Abarzua, S., R. Altenburger, R. Callies, L.H. Grimme, A. Mayer, D. Leibfritz, and U. Schiewer. 1993. Ammonium rhythm in cultures of the cyanobacterium *Microcystis* firma. *Physiologia Plantarum* 89(3):659-663.

Over a period of several days, rhythmic changes in extracellular NH₄⁺ concentration take place in cultures of the cyanobacterium *Microcystis* firma (Breb et Lenorm.) Schmidle, strain Gromov/St. Petersburg. 398, under conditions of restricted CO₂ supply and light/dark alternation. The changes are enhanced by nitrate supply. Among the various processes generating intracellular NH₄⁺ (NH₄⁺ uptake, NO₃⁻ reduction, protein and amino acid degradation, photorespiration), NO₃⁻ reduction appears as the one most important. This can be concluded from experiments with and without nitrate and/or ammonium in the medium. In the presence of saturating CO₂, continuous light, or continuous darkness, rhythmic NH₄⁺ oscillations are not induced. Studies of the incorporation of NH₄⁺ nitrogen by in vivo N-15-NMR show that if CO₂ is supplied, N-15 is accumulated in several components with the following time course: in the first hour in Gln (delta), in the second hour in the alpha- amino groups of most nonbranched amino acids, in the third hour in gamma-aminobutyric acid (GABA), Orn (delta) and Lys (epsilon), and in the sixth hour in Ala. Carbon limitation, however, results in accumulation of label in the amide nitrogen of glutamine only.

Abdin, O.A., X.M. Zhou, B.E. Coulman, D. Cloutier, M.A. Faris, and D.L. Smith. 1998. Effect of sucrose supplementation by stem injection on the development of soybean plants. *Journal of Experimental Botany* 49(329):2013-2018.

Over the past half decade several stem injection methods have been developed for cereal plants. These methods allow researchers to administer solutions to cereal plants to study their effects on plant physiology. However, little work has been done to extend this technique to non-cereals. An experiment was conducted to test an injection technique that could be suitable for soybean plants (*Glycine max* [L.] Merr.), and to study the effect of long-term injection of sucrose on the growth of soybean plants. An injection setup comprising a supporting stand and a fluid injection system was established. Pressure was applied to the plunger of a 5 ml syringe using ceramic bricks to force test solutions into the plants. Solutions of 0, 150, and 300 g sucrose I-1 were injected into soybean plants for 8 weeks starting at the seedling VC stage. Distilled water had the greatest uptake rate, followed by the 150, and then the 300 g sucrose I-1 solutions. The overall average uptake

during the injection period was 77.3 ml. Average sucrose uptake values were 11.8 and 13.5 g per plant for the 150 and 300 g sucrose I-1 treatments. This represented approximately 65% of the total dry weight of the plants. Sucrose injection increased leaf area and pod number relative to the control plants. Nodule numbers were lower for sucrose injected treatments, but their dry weights were higher than the control. Above-soil dry matter was higher for the plants injected with 300 g sucrose I-1 than those injected with water. The injection system tested was able to administer concentrated solutions into soybean plants for most of their period of growth and development. The sucrose supplementation had positive effects on soybean growth but suppressed photosynthesis.

Abdullaev, A.A., B.B. Dzhumayev, Z.N. Abdurakhmanova, V.L. Kaler, and I.M. Magmedov. 1992. Integral effect of environmental factors on photosynthetic metabolism of carbon in cotton leaves. *Soviet Plant Physiology* 39(2):140-144.

We used the method of mathematical experiment planning (a 2(3) scheme) to study the influence of environmental factors separately or in combination on the photosynthetic rate and distribution of C-14 among products of photosynthetic carbon metabolism in the cotton (*Gossypium hirsutum* L.) leaf. Increase of light intensity during cultivation accelerated photosynthesis and stimulated incorporation of C-14 into phosphoglyceric acid (PGA), sugar diphosphate (SDP), fructose monophosphate (FMP), and malate, but suppressed incorporation of C-14 into sucrose, glucose monophosphate (GMP), and glycerate. Temperature increase by itself and in any combination with other factors at the upper level suppressed photosynthesis. Elevated temperature increased accumulation of the label in PGA, sucrose, and malate, but lowered it in GMP, alanine, glycine, and serine. Growing plants at enhanced CO₂ concentration led to acceleration of photosynthesis and increase of the share of C-14 in SDP, GMP, and malate, but decrease of it in sucrose, alanine, glycine, and serine. Very perceptible effects of interaction are discernible in different combinations of factors. All three factors at the upper level appreciably induced activity of phosphoenolpyruvate carboxylase (PEPCase) in cotton leaves.

Nitrogen requirements for maximum growth and photosynthesis of rice, *Oryza sativa* L.-cv. Jarrah grown at 36 And 70 Pa CO₂. *Australian Journal of Plant Physiology* 26(8):759-766.

The hypothesis that growth of rice (*Oryza sativa* L. cv. Jarrah) at elevated atmospheric CO₂ partial pressure alters leaf nitrogen (N) concentrations required to support maximum dry mass production and photosynthetic rates during the period of rapid tiller initiation was tested by growing plants for 30 days in unstirred sand/hydroponic culture with N concentrations of 5, 20, 40, 60 and 100 mg N L⁻¹. Maximum growth and photosynthetic potential was greater at 70 than 36 Pa CO₂ at all N concentrations in the solution. Elevated CO₂ reduced leaf N concentrations required to support 90% of maximum growth and photosynthetic rates (critical concentration) from 40 to 27 g kg⁻¹ for growth and from 45 to 30 g kg⁻¹ for photosynthesis. Morphological changes at elevated CO₂ included increased tiller numbers and reduced leaf area ratio. The latter could be explained by lower plant N concentrations which occurred at high CO₂ at each N concentration in the solution, primarily due to lower leaf blade and root N concentrations. Changes in tiller numbers at high CO₂ were unrelated to leaf or plant N but were strongly correlated with leaf soluble carbohydrate concentrations. We conclude that elevated CO₂ alters the nutritional physiology of rice during the rapid tillering phase in a way that increases the efficiency of N utilisation for growth and photosynthesis.

Aber, J.D., S.V. Ollinger, C.A. Federer, P.B. Reich, M.L. Goulden, D.W. Kicklighter, J.M. Melillo, and R.G. Lathrop. 1995. Predicting the effects of climate change on water yield and forest production in the northeastern United States. *Climate Research* 5(3):207-222.

Rapid and simultaneous changes in temperature, precipitation and the atmospheric concentration of CO₂ are predicted to occur over the next century. Simple, well-validated models of ecosystem function are required to predict the effects of these changes. This paper describes an improved version of a forest carbon and water balance model (PnET-II) and the application of the model to predict stand- and regional-level effects of changes in temperature, precipitation and atmospheric CO₂ concentration. PnET-II is a simple, generalized, monthly time- step model of water and carbon balances (gross and net) driven by nitrogen availability as expressed through foliar N concentration. Improvements from the original model include a complete carbon balance and improvements in the prediction of canopy phenology, as well as in the computation of canopy structure and photosynthesis. The model was parameterized and run for 4 forest/site combinations and validated against available data for water yield, gross and net carbon exchange and biomass production. The validation exercise suggests that the determination of actual water availability to stands and the occurrence or non-occurrence of soil-based water stress are critical to accurate modeling of forest net primary production (NPP) and net ecosystem production (NEP). The model was then run for the entire NewEngland/New York (USA) region using a 1 km resolution geographic information system. predicted long- term NEP ranged from -85 to + 275 g Cm⁻² yr⁻¹ for the 4 forest/site combinations, and from -150 to 350 g C m⁻² yr⁻¹ for the region, with a regional average of 76 g Cm⁻² yr⁻¹. A combination of increased temperature (+6 degrees C), decreased precipitation (-15%) and increased water use efficiency (2x, due to doubling of CO₂) resulted generally in increases in NPP and decreases in water yield over the region.

Ackerly, D.D., and F.A. Bazzaz. 1995. Plant-growth and reproduction along co₂ gradients - nonlinear responses and implications for community change. *Global Change Biology* 1(3):199-207.

The effects of rising atmospheric CO₂ concentrations on natural plant communities will depend upon the cumulative responses of plant growth and reproduction to gradual, incremental changes in climatic conditions. We analysed published studies of plant responses to elevated CO₂ to address whether reproductive and total biomass exhibit similar enhancement to elevated vs. ambient CO₂ concentrations, and to assess the patterns of plant response along gradients of CO₂ concentrations. In six annual plant species, mean enhancement at double ambient vs. ambient CO₂ was 1.13 for total biomass and 1.30 for reproductive biomass. The two measures were significantly correlated, but there was considerable scatter in the relationship, indicating that reproductive responses cannot be consistently predicted from enhancement of total biomass. Along experimental CO₂ gradients utilizing three concentrations, there was a great diversity of response patterns, including positive, negative, non-monotonic and non-significant (nat) responses. The distribution of response patterns differed for plants grown in stands compared to those grown individually. Positive responses were less frequent in competitive environments, and non- monotonic responses were more frequent. These results emphasize that interpolation of plant response based on enhancement ratios measured at elevated vs. ambient CO₂ concentrations is not sufficient to predict community responses to incremental changes in atmospheric conditions. The consequences of differential response patterns were assessed in a simulation of community dynamics for four species of annual plants. The model illustrates that the final community composition at a future point in time depends critically on both the magnitude and the rate of increase of atmospheric CO₂.

Ackerly, D.D., J.S. Coleman, S.R. Morse, and F.A. Bazzaz. 1992. Co₂ and temperature effects on leaf-area production in 2 annual plant-species. *Ecology* 73(4):1260-1269.

We studied leaf area production in two annual plant species, *Abutilon theophrasti* and *Amaranthus retroflexus*, under three day/night temperature regimes (18-degrees/14-degrees, 28- degrees/22-degrees, and 38-degrees/31-degrees-C) and two concentrations of carbon dioxide (400 and 700-mu-L/L). The production of whole-plant leaf area during the first 30 d of growth was analyzed in terms of the leaf initiation rate, leaf expansion, individual leaf area, and, in *Amaranthus*, production of branch leaves. Temperature and CO₂ influenced leaf area production through effects on the rate of development, determined by the production of nodes on the main stem (the plastochron index), and through shifts in the relationship between whole-plant leaf area and the number of main stem nodes. In *Abutilon*, leaf initiation rate was highest at 38- degrees, but area of individual leaves was greatest at 28- degrees. Total leaf area was greatly reduced at 18-degrees due to slow leaf initiation rates. Elevated CO₂ concentration increased leaf initiation rate at 28-degrees, resulting in an increase in whole-plant leaf area. In *Amaranthus*, leaf initiation rate increased with temperature, and was increased by elevated CO₂ at 28-degrees. Individual leaf area was greatest at 28-degrees, and was increased by elevated CO₂ at 28-degrees but decreased at 38-degrees. Branch leaf area displayed a similar response to CO₂, but was greater at 38- degrees. Overall, whole-plant leaf area was slightly increased at 38-degrees relative to 28-degrees, and elevated CO₂ levels resulted in increased leaf area at 28-degrees but decreased leaf area at 38-degrees. The effects on leaf area closely parallel rates of biomass

accumulation in the same experiment, suggesting that responses of developmental processes to elevated CO₂ and interacting factors may play an important role in mediating effects on plant growth.

Acock, B., and G.W. Wall. 1995. A simple conductimetric CO₂ analyzer with automatic recalibration .1. Design, implementation, and functionality. *Agronomy Journal* 87(1):70-75.

Controlled-environment plant growth cabinets may be used to investigate the long-term effect of elevated carbon dioxide concentration ([CO₂]) on plant growth. Infrared gas analyzers (IRGAs) are normally used to monitor and control [CO₂] in plant cabinets. With many cabinets in use, however, it soon becomes impractical to purchase an individual IRGA for each cabinet. A more economical method of monitoring and controlling [CO₂] relies on the change in electrical conductivity when CO₂ is dissolved in demineralized water. This work describes the design, implementation, and functionality of an inexpensive conductimetric system for controlling [CO₂] in plant growth cabinets. Regressing electrical conductivity against [CO₂] over the range 0 to 1000 $\mu\text{m L L}^{-1}$ yields a quadratic response. Calibration drift inherent in the conductimetric CO₂ analyzer requires that each analyzer be recalibrated periodically. Automatically recalibrating with an IRGA every 900 s gave control of the [CO₂] within the plant enclosures to within 10 to 15 $\mu\text{m L L}^{-1}$ of the set point. The [CO₂] control system is robust enough to maintain this accuracy regardless of the desired [CO₂] set point or the mass of plant material within the plant growth cabinet. In this approach, only one IRGA is required to control [CO₂] in many plant growth cabinets if each cabinet has a dedicated conductimetric CO₂ analyzer.

Adams, R.M., R.A. Fleming, C.C. Chang, B.A. McCarl, and C. Rosenzweig. 1995. A reassessment of the economic-effects of global climate-change on US agriculture. *Climatic Change* 30(2):147-167.

This study uses recent GCM forecasts, improved plant science and water supply data and refined economic modeling capabilities to reassess the economic consequences of long-term climate change on U.S. agriculture. Changes in crop yields, crop water demand and irrigation water arising from climate change result in changes in economic welfare. Economic consequences of the three GCM scenarios are mixed; GISS and GFDL-QFlux result in aggregate economic gains, UKMO implies losses. As in previous studies, the yield enhancing effects of atmospheric CO₂ are an important determinant of potential economic consequences. Inclusion of changes in world food production and associated export changes generally have a positive affect on U.S. agriculture. As with previous studies, the magnitude of economic effects estimated here are a small percentage of U. S. agricultural value.

Adamse, P., and S.J. Britz. 1992. Amelioration of uv-b damage under high irradiance .1. Role of photosynthesis. *Photochemistry and photobiology* 56(5):645-650.

Sensitivity to ultraviolet-B radiation (UV-B, 280-315 nm) is generally reduced when background irradiance is high. We tested the involvement of photosynthesis in the amelioration of UV-B damage by treating plants at high PAR (photosynthetically- active radiation. 400-700 nm; 1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$) with supplemental UV-B at double ambient levels of biologically- effective radiation (18 kJ m⁻² d⁻¹) and either "ambient" (450 $\mu\text{mol mol}^{-1}$) or short term elevated (750 $\mu\text{mol mol}^{-1}$) CO₂ levels. Responses to UV-B were assessed by photosynthetic gas exchange, leaf expansion and production of UV-absorbing compounds (presumptive flavonoids) in cultivars of cucumber (*Cucumis sativus* L.) previously demonstrated to be relatively sensitive (cv. Poinsett) and insensitive (cv. Ashley) to UV-B. Except for marginal leaf interveinal chlorosis observed in Poinsett, both cultivars responded similarly. UV-B had little direct effect on leaf photosynthesis, but it did cause reductions in leaf area and corresponding increases in leaf dry matter per area. Increased CO₂ stimulated plant growth, counteracting the effect of UV-B on leaf growth and indicating an important role for photosynthesis. In contrast, the accumulation of UV-absorbing flavonoid compounds was enhanced by UV-B exposure but was not affected by CO₂ enrichment.

Adamsen, F.J., P.J. Pinter, E.M. Barnes, R.L. LaMorte, G.W. Wall, S.W. Leavitt, and B.A. Kimball. 1999. Measuring wheat senescence with a digital camera. *Crop Science* 39(3):719-724.

Documenting crop senescence rates is often difficult because of the need for frequent sampling during periods of rapid change and the subjective nature of human visual observations. The purpose of this study was to determine the feasibility of using images produced by a digital camera to measure the senescence rate of wheat and to compare the results with changes in greenness determined by two established methods. Measurements were made as part of an experiment to determine the effects of elevated CO₂ and limited soil nitrogen on spring wheat (*Triticum aestivum* L.) at the University of Arizona's Maricopa Agricultural Center, near Phoenix, AZ. "Greenness" measurements were made during senescence of the crop with a color digital camera, a hand-held radiometer, and a SPAD chlorophyll meter. The green to red (GIR) for each pixel in an image was calculated and the average GIR computed for cropped images from a digital camera representing 1 m² for each treatment and sample date. The normalized difference vegetation index (NDVI) was calculated from the red and near-infrared canopy reflectances measured with a hand held radiometer. A SPAD reading was obtained from randomly selected flag leaves. All three methods of measuring plant greenness showed similar temporal trends. The relationships between GIR with NDVI and SPAD were linear over most of the range of GIR. However, NDVI was more sensitive at low values than GIR. GIR was more sensitive above G/R values of 1.2 than SPAD because the upper limits of SPAD measurements were constrained by the amount of chlorophyll in the leaf, while GIR responded to both chlorophyll concentration in the leaves as well as the number of leaves present. Color digital imaging appears useful for quantifying the senescence of crop canopies. The cost of color digital cameras is expected to decrease and the quality and convenience of use to improve.

Agar, I.T., J. Streif, and F. Bangerth. 1997. Effect of high CO₂ and controlled atmosphere (CA) on the ascorbic and dehydroascorbic acid content of some berry fruits. *Postharvest Biology and Technology* 11(1):47-55.

High CO₂ concentrations as well as controlled atmosphere storage are widely used to extend the storage and shelf-life of many fruits. To investigate the effect of these storage procedures on several berry fruits, strawberries, raspberries, currants and blackberries were stored at three different elevated CO₂ concentrations, with or without a parallel reduction in O₂. Vitamin C content (ascorbic acid plus dehydroascorbic acid) was reduced by high CO₂ concentrations (10-30% CO₂), particularly in strawberries. This reduction in vitamin C was moderate in black currants and blackberries and almost absent in raspberries and red currants when compared with strawberries. Reducing the O₂ concentration in the storage atmosphere in the presence of high CO₂ had little effect on the vitamin C content. Ascorbic acid was more diminished at high CO₂ than dehydroascorbic acid. This suggests a stimulating effect of high CO₂ concentrations on the oxidation of ascorbic acid and/or an inhibition of mono- or dehydroascorbic acid reduction to ascorbic acid. Aggangan, R.T., A.M. O'Connell, J.F. McGrath, and B. Dell. 1999. The effects of Eucalyptus globulus Labill. leaf litter on C and N mineralization in soils from pasture and native forest. *Soil Biology and Biochemistry* 31(11):1481-1487.

The effects of addition of Eucalyptus globulus leaf litter on carbon and nitrogen mineralization in soils from a pasture and a native forest were evaluated using a long-term laboratory aerobic incubation assay (29 weeks at 20 degrees C) in leaching microlysimeters. The amount of added leaf litter significantly influenced microbial respiration, microbial biomass and N turnover in both the native forest and pasture soils. Cumulative CO₂-C respired increased with increasing rate of leaf litter addition when leaf litter was mixed through the soil or placed on the soil surface. These increases were associated with increases in microbial biomass C content. Cumulative net N mineralization declined in all treatments when litter was added and was lowest when leaf litter was mixed with soil. When leaf litter was added in increasing amounts to the soil surface, there was a concomitant increase in microbial biomass N content ($r(2) = 0.79$, $n = 8$), indicating that the reduction in net N mineralization was primarily due to immobilization of N in microbial tissues. In contrast, when litter was mixed with soil in increasing amounts, there was a decrease in microbial biomass N in forest soil and an increase in pasture soil. Consequently, changes in the rate of net N mineralization were not well related to changes in microbial biomass N content. It is suggested that this may be due to the greater activity and more rapid turnover of microorganisms where litter was incorporated resulting in more of the immobilized N being partitioned into metabolic products or dead microbial cells. Incorporation of litter may also have enhanced loss N through denitrification. (C) 1999 Published by Elsevier Science Ltd. All rights reserved.

Agren, G.I. 1996. Nitrogen productivity or photosynthesis minus respiration to calculate plant growth? *Oikos* 76(3):529-535.

One approach to calculate plant growth rate is from models of photosynthesis, respiration and allocation. This requires that processes with characteristic time constants of seconds to minutes be scaled to hours or days. Another approach is to use aggregate models defined at the time scale of growth, hours and days. I use such an aggregate model, the nutrient productivity, to compare the performance of the two approaches on growth experiments with small, nitrogen-limited birch plants. The problems of error aggregation when using the large number of parameters required to scale from the detailed level of photosynthesis and respiration to the aggregate level of growth are in this case such that whole plant growth rate is more accurately predicted with the nutrient productivity model.

Agren, G.I., R.E. McMurtrie, W.J. Parton, J. Pastor, and H.H. Shugart. 1991. State-of-the-art of models of production decomposition linkages in conifer and grassland ecosystems. *Ecological Applications* 1(2):118-138.

We review the state-of-the-art of models of forests and grasslands that could be used to predict the impact of a future climate change arising from increased atmospheric carbon dioxide concentration. Four levels of resolution are recognized: physiologically based models, population models, ecosystem models, and regional or global models. At the physiological level a number of important processes can be described in great detail, but these models often treat inadequately interactions with nutrient cycles, which operate on longer time scales. Population and ecosystem models can, on the other hand, encapsulate relationships between the plants and the soil system, but at the expense of requiring more ad hoc formulations of processes. At the regional and global scale we have so far only steady-state models, which cannot be used to predict transients caused by climate change. However, our conclusion is that, in spite of the gaps in knowledge, there are several models based on dominant processes that are well enough understood for the predictions of those models to be taken seriously.

Ahmadi, H., W.V. Biasi, and E.J. Mitcham. 1999. Control of brown rot decay of nectarines with 15% carbon dioxide atmospheres. *Journal of the American Society for Horticultural Science* 124(6):708-712.

Effects of short-term exposure to a 15% CO₂ atmosphere on nectarines [Prunus persica (L.) Batsch (Nectarine Group) 'Summer Red'] inoculated with Monilinia fructicola (Wint.) Honey (causal agent of brown rot) were investigated. Nectarines were inoculated with spores of M.fructicola and incubated at 20 degrees C for 24, 48 or 72 hours and then transferred to storage in either air or air enriched with 15% CO₂ at 5 degrees C. Fruit were removed from storage after 5 and 16 days and were examined for brown rot decay immediately and after ripening in air for 3 days at 20 degrees C. Noninoculated nectarines were stored and treated likewise for evaluation of postharvest fruit attributes to determine their tolerance to 15% CO₂. Incubation period after inoculation, storage duration, and storage atmosphere had highly significant effects on fruit decay. 'Summer Red' nectarines tolerated a 15% CO₂ atmosphere for 16 days at 5 degrees C. Development of brown rot decay in fruit inoculated 24 hours before 5 or 16 days storage in 15% CO₂ at 5 OC was arrested.

After 3 days ripening in air at 20 degrees C, the progression of brown rot disease was rapid in all inoculated nectarines, demonstrating the fungistatic effect of 15% CO₂. The quantity of fungal cell wall materials (estimated by glucosamine concentration) was compared to visual estimation of decayed area and visual rating of fungal sporulation. The glucosamine assay defined the onset and progress of brown rot infection more precisely than either of the two visual tests.

Ahmed, F.E., A.E. Hall, and M.A. Madore. 1993. Interactive effects of high-temperature and elevated carbon-dioxide concentration on cowpea [*Vigna unguiculata* (L.) Walp]. *Plant, Cell and Environment* 16(7):835-842.

Limitations in carbohydrate supplies have been implicated as a factor responsible for reproductive failure under heat stress. Heat stress affects two stages of reproductive development in cowpea [*Vigna unguiculata* (L.) Walp.], and genotypes are available with tolerance and sensitivity to heat during these different stages. The objectives of this study were to determine the responses of these cowpea lines to ambient and elevated [CO₂], under heat stress and optimal temperature, and test whether differences in carbohydrate supplies due to genotypes, CO₂ enrichment and heat stress are associated with differences in sensitivity to heat during reproductive development. Plants were grown in reach-in growth chambers and subjected to day/night temperatures of either 33/20 or 33/30- degrees-C, and [CO₂] levels of either 350 or 700 mumol mol⁻¹. Under intermediate night temperature (33/20-degrees-C), all lines set substantial numbers of pods. Under high night temperature (33/30-degrees-C) with either ambient or elevated [CO₂], one heat-sensitive line produced no flowers and the other set no pods, whereas the heat-tolerant line abundantly set pods. High night temperature reduced the overall carbohydrate content of the plants, especially peduncle sugars, and caused decreases in photosynthetic rates. The high pod set of the heat-tolerant line, under high night temperature, was associated with higher levels of sugars in peduncles compared with the heat-sensitive lines. The heat-tolerant line accumulated substantial shoot biomass, exhibited less accumulation of starch in leaves, and possibly had less down-regulation of photosynthesis in response to CO₂ enrichment and heat stress than the heat-sensitive lines. Elevated [CO₂] resulted in higher overall carbohydrate levels in heat-sensitive lines (starch in leaves, stems and peduncles), but it did not increase their heat tolerance with respect to flower production or pod set. Heat-induced damage to floral buds and anthers in the sensitive lines was associated with low sugars levels in peduncles, indicating that heat had greater effects on assimilate demand than on leaf assimilate supply. The heat-tolerant line was the most responsive genotype to elevated [CO₂] with respect to pod production under either high or intermediate temperatures.

Aikman, D.P. 1996. A procedure for optimizing carbon dioxide enrichment of a glasshouse tomato crop. *Journal of Agricultural Engineering Research* 63(2):171-183.

The procedure consists of two parts. A Gompertz model for the kinetics of fruit growth is used to predict the time distribution of photosynthate subsequent harvests. This is combined with predictions of future market prices to compute estimates, one for each day from first anthesis, of a factor to convert CO₂ assimilate to expected financial value, based on the worth anticipated from partitioning to fruit. A model of the climate

and the crop regime is used to predict temperatures and hence allow for the temperature dependence of fruit growth. The conversion estimates are revised to include the deferred benefit given by additional photosynthesis through increasing early vegetative growth, and hence subsequent photosynthesis and yield. This revision also extends the set of conversion factors to include any period before first anthesis. Given the current environmental variables and conversion factor for that day, a real-time system can use a crop photosynthesis model to predict the cash benefit for any CO₂ concentration. The cost of maintaining a concentration can be obtained from a prediction of the ventilation air exchange rate and the unit price of CO₂. The CO₂ set-point is evaluated as the concentration that maximizes the net profit rate. (C) 1996 Silsoe Research Institute

Akimoto, M., A. Shirai, K. Ohtaguchi, and K. Koide. 1998. Carbon dioxide fixation and polyunsaturated fatty acid production by the red alga *Porphyridium cruentum*. *Applied Biochemistry and Biotechnology* 73(2-3):269-278.

Focusing on CO₂ fixation, photoautotrophic cultivation of the red alga *Porphyridium cruentum* was investigated by means of a batch culture under a 5% CO₂-enriched atmosphere. The algal growth kinetics was successfully described with a logistic model, and simulation of a continuous culture under the optimum growth conditions (30 degrees C, 12 klux and 1.18 g-cells/L) showed that the algal CO₂-fixation activity could reach 0.66 g-CO₂/(L X d). Under the same growth conditions, eicosapentaenoic acid (20:5 n-3, EPA) and arachidonic acid (20:4 n-6, ARA) yields were similarly calculated to be 3.6 mg-EPA/(L X d) and 6.5 mg-ARA/(L X d), respectively.

Akin, D.E., B.A. Kimball, J.R. Mauney, R.L. Lamorte, G.R. Hendrey, K. Lewin, J. Nagy, and R.N. Gates. 1994. Influence of enhanced CO₂ concentration and irrigation on sudangrass digestibility. *Agricultural and Forest Meteorology* 70(1-4):279-287.

An experimental line of sudangrass (*Sorghum bicolor* L. Moench) was included in the free-air CO₂ enrichment (FACE) project in 1991 at the University of Arizona Maricopa Agricultural Center to evaluate the effect of ambient (approximately 370 mumol mol⁻¹) and enriched (550 mumol mol⁻¹) CO₂ in well-watered or water-stressed plots. Our specific objective was to determine modifications caused by these environmental effects on the percentages of morphological parts and the fiber components, and on the in vitro digestibility in vegetative and mature harvests. Enrichment with CO₂ did not (P > 0.05) change the percentages of morphological parts or fiber components, or the digestibility of any of the morphological components. Protein levels tended to be lower in CO₂-enriched plants. However, water-stressed plants tended to have a higher proportion of leaves (blades and sheaths) and a lower proportion of stems, were more digestible, and had lower amounts of anti-quality, aromatic compounds within the plant cell. Stems had the highest digestibility of all morphological components (about 75% in vegetative plants) despite the lowest levels of protein. Stems also showed the greatest changes caused by all treatments, including a 20% decline in digestibility from vegetative to mature samples. The results indicate that enriching CO₂ to 550 mumol mol⁻¹ did not reduce digestibility of sudangrass.

Akin, D.E., B.A. Kimball, W.R. Windham, P.J. Pinter, G.W. Wall, R.L. Garcia, R.L. Lamorte, and W.H. Morrison. 1995. Effect of free-air CO₂ enrichment (FACE) on forage quality of wheat. *Animal Feed Science and Technology* 53(1):29-43.

Wheat (*Triticum aestivum* L., cultivar 'Yecora rojo') was grown in ambient (370 $\mu\text{mol mol}^{-1}$) or enriched (550 $\mu\text{mol mol}^{-1}$) concentrations of CO₂ in the free-air CO₂ enrichment (FACE) project, and components were analyzed for in vitro digestibility, fiber constituents, and crude protein. Four replicated plots of each CO₂ treatment were split for irrigation: 'wet' regions received 60 cm of water and 'dry' regions received 30 cm of water through underground tubes. Enriched CO₂ concentrations had no effect on in vitro digestion of intact sections of young (26-32-day-old plants) leaf blades except at 24-27 h incubation, at which time enriched leaves were lower in digestibility than control ones. Enriched CO₂ concentrations increased the content of acid detergent fiber (ADF) and cellulose of young wet leaves. Sections of main shoots at 26 days tended to have increased digestibility with elevated CO₂ levels. Enriched CO₂ concentrations did not alter the digestibility of flag leaves from 105-day-old plants or of flag leaves, uppermost stems, and sheaths from plants at full grain maturity. Enriched CO₂ levels reduced the acid detergent lignin (ADL) and tended to reduce the protein of leaves from 105-day-old plants. For mature leaf blades, neutral detergent fiber, ADF, and cellulose were, or tended to be, higher while protein content tended to be lower in elevated CO₂-grown plants; for both CO₂ treatments, 'dry' leaves were higher in digestibility and lower in ADL than 'wet' samples. Mature stems plus sheaths had lower protein contents in plants grown in elevated CO₂. Results indicated that enriched CO₂ concentrations to 550 $\mu\text{mol mol}^{-1}$ did not substantially alter wheat in vitro digestibility, regardless of irrigation treatment. Elevated CO₂ altered fiber components and protein, but these were not consistent among parts and harvests.

Akin, D.E., L.L. Rigsby, G.R. Gamble, W.H. Morrison, B.A. Kimball, P.J. Pinter, G.W. Wall, R.L. Garcia, and R.L. Lamorte. 1995. Biodegradation of plant-cell walls, wall carbohydrates, and wall aromatics in wheat grown in ambient or enriched CO₂ concentrations. *Journal of the Science of Food and Agriculture* 67(3):399-406.

Mature internodes from wheat (*Triticum aestivum* L.) grown in control (ambient at c 370 $\mu\text{mol mol}^{-1}$) or enriched (to 550 $\mu\text{mol mol}^{-1}$) concentrations of atmospheric CO₂ in the free-air CO₂ enrichment (FACE) system were analyzed for potential changes in biodegradation of constituents due to predicted increases in atmospheric levels of CO₂. The first internodes below the grain were incubated with the lignocellulose-degrading white rot fungus, *Phanerochaete chrysosporium* K-3, or incubated without microorganisms. Plant samples were then analyzed for dry weight loss, disposition of specific cell types to biodegradation using electron microscopy, carbohydrates and lignin using solid state NMR spectroscopy, and ester- and ether-linked aromatics using gas chromatography. *Phanerochaete chrysosporium* extensively degraded stems cells (c 75%) and both carbohydrate and aromatic portions of the wheat stems proportionately more carbohydrates were removed by the fungus from the stems. Enriched CO₂ did not affect the chemical composition of wheat stems or the biodegradation by *P. chrysosporium* of plant cell walls or wall components for the most part. Data from various methods all indicated that enriched CO₂ did not substantially alter the biodegradation of wheat cell wall internodes or wall components. Evidence was not found for an influence on C cycling

due to CO₂ concentrations in this study.

Alagusundaram, K., D.S. Jayas, N.D.G. White, W.E. Muir, and R.N. Sinha. 1995. Controlling cryptolestes-ferrugineus (stephens) adults in wheat stored in bolted-metal bins using elevated carbon-dioxide. *Canadian Agricultural Engineering* 37(3):217-223.

Experiments were conducted in two 5.56 m-diameter farm bins to determine the mortality of caged adult rusty grain beetles, *Cryptolestes ferrugineus* (Stephens) (Coleoptera: cucujidae), under elevated carbon dioxide (CO₂) concentrations. The bins were filled with wheat to a depth of 2.5 m. Dry ice was used to create high CO₂ concentrations in the wheat bulks. Two different modes of application of dry ice were used: (i) pellets on the grain surface and in the aeration duct and (ii) pellets on the grain surface and blocks in insulated boxes on the grain surface. The pellets exposed to the ambient conditions on the grain surface and in the aeration duct sublimated quickly and had to be replenished at frequent intervals. Dry ice blocks in insulated boxes, however, maintained high CO₂ concentrations without replenishment for over 15 d. In both modes of application, the observed CO₂ concentrations in the intergranular gas were about 15% and 30% (all the CO₂ concentrations given in this article are on a volume basis) at 2.05 m and 0.55 m above the floor, respectively. At 0.55 m above the floor, the mortality of rusty grain beetle adults was more than 90% while in the top portions of the bulk (2.05 m above the floor) the mortality was only 30%. On an average about two thirds of the insects were killed. The use of controlled atmosphere treatment within an integrated pest management context is outlined.

Alberto, A.M.P., L.H. Ziska, C.R. Cervancia, and P.A. Manalo. 1996. The influence of increasing carbon dioxide and temperature on competitive interactions between a C3 crop, rice (*Oryza sativa*) and a C-4 weed (*Echinochloa glabrescens*). *Australian Journal of Plant Physiology* 23(6):795-802.

Many of the most troublesome weeds in agricultural systems are C-4 plants. As atmospheric CO₂ increases it is conceivable that competitive ability of these weeds could be reduced relative to C-3 crops such as rice. At the International Rice Research Institute (IRRI) in the Philippines, rice (IR72) and one of its associated C-4 weeds, *Echinochloa glabrescens*, were grown from seeding to maturity using replacement series mixtures (100:0, 75:25, 50:50, 25:75, and 0:100, % rice:% weed) at two different CO₂ concentrations (393 and 594 $\mu\text{mol L}^{-1}$) in naturally sunlit glasshouses. Since increasing CO₂ may also result in elevated growth temperatures, the response of rice to each CO₂ concentration was also examined at day/night temperatures of 27/21 and 37/29 degrees C. At 27/21 degrees C, increasing the CO₂ concentration resulted in a significant increase in above ground biomass (+47%) and seed yield (+55%) of rice when averaged over all mixtures. For *E. glabrescens*, the C-4 species, no significant effect of CO₂ concentration on biomass or yield was observed. When grown in mixture, the proportion of rice biomass increased significantly relative to that of the C-4 weed at all mixtures at elevated CO₂. Evaluation of changes in competitiveness (by calculation of plant relative yield (PRY) and replacement series diagrams) of the two species demonstrated that, at elevated CO₂, the competitiveness of rice was increased relative to that of *E. glabrescens*. However, at the higher growth temperature (37/29 degrees C), growth and reproductive stimulation of rice by elevated CO₂ was reduced compared to the lower growth temperature. This resulted in a reduction in the proportion of rice:weed biomass present in all

mixtures relative to 27/21 degrees C and a greater reduction in PRY in rice relative to *E. glabrescens*. Data from this experiment suggest that competitiveness could be enhanced in a C-3 crop (rice) relative to a C-4 weed (*E. glabrescens*) with elevated CO₂ alone, but that simultaneous increases in CO₂ and temperature could still favour a C-4 species.

Alcamo, J., G.J.J. Kreileman, M.S. Krol, and G. Zuidema. 1994. Modeling the global society-biosphere-climate system .1. Model description and testing. *Water, Air, and Soil Pollution* 76(1-2):1-35.

This paper describes the IMAGE 2.0 model, a multi-disciplinary, integrated model designed to simulate the dynamics of the global society-biosphere-climate system. The objectives of the model are to investigate linkages and feedbacks in the system, and to evaluate consequences of climate policies. Dynamic calculations are performed to year 2100, with a spatial scale ranging from grid (0.5-degrees x 0.5-degrees latitude- longitude) to world regional level, depending on the sub-model. The model consists of three fully linked sub-systems: Energy- Industry, Terrestrial Environment, and Atmosphere-Ocean. The Energy-Industry models compute the emissions of greenhouse gases in 13 world regions as a function of energy consumption and industrial production. End use energy consumption is computed from various economic/demographic driving forces. The Terrestrial Environment models simulate the changes in global land cover on a grid-scale based on climatic and economic factors, and the flux of CO₂ and other greenhouse gases from the biosphere to the atmosphere. The Atmosphere-Ocean models compute the buildup of greenhouse gases in the atmosphere and the resulting zonal-average temperature and precipitation patterns. The fully linked model has been tested against data from 1970 to 1990, and after calibration can reproduce the following observed trends: regional energy consumption and energy-related emissions, terrestrial flux of CO₂ and emissions of greenhouse gases, concentrations of greenhouse gases in the atmosphere, and transformation of land cover. The model can also simulate long term zonal average surface and vertical temperatures.

Modeling the global society-biosphere-climate system .2. Computed scenarios. *Water, Air, and Soil Pollution* 76(1-2):37-78.

This paper presents scenarios computed with IMAGE 2.0, an integrated model of the global environment and climate change. Results are presented for selected aspects of the society- biosphere-climate system including primary energy consumption, emissions of various greenhouse gases, atmospheric concentrations of gases, temperature, precipitation, land cover and other indicators. Included are a "Conventional Wisdom" scenario, and three variations of this scenario: (i) the Conventional Wisdom scenario is a reference case which is partly based on the input assumptions of the IPCC's IS92a scenario; (ii) the "Biofuel Crops" scenario assumes that most biofuels will be derived from new cropland; (iii) the "No Biofuels" scenario examines the sensitivity of the system to the use of biofuels; and (iv) the "Ocean Realignment" scenario investigates the effect of a large-scale change in ocean circulation on the biosphere and climate. Results of the biofuel scenarios illustrate the importance of examining the impact of biofuels on the full range of greenhouse gases, rather than only CO₂. These scenarios also indicate possible side effects of the land requirements for energy crops. The

Ocean Realignment scenario shows that an unexpected, low probability event can both enhance the build-up of greenhouse gases, and at the same time cause a temporary cooling of surface air temperatures in the Northern Hemisphere. However, warming of the atmosphere is only delayed, not avoided.

Allen, D.J., I.F. McKee, P.K. Farage, and N.R. Baker. 1997. Analysis of limitations to CO₂ assimilation on exposure of leaves of two *Brassica napus* cultivars to UV-B. *Plant, Cell and Environment* 20(5):633-640.

Apex and Bristol cultivars of oilseed rape (*Brassica napus*) were irradiated with 0.63 W m⁻² of UV-B over 5 d. Analyses of the response of net leaf carbon assimilation to intercellular CO₂ concentration were used to examine the potential limitations imposed by stomata, carboxylation velocity and capacity for regeneration of ribulose 1,5-bisphosphate on leaf photosynthesis. Simultaneous measurements of chlorophyll fluorescence were used to estimate the maximum quantum efficiency of photosystem II (PSII) photochemistry, the quantum efficiency of linear electron transport at steady-state photosynthesis, and the light and CO₂-saturated rate of linear electron transport. Ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) content and activities were assayed in vitro. In both cultivars the UV-B treatment resulted in decreases in the light-saturated rate of CO₂ assimilation, which were accompanied by decreases in carboxylation velocity and Rubisco content and activity. No major effects of UV-B were observed on end-product inhibition and stomatal limitation of photosynthesis or the rate of photorespiration relative to CO₂ assimilation. In the Bristol cultivar, photoinhibition of PSII and loss of linear electron transport activity were observed when CO₂ assimilation was severely inhibited. However, the Apex cultivar exhibited no major inhibition of PSII photochemistry or linear electron transport as the rate of CO₂ assimilation decreased. It is concluded that loss of Rubisco is a primary factor in UV-B inhibition of CO₂ assimilation.

Elevated carbon dioxide (CO₂) concentration increases plant photosynthesis, biomass and carbohydrate accumulation. Since plants have grown in low CO₂ (200 to 300 $\mu\text{mol mol}^{-1}$) for the last several million years, how will they use extra photoassimilate as the atmospheric CO₂ continues to rise? The objectives were to determine the effects of past, present and projected future levels of CO₂ on diurnal and seasonal patterns of total nonstructural carbohydrate (TNC) concentration of soybean [*Glycine max* (L.) Merr.] tissues. Plants were grown at 160, 220, 280, 330, 660 and 990 $\mu\text{mol mol}^{-1}$ CO₂ in outdoor, sunlit chambers wherein CO₂ uptake rates were measured continuously. Early morning and late afternoon plant samples were taken at eight dates. The

TNC concentration of leaves, petioles and stems increased as CO₂ increased. Canopy photosynthetic rates also increased with increasing CO₂, apparently without any negative impact of increased leaf TNC. Concentrations of TNC in all vegetative tissues were lower in the morning than the afternoon, which indicates overnight mobilization and utilization of carbohydrates for growth processes. The concentration of TNC was lowest in all plant components during rapid vegetative growth at Vg to R2 developmental stages. Leaves of all plants, especially those grown in superambient CO₂, contained large pools of TNC at plant maturity, which indicated that not all of the reserves were utilized for seed yield. Soybean cultivars for the future should be designed to utilize carbohydrates more readily for seed production so that greater benefit can be realized from rising atmospheric CO₂.

Allen, L.H., E.C. Bisbal, K.J. Boote, and P.H. Jones. 1991. Soybean dry-matter allocation under subambient and superambient levels of carbon-dioxide. *Agronomy Journal* 83(5):875-883.

Rising atmospheric carbon dioxide concentration [CO₂] is expected to cause increases in crop growth and yield. The objective of this study was to investigate effects of subambient, as well as superambient, [CO₂] on soybean [*Glycine max* (L.) Merr.] dry matter production and allocation for two reasons: to assess response of plants to prehistoric as well as future expected CO₂ levels and to increase confidence in [CO₂] response curves by imposing a wide range of [CO₂] treatments. Soybean was grown in outdoor, sunlit, controlled- environment chambers at CO₂ levels of 160, 220, 280, 330, 660, and 990- μ -mol (CO₂) mol⁻¹ (air). Total dry matter growth rates during the linear phase of vegetative growth were 5.0, 8.4, 10.9, 12.5, 18.2, and 20.7 g m⁻² d⁻¹ for the above respective [CO₂]. Samples taken from 24 to 94 d after planting showed that the percentage of total plant mass in leaf trifoliolates decreased with increasing [CO₂] whereas the percentage in structural components (petioles and stems) increased. At final harvest the respective [CO₂] treatments resulted in 38, 53, 62, 100, 120, and 92% seed yield with respect to the 330- μ -mol mol⁻¹ treatment. Total dry weight responses were similar. Late season spider mite damage of the 990 and 280- μ -mol mol⁻¹ treatments reduced yields. These data confirm not only that rising CO₂ should increase plant growth, but also that plant growth was probably seriously limited by atmospheric [CO₂] in preindustrial revolution times back to the previous global glaciation.

Allen, L.H., R.R. Valle, J.W. Jones, and P.H. Jones. 1998. Soybean leaf water potential responses to carbon dioxide and drought. *Agronomy*

Journal 90(3):375-383.

Rising CO₂ can have direct effects on crop water relations and indirect effects on water available for growth. We studied the effects of elevated CO₂ and drought on leaf water relations of soybean [*Glycine max* (L.) Merr. cv. Bragg] and considered the hypothesis of osmotic adjustment mediated by increased photosynthesis (Hypothesis 1) vs. the hypothesis of water conservation mediated by decreased stomatal conductance (Hypothesis 2) to explain improved water relations of plants growing under elevated CO₂. In Exp. 1, soybean was grown at 330, 450, 660, and 800 μ mol mol⁻¹ CO₂ in sunlit, closed- circulation, controlled- environment chambers under well-watered conditions. Leaf total water potential (WP), osmotic potential (OP), and turgor potential (TP) were measured at midday during V4 to R6 stages of development. In Exp. 2 (well-watered, R1-R3) and Exp. 3 (13-d drying cycle, R6 seed filling), soybean was grown at 330 and 660 μ mol mol⁻¹ CO₂ and WP, OP, and TP were measured five times per day on sunlit and shaded leaves. In Exp. 3, stomatal conductance (g(s)) and transpiration rate (TR) of leaves were also measured. Experiments 1 and 2 showed that elevated CO₂ increased TP and decreased OP, but did not affect leaf WP, thus favoring Hypothesis 1. In Exp. 3, leaf WP was higher in elevated than ambient CO₂. Diurnal TP was higher in elevated than ambient CO₂ at the beginning of drought, and was maintained longer each day as drought progressed. At the end of drought, TP and WP was higher in elevated than ambient CO₂. Elevated CO₂ leaves had lower TR because of lower g(s) than ambient CO₂ counterparts. Thus, Exp. 3 supported Hypothesis 2, that both stressed and nonstressed plants in elevated CO₂ have a better water status (e.g., higher TP) than plants in ambient CO₂ due to water conservation mediated by decreased g(s). Remobilization of leaf nutrients during seed filling may limit the capability for osmotic adjustment. Regardless of the mechanisms, growth of plants in elevated CO₂ should be less affected by drought than plants in ambient CO₂.

Allen, L.H., R.R. Valle, J.W. Mishoe, and J.W. Jones. 1994. Soybean leaf gas-exchange responses to carbon-dioxide and water-stress. *Agronomy Journal* 86(4):625-636.

As global carbon dioxide concentrations rise, we need to understand the combination of direct effects of this gas and the anticipated effects of climate change, including drought, on physiology and growth of all crops. Effects Of CO₂ on plants begin at the leaf level; our objectives, therefore, were to determine interrelationships among factors governing gas exchange responses of soybean [*Glycine max* (L.) Merr.] leaves to elevated CO₂ and water stress. Photosynthetic CO₂ assimilation and transpiration rates were measured in cuvettes on leaflets of soybean (cv. Bragg) grown in controlled- environment chambers at 330 and 660 μ mol CO₂ Mol⁻¹ air. Leaflets at high CO₂, either water-stressed or well-watered, had higher photosynthetic and lower transpiration rates, and therefore higher water-use efficiencies (WUE), than those at Control CO₂ levels. As irrigation was withheld during an 11-d period, WUE decreased about 30 to 50% with respect to the well- watered treatments. Midday leaf temperature and leaf-to-air vapor pressure gradient levels increased as the water stress progressed. For water stress treatments, midday leaf conductance (G(lw)) was generally higher and residual internal conductance (G(r)) was generally lower in low than in high CO₂. Ratios of midday G(r)/G(lc), were nearly constant throughout the period in both the stressed and the well-watered treatments. The ratios of intercellular C(i), to ambient C(a), CO₂ concentration (i.e., C(i)/C(a)) during the water stress period remained similar to the respective nonstressed treatments within each CO₂ level. These findings support the concept that leaf conductances are governed by CO₂ assimilation rates under water-stressed as well as unstressed conditions.

Almeida, J.P.F., A. Luscher, M. Frehner, A. Oberson, and J. Nosberger. 1999. Partitioning of P and the activity of root acid phosphatase in white clover (*Trifolium repens* L.) are modified by increased atmospheric CO₂ and P fertilisation. *Plant and Soil* 210(2):159-166.

The growth response of white clover (*Trifolium repens* L.) to the expected increase in atmospheric partial pressure of CO₂ (p(CO₂)) may depend on P availability. A decrease in the rate of transpiration due to increased p(CO₂) may reduce the amount of P transported to the shoot, thereby causing a change in the partitioning of P between the root and shoot. To test these hypotheses, four concentrations of P in the nutrient solution, combined with two p(CO₂) treatments, were applied to nodulated white clover plants. Compared to ambient p(CO₂) (35 Pa), twice ambient p(CO₂) (70 Pa) reduced the rate of transpiration but did not impair the total P uptake per plant. However, at twice ambient p(CO₂) and a moderate to high supply of P, concentrations of structural P and soluble P (Pi) were lower in the leaves and higher in the roots. The activity of root acid phosphatase was lower at twice ambient p(CO₂) than at ambient p(CO₂); it depended on the Pi concentration in the roots. At the highest P concentration, twice ambient p(CO₂) stimulated photosynthesis and the growth rate of the plant without affecting the concentration of nonstructural carbohydrates in the leaves. However, at the lower P concentrations, plants at twice ambient p(CO₂) lost their stimulation of photosynthesis in the afternoon, they accumulated nonstructural carbohydrates in the leaves and their growth rate was not stimulated; indicating C-sink limitation of growth. P nutrition will be crucial to the growth of white clover under the expected future conditions of increased p(CO₂).

Alvarez, R., M. Alconada, and R. Lavado. 1999. Sewage sludge effects on carbon dioxide-carbon production from a desurfaced soil. *Communications in Soil Science and Plant Analysis* 30(13-14):1861-1866.

Desurfaced soils are found near cities in the Pampean Region of Argentina because A horizons were used for brick production. These soils are not suitable for agriculture. Application of sewage sludge is a tool for improving soil productivity, but its effects on the environment are not thoroughly understood. Production of carbon dioxide (CO₂)-carbon (C) in the field from a desurfaced soil in which 25 Mg dry matter ha⁻¹ of sewage sludge were applied the first year and 10 Mg dry matter ha⁻¹, the second year was evaluated during a corn (*Zea mays* L.) growing cycle. Microbial biomass and metabolic activity were also measured. Sludge applications produced an increase of the CO₂-C efflux in the field of 30-50% during summer. Microbial biomass was not affected by sludge some months after the application, but metabolic activity and organic matter mineralization were enhanced. The increase of the CO₂-C emission from the soil represented 21% of the sludge C

applied the year of the experiment and 15% of the C applied the year before. Consequently, an important quantity of the sludge C was retained in the soil.

Ambus, P., and G.P. Robertson. 1999. Fluxes of CH₄ and N₂O in aspen stands grown under ambient and twice-ambient CO₂. *Plant and Soil* 209(1):1-8.

Elevated atmospheric CO₂ has the potential to change below- ground nutrient cycling and thereby alter the soil-atmosphere exchange of biogenic trace gases. We measured fluxes of CH₄ and N₂O in trembling aspen (*Populus tremuloides* Michx.) stands grown in open-top chambers under ambient and twice-ambient CO₂ concentrations crossed with 'high' and low soil-N conditions. Flux measurements with small static chambers indicated net CH₄ oxidation in the open-top chambers. Across dates, CH₄ oxidation activity was significantly ($P < 0.05$) greater with ambient CO₂ (8.7 $\mu\text{g CH}_4\text{-C m}^{-2}\text{ h}^{-1}$) than with elevated CO₂ (6.5 $\mu\text{g CH}_4\text{-C m}^{-2}\text{ h}^{-1}$) in the low N soil. Likewise, across dates and soil N treatments CH₄ was oxidized more rapidly ($P < 0.05$) in chambers with ambient CO₂ (9.5 $\mu\text{g CH}_4\text{-C m}^{-2}\text{ h}^{-1}$) than in chambers with elevated CO₂ (8.8 $\mu\text{g CH}_4\text{-C m}^{-2}\text{ h}^{-1}$). Methane oxidation in soils incubated in serum bottles did not show any response to the CO₂ treatment. We suggest that the depressed CH₄ oxidation under elevated CO₂ in the field chambers is due to soil moisture which tended to be higher in the twice-ambient CO₂ treatment than in the ambient CO₂ treatment. Phase I denitrification (denitrification enzyme activity) was 12-26% greater under elevated CO₂ than under ambient CO₂ in the 'high' N soil; one sampling, however, showed a 39% lower enzyme activity with elevated CO₂. In both soil N treatments, denitrification potentials measured after 24 or 48 h were between 11% and 21% greater ($P < 0.05$) with twice- ambient CO₂ than with ambient CO₂. Fluxes of N₂O in the open- top chambers and in separate 44 cm(2) cores +/-N fertilization were not affected by CO₂ treatment and soil N status. Our data show that elevated atmospheric CO₂ may have a negative effect on terrestrial CH₄ oxidation. The data also indicated temporary greater denitrification with elevated CO₂ than with ambient CO₂. In contrast, we found no evidence for altered fluxes of N₂O in response to increases in atmospheric CO₂.

Amiro, B.D., J.I. MacPherson, and R.L. Desjardins. 1999. BOREAS flight measurements of forest-fire effects on carbon dioxide and energy fluxes. *Agricultural and Forest Meteorology* 96(4):199-208.

Fire is the dominant stand-replacing agent in the Canadian boreal forest, but few quantitative measurements are available on the micrometeorological effects of fire. Airborne flux measurements during the BOREAS experiment were referenced to age of burn along a 500-km transect through Saskatchewan and Manitoba, Canada. These data for 1-, 5-, and 7-year-old burns were supplemented with 15- and 30-year-old-burn data from the BOREAS northern study site near Thompson, Manitoba. Data were available near midday only and included the June, July and September campaigns during 1994, and July of 1996. Surface radiometric temperature increased by up to 6 degrees C and remained elevated even 15 years after fire. Net radiation was largely unaffected whereas albedo decreased in the first year post-fire but recovered by the fifth year. Sensible heat flux increased by 10-20% for the first few years

after the fire and then decreased. Latent heat flux slightly decreased after the fire, causing the Bowen ratio to increase by ca. 50% for 7 years post-fire. The CO₂ flux was reduced for the 15-year period after fire with the greatest reduction to ca. 25% of control areas during the year following fire. However, diurnal and annual data are needed to determine the total impact of fire on the boreal-forest carbon balance. (C) 1999 Elsevier Science B.V. All rights reserved.

Amoroso, G., C. Weber, D. Sultemeyer, and H. Fock. 1996. Intracellular carbonic anhydrase activities in *Dunaliella tertiolecta* (Butcher) and *Chlamydomonas reinhardtii* (Dangeard) in relation to inorganic carbon concentration during growth: Further evidence for the existence of two distinct carbonic anhydrases associated with the chloroplasts. *Planta* 199(2):177-184.

Using mass-spectrometric measurements of O-18 exchange from (CO₂)-C-13-O-18 intracellular carbonic anhydrase (CA) activity was investigated in the unicellular green algae *Dunaliella tertiolecta* and *Chlamydomonas reinhardtii* which were either grown on air enriched with 5% CO₂ (high-C-i cells) or on air (low-C-i cells). In *D. tertiolecta* high- and low-C-i cells had detectable levels of internal CA activity when measured under in-vivo conditions and this activity could be split up into three distinct forms. One CA was not associated with the chloroplasts, while two isozymes were found to be located within the plastids. The activities of all intracellular CAs were always about twofold higher in low than in high -C-i cells of *D. tertiolecta* and the chloroplastic enzymes were completely induced within 4 h of adaptation to air. One of the chloroplastic CAs was found to be soluble the other was insoluble. In addition to the physical differences, MgSO₄ in vitro caused a more than twofold stimulation of the soluble activity while the insoluble form of CA remained rather unaffected. In *C. reinhardtii*, MgSO₄ increased the soluble CA activity by 346% and the concentration of MgSO₄ required for half-maximum stimulation was between 10 and 15 mM. Again, the insoluble CA activity was not affected by MgSO₄. Furthermore, the soluble isoenzyme was considerably more sensitive to ethoxycarbonylamine, a potent inhibitor of CA, than the insoluble enzyme. The concentration of inhibitor causing 50% inhibition of soluble CA activity was 110 and 85 μ M ethoxycarbonylamine for *D. tertiolecta* and *C. reinhardtii*, respectively. From these data we conclude that the two chloroplast-associated CAs are distinct enzymes.

Amthor, J.S. 1991. Respiration in a future, higher-CO₂ world. *Plant, Cell and Environment* 14(1):13-20.

Apart from its impact on global warming, the annually increasing atmospheric [CO₂] is of interest to plant scientists primarily because of its direct influence on photosynthesis and photorespiration in C₃ species. But in addition, 'dark' respiration, another major component of the carbon budget of higher plants, may be affected by a change in [CO₂] independent of an increase in temperature. Literature pertaining to an impact of [CO₂] on respiration rate is reviewed. With an increase in [CO₂], respiration rate is increased in some cases, but decreased in others. The effects of [CO₂] on respiration rate may be direct or indirect. Mechanisms responsible for various observations are proposed. These proposed mechanisms relate to changes in: (1) levels of nonstructural

carbohydrates, (2) growth rate and structural phytomass accumulation, (3) composition of phytomass, (4) direct chemical interactions between CO₂ and respiratory enzymes, (5) direct chemical interactions between CO₂ and other cellular components, (6) dark CO₂ fixation rate, and (7) ethylene biosynthesis rate. Because a range of (possibly interactive) effects exist, and present knowledge is limited, the impact of future [CO₂] on respiration rate cannot be predicted. Theoretical considerations and types of experiments that can lead to an increase in the understanding of this issue are outlined.

Amthor, J.S. 1994. Scaling co₂-photosynthesis relationships from the leaf to the canopy. *Photosynthesis Research* 39(3):321-350.

Responses of individual leaves to short-term changes in CO₂ partial pressure have been relatively well studied. Whole-plant and plant community responses to elevated CO₂ are less well understood and scaling up from leaves to canopies will be complicated if feedbacks at the small scale differ from feedbacks at the large scale. Mathematical models of leaf, canopy, and ecosystem processes are important tools in the study of effects on plants and ecosystems of global environmental change, and in particular increasing atmospheric CO₂, and might be used to scale from leaves to canopies. Models are also important in assessing effects of the biosphere on the atmosphere. Presently, multilayer and big leaf models of canopy photosynthesis and energy exchange exist. Big leaf models - which are advocated here as being applicable to the evaluation of impacts of 'global change' on the biosphere - simplify much of the underlying leaf-level physics, physiology, and biochemistry, yet can retain the important features of plant- environment interactions with respect to leaf CO₂ exchange processes and are able to make useful, quantitative predictions of canopy and community responses to environmental change. The basis of some big leaf models of photosynthesis, including a new model described herein, is that photosynthetic capacity and activity are scaled vertically within a canopy (by plants themselves) to match approximately the vertical profile of PPFD. The new big leaf model combines physically based models of leaf and canopy level transport processes with a biochemically based model of CO₂ assimilation. Predictions made by the model are consistent with canopy CO₂ exchange measurements, although a need exists for further testing of this and other canopy physiology models with independent measurements of canopy mass and energy exchange at the time scale of 1 h or less.

Amthor, J.S. 1995. Predicting effects of atmospheric CO₂ partial pressure on forest photosynthesis. *Journal of Biogeography* 22(2-3):269-280.

A mechanistic (i.e. hierarchic or explanatory) model of forest canopy mass and energy exchange that has been previously tested with eddy-correlation measurements in the field - albeit only at present ambient CO₂ partial pressure - was used to predict photosynthetic response of a deciduous Quercus-Acer forest in eastern North America to atmospheric CO₂ partial pressure. Four partial pressures of CO₂ were used in simulations: 28 (pre-industrial), 36 (present), 54 and 72 Pa. This is (one of) the first set(s) of predictions of forest photosynthetic response to

CO₂ partial pressure made by a mechanistic forest physiology model shown to accurately predict independent field measurements of whole-forest CO₂ exchange at the hourly time scale. The model includes a biochemically based Farquhar-type model of leaf mesophyll CO₂ assimilation, which is central to its ability to predict photosynthetic response to different CO₂ partial pressures. Whole-forest photosynthesis was positively related to CO₂ partial pressure, as expected. This was the case under both clear and cloudy skies, but the relative response to CO₂ was greater under a clear sky compared to a cloudy sky (the clear sky day was also warmer). Instantaneous water use efficiency (mol CO₂ assimilated per mol H₂O transpired) was positively related to atmospheric CO₂ partial pressure for all conditions included in the simulations. Model predictions indicate that (1) present forest photosynthesis and water use efficiency may be significantly greater than they were in pre-industrial times (per unit ground area of forest) and (2) future higher CO₂ partial pressures could further stimulate forest photosynthesis and water use efficiency, unless future climatic changes have significant negative effects on photosynthesis or acclimation and adaptation processes markedly downregulate photosynthesis in response to greater CO₂ partial pressure.

Amthor, J.S. 1995. Terrestrial higher-plant response to increasing atmospheric [CO₂] in relation to the global carbon-cycle. *Global Change Biology* 1(4):243-274.

Terrestrial higher plants exchange large amounts of CO₂ with the atmosphere each year; c. 15% of the atmospheric pool of C is assimilated in terrestrial-plant photosynthesis each year, with an about equal amount returned to the atmosphere as CO₂ in plant respiration and the decomposition of soil organic matter and plant litter. Any global change in plant C metabolism can potentially affect atmospheric CO₂ content during the course of years to decades. In particular, plant responses to the presently increasing atmospheric CO₂ concentration might influence the rate of atmospheric CO₂ increase through various biotic feedbacks. Climatic changes caused by increasing atmospheric CO₂ concentration may modulate plant and ecosystem responses to CO₂ concentration. Climatic changes and increases in pollution associated with increasing atmospheric CO₂ concentration may be as significant to plant and ecosystem C balance as CO₂ concentration itself. Moreover, human activities such as deforestation and livestock grazing can have impacts on the C balance and structure of individual terrestrial ecosystems that far outweigh effects of increasing CO₂ concentration and climatic change. In short-term experiments, which in this case means on the order of 10 years or less, elevated atmospheric CO₂ concentration affects terrestrial higher plants in several ways. Elevated CO₂ can stimulate photosynthesis, but plants may acclimate and (or) adapt to a change in atmospheric CO₂ concentration. Acclimation and adaptation of photosynthesis to increasing CO₂ concentration is unlikely to be complete, however. Plant water-use efficiency is positively related to CO₂ concentration, implying the potential for more plant growth per unit of precipitation or soil moisture with increasing atmospheric CO₂ concentration. Plant respiration may be inhibited by elevated CO₂ concentration, and although a naive C balance perspective would count this as a benefit to a plant, because respiration is essential for plant growth and health, an inhibition of respiration can be detrimental. The net effect on terrestrial plants of elevated atmospheric CO₂ concentration is generally an increase in growth and C accumulation in phytomass. Published estimations, and speculations about, the magnitude of global terrestrial-plant growth responses to increasing atmospheric CO₂ concentration range from negligible to fantastic. Well-reasoned analyses point to moderate global plant responses to CO₂

concentration. Transfer of C from plants to soils is likely to increase with elevated CO₂ concentrations because of greater plant growth, but quantitative effects of those increased inputs to soils on soil C pool sizes are unknown. Whether increases in leaf-level photosynthesis and short-term plant growth stimulations caused by elevated atmospheric CO₂ concentration will have, by themselves, significant long-term (tens to hundreds of years) effects on ecosystem C storage and atmospheric CO₂ concentration is a matter for speculation, not firm conclusion. Long-term field studies of plant responses to elevated atmospheric CO₂ are needed. These will be expensive, difficult, and by definition, results will not be forthcoming for at least decades. Analyses of plants and ecosystems surrounding natural geological CO₂ degassing vents may provide the best surrogates for long-term controlled experiments, and therefore the most relevant information pertaining to long-term terrestrial-plant responses to elevated CO₂ concentration, but pollutants associated with the vents are a concern in some cases, and quantitative knowledge of the history of atmospheric CO₂ concentrations near vents is limited. On the whole, terrestrial higher-plant responses to increasing atmospheric CO₂ concentration probably act as negative feedbacks on atmospheric CO₂ concentration increases, but they cannot by themselves stop the fossil-fuel-oxidation-driven increase in atmospheric CO₂ concentration. And, in the very long-term, atmospheric CO₂ concentration is controlled by atmosphere-ocean C equilibrium rather than by terrestrial plant and ecosystem responses to atmospheric CO₂ concentration.

Amthor, J.S. 1998. Perspective on the relative insignificance of increasing atmospheric CO₂ concentration to crop yield. *Field Crops Research* 58(2):109-127.

Average yield of most crops in many countries increased significantly during the past 50 to 100 years. Although atmospheric CO₂ concentration, [CO₂](a), also increased during that time period, and although crop growth and yield can respond positively to [CO₂](a) increase, yield increases were due mainly to factors other than increasing [CO₂](a). Similarly, some yield increases prior to 1900 were also associated primarily with factors other than changes in [CO₂](a). In particular, past national average yield increases were the result chiefly of technological advances such as nitrogen fertilization; selection of genotypes with increased harvest index and disease resistance; mechanization of planting, cultivation, and harvesting; and chemical weed and pest control. If technology continues to increase average yields at recent rates, near-future increases in [CO₂](a) will have only small impacts on yield in comparison to technology in many countries. Conversely, if future increases in [CO₂](a) are the main drivers of future yield increases, those yield increases will be small. These points are demonstrated through a comparison of (i) long-term records of yield, (ii) data from key controlled-[CO₂] experiments, and (iii) records of past [CO₂](a). Finally, it is noted that continued [CO₂](a) increase may bring with it climatic changes that could have negative or positive impacts on future yield. (C) 1998 Elsevier Science B.V. Amthor, J.S., R.J. Mitchell, G.B. Runion, H.H. Rogers, S.A. Prior, and C.W. Wood. 1994. Energy content, construction cost and

phytomass accumulation of glycine-max (L) merr and sorghum-bicolor (L) moench grown in elevated co₂ in the field. *New Phytologist* 128(3):443-450.

Grain sorghum [*Sorghum*] bicolor (L.) Moench, a C-4 crop] and soybean [*Glycine* max (L.) Merr. cv. Stonewall, a C-3 crop] plants were grown in ambient (c. 360 µl l⁻¹) and twice-ambient (c. 720 µl l⁻¹) CO₂ levels in open-top chambers in soil without root constriction. Plant dry mass, energy content, composition and construction cost (i.e. amount of carbohydrate required to synthesize a unit of plant dry mass) were assessed at the end of the growing season. Elevated CO₂ (a) increased phytomass accumulation (kg per plant) in both species, (b) had little effect on energy concentration (MJ kg⁻¹ plant) but caused large increases in the amount of plant energy per ground area (MJ m⁻² ground), and (c) did not alter specific growth cost (kg carbohydrate kg⁻¹ plant growth) but greatly increased growth cost per ground area (kg carbohydrate m⁻² ground) because growth was enhanced. For soybean, twice-ambient CO₂ resulted in a 50 % increase in the amount of nitrogen and energy in grain (seed plus pod) per ground area. This response to elevated CO₂ has important implications for agricultural productivity during the next century because the rate of human population growth is exceeding the rate of increase of land used for agriculture so that future food demands can only be met by greater production per ground area.

Andalo, C., B. Godelle, M. Lefranc, M. Mousseau, and I. TillBottraud. 1996. Elevated CO₂ decreases seed germination in *Arabidopsis thaliana*. *Global Change Biology* 2(2):129-135.

The impact of elevated [CO₂] on seed germination was studied in different genotypes of *Arabidopsis thaliana* from natural populations. Two generations of seeds were studied: the maternal generation was produced in the greenhouse (present-day conditions), the offspring generation was produced in two chambers where the CO₂ concentration was either the present atmospheric concentration (about 350 ppm) or elevated (700 ppm). The seeds were tested for proportion of germinated seeds and mean germination time in both chambers to study the impact of elevated [CO₂] during seed production and germination. Elevated [CO₂] during maturation of seeds on the mother-plants decreased the proportion of germinated seeds, while elevated [CO₂] during germination had no effect on the proportion of germinated seeds. However, when seeds were both produced and germinated under elevated [CO₂] (situation expected by the end of next century), germination was slow and low. Moreover, the effect of the [CO₂] treatment differs among genotypes of *Arabidopsis*: there is a strong treatment x genotype interaction. This means that there is ample genetic variance for a selective response modifying the effects of high levels of [CO₂] in natural populations of *Arabidopsis thaliana*. The outcome at the community level will depend on what seeds are available, when they germinate and the resulting competition following germination.

Andalo, C., C. Raquin, N. Machon, B. Godelle, and M. Mousseau. 1998. Direct and maternal effects of elevated CO₂ on early root growth of germinating *Arabidopsis thaliana* seedlings. *Annals of Botany* 81(3):405-411.

Individuals of *Arabidopsis thaliana*, collected in different natural populations, were grown in controlled and elevated CO₂ in a glasshouse.

Following germination, root growth of progeny of different lines of these populations was studied in control and elevated atmospheric CO₂. No significant direct effect of atmospheric CO₂ concentration could be demonstrated on root growth. An important parental effect was apparent, namely that root length and branching were decreased in seeds collected from a mother plant which had been grown in elevated CO₂. This was correlated with smaller seeds, containing less nitrogen. These parental effects were genetically variable. We conclude that CO₂ may affect plant fitness via parental effects on seed size and early root growth and that the genetic variability shown in our study demonstrates that *Arabidopsis* populations will evolve in the face of this new selective pressure. (C) 1998 Annals of Botany Company.

Anderson, J.M. 1991. The effects of climate change on decomposition processes in grassland and coniferous forests. *Ecological Applications* 1(3):326-347.

Current models of climate change predict a reduction of area covered by northern coniferous forests and tundra, and an increase in grasslands. These scenarios also indicate a northerly shift in agricultural regions, bringing virgin soils under cultivation. The direct effects of man on tundra, boreal forest, and temperate grassland ecosystems are likely to result in less carbon mobilization from soils and vegetation than from tropical forests. However, as a consequence of climate change, carbon mineralization rates from arctic and sub-arctic soils could be very rapid under warmer and drier conditions because of low stabilization of soil organic matter (SOM) and enhanced microbial responses to small changes in soil moisture and temperature. Predicting the response of these systems to climate change is complicated where the edaphic environment regulating SOM dynamics is not a direct function of macroclimatic conditions. Grasslands contain a greater proportion of highly stabilized SOM than coniferous forests, distributed over greater depth in the soil profile, which is less susceptible to changes in mineralization rates. It is concluded that short-term responses of soil processes to climate change are more predictable in well-drained grassland and forest soils than in waterlogged soils of the tundra and boreal region. Over longer periods of time, however, plant species and soil types will alter in response to new temperature and moisture regimes above- and belowground interacting with the effects of carbon enrichment and changes in nutrient availability. The dynamics of these plant-soil interactions and the future status of soils in different life zones as sources or sinks of carbon is poorly understood. More data are also needed on the distribution of waterlogged forest soils in the boreal zone and responses to warming, which include the production of methane as well as CO₂. The primary recommendation for future research is for integrated studies on plant and soil processes.

Anderson, P.D., and P.T. Tomlinson. 1998. Ontogeny affects response of northern red oak seedlings to elevated CO₂ and water stress - I. Carbon assimilation and biomass production. *New Phytologist* 140(3):477-491.

The interactive influences of elevated carbon dioxide, water stress, and ontogeny on carbon assimilation and biomass production were

investigated in northern red oak, a species having episodic shoot growth characteristics. Seedlings were grown from acorns through three shoot-growth hushes (8-11 wk) in controlled-environment chambers at 400, 530 or 700 $\mu\text{mol mol}^{-1}$ CO₂ and under well watered or water-stressed soil-moisture regimes. Increasing CO₂ growth concentration from 400 to 700 $\mu\text{mol mol}^{-1}$ resulted in a 34 % increase in net assimilation rate (A), a 31 % decrease in stomatal conductance to water vapour (g(s)) and a 141 % increase in water use efficiency (WUE) in well watered seedlings. In contrast, water-stressed seedlings grown at 700 $\mu\text{mol mol}^{-1}$ CO₂ demonstrated a 69 % increase in A, a 23 % decrease in g(s), and a 104 % increase in WUE. However, physiological responses to increased CO₂ and water stress were strongly modified by ontogeny. During active third-flush shoot growth, A in first-flush and second-flush foliage of water-stressed seedlings increased relative to the quiescent phase following cessation of second-flush growth by an average of 115 %; g(s) increased by an average of 74 %. In contrast, neither A nor g(s) in comparable foliage of well watered seedlings changed in response to active third-flush growth. Whereas seedling growth was continuous through three flushes in well watered seedlings, growth of water-stressed seedlings was minimal following the leaf-expansion stage of the third flush. Through three growth flushes total seedling biomass and biomass allocation to root, shoot and foliage components were very similar in water-stressed seedlings grown at 700 $\mu\text{mol mol}^{-1}$ CO₂ and well watered seedlings grown at 400 $\mu\text{mol mol}^{-1}$ CO₂. Enhancement effects of elevated CO₂ on seedling carbon (C) assimilation and biomass production may offset the negative impact of moderate water stress and are likely to be determined by ontogeny and stress impacts on carbon sink demand.

Andersson, N.E. 1991. The influence of constant and diurnally changing CO₂ concentrations on plant-growth and development. *Journal of Horticultural Science* 66(5):569-574.

Plants of *Ficus benjamina* and miniature rose (*Rosa hybrida* cv. Red Minimo) were grown under four CO₂ treatments. Two had constant CO₂ levels (600 and 900 ppm) and the other two had diurnal changes in CO₂ levels, one increasing from 600 to 1500 ppm and one decreasing from 1500 to 600 ppm, each in four steps of 300 ppm during the day-time. In all treatments 900 ppm CO₂ was maintained during the night when supplementary light was used, except in the treatment with constant 600 ppm where 600 ppm was also continued throughout the night. Plant growth was monitored under both decreasing and increasing natural daylength and irradiance. The tallest plants and greatest increment in height for *Ficus* occurred with plants grown under constant CO₂ concentration at 600 ppm and also with increasing CO₂ concentration. In both experiments the dry weight per pot was lowest when plants were grown under a constant CO₂ concentration at 900 ppm. In both experiments with miniature roses the number of flower buds was significantly increased under diurnally changing CO₂ concentration or when the CO₂ level was constant at 600 ppm compared with a constant 900 ppm. Time to flowering was decreased by constant CO₂ at 900 ppm as compared with the other treatments.

Andrade, J.L., and P.S. Nobel. 1996. Habitat, CO₂ uptake and growth for the CAM epiphytic cactus *Epiphyllum phyllanthus* in a Panamanian tropical forest. *Journal of Tropical Ecology* 12:291-306.

In the tropical forest of Barro Colorado Island, habitat characteristics, diel acidity changes, CO₂ uptake and growth were investigated for the epiphytic cactus *Epiphyllum phyllanthus* (L.) Haw. It occurred most frequently in tree cavities with its roots in canopy soil and was especially abundant on two tree species: *Platypodium elegans* J. Vogel and *Tabebuia guayacan* (Seem.) Hemsl. Its maximum net CO₂ uptake rates were low under natural conditions (1.4 $\mu\text{mol m}^{-2} \text{s}^{-1}$) but were comparable to those of other CAM and C-3 epiphytes under wet conditions in a screenhouse. Under both natural conditions and in the screenhouse, partial shade enhanced growth and CAM activity. When plants grew under a photosynthetic photon flux of c. 4 $\text{mol m}^{-2} \text{d}^{-1}$, their nocturnal acidity increase and total net CO₂ uptake were twice as much as for plants growing at lower (an average of 2.4 $\text{mol m}^{-2} \text{d}^{-1}$) and higher (7.7 $\text{mol m}^{-2} \text{d}^{-1}$) photosynthetic photon fluxes. Stem elongation was 27% greater at the intermediate photosynthetic photon flux. Seedlings of *E. phyllanthus* survived three months of drought and responded rapidly to rewetting, recovering fully within three days. Transpiration rates and nocturnal acidity increases also recovered to the values of well-watered plants a few days after rewetting, indicating that this species can take advantage of episodic rainfall during the dry season.

Andre, M., and H. Ducloux. 1993. Interaction of CO₂ enrichment and water limitations on photosynthesis and water efficiency in wheat. *Plant Physiology and Biochemistry* 31(1):103-112.

Wheat plants (*Triticum aestivum* L. cv. Capitole) were grown in twin closed growth chambers with continuous monitoring of CO₂ and water exchanges. During the vegetative stage the effect of CO₂ enrichment, from 330 to 660 $\mu\text{mol m}^{-2} \text{s}^{-1}$, was studied under irradiance of 660 $\mu\text{mol m}^{-2} \text{s}^{-1}$ with an optimum watering. Comparisons were made with successive experiments in which daily water supply was fixed to a fraction (0.62-0.50-0.25) of the maximal transpiration of previous experiments. In a well-watered canopy, doubling CO₂ decreased transpiration by only 8%. Water use efficiency was increased (factor 1.45) mainly by the stimulation of photosynthesis. Under restricted water supply, photosynthesis of plants was more limited than transpiration. The inhibition of photosynthesis and the increase of water use efficiency can be predicted by a simple diffusion model applied to the response curve of photosynthesis to CO₂, measured on canopy in standard conditions of watering. The main hypothesis is that the equivalent stomatal conductance is reduced proportionally to the water availability, without closure by patching. Under enriched CO₂, the same reduction of leaf surface by water limitation was observed. Photosynthesis was less affected. Therefore, water-use-efficiency was again increased. Doubling CO₂ concentration can compensate for water stress inhibition on CO₂ assimilation. That model also predicts interactions of CO₂ and water stress observed on water-use-efficiency which was increased by a factor up to 5 in comparison with well-watered plants in standard atmosphere. The implications of this study for global change models are discussed.

Andrews, J.A., K.G. Harrison, R. Matamala, and W.H. Schlesinger. 1999. Separation of root respiration from total soil respiration using carbon-13 labeling during Free-Air Carbon Dioxide Enrichment (FACE). *Soil Science Society of America Journal* 63(5):1429-1435.

Soil respiration constitutes a major component of the global carbon cycle and is likely to be altered by climatic change. However, there is an incomplete understanding of the extent to which various processes contribute to total soil respiration, especially the contributions of root and rhizosphere respiration. Here, using a stable carbon isotope tracer, we separate the relative contributions of root and soil heterotrophic respiration to total soil respiration in situ. The Free-Air Carbon dioxide Enrichment (FACE) facility in the Duke University Forest (NC) fumigates plots of an undisturbed loblolly pine (*Pinus taeda* L.) forest with CO₂ that is strongly depleted in C-13. This labeled CO₂ is found in the soil pore space through live root and mycorrhizal respiration and soil heterotroph respiration of labile root exudates. By measuring the depletion of (CO₂)-C-13 in the soil system, we found that the rhizosphere contribution to soil CO₂ reflected the distribution of fine roots in the soil and that late in the growing season roots contributed 55% of total soil respiration at the surface. This estimate may represent an upper limit on the contribution of roots to soil respiration because high atmospheric CO₂ often increases in root density and/or root activity in the soil.

Andrews, T.J., G.S. Hudson, C.J. Mate, S. Voncaemmerer, J.R. Evans, and Y.B.C. Arvidsson. 1995. Rubisco - the consequences of altering its expression and activation in transgenic plants. *Journal of Experimental Botany* 46:1293-1300.

Transgenic tobacco (*Nicotiana tabacum* W38) hemizygous for a single antisense gene directed against Rubisco's small subunit had 35% of the Rubisco content of control leaves (15% when homozygous). CO₂ assimilation (at 1000 μ mol quanta m⁻² s⁻¹) and 350 μ bar CO₂) by the hemizygous leaves was reduced to 40% of that of the controls without material effect on stomatal conductance, chlorophyll content or other photosynthetic components. Leaf soluble protein was reduced commensurately with the reduction in Rubisco. CO₂ assimilation rate in the hemizygous leaves remained limited by Rubisco activity at all, even very high, CO₂ concentrations. This led to a simple, hyperbolic response of photosynthesis to intraplastid CO₂ concentration from which the in vivo catalytic properties of Rubisco were inferred and compared with those of isolated Rubisco in vitro. Using a similar approach, the content of Rubisco activase was suppressed by incorporating a partial cDNA for activase into the tobacco genome in the antisense orientation with respect to a cauliflower mosaic virus 35S promoter. The progeny of a primary transformant with two anti-activase inserts had from <1% to 20% of the activase content of control plants. Quite severe suppression of activase, to less than 5% of the amount present in control leaves, was required before effects on photosynthesis and growth became apparent, indicating that one activase tetramer must be able to service, continuously, as many as 200 Rubisco octamers. Plants with lower activase contents could not grow unless the atmosphere was enriched with CO₂. Their Rubisco was less carbamylated and they had lower CO₂ assimilation rates than the controls. The rate of release of 2'-carboxyarabinitol-1-phosphate from Rubisco after illumination of the anti-activase leaves was also impaired. Older anti-activase plants accumulated increasing amounts of Rubisco in their younger leaves, but were unable to carbamylate it. The photosynthetic rate per carbamylated Rubisco active site in the strongly suppressed anti-activase leaves was only approximately 25% of that seen in control leaves, suggesting that activase may not only promote carbamylation of uncarbamylated Rubisco sites, but also accelerate turnover at carbamylated sites.

Andriolo, J.L., J. LeBot, C. Gary, G. Sappe, P. Orlando, B. Brunel, and C. Sarrouy. 1996. An experimental set-up to study carbon, water and nitrate uptake rates by hydroponically grown plants. *Journal of Plant Nutrition* 19(10-11):1441-1462.

The experimental system described allows concomitant hourly measurements of CO₂, H₂O, and NO₃ uptake rates by plants grown hydroponically in a greenhouse. Plants are enclosed in an airtight chamber through which air flows at a controlled speed. Carbon dioxide exchange and transpiration rates are determined from respective differences of concentrations of CO₂ and water vapor of the air at the system inlet and outlet. This set-up is based on the "open-system" principle with improvements made on existing systems. For instance, propeller anemometers are used to monitor air flow rates in the chamber. From their signal it is possible to continuously adjust air speed to changing environmental conditions and plant activity. The air temperature inside the system therefore never rises above that outside. Water and NO₃ uptake rates are calculated at time intervals from changes in the volume and the NO₃ concentration of the nutrient solution in contact with the roots. The precise measurement of the volume of solution is achieved using a balance which has a higher precision than any liquid level sensors. Nitrate concentration is determined in the laboratory from aliquots of solution sampled at time intervals. A number of test runs are reported which validate the measurements and confirm undisturbed conditions within the system. Results of typical diurnal changes in CO₂, H₂O, and NO₃ uptake rates by fruiting tomato plants are also presented.

Angell, R., and T. Svejcar. 1999. A chamber design for measuring net CO₂ exchange on rangeland. *Journal of Range Management* 52(1):27-31.

Net carbon exchange of terrestrial ecosystems will likely change as atmospheric CO₂ concentration increases. Currently, little is known of the annual dynamics or magnitude of CO₂ flux on many native and agricultural ecosystems. Remoteness of many ecosystems has limited our ability to measure CO₂ flux on undisturbed vegetation. Today, many plant ecologists have portable photosynthesis systems with which they make single-leaf photosynthesis measurements. Utility of this equipment is enhanced when canopy-level CO₂ flux is also measured. We designed a portable 1-m³ closed chamber for use in measuring CO₂ exchange in short statured vegetation with widely varied canopy structure. The design includes external ductwork equipped with doors which are used to open the chamber for ventilation with outside air between measurements. The chamber was tested on a Wyoming big sagebrush (*Artemisia tridentata* ssp. *Wyomingensis* Nutt.)/Thurber's needlegrass (*Stipa thurberiana* Piper) community using 10 plots equally divided between shrub and interspace. The ductwork and doors provided adequate ventilation to allow consecutive measurements of CO₂ flux without removing the chamber from the plot. The chamber could differentiate CO₂ flux between plots with sagebrush and those with grass only, even at relatively low fluxes. Net CO₂ uptake per unit ground area was greater ($P = 0.04$) on sagebrush-grass plots (7.6 $\pm$ 1.4 μ mol m⁻² s⁻¹) than on interspace plots without sagebrush (3.1 $\pm$ 1.0 μ mol m⁻² s⁻¹). Chamber and leaf temperature increased by an average of 0.5 and 1.2 degrees C, respectively, during measurements.

Apel, P., and M. Peisker. 1995. Variability of photosynthetic gas exchange parameters, dark respiration, and stomatal numbers in species of *Polygonum*. *Physiologia Plantarum* 95(3):365-372.

Within the genus *Polygonum* a large variation was found between species with regard to stomatal number, gas phase resistance, intracellular resistance and dark respiration. Interspecific variation in CO₂ compensation concentration and intercellular CO₂ concentration at constant external concentration were comparatively small. Correlations were found between stomatal number and gas phase resistance, stomatal number and Gamma, and Gamma and the product of dark respiration rate and intracellular resistance. The influence of dark respiration and stomatal number on photosynthetic gas exchange is discussed. It was concluded that dark respiration in light was enhanced by 22% as a mean value in 9 *Polygonum* species and by 62% in *Polygonum lapathifolium*.

Apple, M.E., M.S. Lucash, D.M. Olszyk, and D.T. Tingey. 1998. Morphogenesis of Douglas-fir buds is altered at elevated temperature but not at elevated CO₂. *Environmental and Experimental Botany* 40(2):159-172.

Global climatic change as expressed by increased CO₂ and temperature has the potential for dramatic effects on trees. To determine what its effects may be on Pacific Northwest forests, Douglas-fir (*Pseudotsuga menziesii*) seedlings were grown in sun-lit controlled environment chambers at ambient or elevated (+ 4 degrees C above ambient) temperature, and at ambient or elevated (+ 200 ppm above ambient) CO₂. In 1995-1996 and 1996- 1997, elevated CO₂ had no effect on vegetative bud morphology, while the following unusual morphological characteristics were found with greater frequency at elevated temperature than at ambient: rosetted buds with reflexed and loosened outer scales, convoluted inner scales, clusters of small buds, needles elongating between scales, needle primordia with white, hyaline apical extensions, and buds with hardened scales inside of unbroken buds. Buds became rosetted in elevated temperature chambers after temperatures exceeded 40 degrees C in July, 1996. Rosettes were induced within 48-h in buds placed in a 40 degrees C oven; fewer rosettes formed at 20 degrees C. Induction was reversible in buds transferred from 40 to 20 degrees C, implying that resetting is a physical rather than a growth phenomenon. It appears that rosettes form after long- term exposure to elevated temperature and after shorter periods of exposure to intense heat. Elevated temperature influences bud morphology and may therefore influence the overall branching structure of Douglas-fir seedlings. (C) 1998 Elsevier Science B.V. All rights reserved.

Arakelyan, V.V., G.B. Ibragimova, and Y.S. Nasyrov. 1993. Effects of light, co₂, and temperature on carbonic-anhydrase activity in C3-plants. *Russian Journal of Plant Physiology* 40(6):759-767.

Carbonic anhydrase activity was studied in cotton (*Gossypium hirsutum* L.) and Triticale plants exposed to various light intensities, temperatures, and CO₂ concentrations in the air. The activity was measured using an

original method based on the HCO₃⁻ dehydration reaction, which is carried out in conditions resembling those occurring in the chloroplast stroma in vivo. Carbonic anhydrase activity in stromal fractions from cotton and triticale plant chloroplasts appears to respond to environmental changes. Plant exposure to increased light intensities and temperatures results in increased activity, whereas high ambient CO₂ concentrations lower carbonic anhydrase activity. After examining in vitro the HCO₃⁻ dehydration reaction, which in vivo is catalyzed by carbonic anhydrase, we concluded that the physiological role of the stromal enzyme consists of preventing local CO₂ depletion in the carboxylation sites. Thus, high temperatures and low ambient CO₂ concentrations enhance carbonic anhydrase activity, while impeding CO₂ transport from the air to the carboxylation sites in the leaf. This accelerates HCO₃⁻ dehydration and reduces its concentration in the stroma, thereby producing an additional driving force for HCO₃⁻ transport to the chloroplast.

Archer, S., D.S. Schimel, and E.A. Holland. 1995. Mechanisms of shrubland expansion - land-use, climate or co-2. *Climatic Change* 29(1):91-99.

Encroachment of trees and shrubs into grasslands and the 'thicketization' of savannas has occurred worldwide over the past century. These changes in vegetation structure are potentially relevant to climatic change as they may be indicative of historical shifts in climate and as they may influence biophysical aspects of land surface-atmosphere interactions and alter carbon and nitrogen cycles. Traditional explanations offered to account for the historic displacement of grasses by woody plants in many arid and semi-arid ecosystems have centered around changes in climatic, livestock grazing and fire regimes. More recently, it has been suggested that the increase in atmospheric CO₂ since the industrial revolution has been the driving force. In this paper we evaluate the CO₂ enrichment hypotheses and argue that historic, positive correlations between woody plant expansion and atmospheric CO₂ are not cause and effect.

Arienzo, M., G. Basile, R. Dandria, V. Magliulo, and A. Zena. 1995. Irrigation with carbonated water and nutrient availability - tests on strawberry plants. *Agrochimica* 39(1):61-72.

A research was carried out to study the nutrient availability and yield performances of a strawberry crop cv. 'Chandler' in response to equivalent depths (100% of ETM) of CO₂ enriched water and plain water applied with different irrigation frequencies. Plots were arranged in a complete randomized block design replicated four times, using mulch and a drip irrigation system adopting 4 l/h emitters. The crop was covered by a plastic tunnel following treatment differentiation. The statistical analysis revealed an increased availability of Cu, Zn, Ca, Mg, and Mn for the CO₂ treatment, probably linked with the pH reduction (from 7.5 to 6.5). The increased nutrient uptake in the CO₂ enriched water treatment may be the cause of the commercial yield enhancement (8.6 %) and reduction in the weight of deformed berries (-12.1 %).

Arisi, A.C.M., G. Cornic, L. Jouanin, and C.H. Foyer. 1998.

Overexpression of iron superoxide dismutase in transformed poplar modifies the regulation of photosynthesis at low CO₂ partial pressures or following exposure to the prooxidant herbicide methyl viologen. *Plant Physiology* 117(2):565-574.

Chloroplast-targeted overexpression of an Fe superoxide dismutase (SOD) from *Arabidopsis thaliana* resulted in substantially increased foliar SOD activities. Ascorbate peroxidase, glutathione reductase, and monodehydroascorbate reductase activities were similar in the leaves from all of the lines, but dehydroascorbate reductase activity was increased in the leaves of the FeSOD transformants relative to untransformed controls. Foliar H₂O₂, ascorbate, and glutathione contents were comparable in all lines of plants. Irradiance-dependent changes in net CO₂ assimilation and chlorophyll a fluorescence quenching parameters were similar in all lines both in air (21% O₂) and at low (1%) O₂. CO₂-response curves for photosynthesis showed similar net CO₂-exchange characteristics in all lines. In contrast, values of photochemical quenching declined in leaves from untransformed controls at intercellular CO₂ (C_i) values below 200 µmol L⁻¹ but remained constant with decreasing C_i in leaves of FeSOD transformants. When the O₂ concentration was decreased from 21 to 1%, the effect of FeSOD overexpression on photochemical quenching at limiting C_i was abolished. At high light (1000 µmol m⁻² s⁻¹) a progressive decrease in the ratio of variable (F_v) to maximal (F_m) fluorescence was observed with decreasing temperature. At 6 degrees C the high-light-induced decrease in the F_v/F_m ratio was partially prevented by low O₂ but values were comparable in all lines. Methyl viologen caused decreased F_v/F_m ratios, but this was less marked in the FeSOD transformants than in the untransformed controls. These observations suggest that the rate of superoxide dismutation limits flux through the Mehler-peroxidase cycle in certain conditions.

Arnone, J.A. 1997. Indices of plant N availability in an alpine grassland under elevated atmospheric CO₂. *Plant and Soil* 190(1):61-66.

The objective of this study was to estimate whether elevated atmospheric [CO₂] alters plant N availability in a native high- elevation grassland in the Swiss Alps using two integrative, relatively non-disruptive methods. Estimates based on seasonal net plant N uptake, and those based on the amounts of NH₄⁺-N plus NO₃⁻-N captured by ion exchange resin (IER) bags, did not differ in plots treated with ambient (355 µmol L⁻¹) and elevated (680 µmol L⁻¹) [CO₂] in either the second (1993) or third (1994) growing season under treatment with elevated [CO₂]. The results of this study suggest that the effects of rising atmospheric [CO₂] on plant N availability may be negligible in this grassland. The results also contrast the relatively large effects of elevated atmospheric [CO₂] (increases and decreases) reported for highly disturbed artificial systems.

Arnone, J.A. 1997. Temporal responses of community fine root populations to long- term elevated atmospheric CO₂ and soil nutrient patches in model tropical ecosystems. *Acta Oecologica-International Journal of Ecology* 18(3):367-376.

Biomass and length density of fine roots, as well as overall allocation of

dry matter to root growth, of C-3 plants has been shown to increase under elevated CO₂. However, it is uncertain whether the stimulatory effect of elevated CO₂ on fine root population size in plant communities will persist, or whether fine root populations at high CO₂ simply reach their maximum sooner (or possibly later) than those produced under ambient CO₂. It is also unclear whether increased nutrient demand at the stand-level under elevated CO₂ will lead to more intense nutrient foraging via enhanced fine root proliferation into relatively nutrient-rich soil microsites. I addressed these questions in a 530 day experiment with model tropical plant communities established in four equivalent ecosystem (17 m(3)) in which plants shared a common low fertility soil. Fine root (less than or equal to 2 mm empty set) populations (biomass and length density) in ecosystems maintained at elevated CO₂ (610 µmol L⁻¹) increased more rapidly than those in ecosystems maintained at ambient CO₂ (340 µmol L⁻¹) during the first half of the experiment and also remained greater over the entire experiment. The data also indicate that: (1) fine root populations at both CO₂ levels eventually stabilize, (2) stabilization occurs sooner under elevated CO₂ (occupation of the soil volume), and (3) steady-state populations under elevated CO₂ may be slightly larger than those maintained under ambient CO₂. Fine root proliferation into artificially nutrient- enriched microsites was dramatic in all ecosystems (22% to 75% greater than into non-enriched soil). However, proliferation into enriched microsites was not enhanced by elevated CO₂. Thus, elevated CO₂ may not enhance exploitation of nutrient- rich microsites even in low fertility soils, suggesting that increased plant nutrient capture under elevated CO₂ also may be unlikely.

Arnone, J.A. 1999. Symbiotic N₂ fixation in a high Alpine grassland: effects of four growing seasons of elevated CO₂. *Functional Ecology* 13(3):383-387.

1. Increasing carbon dioxide concentration (E: 680 µmol CO₂ litre⁻¹) vs ambient, A: 355 µmol CO₂ litre⁻¹) around late- successional Alpine sedge communities of the Swiss Central Alps (2450 m) for four growing seasons (1992-1995) had no detectable effect on symbiotic N₂ fixation in *Trifolium alpinum*-the sole N₂-fixing plant species in these communities (74 ± 30 mg N m⁻² year⁻¹, A and E plots pooled). 2. This result is based on data collected in the fourth growing season showing that elevated CO₂ had no effect on *Trifolium* above-ground biomass (4.4 ± 1.7 g m⁻², A and E plots pooled, n = 24) or N content per unit land area (124 ± 51 mg N m⁻², A and E pooled), or on the percentage of N *Trifolium* derived from the atmosphere through symbiotic N₂ fixation (%Ndfa: 61.0 ± 4.1 across A and E plots) estimated using the N-15 dilution method. 3. Thus, it appears that N inputs to this ecosystem via symbiotic N₂ fixation will not be dramatically affected in the foreseeable future even as atmospheric CO₂ continues to rise.

Arnone, J.A., and P.J. Bohlen. 1998. Stimulated N₂O flux from intact grassland monoliths after two growing seasons under elevated atmospheric CO₂. *Oecologia* 116(3):331-335.

Long-term exposure of native vegetation to elevated atmospheric CO₂ concentrations is expected to increase C inputs to the soil and, in

ecosystems with seasonally dry periods, to increase soil moisture. We tested the hypothesis that these indirect effects of elevated CO₂ (600 $\mu\text{mol l}^{-1}$ vs 350 $\mu\text{mol l}^{-1}$) would improve conditions for microbial activity and stimulate emissions of nitrous oxide (N₂O), a very potent and long-lived greenhouse gas. After two growing seasons, the mean N₂O efflux from monoliths of calcareous grassland maintained at elevated CO₂ was twice as high as that measured from monoliths maintained at current ambient CO₂ (70 $\pm$ 9 vs 37 $\pm$ 4 $\mu\text{mol N}_2\text{O m}^{-2} \text{ h}^{-1}$) in October, 27 $\pm$ 5 vs 13 $\pm$ 3 $\mu\text{mol N}_2\text{O m}^{-2} \text{ h}^{-1}$) in November after aboveground harvest). The higher N₂O emission rates at elevated CO₂ were associated with increases in soil moisture, soil heterotrophic respiration, and plant biomass production, but appear to be mainly attributable to higher soil moisture. Our results suggest that rising atmospheric CO₂ may contribute more to the total greenhouse effect than is currently estimated because of its plant-mediated effects on soil processes which may ultimately lead to increased N₂O emissions from native grasslands.

Arnone, J.A., and G. Hirschel. 1997. Does fertilizer application alter the effects of elevated CO₂ on *Carex* leaf litter quality and in situ decomposition in an alpine grassland? *Acta Oecologica-International Journal of Ecology* 18(3):201-206.

The purpose of our investigation was to determine: (1) whether fertilization with NPK would result in an improvement in leaf litter quality of the dominant species (*Carex curvula*) in a high alpine grassland in Switzerland; and especially (2) if fertilization improves the quality of leaf litter produced under elevated atmospheric CO₂ and compensates for the suppressive effects of high CO₂ on the in situ decomposition rates of *C. curvula* litter, observed at this site in an earlier study. Fertilizer application (40 kg N ha⁻¹ yr⁻¹) resulted in 34% higher leaf litter [N] but did not change C:N or lignin N ratios, when viewed across both CO₂ treatments. Improvement in the mean N quality of litter produced under elevated CO₂ resulting from fertilization appeared to lead to a significantly faster mean decomposition rate (+60%), but fertilization had no significant effect on decomposition of litter produced under ambient CO₂. We conclude that the potential stimulatory effect of an increase in atmospheric N deposition on litter quality and decomposition rates may partially compensate for the inhibitory effects of rising atmospheric CO₂ in these high alpine grassland ecosystems.

Arnone, J.A., and C. Kestenholtz. 1997. Root competition and elevated CO₂: Effects on seedling growth in *Linum usitatissimum* populations and *Linum Silene cretica* mixtures. *Functional Ecology* 11(2):209-214.

1. Root competition can be an important determinant of the performance of neighbours within plant populations and communities. Because plants often maintain larger root systems and allocate more of their carbon to root systems under elevated atmospheric CO₂ than they do at lower CO₂

concentrations, root-root interactions could play an increasingly important role in determining competitive outcomes among individuals and plant species as global CO₂ concentration continues to rise. 2. We established 12 pure stands of *Linum usitatissimum* (flax) and 12 mixed stands of *Linum* and its naturally co-occurring weed species *Silene cretica* in opaque plastic trays each filled with the same amount of nutrient-rich soil mix. In half of the trays from each of these stand types, vertical waterproof partitions separated the root systems of individual plants from each other to prevent root competition, while in the other half no partitions were present. Half of the trays from all treatments were allowed to grow under low atmospheric CO₂ concentration (320 $\mu\text{mol l}^{-1}$) and the other half under elevated CO₂ (600 $\mu\text{mol l}^{-1}$), in daylight growth: chambers for 30 days from seedling emergence until harvest in mid-June. All trays received equal amounts of water so that soils in the low CO₂ treatment were maintained at field capacity. 3. Our results indicate that under high soil fertilities: (1) intra-specific root-root interactions alone play a relatively insignificant role in determining plant biomass production within pure *Linum* populations and (2) the impact of an aggressive species (*Silene*) on co-occurring less aggressive species (*Linum*) becomes more severe under elevated CO₂ as a result of amplified interspecific root competition.

Arnone, J.A., and C. Korner. 1993. Influence of elevated CO₂ on canopy development and red - far-red ratios in 2-storied stands of *ricinus-communis*. *Oecologia* 94(4):510-515.

Vertical structure of plant stands and canopies may change under conditions of elevated CO₂ due to differential responses of overstory and understory plants or plant parts. In the long term, seedling recruitment, competition, and thus population or community structure may be affected. Aside from the possible differential direct effects of elevated CO₂ on photosynthesis and growth, both the quantity and quality of the light below the overstory canopy could be indirectly affected by CO₂-induced changes in overstory leaf area index (LAI) and/or changes in overstory leaf quality. In order to explore such possible interactions, we compared canopy leaf area development, canopy light extinction and the quality of light beneath overstory leaves of two-storied monospecific stands of *Ricinus communis* exposed to ambient (340 $\mu\text{mol l}^{-1}$) and elevated (610 $\mu\text{mol l}^{-1}$) CO₂. Plants in each stand were grown in a common soil as closed "artificial ecosystems" with a ground area of 6.7 m². LAI of overstory plants in all ecosystems more than doubled during the experiment but was not different between CO₂ treatments at the end. As a consequence, extinction of photosynthetically active radiation (PAR) was also not altered. However, under elevated CO₂ the red to far-red ratio (R:FR) measured beneath overstory leaves was 10% lower than in ecosystems treated with ambient CO₂. This reduction was associated with increased thickness of palisade layers of overstory leaves and appears to be a plausible explanation for the specific enhancement of stem elongation of understory plants (without a corresponding biomass response) under elevated CO₂. Col enrichment led to increased biomass of overstory plants (mainly stem biomass) but had no effect on understory biomass. The results of this study raise the possibility of an important indirect effect of elevated CO₂ at the stand-level. We suggest that, under elevated CO₂, reductions in the R:FR ratio beneath overstory canopies may affect understory plant development independently of the effects of PAR extinction.

Arnone, J.A., and C. Korner. 1995. Soil and biomass carbon pools in model communities of tropical plants under elevated CO_2 . *Oecologia* 104(1):61-71.

The experimental data presented here relate to the question of whether terrestrial ecosystems will sequester more C in their soils, litter and biomass as atmospheric CO_2 concentrations rise. Similar to our previous study with relatively fertile growth conditions (Korner and Arnone 1992), we constructed four rather nutrient-limited model communities of moist tropical plant species in greenhouses (approximately 7 m² each). Plant communities were composed of seven species (77 individuals per community) representing major taxonomic groups and various life forms found in the moist tropics. Two ecosystems were exposed to 340 $\mu\text{mol CO}_2 \text{ l}^{-1}$ and two to 610 $\mu\text{mol CO}_2 \text{ l}^{-1}$ for 530 days of humid tropical growth conditions. In order to permit precise determination of C deposition in the soil, plant communities were initially established in C-free unwashed quartz sand. Soils were then amended with known amounts of organic matter (containing C and nutrients). Mineral nutrients were also supplied over the course of the experiment as timed-release full-balance fertilizer pellets. Soils represented by far the largest repositories for fixed C in all ecosystems. Almost 5 times more C (ca. 80% of net C fixation) was sequestered in the soil than in the biomass, but this did not differ between CO_2 treatments. In addition, at the whole-ecosystem level we found a remarkably small and statistically non-significant increase in C sequestration (+4%; the sum of C accretion in the soil, biomass, litter and necromass). Total community biomass more than quadrupled during the experiment, but at harvest was, on average, only 8% greater (i.e. 6% per year; n.s.) under elevated CO_2 , mainly due to increased root biomass (+15%, $P = 0.12$). Time courses of leaf area index of all ecosystems suggested that canopy expansion was approaching steady state by the time systems were harvested. Net primary productivity (NPP) of all ecosystems - i.e. annual accumulation of biomass, necromass, and leaf litter (but not plant-derived soil organic matter) - averaged 815 and 910 g m⁻² year⁻¹ at ambient and elevated CO_2 , respectively. These NPPs are remarkably similar to those of many natural moist tropical forested ecosystems. At the same time net productivity of soil organic matter reached 7000 g dry matter equivalent per m² and year (i.e. 3500 g C m⁻² year⁻¹). Very slight yet statistically significant CO_2 -induced shifts in the abundance of groups of species occurred by the end of the experiment, with one group of species (*Elettaria cardamomum*, *Ficus benjamina*, *F. pumila*, *Epipremnum pinnatum*) gaining slightly, and another group (*Ctenanthe lubbersiana*, *Heliconia humilis*, *Cecropia peltata*) losing. Our results show that: (1) enormous amounts of C can be deposited in the ground which are normally not accounted for in estimates of NPP and net ecosystem productivity; (2) any enhancement of C sequestration under elevated atmospheric CO_2 may be substantially smaller than is believed will occur (yet still very important), especially under growth conditions which permit close to natural NPP; and (3) species dominance in plant communities is likely to change under elevated CO_2 , but that changes may occur rather slowly.

Arnone, J.A., J.G. Zaller, C. Ziegler, H. Zandt, and C. Korner. 1995. Leaf quality and insect herbivory in model tropical plant-communities after long-term exposure to elevated atmospheric CO_2 . *Oecologia* 104(1):72-78.

Results from laboratory feeding experiments have shown that elevated atmospheric carbon dioxide can affect interactions between plants and insect herbivores, primarily through changes in leaf nutritional quality occurring at elevated CO_2 . Very few data are available on insect

herbivory in plant communities where insects can choose among species and positions in the canopy in which to feed. Our objectives were to determine the extent to which CO_2 -induced changes in plant communities and leaf nutritional quality may affect herbivory at the level of the entire canopy. We introduced equivalent populations of fourth instar *Spodoptera eridania*, a lepidopteran generalist, to complex model ecosystems containing seven species of moist tropical plants maintained under low mineral nutrient supply. Larvae were allowed to feed freely for 14 days, by which time they had reached the seventh instar. Prior to larval introductions, plant communities had been continuously exposed to either 340 $\mu\text{mol CO}_2 \text{ l}^{-1}$ or to 610 $\mu\text{mol CO}_2 \text{ l}^{-1}$ for 1.5 years. No major shifts in leaf nutritional quality [concentrations of N, total non-structural carbohydrates (TNC), sugar, and starch; ratios of: C/N, TNC/N, sugar/N, starch/N; leaf toughness] were observed between CO_2 treatments for any of the species. Furthermore, no correlations were observed between these measures of leaf quality and leaf biomass consumption. Total leaf area and biomass of all plant communities were similar when caterpillars were introduced. However, leaf biomass of some species was slightly greater - and for other species slightly less (e.g. *Cecropia peltata*) - in communities exposed to elevated CO_2 . Larvae showed the strongest preference for *C. peltata* leaves, the plant species that was least abundant in all communities, and fed relatively little on plants species which were more abundant. Thus, our results indicate that leaf tissue quality, as described by these parameters, is not necessarily affected by elevated CO_2 under relatively low nutrient conditions. Hence, the potential importance of CO_2 -induced shifts in leaf nutritional quality, as determinants of herbivory, may be overestimated for many plant communities growing on nutrient-poor sites if estimates are based on traditional laboratory feeding studies. Finally, slight shifts in the abundance of leaf tissue of various species occurring under elevated CO_2 will probably not significantly affect herbivory by generalist insects. However, generalist insect herbivores appear to become more dependent on less-preferred plant species in cases where elevated CO_2 results in reduced availability of leaves of a favoured plant species, and this greater dependency may eventually affect insect populations adversely.

Arp, W.J. 1991. Effects of source-sink relations on photosynthetic acclimation to elevated CO_2 . *Plant, Cell and Environment* 14(8):869-875.

While photosynthesis of C3 plants is stimulated by an increase in the atmospheric CO_2 concentration, photosynthetic capacity is often reduced after long-term exposure to elevated CO_2 . This reduction appears to be brought about by end product inhibition, resulting from an imbalance in the supply and demand of carbohydrates. A review of the literature revealed that the reduction of photosynthetic capacity in elevated CO_2 was most pronounced when the increased supply of carbohydrates was combined with small sink size. The volume of pots in which plants were grown affected the sink size by restricting root growth. While plants grown in small pots had a reduced photosynthetic capacity, plants grown in the field showed no reduction or an increase in this capacity. Pot volume also determined the effect of elevated CO_2 on the root/shoot ratio: the root/shoot ratio increased when root growth was not restricted and decreased in plants grown in small pots. The data presented in this paper suggest that plants growing in the field will maintain a high photosynthetic capacity as the atmospheric CO_2 level continues to rise.

Arp, W.J., and B.G. Drake. 1991. Increased photosynthetic capacity of scirpus-olneyi after 4 years of exposure to elevated co2. *Plant, Cell and Environment* 14(9):1003-1006.

While a short-term exposure to elevated atmospheric CO₂ induces a large increase in photosynthesis in many plants, long-term growth in elevated CO₂ often results in a smaller increase due to reduced photosynthetic capacity. In this study, it was shown that, for a wild C3 species growing in its natural environment and exposed to elevated CO₂ for four growing seasons, the photosynthetic capacity has actually increased by 31%. An increase in photosynthetic capacity has been observed in other species growing in the field, which suggests that photosynthesis of certain field grown plants will continue to respond to elevated levels of atmospheric CO₂.

Arp, W.J., B.G. Drake, W.T. Pockman, P.S. Curtis, and D.F. Whigham. 1993. Interactions between C-3 and C-4 salt-marsh plant-species during 4 years of exposure to elevated atmospheric co2. *Vegetatio* 104:133-143.

Elevated atmospheric CO₂ is known to stimulate photosynthesis and growth of plants with the C3 pathway but less of plants with the C4 pathway. An increase in the CO₂ concentration can therefore be expected to change the competitive interactions between C3 and C4 species. The effect of long term exposure to elevated CO₂ (ambient CO₂ concentration + 340 µmol CO₂ mol⁻¹) on a salt marsh vegetation with both C3 and C4 species was investigated. Elevated CO₂ increased the biomass of the C3 sedge *Scirpus olneyi* growing in a pure stand, while the biomass of the C4 grass *Spartina patens* in a monospecific community was not affected. In the mixed C3/C4 community the C3 sedge showed a very large relative increase in biomass in elevated CO₂ while the biomass of the C4 species declined. The C4 grass *Spartina patens* dominated the higher areas of the salt marsh, while the C3 sedge *Scirpus olneyi* was most abundant at the lower elevations, and the mixed community occupied intermediate elevations. *Scirpus* growth may have been restricted by drought and salt stress at the higher elevations, while *Spartina* growth at the lower elevations may be affected by the higher frequency of flooding. Elevated CO₂ may affect the species distribution in the salt marsh if it allows *Scirpus* to grow at higher elevations where it in turn may affect the growth of *Spartina*.

Arp, W.J., J.E.M. Van Mierlo, F. Berendse, and W. Snijders. 1998. Interactions between elevated CO₂ concentration, nitrogen and water: effects on growth and water use of six perennial plant species. *Plant, Cell and Environment* 21(1):1-11.

Two experiments are described in which plants of six species were grown for one full season in greenhouse compartments with 350 or 560 µmol mol⁻¹ CO₂. In the first experiment two levels of nitrogen supply were applied to study the interaction between CO₂ and nitrogen. In the second experiment two levels of water supply were added to the experimental set-up to investigate the three-way interaction between

CO₂, nitrogen and water. Biomass and biomass distribution were determined at harvests, while water use and soil moisture were monitored throughout the experiments. In both experiments a positive effect of CO₂ on growth was found at high nitrogen concentrations but not at low nitrogen concentrations. However, plants used much less water in the presence of low nitrogen concentrations. Drought stress increased the relative effect of elevated CO₂ on growth. Available soil moisture was used more slowly at high CO₂ during drought or at high nitrogen concentrations, while at low nitrogen concentrations decreased water use resulted in an increase in soil moisture. The response to the treatments was similar in all the species used. Although potentially faster growing species appeared to respond better to high CO₂ when supplied with a high level of nitrogen, inherently slow-growing species were more successful at low nitrogen concentrations.

Ashenden, T.W., R. Baxter, and C.R. Rafarel. 1992. An inexpensive system for exposing plants in the field to elevated concentrations of co2. *Plant, Cell and Environment* 15(3):365-372.

An inexpensive, potentially mobile field exposure system is described which may be easily constructed by a small workshop. It may be operated as an open-top with a frustum or covered with a polycarbonate 'lid'. The system is cost-effective for CO₂ exposure work because the small size allows provision of CO₂-enriched atmospheres over prolonged periods at relatively low cost. A preliminary assessment of the chambers has been made and concentrations can be maintained at +/- 6% for a target atmosphere of 680 cm³ m⁻³ CO₂ under normal operating conditions. Other chamber environmental conditions are reported.

Atkin, O.K., M. Schortemeyer, N. McFarlane, and J.R. Evans. 1999. The response of fast- and slow-growing *Acacia* species to elevated atmospheric CO₂: an analysis of the underlying components of relative growth rate. *Oecologia* 120(4):544-554.

In this study we assessed the impact of elevated CO₂ with unlimited water and complete nutrient on the growth and nitrogen economy of ten woody *Acacia* species that differ in relative growth rate (RGR). Specifically, we asked whether fast- and slow-growing species systematically differ in their response to elevated CO₂. Four slow-growing species from semi-arid environments (*Acacia aneura*, *A. coleii*, *A. coriacea* and *A. tetragonophylla*) and six fast-growing species from mesic environments (*Acacia dealbata*, *A. implexa*, *A. mearnsii*, *A. melanoxylon*, *A. irrorata* and *A. saligna*) were grown in glasshouses with either ambient (similar to 350 ppm) or elevated (similar to 700 ppm) atmospheric CO₂. All species reached greater final plant mass with the exception of *A. aneura*, and RGR, averaged across all species, increased by 10% over a 12-week period when plants were exposed to elevated

CO₂. The stimulation of RGR was evident throughout the 12-week growth period. Elevated CO₂ resulted in less foliage area per unit foliage dry mass, which was mainly the result of an increase in foliage thickness with a smaller contribution from greater dry matter content per unit fresh mass. The net assimilation rate (NAR, increase in plant mass per unit foliage area and time) of the plants grown at elevated CO₂ was higher in all species (on average 30% higher than plants in ambient CO₂) and was responsible for the increase in RGR. The higher NAR was associated with a substantial increase in foliar nitrogen productivity in all ten *Acacia* species. Plant nitrogen concentration was unaltered by growth at elevated CO₂ for the slow-growing *Acacia* species, but declined by 10% for faster-growing species. The rate of nitrogen uptake per unit root mass was higher in seven of the species when grown under elevated CO₂, and leaf area per unit root mass was reduced by elevated CO₂ in seven of the species. The absolute increase in RGR due to growth under elevated CO₂ was greater for fast- than for slow-growing *Acacia* species.

Atkinson, C.J., and J.M. Taylor. 1996. Effects of elevated CO₂ on stem growth, vessel area and hydraulic conductivity of oak and cherry seedlings. *New Phytologist* 133(4):617-626.

Plants of *Quercus robur* L. and *Prunus avium* L. x *P. pseudocerasus* Lind. were grown in either ambient (350 vpm) or elevated (700 vpm) CO₂. The intention was to examine the effects of elevated CO₂ on the morphological and functional development of the stem. The relationships between stem longitudinal transport capacity and development were explored in several ways: stem hydraulic function was related to stem cross-sectional area, supplied leaf area and total stem vessel lumen area. The mean total vessel number and the total vessel lumen area per stem, for both species, was determined from basal sections of the xylem. In *Prunus* seedlings grown in different CO₂ concentrations there was no significant change in the mean vessel size or number of vessels per stem. *Quercus* seedlings grown at elevated CO₂ showed a significant increase in both vessel number and mean vessel size. When total stem vessel area was calculated it had increased twofold for *Quercus* plants grown at elevated CO₂. Measured stem hydraulic conductivity was shown to increase linearly with supplied leaf area, except in *Quercus* seedlings grown at elevated CO₂. Stem hydraulic conductivity for *Quercus* seedlings grown at elevated CO₂ did not change with the increase in supplied leaf area. This absence of an increase in the stem hydraulic conductivity appeared to relate to changes in total stem vessel area. Despite total stem vessel area being greater at elevated CO₂ than that at ambient, it similarly did not increase with supplied leaf area. The implications of this change in the relationship between leaf area and stem hydraulic conductivity are discussed with respect to the possible effects the change might have on the plant's water balance. The possible causes and significance of the changes in xylem anatomy are also considered in relation to direct effects caused by CO₂ or indirect effects on changes in cambial maturity and tree growth.

Atkinson, C.J., J.M. Taylor, D. Wilkins, and R.T. Besford. 1997. Effects of elevated CO₂ on chloroplast components, gas exchange and growth of oak and cherry. *Tree Physiology* 17(5):319-325.

Specific chloroplast proteins, gas exchange and dry matter production in oak (*Quercus robur* L.) seedlings and clonal cherry (*Prunus avium* L.

x *pseudocerasus* Lind.) plants were measured during 19 months of growth in climate-controlled greenhouses at ambient (350 vpm) or elevated (700 vpm) CO₂. In both species, the elevated CO₂ treatment increased the PPFD saturated-rate of photosynthesis and dry matter production. After two months at elevated CO₂, *Prunus* plants showed significant increases in leaf (55%) and stem (61%) dry mass but not in root dry mass. However, this initial stimulation was not sustained: treatment differences in net assimilation rate (A) and plant dry mass were less after 10 months of growth than after 2 months of growth, suggesting acclimation of A to elevated CO₂ in *Prunus*. In contrast, after 10 months of growth at elevated CO₂, leaf dry mass of *Quercus* increased (130%) along with shoot (356%) and root (219%) dry mass, and A was also twice that of plants grown and measured at ambient CO₂. The amounts of Rubisco and the thylakoid-bound protein cytochrome f were higher in *Quercus* plants grown for 19 months in elevated CO₂ than in control plants, whereas in *Prunus* there was less Rubisco in plants grown for 19 months in elevated CO₂ than in control plants. Exposure to elevated CO₂ for 10 months resulted in increased mean leaf area in both species and increased abaxial stomatal density in *Quercus*. There was no change in leaf epidermal cell size in either species in response to the elevated CO₂ treatment. The lack of acclimation of photosynthesis in oak grown at elevated CO₂ is discussed in relation to the production and allocation of dry matter. We propose that differences in carbohydrate utilization underlie the differing long-term CO₂ responses of the two species.

Atkinson, C.J., P.A. Wookey, and T.A. Mansfield. 1991. Atmospheric-pollution and the sensitivity of stomata on barley leaves to abscisic-acid and carbon-dioxide. *New Phytologist* 117(4):535-541.

Spring barley (*Hordeum vulgare* L. cv. Klaxon) plants were exposed to mixtures of SO₂ + NO₂ (at concentrations of 24-35 nl l⁻¹ of each gas, depending upon fumigation system), or to charcoal-filtered, or unfiltered ambient air during the period in which the second, and subsequent, leaves were emerging. The ability of individual detached leaves to regulate water loss was then examined after terminating the pollutant treatment. Observations of diurnal changes in stomatal resistance of well-watered plants, using a viscous flow porometer, failed to indicate any major alterations which could be attributed to prior exposure to SO₂ + NO₂. By contrast, when an ABA solution (10(-1) mol m⁻³) was applied to detached leaves, the stomata of polluted plants were less responsive than plants previously exposed to control air. The dynamics of the observed responses strongly implicated impaired physiology of the guard cells rather than mechanical changes in the epidermis that might, for example, result from damage to the cuticle. Stomatal closure was considerably slower in polluted leaves compared with the controls. This decline in responsiveness to ABA was observed using leaves excised from well-watered plants and in the absence of any externally visible injury. The ability of stomata to respond to a range of CO₂ concentrations from 195- 735-μmol mol⁻¹ was also examined using individual leaves, attached to the plant, in an environmentally controlled cuvette. Here the stomata of leaves which had been fumigated with SO₂ + NO₂ behaved in a similar manner to the non-fumigated leaves, both showing closure in elevated CO₂ concentrations.

