, and the overpack tubes are spaced further apart than the normal tubes, as shown in Figure A2-7.

5. The fifth model is an earlier version of the fourth model described above. The key differences between the two models are that the fifth model has air in place of the impact absorbers, has concrete boundaries more closely surrounding the storage tube array and immediately above the upper MCO, and has scrap baskets loaded higher than the current limit allows.

6. Figure A6-6 shows the sixth model, which depicts the storage tube matrix modeled as an infinite array. The axial detail in this model is the same as in the fifth model.
The fifth model, like the fourth, neglects the overpack tubes, while the sixth model contains an infinite number of normal tubes. Thus the fifth and sixth models bound the case in which there are MCOs in the six overpack storage tubes. Although the fourth model described above (see Figure A6-5) is the latest and most closely simulates the current design of the MCO, its loadings, and the vault storage tubes, not all calculations of the vault area were repeated using this model. The sixth model, with the infinite array of tubes (see Figure A6-6), proved to give the most conservative results (highest $k_{eff}$ values) where comparative values were available. These results were still below the limit of 0.95 (HNF-SD-SNF-CSER-005). Thus, some of the results reported in the next section were based on the infinite array model and are bounding.

The configurations analyzed using the models described above bound all normal and hypothetical abnormal or accident conditions. Details of the modeling of fuel elements and fuel scrap inside the MCOs are described in HNF-SD-SNF-CSER-005.

Using the six analysis models, criticality calculations were performed for normal and abnormal or accident conditions for MCOs containing N Reactor fuel (Mark IV and Mark IA) and fuel scrap. Under normal conditions, the N Reactor fuel was assumed to be loaded in the MCOs as described in Section A6.3.2.1. That is, the top and bottom baskets were assumed to contain scrap, and the other baskets were assumed to contain intact fuel assemblies, which give the highest $k_{eff}$ for a particular fuel type. Fuel baskets can also contain damaged fuel assemblies (i.e., partial assemblies, individual elements, or pieces of elements). However, any possible configuration of damaged fuel in an MCO is bounded by cases of an MCO containing optimally rubblized and moderated fuel and optimal scrap. Such optimized MCO loadings have been analyzed and found to be critically safe (i.e., $k_{eff} < 0.95$) under the hypothetical flooding scenario analyzed (see HNF-SD-SNF-CSER-005 and Section A6.4.4). The specific cases analyzed, based on the conditions and features identified in Table A6-1, are described in Sections A6.3.4.1, A6.3.4.2, and A6.3.4.3, along with the results obtained.

Under normal conditions, the Mark IA and Mark IV fuel baskets are to be fully loaded (48 Mark IA assemblies in the Mark IA baskets, or 54 Mark IV assemblies in the Mark IV baskets). Fully loaded baskets are slightly undermoderated even when flooded with water to the maximum extent possible. An extensive study was done to determine the most reactive fuel basket loadings when flooded with water (HNF-SD-SNF-CSER-005). That study concluded that the most reactive MCO loadings consist of two scrap baskets plus three Mark IV or four Mark IA partially loaded fuel baskets. For the most reactive Mark IA MCO, the four fuel baskets each contain 47 fuel assemblies with one empty location in the middle row (see Figure 6-4 in the SNF Project FSAR). For the most reactive Mark IV MCO, the three fuel baskets each contain 53 complete fuel assemblies with only an inner element in one outer row location (see Figure 6-5 of the SNF Project FSAR). Unless otherwise noted, the results given in Section A6.3.4 are based on these MCO partial loadings. The $k_{eff}$ values of the most reactive loadings are only about 0.002 higher than those of full basket loadings.

As fuel assemblies were removed from the fully loaded models used in the study (HNF-SD-SNF-CSER-005), the remaining assemblies were not redistributed to optimize the lattice spacing because the assemblies are held in fixed locations within the fuel baskets by design.
Thus, only those assemblies adjacent to a removed assembly benefited from the increased moderation. Under credible accident scenarios, the fuel could move within the baskets. However, the reactivity effects of such movement are bounded by cases in which the fuel is reduced to rubble.

The scrap baskets modeled at each end of the MCO contained optimized fuel scrap. The uranium in the Mark IV scrap baskets was 0.95 wt% $^{235}$U (the same as in Mark IV fuel), while the uranium in the Mark IA scrap baskets was 1.25 wt% $^{235}$U. The size and spacing of the scrap were adjusted to give the highest $k_{\text{eff}}$ in a water-moderated environment — the most limiting condition (HNF-SD-SNF-CSER-005). The optimized scrap is thus more reactive under water moderation than intact fuel or accumulated corrosion products (canister sludge).

Loading intact long-length Mark IA fuel assemblies described in Section A6.3.2.1 from the K West Basin into a Mark IV fuel basket was determined to result in only a small, statistically insignificant increase in $k_{\text{eff}}$ compared to a typical Mark IV fuel basket loading (HNF-SD-SNF-CSER-005). That analysis showed this to be true regardless of the row and basket into which the long-length assemblies are placed. Because there will be only one basket with long-length Mark IA assemblies and these assemblies do not increase $k_{\text{eff}}$ significantly, the results reported in Section A6.3.4 are based on the typical Mark IV fuel basket loadings described above.

A small quantity (about 0.25 metric tons) of Mark IA fuel and scrap is stored in the K East Basin. This material will be loaded into Mark IA fuel and scrap baskets with Mark IV fuel and scrap subject to limits specified in HNF-SD-SNF-CSER-010, *Criticality Safety Evaluation Report for Storage and Removal of Spent Nuclear Fuel in the K Basins*.

### A6.3.4 Criticality Analysis Results

This section presents the results of the analyses performed to evaluate the potential for criticality under normal and abnormal or accident conditions, and provides bases for establishing the criticality safety design limits, the requirements for engineered design features discussed in Sections A6.4.1 and A6.4.2, and the administrative controls for criticality prevention discussed in Section A6.4.3. The results also verify compliance with the double contingency requirement during storage and handling of the SNF contained in the MCOs at the CSB because a criticality has been shown to be incredible. As stated earlier, the principal criterion for prevention of criticality as applied in the analyses is that $k_{\text{eff}}$ must not exceed 0.95 for any single credible contingency. The codes used to perform the criticality analyses, their modeling assumptions, and their validation are described in HNF-SD-SNF-CSER-005.

The criticality analyses are divided into two main parts: normal (dry) conditions and abnormal or accident conditions. The results demonstrate that in the dry condition, the value of $k_{\text{eff}}$ is well below 0.95 even if the fuel geometry is distorted in a postulated accident or if the fuel is misloaded into the wrong baskets (e.g., Mark IA fuel or scrap in Mark IV baskets). Scenarios
involving water inside the MCOs or flooding of vaults concurrent with other abnormal or accident conditions are considered beyond design basis accidents for the CSB.

A6.3.4.1 Normal Conditions. All MCOs received at the CSB have been drained and vacuum dried at the CVDF. The interiors of the MCOs are thus dry except for approximately 3 kg of water, including free water, hydrides, hydrates, and hydroxides, chemically bound in the fuel matrix. Under normal conditions, water or other moderating materials are not added to the MCOs while the MCO is at the CSB. LA-12808, Nuclear Criticality Safety Guide, states that low-enriched uranium (<5 wt% $^{235}$U) cannot be made critical without internal moderation. Analyses documented in HNF-SD-SNF-CSER-005 demonstrate that unmoderated MCOs have $k_{eff}$ values less than 0.4. Since MCOs from the K Basins are received and maintained in a dry state at the CSB, and since they will not contain uranium enriched to more than 1.25 wt% $^{235}$U, a criticality accident while handling and storing these MCOs at the CSB is impossible under normal conditions. Fuels with enrichments over 1.25 wt% $^{235}$U and fuels with mixed plutonium and uranium oxide are stored in the Interim Storage Area at the CSB. Criticality issues associated with these fuels are addressed in Annex D.

A6.3.4.2 Abnormal or Accident Conditions — Loss of Engineered and Administrative Controls during Handling and Storage. The two primary criticality controls at the CSB are the geometry and the absence of moderator. As stated above, drained MCOs containing low-enriched uranium (<5 wt% $^{235}$U) cannot be made critical without internal moderation. Therefore, the CSB operating area is considered a moderator control area in accordance with ANSI/ANS-8.22-1997, American National Standard for Nuclear Criticality Safety Based on Limiting and Controlling Moderators. The only control on moderator that is implemented is for fire fighting. There is no automatic fire suppression system or other source of water in the operating area of the CSB.

The CSB is designed to withstand a design basis earthquake and prevent flooding without loss of its safety function. The only significant neutron moderator normally found in the CSB is in the sampling/weld station, which has a cooling system for the shielding around the upper portion of the MCO and the cover cap. A failure of the cooling system that allows the coolant (a mixture of propylene glycol and water) to leak into an MCO through ports in the shield plug, which are normally closed, is an unlikely event. The volume of coolant in the cooling system is approximately 80 gal; approximately 130 gal of space is available in a full MCO. Thus coolant could flood only the lower two-thirds of the MCO at most. Analysis of the draining of an MCO at the CVDF (HNF-SD-SNF-CSER-005 and HNF-3553, Annex B) showed that a fully flooded MCO bounds all partially filled configurations.

It is also possible, but unlikely, that a flooded MCO could be received and accepted at the CSB. This contingency is prevented by administrative controls at both the CVDF and the CSB. Associated documentation will be examined to verify that the MCO was drained and dried at the CVDF. Other moderators would have to be purposely brought into the facility.

Fire fighting is the only credible reason for deliberately bringing a significant quantity of moderating material into the CSB. Water, by itself, is not a problem at the CSB because the
MCOs are fully flooded when loaded and transported from the K Basins. In addition, the facility pre-fire plan, described in Chapter A11.0, restricts the use of water to fight a fire in the CSB operating area. The pre-fire plan and the requirement to develop a recovery plan, should the drop of an MCO occur, satisfy the requirements of ANSI/ANS 8.22-1997 and HNF-PRO-547, *Criticality Safety for Firefighting*, which specifies the methods to be used in fighting a fire involving fissionable material.

As discussed in Section A6.1, the sequence of events that could lead to loss of geometry control and cause $k_{\text{eff}}$ to exceed 0.95 is incredible. Furthermore, as the Mark IA fuel and scrap settle to a higher-than-optimal packing fraction following the postulated MCO drop and the hypothetical fuel rubblization, maximum potential $k_{\text{eff}}$ rapidly drops below 0.95, as shown in Figure A6-7. This settling will occur shortly after the drop accident, well before any fire fighting activity could introduce moderator. All follow-up actions would be closely controlled by the recovery plan, which would specify the means of fire suppression should a fire occur. Solid streams of water could only be used as a last resort.

It is thus unlikely that the $k_{\text{eff}}$ limit would be exceeded even if the type of drop and hypothetical consequences described above occurred. Therefore, the CSB is designated a Category B fire fighting area.

The conclusion of the evaluation in SNF-4042, *Evaluation of Accident Frequencies at the Canister Storage Building*, is that the expected frequency of a drop accident that results in a breached MCO and cask, an ensuing fire, and the accidental introduction of a significant quantity of water to the exposed SNF is less than $10^{-5}$/yr, making the postulated events incredible.

Credible (single contingency) scenarios for having moderated SNF at the CSB are then (1) receiving and accepting a water-flooded MCO and (2) partial flooding of an MCO with a mixture of propylene glycol and water at the sampling/weld station because of a leak in the system designed to cool the shielding around the upper portion of the MCO and the cover cap. The second scenario is bounded by the first, so only the first was analyzed as described below.

Cases gly4.3, mhm4.9, and oc2.12c in Table A6-2 represent a scenario in which a flooded MCO is received at the CSB, inadvertently bypassing the CVDF. This event could lead to four geometries that were analyzed for criticality potential. The $k_{\text{eff}}$ values computed for all configurations were below the limit of 0.95.

1. A flooded Mark IV MCO is located in the sampling/weld station. It was assumed that there was also a leak in the cooling system and a mixture of propylene glycol and water flooded the annular cooling channel in the radial shielding surrounding the MCO in the pit. The resulting $k_{\text{eff}}$ was 0.926 for case gly4.3 in Table A6-2. A similar calculation for a Mark IA MCO yielded a lower $k_{\text{eff}}$ of 0.901 (case gly1.3 in HNF-SD-SNF-CSER-005).

* MCO loadings for the cases listed in this table contain Mark IV fuel and scrap only. One Mark IV fuel basket will contain 12 long-length Mark IA assemblies as described in Sections A6.3.2 and A6.3.3. These assemblies increase $k_{eff}$ over the values listed, but the differences are not statistically significant.

A small quantity of Mark IA fuel and scrap stored in the K East Basin also will be loaded into Mark IV baskets. Allowed loadings of this material (HNF-SD-SNF-CSER-010) are bounded by analyzed fuel misloading cases, which had $k_{eff}$ values less than 0.95 (HNF-SD-SNF-CSER-005).

* $k_{eff} = k_{calc} + 0.0004 + 0.01 + 1.645^2 (\sigma_k^2 + 0.002083^2)$ as defined in Section 6.3.3 of the SNF Project FSAR. This value must not exceed the criticality prevention criterion of 0.95.

* This MCO loading was not based on the latest design data but is very similar. Fuel baskets contain a full load, which is slightly less reactive (by $\sim 0.002 \Delta k_{eff}$) than optimally loaded fuel baskets. The two scrap baskets, which dominate the reactivity of a flooded MCO, have slightly different dimensions and loadings than those used in the latest models. They contain 7% more fuel mass than the current limit of 2,156 lb but have a $k_{eff}$ comparable to optimized loadings that adhere to the limit.

---

CL = confidence level.
MCO = multi-canister overpack.
MHM = multi-canister overpack handling machine.
2. A flooded Mark IV MCO is housed in the MHM, which is modeled as having 10 in. of steel all around the MCO except at the bottom where 5 ft of concrete represents the operating deck. The space between the outer wall of the MCO and the inner wall of the MHM and the environment outside the MHM are assumed to be dry. The resulting $k_{\text{eff}}$ is 0.930, as shown for case mhm4.7 in Table A6-2. A similar calculation for a Mark IA MCO yielded a lower $k_{\text{eff}}$ of 0.910 (case mhml.7 in HNF-SD-SNF-CSER-005).

3. A flooded Mark IV MCO is being lowered through the concrete floor into a storage tube. The configuration is simulated by using a model of a flooded MCO surrounded radially by concrete with 10 in. of steel above it. The resulting $k_{\text{eff}}$ is 0.930, as shown for case mhm4.9 in Table A6-2. A similar calculation for a Mark IA MCO yielded a lower $k_{\text{eff}}$ of 0.908 (case mhml.9 in HNF-SD-SNF-CSER-005).

4. A flooded Mark IV MCO is located in a storage tube. This configuration is simulated by the bounding case in which all 440 MCOs in the storage vault are flooded. The resulting $k_{\text{eff}}$ is 0.914, as shown for case occ2.12c in Table A6-2. A similar calculation for flooded Mark IA MCOs in the vault yielded a lower $k_{\text{eff}}$ of 0.905 (case occ1.15c in HNF-SD-SNF-CSER-005).

As noted in Table A6-2, the water inside the MCOs was modeled with a density of 1.0 g/cm$^3$ (full flooding) while water assumed to be present in the empty vault spaces outside the MCOs was modeled with a density of 0.008 g/cm$^3$. Both densities were based on sensitivity studies that indicated they resulted in the highest values of $k_{\text{eff}}$ (HNF-SD-SNF-CSER-005).

In the sensitivity analysis, water density in and between the storage tubes was varied from 0.0 g/cm$^3$ to 1.0 g/cm$^3$ using the model shown in Figure A6-6. Water density in empty vault spaces outside the MCOs had a uniform spatial distribution in each case. Conditions inside the MCOs, which were modeled as containing Mark IV fuel, were assumed to be dry (water density of 0.005 g/cm$^3$). Also, the model used did not include the latest MCO loading design.

Each of the three fuel baskets in the MCO contained 54 intact fuel assemblies. The two scrap baskets in each MCO had slightly different dimensions and loadings than those used in the latest models. Consequently they contained about 7% more fuel mass than the latest models but had a $k_{\text{eff}}$ comparable with optimized loadings that adhere to the fuel mass limit of 2,156 lb specified in HNF-SD-SNF-CSER-010.

The results of the study, shown graphically in Figure A6-8, indicate that a water density of 0.008 g/cm$^3$ outside the MCOs yields the peak value for $k_{\text{eff}}$. Increasing the water density between MCOs above 0.008 g/cm$^3$ decouples the MCOs by increasing neutron captures in water, resulting in a reduction of the $k_{\text{eff}}$. With the MCOs flooded, $k_{\text{eff}}$ is much less sensitive to variations in water density outside the MCOs (HNF-SD-SNF-CSER-005).

A6.3.4.3 Abnormal or Accident Conditions — Misloaded Multi-Canister Overpacks.

Scenarios stemming from loss of administrative controls at the K Basins also were postulated.
These scenarios, which all involve fuel basket misloading at the K Basins, are described below. Only dry MCOs are considered because a flooded MCO at CSB requires both the receipt and acceptance of a flooded MCO at the CSB. Thus, no credible MCO misloading at the K Basins can result in a criticality accident at the CSB without the additional contingency of water flooding. Analysis of multiple-contingency accidents is discussed in Section A6.4.4.

1. **One additional scrap basket misloaded into MCO.** As stated in Section A6.3.2.1, the criticality safety analyses assume that two scrap baskets are loaded in each MCO, one scrap basket being on the top of the stack and the other at the bottom. The fuel baskets in the middle of the MCO are loaded with intact fuel assemblies of the same enrichment as the scrap. In this misloading scenario, it was assumed that a third scrap basket was loaded at the second from the top position. This configuration places the misloaded scrap baskets in positions that maximize $k_{en}$ (HNF-SD-SNF-CSER-005).