Austin, M.P. 1992. Modeling the environmental niche of plants - implications for plant community response to elevated CO₂ levels. *Australian Journal of Botany* 40(4-5):615-630.

No simple natural gradients in CO₂ concentration exist for testing predictions about changes in plant communities in response to elevated CO₂. However indirect effects of CO₂ via temperature increases can be tested by reference to natural analogues. Physiologists, vegetation modellers of climate change and community ecologists assume very different temperature responses for plants. Physiologists often assume a skewed non-monotonic curve with a tail towards low temperatures, forest modellers using FORET type models, a symmetric curve, and community ecologists a skewed response with a tail towards high temperatures. These assumptions are reviewed in relation to niche theory, and recent propositions concerning the continuum concept. Confusion exists between the different approaches over the shape of response curves to temperature. Distinctions need to be made between responses due to growth (physiological response), potential fitness (fundamental niche) and observed performance (realised niche). These types of response should be quantified and related to each other if process-models are to be tested for predictive success by reference to naturally occurring communities and temperature gradients. An example of a statistical method for quantifying the realised environmental niche response of a species to temperature is provided. It is based on generalised linear modelling (GLM) of presence/absence data on *Eucalyptus fastigata* for 8377 sites in southern New South Wales, Australia. Seven environmental variables or factors are considered: mean annual temperature, mean annual rainfall, mean monthly solar radiation, topographic position, rainfall seasonality, lithology, and soil nutrient status. The temperature response is modelled with a beta-function, $\log y = a + \alpha \log(t - a) + \delta \log(b - t)$, where t is temperature and letters are parameters. The probability of occurrence is shown to be a skewed function of mean annual temperature. Any process-models of climate change for vegetation incorporating temperature changes due to elevated CO₂ must be capable of generating such realised environmental niche responses for species.

Awmack, C.S., R. Harrington, and S.R. Leather. 1997. Host plant effects on the performance of the aphid *Aulacorthum solani* (Kalt.) (Homoptera : Aphididae) at ambient and elevated CO₂. *Global Change Biology* 3(6):545-549.

In future elevated CO₂ environments, chewing insects are likely to perform less well than at present because of the effects of increased carbon fixation on their host plants. When the aphid, *Aulacorthum solani* was reared on bean (*Vicia faba*) and tansy (*Tanacetum vulgare*) plants under ambient and elevated CO₂, performance was enhanced on both hosts at elevated CO₂. The nature of the response was different on each plant species suggesting that feeding strategy may influence an insect's response to elevated CO₂. On bean, the daily rate of production of nymphs was increased by 16% but there was no difference in development time, whereas on tansy, development time was 10% shorter at elevated CO₂ but the rate of production of nymphs was not affected. The same aphid clone therefore responded differently to elevated CO₂ on different host plants. This increase in aphid performance could lead to larger populations of aphids in a future elevated CO₂ environment.

Azconbieto, J., M.A. Gonzalezmeier, W. Doherty, and B.G. Drake. 1994. Acclimation of respiratory O₂ uptake in green tissues of field-grown native species after long-term exposure to elevated atmospheric CO₂. *Plant Physiology* 106(3):1163-1168.

C-3 and C-4 plants were grown in open-top chambers in the field at two CO₂ concentrations, normal ambient (ambient) and normal ambient + 340 $\mu\text{L L}^{-1}$ (elevated). Dark oxygen uptake was measured in leaves and stems using a liquid-phase Clark-type oxygen electrode. High CO₂ treatment decreased dark oxygen uptake in stems of *Scirpus olneyi* (C-3) and leaves of *Lindera benzoin* (C-3) expressed on either a dry weight or area basis. Respiration of *Spartina patens* (C-4) leaves was unaffected by CO₂ treatment. Leaf dry weight per unit area was unchanged by CO₂, but respiration per unit of carbon or per unit of nitrogen was decreased in the C-3 species grown at high CO₂. The component of respiration in stems of *S. olneyi* and leaves of *L. benzoin* primarily affected by long-term exposure to the elevated CO₂ treatment was the activity of the cytochrome pathway. Elevated CO₂ had no effect on activity and capacity of the alternative pathway in *S. olneyi*. The cytochrome c oxidase activity, assayed in a cell-free extract, was strongly decreased by growth at high CO₂ in stems of *S. olneyi* but it was unaffected in *S. patens* leaves. The activity of cytochrome c oxidase and complex III extracted from mature leaves of *L. benzoin* was also decreased after one growing season of plant exposure to elevated CO₂ concentration. These results show that in some C-3 species respiration will be reduced when plants are grown in elevated atmospheric CO₂. The possible physiological causes and implications of these effects are discussed.

Azevedo, R.A., R.M. Alas, R.J. Smith, and P.J. Lea. 1998. Response of antioxidant enzymes to transfer from elevated carbon dioxide to air and ozone fumigation, in the leaves and roots of wild-type and a catalase-deficient mutant of barley. *Physiologia Plantarum* 104(2):280-292.

A catalase-deficient mutant (RPr 794) and the wild-type (cv. Maris Mink) barley (*Hordeum vulgare* L.) counterpart. were grown for 3 weeks in high CO₂ (0.7%) and then transferred to air and ozone (120 nl l⁻¹) in the light and shade for a period of 3 days. Leaves and roots were analysed for catalase (CAT, EC 1.11.1.6), superoxide dismutase (SOD, EC 1.15.1.1) and glutathione reductase (GR, EC 1.6.4.2) activities. CAT activity in the leaves of the RPr 79/4 catalase-deficient mutant was around 5-10% of that determined in Maris Mink. but in the roots, both genotypes contained approximately the same levels of activity. CAT activity in Maris Mink increased in the leaves after transferring plants from 0.7% CO₂ to air or ozone, reaching a maximum of 5-fold. after 4 days in shade and ozone. For the catalase-deficient mutant, only small increases in CAT activity were observed in light/air and light/ozone treatments. In the roots, CAT activity decreased consistently in both genotypes, after plants were transferred from 0.7% CO₂. The total soluble SOD activity in the leaves and roots of both genotypes increased after plants were transferred from 0.7% CO₂. The analysis of SOD isolated from leaves following non-denaturing PAGE, revealed the presence of up to eight SOD isoenzymes classified as Mn-SOD or Cu/Zn-SODs: Fr-SOD was not detected. Significant changes in Mn- and Cu/Zn-SOD isoenzymes were observed; however, they could not account for the increase in total SOD activity. In leaves, GR activity also increased in Maris Mink and RPr 79/4, following transfer from 0.7% CO₂; however, no constant pattern could be established, while in roots, GR activity was reduced after 4 days of the treatments. The data suggest that elevated CO₂ decreases oxidative stress in barley leaves and that soluble CAT and SOD activities increased rapidly after plants were

transferred from elevated CO₂, irrespective of the treatment (light, shade, air or ozone).

Baattrup-Pedersen, A., and T.V. Madsen. 1999. Interdependence of CO₂ and inorganic nitrogen on crassulacean acid metabolism and efficiency of nitrogen use by *Littorella uniflora* (L.) Aschers. *Plant, Cell and Environment* 22(5):535-542.

The hypothesis is tested that crassulacean acid metabolism (CAM) in isoetids is a mechanism which not only conserves inorganic carbon but also plays a role in nitrogen economy of the plants. This hypothesis was tested in an outdoor experiment, where *Littorella uniflora* (L.) Aschers, were grown at two CO₂ and five inorganic nitrogen concentrations in a crossed factorial design. The growth of *Littorella* responded positively to enhanced nitrogen availability at high but not at low CO₂ indicating that growth was limited by nitrogen at high CO₂ only. For the nitrogen-limited plants, the capacity for CAM (CAM(cap)) increased with the degree of nitrogen limitation of growth and an inverse coupling between CAM and tissue-N was found. Although this might indicate a role of CAM in economizing on nitrogen in *Littorella*, the hypothesis was rejected for the following reasons: (1) although CAM(cap) was related to tissue-N no relationship between tissue-N and ambient CAM activity (CAM(ambient)) was found whereas a close relationship would be expected if CAM was regulated by nitrogen availability; (2) the photosynthetic nitrogen use efficiency for high CO₂-grown plants declined with increased CAM(ambient) and with CAM(cap); and (3) growth per unit tissue-N per unit time declined with increased CAM(ambient) and CAM(cap).

Bacanamwo, M., and J.E. Harper. 1997. Response of a hypernodulating soybean mutant to increased photosynthate supply. *Plant Science* 124(2):119-129.

Growth chamber studies were conducted to determine if increased photoassimilate supply, through light enhancement and CO₂ enrichment, could reverse the deleterious plant growth and enhance nodule function traits of NOD1-3, a hypernodulating mutant of Williams. Both light enhancement and CO₂ enrichment increased nodule number, acetylene reduction activity plant(-1) (but not specific activity) and dry matter accumulation in all tissues in both genotypes. Total biomass and specific nitrogenase activity were always less in the mutant than in Williams 82, indicating that the inferiority of the mutant may not be reversed by enhanced photoassimilate supply. Under all growth conditions, the mutant allocated relatively more photosynthate to nodules and less photosynthate to roots, compared to the control. Despite this, the decreased growth of the mutant relative to the control was not solely attributable to excessive nodulation of the mutant, since decreased growth was observed even on uninoculated plants. It is suggested that light enhancement and CO₂ enrichment may have stimulated nodulation through increased photosynthate supply, independent of the nodulation autoregulatory signal. Bachelet, D., D. Brown, M. Bohm, and P. Russell. 1992. Climate change in Thailand and its potential impact on rice yield. *Climatic Change* 21(4):347-366.

In Thailand, the world's largest rice exporter, rice constitutes a major export on which the economy of the whole country depends. Climate change could affect rice growth and development and thus jeopardize Thailand's wealth. Current climatic conditions in Thailand are compared to predictions from four general circulation models (GCMs). Temperature predictions correlate well with the observed values. Predictions of monthly rainfall correlate poorly. Virtually all models agree that significant increases in temperature (from 1 to 7-degrees-C) will occur in the region including Thailand following a doubling in atmospheric carbon dioxide (CO₂) concentration. The regional seasonality and extent of the rise in temperature varies with each model. Predictions of changes in rainfall vary widely between models. Global warming should in principle allow a northward expansion of rice-growing areas and a lengthening of the growing season now constrained by low temperatures. The expected increase in water-use efficiency due to enhanced CO₂ might decrease the water deficit vulnerability of dryland rice areas and could make it possible to slightly expand them.

91

Bachelet, D., and C.A. Gay. 1993. The impacts of climate change on rice yield - a comparison of 4 model performances. *Ecological Modelling* 65(1-2):71-93.

Increasing concentrations of carbon dioxide (CO₂) and other greenhouse gases are expected to modify the climate of the earth in the next 50-100 years. Mechanisms of plant response to these changes need to be incorporated in models that predict crop yield estimates to obtain an understanding of the potential consequences of such changes. This is particularly important in Asia where demographic forecasts indicate that rice supplies worldwide will need to increase by 1.6% annually to the year 2000 to match population growth estimates. The objectives of this paper are (1) to review the major hypotheses and/or experimental results regarding rice sensitivity to climate change and (2) to evaluate the suitability of existing rice models for assessing the impact of global climate change on rice production. A review of four physiologically-based rice models (RICEMOD, CERES-Rice, MACROS, RICESYS) illustrates their potential to predict rice responses to elevated CO₂ and increased temperature. RICEMOD does not respond to increases in CO₂ nor to large increases in temperature. Both MACROS and CERES (wetland rice) responses to temperature and CO₂ agree with recent experimental data. RICESYS is an ecosystem model which predicts herbivory and inter-species competition between rice and weeds but does not respond to CO₂. Its response to increasing temperature also agrees with experimental data.

Backhausen, J.E., and R. Scheibe. 1999. Adaptation of tobacco plants to elevated CO₂: influence of leaf age on changes in physiology, redox states and NADP-malate dehydrogenase activity. *Journal of*

Transgenic tobacco plants (*Nicotiana tabacum* L. cv. Xanthi) with altered chloroplast NADP-malate dehydrogenase (NADP-MDH) content were grown under ambient or under doubled atmospheric CO₂ in order to analyse the effect of elevated CO₂ on the redox state of the chloroplasts. Since large differences exist between the individual leaves of tobacco plants, gas exchange characteristics, enzyme capacities and metabolite contents were measured separately for each leaf of the plants. Large variations between leaves of different age were found in nearly every parameter analysed, and the differences between younger and older leaves were, in most cases, larger than the differences between comparable leaves at ambient or elevated CO₂. For all parameters (chlorophyll fluorescence, P700 reduction, NADP-MDH activation) that are indicative for the redox situation in the electron transport chains and in the chloroplast stroma, more oxidized values were determined under elevated CO₂. The increased redox state of ferredoxin, observed at ambient conditions in the NADP-MDH-under-expressing plants, disappeared under elevated CO₂. It was concluded that the reduced rate of photorespiration under elevated CO₂ decreases the amount of excess electrons. Interestingly, this lowered not only the activation state of NADP-MDH, but also the expression of the enzyme in the wild-type plants. The results are discussed with respect to a possible interaction between stromal reduction state and gene expression.

Badger, M. 1992. Manipulating agricultural plants for a future high CO₂ environment. *Australian Journal of Botany* 40(4-5):421-429.

This paper discusses the potential ways in which C3 plant performance may benefit from a future high-CO₂ environment. These include increases in the efficiencies for light, nitrogen and water utilisation, particularly at elevated temperatures, resulting from the improvement which will occur in the performance of the primary carboxylating enzyme, Rubisco. However, while growth experiments at elevated CO₂ indicate that C3 plants show stimulation of dry matter accumulation, the potential gains are greatly ameliorated by a redistribution of plant resources. This primarily occurs via a reduction in the leaf area ratio which offsets increases in the net assimilation rate. In addition, there may be an overcommitment of nitrogen in key photosynthetic components such as Rubisco and the thylakoid electron transport system. It is concluded that plants may not be genetically adapted to optimise their growth and performance at elevated CO₂ and that consideration should be given to exploring avenues for manipulating plants for more optimal responses. Targets for improvement of growth at elevated CO₂ include (1) altering source-sink relations; (2) improving the redistribution of nitrogen between the photosynthetic machinery and the rest of the plant; and (3) changing the response of stomata to CO₂ and humidity to increase water-use efficiency even further than is currently predicted.

Badiani, M., A. Dannibale, A.R. Paolacci, F. Miglietta, and A. Raschi. 1993. The antioxidant status of soybean (*glycine-max*) leaves grown under natural CO₂ enrichment in the field. *Australian Journal of Plant Physiology* 20(3):275-284.

The effects of progressively higher CO₂ levels on the foliar antioxidant status were studied by growing soybean (*Glycine max* Merrill cv. Cresir) plants at decreasing distances from natural CO₂ sources of geothermal origin in central Italy. When compared with neighbouring controls grown under normal CO₂ concentration (C), soybean leaves grown at 2 x C, 7 x C and more than 20 x C showed a substantial reduction in the size of ascorbate pool and in the activity of Cu,Zn-superoxide dismutase; both the content of ascorbic acid and the activity of ascorbate peroxidase declined at 2 x C and 7 x C and recovered to the control values at 20 x C. The foliar titre of glutathione disulfide and the activities of glutathione disulfide reductase and Mn-superoxide dismutase progressively increased as CO₂ concentration increased in ambient air. The results obtained suggest that the immanent risk of dioxygen toxicity associated with photosynthetic electron flow could be reduced in the presence of high CO₂ levels. On the other hand, depending on both the CO₂ exposure regimes and the cell compartment considered, high CO₂ could promote oxidative processes which cause GSH oxidation and require an enhanced cellular ability to scavenge superoxide anion and hydrogen peroxide.

Badiani, M., A.R. Paolacci, A. Fusari, I. Bettarini, E. Brugnoli, M. Lauteri, F. Miglietta, and A. Raschi. 1998. Foliar antioxidant status of plants from naturally high-CO₂ sites. *Physiologia Plantarum* 104(4):765-771.

We compared the foliar antioxidant status of native *Agrostis stolonifera* L. communities growing at two distinct CO₂-enriched sites of geothermal origin (E) and at a control field location with normal CO₂. Compared to the control, plants from both E- sites showed an increased size of the GSH pool, essentially due to enhanced GSSG levels, and a consequent decrease in the ratio between reduced and oxidised glutathione forms. Such differences were maintained and even enhanced in the vegetatively-propagated progenies of control and E-plants, grown under both greenhouse conditions and normal CO₂ levels. The above results confirmed previous observations on native and crop plants exposed to elevated CO₂. It is therefore suggested that changes in the glutathione redox balance might be of adaptive significance under conditions of permanent exposure to high CO₂.

Bailey, S., J. Rebbeck, and K.V. Loats. 1999. Interactive effects of elevated ozone plus carbon dioxide on duckweeds exposed in open-top chambers. *Ohio Journal of Science* 99(2):19-25.

The response of *Lemna minor* L. and *Spirodela polyrrhiza* (L.) Schleiden to projected future ambient levels of O₃ and CO₂ was studied under field conditions. The two duckweed species were treated with either charcoal-filtered air (CF), ambient O₃ (IXO(3)), or in ice ambient O₃ (2XO(3)), twice ambient CO₂ plus twice ambient O₃ (2XCO(2)+2XO(3)), or chamberless open-air (OA). Two experiments were conducted. In Experiment I, *L. minor* was treated for 15 d with a cumulative O₃ exposure of 14.4 ppm.h. No O₃ effects were observed during Experiment I. Dry weight of individual fronds and photosynthesis per frond increased in *L. minor* exposed to 2XCO(2)+2XO(3)(-) air. In Experiment II after 25 d of treatment (cumulative O₃ exposure of 16.2 ppm h), negative effects of 2XO(3) on the photosynthetic and growth rates of *L. minor* were observed. Dark respiration of *L. minor* significantly increased in 2XO(3)-air compared with controls, but

declined significantly in 2XCO(2)+2XO(3)-air compared to those grown in 2XO(3)-air. Photosynthesis and drg weight per frond increased in 2XCO(2)+2XO(3)-air when compared with all other treatments. Measurement of A/C-i (assimilation versus intercellular CO₂ concentration) curves in *L. minor* showed a significant reduction in carboxylation efficiency and maximum rates of photosynthesis in 2XCO(2)+2XO(3)-air compared with other treatments when expressed per weight. No differences in carboxylation efficiency were detected between treatments when expressed per frond. After 25 d of treatment, photosynthesis (per frond) and dry weight of *S. polyrhiza* were reduced in 2XO(3)-air, but final frond number was unaffected. Dark respiration of *S. polyrhiza* was unaffected in 2XO(3)-air, but when exposed to 2XCO(2)+2XO(3)-air, it declined significantly. Although *S. polyrhiza* photosynthesis per frond increased in 2XCO(2)+2XO(3)-air, dry weight was unaffected when compared with all other treatments. Only when comparisons were made between *S. polyrhiza* grown in 2XCO(2)+2XO(3)-air and 2XO(3)-air, were significant increases in dry weight observed. The addition of 2XCO(2) to 2XO(3)-air resulted in amelioration of negative O-3 effects for most responses for both duckweed species.

Baille, M., R. RomeroAranda, and A. Baille. 1996. Gas-exchange responses of rose plants to CO₂ enrichment and light. *Journal of Horticultural Science* 71(6):945-956.

This paper describes the response of gas exchange rates and water use efficiency of rose plants, by means of the characterization in situ and the analysis of the response of photosynthesis, transpiration and water use efficiency of whole plants to CO₂ enrichment under the irradiance conditions prevailing in greenhouses of southern France. Net CO₂ assimilation (A(n)) and transpiration (E) of whole rose plants (*Rosa hybrida*, cv. Sonia) were measured during winter and spring periods. The response of A(n) to light and CO₂ were fitted to a double hyperbola function ($r^2 = 0.84$). Maximum net assimilation rate (A(nmax)), light and CO₂ utilization efficiencies (alpha(1), alpha(c)) as well as light and CO₂ compensation points (Gamma(1), Gamma(c)) were calculated for the whole plant and compared with leaf and canopy data in the literature. The whole-plant characteristics generally had values intermediate between those related to leaf and canopy. Light saturation at subambient air CO₂ concentration (C-a) was reached for relatively low PPFD values (300 mu mol m⁻² s⁻¹), whereas at ambient and enriched C-a light saturation occurs for PPFD approximate to 1000 mu mol m⁻² s⁻¹. Doubling C-a from 350 to 700 mu mol mol⁻¹ increased A(nmax) and alpha(1) by respectively 40% and 30%, while reducing Gamma(1) by 27%. A threefold increase of C-a from 350 to 1050 mu mol mol⁻¹ induced a reduction of 20% of E. Instantaneous transpirational water use efficiency, WUE (=A(n)/E), is relatively insensitive to PPFD, although a slight decrease with PPFD is observed at high CO₂ concentration, but shows marked variations with C-a and leaf to air vapour pressure deficit (D-1). Increase of C-a from 350 to 1000 mu mol mol⁻¹ gave about 50% increase in WUE. Increase of D-1 from 0 to 2 kPa induced 30% decrease in WUE at ambient C-a and 50% decrease at 1000 mu mol mol⁻¹.

Bainbridge, G., P. Madgwick, S. Parmar, R. Mitchell, M. Paul, J. Pitts, A.J. Keys, and M.A.J. Parry. 1995. Engineering rubisco to

change its catalytic properties. *Journal of Experimental Botany* 46:1269-1276.

The initial steps of carbon assimilation and photorespiration are catalysed by ribulose-1,5-bisphosphate carboxylase/oxygenase (EC 4.1.1.39). Natural variation in the kinetic properties of the enzyme suggest that it is possible to alter the enzyme to favour the carboxylation activity relative to oxygenation. Mutagenesis in vitro of the gene encoding the large subunit of the enzyme from *Anacystis nidulans* has been used to modify catalytic properties. Residues at the C-terminal end of loop 6 of the beta/alpha barrel structure of the large subunit influence specificity towards the gaseous substrates, CO₂ and O-2. None of the residues altered by mutagenesis appear to interact directly with the transition state analogue and their effect on the reaction of the enediolate intermediate with the gaseous substrates and stabilization of the resulting transition state intermediates by lysine 334 must be indirect. Interactions with other parts of the enzyme must also be important in determining substrate specificity. Backbone carbonyl groups close to lysine 334 interact with lysine 128; mutation of lysine 128 to residues of less positive polarity reduces enzyme activity and favours oxygenation relative to carboxylation, the likely effects on assimilation rates of altering the kinetic properties of Rubisco have been modelled. A leaf with cyanobacterial Rubisco may out-perform a higher plant Rubisco at elevated CO₂ and cool temperatures.

Baker, J.T., S.L. Albrecht, D. Pan, L.H. Allen, N.B. Pickering, and K.J. Boote. 1994. Carbon-dioxide and temperature effects on rice (*oryza-sativa* L, CV ir-72). *Soil and Crop Science Society of Florida Proceedings* 53:90-97.

The current increase in atmospheric carbon dioxide concentration ([CO₂]) along with predictions of possible future increases in global air temperatures have stimulated interest in the effects of [CO₂] and temperature on the growth and yield of food crops. This study was conducted to determine the effects and possible interactions of elevated [CO₂] and temperature on the development, growth and yield of rice (*Oryza sativa* L., cv. IR-72). Rice plants were grown season-long in outdoor, naturally sunlit, controlled-environment, plant growth chambers. Chamber air temperatures were controlled to follow a continuously and diurnally varying, near sine-wave control setpoint that operated between maximum (daytime) and minimum (nighttime) values. Day/night (maximum/minimum) air temperature treatments were: 32/23, 35/26, and 38/29-degrees-C. Dewpoint air temperatures were maintained at 18, 21, 24- degrees-C in the 32/23, 35/26, 38/29-degrees-C dry bulb air temperature treatment, respectively. Daytime [CO₂] was controlled to 330 and 660 mumol CO₂ mol⁻¹ air in each of the air temperature treatments. The time interval between appearance of successive mainstem leaves during reproductive development was reduced by increasing air temperature treatment (P less-than-or-equal-to 0.05) but was not affected by [CO₂] enrichment. In this experiment [CO₂] enrichment did not affect (P less-than-or-equal-to 0.10) grain yield, components of grain yield, final above ground biomass or harvest index. Increasing temperature during growth, particularly from the 35/26 to 38/29-degrees-C reduced grain yield, individual grain mass, and harvest index. The reduced grain yields with increasing temperature treatment suggest potential detrimental effects on rice production in some areas if air temperatures increase.

Baker, J.T., and L.H. Allen. 1993. Contrasting crop species responses to CO₂ and temperature - rice, soybean and citrus. *Vegetatio* 104:239-260.

The continuing increase in atmospheric carbon dioxide concentration ([CO₂]) and projections of possible future increases in global air temperatures have stimulated interest in the effects of these climate variables on plants and, in particular, on agriculturally important food crops. Mounting evidence from many different experiments suggests that the magnitude and even direction of crop responses to [CO₂] and temperature is almost certain to be species dependent and very likely, within a species, to be cultivar dependent. Over the last decade, [CO₂] and temperature experiments have been conducted on several crop species in the outdoor, naturally- sunlit, environmentally controlled, plant growth chambers by USDA-ARS and the University of Florida, at Gainesville, Florida, USA. The objectives for this paper are to summarize some of the major findings of these experiments and further to compare and contrast species responses to [CO₂] and temperature for three diverse crop species: rice (*Oryza sativa*, L.), soybean (*Glycine max*, L.) and citrus (various species). Citrus had the lowest growth and photosynthetic rates but under [CO₂] enrichment displayed the greatest percentage increases over ambient [CO₂] control treatments. In all three species the direct effect of [CO₂] enrichment was always an increase in photosynthetic rate. In soybean, photosynthetic rate depended on current [CO₂] regardless of the long-term [CO₂] history of the crop. In rice, photosynthetic rate measured at a common [CO₂], decreased with increasing long-term [CO₂] growth treatment due to a corresponding decline in RuBP carboxylase content and activity. Rice specific respiration decreased from subambient to ambient and superambient [CO₂] due to a decrease in plant tissue nitrogen content and a decline in specific maintenance respiration rate. In all three species, crop water use decreased with [CO₂] enrichment but increased with increases in temperature. For both rice and soybean, [CO₂] enrichment increased growth and grain yield. Rice grain yields declined by roughly 10% per each 1-degrees-C rise in day/night temperature above 28/21-degrees-C.

Baker, J.T., and L.H. Allen. 1994. Assessment of the impact of rising carbon-dioxide and other potential climate changes on vegetation. *Environmental Pollution* 83(1-2):223-235.

The projected doubling of current levels of atmospheric carbon dioxide concentration ([CO₂]) during the next century along with increases in other radiatively active gases have led to predictions of increases in global air temperature and shifts in precipitation patterns. Additionally, stratospheric ozone depletion may result in increased ultraviolet-B (UV-B) radiation incident at the Earth's surface in some areas. Since these changes in the Earth's atmosphere may have profound effects on vegetation, the objectives of this paper are to summarize some of the recent research on plant responses to [CO₂], temperature and UV-B radiation. Elevated [CO₂] increases photosynthesis and usually results in increased biomass, and seed yield. The magnitude of these increases and the specific photosynthetic response depends on the plant species, and are strongly influenced by other environmental factors including temperature, light level, and the availability of water and nutrients. While elevated [CO₂] reduces transpiration and increases photosynthetic water-use efficiency, increasing air temperature can result in greater water use, accelerated plant developmental rate, and shortened growth duration. Experiments on UV-B radiation exposure have demonstrated a wide range of photobiological responses among plants with decreases

in photosynthesis and plant growth among more sensitive species. Although a few studies have addressed the interactive effects of [CO₂] and temperature on plants, information on the effects of UV-B radiation at elevated [CO₂] is scarce. Since [CO₂], temperature and UV-B radiation may increase concurrently, more research is needed to determine plant responses to the interactive effects of these environmental variables.

Baker, J.T., L.H. Allen, and K.J. Boote. 1990. Growth and yield responses of rice to carbon-dioxide concentration. *Journal of Agricultural Science* 115:313-320.

Rice plants (*Oryza sativa* L., cv. IR30) were grown in paddy culture in outdoor, naturally sunlit, controlled-environment, plant growth chambers at Gainesville, Florida, USA, in 1987. The rice plants were exposed throughout the season to subambient (160 and 250), ambient (330) or superambient (500, 660, 900 $\mu\text{mol CO}_2/\text{mol air}$) CO₂ concentrations. Total shoot biomass, root biomass, tillering, and final grain yield increased with increasing CO₂ concentration, the greatest increase occurring between the 160 and 500 $\mu\text{mol CO}_2/\text{mol air}$ treatments. Early in the growing season, root:shoot biomass ratio increased with increasing CO₂ concentration; although the ratio decreased during the growing season, net assimilation rate increased with increasing CO₂ concentration and decreased during the growing season. Differences in biomass and lamina area among CO₂ treatments were largely due to corresponding differences in tillering response. The number of panicles/plant was almost entirely responsible for differences in final grain yield among CO₂ treatments. Doubling the CO₂ concentration from 330 to 660 $\mu\text{mol CO}_2/\text{mol air}$ resulted in a 32% increase in grain yield. These results suggest that important changes in the growth and yield of rice may be expected in the future as the CO₂ concentration of the earth's atmosphere continues to rise.

Baker, J.T., L.H. Allen, and K.J. Boote. 1992. Response of rice to carbon-dioxide and temperature. *Agricultural and Forest Meteorology* 60(3-4):153-166.

The current increase in atmospheric carbon dioxide concentration ([CO₂]) along with predictions of possible future increases in global air temperatures have stimulated interest in the effects of [CO₂] and temperature on the growth and yield of food crops. This study was conducted to determine the effects and possible interactions of [CO₂] and temperature on the growth and yield of rice (*Oryza sativa* L., cultivar IR-30). Rice plants were grown for a season in outdoor, naturally sunlit, controlled-environment, and plant growth chambers. Temperature treatments of 28/21/25, 34/27/31, and 40/33/37- degrees-C (daytime dry bulb air temperature/night-time dry bulb air temperature/paddy water temperature) were maintained in [CO₂] treatments of 330 and 660- $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$. In the 40/33/37-degrees-C temperature treatment, plants in the 330- $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$ [CO₂] treatment died during stem extension while the [CO₂] enriched plants survived but produced sterile panicles. Plants in the 34/27/31-degrees-C temperature treatments accumulated biomass and leaf area at a faster rate early in the growing season than plants in the 28/21/25-degrees-C temperature treatments.

Tillering increased with increasing temperature treatment. Grain yield increases owing to [CO₂] enrichment were small and non-significant. This lack of [CO₂] response on grain yield was attributed to the generally lower levels of solar irradiance encountered during the late fall and winter when this experiment was conducted. Grain yields were affected much more strongly by temperature than [CO₂] treatment. Grain yields declined by an average of approximately 7-8% per 1-degrees-C rise in temperature from the 28/21/25 to 34/27/31-degrees-C temperature treatment. The reduced grain yields with increasing temperature treatment suggests potential detrimental effects on rice production in some areas if air temperatures increase, especially under conditions of low solar irradiance.

Baker, J.T., L.H. Allen, and K.J. Boote. 1992. Temperature effects on rice at elevated CO₂ concentration. *Journal of Experimental Botany* 43(252):959-964.

The continuing increase in atmospheric carbon dioxide concentration ([CO₂]) and projections of possible future increases in global air temperatures have stimulated interest in the effects of these climate variables on agriculturally important food crops. This study was conducted to determine the effects of [CO₂] and temperature on rice (*Oryza sativa* L., cv. IR-30). Rice plants were grown season-long in outdoor, naturally sunlit, controlled-environment, plant growth chambers in temperature regimes ranging from 25/18/21-degrees-C to 37/30/34-degrees-C (daytime dry bulb air temperature/night-time dry bulb air temperature/paddy water temperature) and [CO₂] of 660-mu-mol CO₂ mol⁻¹ air. An ambient chamber was maintained at a [CO₂] of 330-mu-mol mol⁻¹ and temperature regime of 28/21/25- degrees-C. Carbon dioxide enrichment at 28/21/25-degrees-C increased both biomass accumulation and tillering and increased grain yield by 60%. In the 660-mu-mol mol⁻¹ [CO₂] treatment, grain yield decreased from 10.4 to 1.0 Mg ha⁻¹ with increasing temperature from 28/21/25-degrees-C to the 37/30/34-degrees-C temperature treatment. Across this temperature range, the number of panicles plant⁻¹ nearly doubled while the number of seeds panicle⁻¹ declined sharply. These results indicate that while future increases in atmospheric [CO₂] are likely to be beneficial to rice growth and yield, potentially large negative effects on rice yield are possible if air temperatures also rise.

Baker, J.T., L.H. Allen, K.J. Boote, and N.B. Pickering. 1997. Rice responses to drought under carbon dioxide enrichment .1. Growth and yield. *Global Change Biology* 3(2):119-128.

Projections of future climate change include a strong likelihood of a doubling of current atmospheric carbon dioxide concentration ([CO₂]) and possible shifts in precipitation patterns. Drought stress is a major environmental limitation for crop growth and yield and is common in rainfed rice production systems. This study was conducted to determine the growth and grain yield responses of rice to drought stress under [CO₂] enrichment. Rice (cv. IR-72) was grown to maturity in eight naturally sunlit, plant growth chambers in atmospheric carbon dioxide concentrations [CO₂] of 350 and 700 mu mol CO₂ mol⁻¹ air. In both [CO₂], water management treatments included continuously hooded (CF) controls, flood water removed and drought stress imposed at

panicle initiation (PI), anthesis (ANT), and both panicle initiation and anthesis (PI & ANT). The [CO₂] enrichment increased growth, panicles plant⁻¹ and grain yield. Drought accelerated leaf senescence, reduced leaf area and above-ground biomass and delayed crop ontogeny. The [CO₂] enrichment allowed 1-2 days more growth during drought stress cycles. Grain yields of the PI and PI & ANT droughts were similar to the CF control treatments while the ANT drought treatment sharply reduced growth, grain yield and individual grain mass. We conclude that in the absence of air temperature increases, future global increases in [CO₂] should promote rice growth and yield while providing a modest reduction of near 10% in water use and so increase drought avoidance.

Baker, J.T., L.H. Allen, K.J. Boote, and N.B. Pickering. 1997. Rice responses to drought under carbon dioxide enrichment .2. Photosynthesis and evapotranspiration. *Global Change Biology* 3(2):129-138.

Future climate change is projected to include a strong likelihood of continued increases in atmospheric carbon dioxide concentration ([CO₂]) and possible shifts in precipitation patterns. Due mainly to uncertainties in the timing and amounts of monsoonal rainfall, drought is common in rainfed rice production systems. The objectives of this study were to quantify the effects and possible interactions of [CO₂] and drought stress on rice (*Oryza sativa*, L.) photosynthesis, evapotranspiration and water-use efficiency. Rice (cv. IR-72) was grown to maturity in eight naturally sunlit, plant growth chambers in atmospheric carbon dioxide concentrations [CO₂] of 350 and 700 mu mol CO₂ mol⁻¹ air. In both [CO₂], water management treatments included continuously flooded controls, flood water removed and drought stress imposed at panicle initiation, anthesis, and both panicle initiation and anthesis. Potential acclimation of rice photosynthesis to long-term [CO₂] growth treatments of 350 and 700 mu mol mol⁻¹ was tested by comparing canopy photosynthesis rates across short-term [CO₂] ranging from 160 to 1000 mu mol mol⁻¹. These tests showed essentially no acclimation response with photosynthetic rate being a function of current short-term [CO₂] rather than long- term [CO₂] growth treatment. In both long-term [CO₂] treatments, photosynthetic rate saturated with respect to [CO₂] near 510 mu mol mol⁻¹. Carbon dioxide enrichment significantly increased both canopy net photosynthetic rate (21-27%) and water-use efficiency while reducing evapotranspiration by about 10%. This water saving under [CO₂] enrichment allowed photosynthesis to continue for about one to two days longer during drought in the enriched compared with the ambient [CO₂] control treatments.

Balaguer, L., J.D. Barnes, A. Panicucci, and A.M. Borland. 1995. Production and utilization of assimilates in wheat (triticum- aestivum L) leaves exposed to elevated O₃ and/or CO₂. *New Phytologist* 129(4):557-568.

This study examined the effects of elevated ozone (O₃) and/or carbon dioxide (CO₂) on the diel allocation of photosynthetically fixed carbon in fully expanded leaves of young (growth stages 4-5) spring wheat (*Triticum aestivum* L. cv. Hanno). Plants were grown in controlled environment chambers and exposed to two O₃ regimes ['non-polluted' air (CF), < 5 nmol mol⁻¹; 'polluted' air, CF + 75 nmol mol⁻¹] 7 h d⁻¹

1)] and two CO₂ treatments ('ambient', 354 $\mu\text{mol mol}^{-1}$; 'elevated', 700 $\mu\text{mol mol}^{-1}$) over a 30 d period. Neutral sugars (predominantly sucrose) were found to be the most abundant form of carbohydrate accumulated by leaves during the day, but significant quantities of starch and high degree of polymerization (d.p.) fructans were also present. Elevated concentrations of O-3 and/or CO₂ were found to have marked effects on diel patterns of export, storage and respiration, whilst the proportions of fixed carbon allocated to each of these processes were broadly similar. O-3 depressed the rate of net CO₂ assimilation (-20%) and reduced stomatal conductance (-19%). This was reflected in a reduced amount of carbohydrate accumulated in, and exported by, source tissue during the day. Effects of O-3 on the rate of CO₂ fixation were aggravated by an increased demand for carbon by dark respiratory processes. In contrast, doubling the atmospheric concentration of CO₂ enhanced the rate of net CO₂ assimilation (+47%) and reduced the proportion of fixed carbon retained in the leaf blade, increasing the rate of export. The favourable carbon balance of CO₂ enriched leaves was further enhanced by a decrease in the cost of maintenance respiration, whilst simultaneous measurements of CO₂ efflux and O-2 uptake at night suggested a shift in the substrates metabolized at high CO₂. Effects of elevated CO₂ and O-3 on the carbon balance of individual leaf blades over a single 24 h light/dark cycle were entirely consistent with the cumulative effects of the gases on plant growth over a 30 d period. O-3 reduced the rate of plant growth (-10%), but there were differential effects of O-3 on the growth of root and shoot which exacerbated the decrease in assimilate availability induced by O-3. In contrast the favourable effects of CO₂ enrichment on the carbon balance of individual source leaves was reflected in the enhanced accumulation of dry matter in existing sinks, and the initiation of new sinks (i.e. increased tillering). In the combined treatment (elevated CO₂ + O-3), O-3 counteracted the favourable effects of CO₂ enrichment on the carbon balance of individual leaves, and the combined effects of the individual gases on the diel partitioning of photosynthetically fixed carbon in fully expanded leaf blades was reflected in a decreased rate of plant growth at elevated CO₂, a situation further exacerbated by O-3-induced shifts in the relative partitioning of carbon between root and shoot. There was no evidence that CO₂ enrichment afforded additional protection against O-3 damage: the extent of the O-3-induced reduction in photosynthesis, carbohydrate availability and growth observed at elevated CO₂ was similar to that induced by O-3 in ambient air, despite additive effects of the gases on stomatal conductance that would reduce the effective dose of O-3 by approximate to 30%. The wider ecological significance of interactions between elevated CO₂ and O-3 is discussed in the light of other recent findings.

Balaguer, L., E. Manrique, A. de los Rios, C. Ascaso, K. Palmqvist, M. Fordham, and J.D. Barnes. 1999. Long-term responses of the green-algal lichen *Parmelia caperata* to natural CO₂ enrichment. *Oecologia* 119(2):166-174.

Acclimation to elevated CO₂ was investigated in *Parmelia caperata* originating from the vicinity of a natural CO₂ spring, where the average daytime CO₂ concentration was 729 $\pm$ 39 $\mu\text{mol mol}^{-1}$ dry air. Thalli showed no evidence of a down-regulation in photosynthetic capacity following long-term exposure to CO₂ enrichment in the field; carboxylation efficiency, total Ribulose biphosphate carboxylase/oxygenase (Rubisco) content, apparent quantum yield of CO₂ assimilation, and the light-saturated rate of CO₂ assimilation (measured under ambient and saturating CO₂ concentrations) were similar in thalli from the naturally CO₂ enriched site and an adjacent control site where the average long-term CO₂ concentration was about

355 $\mu\text{mol mol}^{-1}$. Thalli from both CO₂ environments exhibited low CO₂ compensation points and early saturation of CO₂ uptake kinetics in response to increasing external CO₂ concentrations, suggesting the presence of an active carbon-concentrating mechanism. Consistent with the lack of significant effects on photosynthetic metabolism, no changes were found in the nitrogen content of thalli following prolonged exposure to elevated CO₂. Detailed intrathalline analysis revealed a decreased investment of nitrogen in Rubisco in the pyrenoid of algae located in the elongation zone of thalli originating from elevated CO₂, an effect associated with a reduction in the percentage of the cell volume occupied by lipid bodies and starch grains. Although these differences did not affect the photosynthetic capacity of thalli, there was evidence of enhanced limitations to CO₂ assimilation in lichens originating from the CO₂-enriched site. The light-saturated rate of CO₂ assimilation measured at the average growth CO₂ concentration was found to be significantly lower in thalli originating from a CO₂-enriched atmosphere compared with that of thalli originating and measured at ambient CO₂. At lower photosynthetic photon flux densities, the light compensation point of net CO₂ assimilation was significantly higher in thalli originating from elevated CO₂ and this effect was associated with higher usnic acid content.

Balaguer, L., F. Valladares, C. Ascaso, J.D. Barnes, A. DelosRios, E. Manrique, and E.C. Smith. 1996. Potential effects of rising tropospheric concentrations of CO₂ and O-3 on green-algal lichens. *New Phytologist* 132(4):641-652.

Parmelia sulcata Taylor was used as a model to examine the effects of elevated CO₂ and/or O-3 on green algal lichens. Thalli were exposed for 30 d in duplicate controlled-environment chambers to two atmospheric concentrations of CO₂ ('ambient' [350 $\mu\text{mol mol}^{-1}$]) and 'elevated' [700 $\mu\text{mol mol}^{-1}$] 24 h d⁻¹) and two O-3 regimes ('non-polluted' air [CF₃ < 5 nmol mol⁻¹]) and 'polluted' air [15 nmol mol⁻¹] overnight rising to a midday maximum of 75 nmol mol⁻¹), in a factorial design. Elevated CO₂ or elevated O-3 depressed the light saturated rate of CO₂ assimilation (A(sat)) measured at ambient CO₂ by 30%, and 18%, respectively. However, despite this effect ultrastructural studies revealed increased lipid storage in cells of the photobiont in response to CO₂-enrichment. Simultaneous exposure to elevated O-3 reduced CO₂-induced lipid accumulation and reduced A(sat) in an additive manner. Gold-antibody labelling revealed that the decline in photosynthetic capacity induced by elevated CO₂ and/or O-3 was accompanied by a parallel decrease in the concentration of Rubisco in the algal pyrenoid (r = 0.93). Interestingly, differences in the amount of Rubisco protein were not correlated with changes in pyrenoid volume. Measurements of in vivo chlorophyll-fluorescence induction kinetics showed that the decline in A(sat) induced by elevated CO₂ and/or O-3 was not associated with significant changes in the photochemical efficiency of photosystem (PS)II. Although the experimental conditions inevitably imposed some stress on the thalli, revealed a significant decline in the efficiency of PS II photochemistry, and enhanced starch accumulation in the photobiont over the fumigation period, the study shows that the green-algal lichen symbiosis might be influenced by future changes in atmospheric composition. Photosynthetic capacity, measured at ambient CO₂, was found to be reduced after a controlled 30 d exposure to elevated CO₂ and/or O-3 and this effect was associated with a parallel decline in the amount of Rubisco in the pyrenoid of algal chloroplasts.

Baldocchi, D. 1994. A comparative-study of mass and energy-exchange rates over a closed C-3 (wheat) and an open C-4 (corn) crop .2. Co₂ exchange and water-use efficiency. *Agricultural and Forest Meteorology* 67(3-4):291-321.

Major differences exist between the photosynthetic and transpiration rates Of C3 and C4 leaves as a result of biochemical and physiological factors. Whether or not differences between CO₂ and water vapor exchange rates Of C3 and C4 species scale from leaf to field dimensions is poorly known. The aim of this work is to improve our understanding on how environmental, architectural and physiological variables affect the flux densities Of CO₂ and water vapor over C3 and C4 crop stands during day and night periods. Experimental data were obtained over a closed wheat and an open com stand using the eddy correlation method. Interpretation of the field measurements is aided by the use of a canopy photosynthesis/evaporation model. The flux density of absorbed photosynthetically active radiation (Q(a)) had a disproportionate influence on CO₂ flux densities measured over a closed C3 and an open C4 crop. Variations in Q(a) explained over 88% of the variance in daytime CO₂ flux densities, F(c). At night, canopy radiative temperature was the main environmental factor controlling the respiratory CO₂ efflux by the two crops. Leaf area index and growth stage were the plant variables that affected F(c) most. Incremental increases in leaf area index enhanced the com crop's ability to absorb incident solar radiation and enlarged the com's sink strength for CO₂. Heading by the wheat caused rates of daytime CO₂ gains to decrease and rates of night-time CO₂ losses to increase. Water use efficiency of the wheat crop improved as the absolute humidity deficit of the atmosphere decreased. Water use efficiency of the com, on the other hand, was relatively insensitive to humidity deficits. With regard to canopy CO₂ exchange and water use efficiency, differences in canopy structure between the wheat and com overwhelmed physiological differences. The closed C3 wheat crop assimilated CO₂ at a higher rate than the sparse C4 com canopy, even though com uses a more efficient photosynthetic pathway. Consequently, water use efficiency of the com was not greater than values measured over the wheat. Instead, water use efficiencies of the two crops were similar. The com crop assimilated CO₂ at a lower rate than wheat because the com's canopy quantum yield was lower and because its sparse canopy absorbed less photosynthetically active radiation than the closed wheat stand.

Baldocchi, D.D., and P.C. Harley. 1995. Scaling carbon-dioxide and water-vapor exchange from leaf to canopy in a deciduous forest .2. Model testing and application. *Plant, Cell and Environment* 18(10):1157-1173.

The scaling of CO₂ and water vapour transfer from leaf to canopy dimensions was achieved by integrating mechanistic models for physiological (photosynthesis, stomatal conductance and soil/root and bole respiration) and micrometeorological (radiative transfer, turbulent transfer and surface energy exchanges) processes. The main objectives of this paper are to describe a canopy photosynthesis and evaporation model for a temperate broadleaf forest and to test it against field measurements. The other goal of this paper is to use the validated model to address some contemporary ecological and physiological questions concerning the transfer of carbon and water between forest canopies and the atmosphere. In particular, we examine the role of simple versus

complex radiative transfer models and the effect of environmental (solar radiation and CO₂) and ecophysiological (photosynthetic capacity) variables on canopy-scale carbon and water vapour fluxes.

Ball, A.S. 1991. Degradation by *Streptomyces viridosporus* t7a of plant-material grown under elevated CO₂ conditions. *Fems Microbiology Letters* 84(2):139-142.

The biodegradability of plant material derived from wheat grown under different concentrations of atmospheric CO₂ was investigated using the lignocarbhydrate solubilising actinomycete, *Streptomyces viridosporus*. Growth of *S. viridosporus* and solubilisation of lignocarbhydrate were highest when wheat grown at ambient CO₂ concentrations (350 ppm) was used as C-source. Growth of *S. viridosporus* and solubilisation were reduced when the plant material was derived from wheat grown at 645 PPM CO₂. The results suggest that modifications in plant structure occur when wheat is grown under conditions of elevated atmospheric CO₂ which make it more resistant to microbial digestion.

Ball, A.S. 1997. Microbial decomposition at elevated CO₂ levels: effect of litter quality. *Global Change Biology* 3(4):379-386.

The decomposition of senesced plant litter represents an important intermediate step in the cycling of nutrients between above-and below-ground systems. The rate of decomposition of plant litter is sensitive to fluctuations in a number of parameters, including environmental conditions, and particularly to changes in the quality of the litter. Increased C:N ratios of litter are thought to be one possible consequence of growth of plants under elevated [CO₂]. This response is likely to reduce the rate of decomposition of the litter. Evidence from the growth of plants in both pot and field studies suggests that growth of C3 plants in elevated atmospheric [CO₂] (600-700 $\mu\text{mol mol}^{-1}$) may lead to a significant increase in either/both the C:N and the lignin: N ratios of litter. Short-term decomposition of litter from plants showing this response in elevated [CO₂] has confirmed that decomposition occurs at a significantly lower rate. The limited studies of both the response of C4 plants to elevated [CO₂] and the subsequent degradability of the senescent litter suggest that no differences in litter quality or degradability occur. In terms of litter quality the response of plants therefore appears to be dependent upon photosynthetic type; the C:N and lignin:N ratios of litter from C3 plants exposed to elevated [CO₂] are increased, leading to lower degradation rates, while the nutrient ratios and degradation rates of litter from C4 plants grown in elevated [CO₂] remain unchanged. To date, very few ecosystem studies of decomposition have been carried out. Further work is required at the ecosystem level to determine whether the effects observed in laboratory, pot and field studies are also observed in long-term, complex ecosystem studies. Clearly if these results are repeated at the ecosystem level then significant changes in the cycling of C and N in important terrestrial ecosystems may occur as a results of elevated [CO₂].

Ball, A.S., and B.G. Drake. 1997. Short-term decomposition of litter produced by plants grown in ambient and elevated atmospheric CO₂ concentrations. *Global Change Biology* 3(1):29-35.

The effects of elevated atmospheric CO₂ (ambient + 340 $\mu\text{mol mol}^{-1}$) on above-ground litter decomposition were investigated over a 6-week period using a field-based mesocosm system. Soil respiratory activity in mesocosms incubated in ambient and elevated atmospheric CO₂ concentrations were not significantly different (t-test, $P > 0.05$) indicating that there were no direct effects of elevated atmospheric CO₂ on litter decomposition. A study of the indirect effects of CO₂ on soil respiration showed that soil mesocosms to which naturally senescent plant litter had been added (0.5% w/w) from the C-3 sedge *Scirpus olneyi* grown in elevated atmospheric CO₂ was reduced by an average of 17% throughout the study when compared to soil mesocosms to which litter from *Scirpus olneyi* grown in ambient conditions had been added. In contrast, similar experiments using senescent material from the C-4 grass *Spartina patens* showed no difference in soil respiration rates between mesocosms to which litter from plants grown in elevated or ambient CO₂ conditions had been added. Analysis of the C:N ratio and lignin content of the senescent material showed that, while the C:N ratio and lignin content of the *Spartina patens* litter did not vary with atmospheric CO₂ conditions, the C:N ratio (but not the lignin content) of the litter from *Scirpus olneyi* was significantly greater (t-test; $P < 0.05$) when derived from plants grown under elevated CO₂ (105:1 compared to 86:1 for litter derived from *Scirpus olneyi* grown under ambient conditions). The results suggest that the increased C:N ratio of the litter from the C-3 plant *Scirpus olneyi* grown under elevated CO₂ led to the lower rates of biodegradation observed as reduced soil respiration in the mesocosms. Further longterm experiments are now required to determine the effects of elevated CO₂ on C partitioning in terrestrial ecosystems.

Ball, M.C., M.J. Cochrane, and H.M. Rawson. 1997. Growth and water use of the mangroves *Rhizophora apiculata* and *R. stylosa* in response to salinity and humidity under ambient and elevated concentrations of atmospheric CO₂. *Plant, Cell and Environment* 20(9):1158-1166.

Two mangrove species, *Rhizophora apiculata* and *R. stylosa*, were grown for 14 weeks in a multifactorial combination of salinity (125 and 350 mol m^{-3} NaCl), humidity (43 and 86% relative humidity at 30 degrees C) and atmospheric CO₂ concentration (340 and 700 $\text{cm}^3 \text{m}^{-3}$). Under ambient [CO₂], growth responses to different combinations of salinity and humidity were consistent with interspecific differences in distribution along natural gradients of salinity and aridity in northern Australia. Elevated [CO₂] had little effect on relative growth rate when it was limited by salinity but stimulated growth when limited by humidity. Both species benefited most from elevated [CO₂] under relatively low salinity conditions in which growth was vigorous, but relative growth rate was enhanced more in the less salt-tolerant and more rapidly growing species, *R. apiculata*. Changes in both net assimilation

rate and leaf area ratio contributed to changes in relative growth rates under elevated [CO₂], with leaf area ratio increasing with decrease in humidity. Increase in water use efficiency under elevated [CO₂] occurred with increase, decrease or no change in evaporation rates; water use characteristics which depended on both the species and the growth conditions. In summary, elevated [CO₂] is unlikely to increase salt tolerance, but could alter competitive rankings of species along salinity x aridity gradients.

Ball, M.C., and R. Munns. 1992. Plant-responses to salinity under elevated atmospheric concentrations of CO₂. *Australian Journal of Botany* 40(4-5):515-525.

This review explores effects of elevated CO₂ concentrations on growth in relation to water use and salt balance of halophytic and non-halophytic species. Under saline conditions, the uptake and distribution of sodium and chloride must be regulated to protect sensitive metabolic sites from salt toxicity. Salt-tolerant species exclude most of the salt from the transpiration stream, but the salt flux from a highly saline soil is still considerable. To maintain internal ion concentrations within physiologically acceptable levels, the salt influx to leaves must match the capacities of leaves for salt storage and/or salt export by either retranslocation or secretion from glands. Hence the balance between carbon gain and the expenditure of water in association with salt uptake is critical to leaf longevity under saline conditions. Indeed, one of the striking features of halophytic vegetation, such as mangroves, is the maintenance of high water use efficiencies coupled with relatively low rates of water loss and growth. These low evaporation rates are further reduced under elevated CO₂ conditions. This, with increased growth, leads to even higher water use efficiency. Leaves of plants grown under elevated CO₂ conditions might be expected to contain lower salt concentrations than those grown under ambient CO₂ if salt uptake is coupled with water uptake. However, salt concentrations in shoot tissues are similar in plants grown under ambient and elevated CO₂ conditions despite major differences in water use efficiency. This phenomenon occurs in C3 halophytes and in both C3 and C4 non-halophytes. These results imply shoot/root communication in regulation of the salt balance to adjust to environmental factors affecting the availability of water and ions at the roots (salinity) and those affecting carbon gain in relation to water loss at the leaves (atmospheric concentrations of water vapour and carbon dioxide).

Bandara, D.C., H. Nobuyasu, K.G. Ofosu-Budu, T. Ando, and K. Fujita. 1998. Effect of CO₂ enrichment on biomass production, photosynthesis, and sink activity in soybean cv. Bragg and its supernodulating mutant nts 1007. *Soil Science and Plant Nutrition* 44(2):179-186.

Soybean (*Glycine max* L. Merr.) cv. Bragg and its supernodulating mutant nts 1007 were grown in pots containing vermiculite with a N-free nutrient solution in order to examine the effect of elevated CO₂ concentration (100+20 Pa CO₂) on biomass production, photosynthesis, and biological nitrogen fixation. The whole plant weight increase in Bragg was higher than in the mutant at a high CO₂ concentration.

Apparent photosynthetic activities of the upper leaves in both Bragg and the mutant increased up to 14 d after treatment initiation by the CO₂ enrichment and thereafter decreased to some extent. Both leaf area and leaf thickness of Bragg increased more than in nts 1007. With the elevated CO₂ concentration, biological nitrogen fixation (BNF) also responded in the same manner as biomass production in both Bragg and nts 1007. The increase of BNF in Bragg was largely due to an increase in nodule weight. Starch contents in the leaves of both Bragg and the mutant increased significantly by CO₂ enrichment, with a higher increase in Bragg than in its mutant. Sugar content in leaf differed only slightly in both Bragg and the mutant. N content in leaf decreased in both Bragg and its mutant, with the decrease being more pronounced in Bragg. However, in other plant parts (roots, stem, and petiole + pods), N content increased in the mutant while in Bragg, it decreased in the pod. N accumulation rate was higher in Bragg than in the mutant and increased more in Bragg than in the mutant by CO₂ enrichment. The ureide content in leaf decreased in Bragg but increased in the mutant by elevated CO₂ concentration. In the nodules, ureide content increased in both Bragg and the mutant by CO₂ enrichment. Based on these results, it is suggested that in terms of biomass production and photosynthetic rate, Bragg responded more to elevated CO₂ concentration than its mutant nts 1007. The alleviation of the stunted vegetative growth of the mutant by CO₂ enrichment was limited despite the significant increase in the photosynthetic activity, presumably due to the limitation of sink activity in the growing parts and not to insufficient supply of N through BNF.

Barnes, J.D., J.H. Ollerenshaw, and C.P. Whitfield. 1995. Effects of elevated CO₂ and/or O₃ on growth, development and physiology of wheat (*Triticum aestivum* L.). *Global Change Biology* 1(2):129-142.

Two cultivars of spring wheat (*Triticum aestivum* L. cvs. Alexandria and Hanno) and three cultivars of winter wheat (cvs. Riband, Mercia and Haven) were grown at two concentrations of CO₂ [ambient (355 $\mu\text{mol mol}^{-1}$) and elevated (708 $\mu\text{mol mol}^{-1}$)] under two O₃ regimes [clean air (<5 nmol mol⁻¹) O₃ and polluted air (15 nmol mol⁻¹) O₃ at night rising to a midday maximum of 75 nmol mol⁻¹)] in a phytotron at the University of Newcastle-upon-Tyne. Between the two-leaf stage and anthesis, measurements of leaf gas-exchange, non-structural carbohydrate content, visible O₃ damage, growth, dry matter partitioning, yield components and root development were made in order to examine responses to elevated CO₂ and/or O₃. Growth at elevated CO₂ resulted in a sustained increase in the rate of CO₂ assimilation, but after roughly 6 weeks' exposure there was evidence of a slight decline in the photosynthetic rate (c.-15%) measured under growth conditions which was most pronounced in the winter cultivars. Enhanced rates of CO₂ assimilation were accompanied by a decrease in stomatal conductance which improved the instantaneous water use efficiency of individual leaves. CO₂ enrichment stimulated shoot and root growth to an equivalent extent, and increased tillering and yield components, however, non-structural carbohydrates still accumulated in source leaves. In contrast, long-term exposure to O₃ resulted in a decreased CO₂ assimilation rate (c.-13%), partial stomatal closure, and the accumulation of fructan and starch in leaves in the light. These effects were manifested in decreased rates of shoot and root growth, with root growth more severely affected than shoot growth. In the combined treatment growth of O₃-treated plants was enhanced by elevated CO₂, but there was little evidence that CO₂ enrichment afforded additional protection against O₃ damage. The reduction in growth induced by O₃ at elevated CO₂ was similar to that induced by O₃ at ambient CO₂ despite additive effects of the individual gases on stomatal conductance that would be expected to reduce the O₃ flux by 20%, and also CO₂-

induced increases in the provision of substrates for detoxification and repair processes. These observations suggest that CO₂ enrichment may render plants more susceptible to O₃ damage at the cellular level. Possible mechanisms are discussed.

Barnes, J.D., and T. Pfirrmann. 1992. The influence of CO₂ and O₃, singly and in combination, on gas-exchange, growth and nutrient status of radish (*Raphanus sativus* L.). *New Phytologist* 121(3):403-412.

Five days after emergence radish (*Raphanus sativus* L. cv. Cherry Belle) plants were transferred to a phytotron at the GSF Munchen, where they were exposed in four large controlled climate chambers to two atmospheric concentrations of CO₂ ('ambient', daily means of almost-equal-to 385- $\mu\text{mol mol}^{-1}$; elevated, daily means of almost-equal-to 765- $\mu\text{mol mol}^{-1}$) and two O₃ regimes ('non-polluted' air, 24 h mean of 20 nmol mol⁻¹; polluted air, 24 h mean of 73 nmol mol⁻¹) Leaf gas-exchange measurements were made at intervals, and visible O₃ damage, effects on growth, dry matter partitioning and mineral composition were assessed at a final whole-plant harvest after 27 d. In 'non-polluted air' CO₂ enrichment resulted in a progressive stimulation in A(sat), whilst there was a decline in g(s) which decreased E (i.e. improved WUE(i)). The extra carbon fixed in elevated CO₂ stimulated growth of the root (+ hypocotyl) by 43 %, but there was no significant effect on shoot growth or leaf area. Moreover, a decline in SLA and LAR in CO₂-enriched plants suggested that less dry matter was invested in leaf area expansion. Tissue concentrations of N, S, P, Mg and Ca were lower (particularly in the root + hypocotyl) in elevated CO₂, indicating that total uptake of these nutrients was not affected by CO₂, and there was an increase in the C:N ratio in root (+ hypocotyl) tissue. In contrast, O₃ depressed A(sat), (almost-equal-to 26 %) and induced slight stomatal closure, with the result that WUE(i) declined. All plants exposed to 'polluted' air developed typical visible symptoms of O₃ injury, and effects on carbon assimilation were reflected in reduced growth, with shoot growth maintained at the expense of the root. In addition, O₃ increased the P and K concentration in shoot and root (+hypocotyl) tissue, indicating enhanced uptake of these nutrients from the growth medium. However, there was no effect of O₃ on tissue concentrations of N, S, Mg and Ca. Interactions between the gases were complex, and often subtle. In general, elevated CO₂ counteracted (at least in part) the detrimental effects of phytotoxic concentrations of O₃, whilst conversely, O₃ reduced the impact of elevated CO₂. Moreover, there were indications that cumulative changes in source:sink relations in O₃-exposed plants may limit plant response to CO₂-enrichment to an even greater extent in the long-term. The future ecological significance of interactions between CO₂ and O₃ are discussed.

Barnes, J.D., T. Pfirrmann, K. Steiner, C. Lutz, U. Busch, H. Kuchenhoff, and H.D. Payer. 1995. Effects of elevated CO₂, elevated O₃ and potassium deficiency on Norway spruce [*Picea abies* (L.) Karst]: Seasonal changes in photosynthesis and non-structural carbohydrate content. *Plant, Cell and Environment* 18(12):1345-1357.

Two clones of 5-year-old Norway spruce [*Picea abies* (L.) Karst.] were exposed to two atmospheric concentrations of CO₂ (350 and 750 $\mu\text{mol mol}^{-1}$) and O₃ (20 and 75 nmol mol⁻¹) in a phytotron at the

GSF-Forschungszentrum (Munich) over the course of a single season (April to October). The phytotron was programmed to recreate an artificial climate similar to that at a high elevation site in the Inner Bavarian Forest, and trees were grown in Large containers of forest soil fertilized to achieve contrasting levels of potassium nutrition, designated well-fertilized or K-deficient. Measurements of the rate of net CO₂ assimilation were made on individual needle year age classes over the course of the season, chlorophyll fluorescence kinetics were recorded after approximately 23 weeks, and seasonal changes in non-structural carbohydrate composition of the current year's foliage were monitored. Ozone was found to have contrasting effects on the rate of net CO₂ assimilation in different needle age classes. After c. 5 months of fumigation, elevated O-3 increased (by 33%) the rate of photosynthesis in the current year's needles. However, O-3 depressed (by 30%) the photosynthetic rate of the previous year's needles throughout the period of exposure. Chlorophyll fluorescence measurements indicated that changes in photosystem II electron transport played no significant role in the effects of O-3 on photosynthesis. The reasons for the contrasting effects of O-3 on needles of different ages are discussed in the light of other recent findings. Although O-3 enhanced the rate at which CO₂ was fixed in the current year's foliage, this was not reflected in increases in the non-structural carbohydrate content of the needles. The transfer of ambient CO₂-grown trees to a CO₂-enriched atmosphere resulted in marked stimulation in the photosynthetic rate of current and previous year's foliage. However, following expansion of the current year's growth, the photosynthetic rate of the previous year's foliage declined. The extent of photosynthetic adjustment in response to prolonged exposure to elevated CO₂ depended upon the clone, providing evidence of intraspecific variation in the long-term response of photosynthesis to elevated CO₂. The increase in photosynthesis induced by CO₂ enrichment was associated with increased foliar concentrations of glucose, fructose and starch (but no change in sucrose) in the new growth. CO₂ enrichment significantly enhanced the photosynthetic rate of K-deficient needles, but there was a strong CO₂*soil interaction in the current year's needles, indicating that the long-term response of trees to a high CO₂ environment may depend on soil fertility. Although the rate of photosynthesis and non-structural carbohydrate content of the new needles were increased in O-3-treated plants grown at higher levels of CO₂, there was no evidence that elevated CO₂ provided additional protection against O-3 damage. Simultaneous exposure to elevated O-3 modified the effects of elevated CO₂ on needle photosynthesis and non-structural carbohydrate content, emphasizing the need to take into account not only soil nutrient status but also the impact of concurrent increases in photochemical oxidant pollution in any serious consideration of the effects of climate change on plant production.

Barrett, D.J., and R.M. Gifford. 1995. Acclimation of photosynthesis and growth by cotton to elevated CO₂: Interactions with severe phosphate deficiency and restricted rooting volume. *Australian Journal of Plant Physiology* 22(6):955-963.

Acclimation of photosynthesis and growth at three CO₂ concentrations (376, 652 and 935 $\mu\text{mol mol}^{-1}$) was examined in cotton grown under three growth-limiting phosphate (P) supplies (2.1, 6.1 and 18.2

mg P plant⁻¹) and where biomass allocation between roots and shoots was altered by pots of three different sizes (0.32 X 10⁻³, 0.72 X 10⁻³ and 1.56 X 10⁻³ m³ pot⁻¹). Phosphate supplies were chosen such that carbon gain at ambient CO₂ increased linearly with P supply. Relative growth rates of these plants were 5-10-times less and photosynthetic rates 3-16-times less than for cotton supplied with abundant nutrients. Pot sizes were chosen so that root biomass and root:shoot ratios decreased with a decrease in rooting volume. Maximum carboxylation rates per unit leaf area (V-cmax) were lower in leaves grown at two elevated CO₂ concentrations, compared with ambient CO₂ concentrations, under all P and pot size treatments indicating that acclimation of photosynthesis had occurred. The degree of photosynthetic acclimation to elevated CO₂ was not related to the degree by which whole plant carbon gain was stimulated by elevated CO₂ concentration at the different P supplies, or to the degree by which allocation to root and shoots was altered by pot size. Thus there is no simple relationship between photosynthetic and growth acclimation by cotton to elevated CO₂. At ambient CO₂, the maximum carboxylation rate increased linearly with an increase in leaf P per unit area (mg P m⁻²), but rates were lower at elevated CO₂ for a given P content m⁻². V-cmax also increased linearly with an increase in leaf P concentration (mg P g⁻¹ structural dry weight). However, values of V-cmax were similar for plants grown at ambient and elevated CO₂, for a given P concentration. Acclimation of photosynthesis at elevated CO₂ was associated with an increase in leaf starch determined 5 h into the light period. However, increased starch concentration with an increase in P supply was not associated with any decline in V-cmax.

Barrett, D.J., and R.M. Gifford. 1995. Photosynthetic acclimation to elevated CO₂ in relation to biomass allocation in cotton. *Journal of Biogeography* 22(2-3):331-339.

Biomass allocation to leaf tissues and photosynthetic acclimation to CO₂ by cotton were investigated in two experiments. Plants were grown at ambient and elevated CO₂ concentrations with growth restricting phosphorus supplies in both experiments and in root restricting pot volumes in the first experiment. In both experiments, elevated CO₂ concentrations decreased the maximum carboxylation rate (V-cmax) and the CO₂ saturated rate of photosynthesis indicative of photosynthetic acclimation to elevated CO₂ concentrations. In the first experiment, the percentage reduction in V-cmax under elevated CO₂ concentration was least at a P supply of 2.1 mg P plant⁻¹, greatest at 6.1 mg P plant⁻¹, but then decreased at 18.2 mg P plant⁻¹. The greater acclimation at the middle P supply was associated with a higher ratio of leaf mass to plant mass (LMR) than in other treatments and the lesser acclimation at the highest P treatment coincided with a lower LMR. In the second experiment the reduction in V-cmax at elevated CO₂ was less than in the first experiment but was also associated with a greater allocation of dry matter to leaf tissues during growth. In both experiments, V-cmax was not correlated to the relative degree of biomass enhancement at elevated CO₂ nor with the degree of root growth restriction in small pots. These data support the hypothesis that acclimation of photosynthesis to elevated CO₂ concentrations is mediated by shifts in allocation between leaves and the rest of the plant, induced by environmental conditions during growth, such that carbohydrate supply remains in balance with the utilization capacity of sink tissues.

Barrett, D.J., and R.M. Gifford. 1999. Increased C-gain by an endemic Australian pasture grass at elevated atmospheric CO₂ concentration when supplied with non-labile inorganic phosphorus. *Australian Journal of Plant Physiology* 26(5):443-451.

Limited phosphorus (P) availability in Australia's highly weathered soils may constrain an increase in terrestrial net primary productivity (NPP) with the globally increasing atmospheric CO₂ concentration. We examined whether an Australian temperate pasture grass (*Danthonia richardsonii*) grown in sand culture and supplied solely with virtually insoluble Al- and Fe-phosphate was able to increase C-gain when exposed to elevated (731 $\mu\text{mol mol}^{-1}$) compared with ambient (379 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. When supplied with 8 mg kg⁻¹ insoluble P concentration, total citrate efflux by root systems ($\mu\text{mol h}^{-1}$), plant P uptake, shoot photosynthesis rates and plant mass were all significantly greater at elevated than at ambient CO₂ after a growth period of between 55 and 63 days. In this treatment, although the P concentration of the rooting medium limited growth at ambient CO₂, elevated CO₂ increased P-uptake from the non-labile source, increased photosynthesis rates per unit shoot soluble-P and increased plant mass. At P concentrations lower than 8 mg kg⁻¹, plant mass, specific citrate efflux and maximum leaf carboxylation rates were limited by the amount of P available in the rooting medium and no CO₂ effect was observed. In all treatments, carbon supply did not appear to limit citrate efflux. Where an increase in P uptake at elevated CO₂ was achieved, it was due to an increase in root mass (indicative of a potentially larger soil volume explored) rather than to increased specific rates of citrate efflux. Above 8 mg kg⁻¹, the supplied P concentration was sufficient that minimal rates of specific citrate efflux alone solubilised enough P for growth and a strong CO₂ effect on plant mass, photosynthesis and P uptake was observed.

Barrett, D.J., A.E. Richardson, and R.M. Gifford. 1998. Elevated atmospheric CO₂ concentrations increase wheat root phosphatase activity when growth is limited by phosphorus. *Australian Journal of Plant Physiology* 25(1):87-93.

Wheat seedlings were grown in solution culture under adequate and limited phosphorus treatments at current ambient and elevated (approximately 2X ambient) CO₂ concentrations. Acid phosphomonoesterase ('phosphatase') activity of root segments was measured using p-nitrophenyl phosphate as substrate. When plant growth was P-limited, elevated CO₂ concentrations increased phosphatase activity more than at ambient CO₂. This result (1) was evident when expressed on a unit root dry weight or root length basis, indicating that increased root enzyme activity was unlikely to be associated with CO₂-induced changes in root morphology; (2) occurred when plants were grown aseptically, indicating that the increase in phosphatase activity originated from root cells rather than root-associated microorganisms; (3) was associated with shoot P concentrations below 0.18%; (4) occurred only when wheat roots were grown under P deficiency but not when a transient P deficiency was imposed; and (5) suggest that a previously reported increase in phosphatase activity at elevated CO₂ by an Australian native pasture grass (Gifford, Lutze and Barrett 1996; Plant and Soil 187, 369-387) was also a root mediated response. The observed increase in phosphatase activity by plant roots at elevated CO₂, if confirmed for a wide range of field pasture and crop species, is one factor which may increase mineralisation of soil organic P as the anthropogenic increase of atmospheric CO₂ concentrations continues. But, whether a concomitant increase in plant uptake of P occurs will depend on the relative influence

of root and microbial phosphatases, and soil geochemistry in determining the rate of mineralisation of soil organic P for any given soil.

Bartak, M., I. Nijs, and I. Impens. 1996. The effect of long-term exposure of *Lolium perenne* L plants to elevated CO₂ and/or elevated air temperature on quantum yield of photosystem 2 and net photosynthesis. *Photosynthetica* 32(4):549-562.

The effects of long-term exposure of *Lolium perenne* L. plants to CO₂ concentration elevated to 700 $\mu\text{mol (CO}_2\text{) mol}^{-1}$ (EC) and air temperature elevated by 4 degrees C (ET) on the quantum yield of electron transport of photosystem 2, PS2 ($\phi(2)$) and on the potential yield of photochemical reactions of PS2 (F-v/F-m) measured by the chlorophyll (Chl) fluorescence method, were studied. The plants were exposed for 6 months in opened field greenhouses to four treatments simulating global atmospheric changes: (1) ambient CO₂ (AC) and ambient air temperature, AT (ACAT - control), (2) EC and AT (ECAT), (3) AC and ET (ACET), and (4) EC and ET (ECET). When the plants were exposed to stepwise increased irradiance, a decrease in $\phi(2)$ was found under both AC and EC measuring concentrations. At high irradiances a significantly higher yield of PS2 was detected when measured under EC compared to AC regardless of long-term CO₂ and temperature treatment (i.e., positive short-term effect of EC). The short-term effect of EC on $\phi(2)$ as related to net photosynthetic rate (P-N) Shift was detected from irradiance response curves. At high irradiances and AC, $\phi(2)$ was reduced in comparison to control for the plants of EC and ET treatments (i.e., negative long-term effect of treatment). The long-term effect of both EC and ET on the yield of PS2 was attributed to a down-regulation of P-N caused by the treatment. The $\phi(2)$ was related to the actual rate of photosynthesis and the relationship between $\phi(2)$ and $\phi(\text{CO}_2)$ was linear over a wide range of irradiances. No effect of long-term treatments on the dark-adapted F-v/F-m ratio was found in plants cultivated under natural greenhouse irradiance.

Bartak, M., I. Nijs, and I. Impens. 1998. The susceptibility of PS II of *Lolium perenne* to a sudden fall in air temperature - response of plants grown in elevated CO₂ and/or increased air temperature. *Environmental and Experimental Botany* 39(1):85-95.

The effect of a sudden fall in air temperature from 20 to 5 degrees C on fast kinetics of chlorophyll fluorescence, maximum yield of the photosystem II photochemical reactions (Fv/Fm), quantum yield of the photosystem II electron transport ($\Phi(\text{II})$) coefficients of photochemical (qP), non-photochemical quenching (qN) was studied in *Lolium perenne* using a modulated chlorophyll fluorescence technique. Before fluorescence measurement, the plants were cultivated in the treatments simulating the likely future climate characterized with elevated air temperature and CO₂ concentration and combination of both. On fast kinetics curves the risetimes of the I and D points characterizing the redox state of Q(A) were affected by lowering the air temperature. At 5 degrees C both the I and D points were reached later than at 20 degrees C. Also the I to D risetime was prolonged at 5 degrees C and it was found significantly longer in plants cultivated in ambient + 4 degrees C temperature. While a significant difference was found in the area over the rising part of the fluorescence curve between 20 and 5 degrees C, no

difference was found in area over the relaxation curve part. Lowering of air temperature to 5 degrees C had no effect on Fv/Fm values in control plants and in the plants cultivated in elevated CO₂ but brought significant decrease in plants cultivated in the ambient + 4 degrees C air temperature. Both Phi(II) and qP decreased with the temperature lowered to 5 degrees C while the values of qN increased. The changes in fluorescence parameters indicated altered functioning of PS II at low temperature. The changes in parameters are discussed as a consequence of decreased enzymatic activity, decreased turnover of plastoquinone pool and photoinhibition. (C) 1998 Elsevier Science B.V. Barton, C.V.M., and P.G. Jarvis. 1999. Growth response of branches of *Picea sitchensis* to four years exposure to elevated atmospheric carbon dioxide concentration. *New Phytologist* 144(2):233-243.

Branch bags were used to expose branches on mature Sitka spruce trees to either ambient [CO₂] (A) or elevated [CO₂] (E) for 4 yr. This paper reports the effects of this treatment on the growth, development and phenology of the branches, including shoot expansion, shoot numbers, needle dimensions, needle numbers and stomatal density. The effect of elevated [CO₂] on the relationship between leaf area and sapwood area was investigated. Exposure to elevated [CO₂] doubled photosynthetic rates in current-year shoots and, despite some downregulation, 1-yr-old E shoots also had higher rates of photosynthesis than their A counterparts. Thus, the amount of assimilate fixed by E branches was substantially more than that fixed by A branches; however, this increase in the local production of assimilate did not lead to an increase in non-structural carbohydrate or stimulate growth or meristematic activity within the E branches. There was a very consistent relationship between leaf area and stem cross-sectional area that was not influenced by [CO₂]. However, unbagged branches had thicker stems than bagged branches, resulting in a slightly lower ratio of leaf area to cross-sectional area. The implications of the results for the modelling of growth and allocation and the potential utility of the branch bag technique are discussed.

Barton, C.V.M., H.S.J. Lee, and P.G. Jarvis. 1993. A branch bag and CO₂ control-system for long-term CO₂ enrichment of mature sitka spruce [*Picea-sitchensis* (bong) carr]. *Plant, Cell and Environment* 16(9):1139-1148.

This paper describes the construction and performance of branch bags and a CO₂ control system used to fumigate branches of mature Sitka spruce trees with air enriched in CO₂ (700 µmol mol⁻¹). It contains some examples of results obtained using the system over the course of the first two growing seasons. The branch bags have run continuously for 2 years with very few problems. CO₂ concentrations were within 20 µmol mol⁻¹ of the target concentration for more than 90% of the time. Temperatures within the bags were slightly higher than ambient (1-2 degrees C) and this had some effect on phenology. Attenuation of quantum flux density (photosynthetically active radiation) was 10-15%. The branch bag system has enabled investigation into the effects of elevated CO₂ on mature tissue without the problems and expense of fumigating whole trees. Growth in elevated CO₂ resulted in an increase in starch and a decrease in soluble protein content of needles. Stomatal

conductance was higher in elevated CO₂ grown needles, and there was some evidence of an increase in photosynthetic capacity.

Basile, G., M. Arienzo, and A. Zena. 1993. Soil nutrient mobility in response to irrigation with carbon- dioxide enriched water. *Communications in Soil Science and Plant Analysis* 24(11-12):1183-1195.

In our experiments, carbonated water (CW) modified the equilibria in soil. Application of CW decreased the soil pH about 1.5 units one hour after irrigation ended. Minimal, though well defined, differences in soil pH were observed between the two carbonated treatments. The same relationship between the treatments was not found in pH levels of the leachate. This seems strictly related to the temporal and spatial changes in the carbon dioxide (CO₂) acidifying effect caused by chemical and biological factors as water descended the soil column. The temporary reduction in soil pH in the CW treatment induced the highest nutrient mobility for most of the elements.

BassiriRad, H., K.L. Griffin, J.F. Reynolds, and B.R. Strain. 1997. Changes in root NH₄⁺ and NO₃⁻ absorption rates of loblolly and ponderosa pine in response to CO₂ enrichment. *Plant and Soil* 190(1):1-9.

Root growth and physiological uptake capacity for NH₄⁺ and NO₃⁻ were examined for seedlings of loblolly and ponderosa pine grown for 160 days under two CO₂ levels, ambient (35 Pa) and ambient plus 35 Pa (70 Pa). Fraction of biomass allocated to active fine roots as well as total N (NH₄⁺ + NO₃⁻) absorption per unit root dry mass were unaffected by CO₂. On a whole-plant basis, elevated CO₂ led to a significant increase in N acquisition in loblolly but not in ponderosa pine. However, even in loblolly pine where CO₂ significantly increased plant N acquisition, the relative increase, in biomass far exceeded the gain in N, i.e. a 60% increase in total dry weight was accompanied by only a 30% increase in N gain in response to high CO₂. We suggest that the commonly reported decline in tissue N concentration of these and other species at high CO₂ is largely caused by inability of the root systems to sufficiently compensate for increased N demand. Elevated CO₂ significantly altered root uptake capacity of the different N forms, i.e., high CO₂ significantly increased NO₃⁻ absorption rates, but decreased NH₄⁺ absorption rates in both species though the decrease in loblolly was insignificant. However, elevated CO₂ increased root respiration rate in loblolly pine while significantly decreasing it in ponderosa pine. This indicates that CO₂-induced changes in plant preference for inorganic N forms is not simply regulated by root energy status. If changes in plant preference for inorganic N forms represent typical responses to elevated CO₂, the results could have important implications for N dynamics in managed and natural plant communities.

BassiriRad, H., K.L. Griffin, B.R. Strain, and J.F. Reynolds. 1996. Effects of CO₂ enrichment on growth and root (NH₄⁺)-N-15 uptake rate of loblolly pine and ponderosa pine seedlings. *Tree Physiology* 16(11-12):957-962.

We examined changes in root growth and (NH₄⁺)-N-15 uptake capacity of loblolly pine (*Pinus taeda* L.) and ponderosa pine (*Pinus ponderosa* Douglas. Ex Laws.) seedlings that were grown in pots in a phytotron at CO₂ partial pressures of 35 or 70 Pa with NH₄⁺ as the sole N source. Kinetics of N-15-labeled NH₄⁺ uptake were determined in excised roots, whereas total NH₄⁺ uptake and uptake rates were determined in intact root systems following a 48-h labeling of intact seedlings with N-15. In both species, the elevated CO₂ treatment caused a significant downregulation of (NH₄⁺)-N-15 uptake capacity in excised roots as a result of a severe inhibition of the maximum rate of root (NH₄⁺)-N-15 uptake (V-max). Rates of (NH₄⁺)-N-15 uptake in intact roots were, however, unaffected by CO₂ treatment and were on average 4- to 10-fold less than the V-max in excised roots, suggesting that (NH₄⁺)-N-15 absorption from the soil was not limited by the kinetics of root (NH₄⁺)-N-15 uptake. Despite the lack of a CO₂ effect on intact root absorption rates, (NH₄⁺)-N-15 uptake on a per plant basis was enhanced at high CO₂ concentrations in both species, with the relative increase being markedly higher in ponderosa pine than in loblolly pine. High CO₂ concentration increased total (NH₄⁺)-N-15 uptake and the fraction of total biomass allocated to fine roots (< 2 mm in diameter) to a similar relative extent. We suggest that the increased uptake on a per plant basis in response to CO₂ enrichment is largely the result of a compensatory increase in root absorbing surfaces.

Bassirirad, H., J.F. Reynolds, R.A. Virginia, and M.H. Brunelle. 1997. Growth and root NO₃⁻ and PO₄₃⁻ uptake capacity of three desert species in response to atmospheric CO₂ enrichment. *Australian Journal of Plant Physiology* 24(3):353-358.

In a phytotron experiment, we examined growth and rates of NO₃⁻ and PO₄₃⁻ uptake in seedlings of two desert C-3 shrubs (*Larrea tridentata* and *Prosopis glandulosa*) and a desert C-4 perennial grass (*Bouteloua eriopoda*) grown under CO₂ partial pressures of 35 or 70 Pa. Plants were grown in soil but uptake studies were conducted on roots of intact seedlings placed in nutrient solutions containing both NO₃⁻ and PO₄₃⁻. Elevated CO₂ increased total biomass by 69 and 55% in *Larrea* and *Prosopis* seedlings and by 25% in *Bouteloua*. NO₃⁻ and PO₄₃⁻ uptake rates were more than doubled in *Bouteloua* at high compared to ambient CO₂. In contrast, CO₂ enrichment inhibited root NO₃⁻ uptake capacity in *Larrea* by about 55% without a significant effect on PO₄₃⁻ absorption rate; rates of NO₃⁻ and PO₄₃⁻ and uptake in *Prosopis* were insensitive to CO₂ treatment. Elevated CO₂ enhanced the proportion of biomass allocated to the fine roots in *Bouteloua* but markedly reduced this fraction in *Larrea* and *Prosopis*. Foliar N concentration of both shrubs decreased in response to elevated CO₂, but was unaffected in *Bouteloua*. We suggest that compensatory changes in root size and activity are critical in determining interspecies variation in plant nutrient relations under high CO₂.

Bassirirad, H., R.B. Thomas, J.F. Reynolds, and B.R. Strain. 1996. Differential responses of root uptake kinetics of NH₄⁺ and NO₃⁻ to enriched atmospheric CO₂ concentration in field-grown loblolly pine. *Plant, Cell and Environment* 19(3):367-371.

The nitrogen requirement of plants is predominantly supplied by NH₄⁺ and/or NO₃⁻ from the soil solution, but the energetic cost of uptake and

assimilation is generally higher for NO₃⁻ than for NH₄⁺. We found that CO₂ enrichment of the atmosphere enhanced the root uptake capacity for NO₃⁻, but not for NH₄⁺, in field-grown loblolly pine saplings. Increased preference for NO₃⁻ at the elevated CO₂ concentration was accompanied by increased carbohydrate levels in roots. The results have important implications for the potential consequences of global climate change on plant- and ecosystem-level processes in many temperate forest ecosystems.

Bassirirad, H., D.T. Tissue, J.F. Reynolds, and F.S. Chapin. 1996. Response of *Eriophorum vaginatum* to CO₂ enrichment at different soil temperatures: Effects on growth, root respiration and PO₄₃⁻ uptake kinetics. *New Phytologist* 133(3):423-430.

In a phytotron experiment, we examined responses of a tussock sedge, *Eriophorum vaginatum* L., to changes in atmospheric CO₂ concentration and soil temperature. We were particularly interested in phosphorus (P) acquisition and below ground plant characteristics that regulated its uptake in response to CO₂ enrichment. Plants were grown at two CO₂ partial pressures, 35 and 70 Pa, three soil temperature regimes, 5, 15 and 25 degrees C and a constant ambient air temperature of 15 degrees C. Elevated CO₂ increased total plant biomass production, but decreased tissue P concentration. Although high CO₂ enhanced root carbohydrate concentration, it inhibited root respiration with no significant effect on root PO₄₃⁻ absorption capacity or root:shoot ratio. Surprisingly, there were no significant interactions between CO₂ and soil temperature. The inability of *Eriophorum* to exhibit root-level compensatory adjustments, e.g. increased root:shoot ratio or PO₄₃⁻ absorption capacity, was largely responsible for the observed decline in tissue P concentration under elevated CO₂ conditions. This could ultimately limit long-term growth responses of *Eriophorum* to CO₂ enrichment in the field where P availability is limiting. We found that uptake of PO₄₃⁻ in response to elevated CO₂ was independent of changes in root respiration, but changes in root respiration could have important implications for ecosystem carbon budget under elevated CO₂ levels. Our data indicated that although root respiration on a per unit biomass basis declined in response to CO₂ enrichment, this effect was counterbalanced by increased root biomass, so that high CO₂ stimulated root respiration on a whole-plant basis by 30%. This might help to explain why long-term exposure to high CO₂ increases CO₂ efflux from *Eriophorum*-dominated ecosystems.

Bassman, J.H., and J.C. Zwier. 1991. Gas-exchange characteristics of *Populus trichocarpa*, *Populus deltoides* and *Populus trichocarpa* X *Populus deltoides* clones. *Tree Physiology* 8(2):145-159.

Responses of net photosynthesis, dark respiration, photorespiration, transpiration, and stomatal conductance to irradiance, temperature, leaf-to-air vapor density difference (VDD), and plant water stress were examined in two *Populus trichocarpa* clones (one from a moist, coastal climate in western Washington and one from a dry, continental climate in eastern Washington), one *P. deltoides* clone, and two *P. trichocarpa* x *P. deltoides* clones. Light saturation of photosynthesis in greenhouse-grown trees occurred at about 800-μmol m⁻² s⁻¹ for *P. deltoides*, *P. trichocarpa* x *P. deltoides*, and the eastern Washington ecotype of *P. trichocarpa*, but at about 600-μmol m⁻² s⁻¹ for the western

Washington ecotype of *P. trichocarpa*. Average net photosynthesis (at saturating irradiance and the optimum temperature of 25-degrees-C) was 20.7, 18.8, 18.2 and 13.4- $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ for *P. deltoides*, *P. trichocarpa* x *P. deltoides*, and the eastern and western Washington clones of *P. trichocarpa*, respectively. In all clones, net photosynthesis decreased about 14% as VDD increased from 3 to 18 g $\text{H}_2\text{O m}^{-3}$. Stomatal conductance decreased sharply with decreasing xylem pressure potential (XPP) in all clones except the western Washington clone of *P. trichocarpa*. Stomata in this clone were insensitive to changes in XPP and did not control water loss. Complete stomatal closure (stomatal conductance $< 0.05 \text{ cm s}^{-1}$) occurred at about -2.0 MPa in the eastern Washington clone of *P. trichocarpa* and around -1.25 MPa in the *P. deltoides* and *P. trichocarpa* x *P. deltoides* clones. Transpiration rates were highest in the *P. trichocarpa* x *P. deltoides* clone and lowest in the western Washington clone of *P. trichocarpa*. The *P. deltoides* clone and eastern Washington clone of *P. trichocarpa* had the highest water use efficiency (WUE) and the western Washington clone of *P. trichocarpa* had the lowest WUE. The hybrids were intermediate. It was concluded that: (1) gas exchange characteristics of eastern and western Washington clones of *P. trichocarpa* reflected adaptation to their native environment; (2) crossing the western Washington clone of *P. trichocarpa* with the more drought resistant *P. deltoides* clone produced plants better adapted to the interior Pacific Northwest climate, although the stomatal response to soil water deficits in the hybrid was conservative compared with that of the eastern Washington clone of *P. trichocarpa*; and (3) introducing eastern Washington clones of black cottonwood into breeding programs is likely to yield lines with favorable growth characteristics combined with enhanced WUE and adaptation to soil water deficits.

Bassow, S.L., K.D.M. McConnaughay, and F.A. Bazzaz. 1994. The response of temperate tree seedlings grown in elevated CO_2 to extreme temperature events. *Ecological Applications* 4(3):593-603.

Mean global temperatures have been predicted to increase in the next century, if so the frequency of extreme temperature events may also increase. Extreme temperatures may damage plant tissue and consequently limit the survival of certain plant species in a region. Elevated concentrations of CO_2 in the atmosphere alter plant allocation, physiology, and growth, and may accentuate or ameliorate the damage from extreme temperatures. In this paper we explore the interactive effects of atmospheric CO_2 concentration, nutrient levels, and exposure to extreme temperatures on seedlings of three species of temperate deciduous trees. A1-d exposure to extreme heat (45-degrees-C) significantly decreased conductance the following day and decreased biomass as measured at both 35 and 105 d following the extreme temperature event, regardless of atmospheric CO_2 concentration. The most shade-tolerant species, striped maple, was most severely impacted by the extreme heat event in both CO_2 environments. Furthermore, striped maple seedlings grown in elevated CO_2 concentrations had a significantly greater decrease in biomass due to the extreme heat event as compared with striped maple plants grown in ambient CO_2 concentrations at 35 d after the heat event; however, at the end of the growing season at 105 d post treatment, this difference was not significant. A one-night exposure to low temperatures (4- degrees-C) did not affect biomass for any of these species. With an increase in global mean temperatures, the frequency of extreme temperature events, particularly hot weather events, may increase and may extend to shaded understory sites. If the frequency of extremely high temperatures increases, the role that temperature extremes may play in changing competitive interactions and thus affecting community composition may increase in importance, as these temperatures appear to severely alter plant survival and growth in some species.

Batjes, N.H. 1998. Mitigation of atmospheric CO_2 concentrations by increased carbon sequestration in the soil. *Biology and Fertility of Soils* 27(3):230-235.

The International Panel on Climate Change distinguished three main options for the mitigation of atmospheric CO_2 concentrations by the agricultural sector: (1) reduction of agriculture-related emissions, (2) creation and strengthening of C sinks in the soil, and (3) production of biofuels to replace fossil fuels. Options for sustained sequestration of C in the soil through adapted management of land resources are reviewed in the context of the ongoing discussion on the need to reduce greenhouse gas concentrations in the atmosphere. Enhanced sequestration of atmospheric CO_2 in the soil, ultimately as stable humus, may well prove a more lasting solution than (temporarily) sequestering CO_2 in the standing biomass through reforestation and afforestation. Such actions will also help to reverse processes of land degradation, thus contributing to sustained food productivity and security for the people in the regions concerned.

Battaglia, M., and P.J. Sands. 1998. Process-based forest productivity models and their application in forest management. *Forest Ecology and Management* 102(1):13-32.

Few process-based forest productivity models have become incorporated into forest management systems. The prevalent perception is that process-based models are suited only for research applications and that management questions will be solved only by using descriptive empirical models. This is despite the fact that the latter can neither deal satisfactorily with changing environmental and management conditions nor answer all questions currently asked by managers. This paper develops the proposition that the end-use specifies the design and scale of forest simulation models, and that given the range of questions now asked in forest management a range of models is required. The spatial and temporal resolution, and the input and output data required to address typical forest management questions is examined. A survey of recent literature examines in which areas, and by whom, existing forest productivity models are being applied. It is concluded that many current management questions can be adequately answered using models in which a phenomenological approach is applied to predict annual forest growth at the stand-scale. Lumped-parameter process-based models and hybrid models provide the most immediate means through which our understanding of the biological processes underlying forest growth can be included in forest management systems. However, more detailed process-based models can play an important role in validating simpler models, in the development of generalizations applicable over long time scales and for testing hypotheses about the way trees function and respond to interacting stresses. Guidelines are also given on model structures appropriate for different classes of management questions. (C) 1998 Elsevier Science B.V.

Batts, G.R., R.H. Ellis, J.I.L. Morison, and P. Hadley. 1998. Canopy development and tillering of field-grown crops of two contrasting cultivars of winter wheat (*Triticum aestivum*) in response to CO₂ and temperature. *Annals of Applied Biology* 133(1):101-109.

Elevated CO₂ (691 cf. 371 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$) and warmer temperatures (over the range 1.0 degrees C below to 1.6 degrees C above ambient) increased light interception by crops of two contrasting cultivars (Hereward and Soissons) of winter wheat (*Triticum aestivum* L.) during winter growth in the field. The fractional interception of light by the canopy increased more rapidly initially in Soissons than in Hereward, but Hereward showed a much greater response to CO₂ (35% increase in Hereward but only 7% in Soissons) at 500 degrees Cd after sowing. By terminal spikelet formation, in contrast, fractional interception was greater in Hereward than in Soissons, while the effect of CO₂ was the same in both cultivars (9%). Thus, although differences in the relative response of canopy development to CO₂ were detected between cultivars initially, differences were negligible during later development. The greater interception of light by the canopy in elevated CO₂, at any one temperature, resulted from increased tillering. The number of tillers plant⁻¹ at terminal spikelet was a linear function of main stem dry mass at this developmental stage but with a greater response in elevated CO₂, viz 2.3 and 3.8 tillers g⁻¹ main stem dry mass at 371 and 691 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$, respectively; these relations were unaffected by cultivar.

Batts, G.R., R.H. Ellis, J.I.L. Morison, P.N. Nkemka, P.J. Gregory, and P. Hadley. 1998. Yield and partitioning in crops of contrasting cultivars of winter wheat in response to CO₂ and temperature in field studies using temperature gradient tunnels. *Journal of Agricultural Science* 130:17-27.

Diverse cultivars of winter wheat (*Triticum aestivum* L.) were grown in the field in 1993/94 and 1994/95 at Reading UK in temperature gradient tunnels at normal atmospheric (c. 370) or elevated CO₂ concentration (c. 700 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$). In 1993/94, grain yield of cv. Avalon was insensitive to mean temperature (between 8.8 and 10.9 degrees C), while elevated CO₂ increased yield by 1.3 t ha⁻¹ (12.6%). In all other cultivars, warming reduced grain yield and CO₂ increased grain yield. In 1993/94, in cvs Galahad and Mercia the effects of CO₂ and temperature on yield were additive. However, for cv. Hereward in both years and for cv. Soissons in 1994/95, there were negative interactions between the effects of CO₂ and temperature on yield: the maximum benefit of doubling CO₂ to grain yield, 4.5 and 2.7 t ha⁻¹ (65 and 29%) respectively, occurred at cooler temperatures; there was no benefit from doubling CO₂ (i.e. 0%) once the temperature had increased above the seasonal mean by 2.2-2.6 degrees C in cv. Hereward and by 1.3 degrees C in cv. Soissons. The beneficial effect of doubling CO₂ on grain yield in cvs Galahad, Hereward, Mercia and Soissons was negated by an increase in mean seasonal temperature of only 0.7-2.0 degrees C. Warming decreased root dry mass at anthesis in 1994/95 while it increased at elevated CO₂ (49 and 186%, coolest and warmest regime, respectively). Carbon partitioned to roots declined progressively with warming, while at elevated CO₂ there was an average of 56% increase in allocation to roots. The relative impacts of both CO₂ and temperature were greater on root dry mass than on either grain yield or total above-ground biomass, while the effects on grain and biomass yield varied considerably between cultivars, suggesting that the impact of rising CO₂ and temperature are likely to be dependent on cultivar.

Batts, G.R., J.I.L. Morison, R.H. Ellis, P. Hadley, and T.R. Wheeler. 1997. Effects of CO₂ and temperature on growth and yield of crops of winter wheat over four seasons. *European Journal of Agronomy* 7(1-3):43-52.

Crops of winter wheat (*Triticum aestivum* L. cv. Hereward) were grown in the field in four consecutive seasons from 1991/1992 to 1994/1995 at Reading, UK, within polyethylene-covered tunnels along which a temperature gradient was superimposed on the ambient temperature variation at normal atmospheric (ca. 370) or an increased [CO₂] (ca. 700 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$), producing many environments from one sowing date in each season at one location. Mean seasonal temperatures varied by up to 4 degrees C along the temperature gradient. Increased [CO₂] had no effect on crop duration, or on the rate of reproductive development, which had the same temperature sensitivity across all years. A 2 degrees C warming, on the 4-year ambient mean temperature (10 degrees C), reduced crop duration by 42 days (from 254), and reduced the reproductive phase by 16 days (from 130). Crop biomass generally declined with increase in mean temperature, and was greater at increased [CO₂], with the effect of increased [CO₂] varying with temperature and between years (6-34% range in relative stimulation by increased [CO₂]). Grain yield was substantially reduced by warmer temperatures, and increased by doubling [CO₂], but the effect varied greatly between years and with temperature (7-168% range). There were both positive and negative interactions of temperature and increased [CO₂] on biomass and grain yield. In all 4 years, the increase in grain yield from doubling [CO₂] was negated by an increase in mean seasonal temperature of only 1.0-2.0 degrees C. Year-to-year variation in the responses of biomass and grain yield to [CO₂] and temperature resulted from differences in environmental conditions, influencing biomass partitioning and altering the role of different yield components. Batts, G.R., T.R. Wheeler, J.I.L. Morison, R.H. Ellis, and P. Hadley. 1996. Developmental and tillering responses of winter wheat (*Triticum aestivum*) crops to CO₂ and temperature. *Journal of Agricultural Science* 127:23-35.

Winter wheat (*Triticum aestivum* L., cv. Hereward) was grown in the field within four double-walled polyethylene-covered tunnels along which near-linear temperature gradients were imposed at normal atmospheric or at an elevated CO₂ concentration (c. 700 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$) in 1991/92 and in a further experiment in 1992/93. Development was more rapid the warmer the temperature. In 1991/92 an increase in mean seasonal temperature of 3.5 degrees C reduced the duration from sowing to harvest maturity (the stage when grain moisture content reduced naturally to 15-18%) by c. 38 days, and reduced the duration from the double ridge stage to harvest maturity by c. 34 days. A similar difference resulted from only 1.6 degrees C warming in 1992/93. Although the range of mean seasonal temperatures differed between years, the relation between temperature and rate of development from sowing to harvest maturity was common to both years (base temperature, -0.8 degrees C; thermal time 2410 degrees C d). Carbon dioxide concentration had no effect on this relation or on that between temperature and the rate of development from sowing to the double ridge stage and from the double ridge stage to harvest maturity. Carbon dioxide enrichment increased tillering substantially in 1991/92; there were 200 more shoots m⁻² at terminal spikelet formation in crops grown at elevated compared to normal CO₂ (additional shoots were principally coleoptile tillers and those developing after tiller 2) and this

difference was reduced to 100 shoots m⁻²) approaching harvest maturity (additional shoots remaining were those developing after tiller 2). In contrast, no effect of CO₂ enrichment on tillering was detected at any stage of development in 1992/93. The number of tillers per plant at terminal spikelet formation was a linear function of main stem dry weight at this developmental stage; this relationship was not affected by year or CO₂. As CO₂ enrichment increased main stem dry weight in the first year only, when main stem dry weights at normal CO₂ were only one half of those values determined in the following year, it is concluded that any benefit of increase in CO₂ concentration to tillering in winter wheat may be greatest in those crop production environments where main stem dry weights at terminal spikelet are least and vice versa.

Bawa, K.S., and S. Dayanandan. 1998. Global climate change and tropical forest genetic resources. *Climatic Change* 39(2-3):473-485.

Global climate change may have a serious impact on genetic resources in tropical forest trees. Genetic diversity plays a critical role in the survival of populations in rapidly changing environments. Furthermore, most tropical plant species are known to have unique ecological niches, and therefore changes in climate may directly affect the distribution of biomes, ecosystems, and constituent species. Climate change may also indirectly affect plant genetic resources through effects on phenology, breeding systems, and plant-pollinator and plant seed disperser interactions, and may reduce genetic diversity and reproductive output. As a consequence, population densities may be reduced leading to reduction in genetic diversity through genetic drift and inbreeding. Tropical forest plants may respond to climate change through phenotypic plasticity, adaptive evolution, migration to suitable site, or extinction. However, the potential to respond is limited by a rapid pace of change and the non-availability of alternate habitats due to past and present trends of deforestation. Thus climate change may result in extinction of many populations and species. Our ability to estimate the precise response of tropical forest ecosystems to climate change is limited by lack of long-term data on parameters that might be affected by climate change. Collection of correlative data from long-term monitoring of climate as well as population and community responses at selected sites offer the most cost-effective way to understand the effects of climate change on tropical tree populations. However, mitigation strategies need to be implemented immediately. Because many effects of climate change may be similar to the effects of habitat alteration and fragmentation, protected areas and buffer zones should be enlarged, with an emphasis on connectivity among conserved landscapes. Taxa that are likely to become extinct should be identified and protected through *in situ* conservation programs.

Baxter, R., T.W. Ashenden, and J.F. Farrar. 1997. Effect of elevated CO₂ and nutrient status on growth, dry matter partitioning and nutrient content of *Poa alpina* var *vivipara* L. *Journal of Experimental Botany* 48(312):1477-1486.

Poa alpina var. *vivipara* L. was grown in an atmosphere containing either 340 or 680 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ within controlled environment chambers. The available nutrient regime was varied by altering the supply of nitrogen and phosphorus within a complete nutrient solution. At a high, but not low, N and P supply regime, elevated CO₂ markedly

increased growth. Differences between nutrient supply, but not atmospheric CO₂ concentration, altered the allometric relations between root and shoot. Net photosynthesis of mature leaf blades and leaf N and P concentration were reduced in plants grown at the elevated CO₂ concentration. The question was asked: is it possible to ascribe all of these effects to elevated CO₂ or are some due to nutrient deficiency caused by dilution with excess carbon? Several criteria, including the nutrient content of sink tissue, root:shoot allometry and the use of divalent cations to estimate integrated water flows are suggested in order to make this distinction. It is concluded that only at a low supply of N and P, and elevated CO₂ concentration, was low leaf N concentration due to induced nutrient deficiency. The data are consistent with a model where the capacity of sinks to use photosynthetically assimilated carbon sets both the rate of import into those sinks (and thus rate of export from source leaves) and the rate of photosynthesis of source leaves themselves.

Baxter, R., T.W. Ashenden, T.H. Sparks, and J.F. Farrar. 1994. Effects of elevated carbon-dioxide on 3 montane grass species .1. Growth and dry-matter partitioning. *Journal of Experimental Botany* 45(272):305-315.

Upland grasslands are a major component of natural vegetation within the UK. Such grasslands support slow growing relatively stable plant communities. The response of native montane grass species to elevated atmospheric carbon dioxide concentrations has received little attention to date. Of such studies, most have only focused on short-term (days to weeks) responses, often under favourable controlled environment conditions. In this study *Agrostis capillaris* L.(5), *Festuca vivipara* L. and *Poa alpina* L. were grown under semi-natural conditions in outdoor open-top chambers at either ambient (340 $\mu\text{mol mol}^{-1}$) or elevated (680 $\mu\text{mol mol}^{-1}$) concentrations of atmospheric carbon dioxide (CO₂) for periods from 79 to 189 d, with a nutrient availability similar to that of montane *Agrostis-Festuca* grassland in Snowdonia, N. Wales. Whole plant dry weight was increased for *A. capillaris* and *P. alpina*, but decreased for *F. vivipara*, at elevated CO₂. Major components of relative growth rate (RGR) contributing to this change at elevated CO₂ were transient changes in specific leaf area (SLA) and leaf area ratio (LAR). Despite changes in growth rate at 680 $\mu\text{mol mol}^{-1}$ CO₂, partitioning of dry weight between shoot and root in plants of *A. capillaris* and *P. alpina* was unaltered. There was a significant decrease in shoot relative to root growth at elevated CO₂ in *F. vivipara* which also showed marked discoloration of the leaves and increased senescence of the foliage.

Baxter, R., S.A. Bell, T.H. Sparks, T.W. Ashenden, and J.F. Farrar. 1995. Effects of elevated CO₂ concentrations on 3 montane grass species .3. Source leaf metabolism and whole-plant carbon partitioning. *Journal of Experimental Botany* 46(289):917-929.

Agrostis capillaris L.(5), *Festuca vivipara* L. and *Poa alpina* L. were grown in outdoor open-top chambers at either ambient (340 $\pm$ 3 $\mu\text{mol mol}^{-1}$) or elevated (680 $\pm$ 4 $\mu\text{mol mol}^{-1}$) concentrations of atmospheric carbon dioxide (CO₂) for periods from 79-189 d. Photosynthetic capacity of source leaves of plants grown at both ambient and elevated CO₂ concentrations was measured at saturating light and

5% CO₂. Dark respiration of leaves was measured using a liquid phase oxygen electrode with the buffer solution in equilibrium with air (21% O₂, 0.034% CO₂). Photosynthetic capacity of *P. alpina* was reduced by growth at 680 $\mu\text{mol mol}^{-1}$ CO₂ by 105 d, and that of *F. vivipara* was reduced at 65 d and 189 d after CO₂ enrichment began, suggesting down-regulation or acclimation. Dark respiration of successive leaf blades of all three species was unaltered by growth at 680 relative to 340 $\mu\text{mol mol}^{-1}$ CO₂. In *F. vivipara*, leaf respiration rate was markedly lower at 189 d than at either 0 d or 65 d, irrespective of growth CO₂ concentration. There was a significantly lower total non- structural carbohydrate (TNC) concentration in the leaf blades and leaf sheaths of *A. capillaris* grown at 680 $\mu\text{mol mol}^{-1}$ CO₂. TNC of roots of *A. capillaris* was unaltered by CO₂ treatment. TNC concentration was increased in both leaves and sheaths of *P. alpina* and *F. vivipara* after 105 d and 65 d growth, respectively. A 4-fold increase in the water-soluble fraction (fructan) in *P. alpina* and in all carbohydrate fractions in *F. vivipara* accounted for the increased TNC content. In *F. vivipara* the relationship between leaf photosynthetic capacity and leaf carbohydrate concentration was such that there was a strong positive correlation between photosynthetic capacity and total leaf N concentration (expressed on a per unit structural dry weight basis), and total nitrogen concentration of successive mature leaves reduced with time. Multiple regression of leaf photosynthetic capacity upon leaf nitrogen and carbohydrate concentrations further confirmed that leaf photosynthetic capacity was mainly determined by leaf N concentration. In *P. alpina*, leaf photosynthetic capacity was mainly determined by leaf CHO concentration. Thus there is evidence for downregulation of photosynthetic capacity in *P. alpina* resulting from increased carbohydrate accumulation in source leaves. Leaf dark respiration and total N concentration were positively correlated in *P. alpina* and *F. vivipara*. Leaf dark respiration and soluble carbohydrate concentration of source leaves were positively correlated in *A. capillaris*. Changes in source leaf photosynthetic capacity and carbohydrate concentration of plants grown at ambient or elevated CO₂ are discussed in relation to plant growth, nutrient relations and availability of sinks for carbon.

Baxter, R., and J.F. Farrar. 1999. Export of carbon from leaf blades of *Poa alpina* L. at elevated CO₂ and two nutrient regimes. *Journal of Experimental Botany* 50(336):1215-1221.

The hypothesis was tested that, in plants of the alpine! meadow grass (*Poa alpina* L.) exposed to elevated CO₂, net photosynthesis and export from source leaves is; reduced as a result of feedback from sinks. Nutrient supply was used as one way of reducing photosynthesis and export. Single plants were grown in sand culture under specified controlled environmental conditions for a period of 50 d at two levels of nitrogen and phosphorus ('low': 0.2 mol m⁻³ N, 0.04 mol m⁻³ P; 'high': 2.5 mol m⁻³ N, 0.5 mol m⁻³ P). Compartmentation within, and export of carbon from, individual youngest fully expanded leaves of acclimated plants was determined using C-14 feeding and efflux plus mass balance calculations of carbohydrate export. Independent of treatment, the bulk of soluble carbohydrate (65-75%) was present as fructan, with most of the remainder being sucrose. Depending on nutrient supply, CO₂ could alter export from source leaves either by a reduction in the amount of sucrose present in a readily available pool for transport, or by altering the rate constant describing phloem loading.

Baxter, R., M. Gantley, T.W. Ashenden, and J.F. Farrar. 1994. Effects of elevated carbon-dioxide on 3 grass species from montane pasture .2. Nutrient-uptake, allocation and efficiency of use. *Journal of Experimental Botany* 45(278):1267-1278.

Agrostis capillaris L.(4), *Festuca vivipara* L. and *Poa alpina* L. were grown in outdoor open-top chambers at either ambient (340 $\mu\text{mol mol}^{-1}$) or elevated (680 $\mu\text{mol mol}^{-1}$) CO₂ for periods from 79 to 189 d. Under these conditions there is increased growth of *A. capillaris* and *P. alpina*, but reduced growth of *F. vivipara*. Nutrient use efficiency, nutrient productivity (total plant dry weight gain per unit of nutrient) and nutrient allocation of all three grass species were measured in an attempt to understand their individual growth responses further and to determine whether altered nutrient-use efficiencies and productivities enable plants exposed to an elevated atmospheric CO₂ environment to overcome potential limitations to growth imposed by soil fertility. Total uptake of nutrients was, in general, greater in plants of *A. capillaris* and *P. alpina* (with the exception of N and K in the latter) when grown at 680 $\mu\text{mol mol}^{-1}$ CO₂. In *F. vivipara*, however, uptake was considerably reduced in plants grown at the higher CO₂ concentration. Overall, a doubling of atmospheric CO₂ concentration had little effect on the nutrient use efficiency or productivity of *A. capillaris*. Reductions in tissue nutrient content resulted from increased plant growth and not altered nutrient use efficiency. In *P. alpina*, potassium, magnesium and calcium productivities were significantly reduced and photosynthetic nitrogen and phosphorus use efficiencies were doubled at elevated CO₂ with respect to plants grown at ambient CO₂. *F. vivipara* grown for 189 d showed the most marked changes in nutrient use efficiency and nutrient productivity (on an extracted dry weight basis) when grown at elevated CO₂. *F. vivipara* grown at elevated CO₂, however, showed large increases in the ratio of nonstructural carbohydrate to nitrogen content of leaves and reproductive tissues, indicating a substantial imbalance between the production and utilization of assimilate.

Bazzaz, F.A. 1998. Tropical forests in a future climate: Changes in biological diversity and impact on the global carbon cycle. *Climatic Change* 39(2-3):317-336.

Tropical forest ecosystems are large stores of carbon which supply millions of people with life support requirements. Currently tropical forests are undergoing massive deforestation. Here, I address the possible impact of global change conditions, including elevated CO₂, temperature rise, and nitrogen deposition on forest structure and dynamics. Tropical forests may be particularly susceptible to climate change for the following reasons: (1) Phenological events (such as flowering and fruiting) are highly tuned to climatic conditions. Thus a small change in climate can have a major impact on the forest, its biological diversity and its role in the carbon cycle. (2) There are strong coevolutionary interactions, such as pollination seed dispersal, with a high degree of specialization, i.e., only certain animals can effect these activities for certain species. Global change can decouple these tight coevolutionary interactions. (3) Because of high species diversity per unit area, species of the tropical rain forest must have narrow niches. Thus changes in global climate can eliminate species and therefore reduce biological diversity. (4) Deforestation and other forms of disturbance may have significant feedback on hydrology both regionally and globally. The predicted decline in the rainfall in the Amazon Basin and the intensification of the Indian monsoon can have a large effect on water availability and floods which are already devastating low-lying areas. It is concluded that tropical forests may be very sensitive to

climate change. Under climatic change conditions their structure and function may greatly change, their integrity may be violated and their services to people may be greatly modified. Because they are large stores of great biological diversity, they require immediate study before it is too late. The study requires the collaboration of scientists with a wide range of backgrounds and experiences including biologists, climate modellers, atmospheric scientists, economists, human demographers and sociologists in order to carry out holistic and urgently needed work. Global climatic change brings a great challenge to science and to policy makers.

Bazzaz, F.A., D.D. Ackerly, F.I. Woodward, and L. Rochefort. 1992. Co₂ enrichment and dependence of reproduction on density in an annual plant and a simulation of its population-dynamics. *Journal of Ecology* 80(4):643-651.

1. Populations of an annual plant, *Abutilon theophrasti*, were grown at four densities (100, 500, 1500 and 4000 m⁻²) and two CO₂ concentrations (350 and 700 μmol l⁻¹) to examine the influence of CO₂ environment on density-dependent patterns of demography and reproduction. Variables measured included survivorship, proportion of plants flowering and fruiting, number of fruiting individuals, number of seeds per individual, total seed production per population, mean seed mass, and germination of seeds produced in each environment. 2. All variables, except the number of fruiting individuals, declined with increasing density, and at the highest density no individuals set seed. The number of fruiting individuals was highest at a density of 500m⁻². In the elevated CO₂ environment, survivorship was significantly reduced but the proportion of plants flowering and fruiting and the number of fruiting individuals in each population all increased. Total population seed production was higher in the elevated CO₂ environment at all densities, although the differences were not significant. Significant effects of CO₂ concentration were observed only for population-level variables, but not for mean individual fecundity or seed size. Seed germination declined with increasing maternal density, and no germination was recorded for seeds produced at 1500 m⁻². 3. Simple models of population dynamics, utilizing difference equations, were constructed to examine potential population-level consequences of these density and CO₂ effects. In the absence of a persistent seed pool, the simulated populations exhibited damped or stable oscillations under low germination values, but displayed non-cyclic ('chaotic') oscillations or went extinct for higher germination due to the complete failure of seed-set at high density. Because of its higher fecundity, the elevated- CO₂ population generally exhibited greater oscillations, and the critical germination value at which the simulated populations went extinct was much lower for the elevated-CO₂ than for the ambient-CO₂ population.

Bazzaz, F.A., M. Jasienski, S.C. Thomas, and P. Wayne. 1995. Microevolutionary responses in experimental populations of plants to co₂-enriched environments - parallel results from 2 model systems. *Proceedings of the National Academy of Sciences of the United States of America* 92(18):8161-8165.

Despite the critical role that terrestrial vegetation plays in the Earth's carbon cycle, very little is known about the potential evolutionary responses of plants to anthropogenically induced increases in concentrations of atmospheric CO₂. We present experimental evidence that rising CO₂ concentration may have a direct impact on the genetic composition and diversity of plant populations but is unlikely to result in selection favoring genotypes that exhibit increased productivity in a CO₂-enriched atmosphere. Experimental populations of an annual plant (*Abutilon theophrasti*, velvetleaf) and a temperate forest tree (*Betula alleghaniensis*, yellow birch) displayed responses to increased CO₂ that were both strongly density-dependent and genotype-specific. In competitive stands, a higher concentration of CO₂ resulted in pronounced shifts in genetic composition, even though overall CO₂-induced productivity enhancements were small. For the annual species, quantitative estimates of response to selection under competition were 3 times higher at the elevated CO₂ level. However, genotypes that displayed the highest growth responses to CO₂ when grown in the absence of competition did not have the highest fitness in competitive stands. We suggest that increased CO₂ intensified interplant competition and that selection favored genotypes with a greater ability to compete for resources other than CO₂. Thus, while increased CO₂ may enhance rates of selection in populations of competing plants, it is unlikely to result in the evolution of increased CO₂ responsiveness or to operate as an important feedback in the global carbon cycle. However, the increased intensity of selection and drift driven by rising CO₂ levels may have an impact on the genetic diversity in plant populations.

Bazzaz, F.A., and K.D.M. McConnaughay. 1992. Plant interactions in elevated CO₂ environments. *Australian Journal of Botany* 40(4-5):547-563.

Increasing atmospheric carbon dioxide concentrations present a novel resource condition for plant communities. In order to understand and predict how plant community structure and function may be altered in a high CO₂ world, we need to understand how interactions among neighbouring plants within a community will alter the growth and reproduction of component species. Because CO₂ is readily diffusible, plants have little influence on the CO₂ acquisition of their neighbours, except within particularly dense canopies. Thus, plants seldom compete directly for CO₂. Rather, CO₂ availability is likely to alter plant-plant interactions indirectly through its effects on plant growth and competition for other resources. As a consequence, competitive outcome under elevated CO₂ atmospheres within even simple systems is not easy to predict. For example, under some conditions, C₄ species in competitive assemblages have improved competitive ability relative to C₃ competitors as a result of CO₂ enrichment, contrary to expectations based on their photosynthetic pathways. It is now clear that individually grown plants can differ substantially from those within mono- or multispecific stands in response to CO₂ enrichment. At present, our understanding of how stands of interacting plants modify the availability of CO₂ and other resources is incomplete. We urgently need information about how elevated CO₂ atmospheres influence stand formation and population dynamics, specifically with regard to the identities, numbers, sizes and reproductive fitnesses of individuals within single and multiple species stands, if we are to make multi-generational predictions concerning the fate of populations and communities in an elevated CO₂

world.

Bazzaz, F.A., and S.L. Miao. 1993. Successional status, seed size, and responses of tree seedlings to CO₂, light, and nutrients. *Ecology* 74(1):104-112.

We studied how an enriched CO₂ atmosphere in a fully crossed design of light and nutrients, influenced 1 st-yr seedling growth in six New England deciduous forest tree species. The species, in the order of increasing shade tolerance, were gray birch (*Betula populifolia*), ash (*Fraxinus americana* L.), red maple (*Acer rubrum* L.), red oak (*Quercus rubra* L.), yellow birch (*Betula alleghaniensis* Britton), and striped maple (*Acer pensylvanicum*). Elevated CO₂ environments significantly stimulated the seedling growth of all six species. Generally this was more pronounced in low light. The greatest stimulation was found under the condition of low light and high nutrients. However, individual species responded differently to elevated CO₂ levels. Among the three early-successional species, gray birch, ash, and red maple, a significant increase in seedling growth under elevated CO₂ conditions was found only with high nutrients. The three late-successional species grown under elevated CO₂ conditions (red oak, yellow birch, and striped maple) showed a greater percentage increase in seedling growth in low light than in high light. Thus, for the early-successional species, the degree of enhancement of seedling growth by elevated CO₂ levels was more sensitive to nutrient levels, while in the late-successional species the enhancement was more sensitive to the level of light. Moreover, species with large seeds (e.g., red oak) exhibited a greater response to elevated CO₂ levels under low light than species with small seeds (e.g., gray birch). The results emphasize the importance of plant species as well as other environmental resources in modifying the response of plants to elevated CO₂. Considering the light and nutrient environment observed in forest gaps of various sizes, the results of the present experiment suggest seedling regeneration in New England deciduous forests may be altered in a future high CO₂ environment.

Bazzaz, F.A., S.L. Miao, and P.M. Wayne. 1993. CO₂-induced growth enhancements of cooccurring tree species decline at different rates. *Oecologia* 96(4):478-482.

To elucidate how enriched CO₂ atmospheres, soil fertility, and light availability interact to influence the long-term growth of tree seedlings, six co-occurring members of temperate forest communities including ash (*Fraxinus americana* L.), gray birch (*Betula populifolia*), red maple (*Acer rubrum*), yellow birch (*Betula alleghaniensis*), striped maple (*Acer pensylvanicum*), and red oak (*Quercus rubra* L.) were raised in a glasshouse for three years in a complete factorial design. After three years of growth, plants growing in elevated CO₂ atmospheres were generally larger than those in ambient CO₂ atmospheres, however, magnitudes of CO₂-induced growth enhancements were contingent on the availability of nitrogen and light, as well as species identity. For all species, magnitudes of CO₂-induced growth enhancements after one year of growth were greater than after three years of growth, though species' growth enhancements over the three years declined at different rates. These results suggest that CO₂-induced enhancements in forest

productivity may not be sustained for long periods of time. Additionally, species' differential growth responses to elevated CO₂ may indirectly influence forest productivity via long-term species compositional changes in forests.

Beaudry, R.M. 1999. Effect of O₂ and CO₂ partial pressure on selected phenomena affecting fruit and vegetable quality. *Postharvest Biology and Technology* 15(3):293-303.

It is likely that from the time of the Roman Empire and perhaps before, people involved in the storage of plant material as food recognized that atmospheric modification can provide some benefit in improving storability. However, active, commercial modification of the atmosphere for the preservation of fresh fruit and vegetables dates to the early part of this century. Early successes with apple fruit has led to the attempt to apply modified atmospheres to a wide range of commodities. Responses to atmospheric modification are found to vary dramatically among plant species, organ type and developmental stage and include both unwanted and beneficial physiological responses. Desirable responses include a reduction in respiration, a reduction in oxidative tissue damage or discoloration, a reduction in the rate of chlorophyll degradation and a reduction in ethylene sensitivity with the concomitant reduction in the rate of ripening and other ethylene-mediated phenomena. Undesirable responses have included the induction of fermentation, the development of disagreeable flavors? a reduction in aroma biosynthesis, the induction of tissue injury and an alteration in the makeup of microbial fauna. The physiological bases for some of these responses to elevated CO₂ and reduced O₂ are discussed. (C) 1999 Elsevier Science B.V. All rights reserved.

Becker, M., T.M. Nieminen, and F. Geremia. 1994. Short-term variations and long-term changes in oak productivity in northeastern France - the role of climate and atmospheric CO₂. *Annales Des Sciences Forestieres* 51(5):477-492.

A dendroecological study was carried out in 2 forests in northeastern France with the aim of identifying and quantifying possible long-term trends in the radial growth of sessile oak (*Quercus petraea* (Matt) Liebl) and pedunculate oak (*Q. robur* L.). A total of 150 sites were selected to represent the ecological diversity of these forests. An index Cd was used to correct annual ring width in order to compensate for the effect of different competition situations. The data were standardized with reference to the mean curve 'basal area increment vs cambial age'. The growth index curves revealed a strong increase in sessile oak growth (+64% during the period 1888 to 1987) as well as in that of pedunculate oak (+40%). The growth increase in the 'young' rings (<60 years) of sessile oak was +87%, and that of young rings of pedunculate oak was +49%. The corresponding increase in the 'old' rings (>65 years) was +48% and 15% respectively (not significant for the latter). It would thus appear that pedunculate oak has benefited to a lesser extent than sessile oak from the progressive changes in its environment. Years showing a strong growth decrease are more common for pedunculate oak than for sessile oak. These results are consistent with a recent hypothesis about a slow but general retreat of pedunculate oak, including severe episodic

declines, in favour of sessile oak in many regions of France. A model was created using a combination of meteorological data (monthly precipitation and temperature) starting in 1881, and increasing atmospheric CO₂ concentrations. The model explains 78.3% of the variance for sessile oak and 74.3% for pedunculate oak. This includes some monthly parameters of year *y* (year of ring formation), and also some parameters of the years *y*-1 to *y*-4 for sessile oak and *y*-1 to *y*-5 for pedunculate oak. The models satisfactorily reproduce the long-term trends and the interannual variation. The climatic variables alone (ie excluding the CO₂ concentration) were insufficient to explain the trends observed. The possible direct and indirect effects of increasing CO₂ concentration on the growth of both species are discussed.

Beckmann, K., C. Dzuibany, K. Biehler, H. Fock, R. Hell, A. Migge, and T.W. Becker. 1997. Photosynthesis and fluorescence quenching, and the mRNA levels of plastidic glutamine synthetase or of mitochondrial serine hydroxymethyltransferase (SHMT) in the leaves of the wild-type and of the SHMT-deficient *stm* mutant of *Arabidopsis thaliana* in relation to the rate of photorespiration. *Planta* 202(3):379-386.

The regulation by photorespiration of the transcript level corresponding to plastidic glutamine synthetase (GS-2) was investigated in the leaves of *Arabidopsis thaliana* (L.) Heynh. Photorespiration was suppressed by growing the plants in an atmosphere containing 300 Pa CO₂. Suppression of photorespiration was demonstrated by the ability of the conditionally lethal serine hydroxymethyltransferase (SHMT)-deficient *stm* mutant of *A. thaliana* to grow normally under these conditions. In contrast to previous studies with bean or pea that were performed at very high CO₂ partial pressure (2-4 kPa; Edwards and Coruzzi, 1989, *Plant Cell* 1: 241-248; Cock et al., 1991, *Plant Mol Biol* 17: 761-771), suppression of photorespiration during growth of *A. thaliana* in an atmosphere with 300 Pa CO₂ had no effect on the leaf GS-2 transcript level. In the short term, neither suppression of photorespiration induced by the transfer of air-grown *A. thaliana* plants into a CO₂-enriched atmosphere, nor an increase in the rate of photorespiration achieved by the transfer of high-CO₂-grown *A. thaliana* plants into air resulted in a change in the GS-2 mRNA level. The absence of photorespiratory ammonium release in leaves of the *stm* mutant had no effect on the GS-2 transcript level. Overall, our data argue against a control by photorespiration of the *A. thaliana* leaf GS-2 mRNA pool. In contrast, regulation of the leaf SHMT mRNA level may involve a negative feedback effect of at least one metabolite derived from the glycine/serine conversion during photorespiration, as indicated by the overexpression of SHMT transcripts in the leaves of the *stm* mutant.

Beer, S., and E. Koch. 1996. Photosynthesis of marine macroalgae and seagrasses in globally changing CO₂ environments. *Marine Ecology-Progress Series* 141(1-3):199-204.

Photosynthetic rates of many marine macroalgae are saturated by the present day inorganic carbon (Ci) composition of seawater, while those of seagrasses (or marine angiosperms) are CO₂-limited. In this study we attempted to simulate the Ci conditions of near-shore seawater during the time that seagrasses colonised the sea (in the Cretaceous), and compare the photosynthetic performance of representatives of the 2 plant

groups under those versus present day conditions. The results show that the seagrasses have an affinity for Ci at least as high as the algae under the low pH and high CO₂/HCO₃⁻ concentration ratios simulating near-shore areas of the Cretaceous seas, indicating that their photosynthetic capacity then matched that of macroalgae. However, in the high pH and high CO₂/HCO₃⁻ ratios of today, their affinity for Ci is lower than that of the macroalgae, and it is suggested that this deficiency renders them a lower ability for Ci utilisation. This situation may possibly be reversed again as global CO₂ levels of the atmosphere and, consequently, of near-shore marine habitats increase in the future.

Beerling, D.J. 1994. Modeling palaeophotosynthesis - late cretaceous to present. *Philosophical Transactions of the Royal Society of London Series B-Biological Sciences* 346(1318):421-432.

This paper presents an attempt to reconstruct potential changes in the photosynthetic rates of terrestrial C3 leaves over the past 120 Ma. The approach has been to couple palaeoatmospheric reconstructions of O-2, CO₂ and temperature from geochemical modelling, and an independent estimate of ancient CO₂ changes from fossil porphyrins, with a mechanistic biochemical model of C3 photosynthesis. The model accounts for the effect of each of these palaeoenvironmental changes, at the biochemical level, to predict leaf photosynthesis and has been parametrized for a typical gymnosperm and angiosperm. The results indicate clear potential for increased photosynthetic C3 fixation in the warm Cretaceous for both angiosperms and gymnosperms, despite the increased O-2 content of the atmosphere prevailing at the time. Photosynthetic rates are then predicted to progressively decline into the Tertiary, as a result of global cooling. The model simulations also point towards some leaf-level ecophysiological explanations for the rise in angiosperm dominance and the concomitant decline in gymnosperms from the late Cretaceous onwards, at mid-latitudes, which have not been considered previously. This work provides a basis for scaling up to the canopy level to predict the primary productivity of ancient ecosystems and their possible feedback on atmospheric composition and climate.

Beerling, D.J. 1994. Predicting leaf gas-exchange and delta-C-13 responses to the past 30000 years of global environmental-change. *New Phytologist* 128(3):425-433.

Theoretical developments in our understanding of leaf gas exchange processes and carbon isotope composition (delta(13)C) mean that it should now be possible to model their responses to global environmental change. Such a model would be of use for process-based interpretations of historical changes in leaf delta(13)C and for understanding the global stable carbon isotope balance. This paper describes the development and validation of a model towards this aim. The resulting model is used to simulate changes in leaf photosynthesis, stomatal conductance and delta(13)C of limber pine (*Pinus flexilis*) in response to the past 30000 y of global environmental change. The predictions of needle delta(13)C are in line with reported measurements of delta(13)C from fossilized *Pinus flexilis* needles preserved in packrat middens in western USA. Leaf gas exchange predictions show that the increased water use efficiency (WUE) of these trees growing in present-day environments, relative to the past, was brought about through an increase in photosynthetic rates and a decrease in stomatal conductance. This contrasts with the explanation of the recent (past 200 y) increase in the

WUE of temperate and Mediterranean ecosystems inferred from $\delta(13)\text{C}$ measurements which are predicted by the model to have arisen largely by a decrease in stomatal conductance in response to increases in the concentration of atmospheric CO_2 since the pre-industrial era. The model as described offers the potential to contribute to our understanding of vegetation effects on the global carbon isotope balance during the glacial periods, and therefore to provide a further constraint on the carbon cycle models used to explain the low concentrations of atmospheric CO_2 at these times.

Beerling, D.J. 1996. C-13 discrimination by fossil leaves during the late-glacial climate oscillation 12-10 ka BP: Measurements and physiological controls. *Oecologia* 108(1):29-37.

The late-glacial climatic oscillation, 12-10 ka BP, is characterised in ice core oxygen isotope profiles by a rapid and abrupt return to glacial climate. Recent work has shown that associated with this cooling was a drop in atmospheric CO_2 concentration of ca. 50 ppm. In this paper, the impact of these environmental changes on C-13 discrimination is reported, based on measurements made on a continuous sequence of fossil *Salix herbacea* leaves from a single site. The plant responses were interpreted using an integrated model of stomatal conductance, CO_2 assimilation and intercellular CO_2 concentration, influenced by external environmental factors. According to the model, temperature exerts a marked influence on C-13 discrimination by leaves and the pattern of C-13 changes recorded by the fossil leaves is consistent with other palaeotemperature curves for 12-10 ka BP, particularly the deuterium isotope record from Alaskan *Salix* woods, which generally reflects ocean temperatures. The gas exchange model correctly accounts for these changes and so permits the reconstruction of ancient rates of leaf CO_2 uptake and loss of water vapour in response to the abrupt late-glacial changes in global climate and CO_2 . The approach provides the required physiological underpinning for extracting quantitative estimates of past temperatures and for contributing an ecophysiological explanation for changes in C-13 discrimination in the fossil record.

Beerling, D.J. 1997. Carbon isotope discrimination and stomatal responses of mature *Pinus sylvestris* L trees exposed in situ for three years to elevated CO_2 and temperature. *Acta Oecologica-International Journal of Ecology* 18(6):697-712.

The Climate Change Experiment (CLIMEX) is a unique large scale facility in which an entire undisturbed catchment of boreal vegetation has been exposed to elevated CO_2 (560 ppm) and temperature (+3 degrees C summer, +5 degrees C winter) for the past three years with all the soil-plant-atmosphere linkages intact. Here, carbon isotope composition and stomatal density have been analysed from sequential year classes of needles of mature Scots pine trees (*Pinus sylvestris* L.) to investigate the response of time-integrated water-use efficiency (WUE) and stomatal density to CO_2 enrichment and climate change. Carbon isotope discrimination decreased and WUE increased in cohorts of needles developing under increased CO_2 and temperature, compared to needles on the same trees developing in pretreatment years. Mid-season

instantaneous gas exchange, measured on the same trees for the past four years, indicated that these responses resulted from higher needle photosynthetic rates and reduced stomatal conductance. Needles of *P. sylvestris* developing under increased CO_2 and temperature had consistently lower stomatal densities than their ambient grown counterparts on the same trees. The stomatal density of *P. sylvestris* needles was inversely correlated with $\delta(13)\text{C}$ - derived WUE, implying some effect of this morphological response on leaf gas exchange. Future atmospheric CO_2 and temperature increases are therefore likely to improve the water economy of *P. sylvestris*, at least at the scale of individual needles, by affecting stomatal density and gas exchange processes.

Beerling, D.J. 1997. Interpreting environmental and biological signals from the stable carbon isotope composition of fossilized organic and inorganic carbon. *Journal of the Geological Society* 154:303-309.

Stable carbon isotope studies on marine and terrestrial organic and inorganic carbon provide a means for detecting global climate change and for reconstructing past concentrations of atmospheric CO_2 . Comparison between the CO_2 estimates reconstructed from carbon isotope studies for the past 150 Ma show good agreement with the predictions of a long-term carbon-cycle model based on mass-balance studies. Further, the CO_2 estimates from these sources over the entire Phanerozoic show agreement with the fossil record of leaf stomatal density change-a feature inversely related to the concentration of atmospheric CO_2 . Isotopic studies on temporal sequences of fossilized terrestrial organic matter have contributed to palaeoecological studies on shifts in the dominance of plants with the C-4 photosynthetic pathway in ecosystems and historical changes in the metabolic processes of leaves of individual species. The long-term perspective offered by these studies provides critical information for assessing the responses of biological systems to future global environmental change.

Beerling, D.J. 1998. The future as the key to the past for palaeobotany? *Trends in Ecology and Evolution* 13(8):311-316.

Continued increase in the concentration of atmospheric CO_2 and its possible effects on global climate has generated intense research interest on the likely responses of terrestrial plants and vegetation. Results from this new research provide quantitative information on plant function and growth in an environment with a high CO_2 concentration, but are also relevant to understanding plant growth in the distant past and to the techniques employed by palaeobotanists for reconstructing past climates from fossil plant remains. Experimental CO_2 enrichment of plants has demonstrated direct effects on leaf physiognomy, the tolerance of plants to low temperature and the relationship between tree rings, CO_2 and climate; it therefore signals the need for caution in interpreting palaeoclimates from fossils.

Beerling, D.J. 1999. Long-term responses of boreal vegetation to global change: an experimental and modelling investigation. *Global Change Biology* 5(1):55-74.

The response of boreal ecosystems to future global change is an uncertain but potentially critical component of the feedback between the terrestrial biosphere and the atmosphere. To reduce some of the uncertainties in predicting the responses of this key ecosystem, the climate change experiment (CLIMEX) exposed an entire undisturbed catchment of boreal vegetation to CO₂ enrichment (560 ppmv) and climate change (+ 5 degrees C in winter, + 3 degrees C in summer) for three years (1994-96). This paper describes the leaf metabolic responses of the vegetation to the experimental treatment and model simulations of possible future changes in the hydrological and carbon balance of the site. Randomized intervention analysis of the leaf gas exchange measurements for the dominant species indicated *Pinus sylvestris* had significantly ($P < 0.01$) higher photosynthetic rates and *Betula pubescens* and *Vaccinium myrtillus* had significantly ($P < 0.01$) lower stomatal conductances after three years treatment compared to the controls. These responses led to sustained increases in leaf water-use efficiency of all species of trees and ground shrubs, as determined from carbon isotope analyses. Photosynthesis (A) vs. intercellular CO₂ (c(i)) response curves (A/c(i) responses), RuBisCo analysis and leaf nitrogen data together suggested none of the species investigated exhibited down-regulation in photosynthetic capacity. At the whole ecosystem level, the improved water economy of the plants did not translate into increased catchment runoff. Modelling simulations for the site indicate this was most likely brought about by a compensatory increase in evapotranspiration. In terms of the carbon budget of the site, the ecosystem model indicates that increased CO₂ and temperature would lead to boreal ecosystems of the type used in CLIMEX, and typical of much of southern Norway, acting as moderate net sinks for CO₂.

Beerling, D.J., W.G. Chaloner, B. Huntley, A. Pearson, and M.J. Tooley. 1991. Tracking stomatal densities through a glacial cycle - their significance for predicting the response of plants to changing atmospheric CO₂ concentrations. *Global Ecology and Biogeography Letters* 1(5):136-142.

Continued increases in the global atmospheric CO₂ concentration have been predicted from current and projected rates of fossil fuel burning. Understanding the response of stomatal density as an important ecophysiological parameter controlling the productivity of vegetation is essential if the role of plants in the global carbon budget are to be predicted. Experimental exposure of plants to elevated CO₂ regimes in controlled environment chambers can only indicate immediate, phenotypic, short-term responses. The investigation of fossil leaves of extant species growing under the different atmospheric conditions of the last glacial and deglacial transition, when evidence from an Antarctic ice core (Barnola et al., 1987) indicates CO₂ levels markedly different from pre-industrial levels, provides one means for eliciting long-term plant responses to changing CO₂ regimes. We have prepared cuticles from Quaternary leaf fossils, from which stomatal density and index can be calculated. Our preliminary results give promise of extending the record of stomatal density response back at least 10,000 years.

Beerling, D.J., W.G. Chaloner, B. Huntley, J.A. Pearson, M.J. Tooley, and F.I. Woodward. 1992. Variations in the stomatal density of salix-herbacea L under the changing atmospheric CO₂ concentrations of late-glacial and postglacial time. *Philosophical Transactions of the Royal Society of London Series B-Biological Sciences* 336(1277):215-224.

The rapidly rising CO₂ concentration of the past 200 years has been shown to be accompanied by a fall in stomatal density in the leaves of temperate trees. The present study attempts to investigate the relationship of atmospheric CO₂ change and stomatal density in the arctic-alpine shrub, *Salix herbacea*, over the longer time span of 11 500 years offered by fossil leaves from post-glacial deposits. Comparisons of fossil material from Scotland and Norway are made with leaves from living populations growing in Austria, Greenland and Scotland. The Austrian material, from an altitudinal gradient between 2000 and 2670 m above sea level, gives added comparison of contemporary differences of CO₂ partial pressure with altitude. The results of our investigation indicate, rather surprisingly, that the rising CO₂ concentration of the past 11 500 years has been accompanied by an increase in the stomatal density of *S. herbacea* in contrast to the shorter-term observations on the herbarium material of temperate trees. The most likely explanation appears to centre on the temperatures and water availability of the early post-glacial environment overriding the effect of the lower CO₂ regime. However, the scale of the time interval involved may also be significant. Natural selection over the 11 500 year period concerned may have favoured a different response to what is, in effect, an acclimatory response observed in trees within the period of rapid CO₂ rise of the past 200 years.

Beerling, D.J., J. Heath, F.I. Woodward, and T.A. Mansfield. 1996.

It is sometimes assumed that because increases in atmospheric CO₂ concentration usually enhance water use efficiency per unit leaf area, there will be a tendency for plants to show greater drought tolerance as well as increased biomass in the future. A critical examination of the responses to elevated CO₂ in three temperate tree species shows that this assumption might be incorrect in the case of two of them. Both beech (*Fagus sylvatica* L.) and birch (*Betula pubescens* Ehrh.) display minimal stomatal closing responses to elevated CO₂, and in the case of *F. sylvatica* the stomatal control of transpiration per unit leaf area appears to be unable to compensate for the greater development of leaf area. By contrast, the stomata of oak (*Quercus robur* L.) close appreciably in elevated CO₂, to an extent which might be sufficient to compensate for an increase in total leaf area. A simple model for the controls on water supply and consumption for the whole tree suggests that in *F. sylvatica* the potential height attainment for a given sapwood area might decrease as the atmospheric CO₂ concentration rises. The conclusions drawn from experimental data and from modelling are supported by field observations made in the UK in 1995, when the three species responded very differently to severe drought. We suggest that the progressive increase in the concentration of atmospheric CO₂ over the past 200 yr might have accentuated differences in drought sensitivity between these species.

Beerling, D.J., B. Huntley, and J.P. Bailey. 1995. Climate and the distribution of *Fallopia japonica* - use of an introduced species to test the predictive capacity of response surfaces. *Journal of Vegetation Science* 6(2):269-282.

The relationship between present climate and the distribution in Europe of the aggressively invasive exotic *Fallopia japonica* is described by fitting a response surface based on three bioclimatic variables: mean temperature of the coldest month, the annual temperature sum > 5 degrees C, and the ratio of actual to potential evapotranspiration. The close fit between the observed and simulated distributions suggests that the species' European distribution is climatically determined. The response surface also provides a simulation of the extent of the area of native distribution of *F. japonica* in Southeast Asia that is generally accurate, confirming the robustness of the static correlative model upon which it is based. Simulations of the potential distribution of *F. japonica* under two alternative 2 x CO₂ climate change scenarios indicate the likelihood of considerable spread into higher latitudes and possible eventual exclusion of the species from central Europe. However, despite the robustness of the response surface with present-day climate, the reliability of these simulations as forecasts is likely to be limited because no account is taken of the direct effects of CO₂ and their interaction with the species' physiological responses to climate. Similarly, no account is taken of the potential impact of interactions with 'new' species as ecosystems change in composition in response to climate change. Nevertheless, the simulations indicate both the possible magnitude of the impacts of forecast climate changes and the regions that may be susceptible to invasion by *F. japonica*.

Beerling, D.J., and C.K. Kelly. 1997. Stomatal density responses of temperate woodland plants over the past seven decades of CO₂ increase: A comparison of Salisbury (1927) with contemporary data. *American*

We investigated the possible effect of recent (1927-1995) increases in the concentration of atmospheric CO₂ on the stomatal densities of leaves of a wide range of tree, shrub, and herb species (N = 60) by making new measurements for comparison with corresponding data reported by E. J. Salisbury in 1917-a time when ice core studies indicate CO₂ concentrations similar to 55 μ mol/L lower than present. A detailed intraspecific study of the herb *Mercurialis perennis* showed plants of *M. perennis* in a Cambridgeshire woodland in 1994 had significantly lower stomatal densities, irrespective of leaf insertion point, compared with their 1927 counterparts. Comparisons made across species using evolutionary comparative methods (independent contrasts revealed a significant ($P < 0.01$) decrease in stomatal density over the past 70 yr. The results of both the inter- and intraspecific comparisons are consistent with the hypothesis that historical CO₂ increases have influenced leaf morphology in a manner consistent with recent experiments and the palaeoecological record. Further analyses suggested that the strength of the stomatal density response was independent of life form but dependent on "exposure" and the initial leaf stomatal density. Consequently firmer predictions for future changes in stomatal density across all species, expected as a possible result of anthropogenically related CO₂ increases, may now be possible.

Beerling, D.J., J.C. McElwain, and C.P. Osborne. 1998. Stomatal responses of the 'living fossil' *Ginkgo biloba* L. to changes in atmospheric CO₂ concentrations. *Journal of Experimental Botany* 49(326):1603-1607.

Leaf stomatal density and index of *Ginkgo biloba* L. were both significantly ($P < 0.05$) reduced after 3 years growth at elevated CO₂ (560 ppm), with values comparable to those of cuticles prepared from Triassic and Jurassic fossil *Ginkgo* leaves thought to have developed in the high CO₂ 'greenhouse world' of the Mesozoic. A reciprocal transfer experiment indicated that reductions in stomatal density and index irreversibly reduced stomatal conductance, particularly at low leaf-to-air vapour pressure deficits and low internal leaf CO₂ concentrations (C_i). These effects probably contributed to the high water-use efficiency of *Ginkgo* spp. in the Mesozoic relative to those of the present, as determined from carbon isotope measurements of extant and fossil cuticles.

Beerling, D.J., and W.P. Quick. 1995. A new technique for estimating rates of carboxylation and electron-transport in leaves of C-3 plants for use in dynamic global vegetation models. *Global Change Biology* 1(4):289-294.

The possible responses of the terrestrial biosphere to future CO₂ increases and associated climatic change are being investigated using dynamic global vegetation models (DGVMs) which include the Farquhar et al. (1980) biochemical model of leaf assimilation as the primary means of carbon capture. This model requires representative values of the maximum rates of Rubisco activity, V_{max}, and electron transport, J_{max}, for different vegetation types when applied at the global scale. Here, we describe an approach for calculating these values based on measurements of the maximum rate of leaf photosynthesis (A_{max}) and

C-13 discrimination. The approach is tested and validated by comparison with measurements of Rubisco activity assayed directly on wild-type and transgenic *Nicotiana tabacum* (tobacco) plants with altered Rubisco activity grown under ambient and elevated CO₂ mole fractions with high and low N-supply. V-max and J(max) values are reported for 18 different vegetation types with global coverage. Both variables were linearly related reinforcing the idea of optimal allocation of resources to photosynthesis (light harvesting vs. Rubisco) at the global scale. The reported figures should be of value to the further development of vegetation and ecosystem models employing mechanistic DGVMs.

Beerling, D.J., and F.I. Woodward. 1993. Ecophysiological responses of plants to global environmental change since the last glacial maximum. *New Phytologist* 125(3):641-648.

Ecophysiological information on the responses of plants to past global environmental changes may be obtained from Quaternary fossil leaves by measurements of (i) stomatal density, (ii) stomatal dimensions and (iii) C-13 discrimination (DELTA C-13). The stomatal density and stomatal dimensions of leaves can be used to calculate stomatal conductance, while leaf DELTA C-13 values provide independent information on stomatal conductance and plant water use efficiency. In this paper, stomatal conductance is calculated for a sequence of radiocarbon dated fossil leaves of *Salix herbacea* L. which, together with herbarium and fresh material, represents a time-series spanning from the Last Glacial Maximum (LGM) (16 500 yr BP) to the present day. The calculated values were then tested against leaf DELTA C-13 values previously reported for the same material. Our calculations show that stomatal conductance is negatively correlated with increases in atmospheric CO₂ concentration over the last 16 500 yr. This represents the first evidence of long-term response of stomatal conductance to increases in atmospheric CO₂ concentration and confirms the response observed in experimental systems exposing plants to lower-than-present CO₂ concentrations in controlled environments. The calculated decrease in conductance was positively correlated with leaf DELTA C-13 values, supporting this interpretation. The mean leaf DELTA C-13 value for the 18th and 19th centuries was significantly ($P < 0.05$) lower than the mean for the interval LGM-Holocene (10000 yr BP) implying an increase in plant water-use-efficiency over this time. These two lines of evidence, together with the stomatal density record from a glacial cycle, and experimental studies growing C3 plants in glacial-to-present CO₂ concentrations, strongly imply that the water use efficiency of vegetation during the LGM was lower than at present and that it has increased since that time. Further evidence in support of this conclusion comes from the pattern of world vegetation types present during the LGM previously reconstructed using palaeoecological data. This evidence demonstrates that the distribution of vegetation types during the LGM was significantly different from that of the present day and showed a contraction in the area of rain forest and a major expansion of desert areas.

Beerling, D.J., and F.I. Woodward. 1994. The climate-change experiment (climex) - phenology and gas-exchange responses of boreal vegetation to global change. *Global Ecology and Biogeography Letters*

4(1):17-26.

Large-scale whole ecosystem experiments will become increasingly important for predicting and testing hypotheses of complex ecosystem responses to global change. The Climate Change Experiment (CLIMEX) uses a site with an entire undisturbed boreal-forested catchment enclosed within an existing very large scale (1200m² ground area) greenhouse. In the forthcoming year temperature will be increased stepwise to +3-degrees-C in summer, +5-degrees-C in winter and the atmospheric CO₂ concentration enriched to 560 ppm which together simulate future changes in global climate and atmospheric composition predicted by GCMs. Plants growing within this low nutrient ecosystem are strongly dependent upon mycorrhizal associations for nutrient uptake and rates of nutrient uptake. Therefore it will provide an important test of current ideas concerning how mycorrhizas might modify plant responses to global change. We describe predictions of community phenology and gas exchange at the CLIMEX site; in the latter case the effects of including and excluding rates of on nutrient supply are considered. The results are discussed with reference to the opportunities presented by CLIMEX to reveal important aspects of the physiological responses of boreal ecosystems to global change.

Beerling, D.J., and F.I. Woodward. 1995. Leaf stable carbon-isotope composition records increased water-use efficiency of C-3 plants in response to atmospheric CO₂ enrichment. *Functional Ecology* 9(3):394-401.

1. A total of 17 temperate C-3 grass and herb species were grown for 5 weeks at three mole fraction treatments of atmospheric CO₂ (350, 525 and 700 $\mu\text{mol mol}^{-1}$). Leaf stable carbon isotope compositions ($\delta(13)\text{C}$) were determined to record long-term exchange responses together with instantaneous gas exchange measurements. The isotopic composition of the atmospheric CO₂ ($\delta(13)\text{C(a)}$) integrated over the course of the CO₂ treatments was recorded biologically using the C-4 species *Zea mays*. 2. We found that increases in the mole fraction of atmospheric CO₂ above current levels resulted in a sustained increase in instantaneous (photosynthesis, $A/\text{conductance}$, $g(s)$) leaf water-use efficiency (IWUE), as calculated from carbon isotope-derived $p(i)/p(a)$ ratios. Grass species showed a marked decline in the magnitude of WUE increase as the CO₂ mole fraction was increased from 525 to 700 $\mu\text{mol mol}^{-1}$, a response which was absent in herb species. 3. Isotopic derivation of the ratio of intercellular CO₂ mole fraction ($p(i)$) to that in the surrounding atmosphere ($p(a)$), considered as a set point of leaf metabolism, showed no significant ($P = 0.06$) changes in response to increases in the mole fraction of CO₂, for herb and grass species. Measurements of $p(i)/p(a)$ determined from measurements of leaf gas exchange differed significantly ($P < 0.01$) from those derived from stable isotope ratios. These differences are attributed to contrasting stomatal behaviour between herb and grass species. 4. Leaf intercellular CO₂ mole fraction and previously reported above-ground biomass responses to CO₂ increases for the same species were positively correlated ($P < 0.05$). This suggests that as atmospheric CO₂ levels continue to rise species showing sustained higher rates of leaf photosynthesis, may be translated into increased productivity depending on soil water and nutrient status.

Beerling, D.J., and F.I. Woodward. 1995. Stomatal responses of variegated leaves to CO₂ enrichment. *Annals of Botany* 75(5):507-511.

The responses of stomatal density and stomatal index of five species of ornamental plants with variegated leaves grown at two mole fractions of atmospheric CO₂ (350 and 700 $\mu\text{mol mol}^{-1}$) were measured. The use of variegated leaves allowed any potential effects of mesophyll photosynthetic capacity to be uncoupled from the responses of stomatal density to changes in atmospheric CO₂ concentration. There was a decrease in stomatal density and stomatal index with CO₂ enrichment on both white (unpigmented) and green (pigmented) leaf areas. A similar response of stomatal density and index was also observed on areas of leaves with pigmentation other than green indicating that any differences in metabolic processes associated with coloured leaves are not influencing the responses of stomatal density to CO₂ concentrations. Therefore the carboxylation capacity of mesophyll tissue has no direct influence on stomatal density and index responses as suggested previously (Friend and Woodward 1990 *Advances in Ecological Research* 20: 59-124), instead the responses were related to leaf structure. The stomatal characteristics (density and index) of homobaric variegated leaves showed a greater sensitivity to CO₂ on green portions, whereas heterobaric leaves showed a greater sensitivity on white areas. These results provide evidence that leaf structure may play an important role in determining the magnitude of stomatal density and index responses to CO₂ concentrations.

Beerling, D.J., and F.I. Woodward. 1996. In situ gas exchange responses of boreal vegetation to elevated CO₂ and temperature: First season results. *Global Ecology and Biogeography Letters* 5(3):117-127.

The climate change experiment (CLIMEX) uses a large greenhouse to investigate the responses of an entire undisturbed boreal forested catchment to elevated CO₂ (560 ppm) and temperature (+3 degrees C in summer and +5 degrees C in winter) treatments. In July and September of the first season of treatment the two dominant tree species, *Pinus sylvestris* and *Betula pubescens*, and the ground shrub *Vaccinium myrtillus* all showed an increase in leaf photosynthetic rates relative to the plants growing in the control section of the greenhouse and in an outside reference catchment. Stomatal density of needles of *P. sylvestris*, and leaves of *B. pubescens* and *V. myrtillus* decreased under CO₂ enrichment and temperature increases relative to the controls. Gas exchange and stable carbon isotope measurements will be made in future growing seasons to investigate whether acclimatory adjustments in plant metabolism occur—a critical issue affecting the carbon balance of these ecosystems.

Beerling, D.J., and F.I. Woodward. 1996. Palaeo-ecophysiological perspectives on plant responses to global change. *Trends in Ecology and Evolution* 11(1):20-23.

Taxonomic classifications of plant species, based on morphological characteristics, provide a stable and robust approach for inferring taxonomic and phylogenetic relationships between extant and extinct species. This implies that, although evolution is a continuous process for a species, there is no whole-scale change in those suites of morphological characteristics that define higher order (genus and greater) relationships. Recent research suggests that a higher order characteristic stomatal density - may reflect not only the atmospheric CO₂ concentration during initial evolution, but may also strongly

constrain the responses of higher order plant groups to future CO₂-enrichment.

Beerling, D.J., and F.I. Woodward. 1997. Changes in land plant function over the Phanerozoic: Reconstructions based on the fossil record. *Botanical Journal of the Linnean Society* 124(2):137-153.

Major fluctuations in the concentrations of atmospheric CO₂ and O₂ are predicted by historical long-term carbon and oxygen cycle models of atmospheric evolution and will have impacted directly on past climates, plant function and evolutionary processes. Here, palaeobotanical evidence is presented from the stomatal density record of fossil leaves spanning the past 400 Myr supporting the predicted changes in atmospheric CO₂. Evidence from experiments on plants exposed to long-term high CO₂ environments and the newly assembled fossil data indicate the potential for genetic modification of stomatal characters. The influence of tile changes in fossil stomatal characteristics and atmospheric composition on the rates of leaf gas exchange over the course of land plant evolution has been investigated through modelling. Three contrasting eras of plant water economies emerge in the Devonian (high), Carboniferous (low) and from the Upper Jurassic to the present-day (high but declining). These patterns of change result from structural changes of the leaves and the impact of atmospheric CO₂ and O₂ concentrations on RuBisCO function and are consistent with the fossil evidence of sequential appearances of novel plant anatomical changes. The modelling approach is tested by comparing predicted leaf stable carbon isotope ratios with those measured on fossil plant and organic material. Viewed in a geological context, current and future increases in the concentration of atmospheric CO₂ might be considered as restoring-plant function to that more typically experienced by plants over the majority of their evolutionary history. Beerling, D.J., F.I. Woodward, M. Lomas, and A.J. Jenkins. 1997. Testing the responses of a dynamic global vegetation model to environmental change: a comparison of observations and predictions. *Global Ecology and Biogeography Letters* 6(6):439-450.

Dynamic global vegetation - biogeochemistry models are required to predict the likely responses of the terrestrial biosphere to anticipated future global environmental change and for improved representation of an active vegetation surface within general circulation models of the Earth's global climate system. Testing the predictions of such models is essential to their development prior to use in a predictive capacity. The climate change experiment (CLIMEX) has exposed an entire catchment of boreal vegetation to elevated CO₂ (560 ppmv) and temperature (+3 degrees C in summer, +5 degrees C in winter) for the past three years and has a considerable archive of pre-and posttreatment measurements of both CO₂ and water vapour fluxes of the vegetation, catchment runoff and soil nutrient status. These data have been used to test the predictions of the University of Sheffield dynamic global vegetation model (SDGVM) for the same site using historical records of climate as input. Comparisons of observations and predictions at the scale of individual leaves and whole ecosystems are generally favourable, increasing our confidence in the application of the model to forecasting the responses of the terrestrial biosphere to various global change scenarios. The SDGVM has been used to predict the future responses of the ecosystem

at the site into the year 2003AD. The results indicate rather small changes in leaf area index and catchment runoff but quite large increases in net primary productivity. The model predictions are now open to testing further as the CO₂ and temperature treatments continue in the CLIMEX greenhouse.

Beeson, R.C., and M.E.D. Graham. 1991. CO₂ enrichment of greenhouse roses affects neither rubisco nor carbonic-anhydrase activities. *Journal of the American Society for Horticultural Science* 116(6):1040-1045.

The effect of prolonged CO₂ enrichment on the activities of ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) and carbonic anhydrase (CA) of greenhouse roses were studied. Plants of Rosa X hybrida 'Red Success' were grown for 2 years at ambient and 900- μ l CO₂/liter during winter and spring with 75- μ mol.m⁻².s⁻¹ photosynthetically active radiation supplemental lighting for 2 years. Measurements of initial and Mg+2-Co₂-activated activities of Rubisco and CA were made during shoot development and at different positions within the plant canopy. Generally, there were no significant differences measured in the enzyme activities between the two CO₂ concentrations. The results suggest that the photosynthetic capacity did not change and that there were no characteristic adaptations to long-term growth (up to 20 weeks) at elevated CO₂ concentrations. The maintenance of Rubisco and CA activities with prolonged exposure to CO₂-enriched atmospheres is proposed as the reason for long-term yield increases in roses when grown in enriched environments.

Behboudian, M.H., and R. Lai. 1994. Carbon-dioxide enrichment in virosa tomato plant - responses to enrichment duration and to temperature. *Hortscience* 29(12):1456-1459.

Responses of the tomato (*Lycopersicon esculentum* Mill. cv. Virosa) plant to elevated CO₂ concentrations applied throughout the photoperiod or part of it were studied under two temperature regimes. Plants were exposed to CO₂ at 340 (control), 700, and 1000 μ l-liter⁻¹. The highest concentration was applied only at 22/16C (day/night) and 700 μ l-liter⁻¹ at 22/16C and 25/16C. Transpiration rates were lower and photosynthetic rates were higher under elevated CO₂ than at the ambient level. Biomass production was higher only for plants grown at 700 μ l-liter⁻¹ and 25/16C. Concentrations of macronutrients were lower in plants exposed to 1000 μ l CO₂/liter than in the control plants. Intermittent CO₂ was applied using two timing methods. In method 1, plants were exposed to 4- or 8-hour high-CO₂ concentrations during their 12-hour photoperiod. In method 2, plants were exposed for 3.5 days of each week to 700 μ l CO₂/liter. Only two of the 8-hour exposures resulted in greater growth than the controls. The lack of higher growth for CO₂-enriched plants at 22/16C was attributed to a higher dark respiration rate and to respiration rate and a lack of efficient transport of photosynthates out of leaves.

Behboudian, M.H., and R. Lai. 1995. Partitioning of photoassimilates in virosa tomatoes under elevated CO₂ concentration. *Journal of Plant Physiology* 147(1):43-47.

The effect of CO₂ enrichment on the distribution of assimilates in tomato plants, *Lycopersicon esculentum* Mill. cv. 'Virosa', was studied using C-14-label. Plants were defoliated except for leaves 8, 9, and 10 (numbered acropetally). Depending on the experiment, truss 1 or trusses 1 and 2 were maintained on the plant. Within a 24-h period, the labelled leaf (leaf 10) retained high levels of C-14 in both control and CO₂-enriched plants. Truss 1 was the dominant sink for both CO₂ treatments, drawing on a considerable supply of C-14 re-exported from leaf 8 and leaf 9. The stem and root were transitory sinks and had the capacity to re-export C-14 at different rates during the light and dark periods. Pattern of photoassimilate partitioning was not affected by CO₂ treatment.

Behboudian, M.H., and C. Tod. 1995. Postharvest attributes of virosa tomato fruit produced in an enriched carbon-dioxide environment. *Hortscience* 30(3):490-491.

The effect of preharvest CO₂ enrichment (1000 μ l . liter(-1)) on postharvest quality of tomato fruit (*Lycopersicon esculentum* Mill. 'Virosa') was studied with an emphasis on soluble sugars, ripening, and mineral composition. High-CO₂ fruit had higher concentrations of sucrose, glucose, fructose, and total soluble solids than ambient-CO₂ fruit. High-CO₂ fruit also ripened more slowly and was characterized by lower respiration and ethylene production rates than ambient-CO₂ fruit. Concentrations of N, P, and K were lower in the high-CO₂ fruit than in the ambient- CO₂ fruit, whereas those of S, Ca, and Mg were the same for both treatments. Preharvest CO₂ enrichment of 'Virosa' tomato enhances fruit desirability in terms of slower postharvest ripening and higher concentrations of soluble sugars and total soluble solids.

Bellisario, L.M., J.L. Bubier, T.R. Moore, and J.P. Chanton. 1999. Controls on CH₄ emissions from a northern peatland. *Global Biogeochemical Cycles* 13(1):81-91.

We examined the controls on summer CH₄ emission from five sites in a peatland complex near Thompson, Manitoba, Canada, representing a minerotrophic gradient from bog to rich fen at wet sites, where the water table positions ranged from -10 to -1 cm. Average CH₄ flux, determined by static chambers on collars, ranged from 22 to 239 mg CH₄-C m⁻² d⁻¹ and was related to peat temperature. There was an inverse relationship between water table position and CH₄ flux: higher water tables led to smaller fluxes. The determination of anaerobic CH₄ production and aerobic CH₄ consumption potentials in laboratory incubations of peat samples was unable to explain much of the variation in CH₄ flux. Average net ecosystem exchange of CO₂ ranged from 1.4 to 2.5 g CO₂-C m⁻² d⁻¹ and was strongly correlated with CH₄ flux; CH₄ emission averaged 4% of CO₂ uptake. End-of-season sedge biomass was also strongly related to CH₄ flux, indicating the important role that vascular plants play in regulating CH₄ flux. Determination of isotopic signatures in peat pore water CH₄ revealed average δ (13)C values of between -50 and -73 parts per thousand and δ D of between -368 and -388 parts per thousand. Sites with large CH₄ emission rates also had high CO₂ exchange rates and enriched δ (13)C CH₄

signatures, suggesting the importance of the acetate fermentation pathway of methanogenesis. Comparison of δD and $\delta^{13}C$ signatures in pore water CH_4 revealed a slope shallow enough to suggest that oxidation is not an important overall control on CH_4 emissions at these sites, though it appeared to be important at one site. Analysis of $C-14$ in pore water CH_4 showed that most of the CH_4 was of recent origin with percent of modern carbon values of between 112 and 128%. The study has shown the importance of vascular plant activities in controlling CH_4 emissions from these wetland sites through influences on the availability of fresh plant material for methanogenesis, rhizospheric oxidation, and plant transport of CH_4 .

BenBrahim, M., D. Loustau, J.P. Gaudillere, and E. Saur. 1996. Effects of phosphate deficiency on photosynthesis and accumulation of starch and soluble sugars in 1-year-old seedlings of maritime pine (*Pinus pinaster* Ait). *Annales Des Sciences Forestieres* 53(4):801-810.

Maritime pine seedlings were grown in 4 L pots filled with coarse sand in a greenhouse. Seedlings were supplied with a nutrient solution with three different concentrations of phosphorus (0, 0.125 and 0.5 mM). After 1 year of growth, gas exchange measurements were performed on mature needles. From these measurements, the main parameters of CO_2 assimilation (the carboxylation efficiency, the apparent quantum efficiency and the maximal rate of electron transport) were estimated using the biochemical model of photosynthesis as described by Farquhar et al (1980). Leaf nonstructural carbohydrates were also analyzed. Phosphorus deficiency decreased the phosphorus foliar concentration, but did not affect foliar nitrogen concentration. The maximal rate of photosynthesis, the carboxylation efficiency and the apparent quantum efficiency decreased in phosphorus deficient seedlings. However, the maximal rate of electron transport and stomatal conductance were not affected by phosphorus supply. Low phosphorus nutrition caused a dramatic increase in foliar starch level at the end of the photoperiod. These results indicate that inadequate phosphorus nutrition principally affected the dark reactions of photosynthesis, the apparent quantum efficiency and starch accumulation.

Bender, J., U. Hertstein, and C.R. Black. 1999. Growth and yield responses of spring wheat to increasing carbon dioxide, ozone and physiological stresses: a statistical analysis 'ESPACE-wheat' results. *European Journal of Agronomy* 10(3-4):185-195.

One of the major goals of the European Stress Physiology and Climate Experiment (ESPACE-wheat) was to investigate the sensitivity of wheat growth and productivity to the combined effects of changes in CO_2 concentration, ozone and other physiological stresses. Experiments were performed at different sites throughout Europe, over three consecutive growing-seasons using open-top chambers. This paper summarizes the main experimental findings of the effects of CO_2 enrichment and other factors i.e. ozone (O-3), drought stress or nitrogen supply on the biomass and yield of spring wheat (*Triticum aestivum* cv. Minaret). Final harvest data from different sites and seasons were statistically analysed: (1) to identify main effects and interactions between experimentally controlled factors; and (2) to evaluate quantitative relationships between environmental variables and biological responses. Generally, 'Minaret'

wheat did not respond significantly to O-3, suggesting that this cultivar is relatively tolerant to the O-3 levels applied. The main effect of CO_2 was a significant enhancement of grain yield and above-ground biomass in almost all experiments. Significant interactions between CO_2 and other factors were not common, although modifications in different N- and water supplies also led to significant effects on grain yield and biomass. In addition, climatic factors (in particular: mean air temperature and global radiation) were identified as important co-variables affecting grain yield or biomass, respectively. On average, the yield increase as a result of a doubling of $[CO_2]$ was 35% compared with that observed at ambient CO_2 concentrations. However, linear regressions of grain yield or above-ground biomass for individual experiments revealed a large variability in the quantitative responses of 'Minaret' wheat to CO_2 enrichment (yield increase ranging from 11 to 121%). Hence, CO_2 responsiveness was shown to differ considerably when the same cultivar of wheat was grown at different European locations. Multiple regression analyses performed to evaluate the relative importance of the measured environmental parameters on grain yield indicated that although yield was significantly related to five independent variables (24 h mean CO_2 concentration, 12 h mean O-3 concentration, temperature, radiation, and drought stress), a large proportion of the observed variability remained unexplained. Bender, J., U. Hertstein, A. Fangmeier, M. van Oijen, H.J. Weigel, and H.J. Jager. 1998. The impact of climate change on yield of wheat in Europe: Results of the European stress physiology and climate experiment (ESPACE-wheat). *Journal of Applied Botany-Angewandte Botanik* 72(1-2):37-42.

The European Stress Physiology and Climate Experiment (ESPACE-wheat) was funded by the EU from 1994-1997. Major goals of the project were 1) to investigate by means of experiments the sensitivity of wheat growth, development and productivity to the combined effects of changes in CO_2 concentration, climatic variables and other physiological stresses, 2) to use experimental data for extension and improvement of process-based wheat growth simulation models, and 3) to apply models to assess the influences on crops of climatic change, CO_2 concentration and additional stresses in Europe. Experimental studies were performed at different sites in Europe through three consecutive seasons by means of open-top chambers according to a common standard protocol, and two simulation models were used for the analysis: AFRCWHEAT2 and LINTULCC. This paper summarizes the main findings of the effects of CO_2 enrichment and other factors such as ozone, drought stress or nitrogen supply on the yield response of spring wheat (*Triticum aestivum* cv. Minaret). A comparison of the measured data with the main outputs of the LINTULCC model simulations is presented. Generally, Minaret wheat did not respond significantly to ozone. CO_2 enrichment had a positive influence on grain yield in almost all experiments, however, significant interactions between CO_2 and other factors were not common. The average measured yield increase due to CO_2 doubling was 35 % compared to grain yield measured at ambient CO_2 concentrations, although there was a great variability in yield responses between sites and years. LINTULCC predicted a 42 % yield increase, but a much smaller variation between individual experiments. Although the effects of CO_2 and O-2 on crop growth and yield were acceptably simulated, observed process-rates often showed variation not related to light intensity, temperature, CO_2 or O-2, ie, not related to the main driving variables of the models. This unexplained variability in the measured datasets suggested a role of factors which were not accounted for in the models.

Bernstson, G.M., K.D.M. McConnaughay, and F.A. Bazzaz. 1993. Elevated CO₂ alters deployment of roots in small growth containers. *Oecologia* 94(4):558-564.

Previously we examined how limited rooting space and nutrient supply influenced plant growth under elevated atmospheric CO₂ concentrations (McConnaughay et al. 1993). We demonstrated that plant growth enhancement under elevated CO₂ was influenced more by the concentration of nutrients added to growth containers than to either the total nutrient content per pot or amount or the dimensions of available rooting space. To gain insight into how elevated CO₂ atmospheres affect how plants utilize available belowground space when rooting space and nutrient supply are limited we measured the deployment of roots within pots through time. Contrary to aboveground responses, patterns of below-ground deployment were most strongly influenced by elevated CO₂ in pots of different volume and shape. Further, elevated CO₂ conditions interacted differently with limited belowground space for the two species we studied, *Abutilon theophrasti*, a C3 dicot with a deep taproot, and *Setaria faberii*, a C4 monocot with a shallow fibrous root system. For *Setaria*, elevated CO₂ increased the size of the largest region of low root density at the pot surface in larger rooting volumes independent of nutrient content, thereby decreasing their efficiency of deployment. For *Abutilon*, plants responded to elevated CO₂ concentrations by equalizing the pattern of deployment in all the pots. Nutrient concentration, and not pot size or shape, greatly influenced the density of root growth. Root densities for *Abutilon* and *Setaria* were similar to those observed in field conditions, for annual dicots and monocots respectively, suggesting that studies using pots may successfully mimic natural conditions.

Berntson, G.M., and F.A. Bazzaz. 1996. The allometry of root production and loss in seedlings of *Acer rubrum* (Aceraceae) and *Betula papyrifera* (Betulaceae): Implications for root dynamics in elevated CO₂. *American Journal of Botany* 83(5):608-616.

Total root production (Sigma P), total root loss (Sigma L), net root production (NP), and biomass production were determined for seedlings of *Betula papyrifera* and *Acer rubrum* in ambient and elevated CO₂ environments. Sigma P, Sigma L, and NP were calculated from sequential, independent observations of root length production through plexiglass windows. Elevated CO₂ increased Sigma P, Sigma L, and NP in seedlings of *Betula papyrifera* but not *Acer rubrum*. Root production and loss were qualitatively similar to whole-plant growth responses to elevated CO₂. *Betula* showed enhanced Sigma P, Sigma L, and biomass with elevated CO₂ but *Acer* did not. However, the observed effects of CO₂ on root production and loss did not alter the allometric relationship between root production and root loss for either *Acer* or *Betula*. Thus, in this experiment, elevated CO₂ did not affect the relationship between root production and root loss. The results of this study have important implications for the potential effects of elevated CO₂ on root dynamics. Elevated CO₂ may lead to increases in root production and in root loss (turnover) where the changes in root turnover are largely a function of the magnitude of root production increases.

Berntson, G.M., and F.A. Bazzaz. 1996. Belowground positive and negative feedbacks on CO₂ growth enhancement. *Plant and Soil* 187(2):119-131.

In this paper we present a conceptual model of integrated plant-soil interactions which illustrates the importance of identifying the primary belowground feedbacks, both positive and negative, which can simultaneously affect plant growth responses to elevated CO₂. The primary negative feedbacks share the common feature of reducing the amount of nutrients available to plants. These negative feedbacks include increased litter C/N ratios, and therefore reduced mineralization rates, increased immobilization of available nutrients by a larger soil microbial pool, and increased storage of nutrients in plant biomass and detritus due to increases in net primary productivity (NPP). Most of the primary positive feedbacks share the common feature of being plant mediated feedbacks, the only exception being Zak et al.'s hypothesis that increased microbial biomass will be accompanied by increased mineralization rates. Plant nutrient uptake may be increased through alterations in root architecture, physiology, or mycorrhizal symbioses. Further, the increased C/N ratios of plant tissue mean that a given level of NPP can be achieved with a smaller supply of nitrogen. Identification of the net plant-soil feedbacks to enhanced productivity with elevated CO₂ are a critical first step for any ecosystem. It is necessary, however, that we first identify how universally applicable the results are from one study or one ecosystem before ecosystem models incorporate this information. The effect of elevated CO₂ on plant growth (including NPP, tissue quality, root architecture, mycorrhizal symbioses) can vary greatly for different species and environmental conditions. Therefore it is reasonable to expect that different ecosystems will show different patterns of interacting positive and negative feedbacks within the plant-soil system. This inter-ecosystem variability in the potential for long-term growth responses to rising CO₂ levels implies that we need to parameterize mechanistic models of the impact of elevated CO₂ on ecosystem productivity using a detailed understanding of each ecosystem of interest.

Berntson, G.M., and F.A. Bazzaz. 1997. Elevated CO₂ and the magnitude and seasonal dynamics of root production and loss in *Betula papyrifera*. *Plant and Soil* 190(2):211-216.

The impact of elevated atmospheric CO₂ on belowground plant growth is poorly understood relative to its effects on aboveground growth. We carried out a study of the seasonal dynamics of gross root production and death to determine how elevated CO₂ affected the dynamics of net and gross root production through a full growing season. We quantified gross root production and root loss from sequential, in situ images of fine roots of *Betula papyrifera* in ambient (375 ppm) and elevated (700 ppm) CO₂ atmospheres from 2 weeks following germination through leaf senescence. We found that elevated CO₂ led to increases in the magnitude of cumulative gross production (Sigma P) and cumulative gross loss (Sigma L) of roots. However, the effect of elevated CO₂ on these processes was seasonally dependent. Elevated CO₂ led to greater levels of enhancement in Sigma P early in the growing season, prior to maximum standing root length (NP). In contrast, elevated CO₂ led to greater levels of enhancement in Sigma L in the last half of the growing season, after maximum NP had been reached. This difference in the timing of when elevated CO₂ affects Sigma P and Sigma L led to a transitory, early enhancement in NP. By the end of the growing season, there was no significant effect of elevated CO₂ on NP, and Sigma P was 87% greater than NP for ambient CO₂ and 117% greater in elevated

CO₂. We conclude that static assessments of belowground productivity may greatly underestimate gross fine root productivity and turnover and this bias can be exaggerated with elevated CO₂.

Berntson, G.M., and F.A. Bazzaz. 1997. Nitrogen cycling in microcosms of yellow birch exposed to elevated CO₂: Simultaneous positive and negative below-ground feedbacks. *Global Change Biology* 3(3):247-258.

This study investigated simultaneous plant and soil feedbacks on growth enhancement with elevated [CO₂] within microcosms of yellow birch (*Betula alleghaniensis* Britt.) in the second year of growth. Understanding the integrated responses of model ecosystems may provide key insight into the potential net nutrient feedbacks on [CO₂] growth enhancements in temperate forests. We measured the net biomass production, C:N ratios, root architecture, and mycorrhizal responses of yellow birch, in situ rates gross nitrogen mineralization and the partitioning of available NH₄⁺ between yellow birch and soil microbes. Elevated atmospheric [CO₂] resulted in significant alterations in the cycling of N within the microcosms. Plant C/N ratios were significantly increased, gross mineralization and NH₄⁺ consumption rates were decreased, and relative microbial uptake of NH₄⁺ was increased, representing a suite of N cycling negative feedbacks on N availability. However, increased C/N ratios may also be a mechanism which allows plants to maintain higher growth with a constant or reduced N supply. Total plant N content was increased with elevated [CO₂], suggesting that yellow birch had successfully increased their ability to acquire nutrients during the first year of growth. However, plant uptake rates of NH₄⁺ had decreased in the second year. This discrepancy implies that, in this study, nitrogen uptake skewed a trend through ontogeny of decreasing enhancement under elevated [CO₂]. The reduced N mineralization and relatively increased N immobilization are a potential feedback which may drive this ontogenetic trend. This study has demonstrated the importance of using an integrated approach to exploring potential nutrient-cycling feedbacks in elevated [CO₂].

Berntson, G.M., and F.A. Bazzaz. 1998. Regenerating temperate forest mesocosms in elevated CO₂: belowground growth and nitrogen cycling. *Oecologia* 113(1):115-125.

The response of temperate forest ecosystems to elevated atmospheric CO₂ concentrations is important because these ecosystems represent a significant component of the global carbon cycle. Two important but not well understood processes which elevated CO₂ may substantially alter in these systems are regeneration and nitrogen cycling. If elevated CO₂ leads to changes in species composition in regenerating forest communities then the structure and function of these ecosystems may be affected. In most temperate forests, nitrogen appears to be a limiting nutrient. If elevated CO₂ leads to reductions in nitrogen cycling through increased sequestration of nitrogen in plant biomass or reductions in mineralization rates, long-term forest productivity may be constrained. To study these processes, we established mesocosms of regenerating forest communities in controlled environments maintained at either ambient (375 ppm) or elevated (700 ppm) CO₂ concentrations.

Mesocosms were constructed from intact monoliths of organic forest soil. We maintained these mesocosms for 2 years without any external inputs of nitrogen and allowed the plants naturally present as seeds and rhizomes to regenerate. We used N-15 pool dilution techniques to quantify nitrogen fluxes within the mesocosms at the end of the 2 years. Elevated atmospheric CO₂ concentration significantly affected a number of plant and soil processes in the experimental regenerating forest mesocosms. These changes included increases in total plant biomass production, plant C/N ratios, ectomycorrhizal colonization of tree fine roots, changes in tree fine root architecture, and decreases in plant NH₄⁺ uptake rates, gross NH₄⁺ mineralization rates, and gross NH₄⁺ consumption rates. In addition, there was a shift in the relative biomass contribution of the two dominant regenerating tree species; the proportion of total biomass contributed by white birch (*Betula papyrifera*) decreased and the proportion of total biomass contributed by yellow birch (*B. alleghaniensis*) increased. However, elevated CO₂ had no significant effect on the total amount of nitrogen in plant and soil microbial biomass. In this study we observed a suite of effects due to elevated CO₂, some of which could lead to increases in potential long term growth responses to elevated CO₂, other to decreases. The reduced plant NH₄⁺ uptake rates we observed are consistent with reduced NH₄⁺ availability due to reduced gross mineralization rates. Reduced NH₄⁺ mineralization rates are consistent with the increases in C/N ratios we observed for leaf and fine root material. Together, these data suggest the positive increases in plant root architectural parameters and mycorrhizal colonization may not be as important as the potential negative effects of reduced nitrogen availability through decreased decomposition rates in a future atmosphere with elevated CO₂.

Berntson, G.M., N. Rajakaruna, and F.A. Bazzaz. 1998. Growth and nitrogen uptake in an experimental community of annuals exposed to elevated atmospheric CO₂. *Global Change Biology* 4(6):607-626.

Rising levels of atmospheric CO₂ may alter patterns of plant biomass production. These changes will be dependent on the ability of plants to acquire sufficient nutrients to maintain enhanced growth. Species-specific differences in responsiveness to CO₂ may lead to changes in plant community composition and biodiversity. Differences in species-level growth responses to CO₂ may be, in a large part, driven by differences in the ability to acquire nutrients. To understand the mechanisms of how elevated CO₂ leads to changes in community-level productivity, we need to study the growth responses and patterns of nutrient acquisition for each of the species that comprise the community. In this paper, we present a study of how elevated CO₂ affects community-level and species-level patterns of nitrogen uptake and biomass production. As an experimental system we use experimental communities of 11 co-occurring annuals common to disturbed seasonal grasslands in south-western U.S.A. We established experimental communities with approximately even numbers of each species in three different atmospheric CO₂ concentrations (375, 550, and 700 ppm). We maintained these communities for 1, 1.5, and 2 months at which times we applied a N-15 tracer ((NH₄NO₃)-N-15-N-15) to quantify the nitrogen uptake and then measured plant biomass, nitrogen content, and nitrogen uptake rates for the entire communities as well as for each species. Overall, community-level responses to elevated CO₂ were consistent with the majority of other studies of individual- and multispecies assemblages, where elevated CO₂ leads to enhanced biomass production early on, but this enhancement declines through time. In contrast, the responses of the individual species within the communities was highly variable, showing the full range of responses from positive to negative. Due to the large variation in size between the

different species, community-level responses were generally determined by the responses of only one or a few species. Thus, while several of the smaller species showed trends of increased biomass and nitrogen uptake in elevated CO₂ at the end of the experiment, community-level patterns showed a decrease in these parameters due to the significant reduction in biomass and nitrogen content in the single largest species. The relationship between enhancement of nitrogen uptake and biomass production in elevated CO₂ was highly significant for both 550 ppm and 700 ppm CO₂. This relationship strongly suggests that the ability of plants to increase nitrogen uptake (through changes in physiology, morphology, architecture, or mycorrhizal symbionts) may be an important determinant of which species in a community will be able to respond to increased CO₂ levels with increased biomass production. The fact that the most dominant species within the community showed reduced enhancement and the smaller species showed increased enhancement suggest that through time, elevated CO₂ may lead to significant changes in community composition. At the community level, nitrogen uptake rates relative to plant nitrogen content were invariable between the three different CO₂ levels at each harvest. This was in contrast to significant reductions in total plant nitrogen uptake and nitrogen uptake relative to total plant biomass. These patterns support the hypothesis that plant nitrogen uptake is largely regulated by physiological activity, assuming that physiological activity is controlled by nitrogen content and thus protein and enzyme content.

Berntson, G.M., P.M. Wayne, and F.A. Bazzaz. 1997. Below-ground architectural and mycorrhizal responses to elevated CO₂ in *Betula alleghaniensis* populations. *Functional Ecology* 11(6):684-695.

1. Replicate populations of crowded, regenerating stands of *Betula alleghaniensis* were grown in ambient and elevated (700 p.p.m.) atmospheric CO₂ concentrations in monoliths of forest soil. Early in the second year the seedlings were harvested and detailed measurements of individual plant root architectural parameters and ectomycorrhizal colonization were made. 2. Comparing the average responses of individual plants within the populations, elevated CO₂ had no significant effects on architectural parameters that improve a plant's ability to forage for and acquire soil resources. In contrast, the intensity and magnitude of mycorrhizal colonization, and whole plant C/N ratios were significantly enhanced with elevated CO₂. 3. The allometric scaling relationship between total plant biomass and root biomass was not affected by CO₂, suggesting that relative allocation between roots and shoots was not affected. However, the allometric scaling relationships between root architectural parameters and plant biomass, and between fine root biomass and woody root biomass were significantly altered by elevated CO₂. For all of these relationships, elevated CO₂ reduced the 'size bias' of architectural components in relation to plant size within the populations; in elevated CO₂ root architectural size (e.g. root length) per unit biomass was more similar between the smallest and largest individuals within the population than was the case for ambient CO₂. 4. Overall, the results of this study suggest that the average individual seedling biomass and architectural growth responses within populations of plants exposed to elevated atmospheric CO₂ levels may be unresponsive, but that mycorrhizal responses and interactions among plants within populations may be altered significantly. These findings have important implications for how we make predictions about plant growth responses to elevated CO₂ in natural ecosystems. Significant increases in mycorrhizal infection rates and architecture-biomass allometries suggest that below-ground competitive interactions within plant populations may be reduced in elevated CO₂. Alterations in competitive interactions may lead to shifts in productivity and plant population structure.

Berntson, G.M., and F.I. Woodward. 1992. The root-system architecture and development of *Senecio vulgaris* in elevated CO₂ and drought. *Functional Ecology* 6(3):324-333.

1. The impact of elevated CO₂ and drought on the architecture and development of root systems of *Senecio vulgaris* was examined and implications for water and nutrient uptake discussed. Plants were grown in miniature rhizotrons to non-destructively monitor the development of roots in situ at both an elevated (700-μmol mol⁻¹) and ambient (350-μmol mol⁻¹) atmospheric CO₂ concentration and a high or a low supply of water. 2. CO₂ and water had a significant impact on the way that *S. vulgaris* root systems filled the soil matrix. Elevated CO₂ resulted in more branched, longer root systems that foraged through larger volumes of soil. Under elevated CO₂ and a low water supply, root systems had branching and foraging patterns and root length similar to those grown under ambient CO₂ with a high water supply. 3. Overall, water had a more pronounced impact on the growth rate of *S. vulgaris* roots than did CO₂. The density of rooting remained unchanged across all treatments. Thus, under elevated CO₂ the intensity of foraging *S. vulgaris* root systems might be unchanged while the extent of foraging by these root systems, as indicated by the horizontal spread of roots, may be increased.

Berry, S.C., G.T. Varney, and L.B. Flanagan. 1997. Leaf δ¹³C-13 in *Pinus resinosa* trees and understory plants: Variation associated with light and CO₂ gradients. *Oecologia* 109(4):499-506.

Our objective was to evaluate the relative importance of gradients in light intensity and the isotopic composition of atmospheric CO₂ for variation in leaf carbon isotope ratios within a *Pinus resinosa* forest. In addition, we measured photosynthetic gas exchange and leaf carbon isotope ratios on four understory species (*Dryopteris carthusiana*, *Epipactis helleborine*, *Hieracium floribundum*, *Rhamnus frangula*), in order to estimate the consequence of the variation in the understory light microclimate for carbon gain in these plants. During midday, CO₂ concentration was relatively constant at vertical positions ranging from 15 m to 3 m above ground. Only at positions below 3 m was CO₂ concentration significantly elevated above that measured at 15 m. Based on the strong linear relationship between change in CO₂ concentration and δ¹³C values for air samples collected during a diurnal cycle, we calculated the expected vertical profile for the carbon isotope ratio of atmospheric CO₂ within the forest. These calculations indicated that leaves at 3 m height and above were exposed to CO₂ of approximately the same isotopic composition during daylight periods. There was no significant difference between the daily mean δ¹³C values at 15 m (-7.77 parts per thousand) and 3 m (-7.89 parts per thousand), but atmospheric CO₂ was significantly depleted in C-13 closer to the ground surface, with daily average δ¹³C values of -8.85 parts per thousand at 5 cm above ground. The light intensity gradient in the forest was substantial, with average photosynthetically active radiation (PAR) on the forest floor approximately 6% of that received at the top of the canopy. In contrast, there were only minor changes in air temperature, and so it is likely that the leaf-air vapour pressure difference was relatively constant from the top of the canopy to the forest floor. For red pine and elm tree samples, there was a significant correlation between leaf δ¹³C value and the height at which the leaf sample was collected. Leaf tissue sampled near the forest floor, on average, had lower δ¹³C values than samples collected near the top of the canopy. We suggest that the average light intensity gradient through the

canopy was the major factor influencing vertical changes in tree leaf $\delta(13)\text{C}$ values. In addition, there was a wide range of variation (greater than 4 parts per thousand) among the four understory plant species for average leaf $\delta(13)\text{C}$ values. Measurements of leaf gas exchange, under natural light conditions and with supplemental light, were used to estimate the influence of the light microclimate on the observed variation in leaf carbon isotope ratios in the understory plants. Our data suggest that one species, *Epipactus helleborine*, gained a substantial fraction of carbon during sunflecks.

Berryman, C.A., D. Eamus, and G.A. Duff. 1993. The influence of CO_2 enrichment on growth, nutrient content and biomass allocation of *maranthescorymbosa*. *Australian Journal of Botany* 41(2):195-209.

Seedlings of *Maranthescorymbosa* Blume, an evergreen tree of tropical Australia and Indonesia were grown for 32 weeks under conditions of ambient and elevated (700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) CO_2 in tropical northern Australia. Seedlings were exposed to ambient temperature, vapour pressure deficit and photon flux density fluctuations. Rates of germination and percentage germination were not affected by elevated CO_2 . Total plant biomass, height growth, total plant leaf area, numbers of leaves and branches and specific leaf weight were significantly increased by elevated CO_2 . Root:shoot ratio and foliar P, K, Mg, Mn and Ca levels were unaffected but foliar nitrogen levels were decreased by elevated CO_2 . Nutrient-use-efficiency was unaffected for phosphorus, magnesium, manganese, calcium and potassium but nitrogen-use-efficiency increased in response to elevated CO_2 .

Berryman, C.A., D. Eamus, and G.A. Duff. 1994. Stomatal responses to a range of variables in 2 tropical tree species grown with CO_2 enrichment. *Journal of Experimental Botany* 45(274):539-546.

Seedlings of *Maranthescorymbosa* (Blume) and *Eucalyptus tetrodonta* (F. Muell) were grown with or without CO_2 enrichment (700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$). The response of stomatal conductance ($g(s)$) to leaf drying, exogenous abscisic acid and calcium ions was investigated in *M. corymbosa*. Reciprocal transfer experiments were also conducted whereby plants were grown in one treatment and then transferred to the other before $g(s)$ was measured. Stomatal conductance in *M. corymbosa* was more sensitive (a greater percentage decline in $g(s)$ per unit percentage decline in leaf fresh weight) to leaf water status under conditions of CO_2 enrichment compared to ambient conditions. However, the rate of reduction of $g(s)$ in response to exogenous abscisic acid was not influenced by CO_2 treatment. In contrast, the rate of reduction of $g(s)$ in response to exogenous CaCl_2 was decreased under conditions of CO_2 enrichment. Reciprocal transfer experiments showed that exposure to CO_2 enrichment results in a short-term, reversible decline in $g(s)$ as a result of decreased stomatal aperture and a long-term, irreversible decline in $g(s)$ as a result of a decreased stomatal density. Seedlings of *E. tetrodonta* were used to investigate the response of $g(s)$ to light flux density, leaf-to-air vapour pressure difference (LAVPD), leaf internal CO_2 concentration (C_i) and temperature. Reciprocal transfer experiments were also conducted. CO_2 enrichment did not influence the pattern or sensitivity of response of $g(s)$ to LAVPD and C_i

in *E. tetrodonta*. In contrast, the slope of the response of $g(s)$ to temperature decreased for trees grown under elevated $[\text{CO}_2](a)$ conditions and the equilibrium $g(s)$ attained at saturating light was also decreased for plants grown under elevated $[\text{CO}_2](a)$ conditions.

Bertani, A., I. Brambilla, S. Mapelli, and R. Reggiani. 1997. Elongation growth in the absence of oxygen: The rice coleoptile. *Russian Journal of Plant Physiology* 44(4):543-547.

Rice, one of the few plant species adapted to growth in wetland conditions, is able to germinate in waterlogged soils promoting only the growth of a white coleoptile in order to reach the surface of the water, contact the atmosphere, and transfer oxygen to the seed, allowing subsequent growth of the radicle and leaf. In the anoxic cells of rice coleoptiles, an efficient alcoholic fermentation allows an elevated energy charge to be maintained. Significant RNA and protein syntheses including phosphorylation and glycosylation occur too. The cytoplasmic pH is maintained at a level far from acidosis. The anoxic growth of rice coleoptiles, essentially an elongation growth, is sustained by a high turgor pressure, with free amino acids and potassium as main components. Among the metabolic processes involved in the regulation of the elongation of rice coleoptiles, a crucial role is played by amino acid metabolism and the accumulation of putrescine, which is able to stimulate plasmalemma ATPase activity. Anaerobic elongation is also stimulated in the presence of 20% CO_2 in the growth medium, inhibited by light and abscisic acid, unaffected by ethylene, and slightly promoted by auxin. The role of both metabolites and hormones along with environmental factors in maintaining cellular homeostasis and coleoptile elongation are reconsidered and discussed in light of new data.

Bertin, N., and C. Gary. 1993. Evaluation of tomgro, a dynamic-model of growth and development of tomato (*lycopersicon-esculentum* mill) at various levels of assimilate supply-and-demand. *Agronomie* 13(5):395-405.

TOMGRO, a tomato growth and development model, has been examined under different levels of assimilate source and sink activities, induced by CO_2 enrichment and truss thinning. The main purpose was the evaluation of the assumptions on dry matter partitioning and fruit setting. The photosynthesis submodel has been calibrated to fit the daily dry matter production. The main input parameters to the development and growth submodels have been experimentally measured. The calibrated model provides good simulations of the leaf area expansion, but it takes no account of the variations in the assimilates stored in leaf blades. Total fruit growth is well simulated in spite of a small underestimation for development and simulations of source/sink balance leads to good simulations of the number of set fruits. This result confirms the hypothesis that fruit set depends on the ratio between assimilate source and sink activities. This calibration with a beef tomato cultivar proves the robustness of the model and permits some improvements to be suggested. The surplus assimilates should be stored in a pool, which could exert a buffer effect during low supply periods. Sink strength of reproductive and vegetative parts should be measured for different cultivars, and under various climatic conditions. Finally, whether the functions of assimilate distribution and fruit set are still valid under very low supply conditions or whether some organs have

priority over the others remains to be determined.

Bertin, N., and C. Gary. 1998. Short and long term fluctuations of the leaf mass per area of tomato plants - Implications for growth models. *Annals of Botany* 82(1):71-81.

The leaf mass per unit leaf area (LMA) is a key variable in many growth models, since it is often used to predict leaf area expansion from leaf dry weight increase, or vice versa. Influences of source-sink balance on leaf area, leaf dry weight, LMA, and leaf content in non-structural carbohydrates were investigated in glasshouse tomato crops. The source-sink balance was manipulated by artificial shading, CO₂ enrichment or fruit removal using different tomato cultivars. Leaf area was hardly affected by competition for assimilates except under extreme conditions. In contrast, leaf dry weight, and consequently LMA, underwent large and rapid fluctuations in response to any factor that changed source and sink activities. A 60% reduction of photosynthetically active radiation involved a 24% decrease in LMA after 10 d. Carbon dioxide enrichment and fruit removal induced about a 45% and 15% increase in LMA, respectively, on plants with two fruiting trusses, but hardly affected LMA of producing plants. No significant cultivar effect could be identified. Changes in starch and soluble sugar content in leaves accounted for only 29% of diurnal variations in LMA, suggesting regular fluctuations of other components. We propose that structural LMA varies between a maximum and a minimum value according to the ratio of assimilate supply and demand during leaf development. Leaf area is independent of the supply of assimilates when the minimum structural LMA is realised. When the maximum structural LMA is attained, a storage pool of assimilates may accumulate in leaves during periods of high supply and low demand. We present a model including these hypotheses, which predicts structural and non-structural LMA variations of plants with different source-sink ratios. (C) 1998 Annals of Botany Company.

Bertin, N., and E. Heuvelink. 1993. Dry-matter production in a tomato crop - comparison of 2 simulation-models. *Journal of Horticultural Science* 68(6):995-1011.

TOMSIM(1.0) and TOMGRO(1.0) are two dynamic models for tomato growth and development. Their submodels for dry matter production are compared and discussed. In TOMSIM(1.0), dry matter production is simulated by a modified version of SUCROS87 (Spitters et al., 1989). Single leaf photosynthesis rates are calculated separately for shaded and sunlit leaf area at different depths in the canopy, according to the direct and diffuse components of light; daily crop gross assimilation rate (A) is computed by integration of these rates over the different depths and over the day. In TOMSIM(1.0) leaf photochemical efficiency (epsilon) and potential leaf gross photosynthesis rate at saturating light level (P(g,max)) both depend on temperature and CO₂ level. In TOMGRO(1.0) crop gross photosynthesis rate is calculated by the equation of Acock et al. (1978); epsilon is a constant and P(g,max) is a linear function of CO₂. In both models leaf photosynthesis characteristics are assumed to be identical in the whole canopy. Maintenance respiration (R(m)) and conversion efficiency (C(f)) are taken into account in the same way, except that root maintenance respiration is neglected in TOMGRO(1.0). For both models a sensitivity analysis was performed on the input variables (light intensity, temperature, CO₂ and leaf area index (LAI)) and on some of the model parameters. Under most conditions considered, simulated A was found to be 5-30% higher in TOMSIM(1.0) than in TOMGRO(1.0). At

temperatures above 18-degrees-C R(m) was also higher in TOMSIM(1.0), and C(f) was 4% higher in TOMGRO(1.0). The two models were very sensitive to changes in epsilon and to a lesser extent to changes in the light extinction coefficient, whereas the scattering coefficient of leaves had hardly any effect on the simulated A. TOMGRO(1.0) appeared to be rather sensitive to the CO₂ use efficiency, whereas at ambient CO₂ level mesophyll resistance was quite important in TOMSIM(1.0). Four sets of experimental data (differences in cultivar, CO₂ enrichment and planting date) from Wageningen (The Netherlands) and Montfavet (southern France) were used to validate the models. Average 24 h temperature and average daily CO₂ concentration values were used as input to the models. For the Wageningen experiments, hourly PAR values were calculated from the daily global radiation sum by TOMSIM(1.0) and used as input in both models. For the Montfavet experiment, average hourly PAR measurements were used. Also measured LAI, dry matter distribution and organ dry weights (for calculation of R(m)) were input to the simulation. In the Wageningen experiments, total dry matter production was simulated reasonably well by both models, whereas in the Montfavet experiment an under-estimation of about 35% occurred. TOMGRO(1.0) and TOMSIM(1.0) simulated almost identical curves in all four experiments. Strong and weak points of both models are discussed.

Bertoni, G.P., and W.M. Becker. 1996. Expression of the cucumber hydroxypyruvate reductase gene is down-regulated by elevated CO₂. *Plant Physiology* 112(2):599-605.

We examined the effects of CO₂ concentration on the white-light-stimulated expression of the cucumber (*Cucumis sativus* L.) Hpr gene. Hpr encodes hydroxypyruvate reductase, an enzyme important in the photorespiratory glycolate pathway, which plays an integral role in carbon allocation in C-3 plants. Because CO₂ is an end product of this pathway and because increased CO₂ concentrations lessen the need for photorespiration, we tested whether exposure of plants to elevated CO₂ would affect white-light-stimulated Hpr gene expression. Exposure of dark-adapted cucumber seedlings to elevated CO₂ (2 to 3 times ambient) during a 4-h white-light irradiation significantly inhibited the accumulation of Hpr mRNA. Increasing the CO₂ concentration during irradiation to 6 or 9 times ambient did not further inhibit Hpr mRNA accumulation. The depressing effect of high CO₂ on Hpr mRNA accumulation was seen in both high and low light, but was more pronounced in higher light. These results suggest that maximum sensitivity to CO₂ occurs in conditions near those normally encountered by the plant (high light, CO₂ concentration near ambient) and support a model in which white-light-regulated Hpr expression is modulated in part by environmental CO₂ concentration.

Besford, R.T. 1993. Photosynthetic acclimation in tomato plants grown in high CO₂. *Vegetatio* 104:441-448.

The effects of prolonged CO₂ enrichment of tomato plants on photosynthetic performance and Calvin cycle enzymes, including the amount and activity of ribulose-1,5-bisphosphate carboxylase (RuBPCo), were determined. Also the light-saturated rate of photosynthesis (P(max)) of the 5th leaf throughout leaf development was predicted based on the amount and kinetics of RuBPCo. With short-term CO₂ enrichment, i.e. only during the photosynthesis measurements, P(max) of the young leaves did not increase while the leaves reaching full

expansion more than doubled their net rate of CO₂ fixation. However, with longer-term CO₂ enrichment, i.e. growing the crop in high CO₂, the plants did not maintain this photosynthetic gain. Compared with leaves of plants grown in normal ambient CO₂ the high CO₂-grown leaves, when almost fully expanded, contained only about half as much RuBPco protein and P(max) in 300 and 1000 vpm CO₂ was similarly reduced. The loss of RuBPco protein may be a factor associated with the accelerated fall in P(max) since P(max) was close to that predicted from the amount and kinetics of RuBPco assuming RuBP saturation. Acclimation to high CO₂ is fundamentally different from acclimation to high light. In contrast to acclimation to high light, acclimation to high CO₂ does not usually involve an increase in photosynthetic machinery so the synthesis and maintenance costs (as indicated by the dark respiration rate) are generally lower.

Betsche, T. 1994. Atmospheric CO₂ enrichment - kinetics of chlorophyll a fluorescence and photosynthetic CO₂ uptake in individual, attached cotton leaves. *Environmental and Experimental Botany* 34(1):75-86.

Chl fluorescence and gas exchange of attached cotton leaves (*Gossypium hirsutum* L.) were measured in ambient air and in a highly CO₂-enriched atmosphere (4000 μ l l⁻¹ CO₂; photosynthetic saturation). In the short term (hours to one day), net CO₂ uptake approximately doubled in all leaves examined. Photochemical (q(P)) and nonphotochemical (q(NP)) quenching of chlorophyll fluorescence, and calculated linear photosynthetic electron flow, did not change significantly when CO₂ rose from 250 to 4000 μ l l⁻¹ CO₂. These results show that high CO₂ concentration did not inhibit photosynthesis in any leaf. In contrast, the long-term response of leaves to atmospheric CO₂-enrichment was variable. Some leaves sustained the initial high level of photosynthetic stimulation for more than a week while in others photosynthetic CO₂-uptake declined more or less. These leaves turned yellowish-green although chlorophyll content declined little. Variance in the degree of leaf yellowing was also encountered in experiments with clover when sets of plants were CO₂-enriched. Gas exchange and chl fluorescence results suggest that yellowing of cotton leaves in high CO₂ was not equivalent to 'natural' senescence although some chlorophyll fluorescence parameters changed similarly. During extended high CO₂ treatment the level of q(NP) increased notably in the yellowing leaves. The high levels of q(NP) and relaxation kinetics of chl fluorescence quenching recorded upon darkening demonstrate that thylakoid energization increased during the decline of photosynthetic CO₂ uptake in high CO₂. This shows that the photosynthetic decline was not caused by decreasing thylakoid energization because of physical damage by oversized starch grains. Calculated photosynthetic electron flow declined little suggesting that CO₂ at ribulosebiphosphate carboxylase-oxygenase fell and thus photorespiration rose. With regard to growth limitation in high CO₂ concentration, these results support the concept that high CO₂ concentration tends to induce low inorganic phosphate concentrations (Morin et al. *Plant Physiol.* 99, 89-95, 1992; Duchein et al. *J. Exp. Bot.* 44, 17-22, 1993) which can limit chloroplast ATP synthase and thus increase thylakoid energization. It is proposed that the different responses of individual leaves to atmospheric CO₂ enrichment reflects variety among leaves in the phosphate status or in the capacity for Pi-recycling (assimilate utilization).

Bettarini, I., G. Calderoni, F. Miglietta, A. Raschi, and J. Ehleringer. 1995. Isotopic carbon discrimination and leaf nitrogen-content of erica-arborea L along a CO₂ concentration gradient in a CO₂ spring in Italy. *Tree Physiology* 15(5):327-332.

We studied a Mediterranean species (*Erica arborea* L.) growing in a CO₂ spring in Italy that was naturally exposed for generations to a gradient of atmospheric CO₂ concentrations. The CO₂ concentration gradient to which different individual plants were exposed was determined by an indirect method based on radioisotope analysis. The stable carbon isotope ratio of sampled leaves was determined by mass spectrometry, and isotopic discrimination was then calculated. Leaf nitrogen, specific leaf area, total soil nitrogen, soil organic matter content and soil pH were also measured. In one group of plants, grown on a homogeneous soil and exposed to moderate CO₂ enrichment, isotopic discrimination was significantly reduced in response to increasing CO₂ concentrations, whereas the intercellular CO₂ concentration and leaf nitrogen content were almost unaffected. In a second group of plants, grown along a gradient of CO₂ concentration and soil nitrogen content, leaf nitrogen content was reduced when nitrogen availability was limiting. However, when soil nitrogen was available in excess, even very high CO₂ concentrations did not result in increased discrimination or reduced leaf nitrogen content in the long term. The results are discussed with respect to current theories about the long-term CO₂ response of plants based on several years of experimentation with elevated atmospheric CO₂ concentrations under controlled conditions.

Bettarini, I., F.P. Vaccari, and F. Miglietta. 1998. Elevated CO₂ concentrations and stomatal density: observations from 17 plant species growing in a CO₂ spring in central Italy. *Global Change Biology* 4(1):17-22.

Stomatal density (SD) and stomatal conductance (g(s)) can be affected by an increase of atmospheric CO₂ concentration. This study was conducted on 17 species growing in a naturally enriched CO₂ spring and belonging to three plant communities. Stomatal conductance, stomatal density and stomatal index (SI) of plants from the spring, which were assumed to have been exposed for generations to elevated [CO₂], and of plants of the same species collected in a nearby control site, were compared. Stomatal conductance was significantly lower in most of the species collected in the CO₂ spring and this indicated that CO₂ effects on g, are not of a transitory nature but persist in the long term and through plant generations. Such a decrease was, however, not associated with changes in the anatomy of leaves: SD was unaffected in the majority of species (the decrease was only significant in three out of the 17 species examined), and also SI values did not vary between the two sites with the exception of two species that showed increased SI in plants grown in the CO₂-enriched area. These results did not support the hypothesis that long-term exposure to elevated [CO₂] may cause adaptive modification in stomatal number and in their distribution.

Betts, R.A., P.M. Cox, S.E. Lee, and F.I. Woodward. 1997. Contrasting physiological and structural vegetation feedbacks in climate change simulations. *Nature* 387(6635):796-799.

Anthropogenic increases in the atmospheric concentration of carbon

dioxide and other greenhouse gases are predicted to cause a warming of the global climate by modifying radiative forcing(1). Carbon dioxide concentration increases may make a further contribution to warming by inducing a physiological response of the global vegetation-a reduced stomatal conductance, which suppresses transpiration(2). Moreover, a CO₂-enriched atmosphere and the corresponding change in climate may also alter the density of vegetation cover, thus modifying the physical characteristics of the land surface to provide yet another climate feedback(3-6). But such feedbacks from changes in vegetation structure have not yet been incorporated into general circulation model predictions of future climate change. Here we use a general circulation model iteratively coupled to an equilibrium vegetation model to quantify the effects of both physiological and structural vegetation feedbacks on a doubled- CO₂ climate. On a global scale, changes in vegetation structure are found to partially offset physiological vegetation-climate feedbacks in the long term, but overall vegetation feedbacks provide significant regional-scale effects.

Bezemer, T.M., and T.H. Jones. 1998. Plant-insect herbivore interactions in elevated atmospheric CO₂: quantitative analyses and guild effects. *Oikos* 82(2):212-222.

Interactions between insect herbivores and plants grown under conditions of ambient and elevated CO₂ were investigated by analysing data on 43 herbivores, representing 61 plant- herbivore interactions. Changes in herbivore performance in enhanced CO₂ environments were correlated with changes in the quality of the host plants, measured as nitrogen content, water content, carbohydrate content and secondary plant compounds. The data were analysed to determine whether CO₂ mediated effects on insect performance differed between feeding guilds (leaf-chewers, leaf miners, phloem-feeders (root and shoot), xylem-feeders, whole-cell-feeders and seed-eaters) or instar stage. Host-plant quality changed in elevated CO₂; leaf nitrogen content decreased, on average, by 15% while carbohydrates increased by 47% and secondary plant compounds (phenolics) by 31%. Water content did not change. Of the variables measured, changes in nitrogen and carbohydrate levels only were found to be correlated with changes in food consumption. No differences were found in CO₂-mediated herbivore responses on woody plant compared with non-woody plants. Insects from different feeding guilds respond to CO₂ mediated changes in host-plant quality in various ways. Leaf- chewers generally seem able to compensate for the decreased nitrogen levels in the plant tissues by increasing their food consumption (by 30%) and with no adverse effects on pupal weights. Leaf-miners only slightly increase their food consumption. The negative effect on pupal weight suggests that their population dynamics may change over several generations. Limited data on seed-eaters suggest that enhanced CO₂ conditions have no effect on these insects. Phloem-feeders and whole-cell-feeders are the only insects to show a positive CO₂ response. Population sizes generally increased in elevated CO₂ and development time of phloem-feeders was reduced by 17%. Early instar larvae are restricted more by CO₂ enhancement than late instars. Although changes in food consumption are similar, changes in development times are much more pronounced in young instars (18% vs 6%).

Bezemer, T.M., T.H. Jones, and K.J. Knight. 1998. Long-term effects of elevated CO₂ and temperature on populations of the peach potato

aphid *Myzus persicae* and its parasitoid *Aphidius matricariae*. *Oecologia* 116(1-2):128-135.

Model terrestrial ecosystems were set-up in the Ecotron controlled environment facility. The effects of elevated CO₂ (ambient + 200 µmol/mol) and temperature (ambient + 2.0 degrees C) on plant chemistry, the abundance of the peach potato aphid *Myzus persicae*, and on the performance of one of its parasitoids *Aphidius matricariae*, were studied. Total above-ground plant biomass at the end of the experiment was not affected by elevated atmospheric CO₂, nor were foliar nitrogen and carbon concentrations. Elevated temperature decreased final plant biomass while leaf nitrogen concentrations increased. Aphid abundance was enhanced by both the CO₂ and temperature treatment. Parasitism rates remained unchanged in elevated CO₂, but showed an increasing trend in conditions of elevated temperature. Our results suggest that *M. persicae*, an important pest of many crops, might increase its abundance under conditions of climate change.

Bezemer, T.M., K.J. Knight, J.E. Newington, and T.H. Jones. 1999. How general are aphid responses to elevated atmospheric CO₂? *Annals of the Entomological Society of America* 92(5):724-730.

We studied the impact of elevated CO₂ on 2 aphid pest species, *Myzus persicae* and *Brevicoryne brassicae* (Homoptera: Aphididae), on a series of host plants in 3 independent studies each differing in experimental complexity. Measurements on individual aphids showed that host plant and aphid species significantly influenced the response to elevated CO₂. These differences occurred not only in the level of responsiveness but also directionally. *B. brassicae* reared on *Brassica oleracea* produced significantly less offspring at elevated CO₂, whereas the opposite was found for *M. persicae* on the same host. No response was found for *M. persicae* on *Senecio vulgaris*. When populations of *B. brassicae* and *M. persicae* were followed for a longer period, no differences were observed in population sizes. Comparisons between different experimental systems show that long-term population responses to elevated CO₂ can not be reliably predicted from detailed measurements on individual aphids. The consequences of these findings for climate change research are discussed.

Bezemer, T.M., L.J. Thompson, and T.H. Jones. 1998. *Poa annua* shows inter-generational differences in response to elevated CO₂. *Global Change Biology* 4(6):687-691.

Inter-generational effects on the growth of *Poa annua* (L.) in ambient and elevated atmospheric CO₂ conditions (350 and 550 µmol l⁻¹, respectively) were studied in two different experiments. Both experiments showed similar results. In a greenhouse experiment growth, measured as the numbers of tillers produced per week, was compared for plants grown from first and second generation seeds. Second generation seeds were obtained from plants grown for one whole generation in either ambient or elevated atmospheric CO₂ ('ambient' and 'elevated' seeds, respectively). First generation plants and second generation 'ambient' plants did not respond to elevated CO₂. Second generation 'elevated' plants produced significantly more tillers in elevated CO₂. In

the second experiment model terrestrial ecosystems growing in the Ecotron and which included *Poa annua* were used. Above-ground biomass after one and two generations of growth were compared. At the end of Generation 1 no difference was found in biomass production while at the end of Generation 2 biomass increased in elevated CO₂ by 50%. The implications for climate change research are discussed.

Bhattacharya, N.C., D.R. Hileman, P.P. Ghosh, R.L. Musser, S. Bhattacharya, and P.K. Biswas. 1990. Interaction of enriched CO₂ and water-stress on the physiology of and biomass production in sweet-potato grown in open-top chambers. *Plant, Cell and Environment* 13(9):933-940.

The objective of this study was to investigate the effects of water stress in sweet potato (*Ipomoea batatas* L. [Lam] 'Georgia Jet') on biomass production and plant-water relationships in an enriched CO₂ atmosphere. Plants were grown in pots containing sandy loam soil (Typic Paleudult) at two concentrations of elevated CO₂ and two water regimes in open-top field chambers. During the first 12 d of water stress, leaf xylem potentials were higher in plants grown in a CO₂ concentration of 438 and 666- μ mol mol⁻¹ than in plants grown at 364- μ mol mol⁻¹. The 364- μ mol mol⁻¹ CO₂ grown plants had to be rewatered 2d earlier than the high CO₂-grown plants in response to water stress. For plants grown under water stress, the yield of storage roots and root:shoot ratio were greater at high CO₂ than at 364- μ mol mol⁻¹; the increase, however, was not linear with increasing CO₂ concentrations. In well-watered plants, biomass production and storage root yield increased at elevated CO₂, and these were greater as compared to water-stressed plants grown at the same CO₂ concentration.

Bhattacharya, N.C., J.W. Radin, B.A. Kimball, J.R. Mauney, G.R. Hendrey, J. Nagy, K.F. Lewin, and D.C. Ponce. 1994. Leaf water relations of cotton in a free-air CO₂-enriched environment. *Agricultural and Forest Meteorology* 70(1-4):171-182.

As part of an intensive study of crop response to CO₂ enrichment in a free-air CO₂ enrichment (FACE) experiment in the field, we determined aspects of the water relations of a cotton crop on selected dates in 1991. The atmosphere was enriched from 370 μ mol CO₂ mol⁻¹ (control) to about 550 μ mol mol⁻¹ in free air during daylight hours. Under full irrigation, CO₂ enrichment decreased stomatal conductance and single-leaf transpiration only toward the end of the season, and these changes led to increased leaf water potentials only at that time of year. Under water-stressed (deficit irrigation) conditions, CO₂ enrichment decreased conductance throughout the season but there was no corresponding consistent effect on leaf water potentials. As with the fully irrigated controls, CO₂ enrichment increased leaf water potentials only at the end of the season. CO₂ enrichment increased season-long biomass accumulation 39% under full irrigation and 34% under deficit irrigation. These results are consistent with previous studies of cotton in open-top chambers that found only small effects of CO₂ enrichment on internal water relations of cotton, and no water stress-induced increase in crop responsiveness to elevated CO₂.

Bialczyk, J., Z. Lechowski, and A. Libik. 1998. Modification of tannin concentration by abiotic factors in *Lycopersicon esculentum* Mill. seedlings. *Zeitschrift Fur Pflanzenkrankheiten Und Pflanzenschutz-Journal of Plant Diseases and Protection* 105(3):264-273.

Results of the study on the effect of some abiotic factors on the modification of Leaf tannin concentration of greenhouse tomato seedlings are discussed in the work. The total content of soluble and insoluble tannins was calculated as tannic acid equivalent x g(-1) dry matter. The cultivars of tomato were characterized by the differentiated tannin content in leaves, stems; and roots, the proportion being 1 : 1/2 and 1/3, respectively. Two of the investigated cultivars were characterized by extreme values of the natural tannin content (cv. 'Baron' with the greatest content and cv. 'Perkoz' with the smallest one), the differences between them reaching about 240 %. A partial defoliation-or mechanical wounding of leaf blades increased the content of tannins in these organs. In relation to the effect of the partial defoliation (about 50 % of leaves being cut off), the content of tannins was higher in the case of pricking the leaves with needles. Depending on the number of pricks per cm(2) of the leaf blade (8, 20 or; 40), associated with a different degree of its wounding (1 %, 2.5 %, and 5 %, respectively), a maximum increase in tannin content was 180 % with 20 pricks x cm(-2) as compared with the control. The intensity of photosynthetically active radiation (PAR) significantly affected the kinetics of tannin synthesis. In the case of a 90 % reduction of daily PAR intensity, the content of tannins was reduced by about 50 % after a 2-week experiment with the two cultivars. Changes in CO₂ concentration in the environment of seedlings differently modified the level of leaf tannins. With CO₂ concentration reduced to 170 μ mol x mol(-1) air, the content of tannins decreased to about 76 % of the value evidenced in atmospheric air. CO₂ elevated to 680 μ mol x mol(-1) air induced an increase in leaf tannins to about 112- 121 % in relation to the control. The enrichment of soil solution with phosphorus or nitrogen compounds had different and opposing effects on tannin content. With phosphorus enrichment of the substrate, the content of tannins in leaves increased to about 120 % in relation to the control. The elevated nitrogen concentration reduced the content of tannins by about 30 % after a 2-week experiment. The results concerning the effect of abiotic factors on the tannin level in the leaves of greenhouse tomato seedlings could lead to the development of control measures based-on the activation of the natural defense system of plants against herbivores.

Bialczyk, J., Z. Lechowski, and A. Libik. 1999. The protective action of tannins against glasshouse whitefly in tomato seedlings. *Journal of Agricultural Science* 133:197-201.

The synthesis and accumulation of tannins on tomato seedlings are regulated by environmental factors. The variation in the content of tannins was sufficiently important to bring about the occurrence of significant differences in the numbers of glasshouse whitefly on the seedlings. During a 2-week experiment, the treatments included mechanical wounding (20 prickings per cm(2)), spraying with kinetin solutions of 10(-4) mol/dm(3), plant growth regulators, and the atmosphere enrichment to 680 μ mol CO₂/mol air, the content of tannins being increased by c. 40, 70, 10-45 and 25 % above the values obtained in the control. These results were correlated with a decrease in the numbers of insects occurring on the seedlings by c. 35, 45, 8-29 and 18 %, respectively. Contrary to the above results the spraying with solutions of abscisic acid, gibberellic acid, and the incubation of plants in an atmosphere containing 170 μ mol CO₂/mol air, reduced the content of tannins by c. 69, 22 and 25 %, respectively. This was reflected in the respective increases by c. 70, 40 and 35% in the numbers

of insects occurring on the seedlings. The obtained results suggest that tannins seem to have a dosage-dependent effect on glasshouse whitefly. Decreasing the host plant quality by increasing tannin content may act as an important selective agent limiting the losses brought about by glasshouse whitefly in tomato cultivation.

Billes, G., H. Rouhier, and P. Bottner. 1993. Modifications of the carbon and nitrogen allocations in the plant (*triticum-aestivum* L) soil system in response to increased atmospheric CO₂ concentration. *Plant and Soil* 157(2):215-225.

The aim of this work was to examine the response of wheat plants to a doubling of the atmospheric CO₂ concentration on: (1) carbon and nitrogen partitioning in the plant, (2) carbon release by the roots; and (3) the subsequent N uptake by the plants. The experiment was performed in controlled laboratory conditions by exposing fast-growing spring wheat plants, during 28 days, to a (CO₂)-C-14 concentration of 350 or 700 µmol L⁻¹ at two levels of soil nitrogen fertilization. Doubling CO₂ availability increased total plant production by 34% for both N treatment. In the N-fertilized soil, the CO₂ enrichment resulted in an increase in dry mass production of 41% in the shoots and 23% in the roots; without N fertilization this figure was 33% and 37%, respectively. In the N-fertilized soil, the CO₂ increase enhanced the total N uptake by 14% and lowered the N concentration in the shoots by 23%. The N concentration in the roots was unchanged. In the N-fertilized soil, doubling CO₂ availability increased N uptake by 32% but did not change the N concentrations, in either shoots or roots. The CO₂ enrichment increased total root-derived carbon by 12% with N fertilization, and by 24% without N fertilization. Between 85 and 90% of the total root derived-C-14 came from respiration, leaving only 10 to 15% in the soil as organic C-14. However, when total root-derived C-14 was expressed as a function of root dry weight, these differences were only slightly significant. Thus, it appears that the enhanced carbon release from the living roots in response to increased atmospheric CO₂, is not due to a modification of the activity of the roots, but is a result of the increased size of the root system. The increase of root dry mass also resulted in a stimulation of the soil N mineralization related to the doubling atmospheric CO₂ concentration. The discussion is focused on the interactions between the carbon and nitrogen allocation, especially to the root system, and the implications for the acquisition of nutrients by plants in response to CO₂ increase.

Bindi, M., L. Fibbi, B. Gozzini, S. Orlandini, and F. Miglietta. 1996. Modelling the impact of future climate scenarios on yield and yield variability of grapevine. *Climate Research* 7(3):213-224.

A mechanistic growth model was used to evaluate the mean yield and yield variability of grapevine *Vitis vinifera* L. under current and future climates. The model used was previously validated using field experiment data. The effect of elevated CO₂ on grapevine growth was also considered. Adaptation of 2 varieties (Sangiovese and Cabernet Sauvignon) to scenarios of increased CO₂ and climate change, and potential changes in agricultural risk (i.e. inter-seasonal variability), were examined. Before testing the effect of climate scenarios, we analysed the sensitivity of modelled grapevine yield to arbitrary changes in the 3 driving variables (temperature, solar radiation and CO₂). The

results showed the model to be more sensitive to changes in CO₂ concentration and temperature than to changes in radiation. Analyses made using transient GCM (general circulation model) scenarios (UKTR and GFDL) showed different changes in mean fruit dry matter for the different scenarios, whereas mean total dry matter, and fruit and total dry matter variability, were predicted to increase under almost all the scenarios. Predictions based on equilibrium scenarios (UKLO and UKHI) gave similar results. For Sangiovese, variety adaptation analysis suggested a better adaptation in terms of mean production, but a worse adaptation in terms of yield variability.

Biondi, F., and J.E. Fessenden. 1999. Response of lodgepole pine growth to CO₂ degassing at Mammoth Mountain, California. *Ecology* 80(7):2420-2426.

We conducted dendroclimatic and stable isotope analyses of lodgepole pines (*Pinus contorta*) located in high-mortality sites at Mammoth Mountain (California, USA) to test for tree responses to magmatic degassing. Existing climatic and tree-ring data from nearby Yellowstone National Park were used for comparison. Sampled trees were scarcely sensitive to climate, and their growth showed an overall decline during the 20th century. Past growth rates of currently dead and stressed pines plummeted after 1990, when degassing of magmatic CO₂ was first reported in the area. No consistent or strong correlation was found with monthly and seasonal climatic parameters. Stable carbon isotopes were measured on holocellulose extracted from annual rings of a dead pine, a stressed pine, and a live pine. The delta(13)C signature of the dead and stressed pines showed enrichment in heavy carbon beginning in 1990, which could be related to stomatal closure following impairment of root systems by high levels of magmatic CO₂ in the soil.

Bishop, D.L., and B.G. Bugbee. 1998. Photosynthetic capacity and dry mass partitioning in dwarf and semi-dwarf wheat (*Triticum aestivum* L.). *Journal of Plant Physiology* 153(5-6):558-565.

Efficient use of space and high yields are critical for long-term food production aboard the International Space Station. The selection of a full dwarf wheat (less than 30 cm tall) with high photosynthetic and yield potential is a necessary prerequisite for growing wheat in the controlled, volume-limited environments available aboard long-term spaceflight missions. This study evaluated the photosynthetic capacity and carbon partitioning of a full-dwarf wheat cultivar, Super Dwarf, which is routinely used in spaceflight studies aboard U.S. space shuttle and NASA/Mir missions and made comparisons with other dwarf and semidwarf wheat cultivars utilized in other ground-based studies in plant space biology. Photosynthetic capacity of the flag leaf in two dwarf (Super Dwarf, BB-19), and three semi-dwarf (Veery-10, Yecora Rojo, IBWSN 199) wheat cultivars (*Triticum aestivum* L.) was assessed by measuring: net maximum photosynthetic rate, RuBP carboxylation efficiency, chlorophyll concentration and flag leaf area. Dry mass partitioning of carbohydrates to the leaves, sheaths, stems and ear was also assessed. Plants were grown under controlled environmental conditions in three replicate studies: slightly enriched CO₂ (370 µmol mol⁻¹), high photosynthetic photon flux (1000 µmol m⁻² s⁻¹); 58 µmol m⁻² d⁻¹) for a 16 h photoperiod, 22/15 degrees C day/night temperatures, ample nutrients and water provided by one-half strength Hoagland's nutrient solution (Hoagland and Amen, 1950). Photosynthetic capacity of the flag leaf was determined at anthesis using net CO₂ exchange rate versus internal CO₂ concentration curves

measured under saturating light (2000 $\mu\text{mol m}^{-2} \text{s}^{-1}$) and CO_2 (1000 $\mu\text{mol mol}^{-1}$). Dwarf wheat cultivars had greater photosynthetic capacities than the taller semi-dwarfs, they averaged 20 % higher maximum net photosynthetic rates compared to the taller semi-dwarfs, but these higher rates occurred only at anthesis, had slightly greater carboxylation efficiencies and significantly increased chlorophyll concentrations per unit leaf area. The reduced-height wheat had significantly less dry mass fraction in the stem but greater dry mass partitioned to the ear than the taller semi-dwarfs (Yecora rojo, IBWSN-199). Studies with detached heads confirm that the head is a significant sink in the shorter wheat cultivars.

Biswas, P.K., D.R. Hileman, P.P. Ghosh, N.C. Bhattacharya, and J.N. McCrimmon. 1996. Growth and yield responses of field-grown sweetpotato to elevated carbon dioxide. *Crop Science* 36(5):1234-1239.

Root crops are important in developing countries, where food supplies are frequently marginal. Increases in atmospheric CO_2 usually lead to increases in plant growth and yield, but little is known about the response of root crops to CO_2 enrichment under field conditions. This experiment was conducted to investigate the effects of CO_2 enrichment on growth and yield of field-grown sweetpotato [*Ipomoea batatas* (L.) Lam.]. Plants were grown in open-top chambers in the field at four CO_2 levels ranging from 354 (ambient) to 665 $\mu\text{mol mol}^{-1}$ in two growing seasons. Shoot growth was not affected significantly by elevated CO_2 . Yield of storage roots increased 46 and 75% at the highest CO_2 level in the 2 yr. The yield enhancement occurred through increases in the number of storage roots in the first year and through increases in both the number and size of the storage roots in the second year. Storage- root/shoot ratios increased 44% and leaf nitrogen concentrations decreased by 24% at the highest CO_2 level. A comparison of plants grown in the open field to plants grown in open-top chambers at ambient CO_2 concentrations indicated that open-top chambers reduced shoot growth in the first year and storage-root yield in both years. These results are consistent with the majority of CO_2 -enrichment studies done on pot-grown sweetpotato.

Bjorn, L.O., T.V. Callaghan, I. Johnsen, J.A. Lee, Y. Manetas, N.D. Paul, M. Sonesson, A.R. Wellburn, D. Coops, H.S. HeideJorgensen, C. Gehrke, D. GwynnJones, U. Johanson, A. Kyparissis, E. Levizou, D. Nikolopoulos, Y. Petropoulou, and M. Stephanou. 1997. The effects of UV-B radiation on European heathland species. *Plant Ecology* 128(1-2):252-264.

The effects of enhanced UV-B radiation on three examples of European shrub-dominated vegetation were studied in situ. The experiments were in High Arctic Greenland, northern Sweden and Greece, and at all sites investigated the interaction of enhanced UV-B radiation (simulating a 15% reduction in the ozone layer) with artificially increased precipitation. The Swedish experiment also involved a study of the interaction between enhanced UV-B radiation and elevated CO_2 (600 ppm). These field studies were supported by an outdoor controlled environment study in the United Kingdom involving modulated enhancement of UV-B radiation in combination with elevated CO_2 (700

ppm). Effects of the treatments on plant growth, morphology, phenology and physiology were measured. The effects observed were species specific, and included both positive and negative responses to the treatments. In general the negative responses to UV-B treatments of up to three growing seasons were small, but included reductions in shoot growth and premature leaf senescence. Positive responses included a marked increase in flowering in some species and a stimulation of some photosynthetic processes. UV-B treatment enhanced the drought tolerance of *Pinus pinea* and *Pinus halepensis* by increasing leaf cuticle thickness. In general, there were few interactions between the elevated CO_2 and enhanced UV-B treatments. There was evidence to suggest that although the negative responses to the treatments were small, damage may be increasing with time in some long-lived woody perennials. There was also evidence in the third year of treatments for effects of UV-B on insect herbivory in *Vaccinium* species. The experiments point to the necessity for long-term field investigations to predict the likely ecological consequences of increasing UV-B radiation.

Bladier, C., and P. Chagvardieff. 1993. Growth and photosynthesis of photoautotrophic callus derived from protoplasts of *solanum-tuberosum* L. *Plant Cell Reports* 12(6):307-311.

We describe a photoautotrophic culture procedure of potato (cvs Kennebec, Haig, DTO-33) callus derived from mesophyll protoplasts. The protoplast culture was initiated at very low concentration of glucose (down to 0.25 g l⁻¹). Callus was subcultured under CO_2 enriched air and glucose was suppressed by the successive dilutions with glucose free media. Regeneration was successfully obtained under photoautotrophic conditions. The characterization of oxygen exchange and of some enzymes and metabolites of carbon assimilation indicated that chlorophyllous callus, grown on carbohydrate free medium, developed the photosynthetic pathway typical of C3 plants. By comparing the fresh weight of callus cultivated in the light or in non-photosynthetic conditions (in darkness or in the light +3-(3,4-Dichlorophenyl)-1,1-dimethylurea) we concluded that growth depended to about 70 to 88 % on photosynthesis.

Blobner, M., R. Bogdanski, E. Kochs, J. Henke, A. Findeis, and S. Jelen-Esselborn. 1998. Effects of intraabdominally insufflated carbon dioxide and elevated intraabdominal pressure on splanchnic circulation - An experimental study in pigs. *Anesthesiology* 89(2):475-482.

Background Intraabdominally insufflated carbon dioxide (CO_2) during laparoscopy may have a specific effect on splanchnic circulation that may be unrelated to the effects of increased intraabdominal pressure alone. Therefore, the influences of insufflation with CO_2 versus air on splanchnic circulation were compared. Methods: Pigs were chronically instrumented for continuous recording of mesenteric artery, portal venous, inferior vena cava, and pulmonary arterial blood flow and portal venous pressure. After induction of anesthesia, CO_2 or air was insufflated in 14 and 10 pigs, respectively. with the pigs in the supine position, intraabdominal pressure was increased in steps of 4 mmHg up to 24 mmHg by graded gas insufflation. Results: During air insufflation, mesenteric artery vascular resistance was unchanged, whereas mesenteric arterial blood flow decreased with increasing intraabdominal

pressure. Shortly after CO₂ insufflation to an intraabdominal pressure of 4 mmHg, mean arterial pressure, mesenteric arterial blood flow, and mesenteric arterial vascular resistance were increased by 21%, 12% and 9%, respectively. Subsequently, with the onset of CO₂ resorption in the third minute, mean arterial pressure declined to baseline values and mesenteric arterial vascular resistance declined to 85% of baseline values, whereas mesenteric arterial blood flow continued to increase to a maximum of 24% higher than baseline values. At steady-state conditions during CO₂ insufflation, mesenteric arterial blood flow was increased up to an intraabdominal pressure less than or equal to 16 mmHg but decreased at higher intraabdominal pressures. Conclusions: in contrast to air insufflation, intraabdominal insufflation of CO₂ resulted in a moderate splanchnic hyperemia at an intraabdominal pressure less than or equal to 12 mmHg. At higher intraabdominal pressure values, pressure-induced changes became more important than the type of gas used.

Blum, H., G. Hendrey, and J. Nosberger. 1997. Effects of elevated CO₂, N fertilization, and cutting regime on the production and quality of *Lolium perenne* L. shoot necromass. *Acta Oecologica-International Journal of Ecology* 18(3):291-295.

In the Swiss grassland FACE experiment, we measured the effect of elevated CO₂ on the shoot necromass production and quality of *Lolium perenne* in 1995. Dead stubble of reproductive tillers and dead leaf sheaths were the main components of necromass. Elevated CO₂ did not significantly change the amount and the nitrogen concentration of necromass. Significantly more necromass was produced and the N concentration was lower in the low N supply treatments. Total necromass amounted to 250-500 g m⁻². Necromass N content was in the order of 5-6 g m⁻². This underscores the importance of the carbon and nitrogen fluxes included in necromass and their importance for soil biology and fertility.

Blumenthal, C., H.M. Rawson, E. McKenzie, P.W. Gras, E.W.R. Barlow, and C.W. Wrigley. 1996. Changes in wheat grain quality due to doubling the level of atmospheric CO₂. *Cereal Chemistry* 73(6):762-766.

Elevated levels of atmospheric CO₂ have been shown to increase grain yield and reduce grain nitrogen concentration. The object of this study was to determine whether elevated CO₂ levels would modify other aspects of grain quality relevant to processing, particularly protein and starch quality. Wheat of two genotypes (Hartog and Late Hartog) was grown in the field in controlled-atmosphere tunnels at either the ambient level of CO₂ (350 µmol/L) or an elevated level (700 µmol/L). This elevated level of CO₂ produced significant increases in grain yield, but decreases in 1,000-kernel weight. Grain grown in the elevated CO₂ atmosphere produced poorer dough and decreased loaf volume, farinograph development time, and dough extensibility. These changes were largely attributable to the lower protein content of the grain grown at elevated CO₂. There did not appear to be major changes in protein composition or in the functional properties of the protein. Grain produced at elevated CO₂ yielded starch with a significantly higher proportion of large (A-type) starch granules but no overall change in amylose-to-amylopectin ratio. These studies indicate that elevated levels of CO₂ may result in decreased quality of bread wheats largely due to lowered protein content.

Boerner, R.E.J., and J. Rebbeck. 1995. Decomposition and nitrogen release from leaves of 3 hardwood species grown under elevated O₃ and/or CO₂. *Plant and Soil* 170(1):149-157.

Elevated concentrations of O₃ and CO₂ have both been shown to affect structure, nutrient status, and deposition of secondary metabolites in leaves of forest trees. While such studies have produced robust models of the effects of such air pollutants on tree ecophysiology and growth, few have considered the potential for broader, ecosystem-level effects after these chemically and structurally altered leaves fall as leaf litter and decay. To determine the effects of elevated O₃ and/or CO₂ on the subsequent decomposition and nutrient release from the leaves grown in such altered atmospheres, we grew seedlings of three widespread North American forest trees, black cherry (*Prunus serotina*) (BC), sugar maple (*Acer saccharum*) (SM), and yellow-poplar (*Liriodendron tulipifera*) (YP) for two growing seasons in charcoal-filtered air (CF-air—approximately 25% ambient O₃), ambient O₃ (1X) or twice-ambient O₃ (2X) in outdoor open-top chambers. We then assayed the loss of mass and N from the litter derived from those seedlings through one year litterbag incubations in the forest floor of a neighboring forest stand. Mass loss followed linear functions and was not affected by the O₃ regime in which the leaves were grown. Instantaneous decay rates (i.e. k values) averaged SM:-0.707 y⁻¹, BC:-0.613 y⁻¹, and YP:-0.859 y⁻¹. N loss from ambient (1X) O₃-grown SM leaves was significantly greater than from CF-air leaves; N loss from BC leaves did not differ among treatments. Significantly less N was released from CF-air-grown YP leaves than from 1X or 2X O₃-treated leaves. YP leaves from plants grown in pots at 2X O₃ and 350 ppm supplemental CO₂ in indoor pollutant fumigation chambers (CSTRs or Continuously Stirred Tank Reactors) lost 40% as much mass and 27% as much N over one year as did leaves from YP grown in CF-air or 2X O₃. Thus, for leaves from plants grown in pots in controlled environment fumigation chambers, the concentrations of both O₃ and CO₂ can affect N release from litter incubated in the field whereas mass loss rate was affected only by CO₂. Because both mass loss and N release from leaves grown at elevated CO₂ were reduced significantly (at least for yellow-poplar), forests exposed to elevated CO₂ may have significantly reduced N turnover rates, thereby resulting in increased N limitation of tree growth, especially in forests which are already N-limited.

Boese, S.R., D.W. Wolfe, and J.J. Melkonian. 1997. Elevated CO₂ mitigates chilling-induced water stress and photosynthetic reduction during chilling. *Plant, Cell and Environment* 20(5):625-632.

Bean, cucumber and corn plants were grown in controlled- environment chambers at 25/18 degrees C day/night temperature and either ambient (350 µmol mol⁻¹) or elevated (700 µmol mol⁻¹) CO₂ concentration, and at 20-30 d after emergence they were exposed to a 24 h chilling treatment (6.5 +/- 1.5 degrees C) at their growth CO₂

concentration. Whole-plant transpiration rates (per unit leaf area basis) during the first 3 h of chilling were about 26, 28 and 13% lower at elevated than at ambient CO₂ for bean, cucumber and corn, respectively. The decline in leaf water potential (Psi(L)) and visible wilting of bean and cucumber during chilling were significantly less at elevated than at ambient CO₂. Corn Psi(L) was not significantly affected by chilling, and corn did not exhibit any other symptoms of chilling-induced water stress. Leaf osmotic potentials (measured before chilling only) of bean and cucumber were more negative at elevated than at ambient CO₂, and the corresponding calculated leaf turgor potentials were significantly higher at elevated than at ambient CO₂. Leaf relative water content (RWC) during chilling at ambient CO₂ fell to 62 and 48% for bean and cucumber, respectively, RWC during chilling at elevated CO₂ was never below 79% for bean or 63% for cucumber. Corn RWC was not measured. After 24 h of chilling at ambient CO₂, net photosynthetic rate (PN) reductions were 83, 89 and 24% for bean, cucumber and corn, respectively. P-N reductions during chilling were less at elevated CO₂: 53, 40 and 4% for bean, cucumber and corn, respectively. At ambient CO₂, none of the species fully recovered to pre-chilling P-N, but at elevated CO₂ both bean and corn recovered fully. The average percentage leaf area with visible leaf damage due to chilling was 20.6 and 9.6% at ambient and elevated CO₂, respectively, for bean, and 32.4 and 23.6% at ambient and elevated CO₂, respectively, for cucumber. Corn showed no significant permanent leaf damage from chilling at either CO₂ concentration. These results indicate that cucumber was most sensitive to chilling as imposed in this study, followed by bean and corn. The results support the hypothesis that, at least in young plants under controlled-environment conditions, elevated CO₂ improves plant water relations during chilling and can mitigate photosynthetic depression and chilling damage. The implications for long-term growth and reproductive success in managed and natural ecosystems will require testing of this hypothesis under field conditions.

Boetsch, J., J. Chin, M. Ling, and J. Croxdale. 1996. Elevated carbon dioxide affects the patterning of subsidiary cells in *Tradescantia* stomatal complexes. *Journal of Experimental Botany* 47(300):925-931.

The influence of elevated CO₂ concentration (670 ppm) on the structure, distribution, and patterning of stomata in *Tradescantia* leaves was studied by making comparisons with plants grown at ambient CO₂. Extra subsidiary cells, beyond the normal complement of four per stoma, were associated with nearly half the stomatal complexes on leaves grown in elevated CO₂. The extra cells shared characteristics, such as pigmentation and expansion, with the typical subsidiary cells. The position and shape of the extra subsidiary cells in face view differed in the green and purple varieties of *Tradescantia*. Substomatal cavities of complexes with extra subsidiary cells appeared larger than those found in control leaves. Stomatal frequency expressed on the basis of leaf area did not differ from the control. Stomatal frequency based on cell counts (stomatal index) was greater in leaves grown in CO₂-enriched air when all subsidiary cells were counted as part of the stomatal complex. This difference was eliminated when subsidiary cells were included in the count of epidermal cells, thereby evaluating the frequency of guard cell pairs. The extra subsidiary cells were, therefore, recruited from the epidermal cell population during development. Stomatal frequency in plants grown at elevated temperature (29 degrees C) was not significantly different from that of the control (24 degrees C). The linear aggregations of stomata were similar in plants grown in ambient and elevated CO₂. Since enriched CO₂ had no effect on the structure or patterning of guard cells, but resulted in the formation of additional subsidiary cells, it is likely that separate and independent events pattern

the two cell types. Plants grown at enriched CO₂ levels had significantly greater internode lengths, but leaf area and the time interval between the appearance of successive leaves were similar to that of control plants. Porometric measurements revealed that stomatal conductance of plants grown under elevated CO₂ was lower than that of control leaves and those grown at elevated temperature. *Tradescantia* was capable of regulating stomatal conductance in response to elevated CO₂ without changing the relative number of stomata present on the leaf.