2. **A canister of Mark IA scrap misloaded into a Mark IV scrap basket.** In this scenario, the Mark IV scrap basket at the top of the MCO was assumed to be misloaded with a canister (233 kg) of Mark IA scrap (1.25 wt% $^{235}\text{U}$). The remainder of the basket was correctly loaded with Mark IV scrap (0.95 wt% $^{235}\text{U}$). A similar scenario is that of a Mark IA intact fuel canister misloaded into a Mark IV fuel basket. However, because scrap baskets were modeled as containing optimized arrangements of fuel and water and are more reactive than intact fuel baskets (HNF-SD-SNF-CSER-005), this scenario is bounded by the scenario involving a misloaded scrap basket.

The two MCO misloading scenarios were shown to bound all other credible misloading scenarios at the K Basins (HNF-SD-SNF-CSER-005). The first scenario represents the worst-case misloading of a basket into an MCO, and the second scenario represents the worst-case misloading of a canister into a basket. However, both cases are highly subcritical without the addition of water.

### A6.4 CRITICALITY CONTROLS

#### A6.4.1 Passive Engineering Controls

The engineering controls for preventing inadvertent criticality in the CSB include facility structures, features that prevent introduction of water into the vault area, and MCO structures. As described in Chapters A2.0 and A4.0, the CSB structures, including MCO storage tubes, are designed to perform the safety function of providing support for MCOs to maintain their structural integrity before, during, and following all design basis accidents, including the design basis earthquake. The following passive features are designated as safety-class to maintain the MCOs in a critically favorable array:

- Standard and overpack storage tubes
- Tube base assemblies.

---

HNF-3553 REV 0
Annex A — Canister Storage Building
There is no natural groundwater source in the immediate vicinity of the vault walls and floor. The water table in the 200 East Area is more than 200 ft below the bottom of the vault basemat. Area drainage systems route rainwater away from the CSB.

There are no sprinkler systems required or provided for fire protection in the CSB that could flood the operating floor, the sampling/weld stations, or the vault area (see Chapter A2.0). There is no water piping provided adjacent to or above the CSB vaults. However, as described in Chapter A2.0, rooms in the support building, located at the north end of the CSB, are protected by a wet-pipe sprinkler system. A buried 6-in. fire water line running from a fire water main loop to the northwest corner of the support building feeds this sprinkler system.

Safety-class features of the MCO and the Mark 1A baskets provide geometry control sufficient to ensure criticality safety should a flooded MCO be received at the CSB. The analysis that demonstrates this is discussed in Section A6.3.4.2, and the results are summarized in Table A6-2. The following geometry control features of the MCO and Mark 1A baskets have been engineered as safety class according to HNF-SD-SNF-SARR-005, Multi-Canister Overpack Topical Report:

- MCO shell
- Filter guard plate
- Shield plug
- Mark 1A fuel and scrap basket base plate
- Mark 1A fuel and scrap basket center post.

A6.4.2 Active Engineering Controls

There are no active engineering controls required at the CSB to ensure criticality safety.

A6.4.3 Administrative Controls

MCOs arriving at the CSB will have been subject to controls in the K Basins and CVDF to ensure that specifications are met for MCO loading, draining, and drying. Control of operations performed before the MCO is received at the CSB is discussed in Annex B, the CVDF FSAR, and in the K Basins FSAR (HNF-SD-WM-SAR-062). CSB personnel inspect MCO documentation to verify the acceptability of an MCO upon receipt. Verification before acceptance of each MCO delivery ensures the proper processing steps have been carried out and proper conditions met for each MCO. Recovery planning activity for out-of-specification MCOs that arrive at the CSB also is addressed. The disposition of such MCOs will depend on the potential consequences and related risks and on which corrective actions are most appropriate. The CSB criticality safety evaluation was based on the implementation of this program and related controls at the K Basins and the CVDF.
Criticality analysis results discussed in Section A6.3.4.3 show that a failure of administrative
controls at the K Basins, such as misloading a single canister of Mark IA fuel assemblies or scrap
in Mark IV fuel baskets, will not create a criticality concern in the CSB (i.e., $k_{eff}$ remains well
below the criticality safety limit for all credible accidents). Likewise, neither an abnormal event at
the CSB nor the loss of administrative controls at the CVDF that results in a flooded MCO being
received at the CSB will create a criticality concern, as discussed in Section A6.3.4.2. Procedures
will control the introduction of moderator into the CSB to comply with ANSI/ANS-8.22-1997.

Although normal procedures do not allow two or more cask-MCOs in close proximity in
the load-in/load-out area, this situation does not pose a criticality concern because the thick cask
shielding neutronically isolates the SNF inside each cask-MCO (HNF-SD-TP-SARP-017).

CSB procedures for loading MCOs into the standard storage tubes will require an
intermediate impact absorber be inserted between two MCOs. Analysis has shown that loading
MCOs with no intermediate impact absorber is not a criticality concern
(HNF-SD-SNF-CSER-005).

A6.4.4 Application of Double Contingency Principle

See Section 6.4.3 of the SNF Project FSAR for a general discussion about the application of
the double contingency principle. The accident evaluations presented in Sections A6.3.4.2 and
A6.3.4.3 demonstrate the application of the double contingency principle at the CSB. Two
contingencies have been identified for operation at CSB: loss of geometry control and loss of
moderator control. As discussed in Section A6.1, a loss of geometry control that results in
rubblized fuel and scrap achieving optimum size and spacing is incredible. Thus the only credible
contingency is a loss of moderator control. The factors affecting reactivity of each occurrence
have been conservatively defined, within the constraints of the design or the realistic extent of a
control loss, so that the reported consequences represent or exceed all credible situations that can
be involved in the scenario considered.

A6.5 CRITICALITY PROTECTION PROGRAM

See Section 6.5 of the SNF Project FSAR for an overview of the organizational structure
and interfaces and the technical and administrative practices of the criticality protection policy and
programs that are being developed for SNF Project operations.

In accordance with the guidance of HNF-PRO-547 the CSB is a firefighting Category B
facility. MCOs are designed to be criticality-safe when flooded by water
(HNF-SD-SNF-CSER-005), and flooding of the vault reduces neutron multiplication in the array
of MCOs stored there (see Section A6.3.4.2). Also as discussed in Section A6.3.4.2, the pre-fire
plan restricts the use of water to suppress a fire at the CSB.
A6.6 CRITICALITY INSTRUMENTATION

This section addresses the need for a criticality alarm system and a criticality detection system in the CSB. DOE Order 5480.24 references ANSI/ANS-8.3-1997, *Criticality Accident Alarm System*, for requirements relating to nuclear criticality alarm systems. ANSI/ANS-8.3-1997 states that neither a criticality alarm system nor criticality detection system is required where the probability of a criticality accident is determined to be less than $1 \times 10^{-6}$ per year.

The MCO is designed to be criticality safe even when fully moderated by water (HNF-SD-SNF-CSER-005), as it normally is until it is drained at the CVDF. Under normal conditions at the CSB, the MCOs will be dry, and without moderation the SNF stored at the CSB cannot be made critical. The receipt of a flooded MCO at the CSB was shown to be an unlikely event (SNF-4042) because of engineered features and administrative controls at the CSB and administrative controls at the CVDF.

As discussed in Section A6.3.4.3, scenarios involving misloading MCOs at the K Basin were considered in HNF-SD-SNF-CSER-005. Potential errors evaluated included loading a Mark IA fuel or scrap canister into a Mark IV basket and loading more than two scrap baskets into an MCO. No credible loading error resulted in a computed $k_{\text{eff}}$ greater than the limit of 0.95, even if the misloaded MCO was water flooded.

In all cases, with the limits and controls discussed in this chapter, the frequencies were less than $10^{-6/\text{yr}}$. Therefore, a criticality alarm system is not required at the CSB. The above discussion complies with the U.S. Nuclear Regulatory Commission equivalency requirement concerning criticality instrumentation as defined in Item 8 of HNF-4776, *Canister Storage Building Compliance Assessment, SNF Project NRC Equivalency Criteria — HNF-SD-SNF-DB-003*.

A6.7 U.S. NUCLEAR REGULATORY COMMISSION EQUIVALENCY

The requirement identified in HNF-SD-SNF-DB-003, namely that the maximum $k_{\text{eff}}$ including the contribution from any single failure be less than or equal to 0.95, has been satisfied.

A7.0 RADIATION PROTECTION

A7.1 INTRODUCTION

The essential features of radiation protection programs that provide for radiation exposure control, contamination control, radiological monitoring, and radiological protection instrumentation at all the Spent Nuclear Fuel (SNF) Project facilities are addressed in Chapter 7.0 of the SNF Project Final Safety Analysis Report (FSAR). Additional features of radiation protection specific to the Canister Storage Building (CSB) are addressed in this Chapter A7.0. The CSB's primary function is to provide passive interim storage of SNF in air-cooled storage tubes that isolate the SNF from the building air and surrounding atmosphere. To reach this condition, the SNF, packed inside a multi-canister overpack (MCO), is moved into the CSB in a transportation cask, placed into the cask receiving pit, moved to the sampling/weld station, and then moved into the storage tubes for long-term interim storage. Once the MCO is stored, the anticipated exposure levels of personnel depend only upon penetrating radiation resulting from efforts to monitor stored MCOs and direct radiation through the vault ceiling. Exposures to airborne radioactive material during interim storage are expected to be minimal. The major risks of receiving radiation exposure occur while unloading MCOs, staging MCOs, cap welding, and monitoring selected MCOs. The radiation protection precautions employed during MCO servicing and movement will be more extensive to protect against the possibility of the accidents described in Chapter A3.0.

A7.2 REQUIREMENTS

The requirements that form the basis for the radiation protection program are identified in Section 7.2 of the SNF Project FSAR.

A7.3 RADIATION PROTECTION PROGRAM AND ORGANIZATION

The SNF Project radiation protection program and its organization, including safety management policies and philosophies, is described in Section 7.3 of the SNF Project FSAR.

A7.4 ALARA POLICY AND PROGRAM

See Section 7.4 of the SNF Project FSAR for a discussion of the SNF Project ALARA (as low as reasonably achievable) policy and program. The SNF Project policy regarding ALARA during CSB design and construction is described in WHC-SD-W379-PMP-001, Project W-379 Canister Storage Building Project Management Plan. HNF-SD-SNF-DB-003, Spent Nuclear Fuel Project Path Forward, Additional NRC Requirements, requires that the SNF Project incorporate, as applicable, NRC Regulatory Guide 8.8, Information Relevant to Ensuring that
Occupational Radiation Exposures at Nuclear Power Stations will be as Low as is Reasonably Achievable. The CSB radiation protection program complies with NRC Regulatory Guide 8.8, as required by U.S. Nuclear Regulatory Commission (NRC) equivalency Item 23 (HNF-SD-SNF-DB-003), using the ALARA policies noted in Section 7.4 of the SNF Project FSAR. These policies commit the CSB organization to limiting radiation exposures to ALARA levels and acknowledge that the primary method used to achieve ALARA objectives is physical design features.

During design phase ALARA analyses, a block flow diagram was developed identifying all of the individual steps required to process an MCO from receipt to long-term interim storage. This flow diagram identified an estimated time that would be required to complete each of the steps. The time estimates were then used as a basis for estimating personnel radiation exposure.

A model of the CSB processes was developed to determine the personnel exposure to radiation that could be expected during operation of the facility. This model was based on the steps in the block flow diagram. Each activity was evaluated to determine the dose rate at the location where the activity is to be performed. The workforce category and the frequency of each activity was determined from the block flow diagram, and the exposure (person-rem) for each activity was then calculated. These individual activity exposures were then summed to determine the total exposure from processing one cask-MCO. The steps that incurred higher exposures were reviewed, and design features were revised to reduce the estimated exposures.

Numerous design changes to the MCO and cask and to the CSB and its equipment have resulted from this process. Specific design features credited with reducing radiation exposure and achieving ALARA program objectives include:

- Shield wall and doors between the support building and the operating area
- Shielded operator station on the sampling crane
- Rotating shielding at the sampling/weld stations
- Temporary shields at the sampling/weld stations
- MCO shipping cask and lid
- MCO handling machine (MHM) steel shielding
- Tube plug and cover assembly
- MHM boron-infused densified wood shielding
- Service station shield hatch assembly
- Operating deck.

As the previous discussion indicates, the basic principles that were adhered to in the design of the CSB were to (1) determine the major contributors to the dose and examine methods for making the processes more efficient, and (2) provide shielding to reduce the dose.

At the CSB, the operations of primary concern from an ALARA standpoint are MCO receiving and handling operations. Cask-MCO shielding weight limitations have been imposed by the K Basins crane capacity. As a result of these shielding weight limitations, calculated
operational dose rates on the side of the MCO transportation cask are higher than desired. Also, with the transportation cask lid removed for servicing in the MCO service station, exposure levels at the top of the MCO are higher than desired. Permanent or temporary shielding has been incorporated; however, some operations may require hands-on access in radiation fields estimated at 10 to 30 mrem/h. For these operations, strict administrative controls, including personal protective equipment, will be applied to maintain exposures to ALARA levels.

A7.5 RADIOLOGICAL PROTECTION TRAINING

SNF Project requirements and criteria for radiological protection training are described in Section 7.5 of the SNF Project FSAR.

A7.6 RADIATION EXPOSURE CONTROL

SNF Project details of radiation exposure control measures are provided in Section 7.6 of the SNF Project FSAR. Details specific to the CSB follow. Items 20 and 21 of HNF-SD-SNF-DB-003 require that the SNF Project incorporate, as applicable, the following NRC requirements.

- Incorporate control devices for access to high-radiation areas that conform to the requirements of 10 CFR 20, Section 20.1601, “Control of Access to High Radiation Areas.”

For the CSB, the radiological exposure annual dose criteria of 10 CFR 72.104 have been incorporated into the CSB design and safety analysis. These criteria apply to design measures to protect any offsite public individual during normal operations and anticipated occurrences. These annual dose equivalent criteria are 25 mrem to the whole body, 75 mrem to the thyroid, and 25 mrem to any other critical organ.
For the CSB, the criteria for hourly dose limit to the public as described in 10 CFR 20.1301 have been incorporated into the design and safety analysis. This dose limit (0.002 rem) is assumed to be from external sources for any unrestricted area during normal operations and anticipated occurrences.

During the CSB design reviews, no accessible high-radiation areas (≥0.1 rem/h at 30 cm) as defined by 10 CFR 20.1601 were identified; therefore, the requirements of 10 CFR 20.1601 do not apply. If during facility operations, a high-radiation area is identified, the requirements of 10 CFR 20.1601 will apply in accordance with NRC equivalency requirements (HNF-SD-SNF-DB-003, Item 20).

Access to the radiological area of the CSB (see Figure A7-1) is controlled using one or more of the methods listed and discussed in Section 7.6.2.6 of the SNF Project FSAR. Primarily, access control will be by the use of signs and barricades at the CSB, but other measures described in Section 7.6.2.6 of the SNF Project FSAR will be used when needed.

Permanent shielding is provided in the CSB as part of the operating deck and in the design of the MHM, sampling/weld station, the MCO service station, and the biological shield wall between the operating area and the operating support area. Shielding also is provided in the operator control areas and in regions around the vaults. Some of the major shielding and special tooling that is provided is discussed below. Radiological controls are incorporated into the operating procedures for these areas.

The CSB vaults are designed as three independent areas with full-length concrete shielded walls between them. Exterior walls of the subsurface structure are designed to limit dose rates outside the vaults to 0.1 mrem/h. The vault ceilings are designed to limit dose rates above the vaults to 0.05 mrem/h. Intake and exhaust plenums are designed to avoid radiation streaming and to limit dose rates outside the plenums to a maximum of 0.1 mrem/h. The MCO storage tubes are equipped with storage tube plug assemblies constructed of concrete and steel. These plugs limit the dose rate from the MCO stored in the tube to less than 0.2 mrem/h at the surface of the operating deck. A 2-ft-thick shield wall is installed at the north end of the operating deck adjacent to the operations support area.

The MHM is designed with permanent shielding to protect from direct radiation through the sides of the MHM and from radiation streaming through interface gaps between MHM components, and between the MHM and the operating area deck surface. A retractable shield skirt is placed over the storage tube deck opening to limit radiation exposure during shield plug removal and subsequent operations in the tubes. Shielding for the MHM cask and turret system consists of a combination of steel for gamma attenuation and a borated material for neutron absorption. See Chapter A2.0 for a detailed description of MHM shielding. Overall, the MHM shielding is designed to limit gamma exposure to operations personnel to an average of 0.2 mrem/h during MCO movement and handling. Exposure rates may exceed 0.2 mrem/h for short periods during raising and lowering MCOs, but the design will ensure that averaged and
peaking exposure rates will meet ALARA principles. Neutron exposure will be negligible (<10%) with respect to the gamma dose. There will be no direct alpha or beta dose.

The service station uses the transport cask–MCO closure plug as the main shielding for operations in this area. In addition, installation of the MCO mobile station hatch assembly provides some additional shielding. With the cask, this shielding reduces the average cumulative dose rate for cask unloading operations to approximately 1.96 mrem/h. The special tooling provided for operations in this pit is the mobile containment service tent, which is a portable and high-efficiency particulate air (HEPA) filter ventilation containment, to contain any potential airborne radioactivity. The ventilation unit exhausts into the operating area. The mobile service tent is intended for use during off-normal situations to control releases and will probably never be used.

The sampling/weld station uses permanent shielding for protection of the worker from radiation. This permanent shielding consists of immovable shielding and movable, specially designed shielding blocks that allow insertion of the MCO. The permanent shielding is designed to exceed the effectiveness of the cask shielding. The shielding reduces the average cumulative dose rate during sampling or welding operations to approximately 1.86 mrem/h. In addition, a HEPA filter ventilated welding system is provided for mitigation of potential airborne radioactivity during sampling or welding operations.

Based on Title 10, Code of Federal Regulations, Part 835, “Occupational Radiation Protection” (10 CFR 835), dose rate limits, a radiation buffer zone will be established outside of the CSB in the vicinity of the load-in/load-out area for the purpose of personnel protection when a cask–MCO is located within the truck vestibule or the load-in/load-out area. Field implementation of the buffer zone will be the responsibility of the radiological control organization.

Engineering and administrative controls have been included in the CSB design to minimize airborne radioactivity. The CSB ventilation is designed to maintain approximately -0.1 in. of H₂O pressure on the operating area and consists of a building ventilation system providing approximately 44,000 ft³/min of flow divided as follows:

- Approximately 35,500 ft³/min recirculation in the operating bay
- Approximately 9,000 ft³/min HEPA-filtered building exhaust
- Approximately 4,500 ft³/min HEPA-filtered ventilation from a sampling station into the operating bay system
- Approximately 4,500 ft³/min HEPA-filtered ventilation from a weld station into the operating bay system.
These systems will be used to control any potential airborne material as close to the source as possible and to provide general ventilation of the facility. In addition to these installed systems, portable HEPA filter ventilation systems will be utilized as needed by the radiological job planning of the work. These systems range from 500 to 2,000 ft³/min and will exhaust into the operating bay.

Section 20.4 of HNF-SD-SNF-RD-001, SNF Project Standards/Requirements Identification Document, and Title 40, Code of Federal Regulations, Part 61, “National Emission Standards for Hazardous Air Pollutants” (40 CFR 61), require that doses received by the maximally exposed individual from emissions of radionuclides shall not exceed 10 mrem/yr. To meet this standard, engineered ventilation systems as described in Chapter A2.0 have been provided to abate radioactive particulate emissions. The ventilation system HEPA filters are accepted by the Washington State Department of Health as the best available radionuclide control technology. Calculations of projected emissions required by 40 CFR 61 result in the requirement for continuous airborne emission monitoring. The CSB heating, ventilation, and air conditioning airborne emissions monitoring system described in Chapter A2.0 satisfies the 40 CFR 61 monitoring system requirements. This system provides strictly sampling and monitoring functions and provides no operational control functions. Analysis results indicate that abated emissions will be less than the 10 mrem/yr maximally exposed individual limit. The CSB design prevents a release of radioactive liquid during normal operations as described in Section A2.8.6.

See the SNF Project FSAR, Section 7.6.2.4 discussion of MCO and transportation cask shielding.

A7.7 RADIOLOGICAL MONITORING

The radioactive material sampling and monitoring programs conducted internal and external to SNF Project facilities are addressed in Section 7.7 of the SNF Project FSAR. As SNF begins to arrive at the CSB, a startup surveillance and monitoring program will be implemented to define and characterize exposure rates and to ensure that neutron and gamma dose rates are in agreement with anticipated levels.

The CSB stack emissions monitoring system is described in Chapter A2.0.

A7.8 RADIOLOGICAL PROTECTION INSTRUMENTATION

A summary of the SNF Project plans and procedures governing radiation protection instrumentation is provided in Section 7.8 of the SNF Project FSAR. A description of the types and locations of radiation detection instruments used at the CSB is presented in Chapter A2.0.
A7.9 RADIOLOGICAL PROTECTION RECORD KEEPING

Radiological protection record keeping requirements are described in Section 7.9 of the SNF Project FSAR.

A7.10 OCCUPATIONAL RADIATION EXPOSURES

For the CSB, occupational radiation exposures to workers are estimated based on the following:

- Receipt and movement of MCOs into the storage vaults during the first two years of operation and the processes associated with MCO receipt and movement
- MCO validation sampling and monitoring
- Interim storage of SNF and maintenance and operations activities associated with SNF storage.

As discussed in Section A7.4, block flow diagrams and shielding analysis were used to estimate time durations to complete operational tasks, dose equivalent rates, and cumulative dose rates during unloading, sampling, welding, and handling MCOs. Transmittal FDP-788, Canister Storage Building ALARA Analysis 09, documents the ALARA assessment including assumptions and conclusions. The ALARA analysis estimates are based on assumed minimum and maximum dose rates and intervals and a selected probability distribution. For analysis purposes, it was assumed that 200 MCOs would be transported to the facility each year. The main contributors to exposure were MCO receipt and handling, and cap welding.

Occupancy within the CSB vault operation area during interim storage is estimated to be 25% of 2,000 working hours per year. Monte Carlo methods have been employed to determine the exposure levels for this occupancy. Data used to obtain the estimates using the Monte Carlo method included ranges of task duration and dose rate changes for these tasks. A detailed discussion of the Monte Carlo simulations used are included in Transmittal FDP-788.

Based on the ALARA analysis results, average operator exposure levels are expected to be as follows:

- 860 mrem/yr total effective dose equivalent for unloading, sampling, welding, and handling the MCOs
- 50 mrem/yr total effective dose equivalent for general operations during MCO storage.
Exposures for other categories of workers are considerably less. The exposure levels for handling MCOs contains an increment based on neutron dose (40 mrem/year).

A8.0 HAZARDOUS MATERIAL PROTECTION

A8.1 INTRODUCTION

The major provisions of the occupational safety and health program, as the program applies to hazardous material protection for the Spent Nuclear Fuel (SNF) Project, are addressed in Chapter 8.0 of the SNF Project Final Safety Analysis Report (FSAR).

A8.2 REQUIREMENTS

The requirements that form the basis for the hazardous material protection program are identified in Section 8.2 of the SNF Project FSAR.

A8.3 HAZARDOUS MATERIAL PROTECTION PROGRAM AND ORGANIZATION

The SNF Project has an established, visible, and comprehensive occupational safety and health program. This program is described in Section 8.3 of the SNF Project FSAR.

A8.4 ALARA POLICY AND PROGRAMS

While there is no established formal SNF Project as-low-as-reasonably-achievable (ALARA) program for nonradiological hazardous materials, the SNF Project has expanded the classic concept of ALARA (i.e., minimization of radiological exposures) to the application of exposure minimization for all hazardous substances and conditions. The SNF Project's policy is described in Section 8.4 of the SNF Project FSAR.

Work practices for hazardous material protection and control of chemical exposures as stated in Section 8.4 of the SNF Project FSAR will be implemented at the Canister Storage Building (CSB) using approved SNF Project implementing procedures. The occupational safety and health program will use the additional provisions of Section 8.4 of the SNF Project FSAR. These will be implemented at the CSB using approved SNF Project implementing procedures.

Applicable ergonomics considerations, included in DOE Order 5480.10, Contractor Industrial Hygiene Program (Section 9B), under the occupational safety and health program, industrial hygiene subprogram, are included in Chapter A13.0. Ergonomics considerations, along with risk factor control processes and the ergonomics program, are described in the SNF Project human engineering program plan (see Section 8.4 of the SNF Project FSAR and SNF-4399, Spent Nuclear Fuel Project Human Engineering Program Plan).
A8.5 HAZARDOUS MATERIAL TRAINING

Plans and procedures for training SNF Project workers regarding hazardous materials are summarized in Section 8.5 of the SNF Project FSAR.

Section 8.5 of the SNF Project FSAR states that SNF Project management provides training, professional education, and certification opportunities necessary to support, maintain, and enhance industrial hygiene staff proficiency to meet or exceed U.S. Department of Energy industrial hygiene training objectives and goals in accordance with HNF-SD-SNF-RD-001, *SNF Project Standards/Requirements Identification Document*. CSB management is responsible for ensuring that workers assigned to any task involving hazardous materials are trained in the safety and health hazards associated with such hazardous materials. Workers will perform only those tasks for which they have received the proper training. As the CSB mission changes, CSB management will review the training requirements and modify worker training requirements accordingly. CSB management is also responsible for ensuring that retraining is provided within the time allowed by training course requirements.

A8.6 HAZARDOUS MATERIAL EXPOSURE CONTROL

Worker safety features at the CSB are an integral part of facility design and operation. The CSB design encompasses human factors considerations to ensure that operations can be conducted safely. SNF Project occupational exposures to hazardous materials and the spread of hazardous material contamination are controlled by a combination of engineered, operational, and administrative controls, and by the use of personal protective clothing and equipment. These controls are described in Section 8.6 of the SNF Project FSAR.

No significant hazardous materials have been identified at the CSB as a result of a hazard analysis that was performed and documented in HNF-SD-SNF-HIE-001, *Canister Storage Building Hazard Analysis Report*, except for the radionuclide content in the multi-canister overpacks (MCOs). Major features of worker protection are presented in Chapter A3.0 and are categorized by hazard. These features are in addition to safety-class or safety-significant features for design basis accidents. The toxicological hazards of this radionuclide inventory were evaluated in HNF-SD-SNF-TI-059, *A Discussion on the Methodology for Calculating Radiological and Toxicological Consequences for the Spent Nuclear Fuel Project at the Hanford Site*, and found to be bounded by the radiological consequences.

All work activities in the CSB will receive adequate advance planning so that if potential hazardous materials are identified due to changing conditions in the future, specific precautions will be applied. The exposure controls identified in Sections 8.6.1 through 8.6.4 of the SNF Project FSAR will then be implemented at the CSB using approved SNF Project implementing procedures.
Results of detailed CSB hazard analysis are presented in table form in HNF-SD-SNF-HIE-001. The primary inventory of hazardous material in the CSB involves the radionuclide content in the MCOs. Other hazardous material identified by the hazard identification process includes asphyxiants (diesel exhaust, helium, inert gas), biological agents (snakes, spiders), carcinogens (welding fumes), corrosives (battery acid), toxics (fuels, welding fumes, uranium, plutonium), heavy metals (lead in batteries, welding fumes), flammable or combustible materials (gasoline, diesel fuel, paint solvents), and others (used decontamination rags, glycol for cooling). No routine chemical processes will be conducted in the CSB. Some chemicals, such as those used for equipment decontamination, may be used occasionally.

Section 1.2.1 of SNF-3328, Canister Storage Building Design Basis Accident Analysis Documentation, states that there are no chemical inventories of safety concern. Table A3-1 identifies hazards by form, type, location, and total quantity.

The MCO is backfilled to a prescribed pressure at the Cold Vacuum Drying Facility, using helium, just before it is sealed for shipment to the CSB. Internal pressure can increase, as a function of time, because of the radiolytic decomposition of water and aluminum hydroxide inside the MCO and the release of hydrogen from the chemical reaction of water with metallic fuel. Uncontrolled release of this MCO internal gas pressure is an operational accident resulting from failure of MCO sampling system equipment, breach of the MCO, or operator error during the MCO sampling process.

As indicated in Chapter A4.0, safety-class and safety-significant structures, systems, and components prevent or mitigate gaseous release events. In addition, technical safety requirements are developed to govern activities associated with potentially high concentrations of hydrogen. Workers performing such activities are trained on the appropriate precautions to be taken, including evacuation of the area. The monitoring portion of the hydrogen control strategy is described in Section A8.7.

Other hazardous materials at the CSB will be properly inventoried and stored to control hazards inherent to the material in accordance with SNF Project implementing procedures.

A8.7 HAZARDOUS MATERIAL MONITORING

Summaries of the hazardous material sampling and monitoring programs that are conducted internally and externally for SNF Project facilities are provided in Section 8.7 of the SNF Project FSAR. The workplace and external monitoring program described in Sections 8.7.1 and 8.7.2 of the SNF Project FSAR will be implemented at the CSB using approved SNF Project implementing procedures. An environmental, radioactivity, and chemical emissions monitoring program, including requirements, is presented in Section 8.7.2 of the SNF Project FSAR. This program will be implemented for the CSB in accordance with approved SNF Project implementing procedures.
As discussed in Chapter A3.0, the MCO is prone to hydrogen gas generation from metal oxidation reactions and radiolysis of bound and free water. The hydrogen control strategy includes inerting of the MCOs and dilution with inert gas at the Cold Vacuum Drying Facility. As part of the process validation program, a sample of the gas in the MCO is collected and sent to a laboratory for analysis. Sample collection will be discontinued when the validation program determines sampling is no longer required.

A8.8 HAZARDOUS MATERIAL PROTECTION INSTRUMENTATION

Summaries of plans and procedures governing hazardous protection instrumentation are provided in Section 8.8 and Table 8-2 of the SNF Project FSAR. As stated in Section 8.8 of the SNF Project FSAR, safety and health specialists will determine any need for hazardous protection instrumentation and the number and placement of instruments in the CSB under normal and emergency conditions in accordance with the requirements stated in Section 8.8 of the SNF Project FSAR.

A8.9 HAZARDOUS MATERIAL PROTECTION RECORD KEEPING

The SNF Project has an established document control and records management program. This program is summarized in Section 8.9 of the SNF Project FSAR.

A8.10 HAZARD COMMUNICATION PROGRAM

The hazard communication program applies to the purchase, receipt, use, and storage of hazardous chemicals and products. This program is summarized in Section 8.10 of the SNF Project FSAR. The hazard communication program for the CSB will be implemented in accordance with provisions of Sections 8.10.1 through 8.10.6 of the SNF Project FSAR including hazard posting in work areas, chemical management, chemical labeling, chemical product list, material safety data sheets, information, and training. This will be accomplished in accordance with approved SNF Project implementing procedures.

A8.11 OCCUPATIONAL CHEMICAL EXPOSURES

Predicted annual exposures to workers from hazardous material sources are identified in Section 8.11 of the SNF Project FSAR. As discussed in Section 8.11 of the SNF Project FSAR, the projected annual exposures to workers at all SNF Project facilities, including the CSB, are expected to be negligible. Also see Section 8.10 of the SNF Project FSAR for identification of chemical hazard locations, posting, chemical management, and other controls to limit occupational chemical exposure.

A9.0 RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT

A9.1 INTRODUCTION

The essential features of the radioactive and hazardous waste management programs that provide for safe control, collection, and handling of wastes generated during routine operations at Spent Nuclear Fuel (SNF) Project facilities are detailed in Chapter 9.0 of the SNF Project Final Safety Analysis Report (FSAR). This chapter only applies to waste generated within the Canister Storage Building (CSB) and those processes and systems designed to deal with that waste. The only potentially radioactive waste from normal operations at the CSB is radioactively contaminated high-efficiency particulate air (HEPA) filter elements, waste from normal radiation monitoring and decontamination processes, and waste and debris generated from the multi-canister overpack (MCO) cap welding process. Small volumes of nonradioactive hazardous and nonhazardous wastes also will be generated.

A9.2 REQUIREMENTS

The requirements that form the basis for the radioactive and hazardous waste management program are identified in Section 9.2 of the SNF Project FSAR.

A9.3 RADIOACTIVE AND HAZARDOUS WASTE MANAGEMENT PROGRAM AND ORGANIZATION

The facility administrative procedures for solid waste management contain the procedural guidance for the planning, generation, and disposal of generated waste in compliance with applicable requirements. The administrative procedures cover characterization, preplanning, designation, containerization, disposal, and programmatic requirements. A summary of the SNF Project waste management program is provided in Section 9.3 of the SNF Project FSAR.

A9.4 RADIOACTIVE AND HAZARDOUS WASTE STREAMS AND SOURCES

The following subsections identify the CSB waste streams, their sources, and their management.

A9.4.1 Waste Management Process

The goals and policies of the CSB hazardous and radiological waste management process are described in Section 9.4.1 of the SNF Project FSAR.
A9.4.2 Waste Sources and Characteristics

At the CSB, both solid and liquid wastes will be generated in small volumes and gas emissions will be released. The expected generation rates of each CSB waste stream are listed in Table A9-1. The following subsections describe the sources of solid and liquid waste summarized in Table A9-1.

Table A9-1. Waste Generation Rates for the Canister Storage Building.

The emission control and monitoring systems satisfy state and federal requirements and are permitted.</td>
</tr>
</tbody>
</table>

HEPA = high-efficiency particulate air (filter).

A9.4.2.1 Solid Waste Streams and Sources. The HEPA filters will be handled as radioactive solid waste as warranted by the level of activity present. At the CSB, loaded HEPA filters will be generated as a solid waste or a potentially radioactive waste. HEPA filter elements will be used for the MCO servicing system, MCO handling machine, and MCO sampling hood. Chapter A2.0 discusses the operating circumstance under which these filter elements can receive a loading of radioactive particulate. The filters are not expected to have hazardous materials deposited on them. Other process HEPA filters serve as a backup for the MCO filters and should not be contaminated. The building heating, ventilation, and air conditioning HEPA filters are a third level of backup and also are not expected to be contaminated. Solid waste debris is generated during normal operations, equipment maintenance, monitoring of stored SNF, and during any necessary cleanup following abnormal events. Radioactive wastes will be generated from decontamination necessary for maintenance and repair of contaminated equipment, such as the tube vent and purge carts or MCO service station enclosure. The debris wastes will consist of...
contaminated protective clothing, small tools, equipment, vegetation, animal carcasses, and welding debris.

A9.4.2.2 Liquid Effluents and Sources. The only expected water discharges at the CSB are sewage from the temporary office building (a trailer located near the CSB), which will be tied to a septic tank and drain field. A small amount of condensate from the CSB heating, ventilation, and air conditioning cooling coils (less than 40 gal/yr) will be generated during the more humid months of June and July.