Bolker, B.M., S.W. Pacala, F.A. Bazzaz, C.D. Canham, and S.A. Levin. 1995. Species-diversity and ecosystem response to carbon-dioxide fertilization - conclusions from a temperate forest model. *Global Change Biology* 1(5):373-381.

This paper explores how the response of a temperate forest ecosystem to climate change might depend on species diversity and community change. In particular, we look at the dynamics of a model of temperate forest growth under doubled CO₂. We combine a detailed, field-calibrated model of forest dynamics (Pacala et al. 1993) with greenhouse data on the range of seedling biomass growth response to doubled CO₂ concentrations (Bazzaz et al. 1990; Bazzaz & Miao 1993). Because total ecosystem response to climate change depends delicately on many environmental variables other than CO₂, we isolate the effects of community change by comparing runs of the regular model, allowing dynamic community change, with runs of a reduced model that holds species composition static by using a single tree species with average parameters. Simulations that allowed community change instead of holding species composition constant showed a roughly 30% additional increase in total basal area over time scales of 50-150 years. Although the model omits many possible feedbacks and mechanisms associated with climate change, it suggests the large potential effects that species differences and feedbacks can have in ecosystem models and reinforces the possible importance of diversity to ecosystem function (Naeem et al. 1994; Tilman & Downing 1994) over time scales within the planning horizon for global change policy.

Bonghi, C., A. Ramina, B. Ruperti, R. Vidrih, and P. Tonutti. 1999. Peach fruit ripening and quality in relation to picking time, and hypoxic and high CO₂ short-term postharvest treatments. *Postharvest Biology and Technology* 16(3):213-222.

Peach fruits (*Prunus persica* L. Batsch, cv Springercrest) were harvested at two ripening stages (flesh firmness of 60 N, first harvest, and 45 N, second harvest) and maintained at 20 degrees C in air (control) or for 24 and 48 h in streams of ultra low (<1%) oxygen (ULO) or high (30%) CO₂ concentration and then transferred to air for up to 8 days. The decline in flesh firmness was strongly reduced by ULO and CO₂ treatments in fruits of both harvests, although the effect was stronger in fruits picked earlier in which ethylene biosynthesis remained at the basal level. In fruits of the second harvest, endo beta-1,4-glucanase (EGase) activity was lower in ULO- and CO₂-treated fruits than in control fruits at the end of the 24 h treatment and the following two days in air. Acetaldehyde (AA) gradually accumulated in control fruit and the highest concentrations were detected during late ripening. Both treatments induced a strong accumulation of AA but, with the exception of the 24 and 48 h CO₂ treatments performed on fruits of the second harvest, a decrease in AA content was observed when the fruits were transferred to air. A slight increase in ethanol (EtOH) was found throughout the ripening process in control fruits; ULO and CO₂ strongly stimulated EtOH production. When fruits were transferred to air, EtOH concentration declined rapidly. Alcohol dehydrogenase (ADH) activity significantly increased in control fruit only in the late stages of ripening. Greater ADH activity was found throughout the experimental period in fruits of the first harvest treated for 24 h in ULO and CO₂, whereas, at day 8, control and treated fruits of the second harvest showed similar ADH activity values. Hypoxic and, to a lesser extent, CO₂-enriched atmospheres stimulated Adh gene expression. (C) 1999 Elsevier Science B.V. All rights reserved.

Booker, F.L., C.D. Reid, S. BrunschonHarti, E.L. Fiscus, and J.E. Miller. 1997. Photosynthesis and photorespiration in soybean [*Glycine max* (L.) Merr.] chronically exposed to elevated carbon dioxide and ozone. *Journal of Experimental Botany* 48(315):1843-1852.

The effects of elevated carbon dioxide (CO₂) and ozone (O₃) on soybean [*Glycine max* (L.) Merr.] photosynthesis and photorespiration-related parameters were determined periodically during the growing season by measurements of gas exchange, photorespiratory enzyme activities and amino acid levels. Plants were treated in open-top field chambers from emergence to harvest maturity with seasonal mean concentrations of either 364 or 726 $\mu\text{mol mol}^{-1}$ CO₂ in combination with either 19 or 13 nmol mol^{-1} O₃ (12 h daily averages). On average at growth CO₂ concentrations, net photosynthesis (A) increased 56% and photorespiration decreased 36% in terminal mainstem leaves with CO₂-enrichment. Net photosynthesis and photorespiration were suppressed 30% and 41%, respectively, by elevated O₃ during late reproductive growth in the ambient CO₂ treatment, but not in the elevated CO₂ treatment. The ratio of photorespiration to A at growth CO₂ was decreased 61% by elevated CO₂. There was no statistically significant effect of elevated O₃ in the ratio of photorespiration to A. Activities of glycolate oxidase, hydroxypyruvate reductase and catalase were decreased 10-25% by elevated CO₂, and by 46-66% by elevated O₃ at late reproductive growth. The treatments had no significant effect on total amino acid or glycine levels, although serine concentration was lower in the elevated CO₂ and O₃ treatments at several sampling dates. The inhibitory effects of elevated O₃ on photorespiration-related parameters were generally commensurate with the O₃-induced decline in A. The results suggest that elevated CO₂ could promote productivity

both through increased photoassimilation and suppressed photorespiration.

Boone, R.D., K.J. Nadelhoffer, J.D. Canary, and J.P. Kaye. 1998. Roots exert a strong influence on the temperature sensitivity of soil respiration. *Nature* 396(6711):570-572.

The temperature sensitivity of soil respiration will largely determine the effects of a warmer world on net carbon flux from soils to the atmosphere. CO₂ flux from soils to the atmosphere is estimated to be 50-70 petagrams of carbon per year and makes up 20-38% of annual inputs of carbon (in the form of CO₂) to the atmosphere from terrestrial and marine sources(1,2). Here we show that, for a mixed temperate forest, respiration by roots plus oxidation of rhizosphere carbon, which together produce a large portion of total effluxed soil CO₂, is more temperature-sensitive than the respiration of bulk soil. We determine that the Q(10) value (the coefficient for the exponential relationship between soil respiration and temperature, multiplied by ten) is 4.6 for autotrophic root respiration plus rhizosphere decomposition, 2.5 for respiration by soil lacking roots and 3.5 for respiration by bulk soil. If plants in a higher-CO₂ atmosphere increase their allocation of photosynthate to roots(3-6), these findings suggest that soil respiration should be more sensitive to elevated temperatures, thus limiting carbon sequestration by soils.

Borkhsenius, O.N., C.B. Mason, and J.V. Moroney. 1998. The intracellular localization of ribulose-1,5-bisphosphate carboxylase/oxygenase in *Chlamydomonas reinhardtii*. *Plant Physiology* 116(4):1585-1591.

The pyrenoid is a proteinaceous structure found in the chloroplast of most unicellular algae. Various studies indicate that ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) is present in the pyrenoid, although the fraction of Rubisco localized there remains controversial. Estimates of the amount of Rubisco in the pyrenoid of *Chlamydomonas reinhardtii* range from 5% to nearly 100%. Using immunolocalization, the amount of Rubisco localized to the pyrenoid or to the chloroplast stroma was estimated for *C. reinhardtii* cells grown under different conditions. It was observed that the amount of Rubisco in the pyrenoid varied with growth condition; about 40% was in the pyrenoid when the cells were grown under elevated CO₂ and about 90% with ambient CO₂. In addition, it is likely that pyrenoidal Rubisco is active in CO₂ fixation because in vitro activity measurements showed that most of the Rubisco must be active to account for CO₂-fixation rates observed in whole cells. These results are consistent with the idea that the pyrenoid is the site of CO₂ fixation in *C. reinhardtii* and other unicellular algae containing CO₂-concentrating mechanisms.

Borodin, V.B. 1995. Photosynthetic O_2 exchange in chlorella cells adapted to low CO_2 concentration under blue or red-light. *Russian Journal of Plant Physiology* 42(1):31-36.

The effect of light quality on the adaptation to low atmospheric CO_2 concentration was studied on the cells of unicellular green alga *Chlorella pyrenoidosa* 82T grown under 2% CO_2 concentration and white light. The adaptation of *Chlorella* cells was more successful under blue than under red light. Thus, the air-adapted cells under blue light showed a higher affinity for CO_2 , a higher quantum efficiency of apparent photosynthesis at CO_2 limitation, and acceleration of O_2 evolution at light saturation, as compared to the red-light-adapted cells. In air-adapted cells, the photosynthetic rates at low CO_2 concentration were enhanced with increased intensities of both blue and red light, but the differences between the two treatments were retained. It was inferred that *Chlorella* cell adaptation depended on both light intensity and its spectral composition. The light intensity exerts its action via photosynthetic apparatus while spectral composition of light exerts its effect via a system of photoreception, which absorbs blue light. This additional blue light absorption is considered favorable for *Chlorella* cell adaptation to low CO_2 concentration.

Bosac, C., S.D.L. Gardner, G. Taylor, and D. Wilkins. 1995. Elevated CO_2 and hybrid poplar - a detailed investigation of root and shoot growth and physiology of *populus-euramericana*, primo. *Forest Ecology and Management* 74(1-3):103-116.

Exposure of the hybrid poplar clone 'Primo' (*Populus deltoides* X *Populus nigra*) to 580 $\mu\text{mol l}^{-1}$ (-1) carbon dioxide for just 68 days significantly (P less than or equal to 0.05) increased stem height by 13% compared with trees grown in ambient CO_2 concentrations. The stem diameter was significantly (P less than or equal to 0.05) increased and both total biomass and woody stem biomass also showed higher values (38% and 31% increases respectively) in elevated CO_2 . Trees in elevated CO_2 had more leaves and a greater total leaf area, whilst the specific leaf area was decreased in elevated CO_2 on four out of five occasions and was significantly (P less than or equal to 0.05) lower after 68 days, an effect indicating that leaves were thicker and/or heavier. Rates of photosynthesis (A) measured after 49 and 67 days of exposure revealed that trees in the elevated CO_2 treatment had lower values of A when measured at either 350 or 580 $\mu\text{mol l}^{-1}$ (-1) CO_2 . Sequential harvests at intervals during the study in which the root and shoot components were analysed separately allowed the construction of root:shoot ratios and allometric coefficients; there was no significant effect on the allometric coefficient and the root:shoot ratio was significantly increased on only one occasion. However, measurements of the 'apparent' root length suggested that root lengths were greater in the CO_2 treatment. There was a significant increase in the number of fine root tips visible down the surface of specially designed rooting tubes (P less than or equal to 0.05), indicating more fine roots or an increase in fine root branching. The growth rates of individual fine or large roots over 24 h were unaffected, again suggesting that increases in biomass may be due to more root segments rather than longer individual roots. Root water relations were also examined and showed a tendency towards solute accumulation and increases in turgor pressure (P) and effective turgor ($P\text{-e}$) at times when root growth was stimulated, although these were not consistent. Cell wall plasticity of the tips of large roots was significantly (P less than or equal

to 0.01) reduced in elevated CO_2 , possibly indicating a greater tendency to divert resources to the formation of root branches. The results of the study are discussed in the light of the possible consequences of changes in poplar growth and physiology for forestry practice in an increased CO_2 environment.

Bottomley, P.A., H.H. Rogers, and S.A. Prior. 1993. Nmr imaging of root water distribution in intact vicia-faba L plants in elevated atmospheric CO_2 . *Plant, Cell and Environment* 16(3):335-338.

The effect of elevated atmospheric CO_2 on water distribution in the intact roots of *Vicia faba* L. bean seedlings grown in natural soil was studied noninvasively with proton (^1H) nuclear magnetic resonance (NMR) imaging. Exposure of 24-d-old plants to atmospheric CO_2 -enriched air at 650 $\mu\text{mol m}^{-3}$ produced significant increases in water imaged in upper roots, hypogeal cotyledons and lower stems in response to a short-term drying-stress cycle. Above ground, drying produced negligible stem shrinkage and stomatal resistance was unchanged. In contrast, the same drying cycle caused significant depletion of water imaged in the same upper root structures in control plants subject to ambient CO_2 (350 $\mu\text{mol m}^{-3}$), and stem shrinkage and increased stomatal resistance. The results suggest that inhibition of transpiration caused by elevated CO_2 does not necessarily result in attenuation of water transport from lower root structures. Inhibition of water loss from upper roots and lower stem in elevated CO_2 environments may be a mitigating factor in assessing deleterious effects of greenhouse changes on crops during periods of dry climate.

Bouma, T.J., K.L. Nielsen, D.M. Eissenstat, and J.P. Lynch. 1997. Estimating respiration of roots in soil: Interactions with soil CO_2 , soil temperature and soil water content. *Plant and Soil* 195(2):221-232.

Little information is available on the variability of the dynamics of the actual and observed root respiration rate in relation to abiotic factors. In this study, we describe I) interactions between soil CO_2 concentration, temperature, soil water content and root respiration, and II) the effect of short-term fluctuations of these three environmental factors on the relation between actual and observed root respiration rates. We designed an automated, open gas-exchange system that allows continuous measurements on 12 chambers with intact roots in soil. By using three distinct chamber designs with each a different path for the air flow, we were able to measure root respiration over a 50-fold range of soil CO_2 concentrations (400 to 25000 ppm) and to separate the effect of irrigation on observed vs. actual root respiration rate. All respiration measurements were made on one-year-old citrus seedlings in sterilized sandy soil with minimal organic material. Root respiration was strongly affected by diurnal fluctuations in temperature ($Q_{10}=2$), which agrees well with the literature. In contrast to earlier findings for Douglas-fir (Qi et al., 1994), root respiration rates of citrus were not affected by soil CO_2 concentrations (400 to 25000 ppm CO_2 ; pH around 6). Soil CO_2 was strongly affected by soil water content but not by respiration measurements, unless the air flow for root respiration measurements was directed through the soil. The latter method of measuring root respiration reduced soil CO_2 concentration to that of incoming air. Irrigation caused a temporary reduction in CO_2 diffusion, decreasing the observed respiration rates obtained by techniques that depended on diffusion. This

apparent drop in respiration rate did not occur if the air flow was directed through the soil. Our dynamic data are used to indicate the optimal method of measuring root respiration in soil, in relation to the objectives and limitations of the experimental conditions.

Bowden, R.D., K.M. Newkirk, and G.M. Rullo. 1998. Carbon dioxide and methane fluxes by a forest soil under laboratory-controlled moisture and temperature conditions. *Soil Biology and Biochemistry* 30(12):1591-1597.

Carbon dioxide and methane are important greenhouse gases whose exchange rates between soils and the atmosphere are controlled strongly by soil temperature and moisture. We made a laboratory investigation to quantify the relative importance of soil moisture and temperature on fluxes of CO₂ and CH₄ between forest soils and the atmosphere. Forest floor and mineral soil material were collected from a mixed hardwood forest at the Harvard Forest. Long-Term Ecological Research Site (MA) and were incubated in the laboratory under a range of moisture (air-dry to nearly saturated) and temperature conditions (5-25 degrees C). Carbon dioxide emissions increased exponentially with increasing temperature in forest floor material, with emissions reduced at the lowest and highest soil moisture contents. The forest floor Q(10) of 2.03 (from 15-25 degrees C) suggests that CO₂ emissions were controlled primarily by soil biological activity. Forest floor CO₂ emissions were predicted with a multiple polynomial regression model ($r^2 = 0.88$) of temperature and moisture, but the fit predicting mineral soil respiration was weaker ($r^2 = 0.59$). Methane uptake was controlled strongly by soil moisture, with reduced fluxes under conditions of very low or very high soil moisture contents. A multiple polynomial model accurately described CH₄ uptake by mineral soil material ($r^2 = 0.81$), but only weakly ($r^2 = 0.45$) predicted uptake by forest floor material. The mineral soil Q(10) of 1.11 for CH₄ uptake indicates that methane uptake is controlled primarily by physical processes. Our work suggests that inclusion of both moisture and temperature can improve predictions of soil CO₂ and CH₄ exchanges between soils and the atmosphere. Additionally, global change models need to consider interactions of temperature and moisture in evaluating effects of global climate change on trace gas fluxes. (C) 1998 Elsevier Science Ltd. Bowes, G. 1991. Growth at elevated CO₂ - photosynthetic responses mediated through rubisco. *Plant, Cell and Environment* 14(8):795-806.

The global uptake of CO₂ in photosynthesis is about 120 gigatons (Gt) of carbon per year. Virtually all passes through one enzyme, ribulose biphosphate carboxylase/oxygenase (rubisco), which initiates both the photosynthetic carbon reduction, and photorespiratory carbon oxidation, cycles. Both CO₂ and O₂ are substrates; CO₂ also activates the enzyme. In C₃ plants, rubisco has a low catalytic activity, operates below its K_m (CO₂), and is inhibited by O₂. Consequently, increases in the CO₂/O₂ ratio stimulate C₃ photosynthesis and inhibit photorespiration. CO₂ enrichment usually enhances the productivity of C₃ plants, but the effect is marginal in C₄ species. It also causes acclimation in various ways: anatomically, morphologically, physiologically or biochemically. So, CO₂ exerts secondary effects in growth regulation, probably at the molecular level, that are not predictable from its primary biochemical role in carboxylation. After an initial increase with CO₂ enrichment, net

photosynthesis often declines. This is a common acclimation phenomenon, less so in field studies, that is ultimately mediated by a decline in rubisco activity, though the RuBP/P(i)-regeneration capacities of the plant may play a role. The decline is due to decreased rubisco protein, activation state, and/or specific activity, and it maintains the rubisco fixation and RuBP/P(i)-regeneration capacities in balance. Carbohydrate accumulation is sometimes associated with reduced net photosynthesis, possibly causing feedback inhibition of the RuBP/P(i)-regeneration capacities, or chloroplast disruption. As exemplified by field-grown soybeans and salt marsh species, a reduction in net photosynthesis and rubisco activity is not inevitable under CO₂ enrichment. Strong sinks or rapid translocation may avoid such acclimation responses. Over geological time, aquatic autotrophs and terrestrial C₄ and CAM plants have genetically adapted to a decline in the external CO₂/O₂ ratio, by the development of mechanisms to concentrate CO₂ internally; thus circumventing O₂ inhibition of rubisco. Here rubisco affinity for CO₂ is less, but its catalytic activity is greater, a situation compatible with a high-CO₂ internal environment. In aquatic autotrophs, the CO₂ concentrating mechanisms acclimate to the external CO₂, being suppressed at high-CO₂. It is unclear, whether a doubling in atmospheric CO₂ will be sufficient to cause a de-adaptive trend in the rubisco kinetics of future C₃ plants, producing higher catalytic activities.

Bowes, G., J.C.V. Vu, M.W. Hussain, A.H. Pennanen, and L.H. Allen. 1996. An overview of how rubisco and carbohydrate metabolism may be regulated at elevated atmospheric [CO₂] and temperature. *Agricultural and Food Science in Finland* 5(3):261-270.

Although atmospheric CO₂ concentration ([CO₂]) has been up to 16-fold higher than at present, the past several million years have seen atypically low values. Thus, modern-day plants are adapted to cope with a low [CO₂]/[O₂] ratio. The present [CO₂] does not saturate C₃ photosynthesis, so its doubling produces an "efficiency effect", but it is not always fully realized. Acclimation to high [CO₂] during growth can down-regulate photosynthesis, presumably to optimize carbon acquisition and utilization. A primary factor in acclimation is a reduction in rubisco. Two crops, rice and soybean, were used to study this phenomenon. Rice photosynthesis and growth peaked at 500 μmol mol⁻¹, whereas soybean responded up to 990 μmol mol⁻¹. Rubisco concentration declined under CO₂-enrichment and increasing temperatures, more so in rice than soybean. The rubisco k_{cat} of rice was unaffected by growth [CO₂] or temperature, but that from soybean was increased by both. In rice the capacity to handle carbohydrate, as measured by sucrose phosphate synthase activity was up-regulated by CO₂-enrichment, but not by temperature. Leaf carbohydrates were increased by [CO₂], but decreased by higher temperatures, starch more

so than sucrose. Even though C-3 species differ in response to [CO₂] and temperature, CO₂-enrichment can moderate adverse effects of temperature extremes.

Bowler, J.M., and M.C. Press. 1993. Growth-responses of 2 contrasting upland grass species to elevated CO₂ and nitrogen concentration. *New Phytologist* 124(3):515-522.

Growth parameters of *Agrostis capillaris* L. and *Nardus stricta* L. were measured in relation to ambient and elevated concentrations of CO₂ (340 and 550 μ mol CO₂ l⁻¹, respectively) and at low and high concentrations of nitrogen (0.8 and 3 mmol NH₄NO₃, respectively). After 60 d of growth *A. capillaris* had attained approx. four times the total dry weight of *N. stricta* in all treatments, which was attributed to the greater leaf area ratio of the former. *A. capillaris* grown at the low nitrogen concentration attained 30% of the total dry weight of plants grown at high nitrogen. Over the 60 d period, destructive harvests (seven in total) showed the growth of *N. stricta* to be less sensitive than that of *A. capillaris* to the concentration of nitrogen, but in both species growth analysis showed the lower total dry weight at low nitrogen to be attributable to lower unit leaf rate. There was a differential response of both species to elevated concentrations of CO₂ which was nitrogen dependent. *A. capillaris* grown at elevated CO₂ attained a greater total dry weight than at ambient CO₂ and this response was proportionately greater at low nitrogen (78% increase) than at high nitrogen (58% increase). In contrast, in *N. stricta* there was no effect of CO₂ concentration on the total dry weight at low nitrogen whilst at high nitrogen plants grown at elevated CO₂ had a greater total dry weight after 48 d of growth. Calculation of the allometric coefficient (K) relating root growth to shoot growth indicated that the effect of the lower nitrogen concentration was to increase partitioning to the roots while the higher CO₂ concentration did not alter partitioning.

Bowler, J.M., and M.C. Press. 1996. Effects of elevated CO₂, nitrogen form and concentration on growth and photosynthesis of a fast- and slow-growing grass. *New Phytologist* 132(3):391-401.

Growth and photosynthesis of *Agrostis capillaris* L. and *Nardus stricta* L. were measured for plants grown under ambient and elevated concentrations of CO₂ (340 and 550 μ mol CO₂ l⁻¹) respectively) and a range of nitrogen concentrations (0.01, 0.1, 1 and 5 mg N l⁻¹) supplied as either ammonium sulphate or sodium nitrate. After 42 d of growth for *A. capillaris* and 49 d of growth for *N. stricta*, the higher nitrogen concentrations resulted in stimulation of growth. The form of nitrogen did not affect the total dry weight attained by *A. capillaris*. However, ammonium-grown *N. stricta* attained a greater total dry weight than did nitrate-grown plants. Nitrogen form influenced leaf area ratio, which was greater in nitrate-grown *A. capillaris* and in ammonium-grown *N. stricta*. At the two lowest nitrogen concentrations there was no effect of elevated CO₂ on total dry weight in either species, whilst at the two highest nitrogen concentrations positive growth responses to elevated CO₂ were observed. Photosynthetic capacity and carboxylation efficiency were lower in plants grown in elevated CO₂ at the two lowest nitrogen concentrations, and were associated with greater leaf soluble carbohydrate content and lower foliar nitrogen concentrations. By

contrast, the CO₂ treatment did not affect these parameters at the two highest nitrogen concentrations employed.

Brailsford, R.W., L.A.C.J. Voesenek, C.W.P.M. Blom, A.R. Smith, M.A. Hall, and M.B. Jackson. 1993. Enhanced ethylene production by primary roots of zeamays L in response to sub-ambient partial pressures of oxygen. *Plant, Cell and Environment* 16(9):1071-1080.

Ethylene production by primary roots of 72-h-old intact seedlings of *Zea mays* L. cv. LG11 was studied under ambient and sub-ambient oxygen partial pressures (pO₂) using a gas how- through system linked to a photoacoustic laser detector. Despite precautions to minimize physical perturbation to seedlings while setting-up, ethylene production in air was faster during the first 6h than later, in association with a small temporary swelling of the roots. When roots were switched from air (20.8kPa O₂) to 3 or 5kPa O₂ after 6h, ethylene production increased within 2-3h. When, the roots were returned to air 16h later, ethylene production decreased within 2-3h. The presence of 10kPa CO₂ did not interfere with the effect of 3kPa O₂. Transferring roots from air to 12.5kPa did not change ethylene production, while a reduction to 1kPa O₂ induced a small increase. The extra ethylene formed in 3 and 5kPa O₂ was associated with plagiotropism, swelling, root hair production, and after 72h, increased amounts of intercellular space (aerenchyma) in the root cortex. Root extension was also slowed down, but the pattern of response to oxygen shortage did not always match that of ethylene production. On return to air, subsequent growth patterns became normal within a few hours. In the complete absence of oxygen, no ethylene production was detected, even when anaerobic roots were returned to air after 16h.

Brakke, M., and L.H. Allen. 1995. Gas-exchange of citrus seedlings at different temperatures, vapor-pressure deficits, and soil-water contents. *Journal of the American Society for Horticultural Science* 120(3):497-504.

Midday reductions of stomatal conductance and carbon dioxide assimilation rates (A(CO₂)) in Citrus are typically attributed to large leaf-to-air vapor-pressure differences or high atmospheric vapor-pressure deficits (VPD). This study investigated air temperature (T-a) and available soil water (ASW) level as corollary factors of atmospheric VPD that influence midday reduction of net gas exchange in citrus leaves. The influence of elevated atmospheric CO₂ under conditions that inhibit net canopy A(CO₂) was also investigated. Net canopy A(CO₂) and evapotranspiration rates of Carrizo citrange [Poncirus trifoliata Raf x Citrus sinensis (L.) Osbeck] and Swingle citrumelo (P. trifoliata Raf x C. paradisi Macf.) seedlings grown in outdoor controlled- environment growth chambers were measured under two levels of T-a with concomitant changes in VPD and two levels of atmospheric CO₂ concentration, which were changed in steps over time. Cyclical depletion of ASW was allowed to occur at each set of T-a/VPD and CO₂ combinations. Highest net canopy A(CO₂) rates at ambient CO₂ concentration (330 μ mol . mol⁻¹) were obtained at the low T-a/VPD level (29C/2.4 kPa) and ASW >50%. Diurnal canopy CO₂ uptake rates decreased at the high T-a/VPD level (37C/3.6 kPa), and midday depression of canopy A(CO₂) was observed at ASW levels <50%. Net canopy A(CO₂) decreased at higher levels of ASW under the high T-

a/VPD treatment than at the low T-a/VPD treatment. At the elevated CO₂ concentration (840 $\mu\text{mol} \cdot \text{mol}^{-1}$) net canopy CO₂ uptake rates were double those that occurred at ambient CO₂ levels and they did not exhibit midday reduction. Our data indicate that, when soil water is not readily available, citrus seedlings are more sensitive to high levels of T-a and VPD which results in reduction of CO₂ uptake. The inhibitory effects of elevated VPD and reduced ASW on citrus net A(CO₂) were lessened at the elevated atmospheric CO₂ level.

Brandrud, T.E., and J.G.M. Roelofs. 1995. Enhanced growth of the macrophyte *Juncus bulbosus* in S Norwegian limed lakes. A regional survey. *Water, Air, and Soil Pollution* 85(2):913-918.

The effects of liming on the aquatic macrophyte vegetation have been investigated in S and SW Norway. In the western part of the study area, *Juncus bulbosus* was considerably more frequent in the limed than in the unlimed lakes, whilst in the eastern part there were no such differences, and the *J. bulbosus* populations were generally not so vital. In some southwestern areas a luxuriant and massive nuisance growth of *Juncus bulbosus* in the depth zone 0-4 m was recorded. The most vital plants produced up to 1 m long annual shoots, and developed extensive, dense and vital surface mats in shallow areas (depth zone 0-3 m) after 4-5 years. The original isoetid vegetation had disappeared in the areas of dense *J. bulbosus* populations, and this development seems to be more or less irreversible. The massive *J. bulbosus* expansion is seen mainly in directly limed lakes with a sometimes visible layer of calcium carbonate on the sediment surface, but enhanced growth has been observed also in lakes downstream liming. The massive expansion is believed to be due to an increase of CO₂ and ammonium in the sediment pore water, combined with a mild climate with a very high precipitation. In many areas the liming has led to an increase in species diversity, and a (re-)establishment of some acid-intolerant species such as *Myriophyllum alterniflorum* and *Potamogeton* spp.

Bransby, D.I., S.B. McLaughlin, and D.J. Parrish. 1998. A review of carbon and nitrogen balances in switchgrass grown for energy. *Biomass & Bioenergy* 14(4):379-384.

Increased atmospheric CO₂, caused partly by burning fossil fuels, is assumed to elevate the risk of global warming, while nitrate contamination of surface runoff and groundwater from fertilizer and agricultural wastes constitutes a serious environmental hazard on a regional scale. Switchgrass (*Panicum virgatum* L.) grown as an energy crop could reduce atmospheric CO₂ accumulation by replacing fossil fuels and sequestering C. It could also improve soil productivity by C sequestration, and reduce NO₃-I contamination of water by absorbing N lost from fertilizer and agricultural waste if planted in filter strips on adjacent land. The objective of this study was to assess potential impacts of switchgrass on C and N balances by reviewing and synthesizing information from current literature, unpublished data and on-going research. Replacing fossil fuels with switchgrass, or any other biomass, will have a much greater effect on atmospheric CO₂ than C sequestration. This is because replacing fossil fuels provides a cumulative effect, while C sequestration offers only a one-time benefit. Furthermore, switchgrass will provide net gains in C sequestration only if it replaces annual row crops, but not if it replaces grazed pasture. Nitrogen recovery by switchgrass in an Alabama study was 65.6%, which compares favorably with the 50% recovery frequently quoted as

the norm for wheat (*Triticum aestivum* L.) and corn (*Zea mays* L.). (C) 1998 Elsevier Science Ltd. All rights reserved.

Brearley, J., M.A. Venis, and M.R. Blatt. 1997. The effect of elevated CO₂ concentrations on K⁺ and anion channels of *Vicia faba* L. guard cells. *Planta* 203(2):145-154.

The effects of elevated CO₂ concentrations on stomatal movement, anion- and K⁺-channel activities were examined in guard cells from epidermal strips of *Vicia faba*. Membrane voltage was measured using intracellular, double-barrelled microelectrodes and ion-channel currents were recorded under voltage clamp during exposure to media equilibrated with ambient (350 $\mu\text{mol} \cdot \text{mol}^{-1}$), 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$ and 10 000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ in 20% O₂ and 80% N₂. The addition of 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ to the bathing solution caused stomata to close with a half-time of approx. 40 min, and with 10 000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ closure occurred with a similar time course. Under voltage clamp, exposure to 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$ and 10 000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ resulted in a rapid increase (mean, 1.5 $\pm$ 0.2-fold, n = 8; range 1.3- to 2.5-fold) in the magnitude of current carried by outward-rectifying K⁺ channels (I-K_{out}). The effect of CO₂ on I-K_{out} was essentially complete within 30 s and was independent of clamp voltage, but was associated with 25-40% (mean, 30 $\pm$ 4%) decrease in the half-time for current activation. Exposure to CO₂ also resulted in a four-fold increase in background current near the free-running membrane voltage, recorded as the instantaneous current at the start of depolarising and hyperpolarising voltage steps, and a decrease in the magnitude of current carried by inward-rectifying K⁺ channels (I-K_{in}). The effect of CO₂ on I-K_{in} was generally slower than on I-K_{out}; it was allied with a transient acceleration of its activation kinetics during the first 60-120 s of treatment; and it was associated with a negative shift in the voltage-sensitivity of gating over a period of 3-5 min. Measurements carried out to isolate the background currents attributable to anion channels (I-Cl_{in}), using tetraethylammonium chloride and CsCl, showed that CO₂ also stimulated I-Cl_{in} and dramatically altered its relaxation kinetics. Within the timeframe of CO₂ action at the membrane, no significant effect was observed on cytosolic pH, measured using the fluorescent dye 2',7'-bis-(2-carboxyethyl)-5,6-carboxyfluorescein (BCECF) and ratio fluorescence microphotometry. These results are broadly consistent with the pattern of guard-cell response to abscisic acid, and indicate that guard cells control both anion and K⁺ channels to achieve net solute loss in CO₂. By contrast with the effects of abscisic acid, however, the data indicate that CO₂ action is not mediated through changes in cytosolic pH and thereby implicate new and, as yet, unidentified pathway(s) for channel regulation in the guard cells.

Bremer, D.J., J.M. Ham, and C.E. Owensby. 1996. Effect of elevated atmospheric carbon dioxide and open-top chambers on transpiration in a tallgrass prairie. *Journal of Environmental Quality* 25(4):691-701.

Increasing concentrations of atmospheric carbon dioxide (CO₂) may influence plant-water relations in natural and agricultural ecosystems. A tallgrass prairie near Manhattan, KS, was exposed to elevated atmospheric CO₂ using open-top chambers (OTCs). Heat balance sap flow gauges were used to measure transpiration in ironweed [*Vernonia baldwini* var. *interior* (Small) Schub.], a C-3 forb, and on individual grass culms of big bluestem (*Andropogon gerardii* Vitman) and indiangrass [*Sorghastrum nutans* (L.) Nash], both C-4 grasses, in each

of three treatments: (i) CE (chamber enriched, 2x ambient CO₂); (ii) CA (chamber ambient, no CO₂ enrichment); and (iii) NC (no chamber, no CO₂ enrichment). Sap flow data were coupled with measurements of stomatal conductance, plant/canopy resistance, and whole-chamber evapotranspiration (ET) to determine the effect of elevated CO₂ on water use at different scales. Because of frequent rainfall during the study, all data were collected under well-watered conditions. Comparisons of CE and CA showed that sap flow was reduced by 33% in ironweed, 18% in big bluestem, and 22% in indiangrass under CO₂ enrichment. Whole-chamber ET was reduced by 23 to 27% under CO₂ enrichment. Comparisons of CA and NC showed that the environmental effect of the OTCs caused a 21 to 24% reduction in transpiration. Stomatal conductance decreased from 7.9 to 3.6 mm s⁻¹ in big bluestem and from 5.3 to 3.2 mm s⁻¹ in indiangrass under CO₂ enrichment. Soil water was consistently highest under elevated CO₂, reflecting the large reductions in transpiration. During sap flow measurements, whole-plant stomatal resistance to water vapor flow increased from 103 to 194 s m⁻¹ under elevated CO₂.

Bremer, D.J., J.M. Ham, C.E. Owensby, and A.K. Knapp. 1998. Responses of soil respiration to clipping and grazing in a tallgrass prairie. *Journal of Environmental Quality* 27(6):1539-1548.

Soil-surface CO₂ flux (F_s) is an important component in prairie C budgets. Although grazing is common in grasslands, its effects on F_s have not been well documented. Three clipping treatments: (i) early-season clipping (EC); (ii) full-season clipping (FC); and (iii) no clipping (NC), which represented two grazing strategies and a control, were applied to plots in a tallgrass prairie in northeastern Kansas, USA. Measurements of F_s were made with a portable gas-exchange system at weekly to monthly intervals for 1 yr. Concurrent measurements of soil temperature and volumetric soil water content at 0.1 m were obtained with dual-probe heat-capacity sensors. Measurements of F_s also were obtained in grazed pastures. F_s ranged annually from 8.8 x 10⁻³ mg m⁻² s⁻¹ during the winter to 0.51 mg m⁻² s⁻¹ during the summer, following the patterns of soil temperature and canopy growth and phenology. Clipping typically reduced F_s 21 to 49% by the second day after clipping despite higher soil temperatures in clipped plots. Cumulative annual F_s were 4.94, 4.04, and 4.11 kg m⁻² yr⁻¹ in NC, EC, and FC treatments, respectively; thus, clipping reduced annual F_s by 17.5%. Differences in F_s between EC and FC were minimal, suggesting that different grazing strategies had little additional impact on annual F_s. Daily F_s in grazed pastures was 20 to 37% less than F_s in ungrazed pastures. Results suggest that grazing moderates F_s during the growing season by reducing canopy photosynthesis and slowing translocation of carbon to the rhizosphere.

Briones, G.L., P. Varoquaux, Y. Chambroy, J. Bouquant, G. Bureau, and B. Pascat. 1992. Storage of common mushroom under controlled atmospheres. *International Journal of Food Science and Technology* 27(5):493-505.

The effect of controlled atmosphere (CA) on the shelf-life of the common mushroom (*Agaricus bisporus*) was assessed using six parameters correlated with its commercial qualities. Low CO₂ concentrations (up to 2.5%) reduced brown discoloration compared to

the control in air. Higher CO₂ concentrations enhanced both internal and external browning. Low O₂ concentrations reduced growth of microorganisms, including pseudomonads. Respiration rate, when the mushrooms are placed again in normal air, is proportional to CO₂ concentration during storage suggesting that CO₂ exhibits a phytotoxic effect on mushrooms. A lower mannitol content was noted in mushrooms stored under CA than those stored in air (control). Mushrooms stored in a 5% CO₂ atmosphere for 7 days did not break their veil but their texture was very soft and spongy. Texture losses decreased when CO₂ concentrations increased.

Brioua, A.H., and C.T. Wheeler. 1994. Growth and nitrogen-fixation in *Alnus glutinosa* (L.) Gaertn under carbon-dioxide enrichment of the root atmosphere. *Plant and Soil* 162(2):183-191.

The effects of aeration of the N-free rooting medium with elevated CO₂ on (a) acetylene reduction by perlite-grown plants and (b) N₂-fixation and long-term growth of nutrient solution-grown plants were determined for nodulated *Alnus glutinosa* (L.) Gaertn. In the former experiments, roots of intact plants were incubated in acetylene in air in darkened glass jars for 3 hr, followed by a further 3 hr incubation period in air enriched with CO₂ (0-5%). During incubation, the CO₂ content of the jars increased by 0.17% per hour due to respiration of the root system, so that the CO₂ content at 3 hr was 0.5%. Additional enrichment of the rooting medium gas-phase with CO₂ equivalent to 1.1% and 1.75% CO₂ of the gas volume significantly increased nitrogenase activity (ethylene production) by 55% and 50% respectively, while enrichment with greater than 2.5% CO₂ decreased activity. In contrast, ethylene production by control plants, where CO₂ was not added to the assay jars, decreased by 8% over the assay period. In long-term growth experiments, nodulated roots of intact *Alnus glutinosa* plants were sealed into jars containing N-free nutrient solution (pH 6.3) and aerated with air, or air containing elevated levels of CO₂ (1.5% and 5%). Comparison of the appearance of CO₂-treated with air treated plants suggested that 1.5% CO₂ stimulated plant growth. However, at harvest after 5 or 6 weeks variability between plants masked the significance of differences in plant dry weight. A significant increase of 33% in total nitrogen of plants aerated with 1.5% CO₂, compared with air-treated plants, was demonstrated, broadly in line with the short-term increase in acetylene reducing activity observed following incubations with similar CO₂ concentrations. Shoot dry weight was not affected significantly by long-term exposure to 5% CO₂, the main effect on growth being a 20% reduction in dry weight of the root system, possibly through inhibition of root system respiration. However, in contrast to the inhibitory effects of high CO₂ on acetylene reduction there was no significant effect on the amounts of N₂ fixed.

Brklacich, M., P. Curran, and D. Brunt. 1996. The application of agricultural land rating and crop models to CO₂ and climate change

issues in Northern regions: The Mackenzie Basin case study. *Agricultural and Food Science in Finland* 5(3):351-365.

The Mackenzie Basin in northwestern Canada covers approximately 1.8 million km² and extends from 52 degrees N to 70 degrees N. Much of the Basin is currently too cool and remote from markets to support a viable agricultural sector, but the southern portion of the Basin has the physical potential to support commercial agriculture. This case study employed agricultural land rating and crop models to estimate the degree to which a CO₂-induced global warming might alter the physical potential for commercial agriculture throughout the Basin. The two climate change scenarios considered in this analysis would relax the current constraints imposed by a short and cool frost-free season, but without adaptive measures, drier conditions and accelerated crop development rates were estimated to offset potential gains stemming from elevated CO₂ levels and warmer temperatures. In addition to striving for a better understanding of the extent to which physical constraints on agriculture might be modified by climate change, there is a need to expand the research context and to consider the capacity of agriculture to adapt to altered climates.

Broadmeadow, M.S.J., J. Heath, and T.J. Randle. 1999. Environmental limitations to O₃ uptake - Some key results from young trees growing at elevated CO₂ concentrations. *Water, Air, and Soil Pollution* 116(1-2):299-310.

Elevated carbon dioxide concentrations and limited water supply have been shown to reduce the impact of ozone pollution on the growth and physiology of *Quercus petraea* in a long-term factorial experiment. These responses can be explained by observed reductions in stomatal conductance, and thus potential ozone exposure of 28% and 40% for CO₂ and drought treatments respectively. However, parameterisation of a stomatal conductance model for *Quercus robur* and *Fagus sylvatica* grown under ambient and elevated CO₂ concentrations in a separate experiment has demonstrated that elevated CO₂ also reduces the responsiveness of stomata to both saturation deficit (LAVPD) and soil moisture deficit (psi) in beech, and to a lesser extent, in oak. Season-long model simulations of ozone fluxes suggest that LAVPD and psi conductance parameters derived at ambient CO₂ concentrations will lead to these fluxes being underestimated by 24% and 2% for beech and oak respectively at 615 ppm CO₂.

Brooks, G.L., and J.B. Whittaker. 1998. Responses of multiple generations of *Gastrophysa viridula*, feeding on *Rumex obtusifolius*, to elevated CO₂. *Global Change Biology* 4(1):63-75.

Rumex obtusifolius plants and three generations of the tri-voltine leaf beetle *Gastrophysa viridula* were simultaneously exposed to elevated CO₂ (600 ppm) to determine its effect on plant quality and insect performance. This exposure resulted in a reduction in leaf nitrogen, an increase in the C/N ratio and lower concentrations of oxalate in the leaves than in ambient air (350 ppm). Despite these changes in food quality, the effect of elevated CO₂ on larvae of *Gastrophysa viridula* over three generations was minimal. However, the effect of CO₂ did differ slightly between the generations of the insect. For the first generation, the results obtained were different from many of the published results in that elevated CO₂ had no measurable effects on

performance, except that third instar larvae showed compensatory feeding. Food quality, including leaf nitrogen content, declined over time in material grown in both ambient and elevated CO₂. The results obtained for the second generation were similar to the first except that first instar larvae showed reduced relative growth rate in elevated CO₂. Development time from hatching to pupation decreased over each generation, probably as a result of increasing temperatures. Measurements of adult performance showed that fecundity at the end of the second generation was reduced relative to the first, in line with the reduction in food quality. In addition at the end of the second generation, but not at the end of the first generation, adult females in elevated CO₂ laid 30% fewer eggs per day and the eggs laid were 15% lighter than those in ambient conditions. These lighter eggs, coupled with no effect of elevated CO₂ on growth during the third generation, meant that the larvae were consistently smaller in elevated CO₂ during this generation. These results offer further insights into the effect that elevated CO₂ will have on insect herbivores and provide a more detailed basis for population predictions.

Brooks, G.L., and J.B. Whittaker. 1999. Responses of three generations of a xylem-feeding insect, *Neophilaenus lineatus* (Homoptera), to elevated CO₂. *Global Change Biology* 5(4):395-401.

A population of the xylem-feeding spittlebug, *Neophilaenus lineatus*, on blocks of natural vegetation transferred to large hemispherical chambers was studied over two generations with continuous exposure to elevated CO₂ (600 ppm). The third generation was transferred from the blocks to potted *Juncus squarrosus* to enable measurements of fecundity. The principal food plant throughout was *Juncus squarrosus*. Survival of the nymphs was reduced by more than 20% in elevated CO₂ relative to ambient (350 ppm) in both years of the main experiment. Elevated CO₂ also delayed development by one or more nymphal instars in each year. Fecundity was not significantly affected. The C/N ratio of whole *Juncus* leaves was increased in elevated CO₂ and the transpiration rates of the plants were reduced. These changes may have been responsible for the effect of elevated CO₂ on spittlebug performance. However, other factors such as plant architecture and microclimate may also be important.

Brooks, J.R., L.B. Flanagan, N. Buchmann, and J.R. Ehleringer. 1997. Carbon isotope composition of boreal plants: Functional grouping of life forms. *Oecologia* 110(3):301-311.

We tested the hypothesis that life forms (trees, shrubs, forbs, and mosses; deciduous or evergreen) can be used to group plants with similar physiological characteristics. Carbon isotope ratios ($\delta^{13}\text{C}$) and carbon isotope discrimination (Δ) were used as functional characteristics because $\delta^{13}\text{C}$ and Δ integrate information about CO₂ and water fluxes, and so are useful in global change and scaling studies. We examined $\delta^{13}\text{C}$ values of the dominant species in three boreal forest ecosystems: wet *Picea mariana* stands, mesic *Populus tremuloides* stands, and dry *Pinus banksiana* stands. Life form groups explained a significant fraction of the variation in leaf carbon isotope composition; seven life-form categories explained 50% of the variation in $\delta^{13}\text{C}$ and 42% of the variation in Δ and 52% of the variance

not due to intraspecific genetic differences ($n=335$). The life forms were ranked in the following order based on their values: evergreen trees < deciduous trees = evergreen and deciduous shrubs = evergreen forbs < deciduous forbs = mosses. This ranking of the life forms differed between deciduous (*Populus*) and evergreen (*Pinus* and *Picea*) ecosystems. Furthermore, life forms in the *Populus* ecosystem had higher discrimination values than life forms in the dry *Pinus* ecosystem; the *Picea* ecosystem had intermediate Delta values. These correlations between Delta and life form were related to differences in plant stature and leaf longevity. Shorter plants had lower Delta values than taller plants, resulting from reduced light intensity at lower levels in the forest. After height differences were accounted for, deciduous leaves had higher discrimination values than evergreen leaves, indicating that deciduous leaves maintained higher ratios of intracellular to ambient CO_2 ($c(i)/c(a)$) than did evergreen leaves in a similar environment within these boreal ecosystems. We found the same pattern of carbon isotope discrimination in a year with above-average precipitation as in a year with below-average precipitation, indicating that environmental fluctuations did not affect the ranking of life forms. Furthermore, plants from sites near the northern and southern boundaries of the boreal forest had similar patterns of discrimination. We concluded that life forms are robust indicators of functional groups that are related to carbon and water fluxes within boreal ecosystems.

Brooks, J.R., L.B. Flanagan, G.T. Varney, and J.R. Ehleringer. 1997. Vertical gradients in photosynthetic gas exchange characteristics and refixation of respired CO_2 within boreal forest canopies. *Tree Physiology* 17(1):1-12.

We compared vertical gradients in leaf gas exchange, CO_2 concentrations, and refixation of respired CO_2 in stands of *Populus tremuloides* Michx., *Pinus banksiana* Lamb. and *Picea mariana* (Mill.) B.S.P. at the northern and southern boundaries of the central Canadian boreal forest. Midsummer gas exchange rates in *Populus tremuloides* were over twice those of the two conifer species, and *Pinus banksiana* rates were greater than *Picea mariana* rates. Gas exchange differences among the species were attributed to variation in leaf nitrogen concentration. Despite these differences, ratios of intercellular CO_2 to ambient CO_2 ($c(i)/c(a)$) were similar among species, indicating a common balance between photosynthesis and stomatal conductance in boreal trees. At night, CO_2 concentrations were high and vertically stratified within the canopy, with maximum concentrations near the soil surface. Daytime CO_2 gradients were reduced and concentrations throughout the canopy were similar to the CO_2 concentration in the well-mixed atmosphere above the canopy space. Photosynthesis had a diurnal pattern opposite to the CO_2 profile, with the highest rates of photosynthesis occurring when CO_2 concentrations and gradients were lowest. After accounting for this diurnal interaction, we determined that photosynthesizing leaves in the understory experienced greater daily CO_2 concentrations than leaves at the top of the canopy. These elevated CO_2 concentrations were the result of plant and soil respiration. We estimated that understory leaves in the *Picea mariana* and *Pinus banksiana* stands gained approximately 5 to 6% of their carbon from respired CO_2 .

Brooks, P.D., D.H. Campbell, K.A. Tonnessen, and K. Heuer. 1999.

Natural variability in N export from headwater catchments: snow cover controls on ecosystem N retention. *Hydrological Processes* 13(14-15):2191-2201.

The causes of natural variability in catchment scale N export need to be understood and quantified before the effects of increased N deposition in high elevation catchments can be evaluated. This study evaluates controls on the size of the leachable soil N pool concurrent with the spring hydrologic flush that is primarily responsible for the transport of N to surface water. In high elevation catchments in the western United States, sources of N during this snowmelt flush include both atmospheric N deposition stored in the snowpack until melt and mobile soil N pools, and sinks are dominated by biogeochemical processes that occur in soil under snow cover. Because soil processes may serve either as a source or sink for N, controls on the amount of inorganic N leached from soil during the snowmelt period were evaluated in the major landscape types in four catchments in Colorado. Measurements of leached N were inversely related to measurements of over-winter CO_2 flux at all sites, indicating that N was immobilized in soil heterotrophic biomass. Because over-winter soil heterotrophic activity is controlled primarily by the depth and timing of snow accumulation, the importance of these plot scale measurements to catchment scale N export were evaluated using a long-term record of winter precipitation, N deposition, and N export from Loch Vale in Rocky Mountain National Park. This data set identified a strong, linear relationship ($r^2 = 0.68$) between catchment scale N retention and winter snow cover, consistent with subnivean, soil based controls on the mobile N pool identified at the plot scale. These results indicate that the winter snow pack is the major control both on hydrologic N export and on soil source/sink relationships for N concurrent with this transport mechanism. The effect of winter snow cover on the fate of both atmospheric and soil N needs to be considered when evaluating potential the effects of increased N deposition on either terrestrial or aquatic ecosystems in seasonally snow-covered watersheds. In these systems, changes in surface water chemistry are likely to occur in high deposition, snow-covered sites during low snow years before terrestrial vegetation is affected. Brown, K.R. 1991. Carbon-dioxide enrichment accelerates the decline in nutrient status and relative growth-rate of *Populus tremuloides* Michx seedlings. *Tree Physiology* 8(2):161-173.

Changes in growth dynamics and mineral nutrient concentrations were measured in *Populus tremuloides* Michx., trembling aspen, grown for 100 days following germination in atmospheres containing 350 or 750- $\mu\text{l l}^{-1}$ CO_2 . Seedlings were fertilized with nitrogen (N) at concentrations of 15.5 mM (high-N), 1.55 mM (medium-N), or 0.155 mM (low-N). Initially, relative growth rates were enhanced by CO_2 enrichment in each N regime, but the effects did not persist. In plants grown in high-N or medium-N, foliar concentrations of Ca and Mg decreased in response to CO_2 enrichment. During the 100-day study, whole-plant concentrations of N and P decreased in all treatments. The decreases in mineral nutrient concentrations over time were accelerated in CO_2 -enriched plants and accompanied the disappearance of the CO_2 -induced growth enhancement. It is concluded that the depression of relative growth rates often associated with long-term CO_2 enrichment of plants may result from decreases in plant nutrient status.

Brown, R.A., and N.J. Rosenberg. 1999. Climate change impacts on

the potential productivity of corn and winter wheat in their primary United States growing regions. *Climatic Change* 41(1):73-107.

We calculate the impacts of climate effects inferred from three atmospheric general circulation models (GCMs) at three levels of climate change severity associated with change in global mean temperature (GMT) of 1.0, 2.5 and 5.0 degrees C and three levels of atmospheric CO₂ concentration ([CO₂]) - 365 (no CO₂ fertilization effect), 560 and 750 ppm - on the potential production of dryland winter wheat (*Triticum aestivum* L.) and corn (*Zea mays* L.) for the primary (current) U.S. growing regions of each crop. This analysis is a subset of the Global Change Assessment Model (GCAM) which has the goal of integrating the linkages and feedbacks among human activities and resulting greenhouse gas emissions, changes in atmospheric composition and resulting climate change, and impacts on terrestrial systems. A set of representative farms was designed for each of the primary production regions studied and the Erosion Productivity Impact Calculator (EPIC) was used to simulate crop response to climate change. The GCMs applied were the Goddard Institute of Space Studies (GISS), the United Kingdom Meteorological Transient (UKTR) and the Australian Bureau of Meteorological Research Center (BMRC), each regionalized by means of a scenario generator (SCENGEN). The GISS scenarios have the least impact on corn and wheat production, reducing national potential production for corn by 6% and wheat by 7% at a GMT of 2.5 degrees C and no CO₂ fertilization effect, the UKTR scenario had the most severe impact on wheat, reducing production by 18% under the same conditions; BMRC had the greatest negative impact on corn, reducing production by 20%. A GMT increase of 1.0 degrees marginally decreased corn and wheat production. Increasing GMT had a detrimental impact on both corn and wheat production, with wheat production suffering the greatest losses. Decreases for wheat production at GMT 5.0 and [CO₂] = 365 ppm range from 36% for the GISS to 76% for the UKTR scenario. Increases in atmospheric [CO₂] had a positive impact on both corn and wheat production. At GMT 1.0, an increase in [CO₂] to 560 ppm resulted in a net increase in corn and wheat production above baseline levels (from 18 to 29% for wheat and 2 to 5% for corn). Increases in [CO₂] help to offset yield reductions at higher GMT levels; in most cases, however, these increases are not sufficient to return crop production to baseline levels.

Brown, S., C.A.S. Hall, W. Knabe, J. Raich, M.C. Trexler, and P. Woomer. 1993. Tropical forests - their past, present, and potential future - role in the terrestrial carbon budget. *Water, Air, and Soil Pollution* 70(1-4):71-94.

In this paper we review results of research to summarize the state-of-knowledge of the past, present, and potential future roles of tropical forests in the global C cycle. In the pre-industrial period (ca. 1850), the flux from changes in tropical land use amounted to a small C source of about 0.06 Pg yr⁻¹. By 1990, the C source had increased to 1.7 +/- 0.5 Pg yr⁻¹. The C pools in forest vegetation and soils in 1990 was estimated to be 159 Pg and 216 Pg, respectively. No concrete evidence is available for predicting how tropical forest ecosystems are likely to respond to CO₂ enrichment and/or climate change. However, C sources from continuing deforestation are likely to overwhelm any change in C fluxes unless land management efforts become more aggressive. Future changes in land use under a "business as usual" scenario could release 41-77 Pg C over the next 60 yr. Carbon fluxes from losses in tropical forests may be lessened by aggressively pursued agricultural and forestry measures. These measures could reduce the magnitude of the tropical C source by 50 Pg by the year 2050. Policies to mitigate C losses must be multiple and concurrent, including reform of forestry, land tenure, arid

agricultural policies, forest protection, promotion of on-farm forestry, and establishment of plantations on non-forested lands. Policies should support improved agricultural productivity, especially replacing non-traditional slash-and-burn agriculture with more sustainable and approaches.

Bryant, J., G. Taylor, and M. Frehner. 1998. Photosynthetic acclimation to elevated CO₂ is modified by source : sink balance in three component species of chalk grassland swards grown in a free air carbon dioxide enrichment (FACE) experiment. *Plant, Cell and Environment* 21(2):159-168.

Artificial chalk grassland swards were exposed to either ambient air or air enriched to 600 $\mu\text{mol mol}^{-1}$ CO₂, using free-air CO₂ enrichment technology, and subjected to an 8 week simulated grazing regime. After 14 months of treatment, ribulose-1,5-bisphosphate carboxylase (Rubisco) activity (V_c, V_{max}) and electron transport mediated ribulose-1,5-bisphosphate (RuBP) regeneration capacity (J_{max}), estimated from leaf gas exchange, were significantly lower in fully expanded leaves of *Anthyllis vulneraria* L. (a legume) and *Sanguisorba minor* Scop, grown in elevated CO₂. After a change in source:sink balance brought about by defoliation, photosynthetic capacity was fully restored in *A. vulneraria* and *S. minor*, but acclimation continued in the grass *Bromopsis erecta* (Hudson) Fourr. Changes in net photosynthesis (P_n) with growth at elevated CO₂ ranged from a 1.6% reduction in pre-cut leaves of *A. vulneraria* to a 47.1% stimulation in post-cut leaves of *S. minor*. Stomatal acclimation was observed in leaves of *A. vulneraria* (reduced stomatal density) and *B. erecta* (reduced stomatal conductance). The results are discussed in terms of whole-plant resource-use optimization and chalk grassland community competitive interactions at elevated CO₂.

Bucher, J.B., D.P. Tarjan, R.T.W. Siegwolf, M. Saurer, H. Blum, and G.R. Hendrey. 1998. Growth of a deciduous tree seedling community in response to elevated CO₂ and nutrient supply. *Chemosphere* 36(4-5):777-782.

In a FACE experiment, one year old alder, ash, beech, and oak seedlings were planted together in tubs containing calcareous sandy alluvial soil with or without a slow release NPK fertilizer, and exposed to ambient and elevated CO₂ concentrations (360 and 600 $\mu\text{mol l}^{-1}$) for 20 weeks. In addition to the fertilizer, all tubs received N-15-ammonium nitrate as a marker. Elevated CO₂ significantly increased biomass production in alder, but had no effect on oak and ash. In beech, due to disease and mortality in all treatments, any possible effects were obscured. The addition of fertilizer had no effect on biomass production in alder, but increased production in oak and ash significantly. In oak a treatment synergism may be present. The non-appearance of a synergistic CO₂ and fertilizer effect in alder may be explained by a fertilizer induced reduction of the N-fixing root-nodule biomass concurrent with a switch of the N-assimilation from atmospheric N to soil N supply, as the $\delta(15)\text{N}$ measurements in the leaves of alder as opposed to oak indicate. Although elevated CO₂ resulted in a significant biomass increase in alder, it did not lead to an appreciable increase in the proportional presence of the species as measured on total plant biomass in the tub. Increasing the nutrient supply in the soil, however,

did lead to appreciable gains in the proportional presence of oak and ash.

Buchi, R., M. Bachmann, and F. Keller. 1998. Carbohydrate metabolism in source leaves of sweet basil (*Ocimum basilicum* L.), a starch-storing and stachyose-translocating labiate. *Journal of Plant Physiology* 153(3-4):308-315.

Sweet basil (*Ocimum basilicum* L.) is an annual aromatic herb that grows in temperate to tropical regions. During ontogeny, the predominant non-structural carbohydrate of mature leaves of plants older than 2 months after sowing was starch (up to 66 mg.g fresh weight(-1)), followed by the raffinose family oligosaccharides (RFO) and galactinol (metabolic RFO precursor) (both up to 1.0 mg.g fresh weight(-1)). Sucrose was only a minor component (up to 0.5 mg.g fresh weight(-1)). All of these carbohydrates displayed distinct diurnal patterns with an increase during the day and a decrease during the night. Starch concentrations showed the most pronounced diurnal change, with an almost tenfold increase during the day. A treatment combining leaf excision, continuous illumination, and high CO₂ levels was aimed at elevating the leaf carbohydrate status and resulted in an increase of the concentrations of starch and soluble carbohydrates (mainly glucose and fructose) of 60- and 12-fold, respectively. We conclude that sweet basil leaves use starch as their main storage carbohydrate, and not RFO or sucrose. Phloem exudates were collected by the classical EDTA- method and analyzed by HPLC. More than 85 % of the translocated sugars were RFO (mainly stachyose) and only 5 % sucrose. To study the tissue compartmentation of stachyose synthesis in source leaves, leaf pieces and mesophyll protoplasts isolated from them were compared. Stachyose and its anabolic enzyme, stachyose synthase, were totally absent from mesophyll protoplasts. Likewise, isolated mesophyll protoplasts were not capable of photosynthesizing [C-14]stachyose from (CO₂)-C-14, even after GO min, whereas osmotically stressed leaf pieces were. These results are in support of the current polymer tray model of symplastic phloem loading of stachyose, which states that stachyose is synthesized in the intermediary cells of minor vein phloem.

Buchmann, N., J.R. Brooks, K.D. Rapp, and J.R. Ehleringer. 1996. Carbon isotope composition of C-4 grasses is influenced by light and water supply. *Plant, Cell and Environment* 19(4):392-402.

The carbon isotope composition of C-4 grasses has the potential to be used as an indicator of changes in the isotopic composition and concentration of atmospheric CO₂, especially for climate reconstruction. The usefulness of C-4 grasses for this purpose hinges on the assumption that their photosynthetic discrimination against C-13 remains constant in a wide range of environmental conditions. We tested this assumption by examining the effects of light and water stress on the carbon isotope composition of C-4 grasses using different biochemical subtypes (NADP-ME, NAD-ME, PCK) in glasshouse experiments. We grew 14 different C-4 grass species in four treatments: sun-watered, sun-drought, shade-watered and shade-drought. Carbon isotope discrimination (Delta) rarely remained constant. In general, Delta values were lowest in sun-watered grasses, greater for sun-drought plants and even higher for plants of the shade-watered treatment. The highest Delta values were generally found in the most stressed grasses, the shade-drought plants. Grasses of the NADP-ME subtype were the least influenced by a change in environmental variables, followed by PCK and NAD-ME subtypes.

Water availability affected the carbon isotope discrimination less than light limitation in PCK and NAD-ME subtypes, but similarly in NADP-ME subtypes. In another experiment, we studied the effect of increasing light levels (150 to 1500 mu mol photons m(-2) s(-1)) on the Delta values of 18 well-watered C-4 grass species. Carbon isotope discrimination remained constant until photon flux density (PFD) was less than 700 mu mol photons m(-2) s(-1). Below this light level, Delta values increased with decreasing irradiance for all biochemical subtypes. The change in Delta was less pronounced in NADP-ME and PCK than in NAD-ME grasses. Grasses grown in the field and in the glasshouse showed a similar pattern. Thus, caution should be exercised when using C-4 plants under varying environmental conditions to monitor the concentration or carbon isotopic composition of atmospheric CO₂ in field/glasshouse studies or climate reconstruction.

Bugbee, B., B. Spanarkel, S. Johnson, O. Monje, and G. Koerner. 1994. CO₂ crop growth enhancement and toxicity in wheat and rice. *Life Sciences and Space Research XXV (3) 14(11):257-267.*

The effects of elevated CO₂ on plant growth are reviewed and the implications for crop yields in regenerative systems are discussed. There is considerable theoretical and experimental evidence indicating that the beneficial effects of CO₂ are saturated at about 0.12% CO₂ in air. However, CO₂ can easily rise above 1% of the total gas in a closed system, and we have thus studied continuous exposure to CO₂ levels as high as 2%. Elevating CO₂ from 340 to 1200 mu mol mol(-1) can increase the seed yield of wheat and rice by 30 to 40%; unfortunately, further CO₂ elevation to 2500 mu mol mol(-1) (0.25%) has consistently reduced yield by 25% compared to plants grown at 1200 mu mol mol(-1); fortunately, there was only an additional 10% decrease in yield as the CO₂ level was further elevated to 2% (20,000 mu mol mol(-1)). Yield increases in both rice and wheat were primarily the result of increased number of heads per m², with minor effects on seed number per head and seed size. Yield increases were greatest in the highest photosynthetic photon flux. We used photosynthetic gas exchange to analyze CO₂ effects on radiation interception, canopy quantum yield, and canopy carbon use efficiency. We were surprised to find that radiation interception during early growth was not improved by elevated CO₂. As expected, CO₂ increased quantum yield, but there was also a small increase in carbon use efficiency. Super-optimal CO₂ levels did not reduce vegetative growth, but decreased seed set and thus yield. The reduced seed set is not visually apparent until final yield is measured. The physiological mechanism underlying CO₂ toxicity is not yet known, but elevated CO₂ levels (0.1 to 1% CO₂) increase ethylene synthesis in some plants and ethylene is a potent inhibitor of seed set in wheat.

Bugmann, H. 1997. Sensitivity of forests in the European Alps to future climatic change. *Climate Research* 8(1):35-44.

Model-based assessments of the impacts of climatic change on forests are confronted with 2 fundamental problems: first, there is a considerable uncertainty in the predictions of future climate; second, the forest models contain simplified parameterizations of ecological processes. In this paper, the sensitivity of forest models to different steady-state climate scenarios, to different process formulations and to different assumptions on the transient behaviour of climate is studied. The effects of 3 scenarios of climatic change and the behaviour of 5 forest gap models of the FORECE/FORCLIM family are compared at sites along an elevational gradient in the European Alps. A wide variety of species compositions may be obtained at a given site depending on the scenario of future climate. At some sites all future forests differ radically from today's forest, suggesting that these current forests are highly sensitive to climatic change. At some sites, the results of the 5 forest models differ strongly with respect to species composition and carbon storage when subjected to the same climate scenario, showing that the models need to be improved in order to arrive at reliable and robust parameterizations of abiotic and biotic influences in forest models. When comparing the effects of step, Linear, and sigmoid changes of the mean climatic parameters over 100 yr, it becomes evident that the type of change modelled is not crucial because the climatic change proceeds fast compared to the successional dynamics. It is concluded that simulations of the possible effects of climatic change on forests should be considered as sensitivity tests, not as predictions. Given the current uncertainties in atmospheric sciences (climate predictions) and in ecology (modelling of long-term forest dynamics), the most promising research strategy is to compare the effects of several climate scenarios and the projections of several forest models to arrive at state-of-the-art ecological impact assessments.

Bukhov, N.G., N. Boucher, and R. Carpentier. 1997. Aftereffect of short-term heat shock on photosynthetic reactions in barley leaves. *Russian Journal of Plant Physiology* 44(4):526-532.

Effects of preheating 8- to 10-day-old barley (*Hordeum vulgare* L.) leaves at 40-46 degrees C on oxygen evolution, chlorophyll fluorescence, and photoacoustic signals were examined. Preheating of leaves at 40 degrees C led to a threefold decrease in the initial slope of the light-response curve of photosynthesis and a marked enhancement of the nonphotochemical quenching of chlorophyll fluorescence, which indicates a drastic increase in the nonradiative dissipation of absorbed light quanta. The maximum photosynthetic activity attained at saturating light and elevated CO₂ concentration was suppressed by this heat treatment by no more than 30%. The photochemical activity of PS II reaction centers in dark-adapted leaves also decreased to the same extent after the heat treatment. In preheated leaves, strong light pulses increased the photobaric component of the photoacoustic signal (measured at 35 Hz) instead of suppressing the signal. The magnitude of the rise-phase of the photoacoustic signal increased with the preheating temperature. An enhancement of the photoacoustic signal induced by strong light pulses was also observed in leaves in which the normal photosynthetic process was disturbed by feeding them methylviologen. It is concluded that the short-term heating of leaves impairs photochemical conversion of light quanta in reaction centers of PS II due to an increase in the magnitude of the proton gradient across the thylakoid membrane. This indicates that dark reactions of photosynthesis in preheated leaves

cannot efficiently use the ATP and reduced NADP formed in the course of photosynthetic electron transport.

Bunce, J.A. 1992. Light, temperature and nutrients as factors in photosynthetic adjustment to an elevated concentration of carbon-dioxide. *Physiologia Plantarum* 86(1):173-179.

The short-term stimulation of the net rate of carbon dioxide exchange of leaves by elevated concentrations of CO₂ usually observed in C3 plants sometimes does not persist. Experiments were conducted to test whether the patterns of response to the environment during growth were consistent with the hypotheses that photosynthetic adjustment to elevated CO₂ concentration is due to (1) feedback inhibition or (2) nutrient stress. Soybean [*Glycine max* (L.) Merr. cv. Williams] and sugar beet (*Beta vulgaris* L. cv. Mono Hye-4) were grown from seed at 350 and 700 $\mu\text{mol l}^{-1}$ CO₂, at 20 and 25-degrees-C, at a photon flux density of 0.5 and 1.0 $\text{mmol m}^{-2} \text{s}^{-1}$ and with three nutrient regimes until the third trifoliate leaf of soybean or the sixth leaf of sugar beet had finished expanding. Net rates of CO₂ exchange of the most recently expanded leaves were then measured at both 350 and 700 $\mu\text{mol l}^{-1}$ CO₂. Plants grown at the elevated CO₂ concentration had net rates of leaf CO₂ exchange which were reduced by 33% in sugar beet and 23% in soybean when measured at 350 $\mu\text{mol l}^{-1}$ CO₂ and when averaged over all treatments. Negative photosynthetic adjustment to elevated CO₂ concentration was not greater at 20 than at 25-degrees-C, was not greater at a photon flux density of 1.0 than at 0.5 $\text{mmol m}^{-2} \text{s}^{-1}$ and was not greater with limiting nutrients. Furthermore, in soybean, negative photosynthetic adjustment could be induced by a single night at elevated CO₂ concentration, with net rates of CO₂ exchange the next day equal to those of leaves of plants grown from seed at the elevated concentration of CO₂. These patterns do not support either the feedback-inhibition or the nutrient-stress hypothesis of photosynthetic adjustment to elevated concentrations of CO₂.

Bunce, J.A. 1992. Stomatal conductance, photosynthesis and respiration of temperate deciduous tree seedlings grown outdoors at an elevated concentration of carbon-dioxide. *Plant, Cell and Environment* 15(5):541-549.

Seedlings of temperate deciduous tree species were grown outdoors at ambient and at an elevated concentration of carbon dioxide to examine how aspects of their gas exchange would be altered by growth at elevated carbon dioxide concentration. Leaf conductances to water vapour and net carbon dioxide exchange rates were determined periodically near midday. Whole-plant carbon dioxide efflux rates in darkness were also determined. The stomatal conductance of leaves of plants grown and measured at 700 $\text{cm}^3 \text{m}^{-3}$ carbon dioxide did not differ from that of plants grown and measured at 350 $\text{cm}^3 \text{m}^{-3}$ in *Malus domestica*, *Quercus prinus* and *Quercus robur* at any measurement time. In *Acer saccharinum*, lower conductances occurred for plants grown and measured at elevated carbon dioxide concentration only at measurement temperatures above 33-degrees-C. Photosynthetic adjustment to elevated carbon dioxide concentration was evident only in *Q. robur*. All species examined had lower rates of dark respiration per unit of mass when grown and measured at elevated carbon dioxide concentration.

Bunce, J.A. 1993. Effects of doubled atmospheric carbon-dioxide concentration on the responses of assimilation and conductance to humidity. *Plant, Cell and Environment* 16(2):189-197.

Experiments were performed to determine if growth at elevated partial pressure of CO₂ altered the sensitivity of leaf water vapour conductance and rate of CO₂ assimilation to the leaf-to-air difference in the partial pressure of water vapour (DELTA_w). Comparisons were made between plants grown and measured at 350 and 700 μPa Pa-1 partial pressures of CO₂ for amaranth, soybean and sunflower grown in controlled environment chambers, soybean grown outdoors in pots, and orchard grass grown in field plots. In amaranth, soybean and orchard grass, both the absolute and the relative sensitivity of conductance to DELTA_w at the leaf surface were less in plants grown and measured at the elevated CO₂. In sunflower, there was no change in the sensitivity of conductance to DELTA_w for the two CO₂ partial pressures. Tests in soybeans and amaranth showed that the change in sensitivity resulted from elevated CO₂ during the measurement of the DELTA_w response. Assimilation rate of CO₂ was not altered by DELTA_w in amaranth, which has C₄ metabolism. In sunflower, the assimilation rate of plants grown and measured at elevated CO₂ was insensitive to DELTA_w, consistent with the response of assimilation rate to intercellular CO₂ partial pressure in the prevailing range. In soybean, the sensitivity of assimilation rate to DELTA_w was not different between CO₂ treatments, in contrast to what would be expected from the response of assimilation rate to intercellular CO₂ partial pressure.

Bunce, J.A. 1993. Growth, survival competition, and canopy carbon-dioxide and water-vapor exchange of 1st year alfalfa at an elevated CO₂ concentration. *Photosynthetica* 29(4):557-565.

Alfalfa was grown in field plots at the current CO₂ concentration (350 μmol mol⁻¹ = c350) and at 350 μmol mol⁻¹ above the current concentration (= c700). Alfalfa and weed growth, and canopy water vapor (E) and carbon dioxide exchange (F) were determined for the first year. Alfalfa yield summed for the three harvests in the first year was greater for the c700 treatment in two of the years studied, but significantly less in a third year. Weed growth was unaffected. Survival of alfalfa plants was greater at c700 for years in which there was substantial mortality, even when yield was not increased by the c700 treatment. In spite of a persistent reduction in leaf conductance to water vapor (g(l)), total canopy conductance (g(c)) to water vapor did not differ between CO₂ treatments when averaged over years, because of compensating changes in canopy leaf area. CO₂ efflux (F) at night per unit of ground area was consistently less in the c700 treatment even when daytime CO₂ uptake was higher. Hence the periodic harvesting of alfalfa crops does not necessarily allow elevated CO₂ to cause persistent growth stimulation nor reduced water use.

Bunce, J.A. 1995. The effect of carbon-dioxide concentration on respiration of growing and mature soybean leaves. *Plant, Cell and Environment* 18(5):575-581.

Soybean plants were grown continuously at 350 and 700 cm(3) m(-3) CO₂ at constant temperature. Respiration rates of third trifoliolate leaves were measured at the growth CO₂ concentration for the whole dark period from 5d before through to 5d after full area expansion. The short-term response of respiration rate to the measurement CO₂ concentration was also determined at each age. Respiration rates per unit of dry mass declined with age and were significantly less at a given age or RGR in leaves grown and measured at the elevated CO₂. The difference in respiration rate was largest in mature leaves and resulted from the different measurement CO₂ concentrations. The respiratory costs of the tissue synthesis, estimated from the elemental composition of the tissue, did not differ substantially between CO₂ treatments. The response of respiration rate to carbon dioxide concentration was not strongly affected by the form of nitrogen supplied. Maintenance respiration calculated by subtracting growth respiration from total respiration was negative in rapidly growing leaves for both CO₂ treatments. This indicates that CO₂ efflux in the dark does not accurately reflect the average 24h rate of energy expenditure on growth and maintenance for soybean leaves.

Bunce, J.A. 1995. Effects of elevated carbon-dioxide concentration in the dark on the growth of soybean seedlings. *Annals of Botany* 75(4):365-368.

Previous work has shown that elevated carbon dioxide (CO₂) concentrations in the dark reversibly reduce the rate of CO₂ efflux from soybeans. Experiments were performed exposing soybean plants continually to concentrations of 350 or 700 cm(3) m(-3) for 24 h d(-1), or to 350 during the day and 700 cm(3) m(-3) at night, in order to determine the importance of the reduced rate of dark CO₂ efflux for plant growth. High CO₂ applied only at night conserved carbon and increased dry mass during initial growth compared with the constant 350 cm(3) m(-3) treatment. Long-term net assimilation rate was increased by high CO₂ in the dark, without any increase in daytime leaf photosynthesis. However, leaf area ratio was reduced by the dark CO₂ treatment to values equal to those of plants continually exposed to the higher concentration. From days 14-21, leaf area was less for the elevated night-time CO₂ treatment than for either the constant 350 or 700 cm(3) m(-3) treatments. For the day 7-21-period, relative growth rate was significantly reduced by the high night CO₂ treatment compared with the 350 cm(3) m(-3) continuous treatment. The results indicate that some functionally significant component of respiration was reduced by the elevated CO₂ concentration in the dark.

Bunce, J.A. 1995. Long-term growth of alfalfa and orchard grass plots at elevated carbon dioxide. *Journal of Biogeography* 22(2-3):341-348.

Alfalfa (*Medicago sativa* L.) and orchard grass (*Dactylis glomerata* L.) plots were exposed to ambient or ambient plus 350 cm(3) m(-3) carbon dioxide concentrations at Beltsville, Maryland, U.S.A. Replicate plots were established in different years and fertilized annually. We report here data for the second and third years after establishment. There has been no increase in the yearly production of either species at the elevated carbon dioxide concentration after the first season. In orchard grass, reduced growth at the high carbon dioxide concentration in the spring offset growth stimulation in the summer. Weed growth was consistently increased by carbon dioxide enrichment, but weed species composition was unaffected. Leaf photosynthetic capacity was reduced by the high carbon dioxide concentration in both crop species, as was leaf nitrogen

content. Canopy carbon dioxide uptake was slightly higher in the elevated carbon dioxide treatments, consistent with the increased weed growth. In alfalfa, elevated carbon dioxide significantly reduced canopy carbon dioxide efflux at night for the same daytime uptake rate and temperature. The growth conversion efficiency estimated from elemental composition of the tissue was not substantially altered by carbon dioxide treatment in either crop species, indicating little effect of carbon dioxide treatment on the respiratory cost of tissue synthesis. Canopy conductance to water vapour averaged 23% less at high than at low carbon dioxide in the orchard grass plots, and 14% less in the alfalfa plots. This was consistent with the smaller short-term response of conductance to carbon dioxide concentration in the alfalfa plots. It is concluded that a warm climate and fertile soil does not guarantee a persistent response of production to elevated carbon dioxide concentration in these herbaceous perennial species.

Bunce, J.A. 1996. Growth at elevated carbon dioxide concentration reduces hydraulic conductance in alfalfa and soybean. *Global Change Biology* 2(2):155-158.

Hydraulic conductances of alfalfa and soybean plants grown in controlled environment chambers at the current ambient carbon dioxide concentration and at twice the current ambient concentration were determined from measurements of transpiration rate and leaf and stem water potentials in the growth conditions. Growth at elevated carbon dioxide concentration reduced both transpiration rate and hydraulic conductance from the soil to the leaf in both species. Hydraulic conductance from the soil to the base of the stem was also lower at elevated carbon dioxide in soybean, but not alfalfa. These measurements identified the stem to leaf hydraulic pathway as a major target of the carbon dioxide effect in both species. The conductance of excised stem segments was much less in plants grown at elevated carbon dioxide in soybeans.

Bunce, J.A. 1997. Variation in growth stimulation by elevated carbon dioxide in seedlings of some C-3 crop and weed species. *Global Change Biology* 3(1):61-66.

Seven C-3 crop and three C-3 weed species were grown from seed at 360 and at 700 cm³ m⁻³ carbon dioxide concentrations in a controlled environment chamber to compare dry mass, relative growth rate (RGR), net assimilation rate (NAR), leaf area ratio (LAR) and photosynthetic acclimation at ambient and elevated carbon dioxide. The dry mass at the final harvest at elevated carbon dioxide relative to that at ambient carbon dioxide was highly correlated with the RGR at the lower carbon dioxide concentration. This relationship could be quite common, because it does not require that species differ in the response of RGR or photosynthesis to elevated carbon dioxide, and holds even when species differ moderately in these responses. RGR was also measured for a limited period at the end of the experiment to determine relationships with leaf gas exchange measured at this time. Relative increases in RGR at elevated carbon dioxide at this time were more highly correlated with the relative increase in NAR at elevated carbon dioxide than with the response of LAR. The amount of acclimation of photosynthesis was a good predictor of the relative increase in NAR at elevated carbon dioxide, and the longterm increase in photosynthesis in the growth environment. No differences between crops and weeds or between cool and warm climate species were found in the responses of growth or photosynthetic acclimation to elevated carbon dioxide.

Bunce, J.A. 1998. Effects of environment during growth on the sensitivity of leaf conductance to changes in humidity. *Global Change Biology* 4(3):269-274.

Soybeans (*Glycine max*) and grain amaranth (*Amaranthus hypochondriacus*) were grown at a range of temperatures, carbon dioxide concentrations and light conditions in controlled environment chambers, and the response of leaf conductance to water vapour to changes in humidity was then measured under a standard set of conditions. The sensitivity of conductance was analysed in terms of (i) the absolute sensitivity of conductance to changes in leaf to air water vapour pressure difference (LAVPD), (ii) the sensitivity of conductance relative to the absolute value of conductance, and (iii) the slope of the relationship between conductance and an index incorporating assimilation rate, carbon dioxide concentration and relative humidity. The sensitivity of conductance varied substantially with growth conditions for all three analyses in both species. The growth temperature of 25 degrees C increased the sensitivity of conductance by all three measures compared with growth at 20 or 30 degrees C in amaranth, with little difference between 25 and 30 degrees C in soybean. Growth at elevated carbon dioxide decreased sensitivity in amaranth by all three measures, and decreased the absolute but not the relative sensitivity in soybean. Growth at reduced photon flux density and growth at high stand density reduced sensitivity in amaranth by all three measures. In soybean, growth at high stand density reduced sensitivity by all three measures, but growth at low photon flux density increased the relative sensitivity. The sensitivity of leaf conductance to changes in humidity varied by a factor of two or more with growth environment by all measures of sensitivity in both the C3 and the C4 species.

Bunce, J.A. 1998. The temperature dependence of the stimulation of photosynthesis by elevated carbon dioxide in wheat and barley. *Journal of Experimental Botany* 49(326):1555-1561.

The temperature dependencies of the solubility of carbon dioxide and oxygen in water and the temperature dependency of the kinetic characteristics of the ribulose-1,5 bisphosphate carboxylase/oxygenase (Rubisco) enzyme result in the short-term stimulation of photosynthesis with a doubling of carbon dioxide from 350 to 700 $\mu\text{mol mol}^{-1}$ usually decreasing from about 90% at 30 degrees C to about 25% at 10 degrees C at high photon flux. In field-grown wheat and barley, the expected values at 30 degrees C were observed, but also values as high as 60% at 10 degrees C. The much larger than expected stimulation at cool temperatures in these species also occurred in plants grown at 15 degrees C, but not at 23 degrees C in controlled environment chambers. Gas exchange analysis indicated that an unusually high diffusive limitation was not an explanation for the large response. Assessment of the apparent in vivo specificity of Rubisco by determining the carbon dioxide concentration at which carboxylation equalled carbon dioxide release from oxygenation, indicated that growth at row temperatures altered the apparent enzyme specificity in these species compared to these species grown at the warmer temperature. Inserting the observed specificities into a biochemical model of photosynthesis indicated that altered Rubisco specificity was consistent with the observed rates of assimilation. Whether altered apparent Rubisco specificity is caused by altered stoichiometry of photorespiration or an actual change in enzyme specificity, the results indicate that the temperature dependence of the stimulation of photosynthesis by elevated carbon dioxide may vary greatly with species and with prior exposure to low temperatures.

Bunce, J.A., K.B. Wilson, and T.N. Carlson. 1997. The effect of doubled CO₂ on water use by alfalfa and orchard grass: Simulating evapotranspiration using canopy conductance measurements. *Global Change Biology* 3(1):81-87.

Alfalfa and orchard grass crops were grown at ambient and twice ambient carbon dioxide concentrations in field plots for several years in Beltsville, MD, using semiopen chambers. Canopy conductances throughout many days were determined from water vapour exchange measurements, and indicated significant reductions in canopy conductance to water vapour at elevated carbon dioxide in both species. However, recognizing that the artificial ventilation in the chambers made direct comparisons of evapotranspiration rates questionable, we used a soil-vegetation-atmosphere model to determine what field-scale evapotranspiration rates would have been with natural ventilation. Unlike the 'omega' approach, the model used allowed feedbacks between the canopy and the atmosphere, such that, for example, canopy conductance responses affected profiles of temperature and water vapour. Simulations indicated that although canopy conductances were lower at elevated carbon dioxide by as much as 20% in alfalfa and 60% in orchard grass, evapotranspiration rates never differed by more than 3% in alfalfa or 8% in orchard grass. Daily totals of evapotranspiration were only 1-2% lower at elevated carbon dioxide in alfalfa, and 2-5% lower in orchard grass. The results are partly explained by the fact that aerodynamic conductances to water vapour were generally smaller than the stomatal conductance, and also by canopy-atmosphere feedback processes which largely compensated for the lower conductance at elevated carbon dioxide by increasing the gradient for evaporation.

Bunce, J.A., and L.H. Ziska. 1996. Responses of respiration to increases in carbon dioxide concentration and temperature in three soybean cultivars. *Annals of Botany* 77(5):507-514.

The purpose of this experiment was to determine how respiration of soybeans may respond to potential increases in atmospheric carbon dioxide concentration and growth temperature. Three cultivars of soybeans (*Glycine max* L. Merr.), from maturity groups 00, IV, and VIII, were grown at 370, 555 and 740 cm³ m⁻³ carbon dioxide concentrations at 20/15, 25/20, and 31/26 degrees C day/night temperatures. Rates of carbon dioxide efflux in the dark were measured for whole plants several times during exponential growth. These measurements were made at the night temperature and the carbon dioxide concentration at which the plants were grown. For the lowest and highest temperature treatments, the short term response of respiration rate to measurement at the three growth carbon dioxide concentrations was also determined. Elemental analysis of the tissue was used to estimate the growth conversion efficiency. This was combined with the observed relative growth rates to estimate growth respiration. Maintenance respiration was estimated as the difference between growth respiration and total respiration. Respiration rates were generally sensitive to short term changes in the measurement carbon dioxide concentration for plants grown at the lowest, but not the highest carbon dioxide concentration. At all temperatures, growth at elevated carbon dioxide concentrations decreased total respiration measured at the growth concentration, with no significant differences among cultivars. Total respiration increased very little with increasing growth

temperature, despite an increase in relative growth rate. Growth respiration was not affected by carbon dioxide treatment at any temperature, but increased with temperature because of the increase in relative growth rate. Values calculated for maintenance respiration decreased with increasing carbon dioxide concentration and also decreased with increasing temperature. Calculated values of maintenance respiration were sometimes zero or negative at the warmer temperatures. This suggests that respiration rates measured in the dark may not have reflected average 24-h rates of energy use. The results indicate that increasing atmospheric carbon dioxide concentration may reduce respiration in soybeans, and respiration may be insensitive to climate warming. Bunce, J.A., and L.H. Ziska. 1998. Decreased hydraulic conductance in plants at elevated carbon dioxide. *Plant, Cell and Environment* 21(1):121-126.

Previous work indicated that long-term exposure to elevated carbon dioxide levels can reduce hydraulic conductance in some species, but the basis of the response was not determined. In this study, hydraulic conductance was measured at concentrations of both 350 and 700 cm³ m⁻³ carbon dioxide for plants grown at both concentrations, to determine the reversibility of the response. In *Zea mays* and *Amaranthus hypochondriacus*, exposure to the higher carbon dioxide concentration for several hours reduced whole-plant transpiration rate by 22-40%, without any consistent change in leaf water potential, indicating reversible reductions in hydraulic conductance at elevated carbon dioxide levels. Hydraulic conductance in these species grown at both carbon dioxide concentrations responded similarly to measurement concentration of carbon dioxide, indicating that the response was reversible. In *Glycine max*, which in earlier work had shown a long-term decrease in hydraulic conductance at elevated carbon dioxide levels, and in *Abutilon theophrasti*, no short-term changes in hydraulic conductance with measurement concentration of carbon dioxide were found, despite lower transpiration rates at elevated carbon dioxide. In *G. max* and *Medicago sativa*, growth at high dew-point temperature reduced transpiration rate and decreased hydraulic conductance. The results indicate that both reversible and irreversible decreases in hydraulic conductance can occur at elevated carbon dioxide concentrations, and that both could be responses to reduced transpiration rate, rather than to carbon dioxide concentration itself.

Burton, A.J., G.P. Zogg, K.S. Pregitzer, and D.R. Zak. 1997. Effect of measurement CO₂ concentration on sugar maple root respiration. *Tree Physiology* 17(7):421-427.

Accurate estimates of root respiration are crucial to predicting belowground C cycling in forest ecosystems. Inhibition of respiration has been reported as a short-term response of plant tissue to elevated measurement [CO₂]. We sought to determine if measurement [CO₂] affected root respiration in samples from mature sugar maple (*Acer saccharum* Marsh.) forests and to assess possible errors associated with root respiration measurements made at [CO₂]s lower than that typical of the soil atmosphere. Root respiration was measured as both CO₂ production and O₂ consumption on excised fine roots (less than or equal to 1.0 mm) at [CO₂]s ranging from 350 to > 20,000 μl l⁻¹.

Root respiration was significantly affected by the [CO₂] at which measurements were made for both CO₂ production and O₂ consumption. Root respiration was most sensitive to [CO₂] near and below normal soil concentrations (< 1500 µl l⁻¹). Respiration rates changed little at [CO₂]s above 3000 µl l⁻¹ and were essentially constant above 6000 µl l⁻¹ CO₂. These findings call into question estimates of root respiration made at or near atmospheric [CO₂], suggesting that they overestimate actual rates in the soil. Our results indicate that sugar maple root respiration at atmospheric [CO₂] (350 µl l⁻¹) is about 139% of that at soil [CO₂]. Although the causal mechanism remains unknown, the increase in root respiration at low measurement [CO₂] is significant and should be accounted for when estimating or modeling root respiration. Until the direct effect of [CO₂] on root respiration is fully understood, we recommend making measurements at a [CO₂] representative of, or higher than, soil [CO₂]. In all cases, the [CO₂] at which measurements are made and the [CO₂] typical of the soil atmosphere should be reported.

Burton, P.J., and S.G. Cumming. 1995. Potential effects of climatic-change on some western canadian forests, based on phenological enhancements to a patch model of forest succession. *Water, Air, and Soil Pollution* 82(1-2):401-414.

We enhanced the forest patch model, Zelig, to explore the implications of 2xCO₂ climate change scenarios on several forest regions in British Columbia and Alberta, Canada. In addition to the processes and phenomena commonly represented in individual-based models of forest stand dynamics, we added some species-specific phenology and site-specific frost events. The consideration of bud-break heat sum requirements, growing season limits, and chilling requirements for the induction of dormancy and cold hardiness slightly improved the ability of Zelig to predict the present composition of B.C. forests. Simulations of the predicted effects of future climatic regimes (based on the averaged predictions of four general circulation models) include some major shifts in equilibrium, forest composition and productivity. Lowland temperate coastal forests are predicted to be severely stressed because indigenous species will no longer have their winter chilling requirements met. High-elevation coastal forests are expected to increase in productivity, while interior subalpine forests are expected to remain stable in productivity but will gradually be replaced by species currently characteristic of lower elevations. Dry, interior low-elevation forests in southern B.C. are likely to persist relatively unchanged, while wet interior forests are expected to support dramatic increases in yield, primarily by western hemlock. Northern interior sub-boreal forests are likewise expected to increase in productivity through enhanced growth of lodgepole pine. Conversely, the precipitous collapse of spruce stands in the true boreal forests of northeastern B.C. is expected to be associated with reduced productivity as they are replaced by pine species. Boreal-Cordilleran and Moist Boreal Mixedwood forests in Alberta are less likely to undergo compositional change, while becoming somewhat more productive. We believe these model enhancements to be a significant improvement over existing formulations, but the resulting predictions must still be viewed with caution. Model limitations include: (1) the current inability of climate models to predict future variation in monthly temperature and precipitation; (2) sparse information on the phenological behaviour of several important tree species; and (3) a poor understanding of the degree to which growth is constrained by different suboptimal climatic events.

Buse, A., and J.E.G. Good. 1996. Synchronization of larval emergence in winter moth (*Operophtera brumata* L) and budburst in pedunculate oak (*Quercus robur* L) under simulated climate change. *Ecological Entomology* 21(4):335-343.

1. The hypothesis that a 3 degrees C elevation in temperature and doubled CO₂ concentration would have no effect on the synchronization of winter moth egg hatch with budburst in oak was tested by comparing the separate and interactive effects of ambient and elevated (+ 3 degrees C) temperature and ambient and elevated (doubled to 340 p.p.m.) CO₂ in eight experimental Solardomes. In addition, an outdoor control was compared with the ambient temperature/CO₂ treatment combination. 2. Elevated temperature accelerated darkening (preceding egg hatch by about 5-10 days) and hatching of eggs developing off the trees; elevated CO₂ had no effect. The same effects were observed in eggs developing on the trees. 3. Within treatments, date of egg hatch was the same on trees with early or late budburst. 4. Egg darkening and budburst were closely synchronized at both ambient and elevated temperatures. 5. Both eggs and trees required fewer cumulative heat units (day degrees > 4 degrees C), for hatching and budburst, respectively, at ambient than elevated temperatures. The requirements in the outdoor control treatment were similar to those in the ambient Solardome treatment. 6. Egg hatch between 10 and 25 degrees C, on a temperature gradient in the laboratory, required a constant number of heat units; fewer were required below 10 degrees C. 7. Elevated temperatures, in the Solardomes and the field, delayed adult emergence from the pupae. 8. The results suggest that a general increase in temperature with climatic change would not affect the closeness of the synchronization between egg hatch of winter moth and budburst of oak.

Buse, A., J.E.G. Good, S. Dury, and C.M. Perrins. 1998. Effects of elevated temperature and carbon dioxide on the nutritional quality of leaves of oak (*Quercus robur* L.) as food for the Winter Moth (*Operophtera brumata* L.). *Functional Ecology* 12(5):742-749.

1. Pedunculate Oak trees were grown in ambient and elevated temperatures and CO₂. Leaves were fed to Winter Moth caterpillars reared either in constant conditions or with the trees (caged or on-tree). 2. Caterpillars in constant conditions ate the same mass and produced the same mass of faeces whether fed elevated or ambient temperature leaves. However, less was assimilated from elevated leaves, resulting in lighter pupae and fewer, lighter eggs. 3. Caterpillars in constant conditions ate more and produced more faeces when fed elevated CO₂ leaves than when fed ambient CO₂ leaves, but the mass assimilated and pupal mass were unchanged. 4. Caged caterpillars reared with the trees from which they were fed had constant pupal mass in all treatments, but pupated earlier at elevated temperature. Pupal mass was also unaffected when caterpillars fed on the trees. 5. Nitrogen was reduced in both elevated temperature and elevated CO₂ leaves. Increased fibre in the former prevented increased consumption and resulted in reduced pupal mass and fecundity. Reduced fibre in the latter allowed increased consumption, resulting in pupae of normal mass. 6. Despite the clear effect of nutrient quality, experiments rearing caterpillars and trees together suggest that anticipated climatic change will have no nutritional effect on Winter Moth development.

Bytnerowicz, A. 1996. Physiological aspects of air pollution stress in forests. *Phyton-Annales Rei Botanicae* 36(3):15-22.

Air pollutants, such as ozone, sulfur dioxide, nitrogen compounds and others, affect health of forests in Europe and North America. Gaseous air pollutants enter plants mainly through stomata, although transcuticular transport can also be important for some pollutants. Toxic effects of pollutants depend on their effective dose that is proportional to pollutant ambient concentration and plant stomatal conductance. Mechanisms of air pollution toxicity are very complex and depend on various physiological and biochemical properties of plants. These mechanisms (including formation of free radicals) are still poorly understood. In addition, physiological responses of forest plants to air pollution stress can be modified by various biotic (e.g., insects, pathogens, mycorrhizae associations, genetic variation) and abiotic (e.g., increasing CO₂ concentrations, ultraviolet-B radiation, nitrogen deposition, nutrient deficiencies, drought) factors. An example of air pollution effects on forest trees may be responses of ponderosa pine seedlings to elevated concentrations of ozone in the Sierra Nevada. Various physiological changes caused by ozone (e.g., lowered net photosynthesis, altered carbon allocation, deterioration of photosynthetic pigments, etc.) have led to the reduced growth and biomass of the seedlings.

Cairney, J.W.G., and A.A. Meharg. 1999. Influences of anthropogenic pollution on mycorrhizal fungal communities. *Environmental Pollution* 106(2):169-182.

Mycorrhizal fungi form complex communities in the root systems of most plant species and are thought to be important in terrestrial ecosystem sustainability. We have reviewed the literature relating to the influence of the major forms of anthropogenic pollution on the structure and dynamics of mycorrhizal fungal communities. All forms of pollution have been reported to alter the structure of below-ground communities of mycorrhizal fungi to some degree, although the extent to which such changes will be sustained in the longer term is at present not clear. The major limitation to predicting the consequences of pollution-mediated changes in mycorrhizal fungal communities to terrestrial habitats is our limited understanding of the functional significance of mycorrhizal fungal diversity. While this is identified as a priority area for future research, it is suggested that, in the absence of such data, an understanding of pollution-mediated changes in mycorrhizal mycelial systems in soil may provide useful indicators for sustainability of mycorrhizal systems. Callaway, R.M., E.H. Delucia, E.M. Thomas, and W.H. Schlesinger. 1994. Compensatory responses of CO₂ exchange and biomass allocation and their effects on the relative growth-rate of ponderosa pine in different CO₂ and temperature regimes. *Oecologia* 98(2):159-166.

Increases in the concentration of atmospheric carbon dioxide may have a fertilizing effect on plant growth by increasing photosynthetic rates and therefore may offset potential growth decreases caused by the stress associated with higher temperatures and lower precipitation. However, plant growth is determined both by rates of net photosynthesis and by

proportional allocation of fixed carbon to autotrophic tissue and heterotrophic tissue. Although CO₂ fertilization may enhance growth by increasing leaf-level assimilation rates, reallocation of biomass from leaves to stems and roots in response to higher concentrations of CO₂ and higher temperatures may reduce whole-plant assimilation and offset photosynthetic gains. We measured growth parameters, photosynthesis, respiration, and biomass allocation of *Pinus ponderosa* seedlings grown for 2 months in 2 x 2 factorial treatments of 350 or 650 μmole bar CO₂ and 10/25-degrees-C or 15/30-degrees-C night/day temperatures. After 1 month in treatment conditions, total seedling biomass was higher in elevated CO₂, and temperature significantly enhanced the positive CO₂ effect. However, after 2 months the effect of CO₂ on total biomass decreased and relative growth rates did not differ among CO₂ and temperature treatments over the 2-month growth period even though photosynthetic rates increased almost-equal-to 7% in high CO₂ treatments and decreased almost-equal-to 10% in high temperature treatments. Additionally, CO₂ enhancement decreased root respiration and high temperatures increased shoot respiration. Based on CO₂ exchange rates, CO₂ fertilization should have increased relative growth rates (RGR) and high temperatures should have decreased RGR. Higher photosynthetic rates caused by CO₂ fertilization appear to have been mitigated during the second month of exposure to treatment conditions by a almost-equal-to 3% decrease in allocation of biomass to leaves and a almost-equal-to 9% increase in root:shoot ratio. It was not clear why diminished photosynthetic rates and increased respiration rates at high temperatures did not result in lower RGR. Significant diametrical and potentially compensatory responses of CO₂ exchange and biomass allocation and the lack of differences in RGR of ponderosa pine after 2 months of exposure of high CO₂ indicate that the effects of CO₂ fertilization and temperature on whole-plant growth are determined by complex shifts in biomass allocation and gas exchange that may, for some species, maintain constant growth rates as climate and atmospheric CO₂ concentrations change. These complex responses must be considered together to predict plant growth reactions to global atmospheric change, and the potential of forest ecosystems to sequester larger amounts of carbon in the future.

Campbell, B.D., W.A. Laing, D.H. Greer, J.R. Crush, H. Clark, D.Y. Williamson, and M.D.J. Given. 1995. Variation in grassland populations and species and the implications for community responses to elevated CO₂. *Journal of Biogeography* 22(2-3):315-322.

Variation in plant characteristics and potential responses to CO₂ was measured in controlled environments for a set of different forage plant species and populations. The response of the plants to elevated CO₂ was strongly determined by temperature. The greatest responses to elevated CO₂ were observed at warm temperatures in C3 species with high potential growth rates at these temperatures. This suggests that the community composition could change most rapidly in response to CO₂ in warm seasons, with the greatest positive responses to CO₂ occurring in warm-season active species. This prediction was tested in a microcosm experiment. The prediction was confirmed under well-watered conditions but water stress resulted in an ingress of C4 species with low potential responses to CO₂. The results suggest that variation between populations and species must be considered when predicting grassland community responses to CO₂, and that it is inappropriate to ignore compositional changes in communities when modelling CO₂ effects on pasture production. Given the importance of temperature in determining CO₂ responsiveness, phenology may prove to be a useful attribute in plant functional type analyses of community responses to CO₂.

Campbell, B.D., D.M.S. Smith, and G.M. McKeon. 1997. Elevated CO₂ and water supply interactions in grasslands: A pastures and rangelands management perspective. *Global Change Biology* 3(3):177-187.

Water is a key variable driving the composition and productivity of pastures and rangelands, and many of the ecosystems in these grasslands are highly sensitive to changes in water supply. The possibility that elevated CO₂ concentrations may alter plant water relations is therefore particularly relevant to pastures and rangelands, and may have important consequences for grassland ecosystem function, water use, carbon storage and nutrient cycling. The planning of effective research to better understand these changes requires attention to both: (i) gaps in knowledge about CO₂ and water interactions, and (ii) knowledge of how precisely the effects of CO₂ must be understood in relation to other factors, in order to predict changes in grassland structure and production. A recent microcosm experiment illustrates that non-linear effects of CO₂ and water stress could perturb primary production by triggering changes in grassland community composition. The magnitudes of the effects of CO₂ on key grassland ecosystems remain to be precisely determined through ecosystem-level experiments. A simplified simulation of the impact of different levels of productivity change in a water-limited Australian rangeland system was conducted by varying effects of CO₂ on radiation and water use efficiency. The results indicate that direct effects of CO₂ may be moderated at the enterprise scale by accompanying changes in adaptive management by farmers. We conclude that future research should aim to construct quantitative relationships and identify thresholds of response for different grassland systems. The sensitivity of these systems to management (such as grazing pressure) should also be considered when developing integrated predictions of future effects of CO₂ on water supply to grassland ecosystems.

Canadell, J.G., L.F. Pitelka, and J.S.I. Ingram. 1996. The effects of elevated [CO₂] on plant-soil carbon below-ground: A summary and synthesis. *Plant and Soil* 187(2):391-400.

We undertake a synthesis of the most relevant results from the presentations at the meeting "Plant-Soil Carbon Below-Ground: The Effects of Elevated CO₂" (Oxford-UK, September 1995), many of which are published in this Special Issue. Below-ground responses to elevated [CO₂] are important because the capacity of soils for long-term carbon sequestration. We draw the following conclusions: (i) several ecosystems exposed to elevated [CO₂] showed sustained increased CO₂ uptake at the plot level for many years. A few systems, however, showed complete down-regulation of net CO₂ uptake after several years of elevated [CO₂] exposure; (ii) under elevated [CO₂], a greater proportion of fixed carbon is generally allocated below-ground, potentially increasing the capacity of below-ground sinks; and (iii) some of the increased capacity of these sinks may lead to increased long-term soil carbon sequestration, although strong evidence is still lacking. We highlight the need for more soil studies to be undertaken within ongoing ecosystem-level

experiments, and suggest that while some key experiments already established should be maintained to allow long term effects and feedbacks to take place, more research effort should be directed to mechanisms of soil organic matter stabilization.

Cannell, M.G.R., and J.H.M. Thornley. 1998. N-poor ecosystems may respond more to elevated [CO₂] than N-rich ones in the long term. A model analysis of grassland. *Global Change Biology* 4(4):431-442.

The Hurley Pasture Model was used to examine the short and long-term responses of grazed grasslands in the British uplands to a step increase from 350 to 700 $\mu\text{mol mol}^{-1}$ CO₂ concentration ([CO₂]) with inputs of 5 or 100 kg N ha⁻¹ y⁻¹. In N-rich grassland, [CO₂] doubling quickly increased net primary productivity (NPP), total carbon (C-sys) and plant biomass by about 30%. By contrast, the N-poor grassland underwent a prolonged 'transient', when there was little response, but eventually NPP, C-sys and plant biomass more than doubled. The 'transient' was due to N immobilization and severe depletion of the soil mineral N pool. The large long-term response was due to slow N accumulation, as a result of decreased leaching, decreased gaseous N losses and increased N-fixation, which amplified the CO₂ response much more in the N-poor than in the N-rich grassland. It was concluded that (i) ecosystems use extra carbon fixed at high [CO₂] to acquire and retain nutrients, supporting the contention of Gifford et al. (1996), (ii) in the long term, and perhaps on the real timescale of increasing [CO₂], the response (in NPP, C-sys and plant biomass) of nutrient-poor ecosystems may be proportionately greater than that of nutrient-rich ones, (iii) short-term experiments on nutrient-poor ecosystems may observe only the transient responses, (iv) the speed of ecosystem responses may be limited by the rate of nutrient accumulation rather than by internal rate constants, and (v) ecosystem models must represent processes affecting nutrient acquisition and retention to be able to simulate likely real-world CO₂ responses.

Cannell, M.G.R., and J.H.M. Thornley. 1998. Temperature and CO₂ responses of leaf and canopy photosynthesis: A clarification using the non-rectangular hyperbola model of photosynthesis. *Annals of Botany* 82(6):883-892.

The responses of C-3 leaf and canopy gross photosynthesis to increasing temperature and CO₂ can be readily understood in terms of the temperature and CO₂ dependencies of quantum yield ($\phi(i)$) and light-saturated photosynthesis ($A(\text{sat})$) the two principal parameters in the non-rectangular hyperbola model of photosynthesis. Here, we define these dependencies within the mid-range for C-3 herbaceous plants, based on a review of the literature. Then, using illustrative parameter values, we deduce leaf and canopy photosynthesis responses to temperature and CO₂ in different environmental conditions (including shifts in the temperature optimum) from the assumed sensitivities of $\phi(i)$ and $A(\text{sat})$ to temperature and CO₂. We show that: (1) elevated CO₂ increases photosynthesis more at warm than at cool temperatures because of the large combined CO₂-responses of both $\phi(i)$ and $A(\text{sat})$ at high temperatures; (2) elevated CO₂ may substantially raise the temperature optimum of photosynthesis at warm temperatures, but not at the cool temperatures which prevail for much of the time at temperate

and high latitudes; (3) large upward shifts in the temperature optimum of canopy gross photosynthesis occur at high irradiances, following the response of A(sat), and are probably important for global carbon fixation; (4) canopy gross photosynthesis shows smaller CO₂-temperature interactions than leaf photosynthesis, because leaves in canopies receive lower average irradiances and sep more strongly follow the dependencies of phi(i); and (5) at very low irradiances, the temperature optimum of photosynthesis is low and is raised very little by increasing CO₂. (C) 1998 Annals of Botany Company.

Cannon, R.J.C. 1998. The implications of predicted climate change for insect pests in the UK, with emphasis on non-indigenous species. *Global Change Biology* 4(7):785-796.

Recent estimates for global warming predict increases in global mean surface air temperatures (relative to 1990) of between 1 and 3.5 degrees C, by 2100. The impact of such changes on agricultural systems in mid-to high-latitude regions are predicted to be less severe than in low-latitude regions, and possibly even beneficial, although the influence of pests and diseases is rarely taken into account. Most studies have concluded that insect pests will generally become more abundant as temperatures increase, through a number of inter-related processes, including range extensions and phenological changes, as well as increased rates of population development, growth, migration and overwintering. A gradual, continuing rise in atmospheric CO₂ will affect pest species directly (i.e. the CO₂ fertilization effect) and indirectly (via interactions with other environmental variables). However, individual species responses to elevated CO₂ vary: consumption rates of insect herbivores generally increase, but this does not necessarily compensate fully for reduced leaf nitrogen. The consequent effects on performance are strongly mediated via the host species. Some recent experiments under elevated CO₂ have suggested that aphids may become more serious pests, although other studies have discerned no significant effects on sap-feeding homopterans. However, few, if any of these experiments have fully considered the effects on pest population dynamics. Climate change is also considered from the perspective of changes in the distribution and abundance of species and communities. Marked changes in the distribution of well-documented species - including Odonata, Orthoptera and Lepidoptera - in northwestern Europe, in response to unusually hot summers, provide useful indications of the potential effects of climate change. Migrant pests are expected to respond more quickly to climate change than plants, and may be able to colonize newly available crops/habitats. Range expansions, and the removal of edge effects, could result in the increased abundance of species presently near the northern limits of their ranges in the UK. However, barriers to range expansions, or shifts, may include biotic (competition, predation, parasitism and disease), as well as abiotic, factors. Climatic phenomena, ecosystem processes and human activities are interactive and interdependent, making long-term predictions extremely tenuous. Nevertheless, it appears prudent to prepare for the possibility of increases in the diversity and abundance of pest species in the UK, in the context of climate change.

Cantin, D., M.F. Tremblay, M.J. Lechowicz, and C. Potvin. 1997. Effects of CO₂ enrichment, elevated temperature, and nitrogen availability on the growth and gas exchange of different families of jack pine seedlings. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 27(4):510-520.

Many economically important tree species respond positively to an elevated CO₂ environment. However, the variability and stability in growth responses among genotypes grown in a global change environment are generally not documented. The present study investigated the differences, at the seedling stage, among 15 maternal families of jack pine (*Pinus banksiana* Lamb.) in response to an elevated CO₂-temperature environment (CO₂T) (700 mu L CO₂.L⁻¹ with temperatures 4 degrees C higher than in the ambient CO₂T environment), with different nitrogen concentrations. While the elevated CO₂T did not significantly alter the overall height growth of seedlings, it significantly increased their total biomass, with needle and root biomass being most responsive. Growth in the elevated CO₂T resulted in a 24% reduction in the leaf weight ratio as more biomass was allocated to roots. Significant genotypic differences were observed for height, biomass, and water-use efficiency. Generally, most families kept their rank relative to other families, from the ambient to the elevated CO₂T. Also, rank correlations between height of families grown in elevated CO₂T and height of families at 10 years of age in the field were significant. This result, combined with the stability we observed in family response from the ambient to the elevated CO₂T, suggested that jack pine families currently chosen for their fast-growing capacity will probably remain as such in a global change environment, at least during the seedling establishment stage.

Cao, M.K., and F.I. Woodward. 1998. Net primary and ecosystem production and carbon stocks of terrestrial ecosystems and their responses to climate change. *Global Change Biology* 4(2):185-198.

Evaluating the role of terrestrial ecosystems in the global carbon cycle requires a detailed understanding of carbon exchange between vegetation, soil, and the atmosphere. Global climatic change may modify the net carbon balance of terrestrial ecosystems, causing feedbacks on atmospheric CO₂ and climate. We describe a model for investigating terrestrial carbon exchange and its response to climatic variation based on the processes of plant photosynthesis, carbon allocation, litter production, and soil organic carbon decomposition. The model is used to produce geographical patterns of net primary production (NPP), carbon stocks in vegetation and soils, and the seasonal variations in net ecosystem production (NEP) under both contemporary and future climates. For contemporary climate, the estimated global NPP is 57.0 Gt C y⁻¹, carbon stocks in vegetation and soils are 640 Gt C and 1358 Gt C, respectively, and NEP varies from -0.5 Gt C in October to 1.6 Gt C in July. For a doubled atmospheric CO₂ concentration and the corresponding climate, we predict that global NPP will rise to 69.6 Gt C y⁻¹, carbon stocks in vegetation and soils will increase by, respectively, 133 Gt C and 160 Gt C, and the seasonal amplitude of NEP will increase by 76%. A doubling of atmospheric CO₂ without climate change may enhance NPP by 25% and result in a substantial increase in carbon stocks in vegetation and soils. Climate change without CO₂ elevation will reduce the global NPP and soil carbon stocks, but leads to an increase in vegetation carbon because of a forest extension and NPP enhancement in the north. By combining the effects of CO₂ doubling, climate change, and the consequent redistribution of vegetation, we predict a strong enhancement in NPP and carbon stocks of terrestrial ecosystems. This study simulates the possible variation in the carbon

exchange at equilibrium state. We anticipate to investigate the dynamic responses in the carbon exchange to atmospheric CO₂ elevation and climate change in the past and future.

Cao, W.X., and T.W. Tibbitts. 1997. Starch concentration and impact on specific leaf weight and element concentrations in potato leaves under varied carbon dioxide and temperature. *Journal of Plant Nutrition* 20(7-8):871-881.

Foliar concentrations of starch and major elements, nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), and magnesium (Mg), along with specific leaf weight (SLW) were determined in the potato (*Solanum tuberosum* L.) cvs 'Denali', 'Norland', and 'Russet Burbank' grown for 35 days under CO₂ concentrations of 500, 1,000, 1,500 and 2,000 $\mu\text{mol} \cdot \text{mol}^{-1}$ at both 16 degrees C and 20 degrees C air temperature. The starch concentration, pooled from the three cultivars, increased with increasing CO₂ concentration at both 16 degrees C and 20 degrees C and was consistently higher at 16 degrees C than at 20 degrees C. The SLW ($\text{g} \cdot \text{m}^{-2}$) was positively related to the foliar starch concentration on the basis of leaf area or dry weight. The concentrations of N, P, Ca, and Mg in leaves were negatively related to starch concentration under approximate to 14% starch on a dry weight basis. Above 14% starch, there was no significant relationship between element and starch concentrations. Similar patterns were seen when the SLW and element concentrations were expressed on a starch-free basis. In contrast, the leaf concentration of K was not closely related to the starch concentration because the K concentration was similar at varied CO₂ levels. The results of this study indicate that the changes in SLW and concentrations of N, P, Ca, and Mg in potato leaves only partially resulted from the changed starch concentration.

Cao, W., T.W. Tibbitts, and R.M. Wheeler. 1994. Carbon-dioxide interactions with irradiance and temperature in potatoes. *Life Sciences and Space Research XXV (3) 14(11):243-250.*

Separate controlled environment studies were conducted to determine the interaction of CO₂ with irradiance and interaction of CO₂ with temperature on growth of three potato cultivars. In the first study, an elevated CO₂ concentration of 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$ and an ambient CO₂ of 350 $\mu\text{mol} \cdot \text{mol}^{-1}$ were maintained at the photosynthetic photon fluxes (PPF) of 17 and 34 $\text{mol} \cdot \text{m}^{-2} \cdot \text{d}^{-1}$ with 12 h photoperiod, and at the PPF of 34 and 68 $\text{mol} \cdot \text{m}^{-2} \cdot \text{d}^{-1}$ with 24 h photoperiod (400 and 800 $\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ PPF at each photoperiod). Tuber and total dry weights of 90-day old potatoes were significantly increased with CO₂ enrichment, but the CO₂ stimulation was less with higher PPF and longer photoperiod. Shoot dry weight was affected more by photoperiod than by PPF and CO₂ concentrations. The elevated CO₂ concentration increased leaf CO₂ assimilation rates and decreased stomatal conductance with 12 h photoperiod, but had only a marginal effect with 24 h photoperiod. In the second study, four CO₂ concentrations of 500, 1000, 1500 and 2000 $\mu\text{mol} \cdot \text{mol}^{-1}$ were combined with two air temperature regimes of 16 and 20 degrees C under a 12 h photoperiod. At harvest, 35 days after transplanting, tuber and total dry weights of potatoes reached a maximum with 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ at 16 degrees C, but continued to increase up to 2000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ at 20 degrees C. Plant growth was greater at 20 degrees C than at 16 degrees C under all CO₂ concentrations. At 16

degrees C specific leaf weight increased substantially with increasing CO₂ concentrations as compared to 500 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂, but increased only slightly at 20 degrees C. This suggests a carbohydrate build-up in the leaves at 16 degrees C temperature that reduces plant response to increased CO₂ concentrations. The data in the two studies indicate that a PPF of 34 $\text{mol} \cdot \text{m}^{-2} \cdot \text{d}^{-1}$, 20 degrees C temperature, and 1000-2000 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ produces optimal tuber yield in potatoes.

Caporn, S.J.M., A.L. Brooks, M.C. Press, and J.A. Lee. 1999. Effects of long-term exposure to elevated CO₂ and increased nutrient supply on bracken (*Pteridium aquilinum*). *Functional Ecology* 13:107-115.

1. Bracken (*Pteridium aquilinum*) is an important fern with a global distribution. Little is known of the response of this species to elevated CO₂. We investigated the effects of high CO₂ (570 compared with 370 $\mu\text{mol} \cdot \text{mol}^{-1}$) with and without an increased nutrient supply (a combined N, P, K application) on the growth and physiology of bracken, growing in containers in controlled-environment glasshouses, over two full growing seasons. Results of growth and physiology determinations are reported for the second season. 2. Elevated CO₂ had little impact on the growth or allocation of dry mass in bracken. No significant changes were detected in dry mass of the total plant or any of the organs: rhizomes, roots and fronds. In contrast to the small effects of high CO₂ the high nutrient treatment caused a three-fold stimulation of total plant dry mass and an increase in the allocation of dry mass to above ground when compared with low nutrient controls. 3. Net photosynthetic rates in saturating light were increased by both high CO₂ and nutrient treatments, particularly in spring months (May and June). Growth in elevated CO₂ did not cause a down-regulation in light-saturated rates of photosynthesis. The increased carbon gain in the high CO₂ treatments was accompanied, in the low-nutrient plants, by higher concentrations of carbohydrates. However, in high-nutrient plants the CO₂ treatment did not cause an accumulation of carbohydrates. The absence of a growth response to elevated CO₂ in bracken despite significant increases in photosynthesis requires further investigation.

Caporn, S.J.M., D.W. Hand, T.A. Mansfield, and A.R. Wellburn. 1994. Canopy photosynthesis of CO₂-enriched lettuce (*Lactuca sativa* L.) - response to short-term changes in CO₂, temperature and oxides of nitrogen. *New Phytologist* 126(1):45-52.

The canopy net photosynthesis (P_n) of lettuce (*Lactuca sativa* L. cv. 'Ambassador') was analyzed under controlled conditions simulating the winter glasshouse atmosphere. Prior to measurements the plants were grown in CO₂-enriched air of 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$, at a photosynthetic photon flux density (PPFD) of 280 $\mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ (400-700 nm) and a day/night air temperature of 16/13 degrees C. Short-term changes in CO₂ concentration significantly changed the initial gradient of the photosynthetic response to incident PPFD. Maximum photosynthetic efficiency of the crop increased from 0.041 $\text{mol} \cdot \text{CO}_2 \cdot \text{mol} \cdot \text{photons}^{-1}$ (equivalent to 8.2 $\mu\text{g} \cdot \text{CO}_2 \cdot \text{J}^{-1}$) and 9.4% on an energy basis) at 350 $\mu\text{mol} \cdot \text{mol}^{-1}$ to 0.055 $\text{mol} \cdot \text{CO}_2 \cdot \text{mol} \cdot \text{photons}^{-1}$ (10.9 $\mu\text{g} \cdot \text{CO}_2 \cdot \text{J}^{-1}$) and 12.7% on an energy basis) at 1000 $\mu\text{mol} \cdot \text{mol}^{-1}$. Transfer from low to high CO₂ also lowered the light compensation point, but did not affect dark respiration. The large response of P_n to transient changes in CO₂ indicated that the lettuce canopy did not acclimate to growth in

1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$), in contrast with the effect of growth in high CO_2 on P-n in single mature leaves reported earlier. A reduction in air temperature from 16 to 6 degrees C at a concentration of 1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ halved the rate of dark respiration and reduced the light compensation point, but had no direct effect on the maximum efficiency with which the crop utilized light. Subsequently, at low light (below 200 $\mu\text{mol m}^{-2} \text{ s}^{-1}$) P-n was greater at 6 than 16 degrees C. Between a PPFD of 250 and 300 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ canopy P-n was similar at all temperatures. Addition of 2.0 $\mu\text{mol mol}^{-1}$ nitric oxide to an atmosphere of 1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ caused a rapid and reversible reduction of canopy P-n which was greater at the lowest temperatures. The average inhibition was 6.6% at 16 degrees C and 28.8% at 6 degrees C; this was not explained by differences in the rate of pollutant uptake, which was less in the cooler conditions. The results are discussed in relation to development of optimal growing conditions for production of glasshouse lettuce at low light and low temperature during winter in the UK.

Caporn, S.J.M., T.A. Mansfield, and D.W. Hand. 1991. Low temperature-enhanced inhibition of photosynthesis by oxides of nitrogen in lettuce (*Lactuca sativa* L.). *New Phytologist* 118(2):309-313.