A9.4.2.3 Gaseous Effluents and Sources. The CSB is permitted for airborne emissions by DOE/RL-98-30, Radioactive Air Emissions Notice of Construction Canister Storage Building (Revised Sealing Configurations for Spent Nuclear Fuel) Project W-379. See Section 9.4.2.3 of the SNF Project FSAR for general information regarding gaseous effluents and sources. See Chapters A2.0 and A7.0 for information regarding CSB airborne emission criteria and monitoring.

A9.4.3 Waste Handling or Treatment Systems

Solid radioactive wastes including heating, ventilation, and air conditioning HEPA filters; HEPA filters from MCO handling; and other operational wastes (e.g., rags and wipes) will be packaged per the Waste Management Federal Services of Hanford, Incorporated waste acceptance requirements defined in HNF-EP-0063, Hanford Site Solid Waste Acceptance Criteria, described in Section 16 of HNF-SD-SNF-RD-001, SNF Project Standards/Requirements Identification Document, and in facility waste management plans, and then transported to Waste Management Federal Services of Hanford, Incorporated, for disposition.

Hazardous materials such as batteries and fluorescent light bulbs will be picked up and recycled by commercial vendors or other appropriate site disposal methods. Hazardous waste such as waste oils will be collected in approved collection areas and shipped for disposal per site procedures and per the requirements of DOE Order 5820.2A, Radioactive Waste Management.

Sewage from the temporary office building will be sent to a septic tank and drain field. The condensate from the CSB heating, ventilation, and air conditioning cooling coils will be discharged to the ground consistent with the requirements of ST 4509, Washington State Department of Ecology Waste Water Discharge Permit.

Other potential nonregulated wastes will be handled as described in Section 9.4.2.1.3 of the SNF Project FSAR.

Airborne wastes are filtered by HEPA filters and then released per permit as noted in Section A9.4.2.3.
There is no special treatment system for fire sprinkler water in the case of actuation. Water will be noncontaminated and will be allowed to run out of the doors and other building openings.

A10.0 INITIAL TESTING, IN-SERVICE SURVEILLANCE, AND MAINTENANCE

A10.1 INTRODUCTION

Essential features of the initial testing program, the operational readiness review, the in-service surveillance program, and the maintenance program implemented at Spent Nuclear Fuel (SNF) Project facilities are described in Chapter 10.0 of the SNF Project Final Safety Analysis Report (FSAR). Canister Storage Building (CSB)-specific features of these programs are described in this Chapter A10.0.

A10.2 REQUIREMENTS

The requirements that form the basis for the initial testing program, the operational readiness review program, the in-service surveillance program, and the maintenance program are identified in Section 10.2 of the SNF Project FSAR.

A10.3 INITIAL TESTING

The SNF Project initial testing program ensures the operability of equipment and facilities before facility operation. Project details of this program are provided in Section 10.3 of the SNF Project FSAR.

A10.4 IN-SERVICE SURVEILLANCE PROGRAM

The SNF Project in-service surveillance program is designed to maintain the integrity of facility systems and to ensure that systems perform their function of protecting the health and safety of the public, workers, and facility staff by prevention or mitigation of accident consequences. Details of this program are provided in Section 10.4 of the SNF Project FSAR. The technical safety requirements that include the surveillance requirements for the CSB are described in Chapter A5.0.

A10.5 MAINTENANCE PROGRAM

Section 10.5 of the SNF Project FSAR summarizes the maintenance program that supports safe operation of the SNF Project facilities. The structures, systems, and components (SSCs) that are important in the mitigation and prevention of analyzed accidents and are included in the formal CSB maintenance program are identified in Chapters A3.0 and A4.0 of this document.
The maintenance program for the SNF Project facilities is conducted in accordance with DOE Order 4330.4B, *Maintenance Management Program*, which provides general policy and objectives for establishing cost-effective maintenance and repair of U.S. Department of Energy property. The maintenance program will incorporate the results of considerable project activity and subsystem vendor interface activity aimed at ensuring an acceptable design and acceptable operating practices relative to reliability, availability, and maintainability.

Operational design information has been used as input to a process system design basis capacity study of the SNF Project documented in HNF-SD-SNF-RPT-011, *Spent Nuclear Fuel Project Design Basis Capacity Study*. This study used a summary-level model of major SNF Project facilities to determine the impact of facility interactions on the overall time to complete fuel removal operations. The results indicate that to support a CSB throughput of one multi-canister overpack (MCO) per day, one sampling/weld station is required, whereas two sampling/weld stations are provided in the CSB design. Two stations permit sampling and welding operations to proceed concurrently.

HNF-S-0425, *Specification for Spent Nuclear Fuel Canister Storage Building*, includes maintainability and availability requirements for the facility and specifies a 40-year service life for the facility structures and systems that directly support interim storage and a 5- or 10-year life for SSCs used in the preparation of MCOs for storage (e.g., the sampling/weld station). HNF-S-0425 specifies the following concepts for use in the CSB design:

- Maximize equipment interchangeability
- Operate power transmission devices below 75% of ratings
- Provide adequate equipment materials for the operating environment
- Utilize commercially available equipment
- Identify equipment repair methods and egress routes
- Locate complex components including electronic devices or those having a high probability of failure in nonradioactive areas
- Cranes and hoists required for handling radioactive waste shall meet designated requirements including those in the applicable portions of ASME NOG-1-1995, *Rules for Construction of Overhead and Gantry Cranes (Top Running Bridge, Multiple Girder)*.

Operations, startup, and maintenance personnel have participated in the design process through support of design reviews and participation in appropriate portions of factory testing of SSCs, specifically the MCO handling machine (MHM), the tube vent and purge cart, and sampling/weld station equipment. These review activities have resulted in suggested
improvements regarding operability and maintainability. These proposed improvements have been presented to the design organization and evaluated in subsequent design activities to identify impacts on capital, operations, and maintenance costs. Design reviews to date have identified no high-maintenance components.

The design organization has included in subcomponent purchase requests (by applying Specification 01730, Operations and Maintenance Data [W-379-C-CSB-01730]) requirements that vendors provide maintenance recommendations for their components and subsystems based on past experience. These recommendations include spare parts inventories, maintenance and repair procedures and suggested frequencies, and requirements for special maintenance tools. Most of the CSB equipment designs apply commercially available components, and vendors are required to include maintenance accessibility and testability in their designs.

Early in the CSB Project, a reliability analysis plan was developed to guide the preparation of the assessment of the availability and total operational efficiency of the facility. The plan was attached to Transmittal FRT-2660/9600454, Reliability Analysis Plan (Jacobs 1996). Its purpose was to identify cost-effective improvement measures in the design. Several failure modes and effects analyses were performed both on material handling equipment and on key CSB process SSCs including the receiving crane, the vault, the deck, the tube vent and purge cart, and the MHM. Although the emphasis of these analyses was on safety, productivity and maintainability issues were identified as appropriate. Results of these analyses were used to influence designs to enhance the reliability and maintainability of CSB systems and components.

The Project recognizes the critical role of the MHM in the overall success of the CSB facility. Accordingly, numerous studies and analyses have been performed to enhance the reliability, operability, and maintainability of this essential system. Failure modes and effects analyses for two subsystems (control system and hoist and grapple) have been performed. In addition, the analysis documented in Letter DESH-9760688, Reliability/Availability/Maintainability Analysis for the Multi-Canister Overpack Handling Machine (Daughtridge 1997), was performed for the entire MHM based on the 90% design status point. This analysis concluded that the probability of the MHM operating for 8 hours without failure was 98.1%, and identified an availability of the MHM of 90%. The mean times to repair were determined to be relatively short (on the order of a few hours). The analysis in Letter DESH-9760688 (Daughtridge 1997) points out that further simplification of the MHM control system design to reduce the number of interlocks would achieve significant reliability and availability improvements. Subsequently, an independent review of the MHM design was conducted primarily for the purpose of simplifying the design. At about the same time, a second television camera was included in the design for positioning the MHM. A mockup of the control panel was constructed, and a human factors review was conducted. Results of the human factors review were assessed by operations personnel, and an action plan for grouping and labeling controls was adopted. The results of all of these activities coupled with a change in the CSB technical basis (sealed MCO strategy) have resulted in a simpler, more reliable and dependable MHM.
In summary, considerable interface has occurred between organizations contributing to the
design of the CSB relative to availability, operability, and maintainability, and the results have
been considered in the present CSB and MHM designs. This interchange of information will
continue as the facility progresses into startup testing and operational phases.

The SNF Project has completed failure mode and effects analyses and fault tree analyses as
part of the FSAR hazards assessments, which includes evaluating routine maintenance activities.
There are no maintenance activities identified other than the specific technical safety requirement
surveillance items required for operations to be bounded by the authorization basis. The SSCs are
designed to place the MCO in a safe and stable state without operator action. Preventive
maintenance and calibrations are utilized to provide continued operability of facility systems and
components.

The maintenance plan to be described in the SNF maintenance implementation plan, which
is submitted to the U.S. Department of Energy, Richland Operations Office for approval, will
implement a graded approach to CSB maintenance activities based on sound engineering
judgment and knowledge of the facility and will take into consideration the following items.

- Results of the reliability, availability, and maintainability analysis performed on the
  MHM.
- With the exception of the MHM, the design life for the equipment used during the
  preparation for storage is a minimum of 5 years, whereas the expected operational
  life of these systems is 3 years. This short operating life would argue against an
  extensive predictive maintenance program and would justify a simple maintenance
  history program.
- The passive nature of the systems and components supporting interim storage also
  would seem to justify a simple preventive maintenance and overhaul program.
- Wherever practicable, the CSB equipment designs incorporate commercially available
  equipment with readily available spare parts and a proven record of performance.
- No components are subjected to severe duty conditions.
- Availability of an MHM maintenance pit to facilitate the periodic servicing
  recommended by the vendor, plus MCO and tube plug grapple surveillance and load
  testing.
- The sampling/weld stations have built-in redundancy.

Policies and procedures are in place to effectively manage SNF Project facility maintenance
activities. The SNF Project FSAR, Section 10.5, summarizes the maintenance policies and
procedures that are implemented at the CSB and also describes the process used during the
development of the detailed content of the maintenance plan. The SSCs that are important in the
mitigation and prevention of analyzed accidents and that are included in the CSB maintenance
plan are identified in Chapters A3.0 and A4.0. Following completion of the MCO
loading/welding operations, the SNF Project will define the details of the CSB MHM layup
maintenance activities based on operating experience and vendor recommendations.

A11.0 OPERATIONAL SAFETY

A11.1 INTRODUCTION

Features of the Spent Nuclear Fuel (SNF) Project conduct of operations program and fire protection programs are described in the following sections and in Chapter 11.0 of the SNF Project Final Safety Analysis Report (FSAR).

A11.2 REQUIREMENTS

The requirements that establish the basis for conduct of operations and general aspects of operational safety are identified in Section 11.2 of the SNF Project FSAR.

A11.3 CONDUCT OF OPERATIONS

"Conduct of operations" is a set of principles that establishes an overall philosophy for achieving excellence in the operation of the SNF Project facilities. SNF Project application of conduct of operations principles is described in Section 11.3 of the SNF Project FSAR.

A11.4 FIRE PROTECTION

The SNF Project facilities fire protection programs are addressed in Section 11.4 of the SNF Project FSAR. The results of a Canister Storage Building (CSB) fire hazard analysis, documented in HNF-SD-SNF-FHA-002, Final Fire Hazard Analysis for the Canister Storage Building, are addressed in Chapter A3.0 and are summarized in the following subsections.

A11.4.1 Fire Hazards

The fire hazard analysis documented in HNF-SD-SNF-FHA-002 was developed in accordance with Section 12.4.6 of HNF-SD-SNF-RD-001, SNF Project Standards/Requirements Identification Document. The analysis comprehensively assessed the risk from fire at the CSB to determine the following: (1) that the potential for occurrence of fire is minimized; (2) that requirements that will provide an acceptable degree of life safety to SNF Project and contractor workers are in place, and there are no undue hazards to the public from fire and its effects in SNF Project facilities; (3) that the CSB facilities achieve “nuclear safety equivalency” to comparable U.S. Nuclear Regulatory Commission (NRC)-licensed facilities; (4) that the Uniform Building Code (ICBO 1994) Type II-N building construction criteria for the CSB is adequate as compared to the NRC recommended Type I building construction criteria; (5) that the fire protection requirements in Title 10, Code of Federal Regulations, Part 72, “Licensing Requirements for the
Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste,”
Section 72.122(e) “Proximity of Sights” (10 CFR 72), are general and comparable to the
requirements in DOE Order 5480.7A, Fire Protection, and DOE Order 6430.1A, General Design
Criteria; and (6) that safety systems are not damaged by fire. The fire hazard analysis along with
the accident analyses determined that a fire would not cause onsite or offsite release of
radiological or other hazardous materials that would threaten the public health and safety or the
environment. The fire hazard analysis states that consideration should be given to following the
evolving designs of the new SNF Project Path Forward facilities to reconfirm that the CSB fire
protection features continue to provide adequate fire protection meeting the requirements of DOE
Order 5480.7A, and DOE Order 6430.1A.

The CSB fire hazard analysis (HNF-SD-SNF-FHA-002) was prepared to meet the
requirements of DOE Order 5480.7A. As required, this analysis addressed the following
elements. No unacceptable conditions were identified.

- Description of construction
- Protection of essential safety-class equipment
- Fire protection features
- Description of fire hazards
- Life safety considerations
- Critical process equipment
- High value property
- Damage potential; maximum credible fire loss and maximum possible fire loss
- Fire department or brigade response
- Recovery potential
- Potential for toxic, biological, and/or radiation incident due to a fire
- Emergency planning
- Security considerations related to fire protection
- Natural hazards (earthquake, flood, wind) impact on fire safety
- Exposure fire potential, including the potential for fire spread between fire areas.

Facility modifications will be screened to fire hazards analysis requirements and will receive
an unreviewed safety question review.

The CSB consists of two adjoining fire areas: the operating area (which includes the three
storage vault areas, the operating deck, and the trailer vestibule), and the operations support area
(which includes the control room, the change room, and electrical and mechanical equipment
rooms). Analysis of the consequences and probabilities of a worst-case fire for the CSB indicates
that the maximum possible fire loss for the facility would be realized in a fire in the operations
support area. An operating area fire was also evaluated, but losses from a fire event were
determined to be bounded by an operations support area fire because of limited and dispersed
combustible loading within the operating area. The total cost of facility cleanup and equipment
and structure replacement of an operations support area fire would be $11.72 million.
This amount does not include any environmental cleanup of the radionuclides dispersed from the
CSB high-efficiency particulate air filtration system that is included in the postulated fire zone. Because the multi-canister overpacks vent through local high-efficiency particulate air filters at the sampling/weld station before exhausting through the building filters, the radionuclide content on those filters is anticipated to be relatively low. No toxicological or biological consequences resulting from any credible fire are anticipated. Refer to HNF-SD-SNF-FHA-002 for additional detail. The maximum possible fire loss for the operating area is $5.18 million resulting from a fire involving hydraulic fluid and lubricating oil on the multi-canister overpack handling machine trolley drive assembly.

A11.4.2 Fire Protection Program and Organization

The fire protection program for the SNF Project facilities is structured and implemented in accordance with the operating contractor's safety management policies, philosophies, and the criteria identified in SNF Project administrative procedures. CSB-specific aspects of the fire protection program are provided in the following paragraphs.

The operating area and operations support area are separated by two-hour fire rated walls, and the operations support area is protected by a wet pipe sprinkler system. The design also includes automatic shutdown of appropriate heating, ventilation, and air conditioning units upon receipt of a fire alarm. The normal water supply to the facility fire protection systems is the service water system. A second water supply is provided by a storage tank and pumping system dedicated to the fire water loop around the CSB and Building 2704-HV. The CSB fire protection system is classified as general service.

DOE Order 5480.7A and the Uniform Building Code (ICBO 1994) invoked by DOE Order 6430.1A require sprinkler protection for the operating area. An exemption from the DOE Order 5480.7A requirement and a deviation from the DOE Order 6430.1A and Uniform Building Code (ICBO 1994) requirements have been approved by U.S. Department of Energy, Richland Operations Office, as documented in Letter 96-SFD-320, Contract No. DE-AC06-96RL13200 — Project W-379, Spent Nuclear Fuel Canister Storage Building (CSB) Review and Approval of Exemption and Deviation Requests from Automatic Fire Sprinkler/Fire Suppression System Requirements (Sellers 1996). The basis for the deviation and exemption is that sprinklers provide little value to either prevention or mitigation of a hydrogen fire or the other fires evaluated in the fire hazard analysis.

Life safety criteria are met as required by NFPA 101, Life Safety Code. Life safety in the facility is satisfactory.
A11.4.3 Combustible Loading Control

The absence of a sprinkler system in the operating area places an even greater importance on the control (quantity and location) of combustibles in this area; thus, the operating deck will not be used as an area for storing fixed or transient combustible materials.

Calculations contained in HNF-SD-SNF-FHA-002 provide limits for the amount and location of combustibles to preclude damage to the building structure and high-value equipment. Administrative controls will be used to control combustible quantities and separation distances based on HNF-SD-SNF-FHA-002, Table 5-4, calculations. Per HNF-SD-SNF-FHA-002, the following administrative controls will be employed to control combustibles within the operating area with respect to defined fuel packages, arrangement, separations from other fuel packages, and locations on the operating deck.

- Combustible materials inherent to all equipment proposed for use within the operating area shall be as low as reasonably achievable. This includes limiting the use of materials with combustible components and, whenever possible, replacing them with either noncombustible or fire resistant or retardant components.

- To limit the damage potential resulting from a vehicle fuel spill and fire in the trailer vestibule, the receiving crane shall be restricted by administrative procedure or control from that area during those periods when a truck or tractor is located within the trailer vestibule. In addition, a dam in the receiving area crane rail trench prevents diesel fuel from flowing into the load-in/load-out and operating areas.

- Transient combustible materials shall be limited to the minimum type and quantities required to perform the transient activity or operation and shall be removed upon completion of that activity or operation.

- The potential fire size resulting from a transient combustible fire shall be controlled by restricting the size and quantity of potentially combustible materials and maintaining the minimum separation distances identified in HNF-SD-SNF-FHA-002, Table 5-4.

- The leakage of fluid from the receiving crane or multi-canister overpack handling machine shall require the immediate safe shutdown of operations until corrective action to seal the leak is completed and the fire hazard inherent to the leak is eliminated.

These controls will be implemented through operating procedures as prescribed in HNF-SD-SNF-RD-001, Section 12.2.1.
A11.4.4 Fire Fighting Capabilities

The Hanford Fire Department maintains a training program for fire fighting, fire testing, and fire inspection. Fire fighting capabilities that apply to all SNF Project facilities are addressed in Section 11.4.4 of the SNF Project FSAR. CSB-specific fire response procedures are addressed in the following paragraph.

All areas of the CSB are automatically monitored for fire and smoke. Fire alarm features include transmission of signals to the Hanford Fire Department via a radio fire alarm reporter. A fire brigade is not required at the CSB due to the close proximity of the Hanford Fire Department. The standard response to an alarm condition in the 200 East Area is by the Hanford Fire Department from the 200 Area Fire Station, which is fully staffed, trained, and equipped. Hanford Fire Department response time to the CSB is approximately five minutes. These are the response times and the responder locations assumed in HNF-SD-SNF-FHA-002. When manned, a crew from the 100 Area Fire Station also is dispatched, with an estimated response time of 10 minutes. Vehicle access to the CSB is provided by a paved access road. Refer to WHC-SP-1180, Hanford Site Emergency Response Needs, Volume I, “Needs Assessment,” and Volume 2, “Master Plan,” for additional description of Hanford Fire Department response capabilities.

A11.4.5 Fire Fighting Readiness Assurance

A prefire plan for the CSB will be prepared by the Hanford Fire Department prior to facility operations. HNF-SD-SNF-FHA-002 provides a description of fire fighting methods that will be employed in the plan.

Due to the limitation on using large quantities of water in the operating area, fire fighting methods will include, as a first line approach, the following:

- Portable fire extinguishers
- Low-expansion foam
- Water fog.

If these methods fail to extinguish a fire, water hose streams may be employed.

A summary of SNF Project fire prevention inspections, fire safety drills and exercises, and program record keeping requirements is provided in Section 11.4.5 of the SNF Project FSAR.

A12.0 PROCEDURES AND TRAINING

A12.1 INTRODUCTION

A description of the essential features of Spent Nuclear Fuel (SNF) Project procedures and training programs is provided in Chapter 12.0 of the SNF Project Final Safety Analysis Report (FSAR).

A12.2 REQUIREMENTS

The requirements that form the basis for the SNF Project procedures and training programs are identified in Section 12.2 of the SNF Project FSAR.

A12.3 PROCEDURE PROGRAM

SNF Project activities are conducted in accordance with written procedures. A summary of the facility procedures program, including development and maintenance of procedures, is provided in Section 12.3 of the SNF Project FSAR and its subsections.

A12.4 TRAINING PROGRAM

The objective of the SNF Project personnel training program is to provide and maintain a qualified work force for safe and efficient facility operations. A summary of the SNF Project personnel training program—including training development, maintenance of training, and modification of training materials—is provided in Section 12.4 of the SNF Project FSAR and its subsections.

Training needs associated with the multi-canister overpack handling machine (MHM) are determined and developed using a systematic approach to training as stated in Section 12.4.1 of the SNF Project FSAR. A job task analysis that identifies the knowledge and skills required to operate the MHM has been performed. Operations personnel working with the MHM will be required to obtain a certification based on the knowledge and skills identified in the job task analysis. Certification will require passing written examinations and performance evaluations. For the certification of the initial operating crews, it has been determined that knowledge-based training will be primarily presented in the classroom and skills-based tasks will be primarily addressed by on-the-job training activities. Training emphasis will be placed on on-the-job training and will include operation of the MHM with dummy multi-canister overpacks as part of the equipment check dry runs or as part of special training evolutions. Consistent with the
SNF Project training program, detailed MHM operator training will include the following subjects:

- MHM systems including interlocks, controls, and indications
- MHM operations procedures
- MHM alarms and alarm response procedures
- MHM accidents, malfunctions, and emergency procedures.

Instructor qualification will be completed as stated in Section 12.4 of the SNF Project FSAR. MHM operating experience is included in the continuing training program as determined by line management.

Maintenance personnel providing support to the MHM will receive appropriate classroom and on-the-job training as determined by the job task analysis.

A13.0 HUMAN FACTORS

A13.1 INTRODUCTION

Features of the Spent Nuclear Fuel (SNF) Project human factors engineering (HFE) program are described in Chapter 13.0 of the SNF Project Final Safety Analysis Report (FSAR). Specific application of the human factors process to the Canister Storage Building (CSB) is described in this chapter.

The human factors process applies to all operations, facilities, personnel, programs, procedures, and staff associated with the CSB. Human factors were considered through system development (planning, requirements analysis, system design, and system testing and evaluation) as evidenced by the CSB performance specifications documented in HNF-S-0425, Specification for Spent Nuclear Fuel Canister Storage Building, and by procurement specifications. Several HFE analyses of significant CSB structures, systems, and components (SSCs) and operations were also completed during the design phase. The results from these analyses were used to guide the design and procedure development of those SSCs.

The formality and the extent of the systematic inquiry into the human factors associated with the CSB were determined on the basis of the extent of the human interaction, the system design effort, and the risk associated with human performance failures over the life cycle of the CSB project. For example, the most concentrated human activity occurs when the multi-canister overpacks (MCOs) are being accepted and moved into storage. Human activity then declines to that of a monitoring role with periodic inspections and minimum maintenance activity.

The welding equipment, tube vent and purge cart, and the sampling system incorporate appropriate human factors considerations. The tube vent and purge cart vendor design specifications (at paragraph 2.1.7.4. Human Factors Design) include appropriate human factors performance design criteria. These are discussed in this chapter. All systems for the CSB have been reviewed for human–machine interfaces (HMIs). For the sampling/weld station, frog tool, and the tube vent and purge cart, the reviews have been performed on design documentation only. Further HMI review of the equipment will be completed during the factory acceptance testing. The SNF Project will evaluate and report on the final design and implementation in subsequent updates to this FSAR.

This chapter describes the results of the HFE and ergonomics analysis completed on the existing equipment; the review of administrative issues impacting human performance at the CSB (e.g., procedures, staffing, and training); a review of the existing design specifications and documents for SSCs; and, finally, a review of human actions as initiators and mitigators identified in HNF-SD-SNF-HIE-001, Canister Storage Building Hazard Analysis (see Section A3.3).
A13.2 REQUIREMENTS

The requirements that establish the basis for HFE are identified in Section 13.2 of the SNF Project FSAR.

A13.3 HUMAN FACTORS PROCESS

See Section 13.3 of the SNF Project FSAR for a description of the human factors process that was applied to the CSB design. A lessons-learned process is in place for CSB engineers. Lessons learned and operating experience are disseminated as defined in HNF-PRO-067, *Managing Lessons Learned*. Information regarding lessons learned is routinely distributed by the SNF Project Lessons Learned point of contact and acknowledged by the appropriate engineers. The SNF Project has established points of contact whose job is to coordinate the distribution of lessons learned to the appropriate organizations or individuals within the SNF Project. The point of contact typically adds lessons-learned information to required reading, or if applicable, distributes it to the procedures group, training group, operations organization, or maintenance organization. If applicable, lessons learned then are implemented by the organization or group (i.e., procedure modifications, upgraded training, or revised maintenance practices) to avoid recurrence of an adverse work practice or operating experience. The lessons-learned program serves to validate that human tasks can be adequately performed. If a task is found to be outside of human capabilities and limitations, the lessons-learned program is set up to establish corrective action to fix the discrepancy.

A13.4 IDENTIFICATION OF HUMAN-MACHINE INTERFACES

This section summarizes the safety-class and safety-significant SSCs that require HMI to function. The significant HMIs for general-service SSCs pertinent to CSB operation are listed.

A systems requirements analysis using a graded approach was performed as an integral part of the CSB design process. A number of human factors considerations were included in the CSB design, in accordance with HNF-S-0425, *Human System Interface Design Review Guidelines*, and NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants*, Section 18.1, "Human Factors Engineering, Control Room," were reviewed in addition to U.S. Department of Energy guidelines. Application of these guidelines to the CSB for HMIs have been documented for the safety-related SSCs in SNF-3907, *Spent Nuclear Fuel Project Canister Storage Building Human Factors Engineering (HFE) Analysis: Results and Findings*.

The systems listed in Table A13-1 were reviewed. A supplemental HFE and ergonomics review of the CSB has been performed. Table A13-1 shows the application of the graded approach and consideration of HMI in that review. Some systems will continue to be followed as those systems' designs are nearing completion. The heating, ventilation, and air conditioning

Notes:

*System safety classification is provided in Chapter A2.0.

bSignificant HMI includes either operation of system or maintenance of system, or both operation and maintenance of system.

cA system may not have significant HMI but be selected for evaluation of limited HMI following system installation.

CSB = Canister Storage Building.
HEPA = high-efficiency particulate air (filter).
HFE = human factors engineering.
HMI = human–machine interface.
MCO = multi-canister overpack.
MHM = multi-canister overpack handling machine.
(HVAC) system has been reviewed using specification drawings, interviews with the HVAC
engineer and architect-engineer, and by observation at the CSB and has been found to meet or
exceed HFE accessibility requirements. General-service systems at the CSB usually do not
include significant HMI; however, accessibility for routine periodic maintenance by the CSB
operators appears to be acceptable. The general-service systems' accessibility is confirmed during
pre-operational testing and evaluation when the operators will “dry run” all procedures. Much of
the maintenance interaction, in accordance with vendor instruction, will include periodic
changeout of high-efficiency particulate air (HEPA) filters, instrument readings, and calibration
and minor adjustments to the system where necessary.

The systems with “yes” in the Table A13-1 “Significant HMI” column were analyzed using
the HFE checklists, interviews with engineers, observation, or review of design specifications and
drawings. Additional analysis was completed on the following systems or program elements using
established HFE criteria recognized by the U.S. Department of Energy and referenced in the CSB
performance specification document (HNF-S-0425):

- Multi-canister overpack handling machine (MHM)
- Instrumentation and controls
- Operations and maintenance
- Normal and abnormal operations (including recovery actions)
- Maintenance activities
- Procedure development
- Staffing.

Documents that contain the established HFE criteria recognized by the U.S. Department of
Energy include MIL-STD-1472, Human Engineering Design Criteria for Military Systems,
Equipment, and Facilities; and UCRL-15673, Human Factors Design Guidelines for
Maintainability of Department of Energy Nuclear Facilities.

A13.5 OPTIMIZATION OF HUMAN–MACHINE INTERFACES

A13.5.1 Results of the Human Factors Engineering
Analysis of Normal Operations

See Section 13.5.1 of the SNF Project FSAR for a description of the HFE checklist
process. Normal human operations at the CSB are characterized by the flowchart in
Figure A13-1. Operations are involved in determining the appropriate sequence of operational
steps and tools used. Operational block sequence diagrams have been completed for CSB
operations, and the block sequence diagrams have been further detailed into minute-by-minute
activity at the operator level. This forms the basis for a detailed task analysis and critical task
analysis, and provides the training organization and the procedure writers a wealth of information
from which appropriate detailed procedures and training can be constructed. The CSB startup
plan includes a mock-up exercise of MCO handling activities, processing, testing, and other
operations for verification and validation of normal and abnormal operations.

A few items of equipment or tools were undergoing engineering or re-engineering at the
time of the HFE evaluation. An assessment of the HFE work accomplished shows a very high
degree of consideration for human–machine interfacing. For example, where possible, machines
are doing the work of lifting and carrying items of significant weight. The CSB will be operating
with a minimum crew.

It is clear from the review of the SSCs in the beginning of this chapter that HMI is minimal,
with regard to the facility as a whole. The graded approach method presented at the beginning
also indicated that many systems will not have human interaction other than possibly routine or
periodic maintenance. Outside of the major items of equipment (e.g., the receiving crane and
MHM) much of human activity will be involved with sampling, recording data, routine
maintenance activities as described in the system design descriptions, security, communications,
and housekeeping. HMI occurs in a number of critical areas, the most notable of which is
operator control of the MHM or receiving crane. The CSB process is not a fast process, such as
an assembly line, but a slow deliberate process, with lengthy process time between the major
actions.

Where appropriate, designs include HFE inputs or administrative features have been
implemented to meet the intent of the HFE checklists. For example, if there is a biomechanical
disadvantage created in the design, because of ALARA (as low as reasonably achievable)
requirements, an engineering change will first be sought to overcome the disadvantage, taking
into account factors such as cost of change, and time required to redesign based on project
schedule. Engineering is keyed to the practice that when the engineering change is not feasible
because of project factors, administrative controls will be put into place (e.g., certification of
operator capability to perform the task, training before performance of the task).

A radio-controlled crane allows the operator to control the crane from a distance and not
have to use the panel controls; it also allows the operator to better observe the crane operation
and work with the grappling mechanism that attaches to the cask during receiving operations.
The crane control serves as a backup to radio control operations.

The receiving cask lid is removed from the transportation cask by using an automatic bolt
removal and torquing device.

The control room in the support building incorporates adjustable furnishings. The
environmental design (e.g., illumination, HVAC, noise, and aesthetics) meets the requirements of
DOE Order 6430.1A, General Design Criteria, Section 1300.

The HVAC, gaseous effluent monitoring system, and instrument air and service air systems
need mainly routine maintenance performed on them or are interfaced with infrequently.
Attention was focused on HEPA filter accessibility for changeouts, instrument accessibility for
calibrations, and ease of removal and replacement of failed components. The components are readily accessible. Maintainability is the human engineering key to these systems.

The weld pit has been designed with awareness of the biomechanical forces on the human when using long-reach tools. The design concentrates on making the task as simple and as quick as possible to reduce the risk factors associated with the task.

The tube vent and purge cart has included appropriate human factors requirements in the vendor specification. These human factors requirements will be checked during acceptance testing.

The CSB HFE analysis (SNF-3907) includes a checklist evaluation for each CSB subsystem or component, as appropriate. Included are identified deficiencies that were brought to the attention of engineering, and where appropriate, solutions that were suggested. If no identified deficiencies are cited, the system meets the HFE criteria or the checklist criteria are not applicable. The identified deficiencies have been checked and evaluated for appropriate resolution concurrent with pre-operational testing and startup of operations.

The following discussion describes the various human-machine-intensive equipment and systems in the CSB and the impact of the CSB on the operator. The operating ambient temperature (60 °F to 85 °F) is acceptable. The acoustic environment, vibrational environment on the MHM and the receiving crane, and the available illumination at the floor and equipment panels are to be measured by the facility staff during testing. The quality and quantity of the available light are to be evaluated during startup testing and task lighting provided where required. Human performance is to be tested under operating conditions with special attention to the concerns about vibration. The engineering changes and administrative controls identified during the HFE reviews discussed above will be verified and validated during operational testing.

A13.5.1.1 Multi-Canister Overpack Handling Machine. Human factors reviews were completed on the MHM. These were documented in SNF-3907, which concluded that the HFE was satisfactory based upon correction of several items. Letter FDH-9855462, Update of 22 Issues from the U.S. Department of Energy, Richland Operations Office Review of Multi-Canister Overpack Handling Machine, Supporting Key Driver Resolution Committee Process for Multi-Canister Overpack Handling Machine Installation (Williams 1998), stated, “A human factors review was performed as part of the DE&S Hanford, Inc. review of the Multi-Canister Overpack Handling Machine (MHM) control console.” The letter further stated that “significant changes” had been made to the control console layout and color coding. The supplementary HFE and ergonomics evaluations of the MHM were documented in the SNF-4831, Human Factors Engineering and Ergonomics Analysis for the Canister Storage Building: Results and Findings (Supplemental Report), which concluded that enhancements had been made to correct previously identified deficiencies.

A13.5.1.2 Receiving Crane. The receiving crane is designed to move a cask with a loaded MCO from the transporter in the trailer vestibule to the cask receiving pit and then to move a cask
HNF-3553 REV 0
Annex A — Canister Storage Building

with an empty MCO onto the transporter at the trailer vestibule. Review of the receiving crane layout against the appropriate human factors criteria referenced in the CSB performance specification (HNF-S-0425) resulted in the following human factors concerns:

- Joystick controls can be inadvertently activated
- Main and auxiliary hoist controls on the control panel appear inconsistent with direction of operation.

Inadequacies identified during the human factors review of the control panel layout of the crane have been appropriately resolved using engineering and administrative controls.

The cask yoke may be handled by two methods: (1) an additional observer with radio connection to the crane operator manually guides the cask yoke to the proper cask-yoke connecting features, or (2) the crane operator can be positioned on the trailer and, using remote control, manually guide the yoke to the proper cask-yoke connecting features.

A13.5.1.3 Tube Vent and Purge Cart. The tube vent and purge cart system is designed to monitor and maintain an inert gas environment around any MCO placed into the overpack storage tubes as well as to monitor the atmosphere in the tubes. The cart includes features to analyze gas from the storage tube, purge generated gases (containing hydrogen) through a HEPA filter, and replace the purged gas with an inert gas.