The response of photosynthetic gas exchange to oxides of nitrogen ($\text{NO}(x)$) was studied in leaves of lettuce (*Lactuca sativa* L.) at different temperatures. Exposure to high concentrations (e.g. 1.3- $\mu\text{mol NO}(x) \text{ mol}^{-1}$), similar to those often found in commercial glasshouses, caused a rapid inhibition of the net assimilation of CO_2 . This appeared to be by a direct effect on photosynthesis rather than by a change in the stomatal conductance. In ambient CO_2 (345- $\mu\text{mol mol}^{-1}$), the percentage inhibition at 10 and 5-degrees-C was approximately 3 x and 5 x, respectively, that measured at 20-degrees-C. This effect of temperature also occurred when measured in CO_2 enriched air (1050- $\mu\text{mol mol}^{-1}$), which would normally accompany $\text{NO}(x)$ in a glasshouse. The extent of photosynthetic inhibition caused by $\text{NO}(x)$ was, however, always less in high than in low CO_2 . The results suggest that when burning fuel to raise the CO_2 concentration and heat the glasshouse air, growers should avoid generating high concentrations of $\text{NO}(x)$ in conditions of low temperature.

Cardon, Z.G. 1996. Influence of rhizodeposition under elevated CO_2 on plant nutrition and soil organic matter. *Plant and Soil* 187(2):277-288.

Atmospheric CO_2 concentrations can influence ecosystem carbon storage through net primary production (NPP), soil carbon storage, or both. In assessing the potential for carbon storage in terrestrial ecosystems under elevated CO_2 , both NPP and processing of soil organic matter (SOM), as well as the multiple links between them, must be examined. Within this context, both the quantity and quality of carbon flux from roots to soil are important, since roots produce specialized compounds that enhance nutrient acquisition (affecting NPP), and since the flux of organic compounds from roots to soil fuels soil microbial activity (affecting processing of SOM). From the perspective of root physiology, a technique is described which uses genetically engineered bacteria to detect the distribution and amount of flux of particular compounds from single roots to non-sterile soils. Other

experiments from several labs are noted which explore effects of elevated CO_2 on root acid phosphatase, phosphomonoesterase, and citrate production, all associated with phosphorus nutrition. From a soil perspective, effects of elevated CO_2 on the processing of SOM developed under a C4 grassland but planted with C3 California grassland species were examined under low (unamended) and high (amended with 20 g m^{-2} NPK) nutrients; measurements of soil atmosphere $\delta^{13}\text{C}$ combined with soil respiration rates show that during vegetative growth in February, elevated CO_2 decreased respiration of carbon from C4 SOM in high nutrient soils but not in unamended soils. This emphasis on the impacts of carbon loss from roots on both NPP and SOM processing will be essential to understanding terrestrial ecosystem carbon storage under changing atmospheric CO_2 concentrations.

Cardon, Z.G., J.A. Berry, and I.E. Woodrow. 1995. Fluctuating $[\text{CO}_2]$ drives species-specific changes in water use efficiency. *Journal of Biogeography* 22(2-3):203-208.

We have investigated the effects of fluctuating carbon dioxide (CO_2) concentration on water use efficiency of *Zea mays* L. and *Phaseolus vulgaris* L. We found that species-specific kinetics of stomatal movements combine with photosynthetic characteristics to influence short-term water use efficiency strongly under fluctuating environmental conditions. Specifically, under oscillating $[\text{CO}_2]$, average transpiration in *Z. mays* was driven higher than that observed at steady-state at the median CO_2 concentration, while average photosynthesis remained fairly constant. Consequently, water use efficiency was lower during the fluctuations in $[\text{CO}_2]$ than it was at the steady, median $[\text{CO}_2]$. Under similar oscillations in $[\text{CO}_2]$, stomatal conductance and transpiration of *P. vulgaris* were driven lower than observed at steady-state at the median $[\text{CO}_2]$. A concomitant slight restriction of photosynthesis balanced this decrease in transpiration, and in this case water use efficiency under fluctuating $[\text{CO}_2]$ remained practically constant in *P. vulgaris*. The frequency of oscillations in $[\text{CO}_2]$ interacted with asymmetries in stomatal opening and closing kinetics in both *Z. mays* and *P. vulgaris* to determine the extent to which average transpiration (and water use efficiency in *Z. mays*) departed during fluctuations from the steady-state condition at the median CO_2 level.

Carey, E.V., R.M. Callaway, and E.H. DeLucia. 1997. Stem respiration of ponderosa pines grown in contrasting climates: Implications for global climate change. *Oecologia* 111(1):19-25.

We examined the effects of climate and allocation patterns on stem respiration in ponderosa pine (*Pinus ponderosa*) growing on identical substrate in the cool, moist Sierra Nevada mountains and the warm, dry, Great Basin Desert. These environments are representative of current climatic conditions and those predicted to accompany a doubling of atmospheric CO_2 , respectively, throughout the range of many western

north American conifers. A previous study found that trees growing in the desert allocate proportionally more biomass to sapwood and less to leaf area than montane trees. We tested the hypothesis that respiration rates of sapwood are lower in desert trees than in montane trees due to reduced stem maintenance respiration (physiological acclimation) or reduced construction cost of stem tissue (structural acclimation). Maintenance respiration per unit sapwood Volume at 15 degrees C did not differ between populations (desert: 6.39 ± 1.14 SE $\mu\text{mol m}^{-3} \text{s}^{-1}$), montane: 6.54 ± 1.13 SE $\mu\text{mol m}^{-3} \text{s}^{-1}$, $P = 0.71$) and declined with increasing stem diameter ($P = 0.001$). The temperature coefficient of respiration ($Q(10)$) varied seasonally within both environments ($P = 0.05$). Construction cost of stem sapwood was the same in both environments (desert: 1.46 ± 0.009 SE g glucose g⁻¹) sapwood, montane: 1.48 ± 0.009 SE glucose g⁻¹) sapwood, $P = 0.14$). Annual construction respiration calculated from construction cost, percent carbon and relative growth rate was greater in montane populations due to higher growth rates. These data provide no evidence of respiratory acclimation by desert trees. Estimated yearly stem maintenance respiration was greater in large desert trees than in large montane trees because of higher temperatures in the desert and because of increased allocation of biomass to sapwood. By analogy, these data suggest that under predicted increases in temperature and aridity, potential increases in aboveground carbon gain due to enhanced photosynthetic rates may be partially offset by increases in maintenance respiration in large trees growing in CO₂-enriched atmospheres.

Carey, E.V., E.H. DeLucia, and J.T. Ball. 1996. Stem maintenance and construction respiration in *Pinus ponderosa* grown in different concentrations of atmospheric CO₂. *Tree Physiology* 16(1-2):125-130.

To determine whether long-term growth in enriched CO₂ atmospheres changes the woody tissue respiration component of aboveground carbon budgets, we measured woody tissue respiration of stems of 3-year-old *ponderosa* pine (*Pinus ponderosa* Laws.) grown in ambient (350 ppm) or twice ambient (700 ppm) atmospheric CO₂ concentrations in open-top field chambers located in Placerville, CA. Total respiration rate was measured by gas exchange, and construction respiration was calculated from the construction cost, percent carbon of stem samples and relative growth rate. Maintenance respiration was determined as the difference between total and construction respiration. The $Q(10)$ of respiration was greater in stems grown in elevated CO₂ than in stems grown in ambient CO₂ (2.20 versus 1.67). As a result, mean daily respiration per unit volume of wood modeled for the month of September was greater in trees growing in elevated CO₂ than in ambient CO₂ (46.75 versus 40.45 $\text{mol m}^{-3} \text{day}^{-1}$). These effects of atmospheric CO₂ concentration were not the result of differences in relative growth rate. Calorimetric analyses of woody tissue construction cost indicated no difference between treatments; however, trees in the elevated CO₂ treatment showed a 1% lower carbon concentration than trees in the ambient CO₂ treatment. Estimates of construction respiration did not differ between treatments, confirming that the treatment differences in mean daily respiration rate were attributable to the maintenance component. Under future predicted atmospheric conditions, changes in the maintenance respiration of woody tissue may lead to an increase in the respiration component of whole-plant carbon budgets of *ponderosa* pine. Our results suggest that potential increases in the maintenance component of stem respiration should be considered when modeling the response of forest stand growth to enriched CO₂ atmospheres.

Carlsson, A.S., G. Wallin, and A.S. Sandelius. 1996. Species- and age-dependent sensitivity to ozone in young plants of pea, wheat and spinach: Effects on acyl lipid and pigment content and metabolism. *Physiologia Plantarum* 98(2):271-280.

Acyl lipids and pigments were analyzed in young plants of garden pea, spring wheat and spinach exposed to <5 or 65 nl l⁻¹ ozone 12 h per day for 6 days. In one set of experiments, the plants were exposed to (CO₂)-C-14 for 2 h 3 days prior to ozone exposure. The plants responded differently to the moderately enhanced level of ozone used. Spinach was not at all sensitive while in both pea and wheat, leaves of different ages differed in ozone sensitivity. In pea, ozone sensitivity increased with leaf age. In the second and third oldest leaves, the amounts of galactolipids per leaf area and the proportions of 18:3 of the total lipid extract and of phosphatidylglycerol decreased. In the second oldest leaf, ozone also caused a decreased proportion of 18:3 of monogalactosyldiacylglycerol. In the fourth oldest leaf, Lipid composition and galactolipid unsaturation was unaffected, but ozone caused decreased leaf expansion resulting in increased acyl lipid content per leaf area. In both the first and second leaves of wheat, ozone fumigation caused a marked decrease in the content of monogalactosyldiacylglycerol and in the first leaf, the contents of phosphatidylcholine and phosphatidylethanolamine increased. The proportion of 18:3 in phosphatidylcholine was larger in ozone-fumigated than in control plants, while the reverse applied for phosphatidylglycerol. In the oldest sampled leaves of pea and wheat, ozone caused an increase in the radioactivity associated with beta-carotene, indicating increased turnover. Thus, while spinach was unaffected, in both pea and wheat ozone caused a decrease in the proportion of chloroplast membrane lipids to non-chloroplast membrane lipids in older leaves while younger leaves were less sensitive.

Carlsson, B.A., and T.V. Callaghan. 1994. Impact of climate-change factors on the clonal sedge *Carer bigelowii* - implications for population-growth and vegetative spread. *Ecography* 17(4):321-330.

Hypothesized life-cycle responses to climate change for the arctic, clonal perennial *Carer bigelowii* are constructed using a range of earlier observations and experiments together with new information from monitoring and an environmental perturbation study. These data suggest, that under current climate change scenarios, increases in CO₂, temperature and nutrient availability would promote growth in a qualitatively similar way. The evidence suggests that both tiller size and daughter tiller production will increase, and be shifted towards production of phalanx tillers which have a greater propensity for flowering. Furthermore, age at tillering as well as tiller life span may decrease, whereas survival of younger age classes might be higher. Mathematical models using experimental data incorporating these hypotheses were used to a) integrate the various responses and to calculate the order of magnitude of changes in population growth rate (λ), and b) to explore the implications of responses in individual demographic parameters for population growth rate. The models suggest that population growth rate following climate change might increase significantly, but not unrealistically so, with the younger, larger, guerilla tillers being the most important tiller categories contributing to λ . The rate of vegetative spread is calculated to more than double, while cyclical trends in flowering and population growth are predicted to decrease substantially.

Carmi, A. 1993. Effects of shading and CO₂ enrichment on photosynthesis and yield of winter grown tomatoes in subtropical regions. *Photosynthetica* 28(3):455-463.

The effects of exposing winter-grown tomato (*Lycopersicon esculentum* L.) to various sunlight irradiances and CO₂ concentrations, on dark respiration (R(D)), night respiration (R(N)), net photosynthetic-rate (P(N)), dry matter production (DMP), yield earliness and yield amount were studied. Plants were grown in greenhouses under controlled temperatures and exposed to: full (FS) or half (HS) sunlight irradiance in combination with atmospheric (A) or enriched (E) concentrations of 300-330 or 1400-1500 g(CO₂) m⁻³, respectively. The P(N) of intact leaves at noontime reached 10.7, 15.2, 5.9 and 9.6 μmol(CO₂) m⁻² s⁻¹ in treatments of FSA, FSE, HSA and HSE, respectively. The irradiances on the upper leaf surface during the P(N) measurements ranged between 160-190 and 450-550 μmol m⁻² s⁻¹ in the HS and FS treatments, respectively. R(D) of leaves which were kept in darkness following the P(N) measurement arrived at efflux of 2.6, 2.5, 1.4 and 1.4 μmol(CO₂) m⁻² s⁻¹ While their R(N) (between 20:00 and 24:00) reached values of 0.9, 1.3, 0.8 and 0.8 μmol(CO₂) m⁻² s⁻¹ in treatments of FSA, FSE, HSA and HSE, respectively. Elevating the CO₂ concentration from 300 to 1500 g m⁻³ increased P(N) by 16, 28, 30 and 46% under an irradiance of 160 μmol m⁻² s⁻¹, and 19, 34, 59 and 44% under irradiance of 320 μmol m⁻² s⁻¹ in the FSA, FSE, HSA and HSE treatments, respectively. Increasing the measurement irradiance from 160 to 320 μmol m⁻² s⁻¹ enhanced P(N) by 69, 78, 23 and 49% in an atmosphere of 300 g m⁻³ CO₂, and by 73, 84, 49 and 47% in an atmosphere of 1500 g m⁻³ CO₂, in the FSA, FSE, HSA and HSE treatments, respectively. DMP was strongly influenced by the different environmental conditions and the total dry matter accumulation in the shoot per plant during 145 d reached 580, 347, 398 and 235 g in the FSA, FSE, HSA and 14SE treatments, respectively. CO₂ enrichment promoted early yield under both full and partial sunlight irradiance. The HSE treatment led to earlier yield harvesting than the FSA and HSA treatments. The yield of the seven first trusses reached 6.8, 4.6, 5.7 and 3.2 kg per plant in the FSA, FSE, HSA and HSE treatments, respectively. Some increase in fruit fresh matter and diameter of fruits was detected in the CO₂-enriched treatments as compared to the non-enriched ones. Thus the combination of moderate shading and CO₂ enrichment might provide a more productive option for winter-grown tomatoes in regions of subtropical climate, even in the winter, than the conventional management of aerated greenhouses without CO₂ enrichment which are exposed to full sunlight.

Carter, E.B., M.K. Theodorou, and P. Morris. 1997. Responses of *Lotus corniculatus* to environmental change .1. Effects of elevated CO₂, temperature and drought on growth and plant development. *New*

Phytologist 136(2):245-253.

Five clonal plants of three genotypes of *Lotus corniculatus* were grown in each of eight controlled environments under combinations of two temperature regimes (18/10 degrees C and 25/15 degrees C), two CO₂ concentrations (ambient and 700 ppmv) and two water applications (ad libitum or 60% droughted). Plants were harvested at full flower and measurements made of plant growth and development. Of the three environmental variables studied, higher growth temperatures resulted in the largest number of significant changes to the measured variables. Reproductive capacity, growth rate, shoot biomass, water use efficiency and chlorophyll content were all enhanced by raising the growth temperature from 18 to 25 degrees C. Doubling the CO₂ concentration enhanced the growth rate, shoot biomass and water use efficiency and ameliorated some of the effects of drought, including reproductive capacity, and biomass production, but reduced flowering time, specific leaf area, and chlorophyll content of both droughted and undroughted plants. Drought alone reduced reproductive capacity, growth rate and above ground biomass but significantly increased root biomass in all environments. The agronomic effects resulting from a combined increase in growth temperature, doubled CO₂ concentration and mild drought in this experiment were a shorter vegetative period and an increase in biomass, but a fall in reproductive capacity.

Carter, E.B., M.K. Theodorou, and P. Morris. 1999. Responses of *Lotus corniculatus* to environmental change. 2. Effect of elevated CO₂, temperature and drought on tissue digestion in relation to condensed tannin and carbohydrate accumulation. *Journal of the Science of Food and Agriculture* 79(11):1431-1440.

Clonal plants of three genotypes of *Lotus corniculatus* (cv Lee) were grown in eight controlled environments under combinations of two temperature regimes, two CO₂ concentrations and two watering regimes. Condensed tannins (proanthocyanidins), in- vitro digestibility, initial rates of gas evolution as an indicator of the initial rates of fermentation of the substrate), volatile fatty acid evolution, and non-structural carbohydrate (NSC) levels were determined in leaves, stems and roots at full flowering. Under control conditions (average midsummer conditions in the United Kingdom) the total condensed tannin content of leaves varied six-fold between genotypes but condensed tannin contents in stems and roots were similar. Condensed tannin levels were significantly increased in leaves and stems of all three genotypes by doubling the CO₂ concentration while raising the temperature towards the optimum for growth significantly reduced condensed tannin levels. Drought stress significantly reduced condensed tannin levels in leaves and, particularly, in roots. Nutritive value was inversely related to condensed tannin levels in leaves and a negative relationship was observed between condensed tannin concentrations of more than 25-30 g kg⁻¹ dry matter and the initial rates of gas evolution when subjected to in-vitro fermentation with rumen micro-organisms. In leaves, digestibility was significantly increased by drought and by increasing temperature but reduced by high CO₂. In stems, digestibility was significantly increased by drought, but not significantly affected by increasing temperature, or by high CO₂ alone. In roots, digestibility was significantly increased by drought, and decreased by increasing temperature or CO₂. Increasing the growth temperature towards optimum growth reduced the content of NSC in all tissues with the greatest changes occurring in root tissue. Doubling the CO₂ concentration increased NSC levels in leaves and stems with starch content more than doubled under high CO₂ while, in roots, increased levels were only observed in combination with drought stress. There was a linear correlation between condensed tannin concentration and total

NSC that was positive for leaves, neutral for stems and negative for roots. The relationship between carbohydrate levels and rates of gas production was negative for leaves and positive for stem and roots. (C) 1999 Society of Chemical Industry.

Carter, G.A., J. Rebbeck, and K.E. Percy. 1995. Leaf optical-properties in liriiodendron-tulipifera and pinus- strobus as influenced by increased atmospheric ozone and carbon-dioxide. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 25(3):407-412.

Seedlings of Liriiodendron tulipifera L. and Pinus strobus L. were grown in open-top chambers in the field to determine leaf optical responses to increased ozone (O-3) or O-3 and carbon dioxide (CO₂). In both species, seedlings were exposed to charcoal-filtered air, air with 1.3 times ambient O-3 concentrations (1.3X), or air with 1.3 times ambient O-3 and 700 $\mu\text{mol L}^{-1}$ CO₂ (1.3X + CO₂). Exposure to 1.3X increased reflectance in the 633-697 nm range in L. tulipifera. Also, 1.3X decreased transmittance within the 400-420 nm range, increased transmittance at 686-691 nm, and decreased absorptance at 655-695 nm. With 700 $\mu\text{mol L}^{-1}$ CO₂, O-3 did not affect reflectance in L. tulipifera, but decreased transmittance and increased absorptance within the 400-421 nm range and increased transmittance and decreased absorptance in the 694-697 nm range. Under 1.3X, reflectance in P. strobus was not affected. However, 1.3X + CO₂ increased pine reflectance in the 538-647, 650, and 691-716 nm ranges. Transmittances and absorptances were not determined for P. strobus. Reflectance in both species, and transmittance and absorptance in L. tulipifera, were most sensitive to O-3 near 695 nm. Reflectance at 695 nm, but particularly the ratio of reflectance at 695 nm to reflectance at 760 nm, was related closely to ozone-induced decreases in leaf chlorophyll contents, particularly chlorophyll a ($r^2 = 0.82$).

Case, A.L., P.S. Curtis, and A.A. Snow. 1998. Heritable variation in stomatal responses to elevated CO₂ in wild radish, *Raphanus raphanistrum* (Brassicaceae). *American Journal of Botany* 85(2):253-258.

Rising atmospheric carbon dioxide may affect plant populations in the short term through effects on photosynthesis and carbon allocation, and over the long term as an agent of natural selection. To test for heritable effects of elevated CO₂ on stomatal responses and plant fecundity in *Raphanus raphanistrum*, we grew plants from 12 paternal families in outdoor open-top chambers at ambient (35 Pa) or elevated (67 Pa) CO₂. Contrary to results from a previous study of this species, total flower and fruit production were marginally lower under elevated CO₂. Across families, stomatal index and guard cell length showed little response to CO₂ enrichment, but these characters varied significantly among paternal families in both the direction and magnitude of their response to changing CO₂. Although these family-by-CO₂ interactions suggest that natural selection might affect stomatal characters when ambient CO₂ levels increase, we found no significant correlation between either character and flower or fruit production. Therefore, our data suggest that while heritable variation for stomatal index and guard cell length exists in this population, selection due to increasing CO₂ is not likely to act on these traits because they had no detectable effect on lifetime fecundity.

Casella, E., and J.F. Soussana. 1997. Long-term effects of CO₂ enrichment and temperature increase on the carbon balance of a temperate grass sward. *Journal of Experimental Botany* 48(311):1309-1321.

Perennial ryegrass swards were grown in large containers on a soil, at two N fertilizer supplies and were exposed during two years in highly ventilated plastic tunnels to elevated (700 $\mu\text{mol L}^{-1}$ [CO₂]) or ambient atmospheric CO₂ concentration at outdoor temperature and to a 3 degrees C increase in air temperature in elevated CO₂. The irrigation was adjusted to obtain a soil water deficit during summer. The daily net C assimilation was increased in elevated CO₂ by 29 and 36% at the low and high N supplies, respectively. Canopies grown in elevated CO₂ for 14 to 27 months photosynthesized significantly less rapidly, in both elevated and normal CO₂ concentrations, than their counterparts developed in ambient CO₂, but the magnitude of this effect was small (-8% to -13%). Elevated CO₂ resulted in a large increase in the fructan concentration in the pseudostems and laminae (+46% and +189%, respectively). In elevated CO₂, the hexose and sucrose pool increased by 28% in the laminae, whereas it did not vary significantly in the pseudostems. A 3 degrees C temperature increase in elevated CO₂ did not affect significantly the average WSC concentrations in the pseudostems and laminae. The elevated CO₂ effects on the net C assimilation and on the nocturnal shoot respiration were greater in summer than in spring. On average, a 35% increase in the below-ground respiration was measured in elevated CO₂. At the high N supply, a 3 degrees C increase in air temperature led to a decline in the below-ground respiration due to a low soil moisture. The below-ground carbon storage was increased by 32% and 96% in elevated CO₂ at the low and high N supplies, respectively, with no significant increased temperature effect. The role for the below-ground carbon storage of CO₂-induced changes in the root fraction of the grass and of temperature-induced changes in the moisture content of the soil are discussed.

Casella, E., J.F. Soussana, and P. Loiseau. 1996. Long-term effects of CO₂ enrichment and temperature increase on a temperate grass sward .1. Productivity and water use. *Plant and Soil* 182(1):83-99.

Perennial ryegrass swards were grown in large containers on a soil, at two N fertilizer supplies, and were exposed over two years in highly ventilated plastic tunnels to elevated (700 $\mu\text{mol L}^{-1}$ [CO₂]) or ambient atmospheric CO₂ concentration at outdoor temperature and to a 3 degrees C increase in air temperature in elevated CO₂. These swards were either fully irrigated (kept at field capacity) in each climatic condition (W+), or received the same amount of water in the three climate treatments (W-). In the latter case, the irrigation was adjusted to obtain a soil water deficit during summer and drainage in winter. Using a lysimeter approach, the evapotranspiration, the soil water balance, the productivity (dry-matter yield) and the water use efficiency of the grass swards were measured. During both years, elevated CO₂ increased the annual above-ground drymatter yield of the W-swards, by 19% at N- and by 14% at N+. Elevated CO₂ modified yield to a variable extent during the growing season: a small, and sometime not significant effect (+6%, on average) was obtained in spring and in autumn, while the summer growth response was stronger (+48%, on average). In elevated CO₂, the

temperature increase effect on the annual above-ground dry-matter yield was not significant, due to a gain in dry-matter yield in spring and in autumn which was compensated for by a lower summer productivity. Elevated CO₂ slightly reduced the evapotranspiration during the growing season and increased drainage by 9% during winter. A supplemental 3 degrees C in elevated CO₂ reduced the drainage by 29-34%, whereas the evapotranspiration was increased by 8 and 63% during the growing season and in winter, respectively. During the growing season, the soil moisture content at W- and at the high N supply declined gradually in the control climate, down to 20-30% of the water holding capacity at the last cut (September) before rewatering. This decline was partly alleviated under elevated CO₂ in 1993, but not in 1994, and was enhanced at +3 degrees C in elevated CO₂. The water use efficiency of the grass sward increased in elevated CO₂, on average, by 17 to 30% with no significant interaction with N supply or with the soil water deficit. The temperature increase effect on the annual mean of the water use efficiency was not significant. Highly significant multiple regression models show that elevated CO₂ effect on the dry-matter yield increased with air temperatures above 14.5 degrees C and was promoted by a larger soil moisture in elevated compared to ambient CO₂. The rate of change in relative dry-matter yield at +3 degrees C in elevated CO₂ became negative for air temperatures above 18.5 degrees C and was reduced by a lower soil moisture at the increased air temperature. Therefore, the altered climatic conditions acted both directly on the productivity and on the water use of the grass swards and, indirectly, through changes in the soil moisture content.

Cater, M., P. Simoncic, and F. Batic. 1999. Pre-dawn water potential and nutritional status of pedunculate oak (*Quercus robur* L.) in the north-east of Slovenia. *Phyton-Annales Rei Botanicae* 39(4):13-21.

In the 1997 growth period monthly measurements of pre-dawn water potential, electrical resistance of the cambial zone, groundwater level and quality together with annual dynamics of macronutrient elements in leaves and heavy metals (Zn, Pb, Cd) were performed. Two plots having different groundwater tables and crown defoliation were studied in the pedunculate oak forest complex (*Quercus Roboris-Carpinetum* M. Wraber) in the north-east of Slovenia. Results showed lower (more negative) values of pre-dawn water potential and higher values of cambial electrical resistance on the plot with greater crown defoliation, which also had a lower groundwater table. Groundwater seems to be the key factor in the process of oak decline.

Catovsky, S., and F.A. Bazzaz. 1999. Elevated CO₂ influences the responses of two birch species to soil moisture: implications for forest community structure. *Global Change Biology* 5(5):507-518.

Increased levels of atmospheric CO₂ may alter the structure and composition of plant communities by affecting how species respond to their physical and biological environment. We investigated how elevated CO₂ influenced the response of paper birch (*Betula papyrifera* Marsh.) and yellow birch (*Betula alleghaniensis* Britt.) seedlings to variation in soil moisture. Seedlings were grown for four months on a soil moisture gradient, individually and in mixed species stands, in controlled environment facilities at ambient (375 μ L L⁻¹) and elevated (700 μ L L⁻¹) atmospheric CO₂. For both individually and competitively grown

paper birch seedlings, there was a greater CO₂ growth enhancement for seedlings watered less frequently than for well-watered seedlings. This differential change in CO₂ responsiveness across the moisture gradient reduced the difference in seedling growth between high and low water levels and effectively broadened the regeneration niche of paper birch. In contrast, for yellow birch seedlings, elevated CO₂ only produced a significant growth enhancement at the wet end of the soil moisture gradient, and increased the size difference between seedlings at the two ends of the gradient. Gas exchange measurements showed that paper birch seedlings were more sensitive than yellow birch seedlings to declines in soil moisture, and that elevated CO₂ reduced this sensitivity. Additionally, elevated CO₂ improved survival of yellow birch seedlings growing in competition with paper birch in dry stands. Thus, elevated CO₂ may influence regeneration patterns of paper birch and yellow birch on sites of differing soil moisture. In the future, as atmospheric CO₂ levels rise, growth of paper birch seedlings and survival of yellow birch seedlings may be enhanced on xeric sites, while yellow birch may show improved growth on mesic sites.

Catsky, J., J. Pospisilova, J. Solarova, H. Synkova, and N. Wilhelmova. 1995. Limitations on photosynthesis under environment-simulating culture in-vitro. *Biologia Plantarum* 37(1):35-48.

Limitations on photosynthesis, characterized by leaf CO₂ exchange, chlorophyll fluorescence, and thylakoid structure, were studied under environmental conditions simulating culture in vitro. These were simulated by growing *Phaseolus vulgaris* plants in nutrient solution under high relative humidity of air (> 90%), and CO₂ concentrations (c(a)) that decreased with the development of photosynthetic activities during plant ontogeny (1200 to 300 mg m⁻³). The ontogeny of such model plants was more rapid, primary leaves reached photosynthetic maturity 2 to 3 d earlier and their life span was 7 to 14 d shorter than in control plants. Their photosynthetic activity in situ was limited, after reaching "photosynthetic maturity", similarly to plants grown in vitro. When measured under optimal conditions, however, 50 to 70% higher net photosynthetic rate (P(N)) were found in leaves of different ages as compared with plants grown under c(a) of 700 mg m⁻³ and a lower air humidity (30 - 35%). This increase in P(N) was associated with a high conductance for CO₂ transfer by adaxial and abaxial epidermes. In model plants, the dark respiration rate (R(D)) was almost twice that in the control, while the photorespiration rates were similar to controls; CO₂ compensation concentration was about 50% of that in controls. The ratios P(N)/R(D) were similar in control and in model plants. Chlorophyll a+b content in leaves of the model plants was lower than that in the control plants. Grana extent increased with plant age in the model plants while it decreased in the control ones. In both the stomal and granal membranes of the chloroplasts in model plants, a marked accumulation of carotenoids occurred independent of age. The ratio of variable to maximal fluorescence, F(v)/F(m), did not differ in the model and the control plants. In the control plants, photochemical quenching (qp) slightly increased with plant age and was not affected by CO₂ concentration present during measurement. In the model plants, qp increased with elevated CO₂ concentration in young plants and decreased in saturating CO₂ concentrations in older plants. Nonphotochemical quenching (q(NP)) was lower in the model plants and increased under CO₂ saturating conditions. Vitality index, Rfd, was markedly lower in the model plants than in the control ones and a decline was found in saturating CO₂ concentration.

Caulfield, F., and J.A. Bunce. 1994. Elevated atmospheric carbon-dioxide concentration affects interactions between spodoptera-exigua (lepidoptera, noctuidae) larvae and 2 host-plant species outdoors. *Environmental Entomology* 23(4):999-1005.

Beet armyworm, *Spodoptera exigua* (Hubner), larvae were placed on sugarbeet (*Beta vulgaris* L.) and pigweed (*Amaranthus hybridus* L.) plants in outdoor chambers in which the plants were growing at either the ambient (almost-equal-to 350 $\mu\text{mol liter}^{-1}$) or ambient plus 350 $\mu\text{mol liter}^{-1}$ (almost-equal-to 700 $\mu\text{mol liter}^{-1}$) carbon dioxide concentration. A series of experiments was performed to determine if larvae reduced plant growth differently at the two carbon dioxide concentrations in either species and if the insect growth or survival differed with carbon dioxide concentration. Leaf nitrogen, water, starch, and soluble carbohydrate contents were measured to assess carbon dioxide concentration effects on leaf quality. Insect feeding significantly reduced plant growth in sugarbeet plants at 350 $\mu\text{mol liter}^{-1}$ but not at 700 $\mu\text{mol liter}^{-1}$ nor in pigweed at either carbon dioxide concentration. Larval survival was greater on sugarbeet plants at the elevated carbon dioxide concentration. Increased survival occurred only if the insects were at the elevated carbon dioxide concentration and consumed leaf material grown at the elevated concentration. Leaf quality was only marginally affected by growth at elevated carbon dioxide concentration in these experiments. The results indicate that in designing experiments to predict effects of elevated atmospheric carbon dioxide concentrations on plant-insect interactions, both plants and insects should be exposed to the experimental carbon dioxide concentrations, as well as to as realistic environmental conditions as possible.

Cavender-Bares, J.M., P.B. Voss, and F.A. Bazzaz. 1998. Consequences of incongruity in diurnally varying resources for seedlings of *Rumex crispus* (Polygonaceae). *American Journal of Botany* 85(9):1216-1223.

The incongruity of diurnally varying resources essential to plants may detrimentally affect plants early in their development as indicated by reduced water use efficiency and carbon gain. Typical diurnal patterns of light and CO₂ availability in a mid-sized temperate herbaceous or forest gap were simulated in specially designed growth chambers. A sinusoidally varying CO₂ treatment (400 ppm minimum, 800 ppm maximum) approximated the diurnal cycle of CO₂ at the soil surface, while a steady-state CO₂ treatment (600 ppm) with the same average CO₂ concentration provided a control. Crossed with these two CO₂ treatments were two light regimes, one with 3 h of high light (850 $\mu\text{mol m}^{-2}\text{s}^{-1}$) in the morning (west side of a gap), and the other with 3 h of high light in the afternoon (east side). All treatments received baseline low light (55 $\mu\text{mol m}^{-2}\text{s}^{-1}$) for 14 h during the day. *Rumex crispus* was selected as a model species because of its rosette leaves, which grow close to the ground where diurnal CO₂ variation is greatest. The relative timing of diurnal variations in light and CO₂ significantly affected seedling water use efficiency, carbon gain, and morphology. Total biomass, photosynthetic rates, daily integrated carbon, water use efficiency, and leaf area were enhanced by morning exposure to high light. Seedlings that were exposed to peak values of light and CO₂ incongruently, i.e., those plants receiving intense afternoon light with diurnally varying CO₂, were detrimentally affected relative to control plants receiving intense afternoon light with steady-state CO₂. The results of this experiment indicate that the incongruent availability of required resources-such as light and CO₂-can detrimentally affect performance relative to when resources are

congruent. These contrasting resource regimes can occur on the east and west side of gaps.

Cebrian, J. 1999. Patterns in the fate of production in plant communities. *The American Naturalist* 154(4):449-468.

I examine, through an extensive compilation of published reports, the nature and variability of carbon flow (i.e., primary production, herbivory, detrital production, decomposition, export, and biomass and detrital storage) in a range of aquatic and terrestrial plant communities. Communities composed of more nutritional plants (i.e., higher nutrient concentrations) lose higher percentages of production to herbivores, channel lower percentages as detritus, experience faster decomposition rates, and, as a result, store smaller carbon pools. These results suggest plant palatability as a main limiting factor of consumer metabolic and feeding rates across communities. Hence, across communities, plant nutritional quality may be regarded as a descriptor of the importance of herbivore control on plant biomass ("top-down" control), the rapidity of nutrient and energy recycling, and the magnitude of carbon storage. These results contribute to an understanding of how much and why the trophic routes of carbon flow, and their ecological implications, vary across plant communities. They also offer a basis to predict the effects of widespread enhancement of plant nutritional quality due to large-scale anthropogenic eutrophication on carbon balances in ecosystems.

Centritto, M., and P.G. Jarvis. 1999. Long-term effects of elevated carbon dioxide concentration and provenance on four clones of Sitka spruce (*Picea sitchensis*). II. Photosynthetic capacity and nitrogen use efficiency. *Tree Physiology* 19(12):807-814.

Four clones of Sitka spruce (*Picea sitchensis* (Bong.) Carr.) from two provenances, at 53.2 degrees N (Skidegate a and Skidegate b) and at 41.3 degrees N (North Bend a and North Bend b), were grown for three growing seasons in ambient (similar to 350 $\mu\text{mol mol}^{-1}$) and elevated (similar to 700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. The clones were grown in stress-free conditions (adequate nutrition and water) to assess the effect of elevated [CO₂] on tree physiology. Growth in elevated [CO₂] significantly increased instantaneous photosynthetic rates of the clonal Sitka spruce saplings by about 62%. Downward acclimation of photosynthesis (A) was found in all four clones grown in elevated [CO₂]. Rubisco activity and total chlorophyll concentration were also significantly reduced in elevated [CO₂]. Provenance did not influence photosynthetic capacity. Best-fit estimates of J(max) (maximum rate of electron transport), V-cmax (RuBP-saturated rate of Rubisco) and A(max) (maximum rate of assimilation) were derived from responses of A to intercellular [CO₂] by using the model of Farquhar et al. (1980). At any leaf N concentration, the photosynthetic parameters were reduced by growth in elevated [CO₂]. However, the ratio between J(max) and V-cmax was unaffected by CO₂ growth concentration, indicating a tight coordination in the allocation of N between thylakoid and soluble proteins. In elevated [CO₂] the more southerly clones had a higher initial N use efficiency (more carbon assimilated per unit of leaf N) than the more northerly clones, so that they had more N available for those processes or organs that were most limiting to growth at a particular time. This may explain the initial higher growth stimulation by elevated [CO₂] in the North Bend clones

than in the Skidegate clones.

Centritto, M., H.S.J. Lee, and P.G. Jarvis. 1999. Increased growth in elevated [CO₂]: an early, short-term response? *Global Change Biology* 5(6):623-633.

Saplings of four clones of Sitka spruce and cherry were grown for three and two growing seasons, respectively, in open top chambers at two CO₂ concentrations (approximate to 350 and approximate to 700 $\mu\text{mol mol}^{-1}$) to determine whether the increase in total biomass brought about by enhanced [CO₂] is a result of a transient or persistent effect in nonlimiting conditions. Classical growth analysis was applied to both species and mean current relative growth rate of total dry mass (R-T) and leaf dry mass (R-L), and period relative growth rate of total dry mass (R-T(t)) and leaf dry mass (R-L(t)) were calculated. Sitka spruce saplings and cherry seedlings showed a positive growth response to elevated [CO₂], and at the end of the experiments both species were approximate to 40% larger in elevated [CO₂] than in ambient [CO₂]. As a result, the period mean R-T(t) and R-L(t) were significantly higher in elevated [CO₂]. The differences in plant dry mass at the end of the experiments were a consequence of the more rapid growth in the early phase of exposure to elevated [CO₂]. After this initial phase mean R-T and R-L were similar or even lower in elevated [CO₂] than in ambient [CO₂]. NAR of both species was much higher in elevated [CO₂], whereas both LAR, SLA, and LMR showed the opposite trend. The higher LAR and SLA of plants in ambient [CO₂] contributed to a compensation by which they maintained R-T similar to that of elevated [CO₂] saplings despite lower NAR and photosynthetic rate. However, when the same size the trees were similar amongst the [CO₂] treatments, indicating that one of the main effects of elevated [CO₂] on tree growth is to speed-up early development in all aspects.

Centritto, M., H.S.J. Lee, and P.G. Jarvis. 1999. Interactive effects of elevated [CO₂] and drought on cherry (*Prunus avium*) seedlings - I. Growth, whole-plant water use efficiency and water loss. *New Phytologist* 141(1):129-140.

Seeds of cherry (*Prunus avium*) were germinated and grown for two growing seasons in ambient (similar to 350 $\mu\text{mol mol}^{-1}$) or elevated (ambient + similar to 350 $\mu\text{mol mol}^{-1}$) CO₂ mole fractions in six open-top chambers. The seedlings were fertilized once a week, following Ingstad principles in order to supply mineral nutrients at free-access rates. In the first growing season gradual drought was imposed on rapidly growing cherry seedlings by withholding water for a 6-wk drying cycle. In the second growing season, the rapid onset of drought was imposed at the height of the growing season on the seedlings which had already experienced drought in the first growing season. Elevated [CO₂] significantly increased total dry-mass production in both water regimes, but did not ameliorate the growth response to drought of the cherry seedlings subjected to two sequential drying cycles. Water loss did not differ in either well watered or droughted seedlings between elevated and ambient [CO₂]; consequently whole-plant water-use efficiency (the ratio of total dry mass produced to total water consumption) was significantly increased. Similar patterns of carbon allocation between shoot and root were found in elevated and ambient [CO₂] when the seedlings were the

same size. Thus, elevated [CO₂] did not improve drought tolerance, but it accelerated ontogenetic development irrespective of water status.

Centritto, M., H.S.J. Lee, and P.G. Jarvis. 1999. Long-term effects of elevated carbon dioxide concentration and provenance on four clones of Sitka spruce (*Picea sitchensis*). I. Plant growth, allocation and ontogeny. *Tree Physiology* 19(12):799-806.

Four clones of Sitka spruce (*Picea sitchensis* (Bong.) Carr.) from two provenances, at 53.2 degrees N (Skidegate a and Skidegate b) and at 41.3 degrees N (North Bend a and North Bend b), were grown near Edinburgh (55.5 degrees N), U.K., for three growing seasons in ambient (similar to 350 $\mu\text{mol mol}^{-1}$) and elevated (similar to 700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations under conditions of non-limiting water and nutrient supply. Bud phenology was not affected by elevated [CO₂] in the second growing season, but in the third year, the duration of shoot extension growth in three of the four clones (North Bend clones and Skidegate a) was significantly shortened, because of the suppression of lammas growth. Saplings in elevated [CO₂] had significantly greater dry masses of all components than saplings in ambient [CO₂]. However, comparison of relative component dry masses between plants of similar size showed no effect of [CO₂] treatment on plant allometric relationships. This finding, and the observed suppression of lammas growth by high [CO₂] during the third growing season suggests that the main effect of increasing [CO₂] is to accelerate sapling development. Clonal provenance did not affect dry mass production in ambient [CO₂]. However in elevated [CO₂] the more southerly clones significantly outperformed the more northerly clones when grown at a latitude close to the latitudinal provenance of the Skidegate clones. As atmospheric carbon dioxide concentration rises, such changes in the relative performance of genotypes may be exploited for economic gain through appropriate selection of provenances for forest plantings.

Centritto, M., F. Magnani, H.S.J. Lee, and P.G. Jarvis. 1999. Interactive effects of elevated [CO₂] and drought on cherry (*Prunus avium*) seedlings - II. Photosynthetic capacity and water relations. *New Phytologist* 141(1):141-153.

Cherry seedlings (*Prunus avium*) were grown from seed for two growing seasons in three ambient [CO₂] (similar to 350 $\mu\text{mol mol}^{-1}$) and three elevated [CO₂] (ambient + similar to 350 $\mu\text{mol mol}^{-1}$) open-top chambers, and in three outside blocks. A drying cycle was imposed in both the growing seasons to half the seedlings: days 69-115 in the first growing season, and in the second growing season days 212-251 on the same seedlings which had already experienced drought. Stomatal conductance was significantly reduced in elevated [CO₂]-grown, unstressed seedlings in both the first and second growing seasons, but was not caused by a decrease in stomatal density. Droughted seedlings showed little or no reduction in stomatal conductance in response to elevated [CO₂]. However, stomatal conductance was highly correlated with soil water status. Photosynthetic rate increased significantly in response to elevated [CO₂] in both water regimes, leading to improvement in instantaneous transpiration efficiency over the whole duration of the experiment, but there was no relationship between instantaneous transpiration efficiency and long-term water use

efficiency. The A(max) was strongly reduced in the second growing season, but unaffected by [CO₂] treatment. Although photosynthetic rate was not down-regulated, Rubisco activity was decreased by elevated [CO₂], possibly because of the increased leaf carbon:nitrogen ratio which had occurred by the ends of the two growing seasons. Elevated [CO₂] did not improve plant water relations (for example, bulk leaf - water potential, osmotic potentials at full and zero turgor, relative water content at zero turgor, bulk modulus of elasticity of the cell) and thus did not increase water-stress tolerance of cherry seedlings.

Ceulemans, R., I.A. Janssens, and M.E. Jach. 1999. Effects of CO₂ enrichment on trees and forests: Lessons to be learned in view of future ecosystem studies. *Annals of Botany* 84(5):577-590.

Because of their prominent role in global bioproductivity and because of their complex structure and function, forests and tree species deserve particular attention in studies on the likely impact of elevated atmospheric CO₂ on terrestrial vegetation. Besides a synoptic review of some of the most prominent above-ground response processes, particular attention is given to below-ground responses of trees to elevated atmospheric CO₂, while some feedback processes and interactions with Various biotic and abiotic factors are also briefly summarized. At the leaf level there is little evidence of the long-term loss of sensitivity to CO₂ that was suggested by earlier experiments with tree seedlings in pots. Future studies on photosynthesis measurements will probably not alter our conclusions about acclimation, but should focus more on respiration under elevated CO₂, which is still poorly understood. At the tree level, the increase in growth observed in elevated CO₂ results from an increase in both leaf area and leaf photosynthetic rate (per unit leaf area). Tree growth enhancement is generally larger at high rates of nutrient supply; when nutrient supply rates do not meet growth rates, tree nutrient status declines and nutrients become limiting. In many studies at the canopy level, a shift in whole-tree carbon allocation pattern towards below-ground parts has been associated with increased atmospheric CO₂ concentrations. At the ecosystem level, a larger amount of carbon being allocated below-ground could show up by either (1) more root growth and turnover, (2) enhanced activity of root-associated microorganisms, (3) larger microbial biomass pools and enhanced microbial activity, or (4) increased losses of soil carbon through soil respiration. Fine root production is generally enhanced, but it is not clear whether this response would persist in a forest. As elevated CO₂ stimulates biomass production, litterfall and rhizodeposition also increase. This increased delivery of labile organic matter to the soil could influence soil microbial communities and subsequent decomposition rates, nutrient availability and carbon storage in soil. There are, however, contradictory hypothesis about the direction in which nutrient availability will be affected. Knowledge of the response of these and other ecophysiological processes to elevated CO₂ is the key to understanding the functioning of the whole forest ecosystem. Our current knowledge is sufficiently large with regard to how the carbon uptake process and individual tree growth respond under atmospheric changes, but more emphasis should be put in future experiments on the interactions between various processes, such as the carbon and nitrogen cycles, and on below-ground responses. Ceulemans, R., X.N. Jiang, and B.Y. Shao. 1995. Effects of elevated atmospheric CO₂ on growth, biomass production and nitrogen allocation of two Populus clones. *Journal of Biogeography* 22(2-3):261-268.

Two hybrid poplar (Populus) clones (i.e. fast growing clone Beaupre and slower growing clone Robusta) were grown from cuttings at close spacings in four open top chambers (OTCs) on the Campus of the University of Antwerpen, Belgium. The four OTCs represented two atmospheric CO₂ treatments, i.e. ambient and elevated (= ambient + 350 μ mol mol⁻¹). Treatments lasted for a full growing season (April-November 1993) and results of the first growing season are being reported. In both clones the elevated CO₂ treatment resulted in a significant increase in plant height and in biomass production, both of stems and branches. Plants of both clones produced significantly more, but shorter, side branches under the elevated CO₂ treatment. In terms of biomass accumulation the slower growing clone Robusta benefited relatively more (+ 37%) from the elevated CO₂ concentrations than the fast growing clone Beaupre (+ 24%). In terms of leaf weight ratio, the slower growing clone became relatively more efficient under elevated CO₂ than the fast growing clone. The elevated atmospheric CO₂ treatment significantly increased the total leaf area per plant and leaf area index per OTC; maximum LAI increased by 18% in clone Beaupre and by only 8% in the slower growing clone Robusta. In the fast growing clone the increase in leaf area index was entirely caused by an increase in individual leaf area, while in the slower growing clone also a 5% higher leaf production was observed under the elevated CO₂. The total length of the growing season was on average reduced by the elevated CO₂ treatment; in the slower growing clone mainly by an advancement of bud set and in the faster growing clone by a slight delay of bud break in early spring. In both clones elevated CO₂ decreased nitrogen concentration and increased C/N ratio in all plant organs, but no data for the below-ground compartment were available. Therefore, although similar trends in the responses to elevated atmospheric CO₂ were observed in both clones, the relative efficiency of these responses differed between the fast and the slower growing poplar clones, suggesting interactions between growth rate, growth strategy and response to elevated atmospheric CO₂.

Ceulemans, R., X.N. Jiang, and B.Y. Shao. 1995. Growth and physiology of one-year-old poplar (populus) under elevated atmospheric CO₂ levels. *Annals of Botany* 75(6):609-617.

The effects of elevated atmospheric CO₂ concentrations on the ecophysiological responses (gas exchange, chlorophyll a fluorescence, Rubisco activity, leaf area development) as well as on the growth and biomass production of two poplar clones (i.e. Populus trichocarpa x P. deltoides clone Beaupre and P. x euramericana clone Robusta) were examined under open top chamber conditions. The elevated CO₂ treatment (ambient + 350 μ mol mol⁻¹) stimulated above-ground biomass of clones Robusta and Beaupre after the first growing season by 55 and 38 %, respectively. This increased biomass production under elevated CO₂ was associated with a significant increase in plant height, the latter being the result of enhanced internode elongation rather than an increased production of leaves or internodes. Both an increased leaf area index (LAI) and a stimulated net photosynthesis per unit leaf contributed to a significantly higher stem biomass per unit leaf area, and thus to the increased above-ground biomass production under the elevated CO₂ concentrations in both clones. The larger LAI was caused by a larger individual leaf size and leaf growth rate; the number of leaves was not altered by the elevated CO₂ treatment. The higher net leaf photosynthesis was the result of an increase in the photochemical (maximal chlorophyll fluorescence F_m and photochemical efficiency

Fv/Fm) as well as in the biochemical (increased Rubisco activity) process capacities. No significant differences were found in dark respiration rate, neither between clones nor between treatments, but specific leaf area significantly decreased under elevated CO₂ conditions. Ceulemans, R., and M. Mousseau. 1994. Tansley review no-71 - effects of elevated atmospheric CO₂ on woody-plants. *New Phytologist* 127(3):425-446.

Because of their prominent role in the global carbon balance and their possible carbon sequestration, trees are very important organisms in relation to global climatic changes. Knowledge of these processes is the key to understanding the functioning of the whole forest ecosystem which can be modelled and predicted based on the physiological process information. This paper reviews the major methods and techniques used to examine the likely effects of elevated CO₂ on woody plants, as well as the major physiological responses of trees to elevated CO₂. The available exposure techniques and approaches are described. An overview table with all relevant literature data over the period 1989-93 summarizes the percent changes in biomass, root/shoot ratio, photosynthesis, leaf area and water use efficiency under elevated CO₂. Interaction between growth, photosynthesis and nutrition is discussed with a special emphasis on downward regulation of photosynthesis. The stimulation or reduction found in the respiratory processes of woody plants are reviewed, as well as the effect of elevated CO₂ on stomatal density, conductance and water use efficiency. Changes in plant quality and their consequences are examined. Changes in underground processes under elevated CO₂ are especially emphasized and related to the functioning of the ecosystem. Some directions for future research are put forward.

Ceulemans, R., B.Y. Shao, X.N. Jiang, and J. Kalina. 1996. First- and second-year aboveground growth and productivity of two *Populus* hybrids grown at ambient and elevated CO₂. *Tree Physiology* 16(1-2):61-68.

Two hybrid poplar (*Populus*) clones (the fast-growing clone Beaupre (P trichocarpa Torr. and Gray x P. deltoides Bartr. ex Marsh.) and the slow-growing clone Robusta (P deltoides Bartr. ex Marsh. x P. nigra L.)) were grown from hardwood cuttings for one or two growing seasons (1993-1994) in either ambient or elevated (= ambient + 350 $\mu\text{mol mol}^{-1}$) CO₂ in open-top chambers at the University of Antwerpen. Both clones responded positively to the elevated CO₂ treatment with increased stem volume and aboveground biomass production; however, the clones

exhibited different response strategies to the elevated CO₂ treatment, and the responses varied with cutting age and duration of exposure. Clone Beaupre responded to the elevated CO₂ treatment with increases in leaf area and leaf area index during both the first and second growing seasons, but little increase in height growth. Clone Robusta exhibited increased height growth, leaf biomass and total leaf nitrogen content in response to elevated CO₂, but no increase in leaf area index. The elevated CO₂ treatment increased the total number of branches and total branch biomass in both clones during both growing seasons. At the end of the first growing season, woody stem biomass of the fast- and slow-growing clones was increased by 38 and 55%, respectively. At the end of the second growing season, stem volume was increased by 43% in clone Beaupre and by 58% in clone Robusta. The increase in stem volume was a result of the stimulation of both height and diameter growth in the slow-growing clone, whereas only height growth was stimulated in the fast-growing clone. In the fall of the first growing season, the average date of bud set in clone Robusta was advanced by 4 days in the elevated CO₂ treatment; there were no other significant effects of the elevated CO₂ treatment on bud set. The elevated CO₂ treatment enhanced leaf C/N ratios in both clones in both years.

Ceulemans, R., G. Taylor, C. Bosac, D. Wilkins, and R.T. Besford. 1997. Photosynthetic acclimation to elevated CO₂ in poplar grown in glasshouse cabinets or in open top chambers depends on duration of exposure. *Journal of Experimental Botany* 48(314):1681-1689.

The effects of elevated CO₂ were studied on the photosynthetic gas exchange behaviour and leaf physiology of two contrasting poplar (*Populus*) hybrids grown and treated in open top chambers (OTCs in Antwerp, Belgium) and in closed glasshouse cabinets (GHCs in Sussex, UK). The CO₂ concentrations used in the OTCs were ambient and ambient +350 $\mu\text{mol mol}^{-1}$, while in the GHCs they were c. 360 $\mu\text{mol mol}^{-1}$ versus 719 $\mu\text{mol mol}^{-1}$. Measurements of photosynthetic gas exchange were made for euramerican and interamerican poplar hybrids in combination with measurements of dark respiration rate and Rubisco activity. Significant differences in the leaf anatomy and structure (leaf mass per area and chlorophyll content) were observed between the leaves grown in the OTCs and those grown in the GHCs. Elevated CO₂ stimulated net photosynthesis in the poplar hybrids after 1 month in the GHCs and after 4 months in the OTCs, and there was no evidence of downward acclimation (or downregulation) of photosynthesis when the plants in the two treatments were measured in their growth CO₂ concentration. There was also no evidence of downregulation of Rubisco activity and there were even examples of increases in Rubisco activity. Rubisco exerted a strong control over the light-saturated rate of photosynthesis, which was demonstrated by the close agreement between observed net photosynthetic rates and those that were predicted from Rubisco activities and Michaelis-Menten kinetics. After 17 months in elevated CO₂ in the OTCs there was a significant loss of Rubisco activity for one of the hybrid clones, i.e. Beaupre, but not for clone Robusta. The effect of the CO₂ measurement concentration (i.e. the short-term treatment effect) on net photosynthesis was always larger than the effect of the growth concentration in both the OTCs or GHCs (i.e. the long-term growth CO₂ effect), with one exception. For the interamerican hybrid Beaupre dark respiration rates in the OTCs were not significantly affected by the elevated CO₂ concentrations. The results suggest that for rapidly growing tree species, such as poplars, there is little evidence for downward acclimation of photosynthesis when plants are exposed to elevated CO₂ for up to 4 months; longer term exposure reveals loss of Rubisco activity.

Ceulemans, R., L. Vanpraet, and X.N. Jiang. 1995. Effects of CO₂ enrichment, leaf position and clone on stomatal index and epidermal-cell density in poplar (populus). *New Phytologist* 131(1):99-107.

The effects of CO₂ enrichment and leaf position on stomatal characteristics (stomatal density, stomatal index and stomatal pore length) and epidermal cell density were examined for two different Populus clones, Beaupre and Robusta, grown from cuttings in open-top chambers under ambient and elevated atmospheric CO₂ conditions. Both clones had amphistomatous leaves, and stomatal density was significantly larger on the abaxial leaf surface than on the adaxial. Significant interactions between CO₂ enrichment, leaf position and clone were observed for most stomatal and epidermal characteristics. A significant reduction of the number of stomata mm⁻² under elevated CO₂ was observed in expanding leaves near the upper portion of the plant for both leaf surface sides and in both clones. For the abaxial leaf side only, this reduction under elevated CO₂ was accompanied by a similar reduction of the stomatal index in both clones. In mature leaves on the middle and lower portion of the plants, there was no significant effect of the CO₂ treatment on stomatal density. In young, expanding leaves near the upper part of the plant there were significant interactions between the CO₂ treatment and leaf surface side for epidermal cell density. The latter increased under elevated CO₂ at the abaxial leaf surface, but decreased at the adaxial surface on the upper part of the plant. Total epidermal cell numbers of mature, fully expanded leaves increased under elevated CO₂ in both clones. The observation that interactions with leaf age and/or leaf position significantly confound the CO₂ treatment effect on stomatal and epidermal cell densities, might contribute to the elucidation of the problem of the phenomenon of stomatal density reduction under elevated atmospheric CO₂.

Chabot, S., R. Belrhilid, R. Chenevert, and Y. Piche. 1992. Hyphal growth promotion invitro of the va mycorrhizal fungus, gigaspora-margarita becker and hall, by the activity of structurally specific flavonoid compounds under CO₂-enriched conditions. *New Phytologist* 122(3):461-467.

Plant phenolic compounds are known to be inducers of virulence genes in plant-pathogen interactions such as those involving Agrobacterium, and flavonoids are known to be inducers or inhibitors of Nod genes in Rhizobium-legume symbiosis. More recent studies suggest that some of these compounds act as molecular signals in the development of vesicular-arbuscular mycorrhizas (VAM). The present study has shown that hyphal growth of the VAM fungus, Gigaspora margarita Becker & Hall, is affected by both stimulatory and inhibitory flavonoids, when applied at 10 µM together with an optimal carbon dioxide enrichment. Stimulatory compounds were all flavonols (kaempferol, quercetin and morin) and possessed at least one hydroxyl group on the B ring. Conversely, two isoflavones (biochanin A, and genistein), a single flavanone (hesperetin) and two compounds without any hydroxyl group on the B ring, galangin (flavonol) and chrysin (flavone), were all inhibitors of hyphal growth.

Chagvardieff, P., T. Daletto, and M. Andre. 1994. Specific effects of irradiance and CO₂ concentration doublings on productivity and mineral-content in lettuce. *Life Sciences and Space Research XXV* (3) 14(11):269-275.

Experiments in growth chambers with controlled atmosphere were performed to compare the effects on the productivity of two treatments stimulating photosynthesis : the doubling of CO₂ concentration, the doubling of irradiance; the combining of both was also tested. A large effect of light was noticed : (i) the accumulation of carbon was, contrarily to CO₂ effect, amplified within time, and led to the most important dry matter production. (ii) the specific leaf weight was about two-fold increased. (iii) the nitrate content was 2-3 fold less. A significant positive effect of CO₂ was detected on the fresh biomass production and the iron content of lettuce. A synergy was observed on dry matter production by the interaction of the two factors.

Chagvardieff, P., B. Dimon, A. Souleimanov, D. Massimino, S. Le Bras, M. Pean, and D. Louche-Teissandier. UNKNOWN YEAR. Effects of modified atmosphere on crop productivity and mineral content. *Life Sciences: Life Support Systems Studies-I :1971-1974.*

Wheat, potato, pea and tomato crops were cultivated from seeding to harvest in a controlled and confined growth chamber at elevated CO₂ concentration (3700 µm L.L-1) to examine the effects on biomass production and edible part yields. Different responses to high CO₂ were recorded, ranging from a decline in productivity for wheat, to slight stimulation for potatoes, moderate increase for tomatoes, and very large enhancement for pea. Mineral content in wheat and pea seeds was not greatly modified by the elevated CO₂. Short-term experiments (17 d) were conducted on potato at high (3700 µm L.L-1) and very high (20,000 µm L.L-1) CO₂ concentration and/or low O₂ partial pressure (similar to 20,600 µm L.L-1 or 2 kPa). Low O₂ was more effective than high CO₂ in total biomass accumulation, but development was affected: Low O₂ inhibited tuberization, while high CO₂ significantly increased production of tubers. Two mechanistic models for estimating net photosynthesis of a greenhouse canopy are evaluated against measurements using mass balance of CO₂ fluxes. The discrepancies observed between the mechanistic models and the CO₂ mass balance measurement method are

attributed to the underestimation of leakage rate, the error in estimating radiation transmission in direct light conditions, and the spatial inhomogeneity of the CO₂ concentration inside the glasshouse.

Chan, Y.S.G., M.H. Wong, and B.A. Whitton. 1998. Effects of landfill gas on growth and nitrogen fixation of two leguminous trees (*Acacia confusa*, *Leucaena leucocephala*). *Water, Air, and Soil Pollution* 107(1-4):409-421.

A study was made on the effects of landfill gas on ARA (acetylene reducing activity) of nodules of two woody legumes (*Acacia confusa* and *Leucaena leucocephala*) widespread on landfill sites in Hong Kong. The effects of the three main components of landfill gas, O₂, CO₂ and CH₄, were first measured separately over a 1-hr period. Maximum ARA was found at 20% O₂ (close to atmospheric partial pressure) and ARA decreased as the O₂ decreased in the range of 16-1%. *Acacia confusa* nodular ARA was significantly inhibited at 30-50% CO₂, but not *Leucaena leucocephala* nodular ARA. CH₄ had no significant effect on ARA of either species. As the landfill gas concentrations in the landfill topsoil were mostly > 10% O₂ and < 10% CO₂, root nodules should fix N₂ effectively over these ranges of gases. A four-week test was conducted to assess the long-term influence of landfill gas on seedlings of the two legumes. Landfill gas and elevated CO₂ both suppressed their growth and their nodular ARA. Even under the influence of the gases, however, seedlings with nodules formed a higher biomass than seedlings lacking nodules. The growth of the two legumes under actual landfill conditions was investigated by transplanting non-inoculated and pre-inoculated seedlings to two landfill sites in Hong Kong: Junk Bay and Shuen Wan Landfill. After six months, most of the non-inoculated seedlings became infected: *Acacia confusa* 63 and 70%, *Leucaena leucocephala* 17 and 89%, respectively, at the test sites. The results indicate that there were free rhizobia at these landfill sites to infect the legumes and they had formed effective nodules to fix N₂ under landfill conditions.

Chapin, F.S., E. Rincon, and P. Huante. 1993. Environmental responses of plants and ecosystems as predictors of the impact of global change. *Journal of Biosciences* 18(4):515-524.

An understanding of plant responses to fluctuations in environment is critical to predictions of plant and ecosystem responses to climate change. In the northern hemisphere, the northern limits of distribution of major biomes are probably determined by the tolerance of their dominant physiognomic types (e.g., deciduous hardwood trees) to minimum winter temperatures and can thus be predicted from long-term patterns of temperature fluctuations. At a more detailed level, the responses of functional groups of plants to altered climate can be predicted from their known responses to fluctuations in soil resources (nutrients and water) and the expected effect of climatic change on these soil resources. Laboratory and field experiments demonstrate the feasibility of this approach.

Chaves, M.M., and J.S. Pereira. 1992. Water-stress, co₂ and climate

change. *Journal of Experimental Botany* 43(253):1131-1139.

Climatic change may bring about increased aridity to large areas of Europe. Higher temperatures, larger water deficits and high light stress are likely to occur in conjunction with elevated atmospheric CO₂. This raises the question whether a high CO₂ concentration in the atmosphere can compensate for the decrease in carbon gain in water-stressed plants. The processes which determine dry matter production and the ways they are affected by soil water deficits are discussed. It is now well established that in most species and under most circumstances stomata are the main limiting factor to carbon uptake under water deficit, the photosynthetic machinery being highly resistant to dehydration. However, when other stresses are superimposed, a decline in photosynthetic capacity may be observed. In the short term, under drought conditions, the increase in CO₂ in the atmosphere may diminish the importance of stomatal limitation for carbon assimilation, inhibit photorespiration, stimulate carbon partitioning to soluble sugars and increase water-use efficiency. Some recent evidence seems to indicate that under conditions of high irradiance, plants growing at elevated CO₂ may develop protection towards photoinhibition, which might otherwise result in significant losses in plant production under stress conditions. In the longer term though, a negative acclimation of photosynthesis appears to occur in many species, an explanation for which still needs to be clearly identified. Similarly, the effects of extended exposure to elevated CO₂ under arid conditions are not known. Plant production is more closely related to the integral of photosynthesis over time and total foliage area than to the instantaneous rates of the photosynthetic process. Water deficits result in a decrease in foliage area biomass and, therefore, in productivity. On the other hand, the increase in air temperature may result in more respiratory losses. However, experimental as well as simulatory evidence suggests that doubling CO₂ concentration in the air may improve carbon assimilation and compensate partially for the negative effects of water stress even if we assume a down-regulation of the photosynthetic process as a result of acclimation to elevated CO₂.

Chaves, M.M., J.S. Pereira, S. Cerasoli, J. CliftonBrown, F. Miglietta, and A. Raschi. 1995. Leaf metabolism during summer drought in *Quercus ilex* trees with lifetime exposure to elevated CO₂. *Journal of Biogeography* 22(2-3):255-259.

A marginal improvement in the response of *Quercus ilex* adult trees to drought appears to occur under a long-term natural CO₂ enrichment. This is expressed, for example, by the absence of midday stomatal closure in trees growing under elevated CO₂. Some protection against high irradiance and high temperature seems also to occur at the photochemical level, presumably as a result of more carbon available to the consumption of excess light energy. This would allow a better performance of the plants grown under elevated CO₂ during the warmer hours of the day and therefore playing an important adaptation role under drought conditions. A marginal increase in the concentration of soluble sugars and starch was observed in the leaves of trees growing at elevated CO₂ as compared with plants at ambient CO₂, mainly during the midday hours. We may speculate that this will be advantageous both in terms of carbohydrate reserves for growth (e.g. more roots) and osmotic adjustment.

Chemeris, Y.K., L.V. Shenderova, and P.S. Venediktov. 1996. Chloroplast respiration in *Chlorella pyrenoidosa* CALU-175: Effects of nitrogen deficiency, exogenous glucose, and elevated temperature. *Russian Journal of Plant Physiology* 43(4):474-479.

The rate of chloroplast respiration in *Chlorella* was studied with respect to some changes in the physiological state induced by nitrogen deficiency, heterotrophic growth, and incubation at supraoptimal temperature. Iodoacetamide (an inhibitor of glycolysis), salicylhydroxamate (an inhibitor of nonmitochondrial respiration), and 2-deoxy-D-glucose (a nonmetabolizable analogue of glucose), inhibited the respiration of chloroplasts. Treatments that inactivate photosystem II (PS II), i.e., the addition of glucose, nitrogen deprivation, or dark incubation at elevated temperatures (39-43 degrees C), drastically (8-10 times) increased the rate of chloroplast respiration. In the absence of CO₂, no enhancement of chloroplast respiration was recorded in nitrogen-starved cells. Cycloheximide, an inhibitor of cytoplasmic protein synthesis, and 2-deoxy-D-glucose prevented the increase in the chloroplast respiration rate caused by the addition of glucose or incubation at elevated temperatures. It is suggested that the inhibition of PS II, previously described in *Chlorella* incubated for a long time at supraoptimal temperature, is associated with the enhancement of chloroplast respiration.

Chemeris, Y.K., P.S. Venediktov, and A.B. Rubin. 1996. Role of chloroplast respiration in the inactivation of photosystem II in *Chlorella*. *Russian Journal of Plant Physiology* 43(6):716-723.

Nitrogen deficiency, dark incubation on glucose, and dark incubation at an elevated temperature (41 degrees C) were previously shown to inactivate photosystem II (PS II) in *Chlorella pyrenoidosa* Chick, strain CALU-175. These treatments also increased chloroplast respiration by 7-11 times. At the same time, any attempt to inhibit the accumulation of substrates for chloroplast respiration (CO₂ deprivation during nitrogen starvation, inhibition of glucose metabolism by a nonmetabolizable analog of glucose, 2-deoxy-D-glucose, or inhibition of protein synthesis by cycloheximide during dark incubation on glucose or by heat shock) prevented the stimulation of chloroplast respiration and PS II inactivation. Inhibition of the oxygen-dependent oxidation of the plastoquinone pool under anaerobic conditions or in the presence of salicylhydroxamate, an inhibitor of chloroplast oxidases, markedly increased the extent and rate of PS II inactivation in cells subjected to heat shock. The dependencies of chloroplast respiration and the PS II inactivation rate on the heat-shock temperature exactly matched one another. Diuron, an inhibitor of photosynthetic electron transport between the primary and secondary quinone electron acceptors, did not affect the rate of chloroplast respiration, but prevented PS II inactivation. We propose that the inactivation of PS II caused by these treatments is due to the loss of the primary quinone electron acceptor as a consequence of its two-electron reduction from the plastoquinone reduced by the electron flow from the substrates of chloroplast respiration.

Chen, C.L., C.C. Li, and J.M. Sung. 1994. Carbohydrate-metabolism enzymes in CO₂-enriched developing rice grains of cultivars varying in grain-size. *Physiologia Plantarum* 90(1):79-85.

The increased supply of photosynthate from maternal tissue is known to

promote grain growth in several crop species. However, the effect of increasing photosynthate supply on grain growth receives little attention in rice. This study was aimed at evaluating the effect of increasing photosynthate supply through CO₂ enrichment (650 μ mol l⁻¹) on grain growth in three rice cultivars differing in grain size. CO₂ enrichment was applied to the pot-grown plants between anthesis and final harvest. The results indicated that high CO₂ treatment enhanced the CO₂ exchange rate of leaf tissue, and subsequently increased the sucrose level of peduncle exudate, but it did not promote starch accumulation in the developing grains. This phenomenon was linked to the poor CO₂ responses for the grain activities of sucrose synthase, UDP-glucose pyrophosphorylase, ADP-glucose pyrophosphorylase, and starch synthases involved in the conversion of sucrose to starch. Significant cultivar differences also existed for the activities of sucrose to starch conversion enzymes with larger grain size cultivars tending to have higher enzyme activities (expressed on a grain basis), resulting in a greater carbohydrate accumulation.

Chen, D.X., and M.B. Coughenour. 1996. A mechanistic model for submerged aquatic macrophyte photosynthesis: Hydrilla in ambient and elevated CO₂. *Ecological Modelling* 89(1-3):133-146.

There are significant knowledge gaps about the responses of submerged aquatic macrophytes to CO₂ enrichment and global warming. A mechanistic steady-state photosynthesis model for submerged aquatic macrophytes was developed to provide an analysis tool to investigate the responses of plant photosynthesis to CO₂, temperature and light. The model was based upon a general simplified scheme for inorganic carbon assimilation of submerged aquatic macrophytes which integrated the knowledge about aquatic plant photosynthesis from previous research, mainly on Hydrilla. The model includes: (1) diffusion and/or active transfer of inorganic carbon (CO₂ and/or HCO₃⁻) in the bathing medium into the leaf mesophyll and cytosol; (2) diffusion and/or 'pumping' of CO₂ through the PEPcase-related C-4 pathway into the chloroplast; (3) inter-conversions between CO₂ and HCO₃⁻ inside cells; (4) photosynthetic carbon reduction cycle (PCR) in the chloroplast. In the model, the PCR processes in the chloroplast were described using the widely accepted C-3 photosynthesis model. The activity of the C-4 cycle was related to environmental CO₂ 'stress'. In this way, the model can simulate the shift between C-3-like and C-4-like photosynthesis under different environmental conditions. The model was validated using gas exchange data from Hydrilla plants grown in ambient and elevated CO₂. The model predicted quite well photosynthetic responses to incident PAR, temperature and ambient CO₂ for both ambient and elevated atmospheric CO₂ treatments. Model predictions agreed well with measured Hydrilla gas exchange data. The simulated and measured CO compensation points of Hydrilla leaf photosynthesis were about 100 ppm. The light compensation point of photosynthesis was about 25 μ mol m⁻²s⁻¹ (PAR), and photosynthesis rate was saturated at about 100 μ mol m⁻²s⁻¹ (PAR). Higher pH slightly increased photosynthesis rates at ambient CO₂ (similar to 350 ppm). There was no significant acclimation of Hydrilla photosynthesis to elevated CO₂ within the experimental period. Simulated CO₂ compensation point decreased with increasing activity of C-4-cycle processes.

Chen, D.X., M.B. Coughenour, D. Eberts, and J.S. Thullen. 1994. Interactive effects of CO₂ enrichment and temperature on the growth of dioecious hydrilla-verticillata. *Environmental and Experimental Botany* 34(4):345-353.

Experiments of plant growth responses to different CO₂ concentrations and temperatures were conducted in growth chambers to explore the interactive effects of atmospheric CO₂ enrichment and temperature on the growth and dry matter allocation of dioecious Hydrilla [Hydrilla verticillata (L.f.) Royle]. Hydrilla plants were exposed to two atmospheric CO₂ concentrations (350 and 700 ppm) and three temperatures (15, 25 and 32 degrees C) under a 12-hr photoperiod for about 2 months. The plant growth analysis showed that elevated CO₂ appeared to enhance the growth of Hydrilla, and that the percentage of the enhancement is strongly temperature-dependent. Maximum biomass production was achieved at 700 ppm CO₂ and 32 degrees C. At 15 degrees C, the total dry matter production was increased about 27% by doubling CO₂, due to a 26% enhancement of leaf biomass, a 34% enhancement of stem biomass and 16% enhancement of root biomass. At 25 degrees C, the dry matter production was increased about 46% by doubling CO₂, due to a 29% enhancement of leaf biomass, a 27% enhancement of stem biomass and 40% enhancement of root biomass. At 32 degrees C, however, the percentage of the enhancement of total dry matter production by doubling CO₂ was only about 7%. The dry matter allocation among different plant parts was influenced by temperature but not by elevated CO₂ concentration.

Chen, D.X., M.B. Coughenour, A.K. Knapp, and C.E. Owensby. 1994. Mathematical simulation of C₄ grass photosynthesis in ambient and elevated CO₂. *Ecological Modelling* 73(1-2):63-80.

A mechanistic leaf photosynthesis model was developed for C₄ grasses based on a general simplified scheme of C₄ plant carbon metabolism. In the model, the PEPcase-dependent C₄-cycle was described in terms of CO₂ concentration in the mesophyll space using Michaelis-Menten kinetics, and the activity of PEPcase was related to the incident PAR to take account of the influence of light on the activity of C₄-cycle processes. The CO₂ refixation by Rubisco in the bundle sheath was described using a widely accepted C₃ photosynthesis model. The model assumes a steady state balance among CO₂ diffusion from surrounding atmosphere into the mesophyll space, CO₂ transport into the bundle sheath by the C₄-cycle, CO₂ refixation by the C₃-cycle in the bundle sheath, and CO₂ leakage from the bundle sheath. The response to temperature of photosynthesis was incorporated via the temperature dependence of model parameters. The photosynthesis model was coupled with a stomatal conductance model in order to predict leaf photosynthesis rates at different atmospheric conditions. The empirical model of Ball et al. (1987) was adopted and slightly modified to describe responses in stomatal conductance. The coupled model was parameterized for the C₄ grass *Andropogon gerardii* grown in both ambient (350 ppm) and elevated (700 PPM) CO₂ atmospheres. The key parameters of the model were estimated by fitting the model to the measured data using non-linear regression. The model was validated by comparison the predicted photosynthetic response to PAR in both CO₂-pretreatments with the measured data from an independent gas exchange experiment. The predicted photosynthesis and stomatal conductance matched the measured data quite well for both atmospheric CO₂-pretreatments. At 25-degrees-C, the estimated maximum carboxylation

rate of Rubisco $V_{cm,25}$, potential electron transport rate $J_{m,25}$ and quantum efficiency α were increased by CO₂ enrichment. The maximum PEPcase activity $V_{pm,25}$ was lower in elevated CO₂. The model predicted that the light-saturated leaf photosynthesis will increase by about 10% with the rising of atmospheric CO₂ from 350 to 700 ppm at 30-degrees-C, and that the optimal temperature of photosynthesis will shift from 37 to 38.5-degrees-C. The estimated slope of the stomatal conductance model was increased by atmospheric CO₂ enrichment. Stomatal conductance was significantly reduced by increasing atmospheric CO₂ concentration.

Chen, D.X., H.W. Hunt, and J.A. Morgan. 1996. Responses of a C-3 and C-4 perennial grass to CO₂ enrichment and climate change: Comparison between model predictions and experimental data. *Ecological Modelling* 87(1-3):11-27.

Ecological responses to CO₂ enrichment and climate change are expressed at several interacting levels: photosynthesis and stomatal movement at the leaf level, energy and gas exchanges at the canopy level, photosynthate allocation and plant growth at the plant level, and water budget and nitrogen cycling at the ecosystem level. Predictions of these ecosystem responses require coupling of ecophysiological and ecosystem processes. Version GEM2 of the grassland ecosystem model linked biochemical, ecophysiological and ecosystem processes in a hierarchical approach. The model included biochemical level mechanisms of C-3 and C-4 photosynthetic pathways to represent direct effects of CO₂ on plant growth, mechanistically simulated biophysical processes which control interactions between the ecosystem and the atmosphere, and linked with detailed biogeochemical process submodels. The model was tested using two-year full factorial (CO₂, temperature and precipitation) growth chamber data for the grasses *Paspalum smithii* (C-3) and *Bouteloua gracilis* (C-4). The C-3-C-4 photosynthesis submodels fitted the measured photosynthesis data from both the C-3 and the C-4 species subjected to different CO₂, temperature and precipitation conditions. The whole GEM2 model accurately fitted plant biomass dynamics and plant N content data over a wide range of temperature, precipitation and atmospheric CO₂ concentration. Both data and simulation results showed that elevated CO₂ enhanced plant biomass production in both *P. smithii* (C-3) and *B. gracilis* (C-4). The enhancement of shoot production by elevated CO₂ varied with temperature and precipitation. Doubling CO₂ increased modeled annual net primary production (NPP) of *P. smithii* by 36% and 43% under normal and elevated temperature regimes, respectively, and increased NPP of *B. gracilis* by 29% and 24%. Doubling CO₂ decreased modeled net N mineralization rate (N_{min}) of soil associated with *P. smithii* by 3% and 2% at normal and high temperatures, respectively. N_{min} of *B. gracilis* soil decreased with doubled CO₂ by 5% and 6% at normal and high temperatures. NPP increased with precipitation. The average NPP and N_{min} of *P. smithii* across the treatments was greater than that of *B. gracilis*. In the C-3 species the response of NPP to increased temperatures was negative under dry conditions with ambient CO₂, but was positive under wet conditions or doubled CO₂. The responses of NPP to elevated CO₂ in the C-4 species were positive under all temperature and precipitation treatments. N_{min} increased with precipitation in both the C-3 and C-4 species. Elevated CO₂ decreased N_{min} in the C-4 system. The effects of elevated CO₂ on N_{min} in the C-3 system varied with precipitation and temperature. Elevated temperature decreased N_{min} under dry conditions, but increased it under wet conditions. Thus, there are strong interactions among the effects of CO₂ enrichment, precipitation, temperature and species on NPP and N_{min}. Interactions between ecophysiological processes and ecosystem

processes were strong. GEM2 coupled these processes, and was able to represent the interactions and feedbacks that mediate ecological responses to CO₂ enrichment and climate change. More information about the feedbacks between water and N cycling is required to further validate the model. More experimental and modeling efforts are needed to address the possible effects of CO₂ enrichment and climate change on the competitive balance between different species in a plant community and the feedbacks to ecosystem function.

Chen, J.L., and J.F. Reynolds. 1997. GePSi: A generic plant simulator based on object-oriented principles. *Ecological Modelling* 94(1):53-66.

The Generic Plant Simulator (GePSi) is a physiologically-based model that combines modules for canopy, root environment, water relations, and potential growth to generate whole-plant carbon, nitrogen, and water balances. The version presented here is coded in the object-oriented programming (OOP) language, C++, to enhance the implementation of modularity. In the aboveground aerial environment, the Weather module defines the weather conditions above a canopy, and MicroWeather defines the vertical profiles of micro-meteorological variables in a canopy. The belowground soil environment contains the SoilProperty modules, which define vertical profiles of physical and chemical variables in a soil column. The 'part-of' hierarchy in GePSi follows the structure of a real plant: the Plant module calls canopy and root system modules; the Canopy module, in turn, calls leaf, stem and fruit modules, and the RootSystem module calls coarse and fine root modules, etc. Our long-term goal is for GePSi to serve as a template for building a plant growth simulator by simply selecting appropriate modules for the question being asked. We are building a suite of plant modules (and their interfaces) based on general principles that are fundamentally similar for different kinds of plants. This includes photosynthesis, growth, nutrient and carbon allocation, water uptake, etc. These modules can be parameterized for specific species, related groups of species, life-forms, or broader groups depending on how variable the processes are across the groupings and the amount of unexplained variability that is acceptable for the question being investigated. Our modular-based approach has numerous advantages, including improving the understanding of the model, reducing duplication of effort, and facilitating the adaptation of the model for different sites and ecosystems. Chen, K., G.Q. Ha, N. Keutgen, M.J.J. Janssens, and F. Lenz. 1999. Effects of NaCl salinity and CO₂ enrichment on pepino (*Solanum muricatum* Ait.) - I. Growth and yield. *Scientia Horticulturae* 81(1):25-41.

One-month old, rooted, semi-hardwood cutting plants of pepino cv. Xotus in sand-potted culture were treated with 200 ml Hoagland nutrient solution with or without additional 25 mM NaCl twice a week for 2 months, and exposed to 350 +/- 10, 700 +/- 10 or 1050 +/- 10 ppm CO₂ in controlled environment chambers during the last month of the experiment. NaCl salinity in the rhizosphere reduced growth of all the organs, but raised stem dry weight ratio and root dry weight ratio. In contrast, atmospheric CO₂ enrichment increased plant and fruit growth. Leaf dry weight ratio and fruit dry weight ratio rose, but stem dry weight ratio and root dry weight ratio decreased at high CO₂ levels. Daily expansion rate of leaf area, growth rate of side-shoot length, rate of plant dry mass production, and increased rate of fresh fruit weight decreased

due to NaCl stress, but increased with CO₂ enrichment. Side-shoot diameter rose, whereas specific leaf area, leaf area ratio, and side-shoot dry weight ratio declined under both NaCl-stressed and CO₂-enriched conditions. In comparison with the 350 ppm CO₂ treatment without NaCl salinity in the rhizosphere, net assimilation rate and relative growth rate of plants were reduced by 8-13% and 16-32% due to NaCl salinity, and enhanced by 22-23% and 42-64% at 700 ppm CO₂, and by 36-44% and 64-101% at 1050 ppm CO₂, respectively. The simultaneous treatments of NaCl salinity and high CO₂ resulted in indefinite effects on vegetative and reproductive growth as well as on dry mass production of different plant organs. Nevertheless, the negative impacts of NaCl stress on plant growth and fruit yield diminished at high CO₂ levels. Atmospheric CO₂ enrichment increased the tolerance of pepino to NaCl salinity in the root medium. (C) 1999 Elsevier Science B.V. All rights reserved.

Chen, K., G.Q. Hu, N. Keutgen, M. Blanke, and F. Lenz. 1997. Effects of CO₂ concentration on strawberry. II. Leaf photosynthetic function. *Journal of Applied Botany-Angewandte Botanik* 71(5-6):173-178.

Two-week-old strawberry (*Fragaria x ananassa* Duch, cv. 'Elsanta') plants were acclimatized to 300, 450, 600, 750 or 900 ppm CO₂ in controlled environment chambers for 50 days. An elevated CO₂ concentration up to 750 ppm reduced total chlorophyll, chlorophyll a and chlorophyll b contents as well as the a/b ratio. Long-term CO₂ enrichment induced leaf senescence and decreased photosynthetic efficiency as well as photochemical conversion efficiency of PS II. Intercellular CO₂ concentration significantly increased with CO₂ enrichment. Stomatal conductance, transpiration rate, and net photosynthesis rate of young leaves increased with raising CO₂ concentrations. However, CO₂ levels above 600 ppm markedly reduced net photosynthetic rate of adult and old leaves. High CO₂ concentrations up to 900 ppm did not significantly affect dark respiration rate of the leaves. Photosynthetic water-use efficiency was highest in old leaves and lowest in young ones. Increased CO₂ concentrations up to 600-750 ppm improved leaf photosynthetic capacity by increasing photosynthetic water-use efficiency.

Chen, K., G.Q. Hu, N. Keutgen, M.J.J. Janssens, and F. Lenz. 1999. Effects of NaCl salinity and CO₂ enrichment on pepino (*Solanum muricatum* Ait.) - II. Leaf photosynthetic properties and gas exchange. *Scientia Horticulturae* 81(1):43-56.

One-month old, rooted semi-hardwood cutting plants of pepino cv. Xotus in sand-potted culture were treated with 200 ml Hoagland nutrient solution with or without additional 25 mM NaCl twice a week for 2 months, and exposed to 350 +/- 10, 700 +/- 10 or 1050 +/- 10 ppm CO₂ in controlled environment chambers during the last month of the experiment. Both NaCl salinity in the rhizosphere and atmospheric CO₂ enrichment reduced the leaf content of total chlorophyll, chlorophyll a and chlorophyll b, as well as stomatal conductance and transpiration rate, but raised intercellular CO₂ concentration and C₂H₄ emission of leaves. Minimal fluorescence yield, maximal fluorescence yield, variable fluorescence yield of dark-adapted leaves, optimal quantum yield and effective quantum yield of PS II, photochemical quenching coefficient, net photosynthetic rate, leaf water-potential, and photosynthetic water-

use efficiency decreased under NaCl stress, but rose with an increase of the atmospheric CO₂ concentration. In addition, the non-photochemical quenching coefficient and the dark respiration rate of leaves increased due to NaCl salinity and decreased at high CO₂ conditions. On average, net photosynthetic rate and photosynthetic water-use efficiency of leaves decreased by 26-35% and 19-29% due to the presence of NaCl stress in the root medium, but increased by 75-98% and 85-123% at 700 ppm CO₂, and by 72-91% and 124-147% at 1050 ppm CO₂ in comparison with 350 ppm CO₂ treatments. Under NaCl stress, high CO₂ improved photosynthetic water-use efficiency of leaves. (C) 1999 Elsevier Science B.V. All rights reserved.

Chen, K., G.Q. Hu, N. Keutgen, and F. Lenz. 1997. Effects of CO₂ concentration on strawberry. I. Plant Growth analysis. *Journal of Applied Botany-Angewandte Botanik* 71(5-6):168-172.

Two-week-old strawberry (*Fragaria x ananassa* Duch. cv. 'Elsanta') plants were acclimatized to 300, 450, 600, 750 or 900 ppm CO₂ in controlled environment chambers for 50 days. Elevated CO₂ promoted plant growth as indicated by a higher number of leaves, runners and daughter plants, larger leaf area index and dry mass per unit leaf area, increased total length of runners, plant height, canopy diameter, and enhanced daily growth of leaf area, runner and plant biomass. In contrast, specific leaf area and leaf area ratio of the plants decreased with increasing CO₂ concentration, whereas neither average leaf area nor average runner length was significantly affected by CO₂ enrichment. When compared with the 300 ppm CO₂ treatment, 600 and 900 ppm CO₂-treated plants led to a daily increment of 1.6 and 1.9 total leaf area, 1.1 and 1.8 total runner length, and 2.5 and 3.9 plant biomass, respectively. Increased CO₂ concentration from 300 to 600 and 750 ppm markedly accelerated both relative growth rate and net assimilation rate of the plants. Leaf weight ratio and root weight ratio were significantly higher, while stem weight ratio was significantly lower above 600 ppm CO₂ as a result of proportionally more biomass allocated to leaves and roots than to stems. Apart from an enhancement of plant growth, the long-term CO₂ enrichment boosted vegetative propagation of strawberry plants as well. From an economical point of view, however, it is more efficient to use elevated CO₂ concentrations of up to 600-750 ppm rather than 900 ppm for greenhouse cultivation of strawberry.

Chen, K., G.Q. Hu, N. Keutgen, and F. Lenz. 1997. Effects of CO₂ concentration on strawberry. III. Dry matter production and water consumption. *Journal of Applied Botany-Angewandte Botanik* 71(5-6):179-182.

Two-week-old strawberry (*Fragaria x ananassa* Duch. cv. 'Elsanta') plants were acclimatized to 300, 450, 600, 750 or 900 ppm CO₂ in controlled environment chambers for 50 days. Elevated CO₂ concentrations enhanced dry matter production, the root/shoot ratio and total water consumption of the plants. High CO₂ promoted total dry matter increment and total leaf area increment of the plants, and improved dry matter- production efficiency and plant water-use efficiency. Water- consumption rate of plants and water-uptake efficiency of roots, however, declined at CO₂-enriched conditions. In comparison with the 300 ppm CO₂ treatment, 600 and 900 ppm CO₂-grown plants increased dry matter-production efficiency by 37 % and 67 %, water-use efficiency by 137 % and 272 %, while reduced water-consumption rate by 39 % and 55 %, and water- uptake efficiency of roots by 53 % and 76 %, respectively. Increasing CO₂ concentrations

from 300 to 900 ppm enabled strawberry plants to produce dry matter more efficiently and to use soil water more economically because it reduced the impact of water stress on plant productivity.

Chen, K., G.Q. Hu, and F. Lenz. 1997. Effects of CO₂ concentration on strawberry. IV. Carbohydrate production and accumulation. *Journal of Applied Botany-Angewandte Botanik* 71(5-6):183-188.

Two-week-old strawberry (*Fragaria x ananassa* Duch. cv. 'Elsanta') plants were acclimatized to 300, 450, 600, 750 or 900 ppm CO₂ in controlled environment chambers for 50 days. Increasing CO₂ concentration from 300 to 900 ppm promoted carbohydrate production of the plants, and subsequently increased carbohydrate accumulation in the plant organs, especially starch in leaves. Relative distribution of non-structural carbohydrates decreased in leaves and stems at 750 and 900 ppm CO₂, increased in roots from 300 to 750 ppm CO₂. Elevating CO₂ concentration from 300 to 750 ppm reduced the proportions of glucose, fructose, and sucrose, but raised the proportion of starch in non-structural carbohydrates of the plants, as well as increased starch/sucrose ratio in leaves, stems, and whole plants. CO₂ enrichment up to 900 ppm improved carbohydrate-production efficiency of the plants. This effect was particularly pronounced for starch. In comparison with 300 ppm CO₂-grown plants, those treated by 600 and 900 ppm CO₂ raised starch-, glucose-, fructose-, sucrose-, and non- structural carbohydrate-production efficiency by 2.6 and 16.1 fold, 1.6 and 2.1 fold, 0.6 and 1.0 fold, 0.8 and 1.6 fold, and 1.2 and 3.5 fold, respectively.

Chen, K., G.Q. Hu, and F. Lenz. 1997. Effects of CO₂ concentration on strawberry. V. Macronutrient uptake and utilization. *Journal of Applied Botany-Angewandte Botanik* 71(5-6):189-194.

Two-week-old strawberry (*Fragaria x ananassa* Duch. cv. 'Elsanta') plants were acclimatized to 300, 450, 600, 750 or 900 ppm CO₂ in controlled environment chambers for 50 days. Raising CO₂ concentration from 300 to 900 ppm promoted macronutrient accumulation in all organs of the plants, particularly in roots. It, however, reduced contents of macronutrients in most organs of the plants, especially in leaves, because of the dilution effect of larger amounts of carbohydrate accumulation in the plant organs. When compared with the 300 ppm CO₂ treatment, 600 and 900 ppm CO₂ increased accumulation of N by 93 % and 87 %, P by 113 % and 122 %, K by 98 % and 92 %, Ca by 212 % and 244 %, and Mg by 177 % and 200 %, respectively. CO₂ enrichment decreased the proportions of N and K, increased those of Ca and Mg, but did not affect the proportion of P in the plants. Increasing CO₂ levels depressed macronutrient-uptake efficiency of the plant roots, but promoted macronutrient-use efficiency of the plants. In comparison with the 300 ppm CO₂-treated plants, those treated with 600 and 900 ppm CO₂ showed lower N-, P-, K-, Ca-, and Mg- uptake efficiency of the roots and higher N-, P-, K-, Ca-, and Mg-use efficiency of the plants.

Chen, K., G.Q. Hu, and F. Lenz. 1997. Effects of CO₂ concentration on strawberry. VI. Fruit yield and quality. *Journal of Applied Botany-*

Two-week-old strawberry (*Fragaria x ananassa* Duch. cv. 'Elsanta') plants were acclimatized to 300, 450, 600, 750 or 900 ppm CO₂ in controlled environment chambers for 50 and 60 days during vegetative growth in late autumn of 1995 and reproductive growth in early spring of 1996. High CO₂ promoted branch-crown and pedicel development as well as flower-bud differentiation. It also induced a second bloom. Flowering and fruit ripening started earlier and lasted for a longer period under high rather than low CO₂ concentrations. CO₂ enrichment shortened the periods of anthesis and single fruit growth but prolonged the periods of flowering and fruit harvest. Elevated CO₂ concentrations enhanced fruit productivity as indicated by increases in pedicel number per plant, fruit setting per pedicel, fruit size, and dry matter content of the fruits. In comparison with the 300 ppm CO₂ treatment, 450, 600, 750, and 900 ppm CO₂ increased average fruit yield per plant by 0.7, 2.7, 3.6, and 4.1 fold, daily growth per fresh fruit by 0.4, 1.0, 1.1, and 1.3 fold, and growth rate of fruit biomass per plant by 1.0, 3.9, 5.5, and 6.9 fold, respectively. High CO₂ tended to improve fruit quality as well. Raising CO₂ concentrations accelerated dry matter increment and total sugar accumulation in the fruits, especially for sucrose, and decreased titratable acid content, resulting in a higher sugar/acid ratio of the fruits. Contents of starch and minerals in the fruits slightly decreased when CO₂ rose.

Chen, K., and F. Lenz. 1997. Responses of strawberry to doubled CO₂ concentration and phosphorus deficiency .1. Distribution of dry matter, macronutrients, and carbohydrates. *Gartenbauwissenschaft* 62(1):30-37.

One-year-old strawberry (*Fragaria x ananassa* Duch. cv. 'Elsanta') plants grown in controlled environmental chambers were supplied with a modified P-sufficient (0.5 mmol P l⁻¹) or P-deficient (0.05 mmol P l⁻¹) Hoagland nutrient solution and acclimatized by an ambient CO₂ (340 +/- 20 ppm) or doubled CO₂ (680 +/- 20 ppm) concentration for one month. Doubled CO₂ concentration promoted plant vegetative growth and dry matter assimilation, especially in leaf area enlargement, leaf dry weight, and runner extending growth. The plant responses to doubled CO₂ concentration were more pronounced under P- sufficient than P-deficient conditions. P deficiency not only moderated the above plant responses to CO₂ enrichment, but also accelerated premature leaf senescence and aggravated P- deficient symptoms at doubled CO₂ concentration. The mean increment in total dry matter of the plants in virtue of doubled CO₂ concentration and P-sufficiency were 25-63 % and 123-191 %, respectively. Doubled CO₂ concentration reduced N level in the plant organs, particularly in both new and old leaves and runners, while increased the contents of starch, glucose, fructose, sucrose, and total non-structural carbohydrates in most organs; but not particularly affected contents of P, K, Ca, and Mg. P deficiency decreased contents of N, P, K, Mg, and soluble carbohydrates, while increased root : shoot ratio and starch level in roots, stems, runners, and leaves whether at the ambient CO₂ or at doubled CO₂ condition. Neither doubled CO₂ nor P deficiency definitely altered Ca content in the plant organs.

Chen, S.G., I. Impens, and R. Ceulemans. 1997. Modelling the effects of elevated atmospheric CO₂ on crown development, light interception and photosynthesis of poplar in open top chambers. *Global Change Biology* 3(2):97-106.

An open-top chamber experiment was carried out to examine the likely effects of elevated atmospheric [CO₂] on architectural as well as on physiological characteristics of two poplar clones (*Populus trichocarpa* x *P. deltoides* clone Beaupre and *P. deltoides* x *P. nigra* clone Robusta). Crown architectural parameters required as input parameters for a three-dimensional (3D) model of poplar structure, such as branching frequency and position, branch angle, internode length and its distribution pattern, leaf size and orientation, were measured following growth in ambient and elevated [CO₂] (ambient + 350 μ mol mol⁻¹) treated open-top chambers. Based on this information, the light interception and photosynthesis of poplar canopies in different [CO₂] treatments were simulated using the 3D poplar tree model and a 3D radiative transfer model at various stages of the growing season. The first year experiments and modelling results showed that the [CO₂] enrichment had effects on light intercepting canopy structure as well as on leaf photosynthesis properties. The elevated [CO₂] treatment resulted in an increase of leaf area, canopy photosynthetic rate and above- ground biomass production of the two poplar clones studied. However, the structural components responded less than the process components to the [CO₂] enrichment. Among the structural components, the increase of LAI contributed the most to the canopy light interception and canopy photosynthesis; the change of other structural aspects as a whole caused by the [CO₂] enrichment had little effect on daily canopy light interception and photosynthesis.

Chen, X.M., G.B. Begonia, D.M. Alm, and J.D. Hesketh. 1993. Responses of soybean leaf photosynthesis to co₂ and drought. *Photosynthetica* 29(3):447-454.

Soybean [*Glycine max* (L.) Merr. cv. Jack] was grown in the field in rain-protected plots to study effects of drought and atmospheric CO₂ enrichment. on leaf gas exchange. Midday depressions in leaf photosynthetic CO₂ exchange rates (P(N)) were found in drought-stressed plants and the diurnal changes were mostly stomatal-regulated, although accumulated drought stress eventually resulted in some non-stomatal limitations. However, seasonal changes in P(N) were mostly limited by non- stomatal factors. Water use efficiency was always higher for drought stressed plants and depended on the severity of stress and associated stomatal or nonstomatal limitations. At enriched atmospheric CO₂ levels, stomatal limitations to P(N) under drought stress were less important than at ambient atmospheric CO₂ levels. Morning and afternoon leaf starch levels were enhanced in both irrigated and nonirrigated plants in enriched CO₂. Afternoon starch levels were higher in stressed leaves than in non-stressed leaves at normal CO₂ levels.

Chen, X.M., G.B. Begonia, and J.D. Hesketh. 1995. Soybean stomatal acclimation to long-term exposure to co₂- enriched atmospheres. *Photosynthetica* 31(1):51-57.

Soybean [*Glycine max* (L.) cv. Jack] grown in open top chambers under controlled laboratory and field conditions was used to study the

acclimation of leaf gas exchange processes to CO₂ enrichment. Air inside the open top chambers was maintained at either 700-800 or 350-400 $\mu\text{mol}(\text{CO}_2)/\text{mol}(-1)(\text{air})$. Leaf gas exchange rates were measured for some plants switched between treatments. When measured in the CO₂-enriched atmosphere, stomatal conductances (g(s)) were higher in leaves grown in CO₂-enriched atmospheres than in those grown under ambient conditions, and the lower g(s) values for plants in the CO₂-enriched atmospheres were limiting to leaf net photosynthetic CO₂ exchange rates (P-N). P-N of enriched leaves was higher than those of the ambient controls when measured at elevated CO₂ levels in both controlled environment and field studies, while it was depressed in enriched leaves when measured under ambient CO₂ conditions, and this drop in P-N did not recover until 6-15 d after plants were placed back in ambient conditions.

Chenevard, D., C. Jayallemand, M. Gendraud, and J.S. Frossard. 1995. The effect of sucrose on the development of hybrid walnut microcuttings (*Juglans-nigra* X *Juglans-regia*) - consequences on their survival during acclimatization. *Annales Des Sciences Forestieres* 52(2):147-156.

We studied the effect of sucrose concentration in the root- development medium on the formation of adventitious roots and survival of microcuttings during acclimatization in 2 interspecific hybrid walnut (*Juglans nigra* n degrees 23 x *J regia*) clones. Sucrose increased the rooting percentage (fig 1), the number of adventitious roots (fig 2A) and the dry- matter content (table I) per rooted shoot. These effects were due to the energy properties of sucrose rather than to its osmotic function. High sucrose concentrations in the root- development medium (> 20 g.l(-1)) resulted in a high soluble carbohydrate content in the plantlets (fig 3), mainly located in roots and callus. The 2-clones showed different capacities in rooting and growth. Survival of microcuttings during acclimatization was not directly influenced by the sucrose concentration (fig 5) but was correlated with the number of adventitious roots (fig 6A) as well as with the number of leaves (fig 6B) present at the time of transfer to the growth chamber for each individual plant.

Cheng, S.H., B.D. Moore, and J.R. Seemann. 1998. Effects of short- and long-term elevated CO₂ on the expression of ribulose-1,5-bisphosphate carboxylase/oxygenase genes and carbohydrate accumulation in leaves of *Arabidopsis thaliana* (L) Heynh. *Plant Physiology* 116(2):715-723.

To investigate the proposed molecular characteristics of sugar- mediated repression of photosynthetic genes during plant acclimation to elevated CO₂, we examined the relationship between the accumulation and metabolism of nonstructural carbohydrates and changes in ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) gene expression in leaves of *Arabidopsis thaliana* exposed to elevated CO₂. Long-term growth of *Arabidopsis* at high CO₂ (1000 $\mu\text{mol L}^{-1}$) resulted in a 2-fold increase in nonstructural carbohydrates, a large decrease in the expression of Rubisco protein and in the transcript of *rbcL*, the gene encoding the large subunit of Rubisco (approximately 35-40%), and an even greater decline in mRNA of *rbcS*, the gene encoding the small subunit (approximately 60%). This differential response of protein and mRNAs suggests that transcriptional/posttranscriptional processes and protein turnover may determine the final amount of leaf Rubisco protein at high

CO₂. Analysis of mRNA levels of individual *rbcS* genes indicated that reduction in total *rbcS* transcripts was caused by decreased expression of all four *rbcS* genes. Short-term transfer of *Arabidopsis* plants grown at ambient CO₂ to high CO₂ resulted in a decrease in total *rbcS* mRNA by d 6, whereas Rubisco content and *rbcL* mRNA decreased by d 9. Transfer to high CO₂ reduced the maximum expression level of the primary *rbcS* genes (1A and, particularly, 3B) by limiting their normal pattern of accumulation through the night period. The decreased nighttime levels of *rbcS* mRNA were associated with a nocturnal increase in leaf hexoses. We suggest that prolonged nighttime hexose metabolism resulting from exposure to elevated CO₂ affects *rbcS* transcript accumulation and, ultimately, the level of Rubisco protein.

Cheng, W.X. 1999. Rhizosphere feedbacks in elevated CO₂. *Tree Physiology* 19(4-5):313-320.

Understanding rhizosphere processes in relation to increasing atmospheric CO₂ concentrations is important for predicting the response of forest ecosystems to environmental changes, because rhizosphere processes are intimately linked with nutrient cycling and soil organic matter decomposition, both of which feedback to tree growth and soil carbon storage. Plants grown in elevated CO₂ substantially increase C input to the rhizosphere. Although it is known that elevated CO₂ enhances rhizosphere respiration more than it enhances root biomass, the fate and function of this extra carbon input to the rhizosphere in response to elevated CO₂ are not clear. Depending on specific plant and soil conditions, the increased carbon input to the rhizosphere can result in an increase, a decrease, or no effect on soil organic matter decomposition and nutrient mineralization. Three mechanisms may account for these inconsistent results: (1) the "preferential substrate utilization" hypothesis; (2) the "priming effect" hypothesis; and (3) the "competition" hypothesis, i.e., competition for mineral nutrients between plants and soil microorganisms. A microbial growth model is developed that quantitatively links the increased rhizosphere input in response to elevated CO₂ with soil organic matter decomposition. The model incorporates the three proposed mechanisms, and simulates the complexity of the rhizosphere processes. The model also illustrates mechanistically the interactions among nitrogen availability, substrate quality, and microbial dynamics when the system is exposed to elevated CO₂.

Cheng, W.X., and D.W. Johnson. 1998. Elevated CO₂, rhizosphere processes, and soil organic matter decomposition. *Plant and Soil* 202(2):167-174.

The rhizosphere is one of the key fine-scale components of C cycles. This study was undertaken to improve understanding of the potential effects of atmospheric CO₂ increase on rhizosphere processes. Using C isotope techniques, we found that elevated atmospheric CO₂ significantly increased wheat plant growth, dry mass accumulation, rhizosphere respiration, and soluble C concentrations in the rhizosphere. When plants were grown under elevated CO₂ concentration, soluble C concentration in the rhizosphere increased by approximately 60%. The degree of elevated CO₂ enhancement on rhizosphere respiration was

much higher than on root biomass. Averaged between the two nitrogen treatments and compared with the ambient CO₂ treatment, wheat rhizosphere respiration rate increased 60% and root biomass only increased 26% under the elevated CO₂ treatment. These results indicated that elevated atmospheric CO₂ in a wheat-soil system significantly increased substrate input to the rhizosphere due to both increased root growth and increased root activities per unit of roots. Nitrogen treatments changed the effect of elevated CO₂ on soil organic matter decomposition. Elevated CO₂ increased soil organic matter decomposition (22%) in the nitrogen-added treatment but decreased soil organic matter decomposition (18%) without nitrogen addition. Soil nitrogen status was therefore found to be important in determining the directions of the effect of elevated CO₂ on soil organic matter decomposition.

Chomba, B.M., R.D. Guy, and H.G. Weger. 1993. Carbohydrate reserve accumulation and depletion in engelmann spruce (*Picea engelmannii* parry) - effects of cold-storage and prestorage CO₂ enrichment. *Tree Physiology* 13(4):351-364.

The effects of pre-storage CO₂ enrichment on growth, non- structural carbohydrates and post-storage root growth potential of Engelmann spruce (*Picea engelmannii* Parry) seedlings were studied. Seedlings were grown from seed for 202 days in growth chambers with ambient (340 μ mol l⁻¹) or CO₂-enriched (1000 μ mol l⁻¹) air. Some seedlings were transferred between CO₂ treatments at 60 and 120 days. Photoperiod was reduced at 100 days to induce bud set and temperature was reduced at 180 days to promote frost hardiness development for storage at -5 degrees C for 2 or 4 months. Stored seedlings were planted in a growth chamber after thawing for one week at +5 degrees C. At 80, 120, 140 and 202 days, and at each planting time after storage, seedlings were harvested for growth measurements and analysis of starch and soluble sugar concentrations. Planted seedlings were assessed for bud break every two days and new roots > 5 mm long were counted after four weeks. Carbon dioxide enrichment increased root collar diameter and

almost doubled seedling biomass, with the most obvious effects occurring after bud set. Stem height was affected only slightly and shoot/root ratios were not affected at all. Carbon dioxide enrichment increased the rate of reserve carbohydrate accumulation, but did not influence the final concentration attained before storage (accounting for 32% of seedling dry weight). Needles were the major storage organ for soluble sugars, whereas roots were the major storage organ for starch. Soluble sugars were not strongly affected by two or four months of storage, but starch was reduced by more than 50% in all plant parts. None of the CO₂ treatments had an impact on bud break or root growth potential.

Christ, R.A., and C. Korner. 1995. Responses of shoot and root gas-exchange, leaf blade expansion and biomass production to pulses of elevated CO₂ in hydroponic wheat. *Journal of Experimental Botany* 46(292):1661-1667.

Short-term effects of elevated CO₂ during the early life phase of plants may have long lasting consequences for growth and biomass in later periods. We exposed hydroponically grown wheat seedlings to 5 d pulses of elevated CO₂ while leaf expansion growth as well as shoot and root gas exchange were measured simultaneously and continuously. Shoot photosynthesis, night- time shoot respiration and below-ground respiration (largely by roots) roughly doubled when atmospheric CO₂ concentration was doubled. An interruption of CO₂ enrichment caused CO₂ assimilation and respiration to return to control levels. However, while the response of photosynthesis was immediate, that of respiration showed a hysteresis of about 3 d. Since shoot biomass increased at elevated CO₂ (with no change in allocation pattern) equal fluxes per shoot or root system after a return to control CO₂ concentrations indicate substantial downward adjustment of the capacity for CO₂ fixation and release in high-CO₂ grown plants. Leaf expansion growth was completely unaffected by CO₂ enrichment, whereas tiller initiation was significantly increased (doubled in 18 d). We conclude that leaf growth in these wheat plants was already carbon-saturated at ambient CO₂ concentration at optimum mineral nutrient supply. The stimulation of growth of whole plants was exclusively due to enhanced tillering during this very early part of the life of these wheat plants.

Christensen, T.R., S. Jonasson, T.V. Callaghan, and M. Havstrom. 1999. On the potential CO₂ release from tundra soils in a changing climate. *Applied Soil Ecology* 11(2-3):127-134.

About 30% of the carbon in terrestrial ecosystems is stored in northern wetlands and boreal forest regions. Prevailing cold and wet soil conditions have largely been responsible for this carbon accumulation. It has been suggested that a warmer and drier climate in these regions might increase the decomposition rate and, hence, release more CO₂ to the atmosphere than at present. This study reports on the spatial variability and temperature dependence of the potential carbon release after incubating highly organic soils from the European Arctic and Siberia at different temperatures. We found that the decay potential, measured as CO₂ production in laboratory experiments, differed strongly within and among sites, particularly at higher soil temperatures. Furthermore, both the decay potential and its temperature response decreased significantly with depth in the soil, presumably because the older soils at deeper layers contained higher proportions of recalcitrant carbon than the younger soil organic matter at the surface. These results have implications for global models of potential feedbacks on climate

change inferred from changes in the carbon balance of northern wetlands and tundra. Firstly, because the decay potential of the organic matter varies locally as well as regionally, predictions of how the tundra carbon balance may change will be unreliable if these are based on measurements at a few sites only. Secondly, any increase in CO₂ production may be transitional as both the carbon flux and its temperature sensitivity decrease when the most easily degradable organic material near the soil surface has decomposed. Consequently, it is crucial to account for transient responses and regional differences in the models of potential feedbacks on climate change from changed carbon cycling in northern terrestrial ecosystems. Christensen, T.R., S. Jonasson, T.V. Callaghan, M. Havstrom, and F.R. Livens. 1999. Carbon cycling and methane exchange in Eurasian tundra ecosystems. *Ambio* 28(3):239-244.

This paper provides an overview of data and results obtained through a number of studies of actual and potential trace gas exchanges in northern Eurasia, made possible through the Swedish-Russian Tundra Ecology - 94 expedition. It was found that: i) long-term accumulation rates of carbon in organic tundra soils, i.e. net uptake of atmospheric CO₂, correlated with simple climatic parameters, such as mean July temperature and annual precipitation; ii) the release of carbon through ecosystem respiration is also strongly controlled by climate. Increased temperature and decrease of water-logging enhanced the CO₂ flux. However, the release of organic soil carbon as CO₂ is also constrained by other factors such as poor decomposability of the stored organic compounds; and iii) methane emissions from typical tundra habitats in northern Eurasia were found to be slightly lower than from seemingly similar habitats in North America. This difference can probably be attributed to lower temperatures along the Russian arctic coast than at North American sites in general.

Chu, C.C., J.S. Coleman, and H.A. Mooney. 1992. Controls of biomass partitioning between roots and shoots - atmospheric CO₂ enrichment and the acquisition and allocation of carbon and nitrogen in wild radish. *Oecologia* 89(4):580-587.

The effects of CO₂ enrichment on plant growth, carbon and nitrogen acquisition and resource allocation were investigated in order to examine several hypotheses about the mechanisms that govern dry matter partitioning between shoots and roots. Wild radish plants (*Raphanus sativus* x *raphanistrum*) were grown for 25 d under three different atmospheric CO₂ concentrations (200 ppm, 330 ppm and 600 ppm) with a stable hydroponic 150- μ mol l⁻¹ nitrate supply. Radish biomass accumulation, photosynthetic rate, water use efficiency, nitrogen per unit leaf area, and starch and soluble sugar levels in leaves increased with increasing atmospheric CO₂ concentration, whereas specific leaf area and nitrogen concentration of leaves significantly decreased. Despite substantial changes in radish growth, resource acquisition and resource partitioning, the rate at which leaves accumulated starch over the course of the light period and the partitioning of biomass between roots and shoots were not affected by CO₂ treatment. This phenomenon was consistent with the hypothesis that root/shoot partitioning is related to the daily rate of starch accumulation by leaves during the photoperiod, but is inconsistent with hypotheses suggesting that root/shoot partitioning is controlled by some aspect of plant C/N balance.

Chu, C.C., C.B. Field, and H.A. Mooney. 1996. Effects of CO₂ and nutrient enrichment on tissue quality of two California annuals. *Oecologia* 107(4):433-440.

The effects of CO₂ enrichment and soil nutrient status on tissue quality were investigated and related to the potential effect on growth and decomposition. Two California annuals, *Avena fatua* and *Plantago erecta*, were grown at ambient and ambient plus 35 Pa atmospheric CO₂ in nutrient unamended and amended serpentine soil. Elevated CO₂ led to significantly increased *Avena* shoot nitrogen concentrations in the nutrient amended treatment. It also led to decreased lignin concentrations in *Avena* roots in both nutrient treatments, and in *Plantago* shoots and roots with nutrient addition. Concentrations of total nonstructural carbohydrate (TNC) and carbon did not change with elevated CO₂ in either species. As a consequence of increased biomass accumulation, increased CO₂ led to larger total pools of TNC, lignin, total carbon, and total nitrogen in *Avena* with nutrient additions. Doubling CO₂ had no significant effect on *Plantago*. Given the limited changes in the compounds related to decomposability and plant growth, effects of increased atmospheric CO₂ mediated through tissue composition on *Avena* and *Plantago* are likely to be minor and depend on site fertility. This study suggests that other factors such as litter moisture, whether or not litter is on the ground, and biomass allocation among roots and shoots, are likely to be more important in this California grassland ecosystem. CO₂ could influence those directly as well as indirectly.

Ciais, P., P. Friedlingstein, D.S. Schimel, and P.P. Tans. 1999. A global calculation of the delta C-13 of soil respired carbon: Implications for the biospheric uptake of anthropogenic CO₂. *Global Biogeochemical Cycles* 13(2):519-530.

The continuing emissions of fossil CO₂ depleted in C-13 have been causing a gradual decrease in atmospheric delta(13)C by roughly 1.4 parts per thousand since preindustrial times. The progressive penetration of this perturbation into the land biota causes the soil organic matter to be enriched in 13C with respect to recently formed plant material. This effect which we call the "biotic isotope disequilibrium" is important when it comes to deducing the terrestrial carbon fluxes by using delta(13)C in atmospheric CO₂. We have estimated the geographical distribution of the isotopic disequilibrium, which is primarily influenced by the turnover of carbon in the various ecosystems, from the output of two biospheric models, (SLAVE and CENTURY). The disequilibrium is estimated to shift up the delta(13)C of atmospheric CO₂ by the same amount as a net sink of 0.6 Gt C yr⁻¹ in the land biota. This "fake" terrestrial sink due to the isotopic disequilibrium is distributed mainly in northern midlatitudes (0.2 Gt C yr⁻¹) and tropical forests (0.3 Gt C yr⁻¹).

Cipollini, M.L., B.G. Drake, and D. Whigham. 1993. Effects of

elevated CO₂ on growth and carbon/nutrient balance in the deciduous woody shrub *Lindera benzoin* (L.) Blume (Lauraceae). *Oecologia* 96(3):339-346.

We examined the effects of elevated CO₂ on growth and carbon/nutrient balance in a natural population of the deciduous temperate zone shrub *Lindera benzoin*. Our data concern whole plant, leaf, and stem growth for the first two seasons of a long-term field experiment in which CO₂ levels were manipulated in situ. In addition to growth parameters, we evaluated changes in leaf and stem chemistry, including total nitrogen, nonstructural carbohydrates, and total phenolics. Over the course of this study, *L. benzoin* appeared to respond to elevated CO₂ primarily by physiological and biochemical changes, with only a slight enhancement in aboveground growth (ramet height). Positive effects on aboveground growth were primarily evident in young (nonreproductive) ramets. Our results suggest that nitrogen limitation may have constrained plants to allocate carbohydrates produced in response to elevated CO₂ primarily to storage and belowground growth, and perhaps to increased secondary chemical production, rather than to increased stem and leaf growth. We discuss our results in terms of changes in carbon/nutrient balance induced by elevated CO₂, and provide predictions for future changes in this system based upon constraints imposed by intrinsic and extrinsic factors and their potential effects on the reallocation of stored reserves.

Clark, D.G., J.W. Kelly, and N.C. Rajapakse. 1993. Production and postharvest characteristics of *rosa-hybrida* L. 'Meijikatar' grown in pots under carbon-dioxide enrichment. *Journal of the American Society for Horticultural Science* 118(5):613-617.

The effects of carbon dioxide enrichment on growth, photosynthesis, and postharvest characteristics of 'Meijikatar' potted roses were determined. Plants were grown in 350, 700, or 1050 µmol CO₂/liter until they reached 50% flower bud coloration and then were placed into dark storage for 5 days at 4 or 16°C. Plants grown in 700 or 1050 µmol CO₂/liter reached the harvest stage earlier and were taller at harvest than plants produced in 350 µmol CO₂/liter, but there were no differences in the number of flowers and flower buds per plant among CO₂ treatments. Plants grown in early spring were taller and had more flowers and flower buds than plants grown in late winter. Shoot and root growth of plants grown in 700 or 1050 µmol CO₂/liter were higher than in plants produced in 350 µmol CO₂/liter, with plants grown in early spring showing greater increases than plants grown in late winter. Immediately after storage, plants grown in 350 µmol CO₂/liter and stored at 4°C had the fewest etiolated shoots, while plants grown in 1050 µmol CO₂/liter and stored at 16°C had the most. Five days after removal from storage, chlorophyll concentration of upper and lower leaves had been reduced by almost-equal-to 50% from the day of harvest. Carbon dioxide enrichment had no effect on postharvest leaf chlorosis, but plants grown in early spring and stored at 16°C had the most leaf chlorosis while plants grown in late winter and stored at 4°C had the least leaf chlorosis.

Clark, H., P.C.D. Newton, and D.J. Barker. 1999. Physiological and morphological responses to elevated CO₂ and a soil moisture deficit of temperate pasture species growing in an established plant community. *Journal of Experimental Botany* 50(331):233-242.

Periods of limited soil water availability are a feature of many temperate pasture systems and these have the potential to modify pasture plant and community responses to elevated atmospheric CO₂. Using large pasture turves, previously exposed to elevated CO₂ concentrations of 350 or 700 µmol mol⁻¹ for 324 d under well-watered conditions, the morphological and physiological responses of pasture species growing at these CO₂ concentrations were compared when subjected to a soil moisture deficit and to recovery from the deficit with those that continued to be well watered. Net leaf photosynthesis of *Trifolium repens* (C-3 legume), *Plantago lanceolata* (C-3) and *Paspalum dilatatum* (C-4) was increased by exposure to elevated CO₂, but there was no consistent effect of CO₂ on stomatal conductance. At low soil moistures, net photosynthesis declined and stomatal conductance increased in these three species. There was a strong CO₂ x water interaction in respect of net photosynthesis; in *Trifolium repens*, for example, elevated CO₂ increased net photosynthesis by approximately 50% under well-watered conditions and this increased to over 300% when soil moisture levels reached their minimum values. Similar values were recorded for both *Paspalum dilatatum* and *Plantago lanceolata*. Potential water use efficiency (net photosynthesis/stomatal conductance) was increased by both exposure to elevated CO₂ and drought. Leaf water status was measured in three species: *Trifolium repens*, *Paspalum dilatatum* and *Holcus lanatus* (C-3). Total leaf water potential (psi(t)) and osmotic potential (psi(pi)) were decreased by drought, but CO₂ concentration had no consistent effect. psi(t) and psi(pi) were highest in the C-4 species *Paspalum dilatatum* and lowest in the legume *Trifolium repens*. In the wet turves, rates of leaf extension of the C-3 grasses *Holcus lanatus* and *Lolium perenne* at elevated CO₂ were frequently higher than those at ambient CO₂, but there was no effect of CO₂ concentration on the rate recorded in the C-4 grass *Paspalum dilatatum* or the rate of leaf appearance in the legume *Trifolium repens*. Drought reduced leaf extension rate irrespective of CO₂ in all species, but in *Holcus lanatus* the reduction was less severe at elevated CO₂. Immediately after the dry turves were rewatered the leaf extension rates on tillers of *Holcus lanatus* and *Lolium perenne* were higher than on tillers in the wet turves, but only at ambient CO₂. Consequently, despite the greater leaf extension rate during the soil moisture deficit at elevated CO₂, because of the overcompensation after rewatering at ambient CO₂, total leaf extension over both the drying and rewetting period did not differ between CO₂ concentrations for these C-3 grass species. Further investigation of this difference in response between CO₂ treatments is warranted given the frequent drying and wetting cycles experienced by many temperate grasslands.