The cart contains piping and instrumentation necessary to remove air from an overpack storage tube and replace it with inert gas. The system consists of inert gas supply, flexible steel hoses, sampling connection, gas monitor loop with heat exchanger, continuous air monitor unit, radioactive gas monitor, hydrogen gas monitor, associated interlocks and alarms, HEPA filter, and the oxygen monitor and associated alarms. Each of the alarms is annunciated and monitored locally. The operations include tube pressure purging, tube refilling, and tube venting.

The operations sequence to set up the tube vent and purge cart was included as part of the CSB human factors review. During any abnormal or accident operations, whether directly associated with the tube vent and purge operations or elsewhere in the facility, the cart is placed into safe configuration. The design basis has been defined, and a piping and instrumentation diagram is available and was reviewed. CSB project plans to design this and other equipment to the criteria included in the CSB performance specifications. The criteria include appropriate human factors criteria. W-379-P-1305-1305, Tube Vent and Purge Cart Assembly, the tube vent and purge cart specification, calls out appropriate human factors performance criteria. Vendor submittals include HFE requirements. The HFE review concluded that the cart adequately incorporates HFE criteria.

A13.5.1.4 Instrumentation and Controls. The CSB project design requirements for instrumentation and controls include requirements for equipment used in the process, HVAC, and radiation monitoring systems. The requirements exclude hand-held portable monitoring.
equipment. The basic philosophy is to use standard, commercial, off-the-shelf equipment consistent with DOE Order 6430.1A. All mobile equipment are to be monitored and controlled locally, including the tube vent and purge cart. All design media use the English unit system and colors are mostly manufacturer’s standard. CSB performance specifications (HNF-S-0425), which include appropriate human factors criteria, govern the design of any needed instrumentation and control equipment. Therefore, the instrumentation and controls were considered appropriately designed.

A13.5.1.5 Distributed Control System. The distributed control system is designed to provide personnel with status of various process systems and alarms. The system does not provide control functions for the operators. During operations, the distributed control system is not expected to be continuously manned.

During the human factors review of this system, several performance enhancement suggestions were provided to the CSB Project management. Each of these enhancements was considered by the CSB management.

The supplemental HFE and ergonomic review found that the distributed control system demonstration screen displays, in some instances, did not provide adequate contrast between background color and foreground color lettering. Maximum contrast between background and foreground colors is preferred, so what needs to be legible can, in fact, be seen. Engineering will ensure adequate screen contrast is achieved.

A13.5.1.6 Environmental Considerations. CSB lighting systems comply with the Lighting Handbook (IES 1987) and ASHRAE 90-75R, Energy Conservation in New Building Design. The lighting systems include exterior, interior, standby, and emergency lighting. Exterior lighting illuminates the outside of the buildings using wall-mounted, low-pressure, sodium light fixtures and is controlled by light-sensitive photocells in compliance with DOE Order 5480.1A, Environmental Protection, Safety, and Health Protection Standards, Section 1650-1. Interior lighting consists of normal and standby lighting. Illumination levels follow DOE Order 6430.1A, which recommends 50 footcandles for workstation lighting, 30 footcandles for work area lighting, and 10 footcandles for non-work area lighting. Fluorescent light fixtures with energy-saving ballasts are used in the support building rooms. High-intensity discharge lighting fixtures are used in the operating area shelter. Standby lighting systems are controlled using manual light switches. Emergency lighting consists of individual lighting fixtures powered by an integral battery and self-luminous exit lighting that comply with NFPA 101, Life Safety Code, and DOE Order 6430.1A, Section 1635-1. The emergency lighting fixtures are installed in areas essential to life safety—ingress and egress routes to and from the equipment areas. Portable lighting may be needed during inspection of the cask surface to meet the requirements of ANSI/ANS-57.2-1992, Design Requirements for Light Water Reactor Spent Fuel Storage Facilities at Nuclear Power Plants, which calls for 100 footcandles for inspection at the surface of the cask.

Acoustical features in the support area control room include a suspended acoustical tile ceiling and sound board, which are installed on separate metal stud-framed wall partitions on both...
sides of the wall adjoining the empty generator room. The acoustical features are provided to comply with the requirements of DOE Order 6430.1A, Section 950.

The HVAC system is designed to provide, along with physical barriers, part of the contamination confinement system and contamination control within the CSB. The HVAC system provides a controlled pressure gradient flow of air from outside the CSB inward through uncontaminated areas to potentially contaminated areas of the building and out through HEPA filters and a monitored exhaust. The HVAC system also provides climate control to ensure that environmental conditions in the CSB are maintained in the required ranges for personnel and equipment.

Operational requirements for the support area HVAC subsystem are as follows: a support area temperature of 72 °F to 78°F and an entry-related room operating pressure of -0.03 in. water gauge. Maintenance and surveillance requirements for the support area HVAC subsystem include the following.

- Air handlers CSB-AH-003 and CSB-AH-004 filters will be routinely changed.
- Condensing unit CSB-CU-003 will be periodically inspected and cleaned.
- Support area HVAC components and conditions will undergo periodic surveillance.

A13.5.1.7 Mobile Service Station Tent and Hatch Assembly. The mobile service station tent is undergoing redesign and should be put into an HFE and ergonomics tracking system to follow the redesign effort.

A13.5.1.8 Rail Frogs. Specialy designed tools are required to lift, turn, and set back down the rail frogs. The design of the rail frog tools appropriately took into account HFE and ergonomics.

A13.5.1.9 Sampling/Weld Station. The primary issues at the sampling/weld station are ALARA concerns, thus the use of a glove box and special manual extension tools in the sampling/weld station pit to install and operate an MCO valve and a tube hookup to the MCO, which is then hooked up to the sample cart. The design calls for two gantries with hood and ventilation requirements.

A13.5.1.10 Communications System. The design of the CSB communications system provides the cabling and raceway system equipment needed to connect the telephone, public address, intercom, and radio communications systems within the CSB to the communications equipment interface point. All communications system physical interfaces are located in the communications area of the uninterruptible power supply room. A door from the electrical equipment room provides access to the uninterruptible power supply room. Space is provided for telephone exchange equipment, paging equipment, wire terminating frames, radio equipment, and coaxial and fiber-optic transmission equipment.

Telephone requirements are based on providing internal and external communications service to all office and operating areas within the CSB. The telephone system provides tie-ins to
the Hanford Site crash alarm and the Hanford Site 911 emergency telephone systems. An
intercom system is incorporated into the telephone system.

Public address system coverage is required for all areas accessible to personnel, both
interior and exterior. Public address systems within the CSB are accessed through specified
telephone sets within the facility. Master overrides originate from the control room and the
emergency response center. The evacuation alarm, complying with DOE Order 6430.1A,
Section 1300-6.5.5, will be annunciated through the public address system speakers. The
evacuation alarm can be activated from the control room or the emergency response center.

Area alarms are part of the 200 East alarm system, and CSB alarms are incorporated into
the distributed control system. Rimgdown phones are installed for security use. Fire alarm and
detection system signals are transmitted to the central fire alarm system by means of a radio
system integral to the fire alarm control panel. Radiation and hazardous conditions alarms are
annunciated by means of the distributed control system. The Hanford Site crash alarm is
annunciated through the general CSB telephone system ringer and is directed to selected CSB
telephones.

A13.5.2 Staffing

A13.5.2.1 Operator Capabilities. See Section 13.5.2.1 of the SNF Project FSAR for a
discussion on how human factors are addressed for CSB operator capabilities.

A13.5.2.2 Staffing Plan. See Section 13.5.2.2 of the SNF Project FSAR for a discussion of the
SNF Project staffing plan. The CSB staff is responsible for all facility operations in the CSB,
including the following:

- Staging, storing, and monitoring of MCOs
- Controlling locks and tags
- Controlling facility access
- Providing contamination and radiation control
- Handling laundry
- Operating systems
- Controlling radiation area access
- Maintaining radiological control routines
- Supporting radiological work area control as needed
- Supporting seal welding of MCOs.

Two normal 8-hour shifts are planned, with provision for a third shift if necessary. The
activity job hazard/safety analysis and prejob meetings provide the operators with information to
help them identify and control or mitigate hazards. CSB administrative procedures require job
hazard analyses as part of the job planning. Monthly, quarterly, and yearly safety inspections are
conducted to identify unsafe conditions throughout the facility, including the CSB equipment.
Unsafe conditions result in postings, personnel protective equipment requirements, and timely corrective actions, as appropriate. Any technical safety requirements also provide for the appropriate staffing with a basis and a qualification requirement. Chapter A5.0 provides the necessary technical safety requirements information. Chapter A17.0 includes provisions for staffing that may be updated as the operations are finalized. Changes to the staffing plan will be reviewed to ensure that appropriate human performance has been considered (i.e., knowledge, skills, abilities, availability, and sufficient depth). This approach results in human factors being appropriately considered in the staffing plan.

A13.5.3 Procedures

See Section 13.5.3 of the SNF Project FSAR for a discussion of how the human factors process applies to CSB procedures. Procedures are the principal job performance aid used at the CSB and direct the way in which the majority of human tasks are performed. Considering human factors in the development and maintenance of procedures ensures that the procedure is easy to read and follow, the steps of the procedures are presented in a logical and correct order, all documentation (such as labels, equipment representations, and diagrams) contained in the procedure is accurate, and tasks required by the procedure are within the operator’s capabilities.

The documents and standards that form the basis for the procedures and training program are found in HNF-SD-SNF-RD-001, Spent Nuclear Fuel Project Standards/Requirements Identification Report.

A13.5.4 Training

See Section 13.5.4 of the SNF Project FSAR for a discussion on how human factors are addressed for CSB personnel training. The purpose of CSB training is to ensure that all staff have the knowledge, skills, and abilities required to safely operate and maintain CSB facilities, equipment, and processes. Performance-based training techniques are used for operator and maintainer training to ensure that the operators and the maintainers working with the CSB acquire the skills appropriate for successful task performance through initial training and maintain those skills through periodic retraining.

Human factors issues requiring training may be identified during job and task analyses (the CSB training organization currently has a file with over 500 pages of task analyses for all CSB operating systems). Input to the analyses comes from a determination of required skill levels, current skill levels, task complexity, maintenance requirements, and lessons learned. The identified human factors issues are considered and appropriate responses implemented where applicable during the design and development of training. A direct link between the training department and the procedure development staff is provided during the development of procedures to verify that content development includes the necessary training for new procedures or operations.
From an institutional safety perspective, a stable organizational environment and management chain is necessary to ensure that CSB can attain and maintain proficiency required for safe operation. Stability of the organization ensures that links between training, operations and maintenance, and procedures group are maintained to ensure the quality and accuracy of training and operating and maintenance procedures with respect to facility configuration.

Chapter 17.0 of the SNF Project FSAR illustrates the links between the different organizations. Further details of the CSB training program and HFE aspects within the training program are described in Chapter 12.0 of the SNF Project FSAR. Chapter 12.0 encompasses engineering training, operator certification, maintenance qualification, instructor qualification, development of course content, training documentation, and relationship to other programs.

**A13.5.5 Maintenance**

See Section 13.5.5 of the SNF Project FSAR for a discussion of how the human factors process applies to the CSB maintenance program. The work management process in HNF-PRO-069, *Maintenance Management*, describes how work activities that impact facility operations can be safely and effectively managed. The implementation of design changes (i.e., construction and installation) after engineering has completed the design work is a subset of these work activities. The work management process involves several steps. Planning checklists are provided to serve as guidelines for the planning phases of work packages from pre-work planning through pre-operational or post-installation testing and operations acceptance. HFE is addressed in the planning checklist of the work management process. For example, modification packages are checked to ensure training and procedure changes impacted by the modification are adequately addressed. At the completion of construction work for complex modifications and before turnover to operations, a readiness assessment is performed to ensure the modified SSC is safe to operate and within the approved Authorization Basis. Items evaluated during the readiness assessment process typically include completion of all procedures and training documentation. Work package information is checked to ensure that special skills or knowledge required for task performance are used when identified. The work management system is further described in Chapter 10.0 of the SNF Project FSAR.

The provisions for the initial testing, in-service surveillance, and maintenance programs are applied, as appropriate, to the CSB equipment. Three types of testing will be accomplished before startup of the CSB: factory acceptance testing, construction acceptance testing, and pre-operational acceptance testing. The factory acceptance tests demonstrated to the satisfaction of the applicable design authority that the designed equipment can perform its intended operational functions. The major pieces of designed equipment include the MHM, receiving crane, tube vent and purge cart, sampling/weld station equipment, and rail frogs handling tools. The construction acceptance tests demonstrate that the installation matches the design and that all equipment is functional. The pre-operational acceptance tests demonstrate that the design and installation are operable and the equipment can perform its intended functions.
A13.5.6 Abnormal Operations (Including Recovery Actions)

Human actions during abnormal or accident operations have been reviewed by the appropriate CSB personnel. Several recovery action flowcharts were developed to cover each credible postulated incident. Flowcharts are designed to guide recovery team actions during an abnormal or accident operation. The flowcharts were reviewed for human factors concerns, and the action processes were revised to resolve human factors issues.

A procedure involving recovery from a dropped cask–MCO provides the necessary steps to respond to a dropped MCO or a dropped cask containing an MCO in the CSB and includes a checklist to aid in the development of a recovery plan to recover from an event. The initial steps are to stop the activity associated with the dropped item, ensure that equipment is in a safe configuration, evacuate personnel from the operations area to a staging area, initiate appropriate first aid as necessary, establish boundaries around the operating area, and notify the appropriate managers or other emergency personnel. Later, a recovery team will be assembled to develop an appropriate recovery plan. Once the plan is approved, it will be initiated. These completed technical procedures will be covered in detail during the operator training.

The CSB hazard analysis report (HNF-SD-SNF-HIE-001) was also reviewed to isolate those scenarios involving human error as a cause. The facility hazard analysis review ensures that those postulated events include mitigators sufficient to reduce the probability of human error. The CSB hazard analysis (HNF-SD-SNF-HIE-001) covered normal, intended, CSB operations for handling and storing a sealed MCO. Also identified and analyzed were the potential hazards associated with storing an off-normal MCO in an overpack storage tube following undetermined accident recovery actions. The following normal CSB operations were considered:

- Receiving the transporter containing the cask–MCO and moving it into the facility
- Moving the cask–MCO to the service area and removing the cask lid
- Transporting the MCO from the service area to the storage tube with the MHM
- Transporting the MCO from the storage tube to the MCO sampling/weld station and returning it to the storage tube after sampling
- Conducting activities during MCO staging and interim storage.

The following off-normal MCO storage operations were also considered:

- Event or accident leading to MCO damage has been terminated and recovery actions completed
- Off-normal MCO is in place in the overpack storage tube
Overpack storage tube plug cover is installed

An inert atmosphere has been established in the overpack tube.

The hazard identification process systematically and comprehensively identified hazards that can contribute to the uncontrolled release of radioactive or hazardous materials or that can threaten the safety of facility workers. The hazard evaluation process identified hazardous conditions, determined causes and preventive and mitigative features, and qualitatively estimated the frequency and consequences of occurrence (HNF-SD-SNF-HIE-001).

Section 7.2 of SNF-3907 discusses those hazards associated with human error. The report contains a summary of information from the hazard analysis (HNF-SD-SNF-HIE-001), and covers the following seven CSB areas:

- Truck vestibule (TV)
- Service area (SA)
- Operating area, including overpack storage tubes and tube vent and purge cart (OA)
- Sampling/weld station (WS)
- Vault (VL)
- Support building (SB)
- Outside (OU).

The HFE and ergonomics review of the CSB hazard analysis report (HNF-SD-SNF-HIE-001) did not result in a list of human initiators that were not accounted for by the human factors design review. It also did not disclose any human factors initiators that had a high frequency based upon the human initiator. Each of the scenarios involving human initiators included a set of mitigators the hazard analysis team developed. The recommended mitigators were evaluated, and those considered necessary to ensure safe operation were implemented. The results of this review were considered adequate from a human factors standpoint.

A13.5.7 Conclusions

Interviews conducted with engineers and the architect-engineer, design authorities, procedure writers and trainers; use of selected checklists to capture the requirements of DOE Order 6430.1A and guidelines in NUREG 0700 and NUREG 0800; review of specification and drawing; and direct observation of the CSB facility all demonstrate that human factors and ergonomics have been appropriately and adequately considered in the design of the CSB. The
application of human factors continue into the pre-operational testing and evaluation of the entire CSB facility, where each step that the operators and maintainers are expected to accomplish are observed for any deficiencies or unsafe human performance.

A14.0 QUALITY ASSURANCE

A14.1 INTRODUCTION

An introduction to the quality assurance program that includes the objectives and scope that apply to all Spent Nuclear Fuel (SNF) Project quality assurance activities is provided in Chapter 14.0 of the SNF Project Final Safety Analysis Report (FSAR).

A14.2 REQUIREMENTS

The requirements that form the basis of the quality assurance program are identified in Section 14.2 of the SNF Project FSAR. Additional requirements for the Canister Storage Building (CSB) are identified in the following paragraphs. These requirements ensure the quality assurance requirements for federal repository acceptance of SNF and U.S. Nuclear Regulatory Commission (NRC) equivalency requirements are satisfied.

The U.S. Department of Energy, Richland Operations Office (RL), has directed in Letter 95-SFD-098, DOE/RW-0333P (Sellers 1995), that DOE/RW-0333P, Quality Assurance Requirements and Description, published by the Office of Civilian Radioactive Waste Management (OCRWM), be applied as the principal quality assurance document to the SNF Project OCRWM program. RL has directed application of OCRWM Quality Assurance Requirements and Description (QARD) document (DOE/RW-0333P) to the following SNF Project-related activities:

- Characterization or data collection for input and use
- Conditioning into final form
- Handling, packaging, and transportation.

Items, activities, and documentation determined to be important to safety are presented in Table 3-1 in HNF-SD-SNF-RPT-007, Application of the Office of Civilian Radioactive Waste Management Quality Assurance Requirements to the Hanford Spent Nuclear Fuel Project. This document identifies certain high-level structures, systems, components, activities, and documentation that require application of DOE/RW-0333P requirements to ensure compliance with RL direction.

HNF-SD-SNF-RPT-007, Appendix E, identifies specific items, activities, and documentation that require application of QARD requirements, including the following:

- Systems
  - The sample cart features used to provide controlled refill of monitored multi-canister overpacks (MCOs) with helium
The laboratory instruments used to ensure cleanliness and helium quality (e.g., helium gas purity analyzer, an instrument periodically used to ensure that non-approved materials are not introduced into the monitored MCOs)

The helium supply system that connects to the sample cart and passes from there through the sample hood to the MCO

The helium sampling procedure and the approved analytical laboratory procedure used to determine helium purity will comply with OCRWM QARD requirements. The methods of QARD application for the items associated with the quality of the helium supply to the monitored MCO is defined in HNF-SD-SNF-RPT-007, Appendix E, Section E.5

Components

- Helium sample container
- Helium purity analyzer
- Monitored MCO gas sample container
- MCO gas sample analyzer
- PIT-721, pressure indicator transmitter
- TIT-723, temperature indicator transmitter

Activities and documentation

- Records of helium received and the sampling and analysis of helium to ensure non-approved materials are not admitted to a monitored MCO; calibration records of the instruments used to provide these data
- Data developed by CSB that are also needed by OCRWM as identified in formal direction from RL
- Qualification records involving personnel who refill monitored MCOs with helium
- Data collected and controlled during the CSB operations to show compliance with the QARD requirements and summarized and inserted into each MCO data package (traveler) upon completion of periodic monitoring activities
Procedure for operation of sampling station

Procedure for analyzing CSB helium samples

Procedure for analyzing CSB monitored MCO gas samples

Procedure for calculating amount of hydrogen present in a monitored MCO based on sample temperature, pressure, and hydrogen content

Analysis instrument calibration procedure

Qualification of personnel.

The U.S. Department of Energy has established a regulatory policy (Grumbly 1995) that new SNF Project facilities achieve nuclear safety equivalency with NRC-licensed facilities. An evaluation, documented in HNF-SD-SNF-DB-002, *Spent Nuclear Fuel Project Path Forward, Nuclear Safety Equivalency to Comparable NRC-Licensed Facilities*, identified requirements to establish nuclear safety equivalency that are to be met in addition to existing and applicable U.S. Department of Energy requirements. These requirements, except those related to the design basis earthquake, are contained in HNF-SD-SNF-DB-003, *Spent Nuclear Fuel Project Path Forward Additional NRC Requirements*. WHC-SD-SNF-DB-004, *Spent Nuclear Fuel Project Seismic Design Criteria — Nuclear Regulatory Commission Equivalency Evaluation Report*, contains the design basis earthquake requirements.

The NRC nuclear safety equivalency requirements identified in HNF-SD-SNF-DB-003 that will be applied to the CSB include:

- Incorporation of requirements into safety-class procurement specifications that require suppliers to report defects and noncompliances in items or services (Item 15)
- Review and approval by RL of changes to HNF-MP-599, *Project Hanford Quality Assurance Program Description*, that could be interpreted as decreasing the quality assurance program's existing commitments for the CSB (Item 16)
- Implementation of the Project Hanford Management Contract occurrence reporting system for the design and construction of the CSB (Item 17)
- Ensuring that the appropriate quality requirements in existing Project Hanford Management Contract procedures and instructions identified in HNF-SD-SNF-DB-002 remain in effect (Item 18) (a detailed evaluation documented in Attachment A of HNF-SD-SNF-DB-002 indicates that Project Hanford Management Contract procedures and instructions are equivalent to the requirements of Title 10, *Code of Federal Regulations*, Part 72, "Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-Level Radioactive Waste")
(10 CFR 72), Subpart G, "Quality Assurance," and of Title 10, Code of Federal
Regulations, Part 50, "Domestic Licensing of Production and Utilization Facilities"
(10 CFR 50), Appendix B, "Quality Assurance Criteria for Nuclear Power Plants and
Fuel Reprocessing Plants")

- Institution of a process to identify safety-class equipment that has been identified in
the commercial nuclear power industry as being potentially defective (Item 19)

- Ensuring that the areas of vendor and subcontractor quality assurance records and
control of purchased material, equipment, and services considered important to safety
receive emphasis during CSB audits, surveillances, and assessments (Item 19).

Additional requirements apply to an MCO when it resides in the CSB. These requirements
are identified in HNF-SD-SNF-DB-005, Spent Nuclear Fuel Project Multi-Canister Overpack
Additional NRC Requirements.

Design requirements for natural phenomena hazards, other than seismic design
requirements, are identified in WHC-SD-SNF-DB-009, Canister Storage Building Natural
Phenomena Hazards.

The documents cited in this chapter identify the requirements to achieve nuclear safety
equivalency with NRC-licensed facilities and to meet the requirements of DOE/RW-0333P.
SNF-4948, Spent Nuclear Fuel Project Quality Assurance Program Plan, provides for
implementation of these requirements. A graded approach will be used for items and activities
important to safety (i.e., safety-class, safety-significant, and certain general-service items and
activities) in accordance with HNF-MP-599 and NUREG/CR-6407, Classification of
Transportation Packaging and Dry Spent Fuel Storage System Components According to
Importance to Safety.

A14.3 QUALITY ASSURANCE PROGRAM ORGANIZATION

A summary of the SNF Project quality assurance program, including summaries of safety
management policies and philosophies used as a basis for the program, is provided in Section 14.3
of the SNF Project FSAR.

The SNF Project organizational structure, responsibilities, authorities, and interfaces that
apply to the CSB are addressed in Chapter 17.0 of the SNF Project FSAR.
A14.4 QUALITY IMPROVEMENT

Descriptions of SNF Project management programs and processes used to correct adverse conditions affecting quality at all SNF Project facilities are provided in Section 14.4 of the SNF Project FSAR.

A14.5 DOCUMENTS AND RECORDS

A description of the SNF Project document control and records management program associated with quality assurance is provided in Section 14.5 of the SNF Project FSAR.

A14.6 QUALITY ASSURANCE PERFORMANCE

An overview of the SNF Project process to ensure that the performed work meets requirements is provided in Section 14.6 of the SNF Project FSAR and its subsections. The subsections address work processes, design activities, the procurement process, program tests and inspections, and independent assessments.

The CSB incorporates portions of the design and the completed below-grade sections of the canceled Hanford Waste Vitrification Plant. All of the designs and completed sections of the Hanford Waste Vitrification Plant were reviewed and met or exceeded the requirements of the SNF Project CSB. All of the below-grade structures are safety class. Portions of the vault that were completed prior to suspension of the Hanford Waste Vitrification Plant project in 1993, including the base slab and portions of the walls, were reviewed, approved, accepted, and incorporated into the present design by the architect-engineer.

A15.0 EMERGENCY PREPAREDNESS PROGRAM

A15.1 INTRODUCTION

A description of the generic philosophy, objectives, and organization of the Spent Nuclear Fuel (SNF) Project emergency preparedness program for response to emergencies at the SNF Project facilities is provided in Chapter 15.0 of the SNF Project Final Safety Analysis Report (FSAR). This Annex A chapter presents emergency management information specific to the Canister Storage Building (CSB).

A15.2 REQUIREMENTS

The requirements that form the basis for the SNF Project emergency preparedness program are identified in Section 15.2 of the SNF Project FSAR.

A15.3 SCOPE OF EMERGENCY PREPAREDNESS

Potential CSB emergencies could span the spectrum of identified emergencies for SNF Project facilities, from worker injuries to general emergencies with potential public impact. The spectrum of emergencies that the CSB emergency preparedness program is designed to encompass is described in Section 15.3 of the SNF Project FSAR and in Chapter A3.0.

A15.4 EMERGENCY PREPAREDNESS PLANNING

SNF Project emergency preparedness planning includes identification of emergency organizations, assessment actions, notification processes, emergency facilities and equipment, protective actions, training, drills, exercises, and recovery actions. A summary of the emergency response organization (ER0) that is activated during CSB emergencies is provided in Section 15.4 of the SNF Project FSAR and its subsections.

A15.4.1 Emergency Response Organization

Section 15.4.1 of the SNF Project FSAR presents information related to the organizational structure and support resources to meet emergency event requirements. This information also applies to the CSB. The Hanford Site ERO has the responsibility to take actions in response to a CSB emergency to prevent or minimize impacts to workers, the public, facilities, and the environment. Initial directions and control of emergency response at the CSB before establishment of the Incident Command Organization, as described below, is the responsibility of the CSB ERO.
The Hanford Site ERO, responding to a CSB emergency, will consist of two components: the Incident Command Organization and the U.S. Department of Energy (DOE) Hanford Emergency Operations Center (EOC), as stated in Section 15.4.1.1 of the SNF Project FSAR.

**A15.4.1.1 Incident Command Organization.** The Incident Command Organization will consist of the CSB ERO and Site contractor emergency personnel (i.e., Hanford Fire Department and Hanford Patrol). The Incident Commander is the senior Hanford Fire Department official; the Hanford Patrol will provide the Incident Commander for security emergencies. The Incident Commander will direct all emergency response efforts at the CSB and has overall responsibility for the health and safety of all personnel at the event scene.

The CSB ERO, including the building emergency director (BED), will become part of a consolidated Incident Command Organization and functions under the direction of the Incident Commander. In this role, the BED retains responsibility for CSB operations and direct configuration control over CSB systems and components. The Incident Commander controls the overall management strategy associated with the emergency event and ensures that all functional areas are staffed and working effectively to mitigate the accident.

The Incident Command Organization has the authority to commit all SNF Project resources (equipment and personnel) in response to any emergency and to request supporting resources. Other responsibilities include the following: (1) implementing the CSB's building emergency plan; (2) ensuring that the CSB ERO is fully staffed and trained; (3) initially assessing, categorizing, and classifying events; (4) notifying the Patrol Operations Center and applicable contractor and DOE management through the Occurrence Notification Center; (5) implementing protective actions; (6) establishing an initial CSB Incident Command Post; (7) controlling the event scene; (8) initiating mitigating activities; and (9) initiating recovery actions when directed. At the CSB, the BED is a certified operations shift manager.

A listing of the primary and alternate BEDs by title, work location, and work telephone numbers is contained within the CSB's building emergency plan. The BED is on the CSB premises during hazardous operations and is available through an "on-call" list 24 hours a day at all other times. Operations maintains a listing of on-call BED names, with work and home telephone numbers, at the Occurrence Notification Center.

The Incident Command Organization is also composed of a Hanford Fire Department Operations Section Chief (assigned by the Incident Commander), trained support staff (e.g., Health Physics staff), and (as required) Hanford Fire Department medical responders and Hanford Patrol. In addition, personnel accountability aides are responsible for facilitating the implementation of protective actions (evacuation or take cover) and for facilitating the accountability of personnel after the protective actions have been implemented. Staging area managers are responsible for coordinating/conducting activities at the staging area. Personnel accountability aides assist the staging area managers by ensuring that personnel and visitors are properly evacuated from designated staging areas to a safe location. The Incident Command Organization supports actions requested by the Incident Commander and the BED.
A15.4.1.2 U.S. Department of Energy Hanford Emergency Operations Center. As stated in Section 15.4.1.3 of the SNF Project FSAR, the DOE Hanford EOC is an emergency response facility, maintained by the DOE, Richland Operations Office/Office of River Protection, to convene personnel providing essential emergency response functions. The DOE Hanford EOC will be activated for Alert and higher emergencies at the CSB.

A15.4.2 Assessment Actions

Provisions of Section 15.4.2 of the SNF Project FSAR cover development and implementation of the hazards surveys and hazards assessment, consequence assessments, and monitoring activities. These provisions apply to the CSB.

The CSB hazards survey will identify the conditions contained in the comprehensive emergency management program. A CSB emergency planning hazards assessment will be developed for the CSB for hazards that have the potential to generate an Alert or higher emergency. The hazards assessment will be prepared from the hazards survey and safety analyses that are developed and summarized in Chapter A3.0. The hazards assessment will also be derived from other pertinent facility documentation (e.g., safety assessment documents, interim safety basis documents, and special nuclear material accountability documents). The hazards assessment will provide the technical basis for the emergency management program. The scope and extent of planning and preparedness will directly correspond to the type and scope of hazards present and the potential consequences of events.

The hazards assessment will characterize the potential consequences on workers, the public, and the environment for each postulated accident and determine the emergency planning zone (EPZ) for each facility. The assessment also will determine the emergency class, protective actions, and the observable indications and criteria (emergency action levels) corresponding to the range of identified accidents.

A spectrum of potential accidents ranging from minor to beyond design basis are postulated and will be realistically analyzed for the CSB. While not every conceivable situation will be analyzed, the hazards assessments will provide the framework for response to virtually any declared emergency.

The methodology, assumptions, models, and evaluation techniques used in the hazards assessments are documented in Sections 15.4.2.1 and 15.4.2.2 of the SNF Project FSAR. Results from the CSB hazards assessment will be utilized in development of the building emergency plan for the CSB. Hazards assessments will be reviewed at least annually and updated, as necessary, in accordance with Section 15.4.2 of the SNF Project FSAR to delineate significant changes to the CSB or hazardous inventories and will be maintained in accordance with the Site contractor document control requirements.
A15.4.3 Event Categorization and Classification

Event categorization and classification for CSB emergency events will be accomplished in accordance with Section 15.4.3 of the SNF Project FSAR.

A15.4.4 Notifications

Notifications, in the event of an emergency event at the CSB, would be made in accordance with the provisions of Section 15.4.4 of the SNF Project FSAR in order to mitigate consequences and to protect the health and safety of workers, the public, and the environment.

A15.4.5 Emergency Facilities and Equipment

The building emergency plan for the CSB will be prepared and issued in accordance with HNF-IP-0263-GEN, Building Emergency Plan Guidance. A description of the facilities that will be available for coordinating CSB emergency response activities will be specified in the building emergency plan.

Emergency equipment consisting of materials and tools that may be required to measure, control, or mitigate the consequences of an emergency at the CSB is listed in Table A15-1. Detection ranges and types of instruments for radiological and nonradiological hazardous materials will be adequate for CSB emergency conditions as determined in Section A15.4.2. The emergency planning organization will ensure that sufficient emergency equipment is available. Location of this emergency equipment will be stated in the building emergency plan.

A15.4.6 Protective Actions

Protective actions are those actions that will be taken to preclude or reduce the exposure of individuals or the environment impacted by hazards or unsafe conditions during an emergency event at the CSB. These are presented in Section 15.4.6 of the SNF Project FSAR and are applicable to the CSB. Protective actions for the CSB will reflect the use of emergency response planning guidelines identified in Section 15.4.3.1 of the SNF Project FSAR. The planning guidelines published in the Emergency Response Planning Guidelines (AIHA 1988) will be used during a CSB emergency response to determine protective actions for unique exposures to chemical releases (see the SNF Project FSAR, Table 15-5). The protective action guides also are used during an emergency response to determine protective actions for unique exposures to radiological releases (see SNF Project FSAR, Table 15-2). DOE/RL-94-02, Hanford Emergency Management Plan, directs the use of the published protective action guides adopted by the states of Washington and Oregon.

*Respirators for emergency use will be thoroughly inspected at least once a month and after each use. Records of inspection dates and findings will be maintained.

The Hanford Site emergency management program uses the EPZ concept to focus emergency planning activities. EPZs are designated areas where protective actions may be required. The size of a zone is determined primarily by the expected dispersion distance of a particular concentration of a substance. The two exposure pathways for both radiological and nonradiological hazardous materials are the plume exposure pathway and the ingestion exposure pathway. See Section 15.4.6 of the SNF Project FSAR for a description of the exposure pathways.

The plume exposure pathway EPZ is the probable area of exposure to a passing cloud, or plume, of the substance potentially resulting in direct contact with the substance through the exterior of the body or through inhalation. The plume exposure pathway EPZ includes the area where emergency planning is conducted (1) to ensure that prompt and effective actions are taken in the event of an emergency, (2) to protect onsite personnel, and (3) to ensure public health and safety. The plume exposure pathway for the CSB (10 mi) is shown in Table 15-6 and Figure 15-5 in the SNF Project FSAR.

The ingestion exposure pathway EPZ is the probable area of exposure to contaminated foodstuffs or water potentially resulting in deposition of the material in various internal organs following ingestion (eating or drinking). The ingestion exposure pathway EPZ for radiological and nonradiological incidents at all Hanford Site facilities corresponds to the 80-km (50-mi) EPZ for Energy Northwest’s Nuclear Plant 2. The gray area in Figure 15-6 in the SNF Project FSAR represents the ingestion EPZ (80 km [50 mi]) for the Hanford Site.

The protective actions required to minimize the exposure of workers and the public are summarized in Section 15.4.6 of the SNF Project FSAR. Examples of protective actions as a function of accident category and consequences are illustrated in Table 15-7 in the SNF Project FSAR.
A15.4.7 Training and Exercises

An emergency organization for the CSB will be formed, trained, and tested in accordance with the provisions of Section 15.4.7 of the SNF Project FSAR. Drills and exercises will be developed in accordance with the provisions of Section 15.4.7 of the SNF Project FSAR with sufficient scope and detail to emphasize the facility-specific emergency events and response actions applicable to the CSB facility.