Clark, H., P.C.D. Newton, C.C. Bell, and E.M. Glasgow. 1995. The influence of elevated CO₂ and simulated seasonal-changes in temperature on tissue turnover in pasture turves dominated by perennial ryegrass (*Lolium perenne*) and white clover (*Trifolium repens*). *Journal of Applied Ecology* 32(1):128-136.

1. Tissue turnover, leaf morphology and population dynamics of perennial ryegrass and white clover were studied in pasture turves grown at ambient (350 µmol mol⁻¹) or double ambient (700 µmol mol⁻¹) CO₂ concentrations for 217 days in controlled environment rooms. The turves were subjected sequentially to three day/night temperature regimes; 10/4 degrees C, 16/10 degrees C and 22/16 degrees C and harvested at 3-week intervals. The photoperiod was 12 hours for all of the temperature treatments with a mean photon flux density of 480 µmol m⁻² s⁻¹. 2. Ryegrass leaf extension and leaf death rates did not differ between CO₂ treatments and there was no effect of CO₂ on rates of leaf appearance in white clover. Weight per unit length of ryegrass

laminae was unaffected by elevated CO₂ but lamina weight per unit area, lamina area and petiole weight per unit length in white clover showed a small positive response, especially at the two higher temperatures. Rates of growth and senescence per ryegrass tiller were therefore similar between CO₂ treatments, but rates of growth per white clover growing point were increased by 4, 23 and 13% at 10/4 degrees C, 16/10 degrees C and 22/16 degrees C, respectively, at elevated CO₂. Responses to CO₂ could not be attributed to any consistent change in morphological characteristics in either species and exposure to elevated concentrations of CO₂ did not appear to change the relationship between growth and senescence per meristem. 3. Total grass tiller populations were similar at both CO₂ concentrations, but ryegrass tiller densities more than halved in both CO₂ treatments as the temperature was increased. The fall was most severe at 700 $\mu\text{mol mol}^{-1}$ and at the end of the experiment ryegrass tiller densities in this treatment were only 47% of those found at 350 $\mu\text{mol mol}^{-1}$. There was no consistent effect of CO₂ concentration on clover growing point numbers and they increased from 800 m^{-2} to over 3000 m^{-2} in both treatments with maximum densities occurring at 22/16 degrees C. 4. The results imply that, in plant communities dominated by ryegrass and white clover, exposure to elevated CO₂ concentrations will alter the species composition in favour of white clover. Responses in above-ground dry matter yield to elevated CO₂ will be a balance between the positive response shown by white clover and the negative response of perennial ryegrass. Temperature will have a major influence on the magnitude of this response since both the response of white clover to CO₂ and the ratio of white clover growing points to ryegrass tillers are temperature-dependent.

Clark, H., P.C.D. Newton, C.C. Bell, and E.M. Glasgow. 1997. Dry matter yield, leaf growth and population dynamics in *Lolium perenne* Trifolium repens-dominated pasture turves exposed to two levels of elevated CO₂. *Journal of Applied Ecology* 34(2):304-316.

1. Dry matter yield, leaf growth and population dynamics of turves taken from an old *Lolium perenne*/Trifolium repens- dominated pasture were studied in controlled environment rooms at CO₂ concentrations of 350 $\mu\text{mol mol}^{-1}$, 525 $\mu\text{mol mol}^{-1}$ and 700 $\mu\text{mol mol}^{-1}$. Starting with September data the turves were subjected sequentially to the mean monthly temperature and photoperiod taken from long-term climatic data for the area of New Zealand where the pasture was located. Each temperature and photoperiod regime was applied for 21 days to provide 12 different simulated 'months' of environmental conditions. The experiment ran for 14 simulated months, with September and October conditions being repeated at the end of the first simulated 'year'. Mean photon flux density throughout was 500 $\mu\text{mol E m}^{-2} \text{s}^{-1}$. 2. The total quantity of herbage harvested was increased by 7% and 14% at 525 $\mu\text{mol mol}^{-1}$ and 700 $\mu\text{mol mol}^{-1}$ CO₂, respectively. The increase in the amount of T. repens harvested by the end of the experiment was 63% at 525 $\mu\text{mol mol}^{-1}$ CO₂ and 48% at 700 $\mu\text{mol mol}^{-1}$ CO₂. In contrast, neither the yield of C3 grasses nor the yield of the only C4 grass present, *Paspalum dilatatum*, was significantly affected by CO₂ concentration. The implications of this increase in the proportion of T. repens in temperate pastures at elevated CO₂ is discussed briefly. 3. With the exception of a small increase in the specific leaf area of T. repens, detailed measurements of leaf growth on marked tillers (*L. perenne* and *P. dilatatum*) and growing points (T. repens) showed no consistent effects of exposure to elevated CO₂ concentrations. 4. Differences in yield between CO₂ concentrations were mainly attributable to changes in the number and balance of population units. By the middle of the 'winter' conditions T. repens growing point densities at 700 $\mu\text{mol mol}^{-1}$ CO₂ were more than double those

found at 350 $\mu\text{mol mol}^{-1}$ but total grass tiller densities were unchanged. Growing point densities were also more than doubled at 525 $\mu\text{mol mol}^{-1}$ CO₂ compared with 350 $\mu\text{mol mol}^{-1}$ but grass tiller densities were reduced significantly below those recorded in the other two treatments. The relationship between the stability of herbage production and population densities is discussed and the potential interaction between population density, elevated CO₂ and grazing considered. 5. Although exposure to elevated levels of CO₂ did result in large changes in population numbers, this did not happen immediately and so the yield response of this particular community to CO₂ varied with time. The average yield increases recorded here at elevated CO₂ may therefore tend to underestimate those likely to be shown by communities that, at the population level, have become fully adapted to growth in a CO₂-enriched atmosphere.

Claussen, M., and M. Esch. 1994. Biomes computed from simulated climatologies. *Climate Dynamics* 9(4-5):235-243.

The biome model of Prentice et al. (1992a) is used to predict global patterns of potential natural plant formations, or biomes, from climatologies simulated by ECHAM, a model used for climate simulations at the Max-Planck-Institut für Meteorologie. This study is undertaken in order to show the advantage of this biome model in diagnosing the performance of a climate model and assessing effects of past and future climate changes predicted by a climate model. Good overall agreement is found between global patterns of biomes computed from observed and simulated data of present climate. But there are also major discrepancies indicated by a difference in biomes in Australia, in the Kalahari Desert, and in the Middle West of North America. These discrepancies can be traced back to failures in simulated rainfall as well as summer or winter temperatures. Global patterns of biomes computed from an ice age simulation reveal that North America, Europe, and Siberia should have been covered largely by tundra and taiga, whereas only small differences are seen for the tropical rain forests. A potential northeast shift of biomes is expected from a simulation with enhanced CO₂ concentration according to the IPCC Scenario A. Little change is seen in the tropical rain forest and the Sahara. Since the biome model used is not capable of predicting changes in vegetation patterns due to a rapid climate change, the latter simulation has to be taken as a prediction of changes in conditions favourable for the existence of certain biomes, not as a prediction of a future distribution of biomes.

Clifford, S.C., C.R. Black, J.A. Roberts, I.M. Stronach, P.R. Singleton-Jones, A.D. Mohamed, and S.N. Azamali. 1995. The effect of elevated atmospheric CO₂ and drought on stomatal frequency in groundnut (*Arachis hypogaea* (L)). *Journal of Experimental Botany* 46(288):847-852.

The effects of elevated atmospheric CO₂, alone or in combination with water stress, on stomatal frequency in groundnut (*Arachis hypogaea* (L.) cv. Kadiri-3) were investigated. CO₂ exerted significant effects on stomatal frequency only in irrigated plants. The effects of drought on leaf development outweighed the smaller effects of CO₂ concentration, although reductions in stomatal frequency induced by elevated atmospheric CO₂ were still observed. When stands of groundnut were grown under irrigated conditions with unrestricted root systems, an increase in atmospheric CO₂ from 375 to 700 ppmv decreased stomatal

frequency on both leaf surfaces by up to 16%; in droughted plants, stomatal frequency was reduced by 8% on the adaxial leaf surface only. Elevated atmospheric CO₂ promoted larger reductions in leaf conductance than the changes in stomatal frequency, indicating partial stomatal closure. As a result, the groundnut stands grown at elevated CO₂ utilized the available soil moisture more slowly than those grown under ambient CO₂, thereby extending the growing period. Despite the large variations in cell frequencies induced by drought, there was no treatment effect on either stomatal index or the adaxial/abaxial stomatal frequency ratio. The data suggest that the effects of future increases in atmospheric CO₂ concentration on stomatal frequency in groundnut are likely to be small, especially under conditions of water stress, but that the combination of associated reductions in leaf conductance and enhanced assimilation at elevated CO₂ will be important in semi-arid regions.

Clifford, S.C., I.M. Stronach, A.D. Mohamed, S.N. Azamali, and N.M.J. Crout. 1993. The effects of elevated atmospheric carbon-dioxide and water- stress on light interception, dry-matter production and yield in stands of groundnut (*arachis-hypogaea* L.). *Journal of Experimental Botany* 44(269):1763-1770.

Stands of groundnut (*Arachis hypogaea* L.), a C-3 legume, were grown in controlled-environment glasshouses at 28 degrees C (15 degrees C) under two levels of atmospheric CO₂ (350 ppmv or 700 ppmv) and two levels of soil moisture (irrigated weekly or no water from 35 d after sowing). Elevated CO₂ increased the maximum rate of net photosynthesis by up to 40%, with an increase in conversion coefficient for intercepted radiation of 30% (from 1.66 to 2.16 g MJ(-1)) in well-irrigated conditions, and 94% (from 0.64 to 1.24 g MJ(-1)) on a drying soil profile. In plants well supplied with water, elevated CO₂ increased dry matter accumulation by 16% (from 13.79 to 16.03 t ha(-1)) and pod yield by 25% (from 2.7 to 3.4 t ha(-1)). However, the harvest index (total pod dry weight/above-ground dry weight) was unaffected by CO₂ treatment. The beneficial effects of elevated CO₂ were enhanced under severe water stress, dry matter production increased by 112% (from 4.13 to 8.87 t ha(-1)) and a pod yield of 1.34 t ha(-1) was obtained in elevated CO₂, whereas comparable plots at 350 ppmv CO₂ only yielded 0.22 t ha(-1). There was a corresponding decrease in harvest index from 0.15 to 0.05. Following the withholding of irrigation, plants growing on a stored soil water profile in elevated CO₂ could maintain significantly less negative leaf water potentials (P<0.01) for the remainder of the season than comparable plants grown in ambient CO₂, allowing prolonged plant activity during drought. In plants which were well supplied with water, allocation of dry matter between leaves, stems, roots, and pods was similar in both CO₂ treatments. On a drying soil profile, allocation in plants grown in 350 ppmv CO₂ changed in favour of root development far earlier in the season than plants grown at 700 ppmv CO₂, indicating that severe water stress was reached earlier at 350 ppmv CO₂. The primary effects of elevated CO₂ on growth and yield of groundnut stands were mediated by an increase in the conversion coefficient for intercepted radiation and the prolonged maintenance of higher leaf water potentials during increasing drought stress.

Clinton, B.D., and J.M. Vose. 1999. Fine root respiration in mature eastern white pine (*Pinus strobus*) in situ: the importance of CO₂ in controlled environments. *Tree Physiology* 19(7):475-479.

We measured seasonal fine root respiration rate in situ while controlling

chamber temperature and [CO₂]. Atmospheric [CO₂] ([CO₂](a)) and measured soil [CO₂] ([CO₂](s)) were alternately delivered to a cuvette containing intact fine roots of eastern white pine (*Pinus strobus* L.). Respiration rates were consistently higher in [CO₂](a) than in [CO₂](s) and were almost three times higher during midsummer. Respiration rates were immediately reversed after returning to the alternate [CO₂] (i.e., [CO₂](a) --> [CO₂](s) --> [CO₂](a), and vice versa) suggesting a direct effect of elevated [CO₂] on apparent respiration. Soil-[CO₂]-based respiration rates decreased with increasing [CO₂] on a dry mass and tissue [N] basis. We conclude that estimates of soil CO₂ flux and soil carbon budgets may be improved by more completely accounting for the rhizosphere microclimate (i.e., soil temperature and [CO₂](s)) during measurement of fine root respiration.

Colelli, G., F.G. Mitchell, and A.A. Kader. 1991. Extension of postharvest life of mission figs by CO₂-enriched atmospheres. *Hortscience* 26(9):1193-1195.

Good quality of fresh 'Mission' figs (*Ficus carica* L.) was maintained for up to 4 weeks when kept at 0, 2.2, or 5C in atmospheres enriched with 15% or 20% CO₂. The visible benefits of exposure to high CO₂ levels were reduction of decay incidence and maintenance of bright external appearance. Ethylene production was lower, and fruit softening (as measured with a deformation tester) was slower in the high-CO₂-stored figs than in those kept in air. Ethanol content of the CO₂-treated fruit increased slightly during the first 3 weeks and moderately during the 4th week, while acetaldehyde concentration increased during the first week, then decreased. The results may be applicable to the transport and storage of fresh 'Mission' figs, as high CO₂ extended their postharvest life, especially near 0C.

Coleman, J.S., and F.A. Bazzaz. 1992. Effects of co2 and temperature on growth and resource use of cooccurring C3 and C4 annuals. *Ecology* 73(4):1244-1259.

We examined how CO₂ concentrations and temperature interacted to affect growth, resource acquisition, and resource allocation of two annual plants that were supplied with a single pulse of nutrients. Physiological and growth measurements were made on individuals of *Abutilon theophrasti* (C3) and *Amaranthus retroflexus* (C4) grown in environments with atmospheric CO₂ levels of 400 or 700-μL/L and with light/dark temperatures of 28-degrees/22-degrees or 38-degrees/31-degrees-C. Elevated CO₂ and temperature treatments had significant independent and interactive effects on plant growth, resource allocation, and resource acquisition (i.e., photosynthesis and nitrogen uptake), and the strength and direction of these effects were often dependent on plant species. For example, final biomass of *Amaranthus* was enhanced by elevated CO₂ at 28-degrees but was depressed at 38-degrees. For *Abutilon*, elevated CO₂ increased initial plant relative growth rates at 28-degrees but not at 38-degrees, and had no significant effects on final biomass at either temperature. These results are interpreted in light of the interactive effects of CO₂ and temperature on the rates of net leaf area production and loss, and on net whole- plant nitrogen retention. At 28-degrees-C, elevated CO₂ stimulated the initial production of leaf area in both species, which led to an initial stimulation of biomass accumulation at the higher CO₂ level. However, in elevated CO₂ at 28-degrees, the rate of net leaf area loss for *Abutilon* increased while that of *Amaranthus* decreased. Furthermore, high CO₂ apparently enhanced the ability of *Amaranthus* to retain nitrogen at this temperature, which may have helped to enhance photosynthesis, whereas nitrogen retention was

unaffected in Abutilon. Thus, at 28-degrees, final biomass of Abutilon was not stimulated in a high CO₂ environment whereas the final biomass of Amaranthus was. At 38-degrees, Abutilon had slightly reduced peak leaf areas under elevated CO₂ in comparison to ambient CO₂ grown plants, but increased rates of photosynthesis per unit leaf area early in the experiment apparently compensated for reduced leaf area. For Amaranthus at 38-degrees, peak leaf area production was not affected by CO₂ treatment, but the rate of net leaf area loss hastened under elevated CO₂ conditions and was accompanied by substantial reductions of whole-plant nitrogen content and leaf photosynthesis. This may have led to the reduced biomass accumulation of high CO₂ grown plants that we observed during the last 30 d of growth. Plants of both species grown in elevated CO₂ exhibited reduced tissue-specific rates of nitrogen absorption, increased plant photosynthetic rate per unit of conductance, and increased initial allocation of biomass to roots, irrespective of temperature. Plants of both species grown under an elevated temperature regime had substantially decreased reproductive allocation, increased allocation to stem biomass, and increased plant water flux at both CO₂ treatments. The age of plants also affected our interpretations of plant responses to CO₂ and temperature treatments. For example, significant effects of CO₂ treatment on the growth of Abutilon were evident early, prior to the initiation of flowering, when nitrogen availability would have been highest and pot space would not have been limited. Nevertheless, the opposite was true for Amaranthus, in which significant effects of CO₂ treatment on plant growth were not detectable until the final 30 d of the experiment. Elevated CO₂ interacted with temperature to affect plant productivity in different ways than would have been predicted from plant responses to elevated CO₂ alone. Furthermore, a majority of the interactive effects of CO₂ concentration and temperature on plant growth could be interpreted in light of their effects on the rates of net leaf area production and loss, nitrogen retention, and, to a lesser degree, photosynthesis and resource partitioning.

Coleman, J.S., K.D.M. McConaughay, and F.A. Bazzaz. 1993. Elevated CO₂ and plant nitrogen-use - is reduced tissue nitrogen concentration size-dependent. *Oecologia* 93(2):195-200.

Plants often respond to elevated atmospheric CO₂ levels with reduced tissue nitrogen concentrations relative to ambient CO₂-grown plants when comparisons are made at a common time. Another common response to enriched CO₂ atmospheres is an acceleration in plant growth rates. Because plant nitrogen concentrations are often highest in seedlings and subsequently decrease during growth, comparisons between ambient and elevated CO₂-grown plants made at a common time may not demonstrate CO₂-induced reductions in plant nitrogen concentration per se. Rather, this comparison may be highlighting differences in nitrogen concentration between bigger, more developed plants and smaller, less developed plants. In this study, we directly examined whether elevated CO₂ environments reduce plant nitrogen concentrations independent of changes in plant growth rates. We grew two annual plant species, Abutilon theophrasti (C3 photosynthetic pathway) and Amaranthus retroflexus (C4, photosynthetic pathway), from seed in glass-sided growth chambers with atmospheric CO₂ levels of 350 μmol . mol⁻¹ or 700 μmol . mol⁻¹ and with high or low fertilizer applications. Individual plants were harvested every 2 days starting 3 days after germination to determine plant biomass and nitrogen concentration. We found: 1. High CO₂-grown plants had reduced nitrogen concentrations and increased biomass relative to ambient CO₂-grown plants when compared at a common time; 2. Tissue nitrogen concentrations did not vary as a function of CO₂ level when plants were

compared at a common size; and 3. The rate of biomass accumulation per rate of increase in plant nitrogen was unaffected by CO₂ availability, but was altered by nutrient availability. These results indicate that a CO₂-induced reduction in plant nitrogen concentration may not be due to physiological changes in plant nitrogen use efficiency, but is probably a size-dependent phenomenon resulting from accelerated plant growth.

Coleman, J.S., L. Rochefort, F.A. Bazzaz, and F.I. Woodward. 1991. Atmospheric CO₂, plant nitrogen status and the susceptibility of plants to an acute increase in temperature. *Plant, Cell and Environment* 14(7):667-674.

Elevated levels of CO₂ in the atmosphere are expected to affect plant performance and may alter global temperature patterns. Changes in mean air temperatures that might be induced by rising levels of CO₂ and other greenhouse gases could also be accompanied by increased variability in daily temperatures such that acute increases in air temperature may be more likely than at present. Consequently, we investigated whether plants grown in a CO₂ enriched atmosphere would be differently affected by a heat shock than plants grown at ambient CO₂ levels. Plants of a C3 annual (Abutilon theophrasti), a C3 annual crop (Sinapis alba) and a C4 annual (Amaranthus retroflexus) were grown from seed in growth chambers under either 400 or 700 cm³ m⁻³ CO₂, and were fertilized with either a high or low nutrient regime. Young seedlings of S. alba, as well as plants of all species in either the vegetative or reproductive phase of growth were exposed to a 4-h heat shock in which the temperature was raised an additional 14-23-degrees-C (depending on plant age). Total biomass and reproductive biomass were examined to determine the effect of CO₂, nutrient and heat shock treatments on plant performance. Heat shock, CO₂, and nutrient treatments, all had some significant effects on plant performance, but plants from both CO₂ treatments responded similarly to heat shocks. We also found, as expected, that plants grown under high CO₂ had dramatically decreased tissue N concentrations relative to plants grown under ambient conditions. We predicted that high-CO₂-grown plants would be more susceptible to a heat shock than ambient-CO₂-grown plants, because the reduced N concentrations of high-CO₂ grown plants could result in the reduced synthesis of heat shock proteins and reduced thermotolerance. Although we did not examine heat shock proteins, our results showed little relationship between plant nitrogen status and the ability of a plant to tolerate an acute increase in temperature.

Coleman, W.K., and J. McInerney. 1997. Enhanced dormancy release and emergence from potato tubers after exposure to a controlled atmosphere. *American Potato Journal* 74(3):173-182.

The North American potato industry requires an effective and environmentally-appropriate, dormancy-release methodology. The present study examined dormancy release and subsequent sprout emergence based on a modified, controlled-atmosphere (CA) approach using such environmentally-compatible gases as nitrogen, carbon dioxide and oxygen with or without trace amounts of ethylene (50 ppm). This paper is the first published report of a semi-automated, controlled-atmosphere system for dormancy release of potato tubers. The system allows computer-controlled gas application and analysis for up to four gas mixtures simultaneously. Low oxygen concentrations (<10%) for 10

days in the presence of 10 to 60% carbon dioxide or a high carbon dioxide (60%)/oxygen (40%) treatment caused tuber break- down regardless of cultivar. The most effective mixtures for enhanced dormancy release and sprout emergence were 20% CO₂/40% O₂ or 60% CO₂/18-20% O₂ and their effects were further enhanced by 50 ppm C₂H₄ (ethylene). In the presence of 50 ppm C₂H₄, the 20% CO₂/40% O₂ mixture was comparable to bromoethane in effectiveness. Temperature and light exposure affected subsequent Russet Burbank tuber responses to CO₂/O₂/C₂H₄ gas mixtures.

Coley, P.D. 1998. Possible effects of climate change on plant/herbivore interactions in moist tropical forests. *Climatic Change* 39(2-3):455-472.

The interactions between plants and herbivores are key determinants of community structure world wide. Their role is particularly important in lowland tropical rain forests where rates of herbivory are higher, plants are better defended chemically and physically, and herbivores have specialized diets. In contrast to the temperate zone, most of the herbivory in the tropics occurs on ephemeral young leaves (>70%), which requires herbivores to have finely tuned host-finding abilities. As a consequence of these tight ecological and evolutionary linkages, the interplay between plants and herbivores in the tropics may be more susceptible to perturbations of climate change. Increases in global temperature, atmospheric CO₂, and the length of the dry season are all likely to have ramifications for plant/herbivore interactions in the tropics. Here I extrapolate from our current and incomplete understanding of the mechanisms regulating plant/herbivore interactions and present a scenario for possible trends under a changing climate. Although elevated CO₂ tends to enhance plant growth rates, the larger effects of increased drought stress will probably result in lower growth. In atmospheres experimentally enriched in CO₂, the nutritional quality of leaves declines substantially due to a dilution of nitrogen by 10-30%. This response is buffered in plant species associated with nitrogen fixers. Elevated CO₂ should also cause a slight decrease in nitrogen-based defenses (e.g., alkaloids) and a slight increase in carbon-based defenses (e.g., tannins). The most dramatic and robust predicted effect of climate change is on rates of herbivory. Lower foliar nitrogen due to CO₂ fertilization of plants causes an increase in consumption per herbivore by as much as 40% and unusually severe drought appears to cause herbivore populations to explode. In areas where elevated CO₂ is combined with drying, rates of herbivory may rise 2-4 fold. The frequency of insect outbreaks is also expected to increase. Higher herbivory should further reduce plant growth rates, perhaps favoring plant species that are well-defended or fix nitrogen. The predicted increase in the number of herbivores is primarily due to relaxed pressure from predators and parasitoids. Elevated temperatures may increase herbivore developmental times, affording them partial escape from discovery by natural enemies, and drought appears to decimate parasitoid populations. The expected decline in parasitoid numbers may be due to direct effects of dry season drought or to the relative scarcity of herbivores during that period. As a consequence, the relative abundance of species will change, and overall biodiversity should decline.

Colinvaux, P.A. 1998. A new vicariance model for Amazonian endemics. *Global Ecology and Biogeography Letters* 7(2):95-96.

It is unlikely that ice age climates of the Amazon were sufficiently arid to fragment the forest as required by the Haffer refugial hypothesis. However, glacial Amazon climates were colder and had reduced CO₂ concentrations that would have had their strongest effects on the biota in the elevated areas stipulated to have been refugia. If local endemism of butterflies or birds records Pleistocene speciation, this is because glacial climates provided cool, CO₂ starved islands in a sea of continuous forest.

Combe, L., J.M. Bertolini, and P. Quetin. 1993. Effects of carbon-dioxide and light on photosynthesis of primrose (*primula-obconica* hance). *Canadian Journal of Plant Science* 73(4):1149-1161.

Net CO₂ exchange rates were measured on a 1 m² crop of *Primula obconica* placed in a closed loop growing chamber as a function of irradiation and CO₂ concentration. Greenhouse cultivation with CO₂ enrichment (700 ppm) or without (350 ppm) had only very little effect on dry weight or on flowering rate and did not modify photosynthetic capacity of primrose. Productivity differences between horticultural techniques, such as supplemental lighting and/or CO₂ enrichment, can be partly explained by study of photosynthesis curves: light increase is more efficient than carbon dioxide increase, the latter giving the best results with young primroses under strong irradiation.

Comins, H.N. 1994. Equilibrium-analysis of integrated plant-soil models for prediction of the nutrient limited growth-response to co₂ enrichment. *Journal of Theoretical Biology* 171(4):369-385.

Although higher ambient CO₂ concentration is known to promote increased plant productivity under optimal growing conditions, it is not obvious if there will be a sustained growth response in natural and plantation ecosystems, where other resources, such as nutrients, may become limiting. Comins and McMurtrie (1993, *Ecol. Applic.* 3, 666-681) have constructed the G'DAY (Generic Decomposition A nd Field) integrated plant-soil model to investigate this CO₂-nutrient interaction, and have described an analytic method for predicting the long-term response of their model to a step change in CO₂ concentration, using the analytic "two timing" approximation. This analysis gives insights into the interactions of the numerous parameters in a comprehensive plant-soil model, and may be generalizable to other such models. The current paper explores the accuracy of the approximation, and discusses various generalizations of the basic model to which the analytic model can still be applied. The very long-term CO₂ response of G'DAY was predicted by considering the dynamics of the passive soil organic matter pool in the "two timing" approximation. It was found that the two-timing approximation underestimates the 50-100 year CO₂ response in systems that lose a very small proportion of nitrogen per recycling cycle. The other areas considered here are as follows. (i) More complex relationships between N:C ratios and carbon allocation fractions for plant organs, including variable heartwood N:C ratio (which has been identified as an important determinant of long-term CO₂ response). Typical results are presented for a range of sensitivities of heartwood N:C ratio to changes in foliar N:C ratio. (ii) Variants of the CENTURY soil model were examined, having variable N:C ratios in the soil organic matter pools and/or carbon flux partition fractions influenced by N:C ratios. (iii) Results are presented for a preliminary analysis of variable nitrogen fixation.

Comins, H.N., and R.E. McMurtrie. 1993. Long-term response of nutrient-limited forests to CO₂ enrichment - equilibrium behavior of plant-soil models. *Ecological Applications* 3(4):666-681.

Established process-based models of forest biomass production in relation to atmospheric CO₂ concentration (McMurtrie 1991) and soil carbon/nutrient dynamics (Parton et al. 1987) are integrated to derive the "Generic Decomposition and Yield" model (G'DAY). The model is used to describe how photosynthesis and nutritional factors interact to determine the productivity of forests growing under nitrogen-limited conditions. A simulated instantaneous doubling of atmospheric CO₂ concentration leads to a growth response that is initially large (27% above productivity at current CO₂) but declines to <10% elevation within 5 yr. The decline occurs because increases in photosynthetic carbon gain at elevated CO₂ are not matched by increases in nutrient supply. Lower foliar N concentrations at elevated CO₂ have two countervailing effects on forest production: decreased rates of N cycling between vegetation and soils (with negative consequences for productivity), and reduced rates of N loss through gaseous emission, fire, and leaching. Theoretical analysis reveals that there is an enduring response to CO₂ enrichment, but that the magnitude of the long-term equilibrium response is extremely sensitive to the assumed rate of gaseous emission resulting from mineralization of nitrogen. Theory developed to analyze G'DAY is applicable to other published production-decomposition models describing the partitioning of soil carbon among compartments with widely differing decay-time constants.

Conroy, J.P. 1992. Influence of elevated atmospheric CO₂ concentrations on plant nutrition. *Australian Journal of Botany* 40(4-5):445-456.

The rising levels of atmospheric CO₂ are likely to increase biomass production of C3 species in both natural and managed ecosystems because photosynthetic rates will be higher. The greatest absolute increase in productivity will occur when nitrogen and phosphorus availability in the soil is high. Low nitrogen does not preclude a growth response to high CO₂, whereas some C3 species fail to respond to high CO₂ when phosphorus is low, possibly because insufficient phosphorus is available to maintain maximum photosynthetic activity at high CO₂. C3 plants respond to high CO₂ because the flux of carbon through the photorespiratory cycle is increased and photorespiration is suppressed. This change in metabolism appears to alter the foliar nutrient concentration required to promote maximum productivity (critical concentration). Higher phosphorus concentrations are needed at elevated CO₂, whereas the nitrogen requirement is reduced by CO₂ enrichment. Since critical concentrations are used to evaluate nutrient status of crop and forest species and to manage fertilizer programs, they will need reassessing as the atmospheric CO₂ concentration rises. Another consequence of the altered nutrient requirement at high CO₂ is that the nitrogen concentrations of foliage, roots and grain are consistently lower in plants grown at elevated CO₂, irrespective of availability of nitrogen in the soil. In natural ecosystems, the lower nitrogen to carbon ratio of the litter may alter rates of nutrient cycling. For farmers, the rising CO₂ concentrations could cause reductions in grain nitrogen, and therefore protein content. This could have important implications for baking quality of hard wheats as well as affecting the nutrient value of grain

such as rice.

Conroy, J., and P. Hocking. 1993. Nitrogen nutrition of C-3 plants at elevated atmospheric CO₂ concentrations. *Physiologia Plantarum* 89(3):570-576.

The atmospheric CO₂ concentration has risen from the preindustrial level of approximately 290 $\mu\text{mol mol}^{-1}$ to more than 350 $\mu\text{mol mol}^{-1}$ in 1993. The current rate of rise is such that concentrations of 420 $\mu\text{mol mol}^{-1}$ are expected in the next 20 years. For C-3 plants, higher CO₂ levels favour the photosynthetic carbon reduction cycle over the photorespiratory cycle, resulting in higher rates of carbohydrate production and plant productivity. The change in balance between the two photosynthetic cycles appears to alter nitrogen and carbon metabolism in the leaf, possibly causing decreases in nitrogen concentrations in the leaf. This may result from increases in the concentration of storage carbohydrates of high molecular weight (soluble or insoluble) and/or changes in distribution of protein or other nitrogen containing compounds. Uptake of nitrogen may also be reduced at high CO₂ due to lower transpiration rates. Decreases in foliar nitrogen levels have important implications for production of crops such as wheat, because fertilizer management is often based on leaf chemical analysis, using standards estimated when the CO₂ levels were considerably lower. These standards will need to be re-evaluated as the CO₂ concentration continues to rise. Lower levels of leaf nitrogen will also have implications for the quality of wheat grain produced, because it is likely that less nitrogen would be retranslocated during grain filling.

Conroy, J.P., P.J. Milham, and E.W.R. Barlow. 1992. Effect of nitrogen and phosphorus availability on the growth- response of eucalyptus-grandis to high CO₂. *Plant, Cell and Environment* 15(7):843-847.

The response of Eucalyptus grandis seedlings to elevated atmospheric CO₂ concentrations was examined by growing seedlings at either 340 or 660- $\mu\text{mol CO}_2 \text{ mol}^{-1}$ for 6 weeks. Graded increments of phosphorus and nitrogen fertilizers were added to a soil deficient in these nutrients to establish if the growth response to increasing nutrient availability was affected by CO₂ concentration. At 660- $\mu\text{mol CO}_2 \text{ mol}^{-1}$, seedling dry weight was up to five times greater than at 340- $\mu\text{mol CO}_2 \text{ mol}^{-1}$. The absolute response was largest when both nitrogen and phosphorus availability was high but the relative increase in dry weight was greatest at low phosphorus availability. At 340- $\mu\text{mol CO}_2 \text{ mol}^{-1}$ and high nitrogen availability, growth was stimulated by addition of phosphorus up to 76 mg kg⁻¹ soil. Further additions of phosphorus had little effect. However, at 660- $\mu\text{mol CO}_2 \text{ mol}^{-1}$, growth only began to plateau at a phosphorus addition rate of 920 mg kg⁻¹ soil. At 340- $\mu\text{mol CO}_2 \text{ mol}^{-1}$ and high phosphorus availability, increasing nitrogen from 40 to 160 mg kg⁻¹ soil had little effect on plant growth. At high CO₂, growth

reached a maximum at between 80 and 160 mg nitrogen kg⁻¹ soil. Total uptake of phosphorus was greater at high CO₂ concentration at all fertilizer addition rates, but nitrogen uptake was either lower or unchanged at high CO₂ concentration except at the highest nitrogen fertilizer rate. The shoot to root ratio was increased by CO₂ enrichment, primarily because the specific leaf weight was greater. The nitrogen and phosphorus concentration in the foliage was lower at elevated CO₂ concentration partly because of the higher specific leaf weight. These results indicate that critical foliar concentrations currently used to define nutritional status and fertilizer management may need to be reassessed as the atmospheric CO₂ concentration rises.

Conroy, J.P., S. Seneweera, A.S. Basra, G. Rogers, and B. Nissenwooller. 1994. Influence of rising atmospheric co2 concentrations and temperature on growth, yield and grain quality of cereal crops. *Australian Journal of Plant Physiology* 21(6):741-758.

A possible scenario for the end of the 21st century is that the atmospheric CO₂ concentration will be in the range of 510-760 mu L L(-1) and that the mean global temperature will be 1.5-4.5 degrees C higher. Further, there may be greater incidences of extreme climatic events, which together with the CO₂ and temperature changes will influence development, growth and grain yield of cereals such as rice and wheat. For these C-3, plants, the driving force for the growth response to elevated CO₂ is higher leaf CO₂ assimilation rates (4). However, the response of A to CO₂ depends on temperature with maximum absolute increases occurring at temperatures which do not cause flower abortion, while negligible increases are observed at low temperatures. At high temperatures, where A is reduced because of partial inactivation of photosynthetic enzymes, the increase in A due to CO₂ enrichment is still observed. Other factors, such as changes in shoot water relations or hormone concentrations, may influence growth at elevated CO₂ concentrations. Wheat and rice development is accelerated by high temperature and consequently grain yield is reduced because there is less time for radiation to be intercepted during the vegetative phase. Although high CO₂ also accelerates development in rice and, to a lesser extent in wheat, the extra carbohydrate produced by increases in A results in at least a 40% increase in grain yield at temperatures which do not cause flower abortion. This is due mainly to increased tiller

numbers rather than increases in the number or weight of individual grains. However, the yield enhancement due to high CO₂ will not necessarily compensate for decreases in yield caused by accelerated development at high temperatures. As predicted by the response of A to high CO₂, the relative increase in yield, due to rising CO₂ concentrations, is smaller at lower temperatures. Elevated atmospheric CO₂ may improve the tolerance of plants to heat-induced drought stress by facilitating the maintenance of cell volume and photosynthetic function in the leaves. Increased carbohydrate storage in the stems may also be an advantage during grain filling if the flag leaves senesce prematurely. However, it is unlikely that the effect of very high temperatures on newer abortion will be ameliorated by high CO₂. For bread making, the quality of flour produced from grain developed at high temperatures is poorer. High CO₂ may also have an effect through a reduction in the protein content of wheat grain. For rice, the amylose content of the grain, a major determinant of cooking quality is increased under elevated CO₂.

Constable, J.V.H., A.B. Guenther, D.S. Schimel, and R.K. Monson. 1999. Modelling changes in VOC emission in response to climate change in the continental United States. *Global Change Biology* 5(7):791-806.

The alteration of climate is driven not only by anthropogenic activities, but also by biosphere processes that change in conjunction with climate. Emission of volatile organic compounds (VOCs) from vegetation may be particularly sensitive to changes in climate and may play an important role in climate forcing through their influence on the atmospheric oxidative balance, greenhouse gas concentration, and the formation of aerosols. Using the VEMAP vegetation database and associated vegetation responses to climate change, this study examined the independent and combined effects of simulated changes in temperature, CO₂ concentration, and vegetation distribution on annual emissions of isoprene, monoterpenes, and other reactive VOCs (ORVOCs) from potential vegetation of the continental United States. Temperature effects were modelled according to the direct influence of temperature on enzymatic isoprene production and the vapour pressure of monoterpenes and ORVOCs. The effect of elevated CO₂ concentration was modelled according to increases in foliar biomass per unit of emitting surface area. The effects of vegetation distribution reflects simulated changes in species spatial distribution and areal coverage by 21 different vegetation classes. Simulated climate warming associated with a doubled atmospheric CO₂ concentration enhanced total modelled VOC emission by 81.8% (isoprene + 82.1%, monoterpenes + 81.6%, ORVOC + 81.1%), whereas a simulated doubled CO₂ alone enhanced total modelled VOC emission by only + 11.8% (isoprene + 13.7%, monoterpenes + 4.1%, ORVOC + 11.7%). A simulated redistribution of vegetation in response to altered temperatures and precipitation patterns caused total modelled VOC emission to decline by 10.4% (isoprene - 11.7%, monoterpenes -18.6%, ORVOC 0.0%) driven by a decline in area covered by vegetation classes emitting VOCs at high rates. Thus, the positive effect of leaf-level adjustments to elevated CO₂ (i.e. increases in foliar biomass) is balanced by the negative effect of ecosystem-level adjustments to climate (i.e. decreases in areal coverage of species emitting VOC at high rates).

Constable, J.V.H., M.E. Litvak, J.P. Greenberg, and R.K. Monson. 1999. Monoterpene emission from coniferous trees in response to elevated CO₂ concentration and climate warming. *Global Change Biology* 5(3):255-267.

It was hypothesized that high CO₂ availability would increase monoterpene emission to the atmosphere. This hypothesis was based on resource allocation theory which predicts increased production of plant secondary compounds when carbon is in excess of that required for growth. Monoterpene emission rates were measured from needles of (a) Ponderosa pine grown at different CO₂ concentrations and soil nitrogen levels, and (b) Douglas fir grown at different CO₂ concentrations. Ponderosa pine grown at 700 $\mu\text{mol mol}^{-1}$ CO₂ exhibited increased photosynthetic rates and needle starch to nitrogen (N) ratios when compared to trees grown at 350 $\mu\text{mol mol}^{-1}$ CO₂. Nitrogen availability had no consistent effect on photosynthesis. Douglas fir grown at 550 $\mu\text{mol mol}^{-1}$ CO₂ exhibited increased photosynthetic rates as compared to growth at 350 $\mu\text{mol mol}^{-1}$ CO₂ in old, but not young needles, and there was no influence on the starch/N ratio. In neither species was there a significant effect of elevated growth CO₂ on needle monoterpene concentration or emission rate. The influence of climate warming and leaf area index LAD on monoterpene emission were also investigated. Douglas fir grown at elevated CO₂ plus a 4 degrees C increase in growth temperature exhibited no change in needle monoterpene concentration, despite a predicted 50% increase in emission rate. At elevated CO₂ concentration the LAI increased in Ponderosa pine, but not Douglas fir. The combination of increased LAI and climate warming are predicted to cause an 80% increase in monoterpene emissions from Ponderosa pine forests and a 50% increase in emissions from Douglas fir forests. This study demonstrates that although growth at elevated CO₂ may not affect the rate of monoterpene emission per unit biomass, the effect of elevated CO₂ on LAI, and the effect of climate warming on monoterpene biosynthesis and volatilization, could increase canopy monoterpene emission rate.

Constable, J.V.H., G.E. Taylor, J.A. Laurence, and J.A. Weber. 1996. Climatic change effects on the physiology and growth of *Pinus ponderosa*: Expectations from simulation modeling. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 26(8):1315-1325.

The TREGRO model was used to simulate the growth response of mature *Pinus ponderosa* Dougl. ex Laws. to the interacting effects of changes in CO₂ (+200 $\mu\text{mol L}^{-1}$), temperature (+4 degrees C), and O₃ (0.5x, 1x, and 2x ambient). Relative to simulated growth under the base-line climate in Corvallis, Oregon, elevated CO₂ and temperature individually increased total-tree biomass gain by 29% and 13%, respectively, but when combined increased biomass gain by 49%. Ozone at all exposures reduced total-tree biomass gain by 1%, 19%, and 39%, respectively, as compared with simulated base-line conditions. Elevated CO₂ increased photosynthesis and reduced stomatal conductance and partially offset growth reductions due to 2 x O₃. Elevated temperature, however, increased both photosynthesis and stomatal conductance and was less effective at mitigating growth reductions due to 2x O₃. Growth at 2x O₃ in elevated CO₂ and temperature conditions had little effect on total-tree growth, but decreased fine-root growth by 61%. The simulated changes in stomatal conductance and fine-root biomass are expected to interact with the availability of soil resources to affect tree growth and possibly alter the distribution of *Pinus ponderosa*.

Conway, T.J., L.P. Steele, and P.C. Novelli. 1993. Correlations among atmospheric CO₂, CH₄ and CO in the arctic, march 1989. *Atmospheric Environment Part A-General Topics* 27(17-18):2881-2894.

During six aircraft flights conducted as part of the third Arctic Gas and Aerosol Sampling Program (AGASP III, March 1989), 189 air samples were collected throughout the Arctic troposphere and lower stratosphere for analysis of CO₂, CH₄ and CO. The mixing ratios of the three gases varied significantly both horizontally and vertically. Elevated concentrations were found in layers with high anthropogenic aerosol concentrations (Arctic Haze). The mixing ratios of CO₂, CH₄ and CO were highly correlated on all flights. A linear regression of CH₄ vs CO₂ for pooled data from all flights yielded a correlation coefficient ($r(2)$) of 0.88 and a slope of 13.5 ppb CH₄/ppm CO₂ ($n = 186$). For CO vs CO₂ a pooled linear regression gave $r(2) = 0.91$ and a slope of 15.8 ppb CO/ppm CO₂ ($n = 182$). Carbon dioxide, CH₄ and CO also exhibited mean vertical gradients with slopes of 0.37, -4.4 and -4.2 ppb km⁻¹, respectively. Since the carbon dioxide variations observed in the Arctic atmosphere during winter are due primarily to variations in the emissions and transport of anthropogenic CO₂ from Europe and Asia, the strong correlations that we have found suggest that a similar interpretation applies to CH₄ and CO. Using reliable estimates of CO₂ emissions for the source regions and the measured CH₄/CO₂ and CO/CO₂ ratios, we estimate a regional European CH₄ source of 47 $\pm$ 6 Tg CH₄ yr⁻¹ that may be associated with fossil fuel combustion. A similar calculation for CO results in an estimated regional CO source of 82 $\pm$ 2 Tg CO yr⁻¹.

Cook, A.C., D.T. Tissue, S.W. Roberts, and W.C. Oechel. 1998. Effects of long-term elevated [CO₂] from natural CO₂ springs on *Nardus stricta*: Photosynthesis, biochemistry, growth and phenology. *Plant, Cell and Environment* 21(4):417-425.

Plants of *Nardus stricta* growing near a cold, naturally emitting CO₂ spring in Iceland were used to investigate the long-term (> 100 years) effects of elevated [CO₂] on photosynthesis, biochemistry, growth and phenology in a northern grassland ecosystem. Comparisons were made between plants growing in an atmosphere naturally enriched with CO₂ (approximate to 790 $\mu\text{mol mol}^{-1}$) near the CO₂ spring and plants of the same species growing in adjacent areas exposed to ambient CO₂ concentrations (approximate to 360 $\mu\text{mol mol}^{-1}$). *Nardus stricta* growing near the spring exhibited earlier senescence and reductions in photosynthetic capacity (approximate to 25%), Rubisco content (approximate to 26%), Rubisco activity (approximate to 40%), Rubisco activation state (approximate to 23%), chlorophyll content (approximate to 33%) and leaf area index (approximate to 22%) compared with plants growing away from the spring. The potential positive effects of elevated [CO₂] on grassland ecosystems in Iceland are likely to be reduced by strong down-regulation in the photosynthetic apparatus of the abundant *N. stricta* species.

Corey, K.A., M.E. Bates, and S.L. Adams. UNKNOWN YEAR. Carbon-dioxide exchange of lettuce plants under hypobaric conditions. *Physical, Chemical, Biochemical and Biological Techniques and Processes* :301-308.

Growth of plants in a Controlled Ecological Life Support System (CELSS) may involve the use of hypobaric pressures enabling lower mass requirements for atmospheres and possible enhancement of crop productivity. A controlled environment plant growth chamber with hypobaric capability designed and built at Ames Research Center was used to determine if reduced pressures influence the rates of photosynthesis (Ps) and dark respiration (DR) of hydroponically grown lettuce plants. The chamber, referred to as a plant volatiles chamber (PVC), has a growing area of about 0.2 m², a total gas volume of about 0.7 m³, and a leak rate at 50 kPa of < 0.1%/day. When the pressure in the chamber was reduced from ambient to 51 kPa, the rate of net Ps increased by 25% and the rate of DR decreased by 40%. The rate of Ps increased linearly with decreasing pressure. There was a greater effect of reduced pressure at 41 Pa CO₂ than at 81 Pa CO₂. This is consistent with reports showing greater inhibition of photorespiration (Pr) in reduced O₂ at low CO₂ concentrations. When the partial pressure of O₂ was held constant but the total pressure was varied between 51 and 101 kPa, the rate of CO₂ uptake was nearly constant, suggesting that low pressure enhancement of Ps may be mainly attributable to lowered partial pressure of O₂ and the accompanying reduction in Pr. The effects of lowered partial pressure of O₂ on Ps and DR could result in substantial increases in the rates of biomass production, enabling rapid throughput of crops or allowing flexibility in the use of mass and energy resources for a CELSS.

Corlett, R.T., and J.V. LaFrankie. 1998. Potential impacts of climate change on tropical Asian forests through an influence on phenology. *Climatic Change* 39(2-3):439-453.

Changes in plant phenology will be one of the earliest responses to rapid global climate change and could potentially have serious consequences both for plants and for animals that depend on periodically available plant resources. Phenological patterns are most diverse and least understood in the tropics. In those parts of tropical Asia where low temperature or drought impose a seasonal rest period, regular annual cycles of growth and reproduction predominate at the individual, population, and community level. In aseasonal areas, individuals and populations show a range of sub- to supra-annual periodicities, with an overall supra-annual reproductive periodicity at the community level. There is no evidence for photoperiod control of phenology in the Asian tropics, and seasonal changes in temperature are a likely factor only near the northern margins. An opportunistic response to water availability is the simplest explanation for most observed patterns where water is seasonally limiting, while the great diversity of phenological patterns in the aseasonal tropics suggests an equal diversity of controls. The robustness of current phenological patterns to high interannual and spatial variability suggests that most plant species will not be seriously affected by the phenological consequences alone of climate change. However, some individual plant species may suffer, and the consequences of changes in plant phenology for flower- and fruit-dependent animals in fragmented forests could be serious.

Cornelissen, J.H.C., A.L. Carnelli, and T.V. Callaghan. 1999. Generalities in the growth, allocation and leaf quality responses to elevated CO₂ in eight woody species. *New Phytologist* 141(3):401-409.

This paper reports general patterns of relative growth rate and related traits in response to elevated atmospheric CO₂ in eight woody species ranging widely in life form, leaf habit, taxonomy and ecology. Young plants of these species, all of comparable ontogenetic phases, were grown simultaneously in large containers with favourable nutrient and water availability in transparent outdoor chambers at 350 and 700 μ l l⁻¹ CO₂ for one growing season. We found the following consistent responses. (1) All species grew faster at elevated CO₂, whereas the following leaf and allocation traits were consistently lower in CO₂-enriched environments: specific leaf area (quotient of leaf area and leaf weight), leaf area ratio (quotient of total leaf area and plant weight), weight-based foliar N concentration and, to a smaller extent, leaf weight fraction (quotient of leaf weight and plant weight). (2) There was important interspecific variation in the magnitude of the response of relative growth rate to CO₂. Specific leaf area at ambient CO₂ explained 88% of the variation in relative growth rate response to CO₂ among the eight species. At ambient CO₂, relative growth rate itself, was significantly correlated with the relative growth rate response to CO₂ only if the leafless species *Ulex gallii* was excluded from analysis. (3) The four deciduous species had a significantly stronger relative growth rate response to CO₂ than the four evergreens. This corresponded with their generally higher specific leaf area. (4) Specific leaf area and leaf habit might be useful for scaling up exercises, as easy-to-measure substitutes for growth responses of (woody) vegetation to elevated CO₂. However, the usefulness of such traits in this context needs to be tested in realistic, longer-term manipulative experiments in real ecosystems.

Corrigan, V.K., and A. Carpenter. 1993. Effects of treatment with elevated carbon-dioxide levels on the sensory quality of asparagus. *New Zealand Journal of Crop and Horticultural Science* 21(4):349-357.

Asparagus spears (*Asparagus officinalis* L. cv. Limbras 10) were stored for 3-5 days in atmospheres containing between 40 and 90% carbon dioxide (CO₂) to evaluate the effect of insecticidal CO₂ atmospheres on sensory quality based on sensory panel ratings of characteristic asparagus flavour, off-flavours, flavour acceptability, and overall acceptability. Sensory quality of spears after 4 days storage in 60% CO₂ was similar to air-stored spears but 5 days storage caused deterioration in the CO₂-stored spears relative to the air-stored spears. Using higher CO₂ levels than this for shorter storage times resulted in spears with CO₂ injury and poor sensory quality. Spear quality deteriorated with shelf period but previous CO₂ treatment did not affect the rate of deterioration. Storing spears at 5-degrees-C in 60% CO₂ or 0-degrees-C in air gave consistently higher (lower for off-flavours) sensory quality ratings for all characteristics assessed than vice versa. Thick spears had more flavour and were more acceptable than thin spears. Thick spears had more flavour than thin spears when stored in CO₂, but thin spears had more flavour when stored in air than in CO₂. In 60% CO₂, spears stored dry had a more acceptable flavour and were more acceptable overall (where panellists considered aspects such as flavour, texture, and off-flavours in the overall rating) than those stored with their butts in water. Spears stored in air with their butts in water had a more acceptable flavour and were more acceptable overall, spears stored with their butts in water had less characteristic asparagus flavour than those stored dry. High levels of CO₂ could be used as a disinfection treatment of fresh asparagus spears without significant effect on spear quality (compared to spears stored in air under similar conditions).

providing levels >60% CO₂ are not used, and storage time in the atmosphere is kept to 4 days or less.

Cotrufo, M.E., and P. Ineson. 1995. Effects of enhanced atmospheric CO₂ and nutrient supply on the quality and subsequent decomposition of fine roots of *Betula pendula* Roth and *Picea sitchensis* (Bong.) Carr. *Plant and Soil* 170(2):267-277.

Fine root litter derived from birch (*Betula pendula* Roth.) and Sitka spruce (*Picea sitchensis* (Bong.) Carr.) plants grown under two CO₂ atmospheric concentrations (350 ppm and 600 ppm) and two nutrient regimes was used for decomposition studies in laboratory microcosms. Although there were interactions between litter type, CO₂/fertiliser treatments and decomposition rates, in general, an increase in the C/N ratio of the root tissue was observed for roots of both species grown under elevated CO₂ in unfertilized soil. Both weight loss and respiration of decomposing birch roots were significantly reduced in materials derived from enriched CO₂, whilst the decomposition of spruce roots showed no such effect. A parallel experiment was performed using *Betula pendula* root litter grown under different N regimes, in order to test the relationship between C/N ratio of litter and root decomposition rate. A highly significant ($p < 0.001$) negative correlation between C/N ratio and root litter respiration was found, with an $r(2) = 0.97$. The results suggest that the increased C/N ratio of plant tissues induced by elevated CO₂ can result in a reduction of decomposition rate, with a resulting increase in forest soil C stores.

Cotrufo, M.F., M.J.I. Briones, and P. Ineson. 1998. Elevated CO₂ affects field decomposition rate and palatability of tree leaf litter: Importance of changes in substrate quality. *Soil Biology and Biochemistry* 30(12):1565-1571.

Field decomposition rates of ash (*Fraxinus excelsior* L.) and sycamore (*Acer pseudoplatanus* L.) leaf litters were measured for litters grown at ambient and elevated concentration of atmospheric CO₂ inside solar domes. Litter raised at 600 $\mu\text{mol l}^{-1}$ CO₂ retained significantly more mass at the end of the first year of field decomposition than material raised at 350 $\mu\text{mol l}^{-1}$. This reduction in decomposition could be related to changes in tissue quality resulting from growing the plants at higher CO₂ concentrations, with C-to-N ratios and lignin contents being significantly increased. The elevated CO₂ treatment also affected the rate of consumption of ash leaf litter by *Oniscus asellus* L. (Isopoda: Oniscoidae), with significantly less (-16%) material being consumed for litter derived from the high CO₂ regime. Our results indicate that changes in litter quality, which we may expect under elevated CO₂, may affect litter palatability for soil fauna. (C) 1998 Elsevier Science Ltd. All rights reserved.

Cotrufo, M.F., and A. Gorissen. 1997. Elevated CO₂ enhances below-ground C allocation in three perennial grass species at different levels of N availability. *New Phytologist* 137(3):421-431.

Three perennial grass species, *Lolium perenne* L., *Agrostis capillaris* L. and *Festuca ovina* L., were homogeneously labelled in phytotrons with (CO₂)-C-14 at two CO₂ concentrations (350 and 700 $\mu\text{mol l}^{-1}$). Plants were grown under two nitrogen regimes: one with a minor addition of 8 kg N ha⁻¹, the other with an addition of 278 kg N ha⁻¹. Carbon allocation over the different compartments of the plant/soil systems was measured: shoots, roots, rhizosphere soil (soil solution, microbial biomass and soil residue), and bulk soil. Elevated CO₂ increased total net C-14 recovery in all species by 14%, and significantly enhanced the below-ground C-14 allocation by 26%, this enhancement was 24%, 39% and 21%, for root, rhizosphere soil and bulk soil, respectively. Within the rhizosphere soil, the C-14 amounts in the soil solution (+ 69 %) and soil residue (+ 49 %) increased significantly. Total microbial biomass-C in the rhizosphere soil was also increased (15%) by the elevated CO₂ treatment, but only in proportion to the increased root mass. No interactions were observed between the elevated CO₂ and N treatments. The N treatment increased total net C-14 recovery by more than 300% and C-14 was preferentially allocated to the shoots, leading to a significant increase in shoot-to-root ratio. However, N fertilization also increased (+ 111 %) the absolute amount of C-14 in soil. The three species behaved differently, but no interactions were observed between CO₂ treatment and plant species. These results show that elevated CO₂ induces an increased C input into soil for all three grass species at both N levels. However, the highest absolute amounts were found in the soils of the fastest growing species and at the highest N level.

Cotrufo, M.F., and P. Ineson. 1996. Elevated CO₂ reduces field decomposition rates of *Betula pendula* (Roth) leaf litter. *Oecologia* 106(4):525-530.

The effect of elevated atmospheric CO₂ and nutrient supply on elemental composition and decomposition rates of tree leaf litter was studied using litters derived from birch (*Betula pendula* Roth.) plants grown under two levels of atmospheric CO₂ (ambient and ambient+250 ppm) and two nutrient regimes in solar domes. CO₂ and nutrient treatments affected the chemical composition of leaves, both independently and interactively. The elevated CO₂ and unfertilized soil regime significantly enhanced lignin/N and C/N ratios of birch leaves. Decomposition was studied using field litter-bags, and marked differences were observed in the decomposition rates of litters derived from the two treatments, with the highest weight remaining being associated with litter derived from the enhanced CO₂ and unfertilized regime. Highly significant correlations were shown between birch litter decomposition rates and lignin/N and C/N ratios. It can be concluded, from this study, that at levels of atmospheric CO₂ predicted for the middle of the next century a deterioration of litter quality will result in decreased decomposition rates, leading to reduction of nutrient mineralization and increased C storage in forest ecosystems. However, such conclusions are difficult to generalize, since tree responses to elevated CO₂ depend on soil nutritional status.

Cotrufo, M.F., P. Ineson, and A.P. Rowland. 1994. Decomposition of tree leaf litters grown under elevated CO₂ - effect of litter quality. *Plant and Soil* 163(1):121-130.

Ash (*Fraxinus excelsior* L.), birch (*Betula pubescens* Ehrh.), sycamore

(*Acer pseudoplatanus* L.) and Sitka spruce (*Picea sitchensis* (Bong.) Carr.) leaf litters were monitored for decomposition rates and nutrient release in a laboratory microcosm experiment. Litters were derived from solar domes where plants had been exposed to two different CO₂ regimes: ambient (350 µmol L⁻¹ CO₂) and enriched (600 µmol L⁻¹ CO₂). Elevated CO₂ significantly affected some of the major litter quality parameters, with lower N, higher lignin concentrations and higher ratios of C/N and lignin/N for litters derived from enriched CO₂. Respiration rates of the deciduous species were significantly decreased for litters grown under elevated CO₂, and reductions in mass loss at the end of the experiment were generally observed in litters derived from the 600 ppm CO₂ treatment. Nutrient mineralization, dissolved organic carbon, and pH in microcosm leachates did not differ significantly between the two CO₂ treatments for any of the species studied. Litter quality parameters were examined for correlations with cumulative respiration and decomposition rates: N concentration, C/N and lignin/N ratios showed the highest correlations, with differences between litter types. The results indicate that higher C storage will occur in soil as a consequence of litter quality changes resulting from higher atmospheric concentrations of CO₂.

Cotrufo, M.F., P. Ineson, and A. Scott. 1998. Elevated CO₂ reduces the nitrogen concentration of plant tissues. *Global Change Biology* 4(1):43-54.

We summarize the impacts of elevated CO₂ on the N concentration of plant tissues and present data to support the hypothesis that reductions in the quality of plant tissue commonly occur when plants are grown under elevated CO₂. Synthesis of existing data showed an average 14% reduction of N concentrations in plant tissue generated under elevated CO₂ regimes. However, elevated CO₂ appeared to have different effects on the N concentrations of different plant types, as the reported reductions in N have been larger in C₃ plants than in C₄ plants and N-2-fixers. Under elevated CO₂ plants changed their allocation of N between above- and below-ground components: root N concentrations were reduced by an average of 9% compared to a 14% average reduction for above-ground tissues. Although the concentration of CO₂ treatments represented a significant source of variance for plant N concentration, no consistent trends were observed between them.

Cotrufo, M.F., A. Raschi, M. Lanini, and P. Ineson. 1999. Decomposition and nutrient dynamics of *Quercus pubescens* leaf litter in a naturally enriched CO₂ Mediterranean ecosystem. *Functional Ecology* 13(3):343-351.

1. The chemical composition (i.e. N, P, C, lignin and polyphenol concentrations) of *Quercus pubescens* leaf litter derived from a natural CO₂ spring in Tuscany (Italy) was analysed and compared to litter from a nearby reference site. Litter was incubated for 25 months at both the natural CO₂ spring and the reference site, and monitored for decomposition rates, nutrient and lignin concentrations. 2. Long-term exposure to elevated CO₂ concentrations from the natural spring was associated with a change in the chemical composition of the Oak leaf

litter, with decreases in P and polyphenol concentrations and increases in lignin. No differences in N concentrations were observed between the enriched CO₂ litter from the natural spring and the reference litter. 3. Decomposition was reduced in the CO₂ spring, with the lower P concentration of the native litter, combined with the lack of soil fauna observed at that site, being the factors most probably responsible for the measured decreases in mass loss. However, litter from the CO₂ spring and reference litter decomposed at the reference site showed similar rates of decomposition. 4. All litter showed similar N concentrations during decomposition, with N being mineralized throughout the incubation period from both litter regardless of the site of incubation. In contrast, P dynamics differed between litter, with P being immobilized in the litter derived from the spring, and mineralized from the reference litter. When the litter from the spring was incubated at the reference site, there was a trend for net P uptake from the surrounding environment. The chemical composition of decomposing litter from the spring appeared to match that of the reference litter after 3 months of incubation at the reference site. 5. The results from the CO₂ spring suggest that litter decomposition may be retarded under elevated levels of atmospheric CO₂. However, results from field surveys around CO₂ vents should be viewed with caution because differences may relate to factors other than the known differences in CO₂ concentrations.

Coughenour, M.B., and D.X. Chen. 1997. Assessment of grassland ecosystem responses to atmospheric change using linked plant-soil process models. *Ecological Applications* 7(3):802-827.

Models of photosynthesis, plant growth, and biophysical processes were linked with models that simulate water, nutrient, and carbon flows through plant-soil ecosystems. The linked ecosystem model was applied to examine ecosystem-level responses to CO₂, temperature, precipitation, and global- warming scenarios in grasslands of Colorado and Kansas, USA, and Kenya. The model predicted that increased temperatures would decrease primary production at current CO₂ levels, but decreases were reversed by doubling atmospheric CO₂ concentration. Greater increases in daily minimum temperatures than daily maximum temperatures mitigated reductions in photosynthesis and water-use efficiency (WUE) later in the day, more than offsetting increases in nighttime respiration rates under warmer temperatures. A temperature increase of 5 degrees C reduced organic carbon in grassland soils by 20-30%, through effects on plant growth and decomposition, but the doubled CO₂ negated soil carbon losses by increasing plant growth. Under higher precipitation and doubled CO₂, soil carbon stocks increased, or decreased little, in response to warmer temperatures. Doubling CO₂ increased net primary production (NPP) by 31-45% in a simulated Colorado C-4 grassland, by 20- 70% in a Colorado C-3 grassland, by 23-31% in a Kansas C-4 grassland, and by 23-35% in a Kenya C-4 grassland at ambient precipitation levels. Growth was shifted belowground, thus weakening aboveground responses. Higher temperatures strengthened the positive NPP responses to CO₂. Larger positive responses to elevated CO₂ were modeled under drier conditions, and smaller responses were modeled under wetter conditions. NPP increases under elevated CO₂ were mostly caused by increased plant WUE at all sites, which was brought about by partial stomatal closure. Decreased N concentrations in plant litter under elevated CO₂ slowed N mineralization, but greater plant production and thus greater litter inputs into the soil under elevated CO₂ offset the negative effects of lower litter quality. Decreases in plant N concentration under elevated CO₂ also reduced plant N requirements. At current atmospheric CO₂ (350 µmol/mol), a general circulation model (GCM) climate- change scenario decreased NPP and soil organic matter (SOM) in Colorado but not in Kansas or Kenya. A second GCM climate- change scenario either

affected NPP and SOM little, or increased NPP and SOM at current CO₂. NPP and SOM responses in the simulated grasslands were very sensitive to precipitation, which GCMs predict with relatively low confidence. Doubled CO₂ partially or completely offset decreases in NPP and SOM under climate-change scenarios.

Cournac, L., B. Dimon, P. Carrier, A. Lohou, and P. Chagvardieff. 1991. Growth and photosynthetic characteristics of *Solanum tuberosum* plantlets cultivated invitro in different conditions of aeration, sucrose supply, and CO₂ enrichment. *Plant Physiology* 97(1):112-117.

Growth characteristics, oxygen exchange, and carbohydrate and chlorophyll contents were determined 30 days after subculturing of single node-derived plantlets of *Solanum tuberosum* cv Haig cultivated in vitro. Cultivation conditions were: (a) photomixotrophy in closed vessel, (b) photomixotrophy in closed vessel on medium supplemented with silver thiosulfate, (c) photomixotrophy in aerated vessel, (d) photoautotrophy in air, (e) photoautotrophy in CO₂-enriched air. In photomixotrophic conditions, aeration of the vessel enhanced sucrose utilization and had a positive effect on plantlet growth. In photoautotrophic conditions, growth of the plantlets was slow in air and was strongly enhanced by CO₂ enrichment of the atmosphere. Starch to sucrose ratios were higher in plants grown photoautotrophically than in plants grown with sucrose in the medium. Oxygen exchange characteristics on a chlorophyll basis were similar between the plantlets when measured under moderate light, and resembled those of greenhouse plant leaves. In high light, however, plantlets grown photoautotrophically in a CO₂-enriched atmosphere had higher oxygen exchange rates. We concluded from these results that potato plantlets in vitro in conditions (c), (d), and (e) developed C₃-plant photosynthetic characteristics, which were in photoautotrophically grown plantlets comparable to those of field-grown plants.

Cournac, L., B. Dimon, and G. Peltier. 1993. Evidence for o-18 labeling of photorespiratory co₂ in photoautotrophic cell-cultures of higher-plants illuminated in the presence of o-18(2). *Planta* 190(3):407-414.

The O-18-enrichment of CO₂ produced in the light or during the post-illumination burst was measured by mass spectrometry when a photoautotrophic cell suspension of *Euphorbia characias* L. was placed in photorespiratory conditions in the presence of molecular O-18(2). The only O-18-labeled species produced was (COO)-O-18-O-16; no (COO)-O-18-O-16 could be detected. Production of (COO)-O-18-O-16 ceased after addition of two inhibitors of the photosynthetic carbon-oxidation cycle, aminooxyacetate or aminoacetoneitrile, and was inhibited by high levels of CO₂. The average enrichment during the post-illumination burst was estimated to be 46±15% of the enrichment of the O₂ present during the preceding light period. Addition of exogenous carbonic anhydrase, by catalyzing the exchange between CO₂ and H₂O, drastically diminished the O-18-enrichment of the produced CO₂. The very low carbonio-anhydrase level of the photoautotrophic cell suspension probably explains why the O-18 labeling of photorespiratory CO₂ could be observed for the first time. These data allow the establishment of a direct link between O₂ consumption and CO₂

production in the light, and the conclusion that CO₂ produced in the light results, at least partially, from the mitochondrial decarboxylation of the glycine pool synthesized through the photosynthetic carbon-oxidation cycle. Analysis of the (COO)-O-18-O-16 and CO₂ kinetics provides a direct and reliable way to assess in vivo the real contribution of photorespiratory metabolism to CO₂ production in the light.

Couteaux, M.M., C. Kurz, P. Bottner, and A. Raschi. 1999. Influence of increased atmospheric CO₂ concentration on quality of plant material and litter decomposition. *Tree Physiology* 19(4-5):301-311.

Nitrogen (N) and lignin concentrations in plant tissues and litter of plants grown in greenhouses or open-top chambers in elevated atmospheric CO₂ concentration were compared with those of plants grown in ambient air in short-term studies. We also compared the N concentration of plant material of *Quercus ilex* L. and *Q. pubescens* Willd. growing in the vicinity of natural CO₂-springs with that of the same species growing at a control site. In the short-term studies, elevated CO₂ caused significant decreases in tissue N concentration and the extent of the decrease varied with species. Nitrogen amendment of the soil lessened the CO₂-enrichment effect. Lignin concentration was modified by elevated CO₂ and the effect was species specific, but no general positive or negative trend was evident. A comparison of trees growing under natural conditions near a natural CO₂-spring and at a control site revealed no site differences in N concentration of the plant material. A comparison of published results on decomposition rates of litter produced in elevated atmospheric CO₂ and in ambient air indicated that CO₂ enrichment can cause both enhancements and decreases of carbon mineralization. We conclude that (1) long-term responses to elevated CO₂ could differ from the results obtained from short-term studies and that (2) biodiversity could be an important factor altering the sign of the feedback on atmospheric CO₂ concentration. We also discuss the implications of our finding of a long-term, inhibitory effect of the initial N concentration of litter on the decomposition rate of litter and its consequence on ecosystem feedback.

Couteaux, M.M., L.J. Monrozier, and P. Bottner. 1996. Increased atmospheric CO₂: Chemical changes in decomposing sweet chestnut (*Castanea sativa*) leaf litter incubated in microcosms under increasing food web complexity. *Oikos* 76(3):553-563.

Increased concentrations of atmospheric CO₂ induced a lower nitrogen concentration in sweet chestnut litter. The C:N ratio was about 35 at a 350 µl l⁻¹ (-1) CO₂ concentration and about 70 at 700 µl l⁻¹ (-1). The CO₂ enrichment increased the proportion of hemicelluloses and cellulose and decreased the proportion of lignin. Both litters were decomposed in microcosms with animal food webs of different complexities. The chemical composition of the decomposed litter (nitrogen, water-soluble compounds, cellulose, hemicelluloses and lignin) was related to the initial composition and to the mass loss. Rates of hemicelluloses and lignin decomposition and nitrogen dynamics were the most affected by the change in litter quality due to atmospheric CO₂ enrichment. In N-rich litter, hemicelluloses were almost completely decomposed and lignin remained intact without effect of animal grazing.

In N-poor litter derived From CO₂-enriched atmosphere, increased complexity of invertebrates food webs significantly enhanced decomposition of all the chemical components. By adding different groups of animals, some limiting factors were overcome and new substrates were liberated for microbial decomposition. It was hypothesized that the decomposition process was controlled by the interaction between lignin and nitrogen.

Couteaux, M.M., M. Mousseau, M.L. Celerier, and P. Bottner. 1991. Increased atmospheric CO₂ and litter quality - decomposition of sweet chestnut leaf litter with animal food webs of different complexities. *Oikos* 61(1):54-64.

Two-year-old chestnut trees were grown for two yr under ambient (350 ppm) and enriched (700 ppm) CO₂ concentrations, in two naturally lit growth chambers. The doubling of CO₂ resulted in a dilution of the nitrogen concentration in the leaf litter, with C:N ratios of 40 and 75 for the ambient and enriched CO₂ concentrations, respectively. The litter was sterilized and inoculated with microflora and animal groups of increasing complexity (microflora + Protozoa; + nematodes; + Collembola; + Isopoda) and incubated over 24 wk. Every two wk, the CO₂ release was measured and the litter was leached with demineralized H₂O. The following analyses were performed on the leachates: pH, total nitrogen, dissolved and particulate carbon, inorganic nitrogen (NH₄⁺ and NO₃⁻), phosphate, and biological counts (Protozoa, nematodes and Rotifera). The initial decomposition stages (the first 12 wk) were dominated by the litter quality factor: CO₂ release and nitrogen losses in leachates were higher and carbon losses lower in water leaching from the litter with low C:N ratio. Towards the late stages, when carbon mineralization decreased in the control litter, the animal effect emerged in litter with a high C:N ratio. Two groups appeared: (1) In the microflora + Protozoa units, carbon mineralization was reduced by 60% compared with the control litter. (2) In the diversified food web combinations, it became progressively higher with increasing complexity of the animal community and was enhanced by 30% compared with the control litter. This unexpected fundamental difference was explained by a change in the composition and activity of the microflora. Litter bleaching, respiration, C and N leaching and acidification rose with increasing animal complexity of the systems. Biological and chemical reasons explaining the invasion by white-rot fungi and its activity only in the material with a high C:N ratio are discussed. During the 24 wk, nitrogen and phosphorus mineralization was very low, indicating a high incorporation of the nutrient in the soil biomass.

Coviella, C.E., and J.T. Trumble. 1999. Effects of elevated atmospheric carbon dioxide on insect-plant interactions. *Conservation Biology* 13(4):700-712.

In the enriched carbon dioxide atmosphere expected in the next century, many, species of herbivorous insects will confront less nutritious host plants that will induce both lengthened larval developmental times and greater mortality. The limited data currently available suggest that the effect of increased atmospheric CO₂ on herbivory will be not only highly species-specific but also specific to each insect-plant system. Several scenarios can be predicted however. (1) local extinctions will occur; (2) the endangered species status as well as the pest status of

some insect species will change; (3) geographic distributions for some insect species will shift with host-plant ranges; and (4) changes in the population dynamics of affected insect species will influence their interactions with other insects and plants. For insect conservation purposes, it is critical to begin long-term studies on the effects of enhanced CO₂ levels on insect populations. An analysis of the available literature indicates that many orders containing insect species important for ecosystem conservation, and even those important as agricultural or medical pests, have not been examined. Without a major increase in research on this topic, we will be unprepared for the species changes that will occur, we will lose the opportunity to document just how some insects adapt to elevated CO₂ levels, and we will lack the information necessary for effective conservation efforts.

Cowling, S.A. 1999. Simulated effects of low atmospheric CO₂ on structure and composition of North American vegetation at the Last Glacial Maximum. *Global Ecology and Biogeography* 8(2):81-93.

1. Physiological experiments have indicated that the lower CO₂ levels of the last glaciation (200 $\mu\text{mol mol}^{-1}$) probably reduced plant water-use efficiency (WUE) and that they combined with increased aridity and colder temperatures to alter vegetation structure and composition at the Last Glacial Maximum (LGM). 2. The effects of low CO₂ on vegetation structure were investigated using BIOME3 simulations of leaf area index (LAI), and a two-by-two factorial experimental design (modern/LGM CO₂, modern/ LGM climate). 3. Using BIOME3, and a combination of lowered CO₂ and simulated LGM climate (from the NCAR-CCM1 model), results in the introduction of additional xeric vegetation types between open woodland and closed-canopy forest along a latitudinal gradient in eastern North America. 4. The simulated LAI of LGM vegetation was 25- 60% lower in many regions of central and eastern United States relative to modern climate, indicating that glacial vegetation was much more open than today. 5. Comparison of factorial simulations show that low atmospheric CO₂ has the potential to alter vegetation structure (LAI) to a greater extent than LGM climate. 6. If the magnitude of LAI reductions simulated for glacial North America were global, then low atmospheric CO₂ may have promoted atmospheric warming and increased aridity, through alteration of rates of water and heat exchange with the atmosphere.

Cowling, S.A., and R.F. Sage. 1998. Interactive effects of low atmospheric CO₂ and elevated temperature on growth, photosynthesis and respiration in *Phaseolus vulgaris*. *Plant, Cell and Environment* 21(4):427-435.

For most of the past 250 000 years, atmospheric CO₂ has been 30-50% lower than the current level of 360 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ air. Although the effects of CO₂ on plant performance are well recognized, the effects of low CO₂ in combination with abiotic stress remain poorly understood. In this study, a growth chamber experiment using a two-by-two factorial design of CO₂ (380 $\mu\text{mol mol}^{-1}$, 200 $\mu\text{mol mol}^{-1}$) and temperature (25/20 degrees C day/night, 36/29 degrees C) was conducted to evaluate the interactive effects of CO₂ and temperature

variation on growth, tissue chemistry and leaf gas exchange of *Phaseolus vulgaris*. Relative to plants grown at 380 $\mu\text{mol mol}^{-1}$ and 25/20 degrees C, whole plant biomass was 36% less at 380 $\mu\text{mol mol}^{-1}$ x 36/29 degrees C, and 37% less at 200 $\mu\text{mol mol}^{-1}$ x 25/20 degrees C. Most significantly, growth at 200 $\mu\text{mol mol}^{-1}$ x 36/29 degrees C resulted in 77% less biomass relative to plants grown at 380 $\mu\text{mol mol}^{-1}$ x 25/20 degrees C. The net CO₂ assimilation rate of leaves grown in 200 $\mu\text{mol mol}^{-1}$ x 25/20 degrees C was 40% lower than in leaves from 380 $\mu\text{mol mol}^{-1}$ x 25/20 degrees C, but similar to leaves in 200 $\mu\text{mol mol}^{-1}$ x 36/29 degrees C. The leaves produced in low CO₂ and high temperature respired at a rate that was double that of leaves from the 380 $\mu\text{mol mol}^{-1}$ x 25/20 degrees C treatment. Despite this, there was little evidence that leaves at low CO₂ and high temperature were carbohydrate deficient, because soluble sugars, starch and total non-structural carbohydrates of leaves from the 200 $\mu\text{mol mol}^{-1}$ x 36/29 degrees C treatment were not significantly different in leaves from the 380 $\mu\text{mol mol}^{-1}$ x 25/20 degrees C treatment. Similarly, there was no significant difference in percentage root carbon, leaf chlorophyll and leaf/root nitrogen between the low CO₂ x high temperature treatment and ambient CO₂ controls. Decreased plant growth was correlated with neither leaf gas exchange nor tissue chemistry. Rather, leaf and root growth were the most affected responses, declining in equivalent proportions as total biomass production. Because of this close association, the mechanisms controlling leaf and root growth appear to have the greatest control over the response to heat stress and CO₂ reduction in *P. vulgaris*.

Cowling, S.A., and M.T. Sykes. 1999. Physiological significance of low atmospheric CO₂ for plant- climate interactions. *Quaternary Research* 52(2):237-242.

Methods of palaeoclimate reconstruction from pollen are built upon the assumption that plant-climate interactions remain the same through time or that these interactions are independent of changes in atmospheric CO₂. The latter may be problematic because air trapped in polar ice caps indicates that atmospheric CO₂ has fluctuated significantly over at least the past 400,000 yr, and likely the last 1.6 million yr. Three other points indicate potential biases for vegetation-based climate proxies. First, C-3-plant physiological research shows that the processes that determine growth optima in plants (photosynthesis, mitochondrial respiration, photorespiration) are all highly CO₂-dependent, and thus were likely affected by the lower CO₂ levels of the last glacial maximum. Second, the ratio of carbon assimilation per unit transpiration (called water-use efficiency) is sensitive to changes in atmospheric CO₂ through effects on stomatal conductance and may have altered C-3-plant responses to drought. Third, leaf gas- exchange experiments indicate that the response of plants to carbon-depleting environmental stresses are strengthened under low CO₂ relative to today. This paper reviews the scope of research addressing the consequences of low atmospheric CO₂ for plant and ecosystem processes and highlights why consideration of the physiological effects of low atmospheric CO₂ on plant function is recommended for any future refinements to pollen- based palaeoclimatic reconstructions. Cox, P.M., R.A. Betts, C.B. Bunton, R.L.H. Essery, P.R. Rowntree,

and J. Smith. 1999. The impact of new land surface physics on the GCM simulation of climate and climate sensitivity. *Climate Dynamics* 15(3):183-203.

Recent improvements to the Hadley Centre climate model include the introduction of a new land surface scheme called "MOSES" (Met Office Surface Exchange Scheme). MOSES is built on the previous scheme, but incorporates in addition an interactive plant photosynthesis and conductance module, and a new soil thermodynamics scheme which simulates the freezing and melting of soil water, and takes account of the dependence of soil thermal characteristics on the frozen and unfrozen components. The impact of these new features is demonstrated by comparing 1 x CO₂ and 2 x CO₂ climate simulations carried out using the old (UKMO) and new (MOSES) land surface schemes. MOSES is found to improve the simulation of current climate. Soil water freezing tends to warm the high-latitude land in the northern Hemisphere during autumn and winter, whilst the increased soil water availability in MOSES alleviates a spurious summer drying in the mid-latitudes. The interactive canopy conductance responds directly to CO₂, suppressing transpiration as the concentration increases and producing a significant enhancement of the warming due to the radiative effects of CO₂ alone.

Craig, S.G., and K.J. Holmen. 1995. Uncertainties in future CO₂ projections. *Global Biogeochemical Cycles* 9(1):139-152.

The perceived budget imbalance in the global carbon cycle has been suggested to result from, among other processes, CO₂ fertilization of the terrestrial biosphere and/or enhanced regrowth of previously felled temperate forest. These two processes are incorporated into a box diffusion model of the ocean-atmosphere system coupled to a five-box terrestrial biosphere. The extent to which historical fossil fuel and land use change emission data can be reconciled with the observed atmospheric CO₂ concentration record is examined. Furthermore, the sensitivity of future CO₂ projections to the nature of the budget imbalance is investigated. It is found that the CO₂ record can accommodate a carbon budget balanced by CO₂ fertilization but that the balance with forest regrowth is more difficult. Future CO₂ projections are found to be sensitive to how the carbon budget is balanced, even relative to uncertainties in future emissions.

Cramer, M.D., Z.F. Gao, and S.H. Lips. 1999. The influence of dissolved inorganic carbon in the rhizosphere on carbon and nitrogen metabolism in salinity-treated tomato plants. *New Phytologist* 142(3):441-450.

The influence of variation in the concentration of dissolved inorganic carbon (DIC) in the form of CO₂ and HCO₃⁻ in the root media on the C and N metabolism of *Lycopersicon esculentum* cv. F144 was investigated under both saline and non-saline conditions. Tomato seedlings were grown in hydroponic culture (pH 6.5) with or without NaCl, and the root solution was aerated with either ambient CO₂ (360 $\mu\text{mol mol}^{-1}$) or CO₂- enriched air (5000 $\mu\text{mol mol}^{-1}$). Nitrate uptake and root tissue NO₃⁻ concentrations were increased slightly by elevated rhizosphere DIC concentrations in both control and salinity-treated plants. This is associated with 46% higher nitrate reductase activity in the roots of control plants supplied with elevated DIC than in

those supplied with ambient DIG. The activity of phosphoenolpyruvate carboxylase (PEPc) in vitro in control and salinity-treated plants was unaffected by the supply of elevated rhizosphere DIC concentrations. However, PEPc activity in vitro was considerably higher than the rates of PEPc activity in vivo reported previously, indicating that PEPc activity was not in itself a limitation on the provision of anaplerotic C. Therefore elevated DIC concentration in the rhizosphere stimulated the uptake of NO₃⁻ and provided alternative C skeletons for the assimilation of the NH₄⁺ resulting from NO₃⁻ reduction into amino acids within the roots. Salinity stimulated root glutamine synthetase (GS) activity up to double that in control plants. Furthermore, elevated DIC caused an increase in leaf and root GS activity of control plants while inhibiting GS activity in the roots of salinity-treated plants. Glutamine:2-oxoglutarate aminotransferase (GOGAT) activity of salinity-treated plants was doubled by elevated rhizosphere DIC concentrations. These changes in GS and GOGAT activity must reflect changes in amino acid synthesis. Under saline conditions the xylem transport of NO₃⁻ is partly blocked and a larger root assimilation develops, requiring not only the transamination of 2-oxoglutarate to glutamate but also that of oxaloacetate to aspartate and the transamidation of aspartate to asparagine.

Cramer, M.D., and S.H. Lips. 1995. Enriched rhizosphere CO₂ concentrations can ameliorate the influence of salinity on hydroponically grown tomato plants. *Physiologia Plantarum* 94(3):425-432.

Our previous work indicated that salinity caused a shift in the predominant site of nitrate reduction and assimilation from the shoot to the root in tomato plants. In the present work we tested whether an enhanced supply of dissolved inorganic carbon (DIC, CO₂ + HCO₃⁻) to the root solution could increase anaplerotic provision of carbon compounds for the increased nitrogen assimilation in the root of salinity-stressed *Lycopersicon esculentum* (L.) Mill. cv. F144. The seedlings were grown in hydroponic culture with 0 or 100 mM NaCl and aeration of the root solution with either ambient or CO₂-enriched air (5 000 µmol mol⁻¹). The salinity-treated plants accumulated more dry weight and higher total N when the roots were supplied with CO₂-enriched aeration than when aerated with ambient air. Plants grown with salinity and enriched DIC also had higher rates of NO₃⁻ uptake and translocated more NO₃⁻ and reduced N in the xylem sap than did equivalent plants grown with ambient DIC. Incorporation of DIC was measured by supplying a 1-h pulse of (HCO₃⁻)-C-14 to the roots followed by extraction with 80% ethanol. Enriched DIC increased root incorporation of DIC 10- fold in both salinized and non-salinized plants. In salinity-stressed plants, the products of dissolved inorganic C-14 were preferentially diverted into amino acid synthesis to a greater extent than in non-salinized plants in which label was accumulated in organic acids. It was concluded that enriched DIC can increase the supply of N and anaplerotic carbon for amino acid synthesis in roots of salinized plants. Thus enriched DIC could relieve the limitation of carbon supply for ammonium assimilation and thus ameliorate the influence of salinity on NO₃⁻ uptake and assimilation as well as on plant growth.

Cramer, M.D., and S.H. Lips. 1995. The influence of enriched root-zone CO₂ concentrations on growth, nitrogen metabolism and root HCO₃⁻ incorporation in salinity stressed *Lycopersicon esculentum*. *Acta*

Phytopathologica Et Entomologica Hungarica 30(1-2):105-118.

Tomato plants grown with salinity reduce/assimilate a larger proportion of NO₃⁻ taken up in the roots than do non-salinized plants. We investigated whether enriched CO₂ in the root solution could increase anaplerotic provision of carbon for root nitrogen assimilation in salinity stressed plants. Tomato seedlings were grown in hydroponic culture with and without 100 mM NaCl and with aeration of the root solution with either ambient or CO₂ enriched air (5000 µmol mol⁻¹). The salinity treated plants accumulated more dry weight and higher total N when the roots were supplied with CO₂ enriched aeration than when aerated with ambient air. Concentrations of K⁺ in the leaves and roots were higher in plants treated with enriched CO₂. Enriched root-zone CO₂ increased root incorporation of dissolved inorganic carbon (DIC). In salinity stressed plants the products of (DIC)-C-14 were diverted into amino acid synthesis to a greater extent than in non-salinized plants. It was concluded that enriched root-zone DIC could provide an increased anaplerotic source of carbon for amino acid synthesis in roots, partially ameliorating the influence of salinity on plant growth.

Cramer, M.D., and M.B. Richards. 1999. The effect of rhizosphere dissolved inorganic carbon on gas exchange characteristics and growth rates of tomato seedlings. *Journal of Experimental Botany* 50(330):79-87.

The possibility that an enhanced supply of dissolved inorganic carbon (DIC = CO₂ + HCO₃⁻) to the root solution could increase the growth of *Lycopersicon esculentum* (L.) Mill. cv. F144 was investigated under both saline and non-saline root medium conditions. Tomato seedlings were grown in hydroponic culture with and without NaCl and the root solution was aerated with CO₂ concentrations in the range between 0 and 5000 µmol mol⁻¹. The biomass of both control and salinity-stressed plants grown at high temperatures (daily maximum of 37 degrees C) and an irradiance of 1500 µmol m⁻² s⁻¹ was increased by up to 200% by enriched rhizosphere DIC. The growth rates of plants grown with irradiances of less than 1000 µmol m⁻² s⁻¹ were increased by elevated rhizosphere DIC concentrations only when grown at high shoot temperatures (35 degrees C) or with salinity (28 degrees C). At high light intensities, the photosynthetic rate, the CO₂ and light-saturated photosynthetic rate (J(max)) and the stomatal conductance of plants grown at high light intensity were lower in plants supplied with enriched compared to ambient DIC. This was interpreted as 'down-regulation' of the photosynthetic system in plants supplied with elevated DIC. Labelled organic carbon in the xylem sap derived from root (DIC)-C-14 incorporation was found to be sufficient to deliver carbon to the shoot at rates equivalent to 1% and 10% of the photosynthetic rate of the plants supplied with ambient- and enriched-DIC, respectively. It was concluded that organic carbon derived from DIC incorporation and translocated in the xylem from the root to the shoot may provide a source of carbon for the shoots, especially under conditions where low stomatal conductance may be advantageous, such as salinity stress, high shoot temperatures and high light intensities.

Cramer, M.D., N.A. Savidov, and S.H. Lips. 1996. The influence of enriched rhizosphere CO₂ on N uptake and metabolism in wild-type and NR-deficient barley plants. *Physiologia Plantarum* 97(1):47-54.

Positive influences of high concentrations of dissolved inorganic carbon (DIC) in the growth medium of salinity- stressed plants are associated with carbon assimilation through phosphoenolpyruvate carboxylase (PEPc) activity in roots; and also in salinity-stressed tomato plants, enriched CO₂ in the rhizosphere increases NO₃(-)-uptake. In the present study, wild-type and nitrate reductase-deficient plants of barley (*Hordeum vulgare* L. cv. Steptoe) were used to determine whether the influence of enriched CO₂ on NO₃(-)-uptake and metabolism is dependent on the activity of nitrate reductase (NR) in the plant. Plants grown in NH₄⁺ and aerated with ambient air, were transferred to either NO₃⁻ or NH₄⁺ solutions and aerated with air containing between 0 and 6500 $\mu\text{mol mol}^{-1}$ CO₂. Nitrogen uptake and tissue concentrations of NO₃⁻ and NH₄⁺ were measured as well as activities of NR and PEPc. The uptake of NO₃⁻ by the wild-type was increased by increasing CO₂. This was associated with increased in vitro NR activity, but increased uptake of NO₃⁻ was found also in the NR-deficient genotype when exposed to high CO₂ concentrations; so that the influence of CO₂ on NO₃⁻ uptake was independent of the reduction of NO₃⁻ and assimilation into amino acids. The increase in uptake of NO₃⁻ in wild-type plants with enriched CO₂ was the same at pH 7 as at pH 5, indicating that the relative abundance of HCO₃⁻ or CO₂ in the medium did not influence NO₃⁻ uptake. Uptake of NH₄⁺ was decreased by enriched CO₂ in a pH (5 or 7) independent fashion. Thus NO₃⁻ and NH₄⁺ uptakes are influenced by the CO₂ component of DIC independently of anaplerotic carbon provision for amino acid synthesis, and CO₂ may directly affect the uptake of NO₃⁻ and NH₄⁺ in ways unrelated to the NR activity in the tissue.

Crick, S.G., and R. McConchie. 1999. Ethanol vapour reduces leaf blackening in cut flower *Protea* 'Pink Ice' stems. *Postharvest Biology and Technology* 17(3):227-231.

The effect of ethanol vapour on postharvest leaf blackening of *Protea* *susannae* X *compacta* 'Pink Ice' stems stored in plastic bags under darkness at 20 degrees C (+/- 1 degrees C) was assessed over a 19 day period. Application of ethanol vapour to the stems significantly reduced leaf blackening. Stems exposed to 5.6 g ethanol kg⁻¹ stem weight, had the least amount of leaf blackening with less than 20% of leaves blackened by day 14. In contrast, the control stems had 50% of leaves blackened by day 9, and 100% by day 15. The highest ethanol treatment at 11.2 g ethanol kg⁻¹ stem weight caused substantial blackening within the first 24 h of the treatment being applied. Ethanol vapour concentrations in the bag head space decreased rapidly in comparison with the bags with no stems, suggesting that ethanol was rapidly taken up by the stems. Only the highest ethanol treatment had detectable levels of ethanol in the bags after 17 days, and ethanol vapour had no effect on CO₂ concentration in the bag head space. Carbon dioxide concentrations ranged between 1.0 and 2.5%. The rate of leaf blackening on the bagged stems without ethanol was significantly less than on stems not in bags, suggesting that elevated CO₂ levels may have contributed to reduced blackening. Crookshanks, M., G. Taylor, and M. Broadmeadow. 1998. Elevated CO₂ and tree root growth: contrasting responses in *Fraxinus excelsior*, *Quercus petraea* and *Pinus sylvestris*. *New Phytologist* 138(2):241-250.

Root growth and respiration in elevated CO₂ (700 $\mu\text{mol mol}^{-1}$) was studied in three tree species, *Fraxinus excelsior* L., *Quercus petraea* L.

and *Pinus sylvestris* L. grown in open-top chambers (OTCs) during a long-term exposure (20 months), during which root systems were allowed to develop without restriction imposed by pots. Root growth, measured as root length using root in-growth bags was increased significantly in trees exposed to elevated CO₂, although the magnitude of the response differed considerably between species and with time of sampling, the greatest effect observed after 6 months in ash (ratio of elevated:ambient, e:a; 3.40) and the smallest effect observed in oak (e:a; 1.95). This was accompanied by changes in specific root length, with a significant decrease in all species after 6 months, suggesting that root diameter or root density were increased in elevated CO₂. Increases in root length might have resulted from an acceleration in root cell expansion, since epidermal cell size was significantly increased in the zone of elongation in ash root tips ($P < 0.05$). Contrasting effects of elevated CO₂ were observed for root carbohydrates, with significant increases in soluble sugars for all species ($P < 0.05$), but both increases and decreases in starch content were observed, depending on species, and producing a significant interaction between species and CO₂ ($P < 0.001$). Exposure to elevated CO₂ increased the total root d. wt for whole trees of all three species after 8 months of exposure, although the magnitude of this effect, in contrast to the root in-growth study, was greatest in Scots pine and smallest in ash. No significant effect of elevated CO₂ was observed on the root:shoot ratio. Further detailed analysis of whole root systems after 20 months confirmed that species differences in root responses to elevated CO₂ were apparent, with increased coarse and fine root production in elevated CO₂ for Scots pine and ash respectively. Lateral root number was increased in elevated CO₂ for all species, as was mean root diameter. Root respiration rates were significantly reduced in elevated CO₂ for all three species. These results provide firm evidence that exposure of trees to future CO₂ concentrations will have large effects on root system development, growth, carbohydrate status and respiration. The magnitude and direction of such effects will differ, depending on species. The consequences of such responses for the three species studied are discussed.

Crookshanks, M., G. Taylor, and L. Dolan. 1998. A model system to study the effects of elevated CO₂ on the developmental physiology of roots: the use of *Arabidopsis thaliana*. *Journal of Experimental Botany* 49(320):593-597.

Three developmental changes were observed in the roots of *Arabidopsis thaliana* (Columbia) when shoots were exposed to elevated CO₂. (i) The allometric coefficient, k, was enhanced significantly ($P < 0.001$), (ii) primary root length and root extension rate were enhanced ($P < 0.001$). Accelerated cortical cell expansion contributed to this effect and was associated with increased cell wall extensibility, measured as % plasticity. (iii) Lateral root formation and extension were also increased in elevated CO₂ ($P < 0.05$). These results illustrate that root growth and structure was altered following exposure to elevated CO₂. The changes observed suggest that *Arabidopsis* provides a useful model which should, in future, be amenable to study using appropriate mutants allowing the genetic basis of the responses to be identified.

Crosson, P.R., and N.J. Rosenberg. 1993. An overview of the mink study. *Climatic Change* 24(1-2):159-173.

Highlights of the previous papers in this series are reviewed. Methodology developed for the MINK study has improved the ability of impacts analysis to deal with questions of (1) spatial and temporal variability in climate change; (2) CO₂-enrichment effects; (3) the reactions of complex enterprises (farms and forests) to climate change and their ability to adjust and adapt; and (4) integrated effects on current and, more particularly, on future regional economies. The methodology also provides for systematic study of adjustment and adaptation opportunities and of the inter-industry linkages that determine what the overall impacts on the regional economy might be. The analysis shows that with a 1930s 'dust bowl' climate the region-wide economic impacts would be small, after adjustments in affected sectors. In this final paper we consider whether synergistic effects among sectoral impacts and more severe climate change scenarios might alter this conclusion. The MINK analysis, as is, leads to the conclusion that a strong research capacity will be required to ensure that technologies facilitating adaptation to climate change will be available when needed. The capacity to deal with climate change also requires an open economy allowing for free trade and movement of people and for institutions that protect unpriced environmental values. More severe climate scenarios and negative synergisms can only strengthen these conclusions.

Crowley, T.J., and S.K. Baum. 1997. Effect of vegetation on an ice-age climate model simulation. *Journal of Geophysical Research-Atmospheres* 102(D14):16463-16480.

A growing number of studies suggest that vegetation changes can significantly influence regional climate variations. Herein we utilize a climate model (GENESIS) with a land surface vegetation package to evaluate the potential role of the very large vegetation changes that occurred during the last glacial maximum (LGM). In particular, we focus on the potential response to a significant reduction in the area of tropical rainforest. Simulations employed a global vegetation reconstruction for the LGM and Climate/Long-Range Investigation, Mapping and Prediction (CLIMAP) sea surface temperature (SST) estimates. Results indicate that expansion of dryland vegetation causes a 15-30% additional LGM cooling for Australia (0.4 degrees C) and Africa (0.9 degrees C), respectively. Turnover from conifer to tundra also causes cooling of 2 degrees-4 degrees C or more in western Europe and Siberia. However, for the largest rainforest area (Amazon Basin), inclusion of realistic vegetation increased modeled temperatures 2 degrees-4 degrees C and decreased precipitation by 10-35%. These latter results are similar to those obtained with sensitivity experiments of the effects of future Amazon deforestation. Initial assessment of the potential effect of decreased stomatal resistance due to lower ice age CO₂ levels indicates little significant response to this effect. Comparison of model-predicted low-elevation LGM temperature changes with estimates from proxy data indicate that inclusion of realistic vegetation estimates for the LGM results in slightly more than 50% agreement between models and data for low-elevation sites in low-mid latitudes. Data at variance with model predictions would appear to be explainable by considering additional changes in vegetation, ice age dust, or a 1 degree-2 degrees C cooling below CLIMAP values. This conclusion is at variance with a 3 degrees-4 degrees C tropical cooling suggested by some studies for explaining estimated land temperature changes during the LGM. In some western European sites model temperatures are colder than proxy data by 2 degrees-8 degrees C. This model-data discrepancy may be explained by less sea ice in the subpolar North Atlantic than stipulated by CLIMAP, a conclusion consistent with new marine data from that region.

Crush, J.R. 1993. Hydrogen evolution from root-nodules of trifolium-repens and medicago-sativa plants grown under elevated atmospheric co₂. *New Zealand Journal of Agricultural Research* 36(2):177-183.

Nitrogenase activity and hydrogen (H₂) evolution from nodules of *Trifolium repens* L. and *Medicago sativa* L. were measured on plants grown under 700 or 350 µl/l atmospheric CO₂ and day/night temperatures of 18/13-degrees-C or 28/23-degrees-C. Assays were done after 39, 47, and 54 days' exposure to the treatments. In *Trifolium*, nitrogenase activity/plant was stimulated by elevated CO₂ and higher temperatures but in *Medicago* only temperature had an effect. Hydrogen emission/plant was greater in *Trifolium* plants grown at 700 µl/l CO₂ than in plants at 350 µl/l CO₂, but in *Medicago*, H₂ emission rates did not respond to elevated CO₂. Elevated CO₂ reduced nodule relative efficiency (RE) in 39-day-old *Trifolium* plants growing at 18/13-degrees-C, but not under other conditions. It is concluded that predicted future CO₂ concentration will lead to a greater contribution from legume nitrogen (N) fixation to global H₂ sources. The magnitude of the increase will be influenced by the legume species involved and temperature.

Cruz, C., S.H. Lips, and M.A. Martinsloucao. 1993. The effect of nitrogen-source on photosynthesis of carob at high co₂ concentrations. *Physiologia Plantarum* 89(3):552-556.

Carob seedlings (*Ceratonia siliqua* L. cv. *Mulata*), fed with nitrate or ammonium, were grown in growth chambers containing two levels of CO₂ (360 or 800 µl/l (-1)), three root temperatures (15, 20 or 25 degrees C), and the same shoot temperature (20/24 degrees C, night/day temperature). The response of the plants to CO₂ enrichment was affected by environmental factors such as the type of inorganic nitrogen in the medium and root temperature. Increasing root temperature enhanced photosynthesis rate more in the presence of nitrate than in the presence of ammonium. Differences in photosynthetic products were also observed between nitrate- and ammonium-fed carob seedlings. Nitrate-grown plants showed an enhanced content of sucrose, while ammonium led to enhanced storage of starch. Increase in root temperature caused an increase in dry mass of the plants of similar proportions in both nitrogen sources. The enhancement of the rates of photosynthesis by CO₂ enrichment was proportionally much larger than the resulting increases

in dry mass production when nitrate was the nitrogen source. Ammonium was the preferred nitrogen source for carob at both ambient and high CO₂ concentrations. The level of photosynthesis of a plant is limited not only by atmospheric CO₂ concentration but also by the nutritional and environmental conditions of the root.

Cruz, C., S.H. Lips, and M.A. Martins-Loucao. 1997. Changes in the morphology of roots and leaves of carob seedlings induced by nitrogen source and atmospheric carbon dioxide. *Annals of Botany* 80(6):817-823.

Carob seedlings were grown hydroponically for 9 weeks under 360 and 800 $\mu\text{mol L}^{-1}$ CO₂. One of two nitrogen sources, nitrate or ammonium, was added to the nutrient medium at concentrations of 3 mol m^{-3} . Root systems of the developing plants supplied with nitrate compared to those supplied with ammonium were characterized by: (a) more biomass on the lower part of the root; (b) fewer lateral roots of first and second order; (c) longer roots; (d) higher specific root length; (e) a smaller root diameter. The morphology of the root systems of nitrate-fed plants changed in the presence of elevated carbon dioxide concentrations, resembling, more closely, that of ammonium-fed plants. Total leaf area was higher in ammonium- than in nitrate-fed plants. Nitrate-fed plants had greater total leaf area in the presence of high carbon dioxide than in normal CO₂, due to an increase in epidermal cell size that led to development of larger leaflets with lower stomatal frequency. The observed changes in the morphology of roots and shoots agreed with the results observed for total biomass production. Nitrate-fed plants increased their biomass production by 100% in the presence of elevated CO₂ compared to 15% in ammonium-fed plants, indicating that the response of carob to high CO₂ concentrations is very dependent on the nitrogen source. Under elevated CO₂, nitrate grown plants had a larger content of sucrose in both roots and shoots, while no significant difference was observed in the content of sucrose in ammonium-grown plants, whether in ambient or enriched carbon dioxide. Hence, the differences in soluble carbohydrate contents can, at least partly, account for differences in root and shoot morphology. (C) 1997 Annals of Botany Company.

Csintalan, Z., Z. Tuba, H.K. Lichtenthaler, and J. Grace. 1996. Reconstitution of photosynthesis upon rehydration in the desiccated leaves of the poikilochlorophyllous shrub *Xerophyta scabrida* at elevated CO₂. *Journal of Plant Physiology* 148(3-4):345-350.

We report the resynthesis of the photosynthetic apparatus and the restoration of its function in the monocotyledonous C-3 shrub *Xerophyta scabrida* (Pax) Th. Dur. et Schinz (Velloziaceae) following a period of 5 years in the air-dried state. Detached leaves were rehydrated at present (350 $\mu\text{mol mol}^{-1}$) and at elevated CO₂ (700 $\mu\text{mol mol}^{-1}$). Elevated CO₂ concentration had no effect on the rate of rehydration, nor on the de novo resynthesis pattern of the chlorophylls and carotenoids or the development of photochemical activity in the reviving desiccated leaves. The time required to fully reconstitute the photosynthetic apparatus and its function in the air-dried achlorophyllous leaves on rehydration did not differ at the two CO₂ concentrations. However, respiratory activity during rehydration was more intensive and of longer duration at high CO₂ and net CO₂ assimilation first became apparent 12 h later than in the leaves rehydrated at present CO₂. After reconstitution

of the photosynthetic apparatus, the net CO₂ assimilation rate was higher in the high CO₂ leaves, however it rapidly declined to a value lower than that in the present CO₂ plants due to acclimation. This acclimation to elevated CO₂ occurred only after complete reconstitution of the photosynthetic apparatus. The downward acclimation of photosynthesis was accompanied by a decrease in content of photosynthetic pigments (chlorophyll a + b and carotenoids x + c) and stomatal conductance. The initial slope of the A/c(i) curve for the high CO₂ leaves was much lower and net CO₂ assimilation rates were lower at all c(i)'s than in the present CO₂ plants. The rate of respiration also decreased and the C- balance of the high CO₂ leaves therefore remained similar to that of leaves in present CO₂.

Cui, M., P.M. Miller, and P.S. Nobel. 1993. CO₂ exchange and growth of the crassulacean acid metabolism plant *Opuntia ficus-indica* under elevated CO₂ in open-top chambers. *Plant Physiology* 103(2):519-524.

CO₂ uptake, water vapor conductance, and biomass production of *Opuntia ficus-indica*, a Crassulacean acid metabolism species, were studied at CO₂ concentrations of 370, 520, and 720 $\mu\text{mol L}^{-1}$ in open-top chambers during a 23-week period. Nine weeks after planting, daily net CO₂ uptake for basal cladodes at 520 and 720 $\mu\text{mol L}^{-1}$ of CO₂ was 76 and 98% higher, respectively, than at 370 $\mu\text{mol L}^{-1}$. Eight weeks after daughter cladodes emerged, their daily net CO₂ uptake was 35 and 49% higher at 520 and 720 $\mu\text{mol L}^{-1}$ of CO₂, respectively, than at 370 $\mu\text{mol L}^{-1}$. Daily water-use efficiency was 88% higher under elevated CO₂ for basal cladodes and 57% higher for daughter cladodes. The daily net CO₂ uptake capacity for basal cladodes increased for 4 weeks after planting and then remained fairly constant, whereas for daughter cladodes, it increased with cladode age, became maximal at 8 to 14 weeks, and then declined. The percentage enhancement in daily net CO₂ uptake caused by elevated CO₂ was greatest initially for basal cladodes and at 8 to 14 weeks for daughter cladodes. The chlorophyll content per unit fresh weight of chlorenchyma for daughter cladodes at 8 weeks was 19 and 62% lower in 520 and 720 $\mu\text{mol L}^{-1}$ of CO₂, respectively, compared with 370 $\mu\text{mol L}^{-1}$. Despite the reduced chlorophyll content, plant biomass production during 23 weeks in 520 and 720 $\mu\text{mol L}^{-1}$ of CO₂ was 21 and 55% higher, respectively, than at 370 $\mu\text{mol L}^{-1}$. The root dry weight nearly tripled as the CO₂ concentration was doubled, causing the root/shoot ratio to increase with CO₂ concentration. During the 23-week period, elevated CO₂ significantly increased CO₂ uptake and biomass production of *O. ficus-indica*.

Cui, M., and P.S. Nobel. 1994. Gas-exchange and growth-responses to elevated CO₂ and light levels in the CAM species *Opuntia ficus-indica*. *Plant, Cell and Environment* 17(8):935-944.

Gas exchange and dry-weight production in *Opuntia ficus-indica*, a CAM species cultivated worldwide for its fruit and cladodes, were studied in 370 and 750 $\mu\text{mol mol}^{-1}$ CO₂ at three photosynthetic photon flux densities (PPFD: 5, 13 and 20 $\text{mol m}^{-2} \text{d}^{-1}$). Elevated CO₂ and PPFD enhanced the growth of basal cladodes and roots during the 12-week study. A rise in the PPFD increased the growth of daughter cladodes; elevated CO₂ enhanced the growth of first-daughter cladodes but decreased the growth of the second-daughter cladodes produced on them. CO₂ enrichment enhanced daily net CO₂ uptake during the initial 8 weeks after planting for both basal and first- daughter cladodes. Water

vapour conductance was 9 to 15% lower in 750 than in 370 $\mu\text{mol}(-1) \text{CO}_2$. Cladode chlorophyll content was lower in elevated CO_2 and at higher PPFD. Soluble sugar and starch contents increased with time and were higher in elevated CO_2 and at higher PPFD. The total plant nitrogen content was lower in elevated CO_2 . The effect of elevated CO_2 on net CO_2 uptake disappeared at 12 weeks after planting, possibly due to acclimation or feedback inhibition, which in turn could reflect decreases in the sink strength of roots. Despite this decreased effect on net CO_2 uptake, the total plant dry weight at 12 weeks averaged 32% higher in 750 than in 370 $\mu\text{mol}(-1) \text{CO}_2$. Averaged for the two CO_2 treatments, the total plant dry weight increased by 66% from low to medium PPFD and by 37% from medium to high PPFD.

Cure, J.D., T.W. Rufty, and D.W. Israel. 1991. Assimilate relations in source and sink leaves during acclimation to a CO_2 -enriched atmosphere. *Physiologia Plantarum* 83(4):687-695.

Evidence from previous studies suggested that adjustments in assimilate formation and partitioning in leaves might occur over time when plants are exposed to enriched atmospheric CO_2 . We examined assimilate relations of source (primary unifoliate) and developing sink (second mainstem trifoliate) leaves of soybean [*Glycine max* (L.) Merr. cv. Lee] plants for 12 days after transfer from a control (350- $\mu\text{mol}(-1) \text{CO}_2$) to a high (700- $\mu\text{mol}(-1) \text{CO}_2$) environment. Similar responses were evident in the two leaf types. Net CO_2 exchange rate (CER) immediately increased and remained elevated in high CO_2 . Initially, the additional assimilate at high CO_2 levels in the light and was utilized in the subsequent dark period. After approximately 7 days, assimilate export in the light began to increase and by 12 days reached rates 3 to 5 times that of the control. In the developing sink leaf, high rates of export in the light occurred as the leaf approached full expansion. The results indicate that a specific acclimation process occurs in source leaves which increases the capacity for assimilate export in the light phase of the diurnal cycle as plants adjust to enriched CO_2 and a more rapid growth rate.

Curtis, P.S. 1996. A meta-analysis of leaf gas exchange and nitrogen in trees grown under elevated carbon dioxide. *Plant, Cell and Environment* 19(2):127-137.

The response of trees to rising atmospheric CO_2 concentration ($[\text{CO}_2]$) is of concern to forest ecologists and global carbon modellers and is the focus of an increasing body of research work. I review studies published up to May 1994, and several unpublished works, which reported at least one of the following: net CO_2 assimilation (A), stomatal conductance (g(s)), leaf dark respiration (R(d)), leaf nitrogen or specific leaf area (SLA) in woody plants grown at <400 $\mu\text{mol}(-1) \text{CO}_2$ or at 600-800 $\mu\text{mol}(-1) \text{CO}_2$. The resulting data from 41 species were

categorized according to growth conditions (unstressed versus stressed), length of CO_2 exposure, pot size and exposure facility [growth chamber (GC), greenhouse (GH), or open-top chamber (OTC)] and interpreted using meta-analytic methods. Overall, A showed a large and significant increase at elevated $[\text{CO}_2]$ but length of CO_2 exposure and the exposure facility were important modifiers of this response. Plants exposed for <50 d had a significantly greater response, and those from GCs had a significantly lower response than plants from longer exposures or from OTC studies. Negative acclimation of A was significant and general among stressed plants, but in unstressed plants was influenced by length of CO_2 exposure, the exposure facility and/or pot size. Growth at elevated $[\text{CO}_2]$ resulted in moderate reductions in g(s) in unstressed plants, but there was no significant effect of CO_2 on g(s) in stressed plants. Leaf dark respiration (mass or area basis) was reduced strongly by growth at high $[\text{CO}_2]$, while leaf N was reduced only when expressed on a mass basis. This review is the first meta-analysis of elevated CO_2 studies and provides statistical confirmation of several general responses of trees to elevated $[\text{CO}_2]$. It also highlights important areas of continued uncertainty in our understanding of these responses.

Curtis, P.S., A.A. Snow, and A.S. Miller. 1994. Genotype-specific effects of elevated CO_2 on fecundity in wild radish (*Raphanus-raphanistrum*). *Oecologia* 97(1):100-105.

Rising atmospheric CO_2 may lead to natural selection for genotypes that exhibit greater fitness under these conditions. The potential for such evolutionary change will depend on the extent of within-population genetic variation in CO_2 responses of wild species. We tested for heritable variation in CO_2 -dependent life history responses in a weedy, cosmopolitan annual, *Raphanus raphanistrum*. Progeny from five paternal families were grown at ambient and twice ambient CO_2 using outdoor open-top chambers (160 plants per CO_2 treatment). Elevated CO_2 stimulated net assimilation rates, especially in plants that had begun flowering. Across paternal families, elevated CO_2 led to significant increases in flower and seed production (by 22% and 13% respectively), but no effect was seen on time to bolting, leaf area at bolting, fruit set, or number of seeds per fruit. Paternal families differed in their response to the CO_2 treatment: in three families there were no significant CO_2 effects, while in one family lifetime fecundity increased by > 50%. These genotype-specific effects altered fitness rankings among the five paternal families. Although we did not detect a significant genotype X CO_2 interaction, our results provide evidence for heritable responses to elevated CO_2 . In a subset of plants, we found that the magnitude of CO_2 effects on fecundity was also influenced by soil fertility.

Curtis, P.S., and J.A. Teeri. 1992. Seasonal responses of leaf gas-

exchange to elevated carbon- dioxide in populus-grandidentata. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 22(9):1320-1325.

Rising atmospheric carbon dioxide concentrations may have important consequences for forest ecosystems. We studied above- and below-ground growth and leaf gas exchange responses of *Populus grandidentata* Michx. to elevated CO₂ under natural forest conditions over the course of a growing season. Recently emerged *P. grandidentata* seedlings were grown in native, nutrient-poor soils at ambient and twice ambient (707 mubar (1 bar = 100 kPa)) CO₂ partial pressure for 70 days in open-top chambers in northern lower Michigan. Total leaf area and shoot and root dry weight all increased in high CO₂ grown plants. Photosynthetic light and CO₂ response characteristics were measured 28, 45, and 68 days after exposure to elevated CO₂. In ambient grown plants, light saturated assimilation rates increased from day 28 to day 45 and then declined at day 68 (15 September). This late-season decline, typical of senescing *Populus* leaves, was due both to a decrease in the initial slope of the net CO₂ assimilation versus intercellular CO₂ Partial pressure relationship and to decreased CO₂ saturated assimilation rates. Specific leaf nitrogen (mg N . (cm² leaf area)⁻¹) did not change during this period, although leaf carbon content and leaf weight (mg . cm⁻²) both increased. In ambient grown plants stomatal conductance also declined at day 68. In contrast, plants grown at elevated CO₂ showed no late- season decline in photosynthetic capacity or changes in leaf weight, suggesting a delay in senescence with long-term exposure to high CO₂. High CO₂ grown plants also maintained photosynthetic sensitivity to increasing C(i) throughout the exposure period, while ambient CO₂ grown plants were insensitive to C(i) above 400 mubar on day 68. These results indicate the potential for direct CO₂ fertilization of *P. grandidentata* in the field and provide evidence for a new mechanism by which elevated atmospheric CO₂ could influence seasonal carbon gain.

Curtis, P.S., C.S. Vogel, K.S. Pregitzer, D.R. Zak, and J.A. Teeri. 1995. Interacting effects of soil fertility and atmospheric co₂ on leaf-area growth and carbon gain physiology in populus X euramericana (dode) guinier. *New Phytologist* 129(2):253-263.

Two important processes which may limit productivity gains in forest ecosystems with rising atmospheric CO₂ are reduction in photosynthetic capacity following prolonged exposure to high CO₂ and diminution of positive growth responses when soil nutrients, particularly N, are limiting. To examine the interacting effects of soil fertility and CO₂ enrichment on photosynthesis and growth in trees we grew hybrid poplar (*Populus x euramericana*) for 158 d in the field at ambient and twice ambient CO₂ and in soil with low or high N availability. We measured the timing and rate of canopy development, the seasonal dynamics of leaf level photosynthetic capacity, respiration, and N and carbohydrate concentration, and final above- and belowground dry weight. Single leaf net CO₂ assimilation (A) increased at elevated CO₂ over the majority of the growing season in both fertility treatments. At high fertility, the maximum size of individual leaves, total leaf number, and seasonal leaf area duration (LAD) also increased at elevated CO₂, leading to a 49% increase in total dry weight. In contrast, at low fertility leaf area growth was unaffected by CO₂ treatment. Total dry weight nonetheless increased 25% due to CO₂ effects on A. Photosynthetic capacity (A at constant internal p(CO₂), (C-i)) was reduced in high CO₂ plants after 100 d growth at low fertility and 135 d growth at high fertility. Analysis of A responses to changing C-i indicated that this negative adjustment of photosynthesis was due to a reduction in the maximum rate of CO₂ fixation by Rubisco. Maximum rate of electron transport and phosphate

regeneration capacity were either unaffected or declined at elevated CO₂. Carbon dioxide effects on leaf respiration were most pronounced at high fertility, with increased respiration mid-season and no change (area basis) or reduced (mass basis) respiration late- season in elevated compared to ambient CO₂ plants. This temporal variation correlated with changes in leaf N concentration and leaf mass per area. Our results demonstrate the importance of considering both structural and physiological pathways of net C gain in predicting tree responses to rising CO₂ under conditions of suboptimal soil fertility.

Curtis, P.S., and X.Z. Wang. 1998. A meta-analysis of elevated CO₂ effects on woody plant mass, form, and physiology. *Oecologia* 113(3):299-313.

Quantitative integration of the literature on the effect of elevated CO₂ on woody plants is important to aid our understanding of forest health in coming decades and to better predict terrestrial feedbacks on the global carbon cycle. We used meta-analytic methods to summarize and interpret more than 500 reports of effects of elevated CO₂ on woody plant biomass accumulation and partitioning, gas exchange, and leaf nitrogen and starch content. The CO₂ effect size metric we used was the log-transformed ratio of elevated compared to ambient response means weighted by the inverse of the variance of the log ratio. Variation in effect size among studies was partitioned according to the presence of interacting stress factors, length of CO₂ exposure, functional group status, pot size, and type of CO₂ exposure facility. Both total biomass (WT) and net CO₂ assimilation (A) increased significantly at about twice ambient CO₂, regardless of growth conditions. Low soil nutrient availability reduced the CO₂ stimulation of WT by half, from + 31 % under optimal conditions to + 16 %, while low light increased the response to + 52 %. We found no significant shifts in biomass allocation under high CO₂. Interacting stress factors had no effect on the magnitude of responses of A to CO₂, although plants grown in growth chambers had significantly lower responses (+ 19 %) than those grown in greenhouses or in open-top chambers (+ 54 %). We found no consistent evidence for photosynthetic acclimation to CO₂ enrichment except in trees grown in pots < 0.51 (- 36 %) and no significant CO₂ effect on stomatal conductance. Both leaf dark respiration and leaf nitrogen were significantly reduced under elevated CO₂ (- 18 % and - 16 % respectively, data expressed on a leaf mass basis), while leaf starch content increased significantly except in low nutrient grown gymnosperms. Our results provide robust, statistically defensible estimates of elevated CO₂ effect sizes against which new results may be compared or for use in forest and climate model parameterization.

Curtis, P.S., D.R. Zak, K.S. Pregitzer, and J.A. Teeri. 1994. Aboveground and belowground response of populus grandidentata to elevated atmospheric co₂ and soil n-availability. *Plant and Soil* 165(1):45-51.

Soil N availability may play an important role in regulating the long-term responses of plants to rising atmospheric CO₂ partial pressure. To further examine the linkage between above- and belowground C and N cycles at elevated CO₂, we grew clonally propagated cuttings of *Populus*

grandidentata in the field at ambient and twice ambient CO₂ in open bottom root boxes filled with organic matter poor native soil. Nitrogen was added to all root boxes at a rate equivalent to net N mineralization in local dry oak forests. Nitrogen added during August was enriched with N-25 to trace the flux of N within the plant-soil system. Above- and belowground growth, CO₂ assimilation, and leaf N content were measured non-destructively over 142 d. After final destructive harvest, roots, stems, and leaves were analyzed for total N and N-15. There was no CO₂ treatment effect on leaf area, root length, or net assimilation prior to the completion of N addition. Following the N addition, leaf N content increased in both CO₂ treatments, but net assimilation showed a sustained increase only in elevated CO₂ grown plants. Root relative extension rate was greater at elevated CO₂, both before and after the N addition. Although final root biomass was greater at elevated CO₂, there was no CO₂ effect on plant N uptake or allocation. While low soil N availability severely inhibited CO₂ responses, high CO₂ grown plants were more responsive to N. This differential behavior must be considered in light of the temporal and spatial heterogeneity of soil resources, particularly N which often limits plant growth in temperate forests.

Cushman, J.C., and H.J. Bohnert. 1997. Molecular genetics of Crassulacean acid metabolism. *Plant Physiology* 113(3):667-676.

Most higher plants assimilate atmospheric CO₂ through the C-3 pathway of photosynthesis using ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco). However, when CO₂ availability is reduced by environmental stress conditions, the incomplete discrimination of CO₂ over O₂ by Rubisco leads to increased photorespiration, a process that reduces the efficiency of C-3 photosynthesis. To overcome the wasteful process of photorespiration, approximately 10% of higher plant species have evolved two alternate strategies for photosynthetic CO₂ assimilation, C-3 photosynthesis and Crassulacean acid metabolism. Both of these biochemical pathways employ a "CO₂ pump" to elevate intracellular CO₂ concentrations in the vicinity of Rubisco, suppressing photorespiration and therefore improving the competitiveness of these plants under conditions of high light intensity, high temperature, or low water availability. This CO₂ pump consists of a primary carboxylating enzyme, phosphoenolpyruvate carboxylase. In C-4 plants, this CO₂-concentrating mechanism is achieved by the coordination of two carboxylating reactions that are spatially separated into mesophyll and bundle-sheath cell types (for review, see R.T. Furbank, W.C. Taylor [1995] *Plant Cell* 7:797-802; M.S.B. Ku, Y. Kano-Murakami, M. Matsuoka [1996] *Plant Physiol* 111:949-957). In contrast, Crassulacean acid metabolism plants perform both carboxylation reactions within one cell type, but the two reactions are separated in time. Both pathways involve cell-specific changes in the expression of many genes that are not present in C-3 plants.

Dacey, J.W.H., B.G. Drake, and M.J. Klug. 1994. Stimulation of methane emission by carbon-dioxide enrichment of marsh vegetation. *Nature* 370(6484):47-49.

THERE is substantial evidence that many plants respond to increased concentrations of atmospheric carbon dioxide by increasing their

productivity(1-4) This observation has led to the suggestion that, by taking up CO₂, the terrestrial biosphere might mitigate the potential greenhouse warming associated with anthropogenic CO₂ emissions(5). Whiting and Chanton(6) have found, however, that for wetlands of varying productivity around the world, higher net primary production is associated with higher emissions of methane-another important greenhouse gas. Here we present measurements of methane emissions from a marsh that has been exposed to twice the present ambient concentration of atmospheric CO₂. We find that over a one-week period, the CO₂-enriched sites had significantly higher emissions of methane than the control sites. Our results suggest that future increases in atmospheric CO₂ concentration may lead to significant increases in methane emissions from wetlands.

Dahlman, R.C. 1993. Co₂ and plants - revisited. *Vegetatio* 104:339-355.

The decade-long USA research program on the direct effects of CO₂ enrichment on vegetation has achieved important milestones and has produced a number of interesting and exciting findings. Research beginning in 1980 focused on field experiments to determine whether phenomena observed in the laboratory indeed occurred in natural environments. The answer is yes. Data obtained from numerous field studies show mixed response of crop and native species to CO₂ enrichment however. Nearly all experiments demonstrate that plants exhibit positive gain when grown at elevated CO₂; although the magnitude varies greatly. Most crop responses range from 30 to 50 % increase in yield. Results from long-term experiments with woody species and ecosystems are even more variable. Huge growth responses (100 to nearly 300 % increase relative to controls) are reported from several tree experiments and the salt-marsh ecosystem experiment. Other results from experiments with woody species and the tundra ecosystem suggest little no effect of CO₂ on physiology, growth or productivity. Numerous studies of the physiology of the CO₂ effect are continuing in attempts to understand controlling mechanisms and to explain the variable growth responses. Particular emphasis needs to be given to physiological measures of interactions involving the CO₂ effect and other environmental influences, and to the wide-ranging observations of photosynthesis acclimation to CO₂. Prospects for future research are identified.

Dale, H., and M.C. Press. 1998. Elevated atmospheric CO₂ influences the interaction between the parasitic angiosperm *Orobancha minor* and its host *Trifolium repens*. *New Phytologist* 140(1):65-73.

The influence of the root holoparasitic angiosperm *Orobancha minor* Sm. on the biomass, photosynthesis, carbohydrate and nitrogen content of *Trifolium repens* L. was determined for plants grown at two CO₂ concentrations (350 and 550 μ mol mol⁻¹). Infected plants accumulated less biomass than their uninfected counterparts, although early in the association there was a transient stimulation of growth. Infection also influenced biomass allocation both between tissues (infected plants had lower root:shoot ratios) and within tissues: infected roots were considerably thicker before the point of parasite attachment and thinner below. Higher concentrations of starch were also found in roots above the point of attachment, particularly for plants grown in

elevated CO₂. Elevated CO₂ stimulated the growth of *T. repens* only during the early stages of development. There was a significant interaction between infection and CO₂ on growth, with infected plants showing a greater response, such that elevated CO₂ partly alleviated the effects of the parasite on host growth. Elevated CO₂ did not affect total *O. minor* biomass per host, the number of individual parasites supported by each host, or their time of attachment to the host root system. Photosynthesis was stimulated by elevated CO₂ but was unaffected by *O. minor*. There was no evidence of down-regulation of photosynthesis in *T. repens* grown at elevated CO₂ in either infected or uninfected plants. The data are discussed with regard to the influence of elevated CO₂ on other parasitic angiosperm-host associations and factors which control plant responses to elevated CO₂.

Damesin, C., C. Galera, S. Rambal, and R. Joffre. 1996. Effects of elevated carbon dioxide on leaf gas exchange and growth of cork-oak (*Quercus suber* L.) seedlings. *Annales Des Sciences Forestieres* 53(2-3):461-467.

Leaf gas exchange and growth were determined on cork-oak (*Quercus suber* L.) seedlings which were grown from acorns for periods of up to 4 months in greenhouses at ambient (350 $\mu\text{mol mol}^{-1}$) and at elevated (700 $\mu\text{mol mol}^{-1}$) concentrations of carbon dioxide. In well-watered conditions, daily maximum photosynthesis (15 $\mu\text{mol m}^{-2} \text{s}^{-1}$) and stomatal conductance (440 $\text{mmol m}^{-2} \text{s}^{-1}$) of plants grown and measured at 700 $\mu\text{mol mol}^{-1}$ CO₂ did not differ from those of plants grown and measured at 350 $\mu\text{mol mol}^{-1}$. In conditions of moderate drought, net CO₂ assimilation was at least twice as great in elevated CO₂, but stomatal conductance was unchanged. Elevated CO₂ affected total biomass production, the average increase being 76 and 97% at 3 and 4 months, respectively. Shoot biomass, root biomass, stem height and total leaf area were increased by elevated CO₂. Root and stem ramification were also enhanced by elevated CO₂, but no change in root/shoot ratio was observed.

Daniel, E. 1997. The temperature dependence of photoinhibition in leaves of *Phaseolus vulgaris* (L.) - Influence of CO₂ and O₂ concentrations. *Plant Science* 124(1):1-8.

The interactive effect of temperature and CO₂ concentration on the susceptibility to photoinhibition was assessed using chlorophyll a fluorescence to estimate the reduction of the quantum yield of PSII photochemistry (F-w/F-m) after high-light exposure. Leaves exposed to high photon flux density always exhibit a decrease in F-w/F-m, resulting from both a decrease in the rate constant for photochemistry and an increase in the rate constant for non photochemical dissipation of excess excitation energy. At a-given CO₂ concentration, there was almost no

difference in the degree of photoinhibition between leaves exposed to high light in 10 or 210 $\text{mmol O}_2\text{-mol}^{-1}$. But photoinhibition was more pronounced at 10 $\text{mmol O}_2\text{-mol}^{-1}$ and 0 $\mu\text{mol CO}_2\text{-mol}^{-1}$ than at 210 $\text{mmol O}_2\text{-mol}^{-1}$ and 50 $\mu\text{mol CO}_2\text{-mol}^{-1}$, i.e. when both photorespiration and CO₂ refixation are suppressed. Despite this photoprotective role of photorespiration, photoinhibition was enhanced by decreasing CO₂ concentration in bean leaves, especially at elevated (30-35 degrees C) temperatures. Darrah, P.R. 1996. Rhizodeposition under ambient and elevated CO₂ levels. *Plant and Soil* 187(2):265-275.

As global CO₂ levels rise, can soils store more carbon and so buffer atmospheric CO₂ levels? Answering this question requires a knowledge of the rates of C inputs to soil and of CO₂ outputs via decomposition. Below-ground inputs from roots are a major component of the C flow into soils but are still poorly understood. In this article, new techniques for measuring rhizodeposition are reviewed and discussed and the need for cross-comparisons between methods is identified. One component of rhizodeposition, root exudation, is examined in more detail and evidence is presented which suggests that current estimates of exudate flow into soils are incorrect. A mechanistic mathematical model is used to explore how exudate flows might change under elevated CO₂.

Darrigo, R.D., and G.C. Jacoby. 1993. Tree growth-climate relationships at the northern boreal forest tree line of north-america - evaluation of potential response to increasing carbon-dioxide. *Global Biogeochemical Cycles* 7(3):525-535.

Tree growth at the northern limit of the range of boreal forests is primarily limited by temperature-related factors. Thus the position of this range limit, and the growth rates of trees along the northern forest border, may undergo significant change if predictions of enhanced greenhouse warming at northern latitudes are realized. In this paper we evaluate tree ring width and maximum latewood density chronologies of white spruce for three temperature-sensitive tree line sites in northern North America: in the Brooks Range, Alaska, the Franklin Mountains, Northwest Territories, and Churchill, Manitoba. The ring width data, which more strongly integrate low-frequency temperature trends than the density series, show overall enhanced growth and inferred warming during the period of anthropogenic increase in greenhouse gases. The recent growth at these sites equals or exceeds that which has occurred during earlier centuries of more clearly natural climate variability. When the ring width and density variations are estimated using temperature and precipitation data in principal components regression analysis, no substantial residual trends are detected which might require CO₂ or other nutrient fertilization as an additional explanation for recent growth changes.

Davey, P.A., A.J. Parsons, L. Atkinson, K. Wadge, and S.P. Long. 1999. Does photosynthetic acclimation to elevated CO₂ increase photosynthetic nitrogen-use efficiency? A study of three native UK grassland species in open-top chambers. *Functional Ecology* 13:21-28.

1. The photosynthetic response to elevated CO₂ and nutrient stress was investigated in *Agrostis capillaris*, *Lolium perenne* and *Trifolium repens* grown in an open-top chamber facility for 2 years under two nutrient regimes. Acclimation was evaluated by measuring the response of light-saturated photosynthesis to changes in the substomatal CO₂ concentration. 2. Growth at elevated CO₂ resulted in reductions in apparent Rubisco activity in vivo in all three species, which were associated with reductions of total leaf nitrogen content on a unit area basis for *A. capillaris* and *L. perenne*. Despite this acclimation, photosynthesis was significantly higher at elevated CO₂ for *T. repens* and *A. capillaris*, the latter exhibiting the greatest increase of carbon uptake at the lowest nutrient supply. 3. The photosynthetic nitrogen-use efficiency (the rate of carbon assimilation per unit leaf nitrogen) increased at elevated CO₂, not purely owing to higher values of photosynthesis at elevated CO₂, but also as a result of lower leaf nitrogen contents. 4. Contrary to most previous studies, this investigation indicates that elevated CO₂ can stimulate photosynthesis under a severely limited nutrient supply. Changes in photosynthetic nitrogen-use efficiency may be a critical determinant of competition within low nutrient ecosystems and low input agricultural systems.

Davies, S.J., and L. Unam. 1999. Smoke-haze from the 1997 Indonesian forest fires: effects on pollution levels, local climate, atmospheric CO₂ concentrations, and tree photosynthesis. *Forest Ecology and Management* 124(2-3):137-144.

Atmospheric composition, local climate and sapling gas exchange were monitored to assess the short-term effects of smoke-haze from the 1997 Indonesian forest fires. Atmospheric concentrations of particulate matter, SO₂, CO, CH₄ and CO₂, and relative humidity were elevated, and photosynthetically active radiation and ambient temperature were reduced by the smoke-haze. Despite elevated CO₂ levels, photosynthesis in three tree species was reduced by the smoke-haze, both indirectly through reduced PAR levels, and directly through elevated aerosol and atmospheric pollutant levels. Day, F.P., E.P. Weber, C.R. Hinkle, and B.G. Drake. 1996. Effects of elevated atmospheric CO₂ on fine root length and distribution in an oak-palmetto scrub ecosystem in central Florida. *Global Change Biology* 2(2):143-148.

Atmospheric CO₂ concentration is rising and it has been suggested that a portion of the additional carbon is being sequestered in terrestrial vegetation and much of that in below-ground structures. The objective of the present study was to quantify the effects of elevated atmospheric CO₂ on fine root length and distribution with depth with minirhizotrons in an open-top chamber experiment in an oak-palmetto scrub ecosystem at Kennedy Space Centre, Florida, USA. Observations were made five times over a period of one and a half years in three ambient chambers

(350 p.p.m. CO₂), three CO₂ enriched chambers (700 p.p.m. CO₂), and three unchambered plots. Greater root length densities were produced in the elevated CO₂ chambers (14.2 mm cm⁻²) compared to the ambient chambers (8.7 mm cm⁻²). More roots may presumably lead to more efficient acquisition of resources. Fine root abundance varied significantly with soil depth, and there appeared to be enhanced proliferation of fine roots near the surface (0-12 cm) and at greater depth (49-61 cm) in the elevated CO₂ chambers. The vertical root distribution pattern may be a response to availability of nutrients and water. More studies are needed to determine if increased root length under CO₂ enriched conditions actually results in greater sequestering of carbon below ground.

Dayan, E., H. Vankeulen, J.W. Jones, I. Zipori, D. Shmuel, and H. Challa. 1993. Development, calibration and validation of a greenhouse tomato growth-model. 1. Description of the model. *Agricultural Systems* 43(2):145-163.

A dynamic crop growth model. TOMGRO, for an indeterminate tomato variety is presented. The model describes the phenological development and increase in dry weight of various organs (roots, stem nodes, leaves and fruits) from planting till maturity under variable environmental conditions. Phenological development is governed by genetic plant properties and environmental conditions (e.g. air temperature and CO₂ level) and expressed in a plastochron index, i.e. the current stem node number. Total dry matter accumulation is based on a quantitative description of the carbon balance, including gross CO₂ assimilation, maintenance respiration and growth respiration. Partitioning of dry matter increase over the various organs is governed by their relative sink strength, defined on the basis of a genetically determined 'potential' growth rate, achieved under non-limiting carbohydrate supply. The model is both schematic and modular in set-up. This means it can be adapted easily and most of its subroutines can be replaced easily by others if better descriptions become available. It can also be combined with a more comprehensive model describing greenhouse climate and appears robust for use in procedures of economic optimization of climate conditions in greenhouses or for management purposes.

Daymond, A.J., T.R. Wheeler, P. Hadley, R.H. Ellis, and J.I.L. Morison. 1997. The growth, development and yield of onion (*Allium cepa* L.) in response to temperature and CO₂. *Journal of Horticultural Science* 72(1):135-145.

Stands of two cultivars (cv. Hysam and Site) of onion (*Allium cepa* L.) were grown in the held within polyethylene-covered tunnels along which a temperature adient was imposed. Pairs of tunnels were maintained at either 374 or 532 $\mu\text{mol mol}^{-1}$ CO₂. The rates of progress from transplanting to bulbing, and from bulbing to harvest maturity, were positive linear functions of mean temperature for each cultivar. At a given temperature, the time of bulbing was earlier, but the duration of bulb growth longer, at elevated compared with normal CO₂. Canopy architecture was not affected by CO₂, temperature or cultivar; an estimate of 0.25 for the canopy light extinction coefficient was common to all treatment combinations. Radiation use efficiency was greater at elevated compared with normal CO₂ in the period up to bulbing, but was the same at both CO₂ concentrations during subsequent bulb growth. Total crop dry weight at bulbing was increased by 32-44% due to

elevated CO₂. Bulb yields at harvest maturity declined with progressively warmer temperatures and to a greater extent in cv. Site than cv. Hysam. Enrichment with CO₂ increased bulb yields by 29-37% and by 35-51% in cvs Hysam and Site, respectively. From comparison of the temperature rise needed to offset entirely the yield increases of each cultivar due to elevated CO₂, it is concluded that current estimates of climate change should be beneficial for bulb onion production, particularly for long-season cultivars.

De Angelis, P., and G.E. Scarascia-Mugnozza. 1998. Long-term CO₂-enrichment in a Mediterranean natural forest: An application of large open top chambers. *Chemosphere* 36(4-5):763-770.

It is crucial to be able to anticipate the possible effects of environmental changes on the Mediterranean woodland communities given their essential role on protecting lands that are under a strong pressure by man and climate. Predictions of the effects of increasing CO₂ concentration on plants have been inferred by short- and long-term studies, conducted at different scales and by different technologies. Open Top Chambers (OTCs) are experimental facilities that have been widely used to expose field grown plants to different pollutant gases, and more recently to elevated [CO₂]. In this paper, we present the natural site and the experimental system (six large OTCs enclosing clumps of natural vegetation) that we have been utilizing for 3 years, to assess the impact of elevated [CO₂] on a Mediterranean natural forest community. The results show that large OTCs can be usefully used to simulate CO₂ doubling even under the harsh environmental conditions of the mediterranean region. (C) 1998 Elsevier Science Ltd.

Debevec, E.M., and S.F. Maclean. 1993. Design of greenhouses for the manipulation of temperature in tundra plant-communities. *Arctic and Alpine Research* 25(1):56-62.

Passive greenhouses can be used to elevate the temperature of natural communities, but they also introduce other effects. We tested the effects of potential greenhouse materials-clear polyethylene plastic film, polyester fabric, and rigid fiberglass panels-on light transmission, photosynthesis of *Salix planifolia*, elevation of air and soil temperature, and thaw depth. Plastic had the greatest light transmittance and caused the least depression of photosynthesis (-5%). Greenhouses covered with plastic elevated daily maximum and daily mean air temperatures by an average of 7.8 and 2.0- degrees-C and depressed daily minimum temperature by 1.1- degrees-C compared with the control. Plastic is impervious to gases and may alter CO₂ concentration and humidity within greenhouses. Fiberglass had lower transmittance, especially of short wavelength radiation. Fabric had the lowest light transmission and reduced photosynthesis by 10%, but it has the advantage of permeability to CO₂ and water vapor. Greenhouses covered with fabric, alone, produced only a small effect (daily mean temperature elevated 0.4-degrees-C above controls). A mixed greenhouse design (plastic and fabric) raised daily mean temperatures by 0.9-degrees-C and may minimize adverse effects on gas diffusion. Because of the effect of the materials on amount and spectral distribution of radiation and on photosynthesis, the appropriate treatment control for any greenhouse design is an open plot shaded with the same material. Soil temperature at 10 cm depth was elevated in all greenhouses, but no effect on depth of thaw was detected.

Debruin, H.A.R., and C.M.J. Jacobs. 1993. Impact of CO₂ enrichment on the regional evapotranspiration of agroecosystems, a theoretical and numerical modeling study. *Vegetatio* 104:307-318.

This paper gives a brief overview of factors determining evapotranspiration of vegetated surfaces. It indicates which of these factors are sensitive to CO₂ enrichment. A qualitative analysis is presented of the impact of large scale climate changes. Data in literature indicate that the surface resistance of vegetated areas may change within the range -25 % and +50 % if the atmospheric CO₂-concentration doubles. The impact of such changes on regional scale transpiration is evaluated using a numerical model in which the interaction between the evapotranspiration and the Planetary Boundary Layer is accounted for. It is concluded that the impact of CO₂ enrichment on the transpiration at the regional scale is relatively small for aerodynamically smooth surfaces (between +7 % and -11 %). For aerodynamically rough surfaces the effects are somewhat larger (between +15 % and -21 %).

Deepak, S.S., and M. Agrawal. 1999. Growth and yield responses of wheat plants to elevated levels of CO₂ and SO₂, singly and in combination. *Environmental Pollution* 104(3):411-419.

Wheat plants (*Triticum aestivum* L. cv. Malviya 234) were exposed to 600 ppm of carbon dioxide (CO₂) and 0.06 ppm sulphur dioxide (SO₂), singly and in combination for 8 h daily (8 a.m. to 4 p.m.) from germination to maturity in open top chambers (OTCs) in field conditions to investigate their individual as well as interactive influence on plant growth and yield. Exposure of plants to 0.06 ppm SO₂ significantly reduced plant height, leaf area, biomass and yield. Elevated CO₂, on the other hand, stimulated the growth and yield of plants. Combination of CO₂ and SO₂ showed a similar response pattern as that of CO₂ alone. Pattern of biomass allocation also varied in response to different treatments. RGR was significantly increased due to CO₂ and CO₂ + SO₂ treatments, whereas the same reduced due to SO₂ exposure. Root/shoot ratio decreased significantly due to CO₂ and CO₂ + SO₂ treatment at 45 days age. CO₂ modified the responses of plants to SO₂. Combined exposure of SO₂ and CO₂ stimulated the growth as well as the yield maximally. This suggests that the CO₂ enrichment has not only reduced the adverse effect of low level of SO₂, but at the same time the extra carbon provided by CO₂ enrichment took the advantage of air borne sulphur as nutrient and showed maximum increment in growth and yield. Dehaan, B.J., M. Jonas, O. Klepper, J. Krabec, M.S. Krol, and K. Oledrznyski. 1994. An atmosphere-ocean model for integrated assessment of global change. *Water, Air, and Soil Pollution* 76(1-2):283-318.

This paper describes the atmosphere-ocean system of the integrated model IMAGE 2.0. The system consists of four linked models, for

atmospheric composition, atmospheric climate, ocean climate and for ocean biosphere and chemistry. The first model is globally averaged, the latter are zonally averaged with additional resolution in the vertical. The models reflect a compromise between describing the physical, chemical and biological processes and moderate computational requirements. The system is validated with direct observations for current conditions (climate, chemistry) and is consistent with results from General Circulation Model experiments. The system is used in the integrated setting of the IMAGE 2.0 model to give transient climate projections. Global surface temperature is simulated to increase by 2.5 K over the next century for socio-economic scenarios with continuing economic and population growth. In a scenario study with reduced ocean circulation, the climate system and the global C cycle are found to be appreciably sensitive to such changes.

Delatorre, A., B. Delgado, and C. Lara. 1991. Nitrate-dependent O₂ evolution in intact leaves. *Plant Physiology* 96(3):898-901.

Evolution Of O₂ by illuminated intact detached leaves from barley (*Hordeum vulgare* L. cv Athos) and pea (*Pisum sativum* L. cv Lincoln) in a CO₂-saturating atmosphere was enhanced when KNO₃ (1-2.5 millimolar) had been previously supplied through the transpiration stream. The extra O₂ evolution observed after feeding KNO₃ increased with the light intensity, being maximal at near saturating photon flux densities and resulting in no changes in the initial slope of the O₂ versus light-intensity curve. No stimulation Of O₂ evolution was otherwise observed after feeding KCl or NH₄Cl. The data indicate that nitrate assimilation uses photosynthetically generated reductant and stimulates the rate of noncyclic electron flow by acting as a second electron-accepting assimilatory process in addition to CO₂ fixation.

de la Vina, G., F. Pliego-Alfaro, S.P. Driscoll, V.J. Mitchell, M.A. Parry, and D.W. Lawlor. 1999. Effects of CO₂ and sugars on photosynthesis and composition of avocado leaves grown in vitro. *Plant Physiology and Biochemistry* 37(7-8):587-595.

The effects of micropropagation conditions on avocado (*Persea americana* Mill.) have been measured in leaves and plants cultured in vitro. The consequences of the type and concentration of sugar in the medium and of carbon dioxide concentration in the atmosphere on the rates of photosynthesis and amounts of ribulose 1,5-bisphosphate carboxylase-oxygenase (EC 4.1.1.39; Rubisco) and total soluble protein (TSP) were measured. At the highest sucrose supply (87.6 mM), Rubisco content was substantially decreased in leaves, and even more when elevated CO₂ (1 000 µmol mol⁻¹) was supplied. Maximum photosynthetic rate (P-max) was significantly decreased when plants developed in high sucrose and elevated CO₂. However, Rubisco concentration was significantly greater when glucose was supplied at the same molar concentration or when the concentration of sucrose was small (14.6 mM), and no differences were observed due to the CO₂ concentration in the air in these treatments. The ratio of Rubisco to total soluble protein (Rubisco/TSP) was dramatically decreased in plants grown in the highest concentration of sucrose and with elevated CO₂. Leaf area and ratio of leaf fresh weight/(stem + root) fresh weight, were greater in plants grown with CO₂, enriched air. However, upon transplanting, survival was poorer in plants grown on low sucrose/high CO₂ compared to those grown on high sucrose/high CO₂. (C) Elsevier, Paris.

Delesalle, V.A., and S. Blum. 1994. Variation in germination and survival among families of *sagittaria-latifolia* in response to salinity and temperature. *International Journal of Plant Science* 155(2):187-195.

We studied seed germination and seedling growth in eight maternal families of *Sagittaria latifolia* (Alismataceae), a freshwater perennial, in response to salinity (four levels) and temperature effects (two levels) in the greenhouse. Salinity decreased germination, delayed emergence, and decreased survival and growth rates. The negative effects of salinity on germination were greater at the high-temperature regime, but the effects on growth were greater at the low-temperature regime. Some seeds were capable of germinating and surviving (with minimal growth) even in 0.8% NaCl solution. Families also differed in their response to salinity but not to temperature. In particular, high salinities had little effect on the germination of some families. Growth rate always decreased with increasing salinity, but again the magnitude of the effect differed among maternal families. Our data show that *S. latifolia* can germinate but cannot grow well under low-salinity conditions; thus, *S. latifolia* might be minimally affected by short-term salt intrusions. In order to understand how plant populations respond to disturbances, such as increased salinity or increased temperature, we need to consider the source, either environmental or genetic, of maternal effects.

Delgado, E., R.A.C. Mitchell, M.A.J. Parry, S.P. Driscoll, V.J. Mitchell, and D.W. Lawlor. 1994. Interacting effects of CO₂ concentration, temperature and nitrogen supply on the photosynthesis and composition of winter-wheat leaves. *Plant, Cell and Environment* 17(11):1205-1213.

Winter wheat (*Triticum aestivum* L., cv. Mercia) was grown at two different atmospheric CO₂ concentrations (350 and 700 µmol mol⁻¹) two temperatures [ambient temperature (i.e. tracking the open air) and ambient +4 degrees C] and two rates of nitrogen supply (equivalent to 489 kg ha⁻¹ and 87 kg ha⁻¹). Leaves grown at 700 µmol mol⁻¹ CO₂ had slightly greater photosynthetic capacity (10% mean increase over the experiment) than those grown at ambient CO₂ concentration, but there were no differences in carboxylation efficiency or apparent quantum yield. The amounts of chlorophyll, soluble protein and ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) per unit leaf area did not change with long-term exposure to elevated CO₂ concentration. Thus winter wheat, grown under simulated field conditions, for which total biomass was large compared to normal field production, did not experience loss of components of the photosynthetic system or loss of photosynthetic competence with elevated CO₂ concentration. However, nitrogen supply and temperature had large effects on photosynthetic characteristics but did not interact with elevated CO₂ concentration. Nitrogen deficiency resulted in decreases in the contents of protein, including Rubisco, and chlorophyll, and decreased photosynthetic capacity and carboxylation efficiency. An increase in temperature also reduced these components and shortened the effective life of the leaves, reducing the duration of high photosynthetic capacity.

Delmas, R.J. 1998. Ice-core records of global climate and environment changes. *Proceedings of the Indian Academy of Sciences-Earth and Planetary Sciences* 107(4):307-319.

Precipitation accumulating on the Greenland and Antarctic ice sheets records several key parameters (temperature, accumulation, composition of atmospheric gases and aerosols) of primary interest for documenting the past global environment over recent climatic cycles and the chemistry of the preindustrial atmosphere. Several deep ice cores from Antarctica and Greenland have been studied over the last fifteen years. In both hemispheres, temperature records (based on stable isotope measurements in water) show the succession of glacial and interglacial periods. However, detailed features of the climatic stages are not identical in Antarctica and in Greenland. A tight link between global climate and greenhouse gas concentrations was discovered, CO₂ and CH₄ concentrations being lower in glacial conditions by about 80 and 0.3 ppmv, respectively, with respect to their pre-industrial levels of 280 and 0.65 ppmv. Coldest stages are also characterized by higher sea-salt and crustal aerosol concentrations. In Greenland, contrary to Antarctica, ice-age ice is alkaline. Gas-derived aerosol (in particular, sulfate) concentrations are generally higher for glacial periods, but not similar in both the hemispheres. Marine and continental biomass-related species are significant in Antarctica and Greenland ice, respectively. Finally, the growing impact of anthropogenic activities on the atmospheric composition is well recorded in both polar regions for long-lived compounds (in particular greenhouse gases), but mostly in Greenland for short-lived pollutants.

Delucia, E.H., R.M. Callaway, and W.H. Schlesinger. 1994. Offsetting changes in biomass allocation and photosynthesis in ponderosa pine (*Pinus ponderosa*) in response to climate-change. *Tree Physiology* 14(7-9):669-677.

We examined the effect of climate on aboveground biomass allocation of ponderosa pine (*Pinus ponderosa*) by measuring trees in disjunct forest stands growing on the same substrate at high-elevation montane sites and low-elevation desert sites. Climatic differences between the sites were comparable to the difference between present and future climates of interior North America that is expected to result from a doubling of atmospheric CO₂ concentration. Relative to the montane populations, the desert populations allocated a greater proportion of biomass to sapwood (functional xylem) at the expense of foliage. The leaf/sapwood area ratio and percent of aboveground biomass in sapwood for trees of the same height were 0.201 m² cm⁻² and 58% for montane trees and 0.104 m² cm⁻² and 71% for desert trees. In a phytotron experiment, increases in net photosynthesis and net assimilation rate for seedlings grown under future conditions of high CO₂ and temperature were offset by a decrease in leaf area ratio. As was observed for large trees at different elevations, increased temperatures caused an increase in biomass allocation to stem in the phytotron seedlings. Thus, CO₂- and temperature-driven shifts in biomass allocation negated the effect on growth of the CO₂-driven increase in carbon assimilation rate. Our data from the controlled growth chamber and field experiments suggest that future climate conditions, including elevated atmospheric CO₂, may not stimulate growth and productivity of ponderosa pine.

Delucia, E.H., R.M. Callaway, E.M. Thomas, and W.H. Schlesinger. 1997. Mechanisms of phosphorus acquisition for ponderosa pine seedlings under high CO₂ and temperature. *Annals of Botany* 79(2):111-120.

To test the hypothesis that elevated atmospheric CO₂ and elevated temperature, simulating current and predicted future growing season conditions, act antagonistically on phosphorus acquisition of ponderosa pine, seedlings were grown in controlled-environment chambers in a two temperature (25/10 degrees C and 30/15 degrees C) x two CO₂ (350 and 700 mu l(-1)) experimental design. Mycorrhizal seedlings were watered daily with a nutrient solution with P added in organic form as inositol hexaphosphate (64ppm P). Thus seedlings were challenged to use active forms of P acquisition. Elevated CO₂ increased the relative growth rate by approx. 5% which resulted in an approx. 33% increase in biomass after 4 months. There was no main effect of temperature on growth. Increased growth under elevated CO₂ and temperature was supported by increases in specific absorption rate and the specific utilization rate of P. The contribution of mycorrhizae to P uptake may have been greater under simulated future conditions, as elevated CO₂ increased the number of mycorrhizal roots. There was no main effect of temperature on root phosphatase activity, but elevated CO₂ caused a decrease in activity. The inverse pattern of root phosphatase activity and mycorrhizal infection across treatments suggests a physiological coordination between these avenues of P acquisition. The concentration of oxalate in the soil increased under elevated CO₂ and decreased under elevated temperature. This small molecular weight acid solubilizes inorganic P making it available for uptake. Increased mycorrhizal infection and exudation of oxalate increased P uptake in ponderosa pine seedlings under elevated CO₂, and there was no net negative effect of increased temperature. The increased carbon status of pine under elevated CO₂ may facilitate uptake of limiting P in native ecosystems. (C) 1997 Annals of Botany Company.

DeLucia, E.H., J.G. Hamilton, S.L. Naidu, R.B. Thomas, J.A. Andrews, A. Finzi, M. Lavine, R. Matamala, J.E. Mohan, G.R. Hendrey, and W.H. Schlesinger. 1999. Net primary production of a forest ecosystem with experimental CO₂ enrichment. *Science* 284(5417):1177-1179.

The concentration of atmospheric carbon dioxide was increased by 200 microliters per Liter in a forest plantation, where competition between organisms, resource Limitations, and environmental stresses may modulate biotic responses. After 2 years the growth rate of the dominant pine trees increased by about 26 percent relative to trees under ambient conditions. Carbon dioxide enrichment also increased Litterfall and fine-root increment. These changes increased the total net primary production by 25 percent. Such an increase in forest net primary production globally would fix about 50 percent of the anthropogenic carbon dioxide projected to be released into the atmosphere in the year 2050. The response of this young, rapidly growing forest to carbon dioxide may represent the upper Limit for forest carbon sequestration.

De Luis, I., J.J. Irigoyen, and M. Sanchez-Diaz. 1999. Elevated CO₂ enhances plant growth in droughted N-2-fixing alfalfa without improving water status. *Physiologia Plantarum* 107(1):84-89.

The long-term interaction between elevated CO₂ and soil water deficit was analysed in N-2-fixing alfalfa plants in order to assess the possible drought tolerance effect of CO₂. Elevated CO₂ could delay the onset of drought stress by decreasing transpiration rates, but this effect was avoided by subjecting plants to the same soil water content. Nodulated alfalfa plants subjected to ambient (400 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ were either men watered or partially watered by restricting water to obtain 30% of the water content at field capacity (approximately 0.55 g water cm⁻³). The negative effects of soil water deficit on plant growth were counterbalanced by elevated CO₂. In droughted plants, elevated CO₂ stimulated carbon fixation and, as a result, biomass production was even greater than in well-watered plants grown in ambient CO₂. Below-ground production was preferentially stimulated by elevated CO₂ in droughted plants, increasing nodule biomass production and the availability of photosynthates to the nodules. As a result, total nitrogen content in droughted plants was higher than in well-watered plants grown in ambient CO₂. The beneficial effect of elevated CO₂ was not correlated with a better plant water status. It is concluded that elevated CO₂ enhances growth of droughted plants by stimulating carbon fixation, preferentially increasing the availability of photosynthates to below-ground production (roots and nodules) without improving water status. This means that elevated CO₂ enhances the ability to produce more biomass in N-2-fixing alfalfa under given soil water stress, improving drought tolerance.

Demmers-Derks, H., R.A.C. Mitchell, V.J. Mitchell, and D.W. Lawlor. 1998. Response of sugar beet (*Beta vulgaris* L.) yield and biochemical composition to elevated CO₂ and temperature at two nitrogen applications. *Plant, Cell and Environment* 21(8):829-836.

Effects on sugar beet (*Beta vulgaris* L.) of current and elevated CO₂ and temperature alone and in combination and their interactions with abundant and deficient nitrogen supply (HN and LN, respectively) have been studied in three experiments in 1993, 1994 and 1995. Averaged over all experiments, elevated CO₂ (600 $\mu\text{mol mol}^{-1}$) in 1993 and 700 $\mu\text{mol mol}^{-1}$ in 1994 and 1995) increased total dry mass at final harvest by 21% (95% confidence interval (CI) = 21, 22) and 11% (CI = 6, 15) and root dry mass by 26% (CI = 19, 32) and 12% (CI = 6, 18) for HN and LN plants, respectively. Warmer temperature decreased total dry mass by 11% (CI = - 15, - 7) and 9% (CI = - 15, - 5) and root dry mass by 7% (CI = - 12, - 2) and 7% (CI = - 10, 0) for HN and LN plants, respectively. There was no significant interaction between temperature and CO₂ on total or root dry mass. Neither elevated CO₂ nor temperature significantly affected sucrose concentration per unit root dry mass. Concentrations of glycinebetaine and of amino acids, measured as alpha-amino-N, decreased in elevated CO₂ in both N applications; glycinebetaine by 13% (CI = - 21, - 5) and 16% (CI = - 24, - 8) and alpha-amino-N by 24% (CI = - 36, - 11) and 16% (CI = - 26, - 5) for HN and LN, respectively. Warmer temperature increased alpha-amino-N, by 76% (CI = 50, 107) for HN and 21% (CI = 7, 36) for LN plants, but not glycinebetaine.

DeMothes, M.A.G. 1996. Effects of enhanced CO₂ concentration on wheat photosynthesis and long- and short-term stomatal behaviour. *Photosynthetica* 32(2):193-202.

Wheat (*Triticum aestivum* L.) plants were cultivated in a growth chamber at normal (35 Pa = c(35)) and increased (70 Pa = c(70)) CO₂ partial pressure. Environmental conditions other than CO₂ concentration were similar for the c(35) and the c(70) plants. For the c(35) and the c(70) plants stomatal density was similar. When both variants were measured at growth conditions, the net photosynthetic rate (P-N) of c(70) plants was 44 % higher and stomatal conductance to water vapour pressure (g(s)) was 22 % lower than those of the c(35) plants, while the relation between internal partial pressure of CO₂ (p_{ci}) and external partial pressure (p_{ea}) was similar for both variants. Plants were also submitted to a sequence of increments in CO₂ concentration (from 10 Pa up to saturating CO₂ concentration) at saturating photosynthetically active radiation (PAR). Following 1.5 h at saturating CO₂ concentration and PAR, CO₂ concentration was decreased stepwise. Both variants showed hysteresis in the response of P-N, transpiration rate (E), g(s) and water use efficiency (WUE) to p_{ci}. While CO₂ concentration was incremented, P-N and g(s) were linearly related indicating that mesophyll activity and g(s) were correlated. At saturating CO₂ concentration and PAR, end product feedback inhibition on photosynthesis disrupted this correlation for both variants. Plants were also submitted to a sequence of increments in PAR (from 40 $\mu\text{mol m}^{-2}\text{s}^{-1}$ up to saturating PAR) at saturating CO₂ concentration. Following 1.5 h at saturating CO₂ concentration and PAR, PAR was decreased stepwise. While both variants showed hysteresis in the response of P-N, E and g(s), the c(35) plants showed also hysteresis in the response of p_{ci}/p_{ea} and WUE to PAR. Stomatal conductance and activity of mesophyll remained co-ordinated during the whole experiment for the c(70) plants, while for the c(35) plants the correlation between g(s) and mesophyll activity present during step-up PAR response was disrupted at saturating CO₂ concentration and PAR.

DeMothes, M.A.G., M. Baumgarten, and D. Knoppik. 1996. Hysteresis in the response of photosynthesis to CO₂ and saccharide pools of wheat leaves grown at normal and enhanced CO₂. *Photosynthetica* 32(2):181-191.

Wheat plants were cultivated in a growth chamber at 35 Pa (c(35) variant) and 70 Pa CO₂ partial pressure (c(70) variant) during the whole vegetation period. The response of net photosynthetic rate (P-N) of the flag leaf of both variants to successive increases in CO₂ partial pressure (step-up curve) showed hysteresis when the direction of the sequence was reversed (step-down curve) after 1.5 h at saturating CO₂ partial pressure and photosynthetically active radiation (PAR). Saccharose, glucose and fructose accumulated during the measurement of a step-up CO₂ curve for the c(35) and c(70) plants as the export rate was not able to keep pace with the rate of saccharide synthesis. Remaining 1.5 h at saturating CO₂ partial pressure and PAR, the saccharose pool increased further for both variants while glucose and fructose decreased reaching the values at growth conditions. The electron transport rate decreased after 1.5 h at saturating CO₂ partial pressure and PAR for the two variants due to end product feedback. Glucose and fructose contents fell 50 % below the initial contents when partial pressure of CO₂ was lowered stepwise. The c(35) plants showed a double fold increase in the content of saccharose at the end point of the hysteresis curve. Contents

of saccharose for the c(70) variant in contrast were similar to the initial values.

Demothés, M.A.G., and D. Knoppik. 1994. Effects of long-term enhanced co₂ partial-pressure on gas- exchange parameters and saccharide pools of wheat leaves. *Photosynthetica* 30(3):435-445.

Wheat plants were cultivated in a growth chamber at normal (35 Pa, c35 plants) and enhanced (70 Pa, c70 plants) CO₂ partial pressure. In C35 plants the net photosynthetic rate (P(N)) of flag leaves and the concentrations of saccharides such as sucrose, glucose, fructose and starch were increased. The c70 plants possessed higher chlorophyll (Chl) a and Chl b contents. The CO₂ response of P(N) at saturating photosynthetically active radiation (PAR) was very similar for both variants. At the highest CO₂ concentration saccharides accumulated in both variants as a consequence of decreased export rate. The response of P(N) to PAR at saturating CO₂ concentrations was similar in the two variants. On the other hand, the response of water vapour pressure conductance (gH₂O) to PAR in c35 plants followed a hyperbolic response to PAR, while in the c70 plants it was linearly related to PAR up to the mean PAR used for growth. In this variant gH₂O seemed to change parallelly to changes in the mesophyll demand for CO₂ caused by PAR.

Denelzen, M.G.J., and J. Rotmans. 1993. Modeling climate related feedback processes. *Journal of Environmental Science and Health Part A- Environmental Science and Engineering & Toxic and Hazardous Substance Control* 28(9):2095-2151.

Feedback mechanisms play a crucial role in the climate system, amplifying or dampening the climate response to enhanced concentrations of greenhouse gases from anthropogenic perturbations. Many of these feedbacks are known, but most of them only potentially. This article evaluates the role of a number of these feedback processes within the climate system. In order to assess their impact, the feedbacks which at present can be quantified reasonably are built into the Integrated Model to Assess the Greenhouse Effect (IMAGE). Unlike previous studies, this study describes the scenario- and time-dependent role of biogeochemical feedbacks. A number of simulation experiments are performed with IMAGE to project climate changes. Besides estimates of their absolute importance, the relative importance of individual biogeochemical feedbacks is considered by calculating the gain for each feedback process. This study focuses on feedback processes in the carbon cycle and the methane (semi-) cycle. Modeled feedbacks are then used to balance the past and present carbon budget. This results in substantially lower projections for atmospheric carbon dioxide than the Intergovernmental Panel on Climate Change (IPCC) estimates. The difference is approximately 18% from the 1990 level for the IPCC "Business-as-Usual" scenario. Furthermore, the IPCC's "best guess" value of the CO₂ concentration in the year 2100 falls outside the uncertainty range estimated with our balanced modeling approach. For the IPCC "Business-as-Usual" scenario, the calculated total gain of the feedbacks within the carbon cycle appears to be negative, a result of the dominant role of the fertilization feedback. This study also shows that if temperature feedbacks on methane emissions from wetlands, rice paddies, and hydrates do materialize, methane concentrations might be

increased by 30% by 2100. The total effect of the methane feedbacks and the carbon dioxide feedbacks modeled can be expressed in the carbon dioxide- equivalent concentrations. Our simulated CO₂- equivalent concentrations are lower than the IPCC estimates.

Deng, R., and D.J. Donnelly. 1993. In-vitro hardening of red raspberry by co₂ enrichment and reduced medium sucrose concentration. *Hortscience* 28(10):1048-1051.

Micropropagated 'Festival' red raspberry (*Rubus idaeus* L.) shoots were rooted in specially constructed plexiglass chambers in ambient (340 +/- 20 ppm) or enriched (1500 +/- 50 ppm) CO₂ conditions on a medium containing 0, 10, 20, or 30 g sucrose/liter. Plantlet growth and leaf (CO₂)-C-14 fixation rates were evaluated before and 4 weeks after ex vitro transplantation. In vitro CO₂ enrichment promoted in vitro hardening; it increased root count and length, plantlet fresh weight, and photosynthetic capacity but did not affect other variables such as plantlet height, dry weight, or leaf count and area. No residual effects of in vitro CO₂ enrichment were observed on 4-week-old transplants. Sucrose in the medium promoted plantlet growth but depressed photosynthesis and reduced in vitro hardening. Photoautotrophic plantlets were obtained on sucrose-free rooting medium under ambient and enriched CO₂ conditions and they performed better ex vitro than mixotrophic plantlets grown with sucrose. Root hairs were more abundant and longer on root tips of photoautotrophic plantlets than on mixotrophic plantlets. The maximum CO₂ uptake rate of plantlet leaves was 52% that of greenhouse control plant leaves. This did not change in the persistent leaves up to 4 weeks after ex vitro transplantation. The photosynthetic ability of persistent and new leaves of 4-week-old ex vitro transplants related neither to in vitro CO₂ nor medium sucrose concentration. Consecutive new leaves of transplants took up more CO₂ than persistent leaves. The third new leaf of transplants had photosynthetic rates up to 90% that of greenhouse control plant leaves. These results indicate that in vitro CO₂ enrichment was beneficial to in vitro hardening and that sucrose may be reduced substantially or eliminated from red raspberry rooting medium when CO₂ enrichment is used.

Deng, R., and D.J. Donnelly. 1993. In-vitro hardening of red raspberry through co₂ enrichment and relative-humidity reduction on sugar-free medium. *Canadian Journal of Plant Science* 73(4):1105-1113.

Micropropagated shoots of red raspberry (*Rubus idaeus* L. 'Comet') were rooted on modified Murashige-Skoog medium lacking sucrose, in specially 'constructed plexiglass chambers, under ambient (340 +/- 20 ppm) or enriched (1500 +/- 50 PPM) CO₂ and ambient (ca. 100 %) or reduced (90 +/- 5 %) relative humidity. Cultured plantlets were evaluated for their survival, rooting and relative vigor, leaf and root number, stem and root length, total leaf area, total fresh and dry weight, gas exchange rate, and stomatal features, prior to transplantation to soil and at intervals for 6 wk ex vitro. In vitro CO₂ enrichment promoted plantlet growth, rooting and both the survival and early growth of transplants. CO₂ enrichment increased stomatal aperture of plantlet leaves but did not apparently increase water stress at transplantation. Reduced in vitro RH did not affect plantlet growth but decreased stomatal apertures and stomatal index on leaves of cultured plantlets and promoted both the survival and early growth of transplants. In vitro CO₂

and RH levels did not affect the photosynthetic rate of either plantlets or transplants. Only the stomata on leaves of plantlets from the ambient CO₂ and reduced RH treatment were functional. Normal stomatal function was not observed in persistent leaves of transplants from the other treatments, even 2 wk after transplantation. In vitro CO₂ enrichment acted synergistically with RH reduction in improving growth of plantlets both in vitro and ex vitro. Hardened red raspberry plantlets obtained through CO₂ enrichment and RH reduction survived direct transfer to ambient greenhouse conditions without the necessity for specialized ex vitro acclimatization treatment.

Deng, X., and F.I. Woodward. 1998. The growth and yield responses of *Fragaria ananassa* to elevated CO₂ and N supply. *Annals of Botany* 81(1):67-71.

Strawberry plants (*Fragaria ananassa* Duchesne var. Elsanta) were grown in pots at two concentrations of carbon dioxide (partial pressures of 39 and 56 Pa) and with three rates of nitrogen supply (0.04, 0.4 and 4 mM as nutrient solution) to study their individual and interactive effects on plant growth and fruit yield. Nitrogen deficiency reduced total dry biomass and relative growth rate (RGR), mainly through reductions in leaf area ratio (LAR) and plant N concentration (PNC), although both the net assimilation rate (NAR) and root weight ratio (RWR) increased. Elevated CO₂ increased the N productivity (NP) but reduced the LAR. High CO₂ increased the fruit yield by 42% at high N supply and by 17% at low N supply. The CO₂ yield enhancement occurred through an increase in the flower and fruit number of individual plants. This resulted in an increase in the fruit weight ratio (FWR) of plants at high CO₂. Nitrogen deficiency reduced the fruit yield by about 50% through decreases in fruit size, fruit set and the number of fruits. However, N deficiency increased the proportion of total plant dry biomass allocated to fruits. There were no significant interactions between CO₂ and N supply on yield. (C) 1998 Annals of Botany Company.

denHertog, J., I. Stulen, F. Fonseca, and P. Delea. 1996. Modulation of carbon and nitrogen allocation in *Urtica dioica* and *Plantago major* by elevated CO₂: Impact of accumulation of nonstructural carbohydrates and ontogenetic drift. *Physiologia Plantarum* 98(1):77-88.

Doubling the atmospheric CO₂ concentration from 350 to 700 $\mu\text{mol l}^{-1}$ increased the relative growth rate (RGR) of hydroponically grown *Urtica dioica* L. and *Plantago major* ssp. *pleiosperma* Pilger only for the first 10-14 days. Previous experiments with *P. major* led to the conclusion that RGR did not respond in proportion to the rate of photosynthesis. The present paper is focussed on the analysis of the impact of changes in leaf morphology, dry matter partitioning, dry matter chemical composition and ontogenetic drift on this discrepancy. Soon after the start of the treatment, carbohydrate concentrations were higher at elevated CO₂; a reaction that was largely due to starch accumulation. An increase in the percentage of leaf dry matter and decreases in the specific leaf area (SLA) and the shoot nitrogen concentration were correlated with an increase in the total nonstructural carbohydrate concentration (TNC). A combination of accumulation of soluble sugars and starch and ontogenetic drift explains the decrease in SLA at the elevated CO₂ level. A similar ontogenetic effect of elevated CO₂ was observed on the specific root length (SRL). Other variables such as shoot nitrogen concentration and percentage leaf dry matter were not affected by

correction of data for TNC levels. The net diurnal fluctuation of the carbohydrate pool in *P. major* was equal for both CO₂ concentrations, indicating that the growth response to elevated CO₂ may be ruled by variables other than photosynthesis, as for instance sink strength. Elevated CO₂ did not greatly influence the partitioning of nitrogen between soluble and insoluble, reduced N and nitrate, nor the allocation of dry matter between leaf, stem and root. The finding that the root to shoot ratio (R/S) was not affected by elevated CO₂ implies that, in order to maintain a balanced activity between roots and shoot, no shift in partitioning of dry matter upon doubling of the atmospheric CO₂ concentration is required. Our data on R/S are in good agreement with the response of R/S to high CO₂ predicted by models based on such a theorem.

Denhertog, J., I. Stulen, and H. Lambers. 1993. Assimilation, respiration and allocation of carbon in *Plantago major* as affected by atmospheric CO₂ levels - a case-study. *Vegetatio* 104:369-378.

The response of *Plantago major* ssp. *pleiosperma* plants, grown on nutrient solution in a climate chamber, to a doubling of the ambient atmospheric CO₂ concentration was investigated. Total dry matter production was increased by 30 % after 3 weeks of exposure, due to a transient stimulation of the relative growth rate (RGR) during the first 10 days. Thereafter RGR returned to the level of control plants. Photosynthesis, expressed per unit leaf area, was stimulated during the first two weeks of the experiment, thereafter it dropped and nearly reached the level of the control plants. Root respiration was not affected by increased atmospheric CO₂ levels, whereas shoot, dark respiration was stimulated throughout the experimental period. Dry matter allocation over leaves stems and roots was not affected by the CO₂ level. SLA was reduced by 10%, which can partly be explained by an increased dry matter content of the leaves. Both in the early and later stages of the experiment, shoot respiration accounted for a larger part of the carbon budget in plants grown at elevated atmospheric CO₂. Shifts in the total carbon budget were mainly due to the effects on shoot respiration. Leaf growth accounted for nearly 50 % of the C budget at all stages of the experiment and in both treatments.

den Hertog, J., I. Stulen, F. Posthumus, and H. Poorter. 1998. Interactive effects of growth-limiting N supply and elevated atmospheric CO₂ concentration on growth and carbon balance of *Plantago major*. *Physiologia Plantarum* 103(4):451-460.

To assess the interactions between concentration of atmospheric CO₂ and N supply, the response of *Plantago major* ssp. *pleiosperma* Pilger to a doubling of the ambient CO₂ concentration of 350 $\mu\text{mol l}^{-1}$ was investigated in a range of exponential rates of N addition. The relative growth rate (RGR) as a function of the internal plant nitrogen concentration (N_i), was increased by elevated CO₂ at optimal and intermediate N_i. The rate of photosynthesis, expressed per unit leaf area and plotted Versus N_i, was increased by 20-30% at elevated CO₂ for N_i above 30 mg N g⁻¹ dry weight. However, the rate of photosynthesis, expressed on a leaf dry matter basis and plotted versus N_i, was not affected by the CO₂ concentration. The allocation of dry matter between shoot and root was not affected by the CO₂ concentration at any of the N addition rates. This is in good agreement with theoretical models, based on a balance between the rate of photosynthesis of the shoot and

the acquisition of N by the roots. The concentration of total nonstructural carbohydrates (TNC) was increased at elevated CO₂ and at N limitation, resulting in a shift in the partitioning of photosynthates from structural to nonstructural and, in terms of carbon balance, unproductive dry matter. The increase in concentration of TNC led to a decrease in both specific leaf area (SLA) and Ni at all levels of nutrient supply, and was the cause of the increased rate of photosynthesis per unit leaf area. Correction of the relationship between RGR and Ni for the accumulation of TNC made the effect of elevated CO₂ on the relationship between RGR and Ni disappear. We conclude that the shift in the relationship between RGR and Ni was due to the accumulation of TNC and not due to differences in physiological variables such as photosynthesis and shoot and root respiration, changes in leaf morphology or allocation of dry matter.

Denmead, O.T., F.X. Dunin, S.C. Wong, and E.A.N. Greenwood. 1993. Measuring water-use efficiency of eucalypt trees with chambers and micrometeorological techniques. *Journal of Hydrology* 150(2-4):649-664.

Enclosure appears to be the only feasible way to examine the gas exchange of small groups of trees or to answer questions about the effects of increased atmospheric CO₂ on the assimilation, evaporation and water use efficiency of forests. To be effective, enclosures must necessarily change the microclimate, but few studies have been made of the consequences. In this paper, the assimilation, evaporation and water use efficiency of a community of Eucalyptus trees inside a ventilated chamber are compared with the same attributes for the surrounding forest. Assimilation and evaporation for the chamber were measured by the depletion in CO₂ and the enrichment in water vapour of air passing through the chamber. For the forest, assimilation and evaporation were determined by micrometeorological techniques based on the energy balance, and for CO₂, additional chamber measurements of the soil efflux. Water use efficiencies were calculated as the ratio of mol CO₂ assimilated to mol water evaporated. There are some important microclimatic differences between chamber and forest: net radiation is reduced by about 30% in the chamber, the vapour pressure deficit of the chamber air is lower, and the light climate there tends to be diffuse rather than direct. Despite these differences, evaporation rates for both chamber and forest were generally similar, perhaps due to compensating effects in the chamber from higher boundary layer conductances (because of greater ventilation rates) and higher stomatal conductances (because of increased humidity). However, assimilation rates and water use efficiencies were markedly different for the two communities in clear sky conditions, with higher values of both being recorded in the chamber for most of the daylight hours. Only on cloudy days, when the light climate was diffuse in both chamber and forest, were similar assimilation rates and water use efficiencies observed. This behaviour seems to be attributable in part to the light climate in the chamber being predominantly diffuse and that in the forest predominantly direct. Diffuse light enhances the photosynthesis of lower leaves in the canopy. This contention is supported by model calculations of canopy assimilation under diffuse and direct radiation which produced qualitatively the same light response functions as observed for chamber and forest. The study suggests that the use of chambers for exploring questions of forest productivity and water use efficiency must be circumspect. The act of enclosure, by itself, can change the daily water use efficiency of the tree community by as much as 50%.

To study the effect of elevated CO₂ concentration on plant growth and photosynthesis, two clones of *Hevea brasiliensis* were grown in polybags and exposed to elevated concentration (700±25 ppm) for 60 days. There was higher biomass accumulation, leaf area and better growth when compared to ambient air grown plants. From A/Ci curves it is clear that photosynthetic rates increases with increase in CO₂ concentrations. After 60 days of exposure to higher CO₂ concentration, a decrease in the carbon assimilation rate was noticed.

Devakumar, A.S., M. Udayakumar, and T.G. Prasad. 1996. A simple technique to expose tree seedlings to elevated CO₂ for increased initial growth rates. *Current Science* 71(6):469-472.

Initial growth rates of most tree species that are used in afforestation programmes are very low. Therefore, polybag planted seedlings have to be maintained in the nurseries for a long period of time. Growing plants in an elevated CO₂ atmosphere increases the growth rates as well as biomass production in many annual crop and tree species. Higher temperature and relative humidity in association with elevated CO₂ concentration helps to boost the biomass and leaf area production. We demonstrate here an easy and cost-effective method for obtaining elevated CO₂ concentrations for better growth of tree seedlings in the nursery.

de Wild, H.P.J., E.J. Woltering, and H.W. Peppelenbos. 1999. Carbon dioxide and 1-MCP inhibit ethylene production and respiration of pear fruit by different mechanisms. *Journal of Experimental Botany* 50(335):837-844.

Ethylene production in relation to O₂ partial pressure of whole pear fruit stored at 2 degrees C could be described by a Michaelis-Menten equation. This was indicated by the use of a gas exchange model. The maximum ethylene production rate was strongly inhibited while the K-mO₂ value (1.25 kPa) was not affected by elevated CO₂. Ethylene production was also inhibited by 1-MCP, an inhibitor of ethylene perception. The reduction in ethylene production by CO₂ was similar for 1-MCP treated and untreated pears. Elevated CO₂, therefore, must have had an influence on ethylene production other than through ethylene perception. A possible site of inhibition by CO₂ is the conversion of ACC to ethylene. The O₂ uptake rate in relation to O₂ partial pressure of whole pear fruit could be described by a Michaelis-Menten equation. The O₂ uptake rate was inhibited by elevated CO₂ at a level similar to the inhibition of ethylene production. Again the K-mO₂ value (0.68 kPa)

was not affected by CO₂. Using 1-MCP treatments it was shown that there was no direct effect of inhibited ethylene production on O₂ uptake rate.

Deyton, D.E., C.E. Sams, and J.C. Cummins. 1992. Application of dormant oil to peach-trees modifies bud twig internal atmosphere. *Hortscience* 27(12):1304-1305.

Treatments of single applications of 0%, 3%, 6%, 9%, or 12% dormant oil were sprayed on peach (*Prunus persica* L. Batsch) trees on 6 Feb. 1990. A repeat application of 6% oil plus 6% oil applied 6 days later was also made. Internal CO₂ concentrations of oil-treated buds and twigs were higher than the control the day after treatment and continued to be higher for 6 days. The second application of 10% oil prolonged the elevated CO₂ concentration. Applications of 9% or 12% oil delayed flower bud development and bloom. The repeated application of 6% oil delayed bud development and bloom more than a single application of 6% oil. Damage to fruit buds increased as oil concentration increased, but repeated application of 6% oil resulted in less damage than a single application of 12% oil.

Dhakhwa, G.B., and C.L. Campbell. 1998. Potential effects of differential day-night warming in global climate change on crop production. *Climatic Change* 40(3-4):647-667.

Recent studies on the nature of global warming indicate the likelihood of an asymmetric change in temperature, where night-time minimum temperature increases more rapidly than the daytime maximum temperature. We used a physically based scenario of asymmetric warming combined with climate change scenarios from General Circulation Models (GCMs) outputs and the EPIC (Erosion Productivity Impact Calculator) plant process model to examine the effects of asymmetric temperature change on crop productivity. Our results indicated that the potential effects of global change on crop productivity may be less severe with asymmetric day-night warming than with equal day-night warming.

Dhakhwa, G.B., C.L. Campbell, S.K. LeDuc, and E.J. Cooter. 1997. Maize growth: assessing the effects of global warming and CO₂ fertilization with crop models. *Agricultural and Forest Meteorology* 87(4):253-272.

Projected future climate change scenarios derived from two General Circulation Models (GCMs): Geophysical Fluid Dynamics Laboratory (GFDL) and United Kingdom Meteorological Office (UKMO), and two crop models: Crop Estimation through Resources and Environmental Synthesis (CERES), and Erosion/Productivity Impact Calculator (EPIC), were considered to assess the climate change impact on the yield and biomass of maize. Climate change scenarios included changes in temperature, precipitation and solar radiation from two GCMs interpolated to 1 degrees x 1 degrees grid cells in the central Piedmont in

North Carolina. Changes in mean monthly temperature and precipitation from the GCMs were used to adjust observed daily climate records from 1949-1988. There is convincing evidence that future temperature linked to global warming might be characterized by asymmetric change between daily daytime maxima and daily nighttime minima. Two hypotheses regarding how GCM temperature would alter observational record were examined. The first hypothesis assumed that daytime and nighttime warming occurs symmetrically, i.e., maximum and minimum temperatures are raised equally. The second hypothesis assumed that nighttime minima change is three times greater than daytime maxima change and the change in mean diurnal temperature range is approximately equal to the change in daily mean temperature. For the equal day-night warming scenario, when only the effects of climate change (i.e., changes in temperature, precipitation and solar radiation) were considered, simulations with CERES and EPIC indicated substantial losses in maize grain yield and total above ground biomass with both the GCM scenarios. For the asymmetric warming, the reduction in biomass and yield due to climate change was less than that obtained with symmetric warming. Simulated maize yield and biomass with CERES and EPIC increased when only effects due to CO₂-fertilization were considered. The inclusion of CO₂ fertilization effects with those due to climate change resulted in higher biomass and yield compared to values obtained with effects of climate change alone. When CERES was used with the GFDL scenario, and the effects of CO₂ fertilization and the climate change were combined, no difference in simulated yield was found between the two hypotheses; only an 8% difference in aboveground biomass was found when the UKMO scenario was used. When EPIC was used, the differential day-night warming hypothesis resulted in 9-13% less reduction in biomass and yield than did the use of the equal day-night warming hypothesis. Dhillion, S.S., J. Roy, and M. Abrams. 1996. Assessing the impact of elevated CO₂ on soil microbial activity in a Mediterranean model ecosystem. *Plant and Soil* 187(2):333-342.

The fate, as well as the consequence for plant nutrition, of the additional carbon entering soil under elevated CO₂ is largely determined by the activity of soil microorganisms. However, most elevated CO₂ studies have documented changes (generally increases) in microbial biomass and total infection by symbiotic organisms, which is only a first step in the understanding of the modification of soil processes. Using a Mediterranean model ecosystem, we complemented these variables by analyzing changes in enzymatic activities, hyphal lengths, and bacterial substrate assimilation, to tentatively identify the specific components affected under elevated CO₂ and those which suggest changes in soil organic matter pools. We also investigated changes in the functional structures of arbuscular mycorrhizas. Most of the microbial variables assessed showed significant and substantial increase under elevated CO₂ of the same order or less than those observed for root mass and length. The increase in dehydrogenase activity indicates that the larger biomass of microbes was accompanied by an increase in their activity. The increase in hyphal length (predominantly of saprophytic fungi), and xylanase, cellulase and phosphatase activities, suggests an overall stimulation of organic matter decomposition. The higher number of substrates utilized by microorganisms from the soil under elevated CO₂ was significant for the amine/amide group. Total arbuscular and vesicular mycorrhizal infection of roots was higher under elevated CO₂, but the proportion of functional structures was not modified. These insights into the CO₂-induced changes in soil biological activity point towards potential areas of investigation complementary to a direct

analysis of the soil organic matter pools.

Diaz, S. 1995. Elevated CO₂ responsiveness, interactions at the community level and plant functional types. *Journal of Biogeography* 22(2-3):289-295.

Plant responsiveness to elevated carbon dioxide (CO₂) is a relevant dimension for the definition of functional types in the face of global change. Most traits reported to be associated with high CO₂ responsiveness are derived from laboratory experiments on individually grown species. This paper suggests that physiological traits such as photosynthetic pathway and internal sink strength are necessary, but not enough for the prediction of plant responses in mixed stands. A number of examples from the literature are presented to illustrate how predictions based on single-species experiments may not match the behaviour of multi-species assemblages. Individual attributes associated to the interaction of the species with other members of the community should be also considered. Morphogenetic and architectural traits, as well as characteristics related to other trophic levels, such as the presence of root symbionts or the preferential allocation to growth or defences against herbivory, may be useful for a better prediction of plant responsiveness to high CO₂ in the field.

Diaz, S. 1996. Effects of elevated [CO₂] at the community level mediated by root symbionts. *Plant and Soil* 187(2):309-320.

This review examines the effects of elevated [CO₂] on plant symbioses with mycorrhizal fungi and root nodule bacteria, with emphasis on community and ecosystem processes. The effects of elevated [CO₂] on the relationships between single plant species and root symbionts are considered first. There is some evidence that plant infection by and/or biomass of root symbionts are stimulated by elevated [CO₂], but growth enhancement of the host seemingly depends on its degree of dependence on symbiosis and on soil nutrient availability. Second, the effects of elevated [CO₂] on the relationships between plant multispecies assemblages and soil, and likely impacts on above-ground and belowground diversity, are analysed. Experimental and modelling work have suggested the existence of complex feedbacks in the responses of plants and the rhizosphere to CO₂ enrichment. By modifying C inputs from plants to soil, elevated [CO₂] may affect the biomass, the infectivity, and the species/isolate composition of root symbionts. This has the potential to alter community structure and ecosystem functioning. Finally, the incorporation of type and degree of symbiotic dependence into the definition of plant functional types, and into experimental work within the context of global change research, are discussed. More experimental work on the effects of elevated [CO₂] at the community/ecosystem level, explicitly considering the role of root symbioses, is urgently needed.

Diaz, S., and M. Cabido. 1997. Plant functional types and ecosystem function in relation to global change. *Journal of Vegetation Science* 8(4):463-474.

Plant functional types (PFTs) bridge the gap between plant physiology and community and ecosystem processes, thus providing a powerful tool in climate change research. We aimed at identifying PFTs within the flora of central-western Argentina, and to explore their possible consequences for ecosystem function. We analyzed 24 vegetative and regenerative traits of the 100 most abundant species along a steep climatic gradient. Based on plant traits and standard multivariate techniques, we identified eight PFTs. Our results confirmed, over a wide range of climatic conditions, the occurrence of broad recurrent patterns of association among plant traits reported for other floras; namely trade-offs between high investment in photosynthesis and growth on the one hand, and preferential allocation to storage and defence on the other. Regenerative traits were only partially coupled with vegetative traits. Using easily-measured plant traits and individual species cover in 63 sites, we predicted main community- ecosystem processes along the regional gradient. We hypothesized likely impacts of global climatic change on PFTs and ecosystems *in situ*, and analysed their probabilities of migrating in response to changing climatic conditions. Finally, we discuss the advantages and limitations of this kind of approach in predicting changes in plant distribution and in ecosystem processes over the next century.

Diaz, S., M. Cabido, M. Zak, E.M. Carretero, and J. Aranibar. 1999. Plant functional traits, ecosystem structure and land-use history along a climatic gradient in central-western Argentina. *Journal of Vegetation Science* 10(5):651-660.

This paper deals with theoretical concepts, methodological steps, and case studies related to the use of plant functional traits in the assessment of vegetation responses to climate and land use. Trait-environment links are considered, and special emphasis is put on the links between vegetation structure and ecosystem function, and on the role of disturbance history in determining vegetation responses to land use at present. As a basis for discussion, published and new case studies from central-western Argentina are presented. Similar plant traits measured with different levels of precision are utilized in the description of ecosystem structure in different land-use situations along a steep regional climatic gradient. The general protocol followed in the case studies represents a data-driven, non-hierarchical, low-tech approach, that can be applied to a wide range of spatial scales, from plots to regions. Climatic factors (including extreme events and seasonality), disturbance frequency and intensity, and disturbance history are suggested as key factors to be considered in global comparisons of vegetation responses to land use and in predictive models of ecosystem dynamics.

Diaz, S., L.H. Fraser, J.P. Grime, and V. Falczuk. 1998. The impact of elevated CO₂ on plant-herbivore interactions: experimental evidence of moderating effects at the community level. *Oecologia* 117(1-2):177-186.

Surprisingly little research has been published on the responses to elevated [CO₂] at the community level, where herbivores can select their preferred food. We investigated the combined effects of atmospheric [CO₂] and herbivory on synthesised plant communities growing on soils of different fertility. Factorial combinations of two [CO₂] (350 or 700 $\mu\text{mol l}^{-1}$), two fertility (fertilised or non-fertilised), and two herbivory (herbivores present or absent) treatments were applied to a standard mixture of seven fast- and eight slow-growing plants in outdoor microcosms. The herbivores used were the grain aphid (*Sitobion avenae*) and the garden snail (*Helix aspersa*). We measured plant biomass, foliar nitrogen and soluble tannin concentration, aphid fecundity, and snail growth, fecundity, and feeding preferences over one growing season. Elevated [CO₂] did not have a significant impact on (1) the combined biomass of fast-growing or slow-growing plants, (2) herbivore feeding preferences, or (3) herbivore fitness. There was, however, a significant biomass increase of *Carex flacca* (which represented in all cases less than 5% of total live biomass), and some chemical changes in unpalatable plants under elevated [CO₂]. The herbivory treatment significantly increased the biomass of slow-growing plants over fast-growing plants, whereas fertilisation significantly increased the abundance of fast-growing plants over slow-growing plants. Predictions on the effects of elevated [CO₂] based on published single-species experiments were not supported by the results of this microcosm study.

Diaz, S., J.P. Grime, J. Harris, and E. McPherson. 1993. Evidence of a feedback mechanism limiting plant-response to elevated carbon-dioxide. *Nature* 364(6438):616-617.

IN short-term experiments under productive laboratory conditions, native herbaceous plants differ widely in their potential to achieve higher yields at elevated concentrations of atmospheric carbon dioxide¹⁻⁸. The most responsive species appear to be large fast-growing perennials of recently disturbed fertile soils^{7,8}. These types of plants are currently increasing in abundance⁹ but it is not known whether this is an effect of rising carbon dioxide or is due to other factors. Doubts concerning the potential of natural vegetation for sustained response to rising carbon dioxide have arisen from experiments on infertile soils, where the stimulus to growth was curtailed by mineral nutrient limitations^{2,3,10}. Here we present evidence that mineral nutrient constraints on the fertilizer effect of elevated carbon dioxide can also occur on fertile soil and in the earliest stages of secondary succession. Our data indicate that there may be a feedback mechanism in which elevated carbon dioxide causes an increase in substrate release into the rhizosphere by non-mycorrhizal plants, leading to mineral nutrient sequestration by the expanded microflora and a consequent nutritional limitation on plant growth.

Dickson, R.E., M.D. Coleman, D.E. Riemenschneider, J.G. Isebrands, G.D. Hogan, and D.F. Karnosky. 1998. Growth of five hybrid poplar genotypes exposed to interacting elevated CO₂ and O₃. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 28(11):1706-1716.

A wide variety of hybrid poplar clones are being introduced for intensive culture biomass production, but the potential clonal or genotypic

response to increasing tropospheric carbon dioxide (CO₂), ozone (O₃), and their interactions are unknown. To study these effects, we exposed five different hybrid *Populus* clones to increased concentrations of CO₂, O₃, and CO₂ + O₃ in open-top chambers for one growing season and determined growth responses. Exposure to elevated CO₂ increased height growth, dry mass, and basal area; exposure to O₃ decreased all three of these growth responses. Exposure impact differed among the different plant parts (leaf, stem, and roots) and among the clones. These differences were associated with different growth strategies or carbon allocation patterns inherent in the different clones. The fastest growing clones had the greatest response to O₃ treatment. The addition of CO₂ to the O₃ exposure counteracted the negative impact of O₃ in all plant components except leaf mass (e.g., CO₂ + O₃ plant mass equaled control plant mass) in all of the clones. But correspondingly, added O₃ negated increased growth from CO₂. Genetic variation in response to atmospheric pollutants must be considered even in closely related genotypes found in *Populus* culture.

Didham, R.K. 1998. Altered leaf-litter decomposition rates in tropical forest fragments. *Oecologia* 116(3):397-406.

The effects of forest fragmentation on leaf-litter decomposition rates were investigated for the first time in an experimentally fragmented tropical forest landscape in Central Amazonia. Leaf-litter decomposition rates were measured at seven distances (0-420 m) along forest edge-to-interior transects in two 100-ha fragments, two continuous forest edges, and at an identical series of distances along two deep continuous forest transects, as well as at the centers of two 1-ha and two 10-ha fragments. Decomposition rates increased significantly towards the edge of 100-ha forest fragments. Litter turnover times were 3-4 times faster within 50 m of the edge of 100-ha fragments than normally found in deep continuous forest. In contrast, there was no significant change in the rate of leaf-litter decomposition from the interior to the edge of continuous forest. It is difficult to account for these very different edge responses. Decomposition rates were not correlated with air temperature differentials, evaporative drying rates, litter depth, biomass or moisture content, or with total invertebrate densities, either within individual edge transects or across all sites. The difference in edge response may be due to chance, particularly the patchy removal of vast quantities of litter by litter-feeding termites, or may be a real, area-dependent phenomenon. Clearly, however, forest fragmentation increases the variability and unpredictability of litter decomposition rates near forest edges. In addition to edge effects, decomposition rates were strongly affected by decreasing fragment area. While sites at the centers of 10-ha and 100-ha forest fragments and continuous forest had equivalent decomposition rates, rates were markedly lower at the centers of 1-ha fragments. Litter turnover times were 2-3 times slower in 1-ha fragments than in continuous forest, and up to 13 times slower than at 100-ha edges. Litter structure and nutrient cycling dynamics are inevitably altered by forest fragmentation.

Diemer, M.C., and C. Korner. 1996. Lifetime leaf carbon balances of herbaceous perennial plants from low and high altitudes in the central Alps. *Functional Ecology* 10(1):33-43.

1. A combination of demographic analysis of leaf growth, age-specific CO₂ gas exchange and microclimate were employed to calculate lifetime sums of net photosynthesis and dark respiration, in order to obtain leaf carbon balances (Q(c)) of altitudinally disjunct *Ranunculus* and *Geum* species, as well as two altitudinal populations of *Potentilla crantzii*. If carbon costs for construction of leaf tissue are included, leaves fixed a lifetime carbon surplus ranging from 0.4 to 2.0 mmol CO₂ cm⁻² independent of altitude, thereby exceeding initial investments by the plant three- to sixfold. 2. The lack of a consistent difference between the Q(c) of high and related low elevation taxa with similar leaf area ratios (LAR) challenges the view that carbon gain impairs growth and persistence of herbaceous perennials in harsh alpine climates to a greater extent than at low elevation. 3. Evidence from a sensitivity analysis of our carbon balance model as well as rank correlations indicate that the primary determinant of a leaf's carbon balance is its longevity. A comparison of leaf carbon balance data from the literature on wild plants of the temperate zone suggests that daily carbon gain on a leaf area basis is higher in herbaceous plants, compared to deciduous woody shrubs, which could explain the predominance of the herbaceous growth form at high altitudes.

Diemer, M. 1992. Population-dynamics and spatial arrangement of *ranunculus-glacialis* L., an alpine perennial herb, in permanent plots. *Vegetatio* 103(2):159-166.

In 1986 sixteen permanent plots (625 cm² each) were established in scree slopes dominated by *Ranunculus glacialis* at Mt. Glungezer, Austria (2600 m elevation) in order to document the population dynamics of herbaceous perennials near the upper altitudinal limits of plant existence. The abundance and sizes of individual *R. glacialis* shoots, their leaf numbers and reproductive status were evaluated over a 6-year period. On South-facing slopes the population sizes of adult and juvenile shoots remained constant over the years, while seedling numbers fluctuated significantly. Overall density of all developmental stages of *R. glacialis* was significantly lower on North-facing slopes and year-to-year fluctuations were greater, than on thermally-favorable Southern slopes. The spatial pattern of adult shoots and seedlings was clumped, while juvenile shoots had a random or clumped distribution. Fertilization had no effects on population dynamics. Proposed greenhouse effects, e.g. increases in CO₂ and temperature, should result in population growth on North-facing slopes and may increase mortality on South-facing sites.

Diemer, M.W. 1994. Mid-season gas-exchange of an alpine grassland under elevated CO₂. *Oecologia* 98(3-4):429-435.

Ecosystem net CO₂ uptake, evapotranspiration (ET) and night-time CO₂ efflux were measured in an alpine grassland dominated by *Carex curvula*, treated with doubled ambient partial pressure of CO₂ via open-top chambers. One quarter of the plots were treated with mineral nutrients to simulate the effect of lowland nitrogen deposition rates. Depending upon fertilizer supply, ecosystem net CO₂ uptake per ground area in full sunlight (NCE(max)) was 41-81% higher in open-top chambers supplied with doubled ambient partial pressure (p(a)) of CO₂ than in plots receiving ambient CO₂. Short-term reversals of the CO₂ level suggest that the extent of downward adjustment of canopy photosynthesis under elevated CO₂ was 30-40%. ET tended to decline, while water use efficiency (WUE), expressed as the NCE(max):ET ratio, increased more than twofold under elevated CO₂. Night-time ecosystem

CO₂ efflux did not respond to changes in CO₂ p(a). NCE(max) and night-time CO₂ efflux were more responsive to mineral fertilizer than the doubling of CO₂. This suggests that in these alpine plant communities, atmospheric nutrient input may induce equal or greater effects on gas exchange than increased CO₂.

Diemer, M. 1996. The incidence of herbivory in high-elevation populations of *Ranunculus glacialis*: A re-evaluation of stress-tolerance in alpine environments. *Oikos* 75(3):486-492.

Growing conditions in the upper alpine zone are characterized by low temperature, low partial pressures of CO₂ and, in the temperate zone, a short growing period. The plants which have evolved under these conditions presumably share a number of characteristics that were ascribed to stress-tolerance, namely slow growth, extended longevity, resource limitation and low palatability to herbivores. Hence chronic biomass removals by herbivores should be a threat to plant persistence in alpine environments, as predicted by Grime's C-S-R theory. I tested this hypothesis on populations of an alpine buttercup, *Ranunculus glacialis*. A survey along an altitudinal transect in the Central Alps of Austria indicated that between 15 and 26% of the *R. glacialis* plants in each population examined exhibited signs of herbivory damage. Merely a small population, isolated by glaciers, at the highest site (3310 m a.s.l.) showed no traces of herbivory. At two sites (2600 m and 3180 m a.s.l.) twenty plants each were tagged and examined for a two-year period. Herbivory damage was considerable: on an average nearly 25% of a plant's total leaf area was removed in 1987, primarily by snow mice (*Microtus nivalis*). Inflorescences of 65-85% of all flowering plants were removed as well. At the lower site (2600 m, roughly 600 m above the treeline) up to 5 g dry matter and 140 mg nitrogen m⁻² were consumed in one season. Despite the magnitude of these losses both reproductive investment and the number of leaves initiated per plant did not change appreciably in the subsequent year. Since populations of *R. glacialis* are able to support populations of herbivores at the altitudinal limits of plant growth without obvious reductions in vigor, these plants and other food species (e.g. *Oxyria digyna*) cannot fit the stress-tolerator scheme proposed by Grime. The widespread occurrence of herbivory at high elevations and plant traits challenge the concept of stress-tolerance as it is commonly applied to alpine environments.

Diemer, M. 1997. Effects of elevated CO₂ on gas exchange characteristics of alpine grassland. *Acta Oecologica-International Journal of Ecology* 18(3):177-182.

The ecosystem-level gas exchange characteristics of an alpine grassland treated with a combination of elevated CO₂ and moderate additions of NPK fertilizer during the third season of experimental treatments are described. Mid-season maximum daytime net ecosystem CO₂ flux (NEC) increased significantly under elevated CO₂ (+45%), whereas nighttime NEC was unaffected by the CO₂ treatment. Since daytime NEC under elevated CO₂ underwent a seasonal decline, only moderate carbon surpluses accumulated under elevated CO₂. The observed seasonal decline in daytime NEC may be due to reduced sink strength once maximum aboveground biomass is attained, and appears to be a regulatory mechanism of ecosystem carbon accumulation. Moderate additions of NPK fertilizer stimulated both day- (+39%) and nighttime NEC (+29%) due to increased plant biomass, independent of CO₂ treatment. Yet there is no indication that enhanced mineral nutrient

status will increase ecosystem responsiveness to elevated CO₂.

542

Diemer, M., and C. Korner. 1998. Transient enhancement of carbon uptake in an alpine grassland ecosystem under elevated CO₂. *Arctic and Alpine Research* 30(4):381-387.

We investigated the carbon uptake and release of a Central European alpine grassland community subjected to doubled ambient CO₂ during the third (1994) and fourth (1995) season of CO₂ enrichment. Within this period net carbon uptake under elevated CO₂ declined successively, providing evidence of carbon saturation in this high-elevation environment. Third year data were used to calculate a CO₂ balance for the 13-wk growing season and indicated that the grassland still served as net carbon sink in 1994. Integrated over the growth period, plots exposed to doubled ambient CO₂ fixed 22% more CO₂ than control treatments receiving ambient CO₂. Increased carbon uptake under elevated CO₂ was entirely due to a stimulation of daytime net CO₂ uptake, since nighttime CO₂ release remained unaffected. However, enhancement of net canopy CO₂ uptake showed a distinct seasonal response: following substantial net CO₂ gains from snowmelt until attainment of peak biomass (ca. 6 wk), the relative effect of elevated CO₂ declined over the remainder of the season. In contrast to controls, the C balance became negative under CO₂ enrichment during the final weeks of the growth period. Estimates of wintertime respiratory CO₂ losses of unfertilized plots (ca. 9 mo during which soils remain thawed under the snow) indicate a release of 73 to 89% of the amount of CO₂ fixed during the snow-free period. Under elevated CO₂ an estimated mean surplus of 41 g C m⁻² accreted during the third year of CO₂ enrichment, which we hypothesize must be transferred belowground, since aboveground biomass remained unchanged. Moderate additions of mineral fertilizer (NPK) alone had a strong positive effect on seasonal net CO₂ balance (57% increase) mediated by enhanced plant biomass. NPK-treated plots under elevated CO₂ had a 38% higher seasonal CO₂ balance, relative to NPK-plots at ambient CO₂ concentration. Fourth-year (1995) data indicate no further stimulation of daytime net ecosystem CO₂ flux under elevated CO₂, both in unfertilized plots and plots treated with NPK. Hence, it is unlikely that alpine grasslands will serve as carbon sinks in a CO₂-rich world in the long term.

Dietz, T., and E.A. Rosa. 1997. Effects of population and affluence on CO₂ emissions. *Proceedings of the National Academy of Sciences of the United States of America* 94(1):175-179.

We developed a stochastic version of the Impact = Population Affluence Technology (IPAT) model to estimate the effects of population, affluence, and technology on national CO₂ emissions. Our results suggest that, for population, there are diseconomies of scale for the largest nations that are not consistent with the assumption of direct proportionality (log-linear effects) common to most previous research. In contrast, the effects of affluence on CO₂ emissions appear to reach a maximum at about \$10,000 in per-capita gross domestic product and to decline at higher levels of affluence. These results confirm the general value of the IPAT model as a starting point for understanding the anthropogenic driving forces of global change and suggest that population and economic growth anticipated over the next decade will exacerbate greenhouse gas emissions.

Diiorio, A.A., R.D. Cheetham, and P.J. Weathers. 1992. Carbon-dioxide improves the growth of hairy roots cultured on solid medium and in nutrient mists. *Applied Microbiology and Biotechnology* 37(4):463-467.

The effect of varying CO₂ concentrations on the growth of beet and safflower hairy roots was measured for tissues cultured in nutrient mists and on solid media in chambers fed mixtures of humidified air supplemented with different CO₂ concentrations. Hairy root tissue grown on solid media in air enriched with CO₂ showed increased growth, as measured by dry weight increases vs air-fed controls. Growth increased with CO₂ enrichment as much as 2.5 times more than the air-fed control for safflower at 1.0 % CO₂ and 1.4 times more than the air-fed control for beets at 1.5 % CO₂ over a 12-day period. Beet hairy root tissue was also cultured aeroponically in nutrient mists. Beet hairy root cultured in nutrient mists enriched with 1.0 % CO₂ showed a 15 % increase in biomass over a 7-day period vs tissue cultured in nutrient mists (with ambient air) or in shake flasks. The stimulation of root growth via CO₂ enrichment reduced the time required for biomass accumulation.

Dijkstra, P., A.H.M.C. Schapendonk, K. Groenwold, M. Jansen, and S.C. Van de Geijn. 1999. Seasonal changes in the response of winter wheat to elevated atmospheric CO₂ concentration grown in Open-Top Chambers and field tracking enclosures. *Global Change Biology* 5(5):563-576.

Winter wheat was grown at ambient and elevated (ambient plus 350 μ mol L⁻¹) CO₂ concentrations in open top chambers and in field-tracking sun-lit climatic enclosures (elevated is 718 μ mol L⁻¹). There was no significant effect of CO₂ concentration on sheath, leaf and root biomass and leaf area in the early spring (January to April). 24-h canopy CO₂ exchange rate (CCER) was not significantly affected either. However, elevated CO₂ concentration increased CCER at midday, decreased evapotranspiration rate and increased instantaneous water-use-efficiency during early spring. Leaf, sheath and root nitrogen concentration per unit dry weight decreased and nonstructural carbohydrate concentration increased under elevated CO₂, and N-uptake per unit ground area decreased significantly (-22%) towards the end of this period. These results contrast with results from the final harvest, when grain yield and biomass were increased by 19% under elevated CO₂. N concentration per dry weight was reduced by 5%, but N-uptake per unit ground area was significantly higher (+11%) for the elevated CO₂ treatment. 24-h and midday-CCER increased significantly more in late spring (period of 21 April to 30 May) (respectively by +40% and 53%) than in the early spring (respectively 5% and 19%) in response to elevated CO₂. Midday evapotranspiration rate was reduced less by elevated CO₂ in the late spring (-13%) than in early spring (-21%). The CO₂ response of midday and 24-h CCER decreased again (+27% and +23% resp.) towards the end of the growing season. We conclude that the low response to CO₂ concentration during the early spring was associated with a growth-restriction, caused by low temperature and irradiance levels. The reduction of nitrogen concentration, the increase of nonstructural carbohydrate, and the lower evapotranspiration indicated that CO₂ did have an effect towards the end of early spring; but not on biomass accumulation. Regression analysis showed that both irradiance and temperature affected the response to CO₂.

Dippery, J.K., D.T. Tissue, R.B. Thomas, and B.R. Strain. 1995. Effects of low and elevated CO₂ on C-3 and C-4 annuals .1. Growth and biomass allocation. *Oecologia* 101(1):13-20.

In order to study C-3 and C-4 plant growth in atmospheric CO₂ levels ranging from past through predicted future levels, *Abutilon theophrasti* (C-3) and *Amaranthus retroflexus* (C-4) were grown from seed in growth chambers controlled at CO₂ partial pressures of 15 Pa (below Pleistocene minimum) 27 Pa (pre-industrial), 35 Pa (current) and 70 Pa (predicted future). After 35 days of growth, CO₂ had no effect on the relative growth rate, total biomass or partitioning of biomass in the C-4 species. However, the C-3 species had greater biomass accumulation with increasing CO₂ partial pressure. C-3 plants grown in 15 Pa CO₂ for 35 days had only 8% of the total biomass of plants grown in 35 Pa CO₂. In 15 Pa CO₂, C-3 plants had lower relative growth rates and lower specific leaf mass than plants grown in higher CO₂ partial pressures, and aborted reproduction. C-3 plants grown in 70 Pa CO₂ had greater root mass and root-to-shoot ratios than plants grown in lower CO₂ partial pressures. These findings support other studies that show C-3 plant growth is more responsive to CO₂ partial pressure than C-4 plant growth. Differences in growth responses to CO₂ levels of the Pleistocene through the future suggest that competitive interactions of C-3 and C-4 annuals have changed through geologic time. This study also provided evidence that C-3 annuals may be operating near a minimum CO₂ partial pressure for growth and reproduction at 15 Pa CO₂.

Dixon, M., D. Lethiec, and J.P. Garrec. 1995. The growth and gas-exchange response of soil-planted Norway spruce [*Picea abies* (L) karst] and red oak (*Quercus rubra* L) exposed to elevated CO₂ and to naturally-occurring drought. *New Phytologist* 129(2):265-273.

Norway spruce and red oak trees were planted directly into the soil and exposed to 700 $\mu\text{mol mol}^{-1}$ CO₂ in open-top chambers. There were large inter-specific differences in response to naturally occurring drought during the second year of exposure to elevated CO₂. Both species had decreased assimilation rates. CO₂-treated red oak had no loss of photosynthetic enhancement when undroughted, whereas CO₂-treated Norway spruce showed a relative increase in assimilation rates only when droughted. The effect of CO₂ on radial growth of both species was less marked in the second growing season, but this may have been a result of different biomass partitioning as Norway spruce shoot extension had a different pattern of growth in elevated CO₂. Stomatal density and chlorophyll content were largely unaffected by the CO₂ treatment. A precise method for measuring Norway spruce needle surface area was also developed.

Dixon, R.K. 1995. Agroforestry systems - sources or sinks of greenhouse gases. *Agroforestry Systems* 31(2):99-116.

The prominent role of forestry and agroforestry systems in the flux and long-term storage of carbon (C) in the terrestrial biosphere has increased global interest in these land-use options to stabilize greenhouse gas (GHG) emissions. Preliminary assessments suggest that some agroforestry systems (e.g., agrosilvicultural) can be CO₂ sinks and temporarily store C, while other systems (e.g., ruminant-based silvopastoral systems) are probably sources of GHG (e.g., CH₄). Agroforestry systems can be significant sources of GHG emissions, especially at low latitudes. Practices such as tillage, burning, manuring, chemical fertilization, and frequent disturbance can lead to emission of CO₂, CH₄, and N₂O from soils and vegetation to the atmosphere. Establishment and management of agroforestry systems incompatible with prevailing edaphic and climatic conditions can accelerate soil GHG emissions. Non-sustainable agroforestry systems are quickly degraded, and woody and herbaceous crops can become significant GHG sources. Silvopastoral systems can result in soil compaction and erosion with significant loss of labile C and N compounds to the atmosphere. Ruminant-based silvopastoral systems and rice paddy agrosilvicultural systems are well documented sources of CH₄ which significantly contribute to the global CH₄ budget. Early assessments of national and global terrestrial CO₂ sinks reveal two primary beneficial attributes of agroforestry systems: 1) direct near-term C storage (decades to centuries) in trees and soils, and, 2) potential to offset immediate GHG emissions associated with deforestation and subsequent shifting agriculture. Within the tropical latitudes, it is estimated that one ha of sustainable agroforestry can provide goods and services which potentially offset 5-20 ha of deforestation. At a global scale, agroforestry systems could potentially be established on 585-1275 x 10⁶ ha of technically suitable land, and these systems could store 12-228 (median 95) Mg C ha⁻¹ under current climate and edaphic conditions.

Dixon, R.K., S. Brown, R.A. Houghton, A.M. Solomon, M.C. Trexler, and J. Wisniewski. 1994. Carbon pools and flux of global forest ecosystems. *Science* 263(5144):185-190.

Forest systems cover more than 4.1 x 10⁹ hectares of the Earth's land area. Globally, forest vegetation and soils contain about 1146 petagrams of carbon, with approximately 37 percent of this carbon in low-latitude forests, 14 percent in mid-latitudes, and 49 percent at high latitudes. Over two-thirds of the carbon in forest ecosystems is contained in soils and associated peat deposits. In 1990, deforestation in the low latitudes emitted 1.6 +/- 0.4 petagrams of carbon per year, whereas forest area expansion and growth in mid- and high-latitude forest sequestered 0.7 +/- 0.2 petagrams of carbon per year, for a net flux to the atmosphere of 0.9 +/- 0.4 petagrams of carbon per year. Slowing deforestation, combined with an increase in forestation and other management measures to improve forest ecosystem productivity, could conserve or sequester significant quantities of carbon. Future forest carbon cycling trends attributable to losses and regrowth associated with global climate and land-use change are uncertain. Model projections and some results suggest that forests could be carbon sinks or sources in the future.

Dixon, R.K., J.B. Smith, S. Brown, O. Masera, L.J. Mata, and I.

Buksha. 1999. Simulations of forest system response and feedbacks to global change: experiences and results from the US Country Studies Program. *Ecological Modelling* 122(3):289-305.

Large shifts in the response and feedbacks of forest systems are implied by models and systems analysis driven by global change scenarios of general circulation models (GCMs). Prior climate change analyses and modeling efforts have been reported at a global scale in a few developed countries, but relatively few national assessments have been successfully completed in developing countries. Under the auspices of the U.S. Country Studies Program, analysts from 55 countries employed a common set of methods and models to characterize current carbon (C) pools in forests, future impacts of global change on forest distribution, and management options for conserving and sequestering carbon dioxide (CO₂) in forest systems. The analysis revealed that the response and feedbacks of forest systems to global climate change will be profound in the 55 countries studied on five continents. Globally, forest vegetation and soils contain about 1146 Pg C, with approximately 37% of this C in low-latitude forests, 14% in mid-latitudes, and 49% at high latitudes. The impacts of future global change on forest distribution and productivity will be most significant at high latitudes, with more modest changes in distribution and productivity at low latitudes. Future opportunities to conserve and sequester CO₂ in forest systems are potentially significant, but land-use practices and global change will influence the size of this C pool and CO₂ sink. In the future, a greater proportion of forests at all latitudes could become a greenhouse gas (GHG) source if sustained management and conservation policies are not employed. The timing and magnitude of future changes in forest systems are dependent on global environmental factors (for example, global change, biogeochemical Sulphur and Nitrogen cycles), as well as on human factors such as demographics, economic growth, technology, and resource management policies. Dixon, R.K., J.K. Winjum, and P.E. Schroeder. 1993. Conservation and sequestration of carbon - the potential of forest and agroforest management-practices. *Global Environmental Change-Human and Policy Dimensions* 3(2):159-173.

Forests play a major role in Earth's carbon cycle through assimilation, storage, and emission of CO₂. Establishment and management of boreal, temperate, and tropical forest and agroforest systems could potentially enhance sequestration of carbon in the terrestrial biosphere. A biological and economic analysis of forest establishment and management options from 94 nations revealed that forestation, agroforestry, and silviculture could be employed to conserve and sequester one Petagram (Pg) of carbon annually over a 50-year period. The marginal cost of implementing these options to sequester 55 Pg of carbon would be approximately \$10/Mg.

553

Dixon, R.K., and J. Wisniewski. 1995. Global forest systems: An uncertain response to atmospheric pollutants and global climate change? *Water, Air, and Soil Pollution* 85(1):101-110.

Forest systems cover more than 4.1 x 10⁹ ha of the Earth's land area. The future response and feedbacks of forest systems to atmospheric pollutants and projected climate change may be significant. Boreal, temperate and tropical forest systems play a prominent role in carbon

(C), nitrogen (N) and sulfur (S) biogeochemical cycles at regional and global scales. The timing and magnitude of future changes in forest systems will depend on environmental factors such as a changing global climate, an accumulation of CO₂ in the atmosphere, and increase global mineralization of nutrients such as N and S. The interactive effects of all these factors on the world's forest regions are complex and not intuitively obvious and are likely to differ among geographic regions. Although the potential effects of some atmospheric pollutants on forest systems have been observed or simulated, large uncertainty exists in our ability to project future forest distribution, composition and productivity under transient or nontransient global climate change scenarios. The potential to manage and adapt forests to future global environmental conditions varies widely among nations. Mitigation practices, such as liming or fertilization to ameliorate excess NO_x or SO_x or forest management to sequester CO₂ are now being applied in selected nations worldwide.

Docherty, M., D.K. Hurst, J.K. Holopainen, J.B. Whittaker, P.J. Lea, and A.D. Watt. 1996. Carbon dioxide-induced changes in beech foliage cause female beech weevil larvae to feed in a compensatory manner. *Global Change Biology* 2(4):335-341.

The phenology of *Fagus sylvatica* was unaffected by exposure to an atmosphere of elevated CO₂ (600 μ L L⁻¹) after two years of fumigation. Non-significant changes in nitrogen and phenolic content of the leaves decreased the nutritional status of beech for female larvae in elevated CO₂ such that they responded by eating in a compensatory manner; males were unaffected. Rates of development, mortality and adult biomass of *Rhynchaenus fagi* were no different from those in ambient CO₂ concentrations (355 μ L L⁻¹). It is possible that, with the changes in leaf chemistry affecting the females, fecundity will be altered, with important consequences for populations of beech weevil.

Docherty, M., F.A. Wade, D.K. Hurst, J.B. Whittaker, and P.J. Lea. 1997. Responses of tree sap-feeding herbivores to elevated CO₂. *Global Change Biology* 3(1):51-59.

Five species of sap-feeding homoptera were studied on *Fagus sylvatica* and *Acer pseudoplatanus* and exposed to elevated concentrations of carbon dioxide (600 μ L L⁻¹). The concentration of total soluble amino acids in foliage of *F. sylvatica* was unaffected by growing saplings in elevated atmospheric CO₂ concentrations. Although experiments on individual aphids indicated poorer performance of *Phyllaphis fagi* (fewer, smaller nymphs produced), resultant populations did not differ from those in ambient (350 μ L L⁻¹) conditions. The area of beech foliage stippled by the leafhopper *Fagoclypea cruenta* was similar at ambient and elevated CO₂ concentrations. The concentration of total amino acids and that of serine of *A. pseudoplatanus* foliage were significantly lower at elevated CO₂ concentrations. However, the relative growth rates of two aphid species *Drepanosiphum platanoidis* and *Periphyllus testudinaceus* and one leafhopper *Ossiannilssonola callosa* were not significantly different in elevated CO₂. No evidence was found that, under the conditions of these experiments, populations of aphids and leafhoppers will change as concentrations of CO₂ increase.

Doi, M., H. Oda, N. Ogasawara, and T. Asahira. 1992. Effects of CO₂ enrichment on the growth and development of invitro cultured plantlets. *Journal of the Japanese Society for Horticultural Science* 60(4):963-970.

Plantlets of *Caladium bicolor* (C3 plant), *Saccharum officinarum* (C4 plant), and *Phalaenopsis hybrid* (CAM plant) at the preparation stage for acclimatization (the final stage of in vitro culture) were cultured on the medium containing 2% sucrose. The culture vessels were kept under continuous, 16 hr, or 8 hr lighting conditions; half of the vessels were ventilated continuously with 0.8 +/- 0.4% CO₂ enriched atmosphere; while the remainder was exposed to ambient atmosphere. The growth of plantlets was promoted with an increase in daylength under both ambient and CO₂ enriched atmospheres. When the plantlets were supplied with adequate CO₂, dry matter production increased under all daylength treatments except *Caladium* cultured under continuous lighting. This promotive effect of CO₂ enrichment was especially noticeable in root growth. In *Caladium* and *Phalaenopsis*, the leaf chlorophyll content of plantlets cultured under CO₂ enriched atmosphere was less than that of leaves from plantlets grown in ambient atmosphere. Although the chlorophyll was less concentrated in leaves of plantlets growing under the CO₂ enriched treatment, the rate of CO₂ uptake of these plantlets measured at the midpoint of the light period was higher than that of leaves exposed to ambient atmosphere. Increasing the O₂ concentration in culture vessels to 37% also promoted the growth of *Caladium* and *Dendrobium phalaenopsis* (CAM plant) under CO₂ enriched condition. Because of the development of photoautotrophy, the *Caladium* plantlets exposed to enriched CO₂ atmosphere and cultured on sugar-free medium using ceramic wool plug system responded with vigorous growth when transplanted into pots.

DolcetSanjuan, R., E. Claveria, and A. Huerta. 1997. Androgenesis in *Capsicum annuum* L - Effects of carbohydrate and carbon dioxide enrichment. *Journal of the American Society for Horticultural Science* 122(4):468-475.

A new and simple protocol for androgenesis in bell pepper is described. The initial medium, a modification of Nitsch and Nitsch's H medium, consisted of a two-phase system of semi- solid and liquid medium and contained maltose as carbon source. The total number of embryos formed was greater with maltose at 40 g . L⁻¹, but embryos developed better at 10 to 20 g . L⁻¹. Depending on the genotype, the number of embryos and plants recovered ranged from 3 to 750 and 0.25 to 8, respectively, per 100 flowers. Further increases in the number of embryos (up to 3561 per 100 flowers) and plants (up to 23 per 100 flowers) could be attained by flushing cultures with air enriched with CO₂ at 900 mu L . L⁻¹. The ploidy level and the microspore origin of the recovered plants were determined by flow cytometry and zymograms for isocitrate dehydrogenase. Nearly 65% of the acclimated plants had undergone spontaneous doubling of the chromosome number, as confirmed by flow cytometry of leaf nuclei. Isocitrate dehydrogenase zymograms demonstrated that plants originated from microspores and that the two parental alleles were equally represented among the haploid and dihaploid plants.

Donnelly, A., M.B. Jones, J.I. Burke, and B. Schnieders. 1999. Does elevated CO₂ protect grain yield of wheat from the effects of ozone stress? *Zeitschrift Fur Naturforschung C-A Journal of Biosciences* 54(9-10):802-811.

This study has investigated the effects of elevated CO₂ and elevated O₃, both singly and in combination, on the yield of spring wheat (*Triticum aestivum* L., cv. Minaret). Plants were grown in open-top chambers and exposed to three CO₂ concentrations (ambient, 510 and 680 ppmv) and two O₃ concentrations (ambient and ambient +50 or +90 ppbv) either from anthesis onwards or for the full growing season. To date, experiments that have investigated the interactive effects of these gases have shown a variety of responses, ranging from an amelioration of the damaging effects of high O₃ to a greater sensitivity to O₃, at elevated CO₂. The effects on grain yield and yield components were determined. Our results confirm that elevated CO₂ provides some protection to a wheat crop against the damaging effects of O₃ on grain yield. However, the level of protection varies from one growing season to the next and also appears to be related particularly to the timing of exposure to elevated O₃.

Dorais, M., J. Charbonneau, and A. Gosselin. 1993. Gas-exchange in greenhouse tomatoes grown under supplemental light. *Canadian Journal of Plant Science* 73(2):577-585.

This study reports on in situ gas-exchange measurements in tomatoes grown under a sequential intercropping system with supplemental lighting provided by high-pressure sodium-vapour lamps. A supplemental photosynthetic photon flux (PPF) of 150 mumol m⁻² s⁻¹ significantly increased the amount of light energy penetrating the canopy of intercropped tomato seedlings. During the day, the supplemental 150 mumol m⁻² s⁻¹ light regime increased the photosynthetic rate of leaves 5 and 10 by 67%, while at night the increases were 93 and 12%, respectively. Regression analysis of the photosynthetic rate of leaves 5 and 10 as a function of PPF received accounts for 58 and 45% of the variation, respectively. Hierarchical analysis demonstrated a significant linear relationship between PPF received during the day and photosynthetic activity of leaves 5 and 10 accounting for 46 and 28%, respectively, of the variance in the model. Regression analysis of the photosynthetic activity as a function of PPF received at night accounts for 41 and 32 %, respectively, of the variation in the photosynthetic rate of leaves 5 and 10. Using a high level of supplemental lighting during the day or at night had no significant effect on stomatic conductance or on the transpiration rate of leaves.

Downing, J.P., and D.A. Cataldo. 1992. Natural sinks of CO₂ - technical synthesis from the palmas-del-mar workshop. *Water, Air, and Soil Pollution* 64(1-2):439-453.

Natural CO₂ sinks in terrestrial and marine environments are important components of the global carbon cycle, yet the sign and magnitudes of key fluxes among them are unknown. The results of the Palmas Del Mar Workshop - Natural Sinks of CO₂ presented in this special issue and its companion hard-bound volume of Water, Air, & Soil Pollution, provide

a synthesis of current research on the carbon cycle, CO₂ sinks and associated processes and fluxes, and critical research needs to assess the potential role of forest and land-use management in carbon sequestration. The papers in this volume present data, observations, and model simulations that demonstrate: 1) the existence of natural CO₂ sinks that could mitigate a significant amount of CO₂ emissions from fossil-fuel combustion; 2) probable, human-caused imbalances in C exchanges among vegetation, soils, and the atmosphere; 3) enhanced C storage in vegetation in response to excess atmospheric CO₂; 4) strong interactions among carbon, nutrient and hydrological cycles; and 5) an excess of carbon production over consumption in several, large managed forests. Although it appears unlikely that the search for the "missing" C sink required to balance the C budget will end in the open ocean, new estimates of C storage in mangrove wood and peat, suggest that coastal ecosystems have the capacity to store significant amounts of carbon in vegetation and sediments. Convincing analyses are also presented indicating the technical and economical feasibility of managing existing lands to sequester additional carbon. Long-term field studies of CO₂ fertilization effects and carbon cycling by plants and soils in geographically important systems, native forests, and coastal ecosystems will go a long way toward meeting the research needs identified at the workshop.

Downton, W.J.S., and W.J.R. Grant. 1994. Photosynthetic and growth-responses of variegated ornamental species to elevated CO₂. *Australian Journal of Plant Physiology* 21(3):273-279.

Variegated and completely green cultivars of oleander (*Nerium oleander* L.) and willow myrtle (*Agonis flexuosa* (Willd.) Sweet) were grown in controlled environment cabinets for 3 and 5 months, respectively, under either ambient levels of CO₂ or with supplementary CO₂ to a partial pressure of 800 μ bar. Photosynthesis of entirely green leaves and the green portions of variegated leaves on both species was greatly stimulated by high CO₂ and there was no evidence of downward adjustment (acclimation) of photosynthetic rates to high CO₂ during the experiment. Dark respiration rates of these leaves were lowered by high CO₂. The yellow portions of willow myrtle leaves showed a low level of photosynthetic activity which was stimulated by high CO₂; however, dark respiration rates showed little response to elevated CO₂. Green and yellow areas on variegated leaves of willow myrtle had much lower dark respiration rates than completely green leaves, but this difference was not evident for oleander. Yellow portions of oleander leaves showed little evidence of photosynthetic capacity. This was also confirmed by a low photochemical efficiency as determined by chlorophyll fluorescence. A major effect of variegation was to slow overall plant growth compared with completely green plants. The respective 3-fold and 6-7-fold differences in biomass between fully green and variegated cultivars of oleander and willow myrtle was closely related to estimated net carbon gain per day by the plant canopy. Variegation for both species averaged close to 50:50, green:yellow areas. Variegated plants developed about twice the leaf area ratio and specific leaf area compared with their completely green counterparts. The relative growth response to high CO₂ was significantly greater for the variegated plants compared to the completely green plants.

Drake, B.G. 1992. A field-study of the effects of elevated CO₂ on ecosystem processes in a Chesapeake Bay wetland. *Australian Journal of Botany* 40(4-5):579-595.

Open top chambers are being used in a long-term project to determine the effects of elevated CO₂ on ecosystem processes on a Chesapeake Bay wetland. Three communities are studied: mono-specific stands of the C3 sedge, *Scirpus olneyi*, and the C4 grass, *Spartina patens*, and a mixed community of these two species and the C4 grass, *Distichlis spicata*. Treatment began in the spring of 1987 and will continue through the 1994 growing season. During the first 4 years of exposure, elevated CO₂ had the following effects on mono-specific stands of the C3 sedge, *Scirpus olneyi*: increased quantum yield and photosynthetic capacity, reduced dark respiration, increased numbers of shoots, roots and rhizomes, reduced nitrogen concentration of all tissues, increased nitrogen fixation and increased ecosystem carbon accumulation. In a mixed community of the sedge and C4 grass species, *Spartina patens* and *Distichlis spicata*, biomass of the C3 component increased over 100% and this was accompanied by decreased biomass in the C4 component of the community. Elevated CO₂ reduced water loss, increased water potential and delayed senescence in all three species. Many factors contributed to CO₂ stimulated carbon accumulation in the plant community dominated by the C3 sedge, *Scirpus olneyi*, including: sustained high photosynthetic capacity, decreased respiration, delayed senescence, and allocation of the additional carbon to roots and rhizomes. The complex interaction of these diverse responses suggests that the rising atmospheric CO₂ may have a significant impact on ecosystem processes.

Drake, B.G. 1992. The impact of rising CO₂ on ecosystem production. *Water, Air, and Soil Pollution* 64(1-2):25-44.

A fundamental property of green plants is that the rate of photosynthesis is dependent in the ambient CO₂ concentration. There is overwhelming experimental evidence that this effect increases plant production in most C3 Plants: hundreds of experiments with many species show that plant growth increases an average 30% to 40% for a doubling of the present normal ambient CO₂ concentration (Kimball, 1986). External environmental factors, such as temperature and the availability of nutrients, modify this response. The greatest stimulation of photosynthesis and growth can be expected to occur at high temperatures and much smaller responses at low temperature. Factors which restrict growth, such as low nutrients, will reduce but usually do not eliminate the stimulation of production with increasing CO₂ even when nitrogen is severely limiting. There are also reports of direct effects of ambient CO₂ concentration on dark respiration which show that there is an immediate reduction in the rate of CO₂ efflux or O₂ consumption when the CO₂ around plant tissues is increased. There have been very few long-term field studies of the effects of increased CO₂ on whole plants and ecosystem processes but the data from these studies are consistent in showing an increase in plant production with an increase in CO₂ concentration of the ambient air.

Drake, B.G., J. Azcon-Bieto, J. Berry, J. Bunce, P. Dijkstra, J. Farrar, R.M. Gifford, M.A. Gonzalez-Meler, G. Koch, H. Lambers,

J. Siedow, and S. Wullschleger. 1999. Does elevated atmospheric CO₂ concentration inhibit mitochondrial respiration in green plants? *Plant, Cell and Environment* 22(6):649-657.

There is abundant evidence that a reduction in mitochondrial respiration of plants occurs when atmospheric CO₂ (C-a) is increased. Recent reviews suggest that doubling the present C-a will reduce the respiration rate [per unit dry weight (DW)] by 15 to 18%. The effect has two components: an immediate, reversible effect observed in leaves, stems, and roots of plants as well as soil microbes, and an irreversible effect which occurs as a consequence of growth in elevated C-a and appears to be specific to C-3 species. The direct effect has been correlated with inhibition of certain respiratory enzymes, namely cytochrome-c-oxidase and succinate dehydrogenase, and the indirect or acclimation effect may be related to changes in tissue composition. Although no satisfactory mechanisms to explain these effects have been demonstrated, plausible mechanisms have been proposed and await experimental testing. These are carbamylation of proteins and direct inhibition of enzymes of respiration. A reduction of foliar respiration of 15% by doubling present ambient C-a would represent 3 Gt of carbon per annum in the global carbon budget.

Drake, B.G., M.A. GonzalezMeler, and S.P. Long. 1997. More efficient plants: A consequence of rising atmospheric CO₂? *Annual Review of Plant Physiology and Plant Molecular Biology* 48:609-639.

The primary effect of the response of plants to rising atmospheric CO₂ (C-a) is to increase resource use efficiency. Elevated C-a reduces stomatal conductance and transpiration and improves water use efficiency, and at the same time it stimulates higher rates of photosynthesis and increases light- use efficiency. Acclimation of photosynthesis during long-term exposure to elevated C-a reduces key enzymes of the photosynthetic carbon reduction cycle, and this increases nutrient use efficiency. Improved soil-water balance, increased carbon uptake in the shade, greater carbon to nitrogen ratio, and reduced nutrient quality for insect and animal grazers are all possibilities that have been observed in field studies of the effects of elevated C-a. These effects have major consequences for agriculture and native ecosystems in a world of rising atmospheric C-a and climate change.

Drake, B.G., and P.W. Leadley. 1991. Canopy photosynthesis of crops and native plant-communities exposed to long-term elevated CO₂. *Plant, Cell and Environment* 14(8):853-860.

There have been seven studies of canopy photosynthesis of plants grown in elevated atmospheric CO₂: three of seed crops, two of forage crops and two of native plant ecosystems. Growth in elevated CO₂ increased canopy photosynthesis in all cases. The relative effect of CO₂ was correlated with increasing temperature: the least stimulation occurred in tundra vegetation grown at an average temperature near 10-degrees-C and the greatest in rice grown at 43-degrees-C. In soybean, effects of CO₂ were greater during leaf expansion and pod fill than at other stages

of crop maturation. In the longest running experiment with elevated CO₂ treatment to date, monospecific stands of a C3 sedge, *Scirpus olneyi* (Grey), and a C4 grass, *Spartina patens* (Ait.) Muhl., have been exposed to twice normal ambient CO₂ concentrations for four growing seasons, in open top chambers on a Chesapeake Bay salt marsh. Net ecosystem CO₂ exchange per unit green biomass (NCE(b)) increased by an average of 48% throughout the growing season of 1988, the second year of treatment. Elevated CO₂ increased net ecosystem carbon assimilation by 88% in the *Scirpus olneyi* community and 40% in the *Spartina patens* community.

Drake, B.G., M.S. Muehe, G. Peresta, M.A. GonzalezMeler, and R. Matamala. 1996. Acclimation of photosynthesis, respiration and ecosystem carbon flux of a wetland on Chesapeake Bay, Maryland to elevated atmospheric CO₂ concentration. *Plant and Soil* 187(2):111-118.

Acclimation of photosynthesis and respiration in shoots and ecosystem carbon dioxide fluxes to rising atmospheric carbon dioxide concentration (C-a) was studied in a brackish wetland. Open top chambers were used to create test atmospheres of normal ambient and elevated C-a (=normal ambient+34 Pa CO₂) over mono-specific stands of the C-3 sedge *Scirpus olneyi*, the dominant C-3 species in the wetland ecosystem, throughout each growing season since April of 1987. Acclimation of photosynthesis and respiration were evaluated by measurements of gas exchange in excised shoots. The impact of elevated C-a on the accumulation of carbon in the ecosystem was determined by ecosystem gas exchange measurements made using the open top chamber as a cuvette. Elevated C-a increased carbohydrate and reduced Rubisco and soluble protein concentrations as well as photosynthetic capacity(A) and dark respiration (R-d; dry weight basis) in excised shoots and canopies (leaf area area basis) of *Scirpus olneyi*. Nevertheless, the rate of photosynthesis was stimulated 53% in shoots and 30% in canopies growing in elevated C-a compared to normal ambient concentration. Elevated C-a inhibited R-d measured in excised shoots (-19 to -40%) and in seasonally integrated ecosystem respiration (R-e; -36 to -57%). Growth of shoots in elevated C-a was stimulated 14-21%, but this effect was not statistically significant at peak standing biomass in midseason. Although the effect of elevated C-a on growth of shoots was relatively small, the combined effect of increased number of shoots and stimulation of photosynthesis produced a 30% stimulation in seasonally integrated gross primary production (GPP). The stimulation of photosynthesis and inhibition of respiration by elevated C-a increased net ecosystem production (NEP=GPP-R-e) 59% in 1993 and 50% in 1994. While this study consistently showed that elevated C-a produced a significant increase in NEP, we have not identified a correspondingly large pool of carbon below ground.

Drake, S.R. 1994. Elevated carbon-dioxide storage of anjou pears using purge- controlled atmosphere. *Hortscience* 29(4):299-301.

'Anjou' pears (*Pyrus communis* L.) were placed in controlled-atmosphere (CA) storage immediately after harvest (<24 hours) or after a 10-day delay in refrigerated storage, and held there for 9 months at 1C. Oxygen in all atmospheres was 1.5% and CO₂ was at either 1% or 3%.

Atmospheres in the flow-through system were computer-controlled at $\pm 0.1\%$. After removal from CA storage, pears were evaluated immediately and after ripening at 21C for 8 days. Pears stored in 3% CO₂ were firmer, greener, and displayed less scald, internal breakdown, and stem-end decay than pears stored in 1% CO₂. In addition, no internal discoloration of 'Anjou' pears was evident when held with 3% CO₂. 'Anjou' pears held in 3% CO₂ retained the ability to ripen after long-term storage. A 10-day delay in atmosphere establishment had little or no influence on the long-term keeping quality or ripening ability of 'Anjou' pears.

Drake, S.R. 1999. Quality of 'Bosc' pears as influenced by elevated carbon dioxide storage. *Journal of Food Quality* 22(4):417-425.

'Bosc' pears (*Pyrus communis* L.) were placed in a purge-type controlled-atmosphere (CA) storage immediately after harvest (<24 h) and held for 180 days at 1C. Oxygen in all atmospheres was 1.5% and CO₂ was 1%, 3% or 5%. Pears were evaluated immediately after removal from CA storage and after ripening for an additional 7 days at 21 C. Pears stored in 3% CO₂ were firmer, had a superior finish, with significantly reduced decay and internal breakdown than pears stored in 1% CO₂. In 3% CO₂, pears retained the ability to ripen after long-term storage. A 10 day delay in atmosphere establishment had little or no influence on the long-term keeping quality or ripening ability of 'Bosc' pears. Firmness, soluble solids content and starch either alone or together were good indices of maturity for 'Bosc' pears.

Drake, S.R., and D.C. Elfving. 1999. Response of three strains of 'Gala' apples to high carbon dioxide prior to controlled atmosphere storage. *Fruit Varieties Journal* 53(1):16-21.

The postharvest fruit quality of three strains ('Royal Gala', 'Imperial Gala' and 'Crimson Gala') of apples was evaluated over two or three storage seasons. To determine the influence of carbon dioxide treatment on storage quality, apples were stored in normal controlled atmosphere (1% O₂ & 1% CO₂), or treated with 12% CO₂ for 7 or 14 days prior to normal CA and evaluated after 90 or 150 days of storage. The use of 12% CO₂ prior to storage helped to maintain firmness of 'Royal Gala' apples in 1 of 3 seasons. Firmness of 'Imperial Gala' and 'Crimson Gala' apples was not influenced by high CO₂ treatment, regardless of storage season. Other quality factors (color, soluble solids, acidity and carbohydrates) were not influenced to the extent that high CO₂ would be a viable option for the quality enhancement of 'Gala' apples during storage, regardless of strain. Use of normal CA maintained 'Gala' apple quality for 150 days of storage. Harvest date had a major influence on 'Gala' apple quality. A delay of one week reduced firmness and acidity, but enhanced color and content of sucrose, glucose and fructose in 'Royal Gala', 'Imperial Gala' and 'Crimson Gala' apples.

Drake, S.R., and A. Yazdaniha. 1999. Short-term controlled atmosphere storage for shelf-life extension of apricots. *Journal of Food Processing and Preservation* 23(1):57-70.

Shelf-life of 'Perfection' and 'Rival' apricots can be enhanced with the use of controlled atmosphere (CA) storage. Apricots were harvested at commercial maturity and immediately stored in CA at 1 or 2 % O₂ and

3, 6, 9, 12 or 15 % CO₂ for 30, 45 and 60 days. No differences in fruit quality were evident between O₂ atmospheres of 1 and 2 %, except that fruit stored in 1 % O₂ displayed less rot development and higher acid content. Apricots stored in 9 % or less CO₂ displayed reduced external and internal color, inadequate finish, increased internal breakdown and more rot development with unacceptable firmness retention for additional handling. Apricots stored in 12 or 15 % CO₂ retained firmness and displayed enhanced finish with reduced rots and very little internal breakdown with storage duration of 60 days. Color was much slower to develop in apricots stored in 12 or 15 % CO₂ for all storage periods.

Drennan, P.M., and P.S. Nobel. 1996. Temperature influences on root growth for *Encelia farinosa* (Asteraceae), *Pleuraphis rigida* (Poaceae), and *Agave deserti* (Agavaceae) under current and doubled CO₂ concentrations. *American Journal of Botany* 83(2):133-139.

To help evaluate root distribution patterns, elongation rates of individual roots were measured as a function of soil temperature for *Encelia farinosa* (a C-3 species), *Pleuraphis rigida* (C-4), and *Agave deserti* (CAM), sympatric codominants in the northwestern Sonoran Desert. Measurements were made at current and doubled CO₂ concentrations under winter and summer conditions of air temperature (day/night temperatures of 17 C/10 C and 33 C/22 C, respectively). The three species had different optimal temperatures for root elongation (T-opt) under winter conditions (25 C for *E. farinosa*, 35 C for *P. rigida*, and 30 C for *A. deserti*); T-opt increased by 2-3 C under summer conditions for all three species. The limiting temperatures for elongation also acclimated from winter to summer conditions. The rate of root elongation at T-opt was higher under summer than winter conditions for *E. farinosa* (3 vs. 6 mm d⁻¹) and *P. rigida* (20 vs. 14 mm d⁻¹), reflecting conditions for maximum photosynthesis; no difference occurred for *A. deserti* (9 vs. 10 mm d⁻¹). Decreased elongation rates at extreme temperatures were associated with less cell division and reduced cell extension. The doubled CO₂ concentration increased average daily root elongation rates for *A. deserti* under both winter (7%) and summer (12%) conditions, reflecting increased cell extension, but had no effect for the other two species. Simulations of root elongation as a function of soil temperatures showed that maximum elongation would occur at different depths (16-20 cm for *E. farinosa*, 4-8 cm for *P. rigida*, and 0-4 cm for *A. deserti*) and during different seasons (winter to spring for *E. farinosa*, spring to summer for *P. rigida*, and all year for *A. deserti*), contributing to their niche separation. Shading of the soil surface moderated daily variations in soil temperature, reducing seasonal root elongation for winter and spring and increasing elongation for summer. Shading also altered root distribution patterns, e.g., optimal rooting depth for *A. deserti* and especially *P. rigida* increased for a hot summer day.