A15.4.8 Reentry and Recovery

The provisions applicable to a CSB emergency event termination, facility entry, transition from an emergency organization to a recovery organization, and the recovery process are provided in Section 15.4.8 of the SNF Project FSAR.

A15.5 DOCUMENT CONTROL

The building emergency plan, implementing procedures, reports of drills and exercises, and emergency event documentation for the CSB will be controlled and updated in accordance with the provisions of Section 15.5 of the SNF Project FSAR.

A16.0 PROVISIONS FOR DECONTAMINATION AND DECOMMISSIONING

A16.1 INTRODUCTION

The provisions that apply to future decontamination and decommissioning (D&D) of Spent Nuclear Fuel (SNF) Project facilities are addressed in Chapter 16.0 of the SNF Project Final Safety Analysis Report (FSAR). Provisions specific to the Canister Storage Building (CSB) are addressed in this Chapter A16.0.

A16.2 REQUIREMENTS

The requirements that form the basis for D&D provisions are identified in Section 16.2 of the SNF Project FSAR.

A16.3 DESCRIPTION OF CONCEPTUAL PLANS

This section describes the design features and operational considerations pertinent to the CSB that will facilitate decontamination and ultimate decommissioning and environmental restoration activities. Design and operating practices that minimize the production of contamination and confine it to designated areas are important for final D&D considerations. General considerations applicable to all SNF Project facilities are provided in Section 16.3 of the SNF Project FSAR.

The multi-canister overpacks (MCOs), CSB, and MCO handling machine (MHM) are designed to prevent the spread of radioactive contamination from inside the MCOs. Baseline operations for the CSB ensure that the spread of radiological contamination from the MCOs or the transportation cask to the interior surfaces of the MHM, storage tubes, or CSB operating area is minimal during normal operations.

The fuel loading operation at the K Basins is designed to minimize contamination of the MCO and the cask–MCO during fuel loading. At K Basins, installing the immersion pail lid on the cask–MCO and inflating the immersion pail seals prevents pool water from coming in contact with the cask exterior and the cask–MCO interior cavity. The space between the pail and the cask and the cask cavity is filled with clean deionized water during in-pool loading operations to further prevent contaminants in the pool water from contacting the outside of the cask or entering the cavity between the MCO and the cask. After completing K Basin underwater fuel loading operations, the immersion pail is brought to the surface where all surfaces of the MCO shield plug top and immersion pail lid are rinsed with clean deionized water, surveyed, and decontaminated as required before the cask lid is installed.

At the Cold Vacuum Drying Facility, operators use a lid with inflatable seals to wash the cask exterior with tempered water before transporting the cask–MCO to the CSB.
A16.3.1 Design Features

If radiological contamination occurs, the CSB design features preclude the spread of contamination during normal operations and accident conditions. The four MCO access ports are sealed at the Cold Vacuum Drying Facility using gasketed, bolted cover plates before an MCO is received at the CSB. The initially selected MCOs will be monitored using the sampling/weld station equipment to ensure that pressure buildup in the MCO does not cause a hazardous condition and that the MCO is safe for interim storage at the CSB. The sampling/weld station hood limits the spread of contamination. After monitoring, a welded cap is installed on each MCO, providing additional protection to minimize the potential for release of radioactive contamination. In the overpressurization of an MCO (prior to having the cap welded on), the pressure is relieved using the sampling cart at the MCO sampling/weld station. The storage tube is designed to withstand all postulated design basis accidents and applicable natural phenomena hazard events listed in Chapter 1.0 of the SNF Project FSAR. The storage tube assembly is designed not to release contamination past the tube plug to the operating deck or into the vault. The operating deck area is isolated from the vault to prevent the migration of contamination from one zone to the other in the unlikely event of a release from an MCO. Deck area ventilation air is exhausted through a high-efficiency particulate air (HEPA) filter to the environment. All of the equipment, utilities, and operating stations that do not have a function in the operating area are isolated in the support area of the building to minimize risk of exposure to contamination. The support area is on a separate heating, ventilation, and air conditioning (HVAC) system from the operating area to minimize cross-contamination of zones. The support area is separated from the operating area by a shield wall with penetrations thoroughly sealed for maximum isolation.

Cracks and crevices have been minimized in the operating area to facilitate decontamination. Equipment used routinely to handle MCOs has seal welds to facilitate cleanup. Welded piping has been used where practical.

The design features that are of importance to D&D will be controlled through the design change control process to ensure that changes to the facility consider the impact on D&D.

A16.3.1.1 Load-In/Load-Out Area. MCOs are retrieved from or placed in transportation casks in the load-in/load-out area, located at the north end of the operating area. The equipment in the load-in/load-out area maintains secondary confinement as needed by operations to contain contamination in the unlikely event of a release from an MCO. The cask is placed in an open pit for MHM accessibility. During stages of the MCO handling process in which the cask is open and the MCO exposed, the area around the pit may be enclosed with a mobile service station enclosure. The concrete deck of the service station is covered with a coating that facilitates decontamination.

In the MCO service station with the mobile service station enclosure in place, the operating area atmosphere that could come into contact with the cask interior or MCO exterior is confined. The mobile service station enclosure is equipped with a HEPA-filtered exhaust system that maintains a negative pressure relative to the operating area and minimizes the potential for an
uncontrolled release of contamination to the operating deck. Thus, all air that exits the enclosure
is HEPA filtered before release to the operating area. The ventilation unit discharge is directed to
a nearby exhaust system collection point. The atmosphere inside the MCO (an abnormal MCO
may require servicing and purging) is HEPA filtered before being released to the operating area,
through the operating area ventilation system, and to the environment.

A16.3.1.2 Multi-Canister Overpack Handling Machine. The MHM provides a ventilated
chamber for transport of the MCO. In the MHM, the air atmosphere surrounding the MCO can
be maintained at a negative pressure relative to the operating area. Discharged exhaust is HEPA
filtered before release to the operating area. Any surface contamination released from the MCO
(as airborne contamination) will be filtered before it is released. The MCO provides the primary
confinement barrier for the SNF. The MHM serves as a secondary confinement when it contains
an MCO. The MHM has been designed to couple with equipment with which it performs an
MCO transfer function.

A16.3.1.3 Storage Tubes. The standard storage tubes have been designed as sealed vessels to
prevent particulate contamination from escaping. The overpack storage tubes have been designed
as sealed vessels to prevent contamination from escaping and to maintain an inert atmosphere.
The tubes are all welded construction. Welds having exposure to the MCO are seal welded,
including the bellows welds and the tube flange to the embed weld. With the tube plug in place,
the tube provides confined storage for the MCO. The standard tube plug has an O-ring seal, and
the overpack storage tube plug has double O-ring seals for the mating surface on the tube. The
standard tube plug has a filtered vent to minimize the potential for a release of contaminated
particulates. The overpack storage tube plug has a sealed port and a valved port. The overpack
storage tube is designed to contain releases from a stored MCO. A hold-down device for the
overpack storage tube plug prevents loss of gases if the overpack storage tube pressure increases.
During normal operations when a plug is removed from the storage tube, it is always contained in
a dedicated chamber within the MHM and has no opportunity to spread contamination.

A16.3.1.4 Sampling/Weld Area. The sampling/weld area comprises a row of seven process pits
and the equipment required for MCO canister cover assembly welding operations and monitoring
operations (sampling and monitoring). Each pit is recessed into the deck and covered. Welding
equipment is available for use at pits 2 and 7, and pits 3 and 6 provide helium gas and electrical
services to pits 2 and 7. Sampling and monitoring equipment is available for use at pit 7 for
monitoring and sampling the MCOs used in the monitoring process. Hoods are used during
sampling, monitoring, and welding operations to reduce the potential for release of contamination.
The pit cover has shield halves and a fitted center shield plate that allows working access to the
pit and serves a purpose similar to that of the tube plug. The design of the center shield plate and
shield halves enable the MHM to dock with the sampling/weld station, remove the center shield
plate, and perform MCO transfers while providing shielding for the operators. The portable,
ventilated, HEPA-filtered hoods (sampling and welding) maintain a negative pressure relative to
the operating area for contamination control. The hoods discharge to an area duct, which
discharges to the operating area ventilation system. The low volume of potentially contaminated
gases from an MCO being sampled or the minuscule amount of airborne contamination from the
welding process is further diluted by the approximately 100 ft³/min airflow through the hood into the exhaust duct. Filtration by the HEPA filter ensures that the length of ductwork exposed to potentially contaminated sample gases or weld fumes is kept to a minimum.

The center shield plate and shield halves must be removed, exposing the MCO, to perform sampling, monitoring, and welding operations. The portable hoods maintain a confined environment around the sampling, monitoring, and welding operations.

As discussed previously, the K Basin fuel loading operations use an immersion pail with inflatable lid seals, rinse with deionized water, survey the cask exterior, and decontaminate as required to ensure that contamination of the MCO exterior is as low as reasonably achievable. Radioactive airborne contamination, if any, should be minuscule when a canister cover assembly is welded to the MCO.

A16.3.1.5 Maintenance Pit. The maintenance pit is located on the east side of the load-in/load-out area. The pit will serve a number of uses relating to MHM and other equipment maintenance. The maintenance pit enables maintenance workers to gain access to all the serviceable components of the MHM. During recovery actions, it could serve as a work area for decontamination operations on the MHM and other equipment. Features associated with D&D activities include a sloped floor to a recessed pump-out pit and an industrial resinous coating on floor and wall surfaces.

A16.3.1.6 Electrical System. Electrical conduits and wiring cross between the operating area and the support area of the CSB. Sleeves have been included in the design for penetrations through the shielding wall. The sleeves facilitate the replacement of conduit should a contamination problem develop, and they also facilitate decommissioning. The pass-through openings of the sleeves are sealed to prevent the migration of contamination.

A16.3.1.7 Piping. Piping crosses between the operating area and the support area of the CSB. Sleeves have been included in the design for penetrations through the shielding wall. The sleeves facilitate the replacement of piping sections should a contamination problem develop and also facilitate decommissioning. The pass-through openings of the sleeves are sealed to prevent the migration of contamination. The piping systems in the operating area that have the potential for exposure to contamination include the inert gas, exhaust, and compressed air systems. The inert gas line is stainless steel and socket welded, which offers better resistance to external contamination. Piping in the pits is stainless steel for better decontamination. All piping in the service station area is socket welded.

A16.3.1.8 Tube Vent and Purge Cart. The tube vent and purge cart interfaces with the overpack storage tube plugs on an as-needed basis for abnormal or accident MCOs. In so doing, the cart breaks the sealed boundary of the tube and becomes the boundary for secondary confinement. The cart connects to the tube by means of a flexible metal hose. The contents of the storage tube are sampled, then if acceptable, may be vented to the operating area through a...
HEPA filter. All piping on the storage tube side of the HEPA filters is welded stainless steel. The cart piping will be pressure tested regularly to verify leak tightness.

**A16.3.1.9 Heating, Ventilation, and Air Conditioning System.** The HVAC system is designed to act, along with physical barriers, as a part of the CSB contamination confinement system to ensure contamination control within the facility. The HVAC system provides a controlled pressure gradient as air flows from outside the building inward through uncontaminated areas to potentially contaminated areas of the building, and out through HEPA filters and a monitored exhaust. The HVAC units are located in the HVAC equipment room of the support area building.

The operating area HVAC system is designed to maintain a negative pressure relative to the outside environment to ensure airflow from areas of lower contamination potential to areas of higher contamination potential. To prevent the possible migration of contamination to the outside of the building, ducts for outside air supply are equipped with back draft dampers to stop any backflow of air when the fans are not operating. Double doors provide an airlock at the north and south ends of the operating area to prevent loss of confinement during the movement of MCOs or equipment. The building air exchange rate is kept low (1.5 air changes per hour) by the use of local ventilation provided by the MHM, the mobile containment service tent, the tube vent and purge cart, and the sampling/weld area portable enclosures.

Each exhaust stream is HEPA filtered before release. Those streams discharged initially into the CSB operating area mix with the air in the operating area and are HEPA filtered a second time before discharge to the atmosphere. Exhaust duct work is welded stainless steel construction that minimizes contamination traps and provides an easily decontaminated surface. HEPA filters are located on short runs as close to the source as possible to minimize the amount of contaminated duct work. Bag-out filter housings are used to minimize contamination spread during filter changes except in the case of small specialty filters where bag-out filter housings are unavailable. Operating area ventilation system HEPA filters are changed out in the filter room, which has an airlock entrance that assists in containing the potential spread of contamination.

**A16.3.1.10 Personnel Contamination Control.** A room is provided in the support area building for surveying and decontaminating personnel. The facility design includes a dedicated change room for personnel working in radiation areas and potential contamination zones to keep contamination confined in a smaller area. An area within the support area building has been identified for step-off with access to the surveying/counting room and to the change room.

**A16.3.1.11 Concrete.** The likelihood of uncontained contamination being present in the CSB is small. The operating area floor is specified to have a trowel-finished class A finish. An industrial-grade chemical concrete sealer has been applied to its trowel-finished surface. The sampling/weld area also is coated with a chemical concrete sealer. The load-in/load-out floor area has an industrial resinous coating. This is sufficient to meet the intent of the requirement in ANSI/ANS-57.9-1992, *Design Criteria for an Independent Spent Fuel Storage Installation (Dry Type)*, paragraph 6.14(1), to provide concrete with an impervious surface. Metal liners for pits...
(maintenance pit and Fast Flux Test Facility pit) and the service station area were considered but are not included in the design. Metal liners and additional concrete coatings may be added to the facility if enhancement of decontamination capability is required for future operations.

A16.3.1.12 Safety Features. Chapters A3.0, A4.0, A5.0, and A6.0 identify the selected safety features for preventing or mitigating the postulated accidents (see tables identified in Chapter A3.0 for each accident). These implemented engineered barriers and administrative programs will prevent or greatly reduce the consequences of any postulated abnormal event or accident, thus the amount and location of any radiological material releases inside the CSB will be diminished for D&D cleanup activities.

A16.3.2 Operational Considerations

Because baseline operations assume no spread of contamination from the transportation cask or MCO to the operating area of the CSB, no special facilities for the support of decontamination activities have been provided. Although the risk of contamination is minimal, operating procedures address requirements for radiological control surveys during stages of the MCO handling process to determine whether an MCO is leaking contamination and to prevent its spread. The load-in/load-out area and mobile service station enclosure, as well as the top of the sampling/weld pits and the top of the storage tubes and plugs, may require survey and decontamination following use.

The potential for personnel, equipment, and building contamination within the CSB is minimized by the design of the facility and equipment and by administrative controls, radiological contamination surveys, and work guidelines defined in operating procedures and work permits. The general design features and operating practices described in Sections 16.3.1 and 16.3.2 of the SNF Project FSAR were considered in the design of the CSB to minimize the spread of contamination, simplify D&D operations, and help minimize site and environmental contamination.

During CSB operations, site environmental contamination is minimized because of the following protection features:

- No expected liquid releases
- HEPA-filtered final exhaust
- Sealed MCOs
- Negative building pressure maintained by HVAC system.

Following the initial vault loading phase, no activities are expected to occur that would contaminate CSB facility components or structures. The CSB facility will continue to receive periodic surveillance and maintenance as required to ensure that critical items listed above required to support D&D activities are operable.
A16.3.3 Decommissioning

The construction of the operating areas of the CSB superstructure as metal frame and siding, and the vault and deck as concrete, will simplify decontamination and dismantling. The CSB has no floor drains or drain system but operates with collection sumps. This eliminates the possibility of a contaminated drain system to contend with in decommissioning. The CSB and its process equipment may be removed at a future time in compliance with applicable regulations. This could be required when equipment is obsolete or there is no continuing need for the facility. A program would be established at that time to address the decontamination required for decommissioning of the CSB and its related process equipment to eliminate the need for active maintenance of that site.

Conceptual plans for D&D will include an updated facility hazard analysis for the D&D activities, which will be used to prepare the plan to administer the expected D&D strategy. Conceptual plans also will include a preliminary deactivation plan that contains at least the following information:

- Structures, systems, and components in their final configuration
- Review and determination of status for structures, systems, and components based on mission and life cycle phase
- Configuration management for missing or inaccurate design baseline documentation, voiding and downgrading of design documents, and turnover of design baseline documents to the environmental restoration contractor.

If the CSB is identified for future use, an active maintenance plan will be instituted in place of the decommissioning plan. Decommissioning plans for the CSB facility will be developed and reviewed against the existing environmental impact statement. The environmental impact statement will be updated to include D&D activities in accordance with the National Environmental Policy Act (NEPA) of 1969 process if deemed appropriate. See Section 16.3.3 of the SNF Project FSAR for the process used to develop the CSB D&D plan.

A17.0 MANAGEMENT, ORGANIZATION, AND INSTITUTIONAL SAFETY PROVISIONS

A17.1 INTRODUCTION

A description of the organizational structure, responsibilities, and interfaces that support safe design, construction, and operational activities of the Canister Storage Building (CSB) as a subproject of the Spent Nuclear Fuel (SNF) Project are addressed in Chapter 17.0 of the SNF Project Final Safety Analysis Report (FSAR).

A17.2 REQUIREMENTS

The requirements that form the basis for management, organizational, and safety provisions are identified in Section 17.2 of the SNF Project FSAR.

A17.3 ORGANIZATIONAL STRUCTURE, RESPONSIBILITIES, AND INTERFACES

The overall structure, responsibilities, and interfaces for CSB operations are identified in Section 17.3 of the SNF Project FSAR.

A17.4 SAFETY MANAGEMENT POLICIES AND PROGRAMS

The safety management policies and programs applicable to CSB are identified in Section 17.4 of the SNF Project FSAR.