Drennan, P.M., and P.S. Nobel. 1998. Root growth dependence on soil temperature for *Opuntia ficus-indica*: influences of air temperature and a doubled CO₂ concentration. *Functional Ecology* 12(6):959-964.

1. Root elongation as a function of soil temperature was determined for the CAM succulent *Opuntia ficus-indica*, under three different day/night air temperatures (15 degrees C/5 degrees C, 25 degrees C/15 degrees C and 35 degrees C/25 degrees C) and an ambient (360 mu mol mol⁻¹) vs a doubled CO₂ concentration (720 mu mol mol⁻¹) at 25 degrees

C/15 degrees C, the optimum temperature for net CO₂ uptake. 2. Root elongation occurred at soil temperatures from 12 degrees C (at 15 degrees C/5 degrees C) to 43 degrees C (at 35 degrees C/25 degrees C) with optimum temperatures of 27-30 degrees C, similar to other CAM succulents and consistent with the distribution of this shallow-rooted species in warm regions. Although a doubled CO₂ concentration did not alter the optimum or limiting soil temperatures, increases of up to 5 degrees C in these temperatures accompanied the 20 degrees C increase in day/night air temperatures. 3. Root elongation rates at optimum soil temperatures ranged from 5.4 mm day⁻¹ (15 degrees C/5 degrees C), through 6.6 mm day⁻¹ (25 degrees C/15 degrees C), to 10.4 mm day⁻¹ (35 degrees C/25 degrees C) with a 25% increase under a doubled CO₂ concentration. Highest root elongation rates at 35 degrees C/25 degrees C may reflect changing root vs shoot sink strengths in a species with a highly plastic root system. 4. At limiting soil temperatures, the length of the cell division zone was reduced by an average of 20% and cell length at the mid-point of the elongation zone by 10%. Increased root elongation rates under a doubled CO₂ concentration reflected increased cell elongation. 5. The temperature response for the roots of *O. ficus-indica* and stimulation of elongation by a doubled CO₂ concentration indicate that root growth for this highly productive species should be enhanced by predicted global climate change.

Dube, S.L., and W. Vidaver. 1992. Photosynthetic competence of plantlets grown-in-vitro - an automated-system for measurement of photosynthesis invitro. *Physiologia Plantarum* 84(3):409-416.

An aseptic gas exchange and hydroponic system (AGEHS) has been developed in an attempt for characterization of physiological requirements for photoautotrophic growth in vitro and alleviation of the needs for ex vitro acclimatization. The AGEHS monitors and controls several parameters relevant to plant growth. Shootlets of *Chrysanthemum*, x *morifolium* Ramat. cv. Envy were treated with flow of air or CO₂-enriched air under controlled relative humidity, elevated photosynthetic photon flux density (PPFD) and hydroponic irrigation. After 15 days of treatment, plantlets gained more than 3 times as much dry weight as those from a conventional culture tube treatment. This study shows that it is possible to favour photoautotrophic growth when elevated PPFD, enhanced air-exchange and hydroponic medium flow are provided concurrently. This enhancement is achievable through careful increments of light quanta, balanced with increments of humidified air flow and/or CO₂ content in air which seem to be necessary to avoid potential photoinhibition and premature water exhaustion from gelled media.

Duchain, M.C., A. Bonicel, and T. Betsche. 1993. Photosynthetic net co₂ uptake and leaf phosphate concentrations in co₂ enriched clover (*trifolium-subterraneum* L.) at 3 levels of phosphate nutrition. *Journal of Experimental Botany* 44(258):17-22.

Net CO₂-uptake of sets of clover plants (*Trifolium subterraneum* L. was measured over three weeks in ambient air and in a highly CO₂-enriched atmosphere (400 Pa CO₂). Phosphate (P) in the nutrient solution was varied between 0-05 mol m⁻³ P (reduced P) and 2.0 mol m⁻³ P (high P). In ambient air, the daily increments of the daily rate of net CO₂-uptake (DICU; a parameter related to relative growth) were higher at reduced P than at high P. Stimulation by high CO₂ of net CO₂-uptake in the first

day was less at reduced P than at high P. In the following days, high CO₂ markedly inhibited DICU at reduced P, and thus growth stimulation by high CO₂ ceased after between 4 and 12 d. By contrast, at high P, DICU increased more than 2- fold upon CO₂-enrichment, and thus growth stimulation by high CO₂ was maintained. Intermediate results were obtained with half-strength Hoagland's solution (0-5 mol m⁻³ P). Leaf pools of inorganic ortho P, soluble esterified P, and total P declined markedly in high CO₂ when P-nutrition had been reduced. Considerable decline also occurred in high CO₂ when P- nutrition had been increased suggesting that P-uptake was not well tuned with net CO₂-uptake (growth). It is proposed that high CO₂ can perturb the P-metabolism of clover, the impairment being less at high levels of P-nutrition. With regard to high CO₂ as a growth stimulus, these results demonstrate that increasing P-nutrition to a level supraoptimal in ambient air can considerably improve the growth of a C3-plant in high CO₂.

Duff, G.A., C.A. Berryman, and D. Eamus. 1994. Growth, biomass allocation and foliar nutrient contents of 2 eucalyptus species of the wet dry tropics of australia grown under co₂ enrichment. *Functional Ecology* 8(4):502-508.

1. Seeds of *Eucalyptus tetrodonta* and *E. miniata* were sown in duplicated air-conditioned tents which were ventilated with either ambient or CO₂-enriched (700 mumol mol⁻¹) air. Growth, foliar nutrient content, soluble protein and biomass allocation were investigated over the subsequent 32-week experimental period. 2. It was found that CO₂ enrichment significantly increased the total biomass and tree height of *E. tetrodonta*, but had no effect on total biomass or tree height of *E. miniata*. 3. Allocation of biomass to main-stem wood and main- stem leaf mass increased and allocation to branch wood and branch leaves declined, under CO₂ enrichment for *E. tetrodonta*. No change in allocation patterns for *E. miniata* was observed in response to CO₂ enrichment. 4. Foliar nitrogen, manganese and phosphorus contents were decreased under CO₂ enrichment in *E. tetrodonta*, but there was no effect of CO₂ concentration in *E. miniata*. Soluble protein contents were not affected by CO₂ enrichment in either species. These results are discussed in relation to the competitive relationship between these two species in northern Australia.

Dufrene, E., J.Y. Pontailier, and B. Saugier. 1993. A branch bag technique for simultaneous co₂ enrichment and assimilation measurements on beech (*fagus-sylvatica* L). *Plant, Cell and Environment* 16(9):1131-1138.

A cheap CO₂ enrichment system was designed to perform continuous gas exchange measurements of branches of mature European beech trees (*Fagus sylvatica* L.). Branches were grown at ambient (350 cm(3) m(-3)) and elevated CO₂ (700 cm(3) m(-3)) during the whole 1992 leafy period. Leaks resulting from airtightness defaults in the system appeared to be low enough to measure accurately net CO₂ assimilation and transpiration rates during the day. However, the CO₂ exchange rates during the night (respiration) were too low to allow accurate measurements. Elevated CO₂ had a great effect on the net assimilation rate of branches via its influence on both the C-3 photosynthetic pathway and the shade-tolerance of beech frees (85% increase). The A/C-a curves showed no acclimation effect to high CO₂, both control and enriched branches increasing their net assimilation in the same way. The decrease of net assimilation rates in mature leaves was similar for

both control and enriched branches. The pattern of daily transpiration rates remained the same for both control and enriched branches, hence we can assume that there was no visible CO₂ effect on stomata.

Dugas, W.A., M.L. Heuer, D. Hunsaker, B.A. Kimball, K.F. Lewin, J. Nagy, and M. Johnson. 1994. Sap flow measurements of transpiration from cotton grown under ambient and enriched CO₂ concentrations. *Agricultural and Forest Meteorology* 70(1-4):231-245.

Increasing atmospheric CO₂ concentration has many implications for agriculture and forestry, one of which is the effect it will have on transpiration (T). The objective of this work was to quantify T of cotton (*Gossypium hirsutum* L.) grown in the field under ambient (370 μmol mol⁻¹) and enriched (550 μmol mol⁻¹) CO₂ concentrations. Measurements were made in 1990 and 1991 at the Maricopa Agricultural Center, Arizona. Constant- power sap flow gauges were used to measure T. In 1990, three plants and in 1991, 10 plants were simultaneously instrumented with gauges in each of the CO₂ treatments. Leaf area of plants with gauges was measured. T measured by sap flow was compared with evapotranspiration (ET) calculated by water balance in 1990 and with T calculated by water balance in 1991. Soil evaporation was measured using microlysimeters in 1991, and was found to be essentially equal (approximately 0.8 mm day⁻¹, or about 10% of T) in the two CO₂ treatments. There were no consistent differences in leaf area of plants with gauges between the two CO₂ treatments. Sap flow, for periods from 15 min to 2 weeks, was not significantly different between the two CO₂ treatments in either year, except for a few days in 1990. In 1991, the coefficient of variation of daily sap flow across plants was the same (about 30%) for both CO₂ treatments throughout the year. The water balance ET (1990) and T (1991) were similar to sap flow in both years, and also showed no effect of CO₂ treatment. These results show that for this crop, grown under well-watered and high-fertility conditions, there was no effect of CO₂ on T, on a per unit ground area or per plant basis. These results are relevant for assessing the effects of increasing atmospheric CO₂ concentrations on transpiration by cotton.

Dugas, W.A., S.A. Prior, and H.H. Rogers. 1997. Transpiration from sorghum and soybean growing under ambient and elevated CO₂ concentrations. *Agricultural and Forest Meteorology* 83(1-2):37-48.

The increasing concentration of carbon dioxide in the atmosphere ([CO₂]) has several direct effects on plants and these effects may be different for C-3 and C-4 plants. Our objective was to measure hourly and daily whole-plant transpiration rates from the C-4 plant grain sorghum (*Sorghum bicolor* (L.) Moench) and the C-3 plant soybean (*Glycine max* (L.) Merr.) grown under ambient (359 μmol CO₂ mol⁻¹ dry atmospheric air) and elevated (705 μmol mol⁻¹) [CO₂] values.

Transpiration measurements were made for 22 days in August 1994 at Auburn, Alabama, USA, using stem flow gauges on plants growing in open top chambers, n = 8 for each [CO₂] and species. Leaf area averaged slightly more than 0.1 m² per plant for sorghum and about 0.2 m² per plant for soybean. Averages (15 min and daily) of transpiration, per unit leaf area, were consistently greater from plants growing under the ambient [CO₂] for both sorghum and soybean. Average daily transpiration from plants growing under the elevated [CO₂] was significantly smaller (P = 0.05) on all but 2 days for soybean and on 9 of the 22 days of measurements for sorghum. Average daily sorghum transpiration was 1128 gm⁻² day⁻¹ and 772 gm⁻² day⁻¹ from plants growing under an ambient and elevated [CO₂], respectively. Corresponding soybean averages were 731 gm⁻² day⁻¹ and 416 gm⁻² day⁻¹. The transpiration reduction under elevated [CO₂] was greater for the C-3 plant soybean than for the C-4, plant sorghum. These results support previous studies showing that transpiration, per unit leaf area, from sorghum and soybean will both be reduced if atmospheric [CO₂] continues to increase, although the reduction may be greater for C-3, plants.

Dukes, J.S., and H.A. Mooney. 1999. Does global change increase the success of biological invaders? *Trends in Ecology and Evolution* 14(4):135-139.

Biological invasions are gaining attention as a major threat to biodiversity and an important element of global change. Recent research indicates that other components of global change, such as increases in nitrogen deposition and atmospheric CO₂ concentration, favor groups of species that share certain physiological or life history traits. New evidence suggests that many invasive species share traits that will allow them to capitalize on the various elements of global change. Increases in the prevalence of some of these biological invaders would alter basic ecosystem properties in ways that feed back to affect many components of global change.

Duquesnay, A., N. Breda, M. Stievenard, and J.L. Dupouey. 1998. Changes of tree-ring delta C-13 and water-use efficiency of beech (*Fagus sylvatica* L.) in north-eastern France during the past century. *Plant, Cell and Environment* 21(6):565-572.

We investigated variation in intrinsic water-use efficiency during the past century by analysing delta(13)C in tree rings of beech growing in north-eastern France. Two different silvicultural systems were studied: high forest and coppice- with-standards. We studied separately effects related to the age of the tree at the time the ring was formed and effects attributable to environmental changes. At young ages, delta(13)C shows an increase of more than 1 parts per thousand. However, age-related trends differ in high forest and coppice- with-standards. Changes in microenvironmental variables during stand maturation, and physiological changes related to structural development of the trees with ageing, could explain these results. During the past century, delta(13)C in tree rings shows a pattern of decline that is not paralleled by air delta(13)C changes. Isotopic discrimination has significantly decreased from 18.1 to 16.4 parts per thousand in high forest and varied insignificantly between 17.4 and 16.9 parts per thousand in coppice-

with-standards. As a consequence, intrinsic water-use efficiency has increased by 44% in high forest and 23% in coppice-with-standards during the past century. These results accord with the increased water-use efficiency observed in controlled experiments under a CO₂-enriched atmosphere. However other environmental changes, such as nitrogen deposition, may be responsible for such trends.

During, H., and M. Harst. 1996. Stomatal behaviour, photosynthesis and photorespiration of in vitro-grown grapevines: Effects of light and CO₂. *Vitis* 35(4):163-167.

To improve photosynthesis and growth of grapevines cultivated in vitro (Seyval blanc and SO 4) effects of light intensity, spectral irradiance and CO₂ concentration on stomatal behaviour, CO₂ fixation and photorespiration were studied. Stomata were shown to respond to changes of light intensity but, unlike photosynthesis, their reactions were delayed and stomatal closure was incomplete in the dark. In contrast, alterations of the CO₂ concentration in the headspace (50-2200 ppm) did not cause stomatal reactions. Photosynthesis vs. light intensity relationships indicated lower light compensation points, higher quantum yield and higher rates of light-saturated photosynthesis with "Fluora" lamps (maximal spectral irradiance at 460 and 680 nm) compared to "projector" lamps (maximal spectral irradiance at 620 nm). Photosynthesis vs. intercellular CO₂ concentration relationships indicated varietal differences, the carboxylation efficiency and rates of photosynthesis at CO₂ saturation being distinctly higher in the more vigorous variety SO 4 compared to Seyval blanc. Under the usual light conditions of our in vitro culture (50-60 μ mol quanta $\cdot$ m⁻² $\cdot$ s⁻¹), Fluora the headspace CO₂ concentration ranged from 145 to 155 ppm while at the end of a 10-hour dark period it increased to values >3000 ppm. Rates of photorespiration were high (>50 % of photosynthesis) due to the relative low CO₂ concentrations and, presumably, due to elevated O₂ concentrations in the headspace. It is concluded that the often observed low rates of photosynthesis of in vitro plantlets are mainly due to low light intensity and CO₂ concentration in the headspace, the latter depending on the low rates of gas diffusion between ambient air and headspace.

Dury, S.J., J.E.G. Good, C.M. Perrins, A. Buse, and T. Kaye. 1998. The effects of increasing CO₂ and temperature on oak leaf palatability and the implications for herbivorous insects. *Global Change Biology* 4(1):55-61.

Rising levels of atmospheric CO₂ are expected to perturb forest ecosystems, although the extent to which specific ecological interactions will be modified is unclear. This research evaluates the effects of elevated CO₂ and temperature, alone and in combination, on the leaf nutritional quality of Pendunculate oak (*Quercus robur* L.), and the implications for herbivorous insect defoliators are discussed. A 3 degrees C temperature rise reduced leaf nutritional quality, by reducing foliar nitrogen concentration and increasing condensed tannin content. Doubling atmospheric CO₂ temporarily increased total phenolics, but also reduced leaf toughness. The nutritional quality of the second leaf flush (lammas growth) was considerably reduced at elevated CO₂. It is concluded that larval development of spring-feeding defoliators and hence adult fecundity may be adversely affected by increased temperatures.

Eamus, D. 1991. The interaction of rising CO₂ and temperatures with water-use efficiency. *Plant, Cell and Environment* 14(8):843-852.

Recent data concerning the impact of elevated atmospheric CO₂ upon water use efficiency (WUE) and the related measure, instantaneous transpiration efficiency (ITE), are reviewed. It is concluded from both short and long-term studies that, at the scale of the individual leaf or plant, an increase in WUE or ITE is generally observed in response to increased atmospheric CO₂ levels. However, the magnitude of this increase may decline with time. The opinion that elevated CO₂ may substantially decrease transpiration at the regional scale is discussed. The mechanisms by which elevated CO₂ may cause a change in these measures are discussed in terms of stomatal conductance, assimilation and respiration responses to elevated CO₂. Finally, recent experimental data and model outputs concerning the impact of the interaction of increased temperature with elevated CO₂ on WUE, ITE and yield are reviewed. It is concluded that substantially more data is required before reliable predictions about the regional scale response of WUE and catchment hydrology can be made.

Eamus, D. 1996. Tree responses to CO₂ enrichment: CO₂ and temperature interactions, biomass allocation and stand-scale modeling. *Tree Physiology* 16(1-2):43-47.

In this review, I focus on modeling studies of tree responses to CO₂ enrichment. First, I examine leaf-scale models of assimilation with respect to the interaction between low temperature and CO₂ enrichment. Second, because changes in allocation within a tree may be significant in determining the growth response of trees to CO₂ enrichment and low temperatures, I review models of the control of allocation in plants. Finally, models of stand-scale processes are discussed with respect to their ability to make reliable estimates of likely vegetation responses to predicted climate change. I conclude that our ability to make reliable predictions is hindered by our lack of understanding of several processes, namely: the interaction between increased atmospheric CO₂ concentration and low temperatures; the control of allocation in plants; and the modeling of stand-scale processes.

Eamus, D., C.A. Berryman, and G.A. Duff. 1993. Assimilation, stomatal conductance, specific leaf-area and chlorophyll responses to elevated CO₂ of *Maranthos corymbosa*, a tropical monsoon rain-forest species. *Australian Journal of Plant Physiology* 20(6):741-755.

Seeds of *Maranthos corymbosa* Blume, a monsoon rain forest species of northern Australia, were sown under ambient or elevated CO₂ concentrations in tropical Australia. Seedlings were grown under conditions of photon flux density, temperature and atmospheric vapour pressure deficit which followed ambient variations as closely as possible. Specific leaf area, chlorophyll, stomatal density, stomatal conductance

and assimilation responses to photon flux density were measured after 30 weeks growth. Gas exchange characteristics were divided into morning and afternoon data sets and analysed separately. Stomatal density decreased and leaf area:dry weight ratio decreased in response to elevated CO₂. In contrast there was no effect of elevated CO₂ upon chlorophyll (total or ratio of a:b). Apparent quantum yield and rates of light saturated assimilation (A(max)) increased in response to elevated CO₂. There was a significant decline in apparent quantum yield for both treatments between morning and afternoon. Stomatal conductance (g(s)) declined in response to elevated CO₂. There was no significant difference in g(s) between morning and afternoon for ambient grown trees, but g(s) declined significantly between morning and afternoon for elevated CO₂ grown trees. Instantaneous transpiration efficiency (ITE) was higher for elevated CO₂ grown trees compared with control trees. There was a significant increase in ITE between morning and afternoon data for ambient grown trees; in contrast a significant decline in ITE was observed for elevated CO₂ grown trees between morning and afternoon data sets. The slope of the regression between assimilation rate and stomatal conductance increased for plants grown under elevated CO₂. These data are discussed and compared with the responses of plants adapting to different photon flux densities.

Eamus, D., C.A. Berryman, and G.A. Duff. 1995. The impact of CO₂ enrichment on water relations in *Maranthus corymbosa* and *Eucalyptus tetrodonta*. *Australian Journal of Botany* 43(3):273-282.

Seeds of *Maranthus corymbosa* Blume and *Eucalyptus tetrodonta* F.Muell were sown under ambient or CO₂ enriched conditions (two replicate tents per treatment) in tropical Australia and allowed to grow, rooted in the ground, for 20 months. For both species, periodic measurements of leaf water potential, stomatal conductance and leaf temperature were made on four replicate leaves on each of four replicate trees within each tent. Measurements were made in November (M. *corymbosa*) and June (E. *tetrodonta*). At the same time, atmospheric wet and dry bulb temperatures were recorded and hence leaf-to-air vapour pressure difference (LAVPD) calculated. Measurements of pre-dawn leaf water potential were also made on E. *tetrodonta*. Leaves were also taken to the laboratory, rehydrated to full turgor and pressure-volume analyses undertaken. For M. *corymbosa*, leaf water potential was lower throughout the day for control leaves compared to leaves growing in CO₂ enriched air. Similarly, pre dawn leaf water potential was lower for control E. *tetrodonta* trees than for trees grown with CO₂ enrichment. However, mid-morning and mid-afternoon values of leaf water potential for E. *tetrodonta* were slightly lower for plants growing in CO₂ enriched air compared to control plants. In both species, stomatal conductance was consistently lower for trees grown in CO₂ enriched air than for controls. Whole plant hydraulic conductivity of both species was significantly lower for trees grown in CO₂ enriched air than for control trees. For both species, maximum turgor and bulk volumetric elastic modulus increased and osmotic potential at zero turgor decreased for trees grown in CO₂ enriched air.

Eamus, D., G.A. Duff, and C.A. Berryman. 1995. Photosynthetic responses to temperature, light flux-density, CO₂ concentration and vapor-pressure deficit in *Eucalyptus tetrodonta* grown under CO₂ enrichment. *Environmental Pollution* 90(1):41-49.

Seeds of *Eucalyptus tetrodonta* were sown under ambient or CO₂ enriched (700 μ l litre⁻¹) conditions in tropical Australia. Four sets of measurements were made, the first two after 12 months, on trees growing either in pots or planted in the ground. The third and fourth set were made after 18 and 30 months exposure to CO₂ enrichment, on trees growing in the ground. After 12 months exposure to CO₂ enrichment, the rate of light-saturated assimilation (A(max)) of plants growing in the ground was determined. Responses of CO₂ assimilation to variations in leaf temperature, leaf-to-air vapour pressure deficit (LAVPD), Eight flux density and CO₂ concentration were also measured in the laboratory using plants growing in large pots. There was no significant difference in A(max) between pot and ground located plants. Assimilation of E. *tetrodonta* was relatively insensitive to changes in LAVPD for both ambient and CO₂ enriched plants but the temperature optimum of assimilation was increased in plants grown and measured under CO₂ enrichment. Plants grown with CO₂ enrichment had an increased rate of light-saturated assimilation and apparent quantum yield I was significantly increased by CO₂ enrichment. In contrast, carboxylation efficiency was decreased significantly by CO₂ enrichment. After 18 months growth with CO₂ enrichment, there was no sign of a decline in assimilation rate compared to measurements undertaken after 12 months. At low LAVPD values, assimilation rate was not influenced by CO₂ treatment but at moderate to high LAVPD, plants grown under CO₂ enrichment exhibited a larger assimilation rate than control plants. Specific leaf area and chlorophyll contents decreased in response to CO₂ enrichment, whilst foliar soluble protein contents and chlorophyll a/b ratios were unaffected by CO₂ treatment. Changes in soluble protein and chlorophyll contents in response to CO₂ enrichment did not account for changes in assimilation between treatments. After 30 months exposure to CO₂ enrichment, the rate of light-saturated assimilation was approximately 50% larger than controls and this enhancement was larger than that observed after 18 months exposure to CO₂ enrichment.

Eamus, D., and M. Murray. 1991. Photosynthetic and stomatal conductance responses of Norway spruce and beech to ozone, acid mist and frost - a conceptual model. *Environmental Pollution* 72(1):23-44.

Two-year-old beech and Norway spruce seedlings were exposed to a combination of ozone and acid mist treatments in open-top chambers in Scotland during the months of July through to September 1988. Replicate pairs of chambers received charcoal-filtered air (control), ozone-enriched air (140 nl ozone litre⁻¹) or 140 nl ozone litre⁻¹ plus a synthetic acid mist (pH 2.5) composed of ammonium nitrate and sulphuric acid. Field measurements of assimilation and stomatal conductance were made during August. In addition, measurements of assimilation and conductance were made during September in the laboratory. Light response curves of assimilation and conductance were determined using a GENSTAT non-rectangular hyperbolic model. During February 1988/9 the Norway spruce were subject to a four day warming period at 12-degrees-C and the light response of assimilation determined. The same plants were then subject to a 3-h night-time frost of -10-degrees-C. The following day the time-course of the recovery of assimilation was determined. It was found that ozone fumigation did not influence the light response of assimilation of beech trees in the field, although stomatal conductance was reduced in the ozone-fumigated trees. The rate of light-saturated assimilation of Norway spruce was increased by ozone fumigation when measured in the field. Measurements of assimilation of Norway spruce made during the winter showed that prior to rewarming there was no difference in the rate of light-saturated assimilation for control and ozone-fumigated trees. However, the ozone plus acid mist-treated trees exhibited a significantly

higher rate. The 4-day period of warming to 12-degrees-C increased the rate of light-saturated assimilation in all treatments but only the ozone plus acid mist-treated trees showed a significant increase. Following a 3-h frost to -10-degrees-C the control trees exhibited a reduction in the rate of light-saturated assimilation ($A_{\max}$) to 80% of the pre-frost value. In comparison, following the frost, the ozone-fumigated trees showed an $A_{\max}$ of 74% of the pre-frost value. The ozone plus acid mist-treated trees showed an $A_{\max}$ of 64% of the pre-frost trees. The time taken for $A_{\max}$ to attain 50% of the pre-frost value increased from 30 min (control) to 85 min for ozone-fumigated trees to 190 min (ozone plus acid mist). These results are discussed in relation to the impact of mild, short-term frosts, which are known to occur with greater frequency than extreme, more catastrophic frost events. A simple conceptual framework is proposed to explain the variable results obtained in the literature with respect to the impact of ozone upon tree physiology.

Easterling, W.E., P.R. Crosson, N.J. Rosenberg, M.S. McKenney, L.A. Katz, and K.M. Lemon. 1993. Agricultural impacts of and responses to climate-change in the missouri-iowa-nebraska-kansas (mink) region. *Climatic Change* 24(1-2):23-61.

The climate of the 1930s was used as an analog of the climate that might occur in Missouri, Iowa, Nebraska and Kansas (the MINK region) as a consequence of global warming. The analog climate was imposed on the agriculture of the region under technological and economic conditions prevailing in 1984/87 and again under a scenario of conditions that might prevail in 2030. The EPIC model of Williams et al. (1984), modified to allow consideration of the yield enhancing effects of CO₂ enrichment, was used to evaluate the impacts of the analog climate on the productivity and water use of some 50 representative farm enterprises. Before farm level adjustments and adaptations to the changed climate, and absent CO₂ enrichment (from 350 to 450 ppm), production of corn, sorghum and soybeans was depressed by the analog climate in about the same percent under both current and 2030 conditions. Production of dryland wheat was unaffected. Irrigated wheat production actually increased. Farm level adjustments using low-cost currently available technologies, combined with CO₂ enrichment, eliminated about 80% of the negative impact of the analog climate on 1984/87 baseline crop production. The same farm level adjustments, plus new technologies developed in response to the analog climate, when combined with CO₂ enrichment, converted the negative impact on 2030 crop production to a small increase. The analog climate would have little direct effect on animal production in MINK. The effect, if any, would be by way of the impact on production of feed-grains and soybeans. Since this impact would be small after on-farm adjustments and CO₂ enrichment, animal production in MINK would be little affected by the analog climate.

Easterling, W.E., N.J. Rosenberg, K.M. Lemon, and M.S. McKenney. 1992. Simulations of crop responses to climate change - effects with present technology and currently available adjustments (the smart farmer scenario). *Agricultural and Forest Meteorology* 59(1-2):75-102.

If climate changes, farmers will have to adapt to a new set of climate constraints. In this paper we examine the efficacy of strategies for

dealing with climate change that are currently available to farmers and that are inexpensive to use; we refer to this group of strategies as 'adjustments'. Adjustment schemes of various kinds were identified for us by agricultural experts in the Missouri-Iowa-Nebraska-Kansas (MINK) states. These can involve changes in land use, changes in variety and crop selection, changes in planting and harvesting practices, and changes in fertility and pest management. Using the erosion productivity impact calculator (EPIC) model on a small set of representative farms, we tested adjustments of these kinds. The simulations show that earlier planting, longer-season cultivars and the use of furrow diking for moisture conservation would offset some of the yield losses induced by climate change in warm-season crops. Longer-season varieties of wheat (a cool-season crop) and shorter-season varieties of the perennials wheatgrass and alfalfa were also effective. The adjustments to climate change diminished yield losses in all crops but irrigated wheat. Despite the positive effects of adjustments, however, yields of all dryland warm-season crops remained lower than control levels. The adjustments also increased demand for irrigation water. Carbon dioxide enrichment had the same incremental effect on crop yields with or without adjustments (see the fourth paper in this issue), except in the case of alfalfa and sorghum, where a CO₂-adjustment interaction was found. We conclude that currently available techniques would partially offset the yield reductions caused by a 1930s-like climate, but that in most crops the yield reductions would still be substantial.

Edwards, N.T., and R.J. Norby. 1998. Below-ground respiratory responses of sugar maple and red maple saplings to atmospheric CO₂ enrichment and elevated air temperature. *Plant and Soil* 206(1):85-97.

The research described in this paper represents a part of a much broader research project with the general objective of describing the effects of elevated [CO₂] and temperature on tree growth, physiological processes, and ecosystem-level processes. The specific objective of this research was to examine the below-ground respiratory responses of sugar maple (*Acer saccharum* Marsh.) and red maple (*Acer rubrum* L.) seedlings to elevated atmospheric [CO₂] and temperature. Red maple and sugar maple seedlings were planted in the ground in each of 12 open-top chambers and exposed from 1994 through 1997 to ambient air or air enriched with 30 Pa CO₂, in combination with ambient or elevated (+4 degrees C) air temperatures. Carbon dioxide efflux was measured around the base of the seedlings and from root-exclusion zones at intervals during 1995 and 1996 and early 1997. The CO₂ efflux rates averaged 0.4 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ in the root-exclusion zones and 0.75 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ around the base of the seedlings. Mineral soil respiration in root-exclusion zones averaged 12% higher in the high temperature treatments than at ambient temperature, but was not affected by CO₂ treatments. The fraction of total efflux attributable to root + rhizosphere respiration ranged from 14 to 61% in measurements made around red maple plants, and from 35 to 62% around sugar maple plants. Root respiration rates ranged from 0 to 0.94 $\mu\text{mol CO}_2 \text{ s}^{-1} \text{ m}^{-2}$ of soil surface in red maple and from 0 to 1.02 in sugar maple. In both 1995 and 1996 root respiration rates of red maple were highest in high-CO₂ treatments and lowest in high temperature treatments. Specific red maple root respiration rates of excised roots from near the soil surface in 1996 were also highest under CO₂ enrichment and lowest in high temperature treatments. In sugar maple the highest rates of CO₂ efflux were from around the base of plants exposed to both high temperature and high-CO₂, even though specific respiration rates were lowest for this species under the high temperature and CO₂ enrichment regime. In both species, patterns of response to treatments were similar in root respiration and root mass, indicating that the root respiration responses were due in part to differences in root mass. The results underscore the need for separating the processes occurring in the roots from those in the

forest floor and mineral soil in order to increase our understanding of the effects of global climate change on carbon sequestration and cycling in the below-ground systems of forests.

Egli, P., and C. Korner. 1997. Growth responses to elevated CO₂ and soil quality in beech- spruce model ecosystems. *Acta Oecologica-International Journal of Ecology* 18(3):343-349.

Growth responses of beech (*Fagus sylvatica* L.) and Norway spruce (*Picea abies* Karst.) to elevated atmospheric CO₂ (366 and 550 $\mu\text{mol l}^{-1}$) and increased wet deposition of nitrogen (2.5 and 25 kg N ha⁻¹ a⁻¹) in combination with two soil types were studied in open-top chambers. Eight young beech and spruce trees, together with five understory species, were established in each of 32 model ecosystems. We present initial growth responses of trees during the first year of treatment which may set the trends for longer term responses to elevated CO₂. Above-ground biomass production at the system level (biometric data) during the first year and root biomass (coring data) did not show significant responses to elevated CO₂, irrespective of other co-treatments. Increased nitrogen deposition (treatment commencing by mid-season) also had no effect on above-ground biomass, whereas end of season root biomass was significantly increased in the high-nitrogen treated low fertility acidic soil (74 g m⁻²) in the high-N versus 49 g m⁻²) in the low N-treatment), but not in the more fertile calcareous soil. Stem diameter increment of beech was significantly increased (+9%) under elevated CO₂ in the calcareous soil, but not in the acidic soil. The opposite was found for spruce stems, which responded positively to elevated CO₂ in the acidic soil (+ 11%; $P < 0.05$) but not in the calcareous soil. These results suggest that soil type co-determines the CO₂ response of young forest trees and that these interactions are species specific. These initial differences are likely to affect long-term responses of community structure and ecosystem functioning. Soil type appears to be a key factor in predictions of forest responses to continued atmospheric CO₂ enrichment.

Egli, P., S. Maurer, M.S. Gunthardt-Goerg, and C. Korner. 1998. Effects of elevated CO₂ and soil quality on leaf gas exchange and above-ground growth in beech-spruce model ecosystems. *New Phytologist* 140(2):185-196.

Responses of leaf gas exchange and above-ground growth of beech (*Fagus sylvatica* L.) and Norway spruce (*Picea abies* Karst.) to atmospheric CO₂ enrichment (374 $\mu\text{mol l}^{-1}$ VS. 590 $\mu\text{mol l}^{-1}$) and increased wet deposition of N (5 vs. 50 kg N ha⁻¹ a⁻¹) in combination with two natural forest soil types ('acidic' and 'calcareous') were studied in large open-top chambers. Eight juvenile beech and spruce trees from different provenances, together with a ground cover composed of five understorey species, were established in each of 32 model ecosystems. Both beech and spruce showed sustained enhancement of photosynthesis in response to atmospheric CO₂ enrichment during the first 2 yr of treatment. Nevertheless, switching measurement CO₂ concentrations revealed partial downward adjustment of photosynthesis in trees grown in elevated CO₂, beech generally showing more pronounced downward adjustment than spruce. The responsiveness of photosynthesis to CO₂ enrichment did not vary significantly among trees from different provenances. Stomatal conductance was reduced under elevated CO₂ in both tree species. In spruce, the radial growth of the main stem and the annual production of

wood (shoot-wood dry mass of current-year lateral shoots), needle dry mass, and assimilation area per tree were stimulated both by CO₂ enrichment and increased N deposition, but were not significantly affected by soil type by year 2. In contrast, in beech, the radial growth of the stem and the total leaf number, foliage dry mass, and assimilation area per tree were all not significantly affected by elevated CO₂ and increased N deposition when responses of the two soil types were pooled, but were greater on calcareous than on acidic soil by year 2. However, CO₂ interacted with soil type in beech: irrespective of the N deposition rate, saplings showed growth stimulation on the calcareous soil but responded negatively to CO₂ enrichment on the acidic soil (where growth was slower). Our results suggest that complex interactions between CO₂, species and soil quality need to be accounted for when attempting to predict forest development in a future CO₂-rich world.

Ehler, N., and P. Karlsen. 1993. Optico - a model-based real-time expert-system for dynamic optimization of CO₂ enrichment of greenhouse vegetable crops. *Journal of Horticultural Science* 68(4):485-494.

To improve the economic yield of CO₂ enrichment for greenhouse crops, an expert system (OPTICO) was constructed. The system continually adapts the setpoints of a standard climate computer to the climate, the greenhouse regulation equipment and the crop's physiological status and stage of development. Models describing air loss and photosynthesis were used for selecting an optimized CO₂ setpoint by choosing the largest positive difference between expected income and cost. During the autumn of 1991 the sweet pepper (*Capsicum annuum* L.) cv. Trophy was used as experimental plant in two standard greenhouse compartments. One treatment used the optimized CO₂ enrichment, the other a fixed CO₂ level of 600 ppm. The optimized treatment resulted in greater yield using less CO₂. The results stress the importance of adapting the CO₂ level to the immediate irradiance and current leaf area and carbon partitioning behaviour of the crop.

Ehleringer, J.R., and T.E. Cerling. 1995. Atmospheric CO₂ and the ratio of intercellular to ambient CO₂ concentrations in plants. *Tree Physiology* 15(2):105-111.

Much attention is focused today on predicting how plants will respond to anticipated changes in atmospheric composition and climate, and in particular to increases in CO₂ concentration. Here we review the long-term global fluctuations in atmospheric CO₂ concentration as a framework for understanding how current trends in atmospheric CO₂ concentration fit into a selective, evolutionary context. We then focus on an integrated approach for understanding how gas exchange metabolism responds to current environmental conditions, how it previously responded to glacial-interglacial conditions, and how it may respond to future changes in atmospheric CO₂ concentration.

Ehleringer, J.R., T.E. Cerling, and B.R. Helliker. 1997. C-4 photosynthesis, atmospheric CO₂ and climate. *Oecologia* 112(3):285-299.

The objectives of this synthesis are (1) to review the factors that influence the ecological, geographical, and palaeoecological distributions of plants possessing C-4 photosynthesis and (2) to propose a hypothesis/model to explain both the distribution of C-4 plants with respect to temperature and CO₂ and why C-4 photosynthesis is relatively uncommon in dicotyledonous plants (hereafter dicots), especially in comparison with its widespread distribution in monocotyledonous species (hereafter monocots). Our goal is to stimulate discussion of the factors controlling distributions of C-4 plants today, historically, and under future elevated CO₂ environments. Understanding the distributions of C-3/C-4 plants impacts not only primary productivity, but also the distribution, evolution, and migration of both invertebrates and vertebrates that graze on these plants. Sixteen separate studies all indicate that the current distributions of C-4 monocots are tightly correlated with temperature: elevated temperatures during the growing season favor C-4 monocots. In contrast, the seven studies on C-4 dicot distributions suggest that a different environmental parameter, such as aridity (combination of temperature and evaporative potential), more closely describes their distributions. Differences in the temperature dependence of the quantum yield for CO₂ uptake (light-use efficiency) of C-3 and C-4 species relate well to observed plant distributions and light-use efficiency is the only mechanism that has been proposed to explain distributional differences in C-3/C-4 monocots. Modeling of C-3 and C-4 light-use efficiencies under different combinations of atmospheric CO₂ and temperature predicts that C-4-dominated ecosystems should not have expanded until atmospheric CO₂ concentrations reached the lower levels that are thought to have existed beginning near the end of the Miocene. At that time, palaeocarbonate and fossil data indicate a simultaneous, global expansion of C-4-dominated grasslands. The C-4 monocots generally have a higher quantum yield than C-4 dicots and it is proposed that leaf venation patterns play a role in increasing the light-use efficiency of most C-4 monocots. The reduced quantum yield of most C-4 dicots is consistent with their rarity, and it is suggested that C-4 dicots may not have been selected until CO₂ concentrations reached their lowest levels during glacial maxima in the Quaternary. Given the intrinsic light-use efficiency advantage of C-4 monocots, C-4 dicots may have been limited in their distributions to the warmest ecosystems, saline ecosystems, and/or to highly disturbed ecosystems. All C-4 plants have a significant advantage over C-3 plants under low atmospheric CO₂ conditions and are predicted to have expanded significantly on a global scale during full-glacial periods, especially in tropical regions. Bog and lake sediment cores as well as pedogenic carbonates support the hypothesis that C-4 ecosystems were more extensive during the last glacial maximum and then decreased in abundance following deglaciation as atmospheric CO₂ levels increased.

Eichmann, H., and A. Laisk. 1994. CO₂ uptake and electron-transport rates in wild-type and a starchless mutant of *Nicotiana sylvestris* - the role and regulation of starch synthesis at saturating CO₂ concentrations. *Plant Physiology* 106(2):679-687.

CO₂ uptake rate, chlorophyll fluorescence, and 830-nm absorbance were measured in wild-type (wt) *Nicotiana sylvestris* (Speg. et Comes) and starchless mutant NS 458 leaves at different light intensities and CO₂ concentrations. Initial slopes of the relationships between CO₂ uptake

and light and CO₂ were similar, but the maximum rate at CO₂ and light saturation was only 30% in the mutant compared with the wt. O-2 enhancement of photosynthesis at CO₂ and light saturation was relatively much greater in the mutant than in the wt. In 21% O-2, the electron transport rate (ETR) calculated from fluorescence peaked near the beginning of the CO₂ saturation of photosynthesis. With the further increase of CO₂ concentration ETR remained nearly constant or declined a little in the wt but drastically declined in the mutant. Absorbance measurements at 830 nm indicated photosystem I acceptor side reduction in both plants at saturating CO₂ and light. Assimilatory charge (postillumination CO₂ uptake) measurements indicated trapping of chloroplast inorganic phosphate, supposedly in hexose phosphates, in the mutant. It is concluded that starch synthesis gradually substitutes for photorespiration as electron acceptor with increasing CO₂ concentration in the wt but not in the mutant. It is suggested that starch synthesis is controlled by the activity of the chloroplast fructose biphosphatase.

Elhottova, D., J. Triska, H. Santruckova, J. Kveton, J. Santrucek, and M. Simkova. 1997. Rhizosphere microflora of winter wheat plants cultivated under elevated CO₂. *Plant and Soil* 197(2):251-259.

We studied an effect of elevated atmospheric CO₂ on rhizosphere microorganisms in a hydroponics system where young wheat plants provided the only source of C for microorganisms. Plants were cultivated in mineral solution in sterile silica sand and exposed to control (ambient) and elevated (double) CO₂ concentrations for periods of 13, 20, 25 and 34 days. Microbial biomass C (C content in fraction of size 0.3-2.7 µm) was not affected by the elevated CO₂ concentration during the first 25 days of plant growth and was increased after 34 days of plant growth. A content of poly-beta-hydroxybutyrate (PHB) reserve compounds (measured as derivatized product of 3-hydroxy-butyric acid and N-tert-butylidimethylsilyl-N-methyltrifluoroacetamide using GC-MS) was lowered significantly (p<0.001) in the elevated CO₂ after 25 and 34 days. It was accompanied with a shift of bacterial distribution towards the nutritional groups utilising more complex organic material (number of CFUs on media with different sources of C and N). A coincidence of several events connected with plant and microbial carbon economy (decrease of an assimilation rate and relative growth rate of plants, small increase of microbial biomass, PHB decrease and suppression within the bacterial nutritional group requiring the most readily available source of C and energy) was observed in the system under elevated CO₂ on the 25th day. A modification of the CC-MS method for the detection of low levels of PHB compounds in natural samples was developed. We excluded the lipids fractionation step and we used EI MS/MS detection of the main fragment ions of the derivatized compound. This guarantees that the ion profiles have high signal-to-noise ratio at correct retention time. The detection limit is then about 30 pg g⁻¹ of sand or soil. The rhizosphere microflora responded very sensitively to the short-term changes in C partitioning in plants caused by the elevated CO₂.

Elkohen, A., and M. Mousseau. 1994. Interactive effects of elevated CO₂ and mineral-nutrition on growth and CO₂ exchange of sweet chestnut seedlings (*castanea-sativa*). *Tree Physiology* 14(7-9):679-690.

The effects of elevated atmospheric CO₂ (700 µmol mol⁻¹) and

fertilization were investigated on 2-year-old sweet chestnut (*Castanea sativa* Mill.) seedlings grown outdoors in pots in constantly ventilated open-sided chambers. Plants were divided into four groups: fertilized controls (+F/-CO₂), unfertilized controls (-F/-CO₂), fertilized + CO₂-treated plants (+F/+CO₂) and unfertilized + CO₂-treated plants (-F/+CO₂). Dry matter accumulation and allocation were measured after one growing season and CO₂ exchange of whole shoots was measured throughout the growing season. Shoot growth and total leaf area of unfertilized plants were not affected by elevated CO₂, whereas both parameters were enhanced by elevated CO₂ in fertilized plants. Elevated CO₂ increased total biomass by about 20% in both fertilized and unfertilized plants; however, biomass partitioning differed. In unfertilized plants, elevated CO₂ caused an increase in root growth, whereas in fertilized plants, it stimulated aboveground growth. At the whole-shoot and leaf levels, photosynthetic activity of both fertilized and unfertilized plants increased in response to elevated CO₂, but the seasonal pattern of this enhancement varied with nutrient treatment. In unfertilized plants, a downward acclimation of photosynthesis was observed early in the season (June), and was related to reductions in nitrogen and chlorophyll content and to starch accumulation. The decrease in the slope of the A/Ci curve suggested a decrease in Rubisco activity. In both fertilized and unfertilized plants, shoot respiration decreased during the night in response to elevated CO₂ until mid-July. The decrease was not related to changes in sugar concentration.

602

Elkohen, A., J.Y. Pontailier, and M. Mousseau. 1991. Effect of doubling of atmospheric CO₂ concentration on dark respiration in aerial parts of young chestnut trees (*Castanea sativa* mill). *Comptes Rendus De L Academie Des Sciences Serie III-Sciences De La Vie-Life Sciences* 312(9):477-481.

Two-year-old sweet chestnut seedlings were grown in constantly ventilated tunnels at ambient (350 vpm) or double (700 vpm) CO₂ concentration during a full growing season. End-of-night dark respiration of aerial parts was measured in each CO₂ concentration throughout the growing season. Dark respiration rate of enriched plants showed a net decrease as compared to control plants during the first half of the growing season. This difference decreased with time and became negligible in the fall. Atmospheric CO₂ concentration acted instantaneously on the respiration rate: when doubled, it decreased control plant respiration and when decreased, it enhanced CO₂ enriched plant respiration. The explanation of these findings remains hypothetical. It is concluded that the rise in carbon dioxide level of the atmosphere will affect the carbon balance of young trees not only through an increase in net photosynthesis during the day, but also at night by reducing respiratory losses.

Elkohen, A., H. Rouhier, and M. Mousseau. 1992. Changes in dry-weight and nitrogen partitioning induced by elevated CO₂ depend on soil nutrient availability in sweet chestnut (*castanea-sativa* mill). *Annales Des Sciences Forestieres* 49(2):83-90.

The effect of 2 levels of atmospheric carbon dioxide (ambient, ie 350 ppm, and double, ie 700 ppm) and 2 contrasting levels of mineral nutrition on dry weight, nitrogen accumulation and partitioning were examined in 2-year-old chestnut seedlings (*Castanea sativa* Mill), grown in pots outdoors throughout the vegetative season. Fertilization had a pronounced effect on dry weight accumulation, tree height, leaf area, and plant nitrogen content. Carbon dioxide enrichment significantly increased total biomass by about 20%, both on fertilized and on unfertilized forest soil. However, the partitioning of biomass was very

different: on the unfertilized soil, only the root biomass was increased, leading to an increase in the root: shoot ratio. Contrastingly, on fertilized soil only stem biomass and diameter but not height were increased. Carbon dioxide enrichment significantly reduced the nitrogen concentration in all organs, irrespective of the nutrient availability. However, the biomass increase made up for this reduction in such a way that the total nitrogen pool per tree remained unchanged.

Elkohen, A., L. Venet, and M. Mousseau. 1993. Growth and photosynthesis of 2 deciduous forest species at elevated carbon-dioxide. *Functional Ecology* 7(4):480-486.

1. Two-year-old sweet chestnut (*Castanea sativa*) and beech (*Fagus sylvatica*) seedlings were grown in large pots of forest soil, at ambient (+/-350 mul l-1) and double (700 mul l-1) atmospheric CO₂ Concentration in constantly ventilated mini-green-houses during an entire growing season. 2. CO₂ enrichment caused very different changes in these two temperate deciduous species. A 20% dry weight enhancement was obtained for sweet chestnut, and a 60% enhancement in beech. This greater effect of elevated CO₂ in beech was the result of a significant increase of net photosynthesis of the seedlings occurring during the whole season. However, in sweet chestnut, this increase in photosynthesis lasted only a few weeks and then an acclimation process took place. 3. No effect of increased CO₂ could be found on sweet chestnut leaf area or leaf number, while a significant effect was found with beech, in which total leaf area per plant increased, owing to a greater number of growth flushes, of progressively larger leaves. 4. The partitioning of the biomass increase due to elevated CO₂ was very different in the two species. All additional dry matter was allocated to the roots in sweet chestnut, while it was partitioned equally amongst all organs of the beech seedling. 5. The reactions to elevated CO₂ of different tree species is discussed in relation to their specific growth strategy.

Ellert, B.H., and H.H. Janzen. 1999. Short-term influence of tillage on CO₂ fluxes from a semi-arid soil on the Canadian Prairies. *Soil & Tillage Research* 50(1):21-32.

The flux of CO₂ from soil determines the extent to which carbon (C) deposited as plant litter is retained in the soil. Retention of soil C is beneficial for soil physical, chemical and biological properties, and is essential if soils are to be used as a repository of C to mitigate atmospheric CO₂ increases. Although tillage is assumed to have a major influence on soil C retention, the extent to which tillage enhances the transfer of soil C to the atmosphere is uncertain. We assessed the short-term (50 h) influence of tillage on CO₂ fluxes from Chernozemic soils under a two-year wheat (*Triticum aestivum* L.)-summerfallow rotation in a semi-arid region of the Canadian Prairie. The tillage effect and its persistence were assessed by using a portable CO₂ analyzer to record several temporal series of CO₂ fluxes, along undisturbed and tilled transects, at successive time intervals (from -0.5 to 50 h) after a single pass with a heavy-duty cultivator. Immediately after tillage, CO₂ fluxes along the tilled transects increased from 2 to 4-fold above pre-tillage fluxes, but the increases were short-lived and fluxes along undisturbed and tilled transects were again similar within 24 h of cultivation. Total amounts of CO₂ released by a tillage operation were quantified by: 1. linear interpolations among successive fluxes along tilled and undisturbed transects, and 2. by fitting a model to successive differences between fluxes along the transects. Both methods estimated the amounts of tillage-susceptible CO₂ to be in the range of 3.6-7.2 kg C ha⁻¹. The

tillage-induced flush of CO₂ was attributed mainly to enhanced transport of CO₂ already in the soil, but enhanced production of CO₂ by heterotrophic soil organisms also may have contributed to the flush. Regardless of the sources of CO₂ released by single tillage operations, amounts of tillage-susceptible soil C were minor; even 10 passes with a cultivator would account for less than 5% of annual soil CO₂ emissions or crop residue production in these cropping systems. Our study suggested that the short-term influence of tillage on the transfer of soil C to atmospheric CO₂ is small under semi-arid conditions like those in southern Alberta, Canada. Ellis, R.H., P.Q. Craufurd, R.J. Summerfield, and E.H. Roberts. 1995. Linear relations between carbon-dioxide concentration and rate of development towards flowering in sorghum, cowpea and soybean. *Annals of Botany* 75(2):193-198.

Negative linear relations were detected ($P < 0.005$) between the rate of progress from sowing to panicle initiation and CO₂ concentration (210-720 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ air) for two genotypes of sorghum [*Sorghum bicolor* (L.) Moench]. Relations between CO₂ concentration and the rate of progress from sowing to first flowering were also negative in soybean [*Glycine max* (L.) Merrill] ($P < 0.025$), but positive in cowpea [*Vigna unguiculata* (L.) Walp.] ($P < 0.025$), albeit that in both grain legumes sensitivity was much less than in sorghum. Thus CO₂ elevation does not delay flowering in all short-day species. The considerable effect of CO₂ concentration on times to panicle initiation resulted in large differences among the sorghum plants at this developmental stage; with increase in CO₂ concentration, plants were taller with slightly more leaves and more pronounced apical extension. At the same time after sowing however, sorghum plants were heavier ($P < 0.05$) at 210 than at 360 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ air. In contrast, relations between the dry masses of the soybean and cowpea plants and CO₂ concentration were positive and curvilinear ($P < 0.05$). It is suggested that the impact of global environmental change could be severe for sorghum production in the semi-arid tropics.

Ellsworth, D.S. 1999. CO₂ enrichment in a maturing pine forest: are CO₂ exchange and water status in the canopy affected? *Plant, Cell and Environment* 22(5):461-472.

Elevated CO₂ is expected to reduce forest water use as a result of CO₂-induced stomatal closure, which has implications for ecosystem-scale phenomena controlled by water availability. Leaf-level CO₂ and H₂O exchange responses and plant and soil water relations were examined in a maturing loblolly pine (*Pinus taeda* L.) stand in a free-air CO₂ enrichment (FACE) experiment in North Carolina, USA to test if these parameters were affected by elevated CO₂. Current-year foliage in the canopy was continuously exposed to elevated CO₂ (ambient CO₂ + 200 $\mu\text{mol mol}^{-1}$) in free-air during needle growth and development for 1 to 400 d. Photosynthesis in upper canopy foliage was stimulated by 50-60% by elevated CO₂ compared with ambient controls. This enhancement was similar in current-year, ambient-grown foliage temporarily measured at elevated CO₂ compared with long-term elevated CO₂ grown foliage. Significant photosynthetic enhancement by CO₂ was maintained over a range of conditions except during peak drought. There was no evidence of water savings in elevated CO₂ plots

in FACE compared to ambient plots under drought and non-drought conditions. This was supported by evidence from three independent measures. First, stomatal conductance was not significantly different in elevated CO₂ versus ambient trees of *P. taeda*. Calculations of time-integrated $c(i)/c(a)$ ratios from analysis of foliar $\delta(13)\text{C}$ showed that these ratios were maintained in foliage under elevated CO₂. Second, soil moisture was not significantly different between ambient and elevated CO₂ plots during drought. Third, pre-dawn and mid-day leaf water potentials were also unaffected by the seasonal CO₂ exposure, as were tissue osmotic potentials and turgor loss points. Together the results strongly support the hypothesis that maturing *P. taeda* trees have low stomatal responsiveness to elevated CO₂. Elevated CO₂ effects on water relations in loblolly pine-dominated forest ecosystems may be absent or small apart from those mediated by leaf area. Large photosynthetic enhancements in the upper canopy of *P. taeda* by elevated CO₂ indicate that this maturing forest may have a large carbon sequestration capacity with limiting water supply.

Ellsworth, D.S., R. Oren, C. Huang, N. Phillips, and G.R. Hendrey. 1995. Leaf and canopy responses to elevated CO₂ in a pine forest under free-air CO₂ enrichment. *Oecologia* 104(2):139-146.

Physiological responses to elevated CO₂ at the leaf and canopy-level were studied in an intact pine (*Pinus taeda*) forest ecosystem exposed to elevated CO₂ using a free-air CO₂ enrichment (FACE) technique. Normalized canopy water-use of trees exposed to elevated CO₂ over an 8-day exposure period was similar to that of trees exposed to current ambient CO₂ under sunny conditions. During a portion of the exposure period when sky conditions were cloudy, CO₂-exposed trees showed minor (less than or equal to 7%) but significant reductions in relative sap flux density compared to trees under ambient CO₂ conditions. Short-term (minutes) direct stomatal responses to elevated CO₂ were also relatively weak (approximate to 5% reduction in stomatal aperture in response to high CO₂ concentrations). We observed no evidence of adjustment in stomatal conductance in foliage grown under elevated CO₂ for nearly 80 days compared to foliage grown under current ambient CO₂ so intrinsic leaf water-use efficiency at elevated CO₂ was enhanced primarily by direct responses of photosynthesis to CO₂. We did not detect statistical differences in parameters from photosynthetic responses to intercellular CO₂ ($A(\text{net})-C_i$ curves) for *Pinus taeda* foliage grown under elevated CO₂ (550 $\mu\text{mol mol}^{-1}$) for 50-80 days compared to those for foliage grown under current ambient CO₂ from similar-sized reference trees nearby. In both cases, leaf net photosynthetic rate at 550 $\mu\text{mol mol}^{-1}$ CO₂ was enhanced by approximately 65% compared to the rate at ambient CO₂ (350 $\mu\text{mol mol}^{-1}$). A similar level of enhancement under elevated CO₂ was observed for daily photosynthesis under field conditions on a sunny day. While enhancement of photosynthesis by elevated CO₂ during the study period appears to be primarily attributable to direct photosynthetic responses to CO₂ in the pine forest, longer-term CO₂ responses and feedbacks remain to be evaluated.

ElMaayar, M., B. Singh, P. Andre, C.R. Bryant, and J.P. Thouez. 1997. The effects of climatic change and CO₂ fertilisation on agriculture in Quebec. *Agricultural and Forest Meteorology* 85(3-4):193-208.

The agricultural sector forms an important part of the economy of Quebec. The risk of global increase of atmospheric CO₂ concentration and associated climatic change and their influence on agriculture need to be assessed. Although many studies have been conducted on the effect of climate change on agriculture in various parts of the world, fewer studies have focused on the combined effects of climatic change and CO₂ fertilisation on agriculture. This study, using the outputs of the Canadian Climate Centre (CCC) general circulation model coupled with the Food and Agricultural Organization (FAG) crop model, attempts to assess the response of agricultural productivity to both direct (or fertilisation) and indirect (or climatic) effects of increased atmospheric CO₂ concentration, for a variety of crops including C-3 and C-4 cereals, legumes, vegetables and special crops grown in Quebec. It appears that C-4 cereal (corn and sorghum) crops would benefit by climate change but would be least favoured by CO₂ fertilisation effect. (C) 1997 Published by Elsevier Science B.V.

Elmeskaoui, A., J.P. Damont, M.J. Poulin, Y. Piche, and Y. Desjardins. 1995. A tripartite culture system for endomycorrhizal inoculation of micropropagated strawberry plantlets in-vitro. *Mycorrhiza* 5(5):313-319.

The objective of the current investigation was to develop a reliable method to obtain vesicular-arbuscular mycorrhizae (VAM) in micropropagated plantlets and to determine their influence on growth. An in vitro system for culturing the VA mycorrhizal fungus *Glomus intraradices* with Ri T-DNA-transformed carrot roots or nontransformed tomato roots was used in this study as a potential active source of inoculum for the colonization of micropropagated plantlets. After root induction, micropropagated plantlets grown on cellulose plugs (sorbarod) were placed in contact with the primary mycorrhizae in growth chambers enriched with 5000 ppm CO₂ and fed with a minimal medium. After 20 days of tripartite culture, all plantlets placed in contact with the primary symbiosis were colonized by the VAM fungus. As inoculum source, 30-day-old VA mycorrhizal transformed carrot roots had a substantially higher infection potential than 5-, 10- or 20-day-old VAM. Colonized plantlets had more extensive root systems and better shoot growth than control plants. The VAM symbiosis reduced the plantlet osmotic potential. This response may be a useful pre-adaptation for plantlets during transfer to the acclimatization stage.

Endo, M., and I. Ikushima. 1997. Effects of CO₂ enrichment on yields and preservability of cut flowers in Phalaenopsis. *Journal of the Japanese Society for Horticultural Science* 66(1):169-174.

The effect of CO₂ enrichment on Phalaenopsis cut flower production was examined for 30 months throughout five flowering cycles. The plant

was cultured in three greenhouses with different CO₂ levels of (A) : control, daily mean of ambient air = 438 ppm; (B) : 700 ppm; and (C) : 1000 ppm. 1. The fresh weight of cut flowers, the numbers of inflorescence and flowers per 20 plants varied, depending on the CO₂ concentration for each flowering cycle. 2. The preservability (vase life) of cut flowers always improved under higher CO₂ levels. Organic acid contents of plants were also higher under higher CO₂ levels. The malic acid content in the flowers was higher than in the younger leaf and flower stalk at 1:00 PM and 10:00 PM; and it was also higher in the younger leaf than in the flower stalk at 10:00 PM, but lower at 1:00 PM. The pH value of plants was always lower at higher ambient CO₂ levels, and lower in the younger leaf and flower stalk at 1:00 PM than at 10:00 PM, whereas at those same times the sugar content at the higher ambient CO₂ levels reached its maximum.

Endo, M., and I. Ikusima. 1997. Effects of CO₂ enrichment by complete combustion of liquid petroleum gas on growth of Doritaenopsis. *Journal of the Japanese Society for Horticultural Science* 66(1):163-168.

The effects of increasing ambient CO₂ levels on the growth of developing Doritaenopsis plants in a greenhouse were studied for 840 days. Leaf area, dry weight, and content of total carbon and total nitrogen in dry matter were measured every three months, and the time course of the relative growth rate (RGR) was investigated. Leaf area and dry weight increased with increasing CO₂ concentration from 438 ppm to 946 ppm in the atmosphere. In an initial growth stage when plants were transplanted from flasks to pots, RGR increased as the CO₂ level increased. RGR during a later vegetative growth stage was not affected by the CO₂ concentration, and its value was 0.006/day. The value of RGR was less than that of the other C-3, C-4, and CAM plants.

Enoch, H.Z., and J.M. Olesen. 1993. Plant-response to irrigation with water enriched with carbon-dioxide. *New Phytologist* 125(2):249-258.

The influence of irrigation with CO₂-enriched water on plant development and yield is reviewed. The reason for irrigation with CO₂-enriched water was - in most cases - to increase yield. The present evaluation considers results from over a hundred studies performed since the first experiment in 1866. Special emphasis is given to the comparison of 85 experiments made by Mitscherlich in 1910 with 358 irrigation experiments made in the last 80 years. In a statistical analysis of these experiments, the measured plant parameter (often growth and/or gas exchange rates) showed a highly significant mean increase of 2.9 % in plants irrigated with CO₂-enriched water as compared with control. Evidence of five mechanisms was found. The subterranean carbon dioxide concentration influences: (a) the rate of nitrification and hence of nitrogen availability; (b) the rate of weathering and pH, and hence the availability of other plant nutrients; (c) the CO₂ uptake via roots into the transpiration stream, contributing to the rate of leaf photosynthesis; (d) the hormone levels in the plant; and (e) the rate of pesticide decomposition in soils. After examining the available evidence we found that (a) and (b) in some experiments are important to plant growth, since they change the physiochemical environment of the roots. On the other hand, while (c) could theoretically contribute up to 5% of plant carbon assimilation, it usually contributes less than 1%, while (d) contributes most of the observed effects of CO₂-enriched water on plants. In addition, pesticide decomposition in soils can be delayed by supra- or sub-optimal CO₂ concentrations.

Entry, J.A., G.B. Runion, S.A. Prior, R.J. Mitchell, and H.H. Rogers. 1998. Influence of CO₂ enrichment and nitrogen fertilization on tissue chemistry and carbon allocation in longleaf pine seedlings. *Plant and Soil* 200(1):3-11.

One-year old, nursery-grown longleaf pine (*Pinus palustris* Mill.) seedlings were grown in 45-L pots containing a coarse sandy medium and were exposed to two concentrations of atmospheric CO₂ (365 or 720 $\mu\text{mol}(-1)$) and two levels of nitrogen (N) fertility (40 or 400 kg N ha⁻¹) within open top chambers for 20 months. At harvest, needles, stems, coarse roots, and fine roots were separated and weighed. Subsamples of each tissue were frozen in liquid N, lyophilized at -50 degrees C, and ground to pass a 0.2 mm sieve. Tissue samples were analyzed for carbon (C), N, nonpolar extractives (fats, waxes, and oils = FWO), nonstructural carbohydrates (total sugars and starch), and structural carbohydrates (cellulose, lignin, and tannins). Increased dry weights of each tissue were observed under elevated CO₂ and with high N; however, main effects of CO₂ were significant only on belowground tissues. The high N fertility tended to result in increased partitioning of biomass aboveground, resulting in significantly lower root to shoot ratios. Elevated CO₂ did not affect biomass allocation among tissues. Both atmospheric CO₂ and N fertility tended to affect concentration of C compounds in belowground, more than aboveground, tissues. Elevated CO₂ resulted in lower concentrations of starch, cellulose, and lignin, but increased concentrations of FWO in root tissues. High N fertility increased the concentration of starch, cellulose, and tannins, but resulted in lower concentrations of lignin and FWO in roots. Differences between CO₂ concentrations tended to occur only with high N fertility. Atmospheric CO₂ did not affect allocation patterns for any compound; however the high N treatment tended to result in a lower percentage of sugars, cellulose, and lignin belowground.

Epron, D., E. Dreyer, C. Picon, and J.M. Guehl. 1994. Relationship between CO₂-dependent O₂ evolution and photosystem-II activity in oak (*quercus-petraea*) trees grown in the field and in seedlings grown in ambient or elevated CO₂. *Tree Physiology* 14(7-9):725-733.

The light-response of the apparent quantum yield of photosynthetic O₂ evolution (PHI(O₂)) under non- photorespiratory conditions was measured together with the photochemical efficiency Of PS II (DELTA F/F(m)'), the photochemical efficiency of open PS II reaction centers (F(v)/F(m)') and the photochemical fluorescence quenching (q(p)) of leaf disks punched from oak leaves of seedlings grown in ambient (350 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ in a greenhouse, and from sunlit leaves of mature oak trees (*Quercus petraea* (Matt.) Liebl.). There were marked differences between seedlings and trees. In seedlings, CO₂ concentration during growth did not modify the light response of photosynthesis or PS II activity. There was a single linear relationship between PHI(O₂) and DELTA F/F(m)' in seedling leaves that was independent of the CO₂ concentration imposed during growth. In contrast, this relationship was curvilinear in sunlit leaves of adult trees. In seedling leaves, the decrease in q(p) (i.e., the proportion of open PS II reaction centers) largely accounted for the decrease in DELTA F/F(m)', whereas the decrease in DELTA F/F(m)' in sunlit leaves of mature oak trees was dependent on both q(p) and F(v)/F(m)'.

Epron, D., D. Godard, G. Cornic, and B. Genty. 1995. Limitation of net CO₂ assimilation rate by internal resistances to CO₂ transfer in the leaves of 2 tree species (*fagus- sylvatica* L and *castanea-sativa* mill). *Plant, Cell and Environment* 18(1):43-51.

Using a combination of gas-exchange and chlorophyll fluorescence measurements, low apparent CO₂/O₂ specificity factors (1300 mol mol^{-1}) were estimated for the leaves of two deciduous tree species (*Fagus sylvatica* and *Castanea sativa*). These low values contrasted with those estimated for two herbaceous species and were ascribed to a drop in the CO₂ mole fraction between the intercellular airspace (C-i) and the catalytic site of Rubisco (C-c) due to internal resistances to CO₂ transfer. C-c was calculated assuming a specificity of Rubisco value of 2560 mol mol^{-1} . The drop between C-i and C-c was used to calculate the internal conductance for CO₂ (g(i)). A good correlation between mean values of net CO₂ assimilation rate (A) and g(i) was observed within a set of data obtained using 13 woody plant species, including our own data. We report that the relative limitation of A, which can be ascribed to internal resistances to CO₂ transfer, was 24-30%. High internal resistances to CO₂ transfer may explain the low apparent maximal rates of carboxylation and electron transport of some woody plant species calculated from A/C-i curves.

Epron, D., R. Liozon, and M. Mousseau. 1996. Effects of elevated CO₂ concentration on leaf characteristics and photosynthetic capacity of beech (*Fagus sylvatica*) during the growing season. *Tree Physiology* 16(4):425-432.

Two-year-old beech (*Fagus sylvatica* L.) saplings were planted directly in the ground at high density (100 per m²), in an experimental design that realistically mimicked field conditions, and grown for two years in air containing CO₂ at either ambient or an elevated (ambient + 350 ppm) concentration. Plant dry mass and leaf area were increased by a two-year exposure to elevated CO₂. The saplings produced physiologically distinct types of sun leaves associated with the first and second growth flushes. Leaves of the second flush had a higher leaf mass per unit area and less chlorophyll per unit area, per unit dry mass and per unit nitrogen than leaves of the first flush. Chlorophyll content expressed per unit nitrogen decreased over time in plants grown in elevated CO₂, which suggests that, in elevated CO₂, less nitrogen was invested in machinery of the photosynthetic light reactions. In early summer, the photosynthetic capacity measured at saturating irradiance and CO₂ was slightly but not significantly higher in saplings grown in elevated CO₂ than in saplings grown in ambient CO₂. However, a decrease in photosynthetic capacity was observed after July in leaves of saplings grown in CO₂-enriched air. The results demonstrate that photosynthetic acclimation to elevated CO₂ can occur in field-grown saplings in late summer, at the time of growth cessation.

Erhardt, A., and H.P. Rusterholz. 1997. Effects of elevated CO₂ on flowering phenology and nectar production. *Acta Oecologica-International Journal of Ecology* 18(3):249-253.

Effects of elevated CO₂ on flowering phenology and nectar production were studied in five important nectar plants of calcareous grasslands, i.e. *Lotus corniculatus*, *Trifolium pratense*, *Betonica officinalis*, *Scabiosa columbaria* and *Centaurea jacea*. Glasshouse experiments showed that flowering probability was significantly enhanced in *C. jacea*. *B. officinalis* flowered earlier and *L. corniculatus* produced more flowers under elevated CO₂. In contrast, the number of flowers decreased in *T. pratense*. The amount of nectar produced per flower was not affected in the investigated legumes (*T. pratense*, *L. corniculatus*), but was significantly reduced in the other forbs. Elevated CO₂ did not significantly affect nectar sugar concentration and sugar composition. However, *S. columbaria* and *C. jacea* produced significantly less total sugar per flower under elevated CO₂. The nectar amino acid concentration remained unaffected in all investigated plant species whereas the total of amino acids produced per flower was significantly reduced in all non-legumes. In addition, the amino acid composition changed significantly in all investigated species except for *C. jacea*. The observed effects are unexpected and are a potential threat to flower visitors such as most butterflies which have no alternative food resources except nectar. Changes in nectar production due to elevated CO₂ could also generally have detrimental effects on the interactions of flowers and their pollinators.

Erickson, D.J. 1999. Nitrogen deposition, terrestrial carbon uptake and changes in the seasonal cycle of atmospheric CO₂. *Geophysical Research Letters* 26(21):3313-3316.

Observational evidence indicates an increasing trend in the amplitude of the seasonal cycle of atmospheric CO₂ over the last several decades. Here, the influence of nitrogen deposition on the seasonal cycle of atmospheric CO₂ is investigated using a global carbon cycle model embedded in a 3-D general circulation model. We employ a recently published estimate of the enhancement of carbon dioxide uptake induced by the atmospheric deposition of NO_y and NH_x. We partition the carbon sink related to nitrogen deposition over the seasonal cycle of CO₂ uptake. The modeled increase in the amplitude of the seasonal cycle of CO₂ in the Northern Hemisphere related to the simulated nitrogen deposition alone is 25%-50% of observed. At Mauna Loa the increased amplitude in the CO₂ seasonal cycle due to nitrogen deposition is 50-90% of that observed. The subtle interaction between 3-D atmospheric transport, atmospheric nitrogen deposition, and seasonal CO₂ uptake results in significant changes in the amplitude of the seasonal cycle of atmospheric CO₂. The magnitude of these nitrogen deposition-induced changes in the atmospheric behavior of CO₂ is comparable to other processes that are thought to influence global carbon cycle dynamics.

Ericsson, T. 1995. Growth and shoot - root ratio of seedlings in relation to nutrient availability. *Plant and Soil* 169:205-214.

The influence of mineral nutrient availability, light intensity and CO₂ on growth and shoot:root ratio in young plants is reviewed. Special emphasis in this evaluation is given to data from laboratory experiments with small *Betula pendula* plants, in which the concept of steady-state nutrition has been applied. Three distinctly different dry matter allocation patterns were observed when growth was limited by the availability of mineral nutrients: 1, Root growth was favoured when N, P or S were the major growth constraints. 2, The opposite pattern obtained when K, Mg and Mn restricted growth. 3, Shortage of Ca, Fe and Zn had almost no effect on the shoot:root ratio. The light regime had no effect on dry matter allocation except at very low photon flux densities (< 6.5 mol m⁻² day⁻¹), in which a small decrease in the root

fraction was observed. Shortage of CO₂ on the other hand, strongly decreased root development, while an increase of the atmospheric CO₂ concentration had no influence on dry matter partitioning. An increased allocation of dry matter to below-ground parts was associated with an increased amount of starch in the tissues. Depletion of the carbohydrate stores occurred under all conditions in which root development was inhibited. It is concluded that the internal balance between labile nitrogen and carbon in the root and the shoot system determines how dry matter is being partitioned in the plant. The consistency of this statement with literature data and existing models for shoot:root regulation is examined.

Ershova, A.N., and V.A. Khripach. 1996. Effect of epibrassinolide on lipid peroxidation in *Pisum sativum* at normal aeration and under oxygen deficiency. *Russian Journal of Plant Physiology* 43(6):750-752.

The effect of epibrassinolide on oxidative lipid degradation in pea seedlings was studied at normal aeration and in oxygen-deprived and CO₂-enriched media. The content of various products of lipid peroxidation (POL), including the primary derivatives (conjugated dienoic acids) and end products (malonyl dialdehyde, MDA), was shown to decrease in seedlings treated with epibrassinolide (10 mg/l). Epibrassinolide inhibited POL in pea seedlings more strongly than kinetin. These effects became even more pronounced in plants under hypoxia or in the CO₂-enriched medium. The content of conjugated dienes declined by 13 and 21% at hypoxia and in the CO₂-medium compared to their content in air-grown seedlings, whereas the content of MDA was 38 and 26% below the level in the untreated plants, respectively. We presume that as a protector, epibrassinolide can inhibit the oxidative degradation of lipids in biological membranes and prevent the disruption of membrane structures. Thus it increases the tolerance of plants to deleterious factors.

Esler, K.J., P.W. Rundel, and P. Vorster. 1999. Biogeography of prostrate-leaved geophytes in semi-arid South Africa: hypotheses on functionality. *Plant Ecology* 142(1-2):105-120.

Nowhere is the species diversity of geophytes greater than in the five Mediterranean-climate ecosystems of the world. Of these, the Cape Mediterranean zone of South Africa is the most speciose. While the relative diversity and importance of geophytes of all of the other four Mediterranean regions of the world drops off sharply as one moves into adjacent winter-rainfall desert regions, geophytes in the semi-arid to arid Succulent Karoo (including Namaqualand) remain a very important component of the flora, both in terms of abundance and diversity (comprising 13 to 29% of the regional floras in this region). Apart from species richness, there are also a number of interesting geophyte growth forms in this region. One unusual growth form is geophytes with flattened leaves that lie prostrate on the soil surface. At least eight families (Amaryllidaceae, Colchicaceae, Eriosemaceae, Geraniaceae, Hyacinthaceae, Iridaceae, Orchidaceae and Oxalidaceae) exhibit this growth form. While this growth form is relatively common in many geophyte lineages in the Succulent Karoo biome and the Cape Mediterranean zone (Fynbos biome), and occurs infrequently through the summer-rainfall temperate regions of Africa, it is virtually absent in other regions worldwide. A null hypothesis is that the prostrate leaved trait is a neutral characteristic, however biogeographical data do not support this. A neutral trait would be unlikely to show such a clear

pattern of distribution. Several alternative hypotheses on the adaptive significance of this growth form are discussed. These include: avoidance of herbivory, reduction in competition from neighbors, creation of a CO₂ enriched environment below the leaves, reduction of water loss around the roots, reduction of water loss through transpiration, precipitation of dew on the leaves and maintenance of optimal leaf temperatures for growth.

Estiarte, M., J. Penuelas, B.A. Kimball, D.L. Hendrix, P.J. Pinter, G.W. Wall, R.L. LaMorte, and D.J. Hunsaker. 1999. Free-air CO₂ enrichment of wheat: leaf flavonoid concentration throughout the growth cycle. *Physiologia Plantarum* 105(3):423-433.

To test the predictions that plants will have a larger flavonoid concentration in a future world with a CO₂-enriched atmosphere, wheat (*Triticum aestivum* L. cv. Yecora Rojo) was grown in a field experiment using FACE (free-air CO₂ enrichment) technology under two levels of atmospheric CO₂ concentration: ambient (370 pmol mol⁻¹) and enriched (550 pmol mol⁻¹), and under two levels of irrigation: well-watered (100% replacement of potential evapotranspiration) and half-watered. We also studied the effects of CO₂ on the concentration of total non-structural carbohydrates (TNC) and nitrogen (N), two parameters hypothesized to be linked to flavonoid metabolism. Throughout the growth cycle the concentration of isoorientin, the most abundant flavonoid, decreased by 62% (from an average of 12.5 mg g⁻¹) on day of year (DOY) 41 to an average of 4.8 mg g⁻¹ on DOY 123), whereas the concentration of tricetin, another characteristic flavone, increased by two orders of magnitude (from an average of 0.007 mg g⁻¹) of isoorientin equivalents on DOY 41 to an average of 0.6 mg g⁻¹ of isoorientin equivalents on DOY 123). Although flavonoid concentration was dependent on growth stage, the effects of treatments on phenology did not invalidate the comparisons between treatments. CO₂-enriched plants had higher flavonoid concentrations (14% more isoorientin, an average of 7.0 mg g⁻¹ for ambient CO₂ vs an average of 8.0 mg g⁻¹) for enriched CO₂, higher TNC concentrations and lower N concentrations in upper canopy leaves throughout the growth cycle. Well-irrigated plants had higher flavonoid concentrations (11% more isoorientin, an average of 7.1 mg g⁻¹) for half watered vs an average of 7.9 mg g⁻¹) for well-watered) throughout the growth cycle, whereas the effect of irrigation treatments on TNC and N was more variable. These results are in accordance with the hypotheses that higher carbon availability promoted by CO₂-enrichment provides carbon that can be invested in carbon-based secondary compounds such as flavonoids. The rise in atmospheric CO₂ may thus indirectly affect wheat-pest relations, alter the pathogen predisposition and improve the UV-B protection by changing flavonoid concentrations.

Estiarte, M., J. Penuelas, B.A. Kimball, S.B. Idso, R.L. Lamorte, P.J. Pinter, G.W. Wall, and R.L. Garcia. 1994. Elevated CO₂ effects on stomatal density of wheat and sour orange trees. *Journal of Experimental Botany* 45(280):1665-1668.

No significant differences were found in stomatal densities or stomatal indices of wheat or sour orange trees grown at high CO₂ concentrations in two different CO₂ enrichment systems (Free-Air CO₂ enrichment for wheat and Open-Top Chambers for orange trees). These results are in

accordance with most of the previous results obtained in short-term experimental studies which suggest that plants do not acclimate to increasing CO₂ concentration by changing stomatal density within a single generation.

Ewert, F., and H. Pleijel. 1999. Phenological development, leaf emergence, tillering and leaf area index, and duration of spring wheat across Europe in response to CO₂ and ozone. *European Journal of Agronomy* 10(3-4):171-184.

Phenological development, leaf emergence, tillering and leaf area index (LAI), and duration (LAD) of spring wheat cv. Minaret, grown in open-top chambers at different sites throughout Europe for up to 3 years at each site, were investigated in response to elevated CO₂ (ambient CO₂ x2) and ozone (ambient ozone x1.5) concentrations. Phenological development varied among experiments and was partly explained by differences in temperature among sites and years. There was a weak positive relationship between the thermal rate of development and the mean daylength for the period from emergence to anthesis. Main stems produced on average 7.7 leaves with little variation among experiments. Variation was higher for the thermal rate of leaf emergence, which was partly explained by differences in the rate of change of daylength at plant emergence among seasons. Phenological development, rate of leaf emergence and final leaf number were not affected by CO₂ and ozone exposure. Responses of tillering and LAI to CO₂ and ozone exposure were significant only in some experiments. However, the direction of responses was consistent for most experiments. The number of tillers and ears per plant, respectively, was increased as a result of CO₂ enrichment by about 13% at the beginning of stem elongation (DC31), at anthesis and at maturity. Exposure to ozone had no effect on tillering. LAI was increased as a result of CO₂ elevation by about 11% at DC31 and by about 14% at anthesis. Ozone exposure reduced LAI at anthesis by about 9%. No such effect was observed at DC31. There were very few interactive effects of CO₂ and ozone on tillering and LAI. Variations in tillering and LAI, and their responses to CO₂ and ozone exposure, were partly explained by single linear relationships considering differences in plant density, tiller density and the duration of developmental phases among experiments. Consideration of temperature and incident photosynthetically active radiation in this analysis did not reduce the unexplained variation. There was a negative effect of ozone exposure on leaf area duration at most sites. Direct effects of elevated CO₂ concentration on leaf senescence, both positive and negative, were observed in some experiments. There was evidence in several experiments that elevated CO₂ concentration ameliorated the negative effect of ozone on leaf area duration. It was concluded from these results that an analysis of the interactive effects of climate, CO₂ and ozone on canopy development requires reference to the physiological processes involved. Ewert, F., M. van Oijen, and J.R. Porter. 1999. Simulation of growth and development processes of spring wheat in response to CO₂ and ozone for different sites and years in Europe using mechanistic crop simulation models. *European Journal of Agronomy* 10(3-4):231-247.

The response of crop growth and yield to CO₂ and ozone is known to depend on climatic conditions and is difficult to quantify due to the complexity of the processes involved. Two modified mechanistic crop

simulation models (AFRCWHEAT2-O3 and LINTULCC), which differ in the levels of mechanistic detail, were used to simulate the effects of CO₂ (ambient, ambient x2) and ozone (ambient, ambient x1.5) on growth and developmental processes of spring wheat in response to climatic conditions. Simulations were analysed using data from the ESPACE-wheat project in which spring wheat cv. Minaret was grown in open-top chambers at nine sites throughout Europe and for up to 3 years at each site. Both models closely predicted phenological development and the average measured biomass at maturity. However, intermediate growth variables such as biomass and leaf area index (LAI) at anthesis, seasonal accumulated photosynthetically active radiation intercepted by the crop (Sigma IPAR), the average seasonal light use efficiency (LUE) and the light saturated rate of flag leaf photosynthesis (A(sat)) were predicted differently and less accurately by the two models. The effect of CO₂ on the final biomass was underestimated by AFRCWHEAT2-O3 due to its poor simulation of the effect of CO₂ on tillering, and LALINTULCC overestimated the response of biomass production to changes in CO₂ level due to an overprediction of the effect of CO₂ on LUE. The measured effect of ozone exposure on final biomass was predicted closely by the two models. The models also simulated the observed interactive effect of CO₂ and ozone on biomass production. However, the effects of ozone on LAI, Sigma IPAR and A(sat) were simulated differently by the models and less accurately with LINTULCC for the ozone effects on LAI and Sigma IPAR. Predictions of the variation between sites and years of growth and development parameters and of their responses to CO₂ and ozone were poor for both AFRCWHEAT2-O3 and LINTULCC. It was concluded that other factors than those considered in the models such as chamber design and soil properties may have affected the growth and development of cv. Minaret. An analysis of the relationships between growth parameters calculated from the simulations supported this conclusion. In order to apply models for global change impact assessment studies, the difficulties in simulating biomass production in response to CO₂ need to be considered. We suggest that the simulation of leaf area dynamics deserves particular attention in this regard. (C) 1999 Elsevier Science B.V. All rights reserved.

Fajer, E.D., M.D. Bowers, and F.A. Bazzaz. 1991. Performance and allocation patterns of the perennial herb, *Plantago lanceolata*, in response to simulated herbivory and elevated CO₂ environments. *Oecologia* 87(1):37-42.

We tested the prediction that plants grown in elevated CO₂ environments are better able to compensate for biomass lost to herbivory than plants grown in ambient CO₂ environments. The herbaceous

perennial *Plantago lanceolata* (Plantaginaceae) was grown in either near ambient (380 ppm) or enriched (700 ppm) CO₂ atmospheres, and then after 4 weeks, plants experienced either 1) no defoliation; 2) every fourth leaf removed by cutting; or 3) every other leaf removed by cutting. Plants were harvested at week 13 (9 weeks after simulated herbivory treatments). Vegetative and reproductive weights were compared, and seeds were counted, weighed, and germinated to assess viability. Plants grown in enriched CO₂ environments had significantly greater shoot weights, leaf areas, and root weights, yet had significantly lower reproductive weights (i.e. stalks + spikes + seeds) and produced fewer seeds, than plants grown in ambient CO₂ environments. Relative biomass allocation patterns further illustrated differences in plant responses to enriched CO₂ atmospheres: enriched CO₂-grown plants only allocated 10% of their carbon resources to reproduction whereas ambient CO₂-grown plants allocated over 20%. Effects of simulated herbivory on plant performance were much less dramatic than those induced by enriched CO₂ atmospheres. Leaf area removal did not reduce shoot weights or reproductive weights of plants in either CO₂ treatment relative to control plants. However, plants from both CO₂ treatments experienced reductions in root weights with leaf area removal, indicating that plants compensated for lost above-ground tissues, and maintained comparable levels of reproductive output and seed viability, at the expense of root growth.

Fajer, E.D., M.D. Bowers, and F.A. Bazzaz. 1992. The effect of nutrients and enriched CO₂ environments on production of carbon-based allelochemicals in *Plantago* - a test of the carbon nutrient balance hypothesis. *The American Naturalist* 140(4):707-723.

In a test of the carbon/nutrient (C/N) balance hypothesis, we grew the perennial herb *Plantago lanceolata* in different CO₂ and nutrient environments and then (1) measured the total allocation to shoots, roots, and reproductive parts and (2) quantified aucubin, catalpol, and verbascoside contents of replicate plants of six genotypes. Plants grown under low- nutrient conditions do have higher concentrations of carbon-based allelochemicals than plants grown under high-nutrient conditions. However, in contrast to the C/N balance hypothesis, plants grown in elevated (700-mu-L-L-1) CO₂ conditions had similar, or lower, concentrations of carbon-based allelochemicals than plants grown in ambient (350-mu-L-L-1) CO₂ conditions. We suggest that augmented substrate concentrations (i.e., excess carbohydrates) are a necessary but insufficient trigger for increased secondary metabolism; instead, hormonal and/or direct physical cues (such as light) may be essential to synthesize or activate the appropriate enzyme systems. Moreover, although plant genotype significantly affected plant growth, reproduction, and chemistry, we never observed significant genotype-by-CO₂ interactions for these factors, which suggests that changing CO₂ environments may not improve the fitness of certain genotypes over others.

Falge, E., R.J. Ryel, M. Alsheimer, and J.D. Tenhunen. 1997. Effects of stand structure and physiology on forest gas exchange: a simulation study for Norway spruce. *Trees-Structure and Function* 11(7):436-448.

The process-based simulation model STAND-FLUX describes canopy water vapor and carbon dioxide exchange based on rates calculated for

individual trees and as affected by local gradients in photon flux density (PFD), atmospheric humidity, atmospheric carbon dioxide concentration, and air temperature. Direct, diffuse, and reflected PFD incident on foliage elements within compartments of individual trees (defined by vertical layers and a series of concentric cylinders centered on the trunk) is calculated for a 3-dimensional matrix of points. Foliage element gas exchange rates are based on estimates of carboxylation, RuBP regeneration, and respiratory capacities as well as the correlated behavior found between stomatal conductance and assimilation rate. Because of the difficulties associated with effective sampling and description of spatial variation in structure and leaf level gas exchange parameters for trees comprising the forest canopy, the significance for canopy water and carbon dioxide exchange of varied representations of tree foliage distribution and of physiology is examined. The additional interactive effects encountered due to changes in tree density and, thus, spatial aggregation or disaggregation of foliage is also studied. The analysis is conducted within the context of observed structural and physiological variation encountered in Norway spruce (*Picea abies*) stands in the Fichtelgebirge region of central Germany. Potentials for simplifying the three-dimensional canopy gas exchange model without sizable influence on canopy flux rates were small. A relatively large number of sample points within the tree crowns is necessary to obtain consistent calculations of flux rates because of the nonlinear relationship between PFD and net photosynthesis. Transpiration and net photosynthesis for stands with a low leaf area index (LAI) may be obtained from single tree estimates for each tree class weighted by class frequency, while 30 or more trees per class in differing relation to neighboring trees may be necessary to calculate reliable estimates of net photosynthesis in canopies with high LAI. The complexity in structure assumed for modeled trees was important, especially when overall canopy foliage area was either high or low due to spatial heterogeneity in clumping, e.g., potential canopy overlaps or side-lighting. Effects were greater for calculated net photosynthesis than for transpiration, reflecting higher sensitivity of net photosynthesis to differences in light distribution within individual trees. Accuracy in estimates of physiological parameters is equally important, and these characteristics have profound effects on estimated canopy gas exchange rates. While one-dimensional representations of canopy structure or approximations of tree physiological characteristics from other canopies or species may often be necessary in assessing vegetation/atmosphere exchanges, especially in the study of water balance of landscapes or regions, STANDFLUX provides a tool that can aid in evaluating the limitations of these simpler approaches.

Falloon, P.D., P. Smith, J.U. Smith, J. Szabo, K. Coleman, and S. Marshall. 1998. Regional estimates of carbon sequestration potential: linking the Rothamsted Carbon Model to GIS databases. *Biology and Fertility of Soils* 27(3):236-241.

Soil organic matter (SOM) represents a major pool of carbon within the biosphere. It is estimated at about 1400 Pg globally, which is roughly twice that in atmospheric CO₂. The soil can act as both a source and a sink for carbon and nutrients. Changes in agricultural land use and climate can lead to changes in the amount of carbon held in soils, thus, affecting the fluxes of CO₂ to and from the atmosphere. Some agricultural management practices will lead to a net sequestration of carbon in the soil. Regional estimates of the carbon sequestration potential of these practices are crucial if policy makers are to plan future land uses to reduce national CO₂ emissions. In Europe, carbon sequestration potential has previously been estimated using data from the Global Change and Terrestrial Ecosystems Soil Organic Matter

Network (GCTE SOMNET). Linear relationships between management practices and yearly changes in soil organic carbon were developed and used to estimate changes in the total carbon stock of European soils. To refine these semi-quantitative estimates, the local soil type, meteorological conditions and land use must also be taken into account. To this end, we have modified the Rothamsted Carbon Model, so that it can be used in a predictive manner with SOMNET data. The data is then adjusted for local conditions using Geographical Information Systems databases. In this paper, we describe how these developments can be used to estimate carbon sequestration at the regional level using a dynamic simulation model linked to spatially explicit data. Some calculations of the potential effects of afforestation on soil carbon stocks in Central Hungary provide a simple example of the system in use.

Fangmeier, A., L. De Temmerman, L. Mortensen, K. Kemp, J. Burke, R. Mitchell, M. van Oijen, and H.J. Weigel. 1999. Effects on nutrients and on grain quality in spring wheat crops grown under elevated CO₂ concentrations and stress conditions in the European, multiple-site experiment 'ESPACE-wheat'. *European Journal of Agronomy* 10(3-4):215-229.

Nutrient element concentrations and grain quality were assessed in spring wheat grown under elevated CO₂ concentrations and contrasting levels of tropospheric ozone at different nitrogen supply rates at several European sites. Carbon dioxide enrichment proved to affect nutrient concentrations in a complex manner. In green leaves, all elements (with exception of phosphorus and iron) decreased. In contrast, effects on the element composition of grains were restricted to reductions in nitrogen, calcium, sulphur and iron. Ozone exposure resulted in no significant effects on nutrient element concentrations in different tissues in the overall analysis. The nitrogen demand of green tissues was reduced due to CO₂ enrichment as shown by reductions in the critical leaf nitrogen concentration and also enhanced nitrogen use efficiency. Reductions in the content of ribulose-bisphosphate carboxylase/oxygenase and repression of the photorespiratory pathway and reduced nitrogen allocation to enzymes driving the photosynthetic carbon oxidation cycle were chiefly responsible for this effect. Thus, nitrogen acquisition by the crop did not match carbon acquisition under CO₂ enrichment. Since crop nitrogen uptake from the soil was already completed at anthesis, nitrogen allocated to the grain after anthesis originated from vegetative pools-causing grain nitrogen concentrations to decrease under CO₂ enrichment (on average by 15% when CO₂ concentrations increased from 360 to 680 $\mu\text{mol mol}^{-1}$). Correspondingly, grain quality was reduced by CO₂ enrichment. The Zeleny value, Hagberg value and dry/wet gluten content decreased significantly with increasing [CO₂]. Despite the beneficial impact of CO₂ enrichment on growth and yield of C-3 cereal crops, declines in flour quality due to reduced nitrogen content are likely in a future, [CO₂]-rich world. Fangmeier, A., U. Gruters, U. Hertstein, A. SandhageHofmann, B. Vermehren, and H.J. Jager. 1996. Effects of elevated CO₂, nitrogen supply and tropospheric ozone on spring wheat .1. Growth and yield. *Environmental Pollution* 91(3):381-390.

Spring wheat (*Triticum aestivum* L. cv. Minaret) was exposed to three CO₂ levels, in combination with two nitrogen fertilizer levels and two

levels of tropospheric ozone, from sowing to ripening in open-top chambers. Three additional nitrogen fertilizer treatments were carried out at the lowest and the highest CO₂ level, respectively. Plants were harvested at growth stages 31, 65 and 93 and separated into up to eight fractions to gain information about biomass partitioning. CO₂ enrichment (263 µmol litre⁻¹) above ambient levels) drastically increased biomass of organs serving as long-term carbohydrate pools. Peduncle weight increased by 92%, stem weight by 73% and flag leaf sheath weight by 59% at growth stage 65. Average increase in shoot biomass due to CO₂ enrichment amounted to 51% at growth stage 65 and 36% at final harvest. Average yield increase was 34%. Elevated nitrogen application was most effective on biomass of green tissues. Yield was increased by 30% when nitrogen application was increased from 150 to 270 kg N ha⁻¹. Significant interactions were observed between CO₂ enrichment and nitrogen application. Yield increase due to CO₂ ranged from 23% at 120 kg N to 47% at 330 kg N. *Triticum aestivum* cv. Minaret was not very responsive to ozone at 1.5 times ambient levels. 1000 grain weight was slightly decreased, which was compensated by an increased number of grains.

Fangmeier, A., U. Gruters, P. Hög, B. Vermehren, and H.J. Jäger. 1997. Effects of elevated CO₂ nitrogen supply and tropospheric ozone on spring wheat. 2. Nutrients (N, P, K, S, Ca, Mg, Fe, Mn, Zn). *Environmental Pollution* 96(1):43-59.

CO₂ enrichment is expected to alter leaf demand for nitrogen and phosphorus in plant species with C-3 carbon dioxide fixation pathway, thus possibly causing nutrient imbalances in the tissues and disturbance of distribution and redistribution patterns within the plants. To test the influence of CO₂ enrichment and elevated tropospheric ozone in combination with different nitrogen supply, spring wheat (*Triticum aestivum* L. cv. Minaret) was exposed to three levels of CO₂ (361, 523, and 639 µmol litre⁻¹), 24 h mean from sowing to final harvest), two levels of ozone (28.4 and 51.3 nl litre⁻¹) and two levels of nitrogen supply (150 and 270 kg ha⁻¹) in a full-factorial design in open-top field chambers. Additional fertilization experiments (120, 210, and 330 kg N ha⁻¹) were carried out at low and high CO₂ levels. Macronutrients (N, P, K, S, Ca, Mg) and three micronutrients (Mn, Fe, Zn) were analysed in samples obtained at three different developmental stages: beginning of shoot elongation, anthesis, and ripening. At each harvest, plant samples were separated into different organs (green and senescent leaves, stem sections, ears, grains). According to analyses of tissue concentrations at the beginning of shoot elongation, the plants were sufficiently equipped with nutrients. Elevated ozone levels neither affected tissue concentrations nor shoot uptake of the nutrients. CO₂ and nitrogen treatments affected nutrient uptake, distribution and redistribution in a complex manner. CO₂ enrichment increased nitrogen-use efficiency and caused a lower demand for nitrogen in green tissues which was reflected in a decrease of critical nitrogen concentrations, lower leaf nitrogen concentrations and lower nitrogen pools in the leaves. Since grain nitrogen uptake during grain filling depended completely on redistribution from vegetative pools in green tissues, grain nitrogen concentrations fell considerably with severe implications for grain quality. Ca, S, Mg and Zn in green tissues were influenced by CO₂ enrichment in a similar manner to nitrogen. Phosphorus concentrations in green tissues, on the other hand, were not, or only slightly, affected by elevated CO₂. In stems, 'dilution' of all nutrients except manganese was observed, caused by the huge accumulation of water soluble carbohydrates, mainly fructans, in these tissues under CO₂ enrichment. Whole shoot uptake was either remarkably increased (K, Mn, P, Mg), nearly unaffected (N, S, Fe, Zn) or decreased (Ca) under CO₂ enrichment. Thus, nutrient cycling in plant-soil systems is expected to

be altered under CO₂ enrichment. (C) 1997 Elsevier Science Ltd.

Fangmeier, A., U. Gruters, B. Vermehren, and H.J. Jäger. 1996. Responses of some cereal cultivars to CO₂ enrichment and tropospheric ozone at different levels of nitrogen supply. *Journal of Applied Botany-Angewandte Botanik* 70(1-2):12-18.

Two cultivars of spring wheat (*Triticum aestivum* L. cv. 'Nandu' and cv. 'Minaret') and one cultivar of spring barley (*Hordeum vulgare* L. cv. 'Alexis') were exposed to CO₂ enrichment (concentrations ranging from 363 to 650 µmol l⁻¹), ozone (ambient and 1.7 times ambient levels) at different levels of nitrogen nutrition in open-top field chambers from sowing to maturity. CO₂ increased grain yield and shoot biomass, barley showing the smallest response and wheat 'Nandu' being most responsive. The cultivars were rather insensitive to ozone, however, a decrease of thousand grain weight was observed in one of the wheat cultivars ('Minaret') at high ozone levels. In this cultivar, interactions between CO₂ and ozone were observed. Elevated CO₂ appeared to be protective against impairments caused by ozone. CO₂ and nitrogen supply strongly interacted. CO₂ fertilizing effects on grain yield of wheat 'Minaret' ranged from 22.9 % at 120 kg N ha⁻¹ to 47.4 % at 330 kg N ha⁻¹. Increase in grain yield by CO₂ was accompanied with a decrease of grain nitrogen content. Grain yield increase and grain nitrogen content depression exactly compensated each other and led to constant amounts of nitrogen stored in the grains on an area unit basis independent from the applied CO₂ concentration. The grain quality, assessed as nitrogen content, was severely decreased by CO₂ enrichment. The regressions obtained from the data suggest that nearly twice the nitrogen supply will be required to maintain the nitrogen content in grains at the same level if CO₂ concentrations rise from the current 363 µmol l⁻¹ (seasonal mean 1994) to 650 µmol l⁻¹.

Farage, P.K., I.F. McKee, and S.P. Long. 1998. Does a low nitrogen supply necessarily lead to acclimation of photosynthesis to elevated CO₂? *Plant Physiology* 118(2):573-580.

Long-term exposure of plants to elevated partial pressures of CO₂ (pCO₂) often depresses photosynthetic capacity. The mechanistic basis for this photosynthetic acclimation may involve accumulation of carbohydrate and may be promoted by nutrient limitation. However, our current knowledge is inadequate for making reliable predictions concerning the onset and extent of acclimation. Many studies have sought to investigate the effects of N supply but the methodologies used generally do not allow separation of the direct effects of limited N availability from those caused by a N dilution effect due to accelerated growth at elevated pCO₂. To dissociate these interactions, wheat (*Triticum aestivum* L.) was grown hydroponically and N was added in direct proportion to plant growth. Photosynthesis did not acclimate to elevated pCO₂ even when growth was restricted by a low-N relative addition rate. Ribulose-1,5-bisphosphate carboxylase/oxygenase activity and quantity were maintained, there was no evidence for triose phosphate limitation of photosynthesis, and tissue N content remained within the range recorded for healthy wheat plants. In contrast, wheat grown in sand culture with N supplied at a fixed concentration suffered

photosynthetic acclimation at elevated pCO₂ in a low-N treatment. This was accompanied by a significant reduction in the quantity of active ribulose-1, 5- biphosphate carboxylase/oxygenase and leaf N content.

Faria, T., M. Vaz, P. Schwanz, A. Polle, J.S. Pereira, and M.M. Chaves. 1999. Responses of photosynthetic and defence systems to high temperature stress in *Quercus suber* L-seedlings crown under elevated CO₂. *Plant Biology* 1(3):365-371.

Growth in elevated CO₂ led to an increase in biomass production per plant as a result of enhanced carbon uptake and lower rates of respiration, compared to ambient CO₂-grown plants. No down-regulation of photosynthesis was found after six months of growth under elevated CO₂. Photosynthetic rates at 15 degrees C or 35 degrees C were also higher in elevated than in ambient CO₂-grown plants, when measured at their respective CO₂ growth condition. Stomata of elevated CO₂-grown plants were less responsive to temperature as compared to ambient CO₂ plants. The after effect of a heat-shock treatment (4 h at 45 degrees C in a chamber with 80% of relative humidity and 800-1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photon flux density) on A(max) was less in elevated than in ambient CO₂-grown plants. At the photochemical level, the negative effect of the heat-shock treatment was slightly more pronounced in ambient than in elevated CO₂-grown plants. A greater tolerance to oxidative stress caused by high temperatures in elevated CO₂-grown plants, in comparison to ambient CO₂ plants, is suggested by the increase in superoxide dismutase activity, after 1 h at 45 degrees C, as well as its relatively high activity after 2 and 4 h of the heat shock in the elevated CO₂-grown plants in contrast with the decrease to residual levels of superoxide dismutase activity in ambient CO₂-grown plants immediately after 1 h at 45 degrees C. The observed increase in catalase after 1 h at 45 degrees C in both ambient and elevated CO₂-grown plants, can be ascribed to the higher rates of photorespiration and respiration under this high temperature.

Faria, T., D. Wilkins, R.T. Besford, M. Vaz, J.S. Pereira, and M.M. Chaves. 1996. Growth at elevated CO₂ leads to down-regulation of photosynthesis and altered response to high temperature in *Quercus suber* L seedlings. *Journal of Experimental Botany* 47(304):1755-1761.

The effects of growth at elevated CO₂ on the response to high temperatures in terms of carbon assimilation (net photosynthesis, stomatal conductance, amount and activity of Rubisco, and concentrations of total soluble sugars and starch) and of photochemistry (for example, the efficiency of excitation energy captured by open photosystem II reaction centres) were studied in cork oak (*Quercus suber* L.). Plants grown in elevated CO₂ (700 ppm) showed a down-regulation of photosynthesis and had lower amounts and activity of Rubisco than plants grown at ambient CO₂ (350 ppm), after 14 months in the greenhouse. At that time plants were subjected to a heat-shock treatment (4 h at 45 degrees C in a chamber with 80% relative humidity and 800-1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photon flux density). Growth in a CO₂-enriched atmosphere seems to protect cork oak leaves from the short-term effects of high temperature. Elevated CO₂ plants had positive net carbon uptake rates during the heat shock treatment whereas plants

grown at ambient CO₂ showed negative rates. Moreover, recovery was faster in high CO₂-grown plants which, after 30 min at 25 degrees C, exhibited higher net carbon uptake rates and lower decreases in photosynthetic capacity (A(max) as well as in the efficiency of excitation energy captured by open photosystem II reaction centres (F-v/F-m) than plants grown at ambient CO₂. The stomata of elevated CO₂ plants were also less responsive when exposed to high temperature.

Farnsworth, E.J., and F.A. Bazzaz. 1995. Inter-generic and intra-generic differences in growth, reproduction, and fitness of 9 herbaceous annual species grown in elevated CO₂ environments. *Oecologia* 104(4):454-466.

In assessing the capacity of plants to adapt to rapidly changing global climate, we must elucidate the impacts of elevated carbon dioxide on reproduction, fitness and evolution. We investigated how elevated CO₂ influenced reproduction and growth of plants exhibiting a range of floral morphologies, the implications of shifts in allocation for fitness in these species, and whether related taxa would show similar patterns of response. Three herbaceous, annual species each of the genera *Polygonum*, *Ipomoea*, and *Cassia* were grown under 350 or 700 ppm CO₂. Vegetative growth and reproductive output were measured non-destructively throughout the full life span, and vegetative biomass was quantified for a subsample of plants in a harvest at first flowering. Viability and germination studies of seed progeny were conducted to characterize fitness precisely. Early vegetative growth was often enhanced in high-CO₂ grown plants of *Polygonum* and *Cassia* (but not *Ipomoea*). However, early vegetative growth was not a strong predictor of subsequent reproduction. Phenology and production of floral buds, flowers, unripe and abscised fruits differed between CO₂ treatments, and genera differed in their reproductive and fitness responses to elevated CO₂. *Polygonum* and *Cassia* species showed accelerated, enhanced reproduction, while *Ipomoea* species generally declined in reproductive output in elevated CO₂. Seed "quality" and fitness (in terms of viability and percentage germination) were not always directly correlated with quantity produced, indicating that output alone may not reliably indicate fitness or evolutionary potential. Species within genera typically responded more consistently to CO₂ than unrelated species. Cluster analyses were performed separately on suites of vegetative and reproductive characters. Some species assorted within genera when these reproductive responses were considered, but vegetative responses did not reflect taxonomic affinity in these plants. Congeners may respond similarly in terms of reproductive output under global change, but fitness and prognoses of population persistence and evolutionary performance can be inferred only rarely from examination of vegetative characters alone.

Farnsworth, E.J., A.M. Ellison, and W.K. Gong. 1996. Elevated CO₂ alters anatomy, physiology, growth, and reproduction of red mangrove (*Rhizophora mangle* L.). *Oecologia* 108(4):599-609.

Mangroves, woody halophytes restricted to protected tropical coasts, form some of the most productive ecosystems in the world, but their capacity to act as a carbon source or sink under climate change is unknown. Their ability to adjust growth or to function as potential carbon sinks under conditions of rising atmospheric CO₂ during global

change may affect global carbon cycling, but as yet has not been investigated experimentally. Halophyte responses to CO₂ doubling may be constrained by the need to use carbon conservatively under water-limited conditions, but data are lacking to issue general predictions. We describe the growth, architecture, biomass allocation, anatomy, and photosynthetic physiology of the predominant neotropical mangrove tree, *Rhizophora mangle* L., grown solitarily in ambient (350 µmol l⁻¹) and double-ambient (700 µmol l⁻¹) CO₂ concentrations for over 1 year. Mangrove seedlings exhibited significantly increased biomass, total stem length, branching activity, and total leaf area in elevated CO₂. Enhanced total plant biomass under high CO₂ was associated with higher root:shoot ratios, relative growth rates, and net assimilation rates, but few allometric shifts were attributable to CO₂ treatment independent of plant size. Maximal photosynthetic rates were enhanced among high-CO₂ plants while stomatal conductances were lower, but the magnitude of the treatment difference declined over time, and high-CO₂ seedlings showed a lower P-max at 700 µmol l⁻¹ CO₂ than low-CO₂ plants transferred to 700 µmol l⁻¹ CO₂: possible evidence of downregulation. The relative thicknesses of leaf cell layers were not affected by treatment. Stomatal density decreased as epidermal cells enlarged in elevated CO₂. Foliar chlorophyll, nitrogen, and sodium concentrations were lower in high CO₂. Mangroves grown in high CO₂ were reproductive after only 1 year of growth (fully 2 years before they typically reproduce in the field), produced aerial roots, and showed extensive lignification of the main stem; hence, elevated CO₂ appeared to accelerate maturation as well as growth. Data from this long-term study suggest that certain mangrove growth characters will change flexibly as atmospheric CO₂ increases, and accord with responses previously shown in *Rhizophora apiculata*. Such results must be integrated with data from sea-level rise studies to yield predictions of mangrove performance under changing climate.

Farrar, J.F., and M.L. Williams. 1991. The effects of increased atmospheric carbon-dioxide and temperature on carbon partitioning, source-sink relations and respiration. *Plant, Cell and Environment* 14(8):819-830.

Herbaceous C₃ plants grown in elevated CO₂ show increases in carbon assimilation and carbohydrate accumulation (particularly starch) within source leaves. Although changes in the partitioning of biomass between root and shoot occur, the proportion of this extra assimilate made available for sink growth is not known. Root:shoot ratios tend to increase for CO₂-enriched herbaceous plants and decrease for CO₂-enriched trees. Root:shoot ratios for cereals tend to remain constant. In contrast, elevated temperatures decrease carbohydrate accumulation within source and sink regions of a plant and decrease root:shoot ratios. Allometric analysis of at least two species showing changes in root:shoot ratios due to elevated CO₂ show no alteration in the whole-plant partitioning of biomass. Little information is available for interactions between temperature and CO₂. Cold-adapted plants show little response to elevated levels of CO₂, with some species showing a decline in biomass accumulation. In general though, increasing temperature will increase sucrose synthesis, transport and utilization for CO₂-enriched plants and decrease carbohydrate accumulation within the leaf. Literature reports are discussed in relation to the hypothesis that sucrose is a major factor in the control of plant carbon partitioning. A model is presented in support.

Favis-Mortlock, D.T., and S.J.T. Guerra. 1999. The implications of general circulation model estimates of rainfall for future erosion: a case study from Brazil. *Catena* 37(3-4):329-354.

One consequence of global change will be shifts in the probability of occurrence of soil erosion by water. This could have serious consequences for those areas of the world which are present-day 'hotspots' for erosion. By means of a case study, this paper suggests an approach to quantifying the change in risk of serious erosion for sites in such areas. The case study focuses on future erosion under intensive soya bean cultivation in the Mate Grosso area of Brazil. On the area's highly erodible latosols, current erosion problems are severe. Scenarios of change future climate change are taken from general circulation models (GCMs) and used to perturb current-climate weather data. These are input to an erosion model (water erosion prediction project (WEPP)-CO₂), together with local knowledge regarding current and probable future land use, in order to estimate future changes in erosion rates. WEPP-simulated average annual sediment yield increases in one of the scenarios and decreases in the other two, reflecting the range of uncertainty in predictions of future rainfall. Using the 'best-guess' climate scenario from the UK Meteorological Office's HADCM2 GCM, the increase in mean annual sediment yield is 27%. Increases are disproportionately greater in wetter years. Average rates for individual months increase by over 100%. Erosion increases most on those parts of the hillslope profile which are currently hardest-hit by erosion. At present, an annual sediment yield of 5 t ha⁻¹ is currently exceeded in about 1 year in 2. The HADCM2 simulations suggest that an equal or greater rate will occur in about 70% of years by around 2050. A rate of at least 10 t ha⁻¹ yr⁻¹ is currently exceeded in about 1 year in 5. The HADCM2 simulations suggest that this will rise, to about 1 year in 4. (C) 1999 Elsevier Science B.V. All rights reserved.

Fearnside, P.M. 1999. Plantation forestry in Brazil: the potential impacts of climatic change. *Biomass & Bioenergy* 16(2):91-102.

Most climatic changes predicted to occur in Brazil would reduce yields of silvicultural plantations, mainly through increased frequency and severity of droughts brought on by global warming and by reduction of water vapor sources in Amazonia caused by deforestation. Some additional negative effects could result from changes in temperature, and positive effects could result from CO₂ enrichment. The net effects would be negative, forcing the country to expand plantations onto less-productive land, requiring increased plantation area land consequent economic losses) out of proportion to the climatic change itself. These impacts would affect carbon sequestration and storage consequences of any plans for subsidizing silviculture as a global warming mitigation option. Climate change can be expected to increase the area of plantations needed to supply projected internal demand for and exports of end products from Brazil. June-July-August (dry season) precipitation reductions indicated by simulations reported by the Intergovernmental Panel on Climate Change (IPCC) correspond to rainfall declines in this critical season of approximately 34% in Amazonia, 39% in Southern Brazil and 61% in the Northeast. As an example, if rainfall in Brazilian plantation areas (most of which are now in Southern Brazil) were to decline by 50%, the area needed in 2050 would expand by an estimated 38% over the constant climate case, bringing the total plantation area to 4.5 times the 1991 area. These large areas of additional plantations imply substantial social and environmental impacts. Further addition of

plantation area as a global warming response option would augment these impacts, indicating the need for caution in evaluating carbon sequestration proposals. (C) 1999 Elsevier Science Ltd. All rights reserved.

Feng, X.H., and S. Epstein. 1996. Climatic trends from isotopic records of tree rings: The past 100-200 years. *Climatic Change* 33(4):551-562.

There has been a great deal of discussion about global warming from accumulation of anthropogenic greenhouse gases in the atmosphere (Houghton et al., 1990). Relatively less attention has been paid to spatial and/or temporal climatic variations that may be associated with a warmer climate (Rind et al., 1989) or with anthropogenic activities (Schneider, 1994). In this article; we show that an increase in climatic variability may have started. Fourteen isotopic time series of tree rings are presented. These trees were randomly collected from world- wide locations and cover time periods of 120 to over 200 years. The isotopic records show increasing delta D values that suggest a consistent and progressive warming occurred in the 19th century in all locations where the trees were sampled. The rate of warming is greater at relatively cold locations than at warm locations with two exceptions. The records also suggest greater climatic variations both temporally and spatially in the 20th century than in the 19th century.

Ferguson, S.A. 1997. A climate-change scenario for the Columbia River basin. *Usda Forest Service Pacific Northwest Research Station Research Paper* (499):CP1-CP&.

This work describes the method used to generate a climate- change scenario for the Columbia River basin. The scenario considers climate patterns that may change if the atmospheric concentration of carbon dioxide (CO₂), or its greenhouse gas equivalent, were to double over pre-Industrial Revolution values. Given the current rate of increase in atmospheric CO₂ concentration, doubling could occur within the next 50 to 100 years. The Columbia River basin is in a transition climate zone between predominating maritime to the west, arctic to the north, and continental to the east. Consequently, it is difficult to characterize through means and averages. Therefore, many of the current stochastic methods for developing climate-change scenarios cannot directly apply to the basin. To circumvent this problem, a composite approach was taken to generate a climate scenario that considers knowledge of current regional climate controls, available output from general circulation and regional climate models, and observed changes in climate. The resulting climate-change scenario suggests that precipitation could increase substantially during winter (+20 to +50 percent) and moderately during spring and autumn (+5 to +35 percent). A slight decrease (0 to -5 percent) in summer precipitation is possible, except for the southeastern portions of the basin that may experience an increase in convective precipitation (+5 percent). Low- elevation (<1 kilometer) temperatures throughout the year may increase 1 to 3 degrees C, with greatest increases during winter. This amount of temperature change is possible because of an expected loss of low-elevation snow cover. At high elevations, increased cloud cover could cause average temperatures to decrease during winter but be synchronized with possible warming at low elevations during summer. The diurnal range of temperature could decrease, especially in summer and autumn.

Fernandez, M.D., A. Pieters, C. Donoso, W. Tezara, M. Azkue, C. Herrera, E. Rengifo, and A. Herrera. 1998. Effects of a natural source of very high CO₂ concentration on the leaf gas exchange, xylem water potential and stomatal characteristics of plants of *Spatiphyllum cannifolium* and *Bauhinia multinervia*. *New Phytologist* 138(4):689-697.

The effect of a very high CO₂ mole fraction (27 000-35 000 mu mol mol⁻¹) on photosynthesis and water relations was studied during the dry and the rainy season in plants of *Spatiphyllum cannifolium* (Dryand.) Schott and *Bauhinia multinervia* (H.B.K.) DC. growing near natural cold CO₂ springs. Xylem water potential in plants of both species was lowered by drought, high CO₂ growth-concentration decreasing it further in *S. cannifolium*. In plants of both species growing under high CO₂ concentration photosynthetic rates measured at a CO₂ mole fraction of 1000 mu mol mol⁻¹ were higher than in plants growing at ambient CO₂ mole fraction and measured at 350 mu mol mol⁻¹. The response was the result of a direct effect of CO₂ on the photosynthetic machinery. Changes in carboxylation efficiency in response to high CO₂ were found during the rainy season, with an increase in *S. cannifolium* and a decrease in *B. multinervia*; a significant interaction between growth CO₂ concentration and season in *B. multinervia* resulted from significant effects of both factors. An increase in intrinsic water-use efficiency due to high CO₂ was determined in both species by an increase in photosynthetic rate as well as a decrease in leaf conductance. In high-CO₂ plants of *S. cannifolium* a 71 % decrease in stomatal density and 73 % in stomatal index suggested that CO₂ affected stomatal initiation, whereas in *B. multinervia* an 85 % decrease in stomatal index and a 72 % decrease in stomatal density indicated that CO₂ influenced stomatal initiation as well as epidermal cell expansion. Our results indicate that very high CO₂ concentrations did not inhibit photosynthesis in these species, and that growth under high CO₂ allowed plants to attain carbon balances higher than those of plants growing under low CO₂. This was particularly so during the dry season, since the photosynthetic rates at the corresponding ambient concentration were higher in plants nearer the springs, and carboxylation efficiency and some stomatal characteristics of both species apparently acclimated to high CO₂, but patterns were not consistent and bore no obvious relationship to photosynthetic capacity.

FerrarioMery, S., M.C. Thibaud, T. Betsche, M.H. Valadier, and C.H. Foyer. 1997. Modulation of carbon and nitrogen metabolism, and of nitrate reductase, in untransformed and transformed *Nicotiana plumbaginifolia* during CO₂ enrichment of plants grown in pots and in hydroponic culture. *Planta* 202(4):510-521.

Transformed plants of *Nicotiana plumbaginifolia* Viv. constitutively expressing nitrate reductase (35S-NR) or beta- glucuronidase (35S-GUS) and untransformed controls were grown for two weeks in a CO₂-enriched atmosphere. Whereas CO₂ enrichment (1000 mu l l⁻¹) resulted in an increase in the carbon (C) to nitrogen (N) ratio of both the tobacco lines grown in pots with vermiculite, the C/N ratio was only slightly modified when plants were grown in hydroponic culture in high CO₂ compared to those grown in air. Constitutive nitrate reductase (NR) expression per se did not change the C/N ratio of the shoots or roots. Biomass accumulation was similar in both types of plant when hydroponic or pot-grown material, grown in air or high CO₂, were

compared. Shoot dry matter accumulation was primarily related to the presence of stored carbohydrate (starch and sucrose) in the leaves. In the pot-grown tobacco, growth at elevated CO₂ levels caused a concomitant decrease in the N content of the leaves involving losses in NO₃- and amino contrast, the N content and composition were similar in all plants grown in hydroponic culture. The 35S-NR plants grown in air had higher foliar maximum extractable NR activities and increased glutamine levels (on a chlorophyll or protein basis) than the untransformed controls. These increases were maintained following CO₂ enrichment when the plants were grown in hydroponic culture, suggesting that an increased flux through nitrogen assimilation was possible in the 35S-NR plants. Under CO₂ enrichment the NR activation state in the leaves was similar in all plants. When the 35S-NR plants were grown in pots, however, foliar NR activity and glutamine content fell in the 35S-NR transformants to levels similar to those of the untransformed controls. The differences in NR activity between untransformed and 35S-NR leaves were much less pronounced in the hydroponic than in the pot-grown material but the difference in total extractable NR activity was more marked following CO₂ enrichment. Foliar NR message levels were decreased by CO₂ enrichment in all growth conditions but this was much more pronounced in pot-grown material than in that grown hydroponically. Since beta-glucuronidase (GUS) activity and message levels in 35S-GUS plants grown under the same conditions of CO₂ enrichment (to test the effects of CO₂ enrichment on the activity of the 35S promoter) were found to be constant, we conclude that NR message turnover was specifically accelerated in the 35S-NR plants as well as in the untransformed controls as a result of CO₂ enrichment. The molecular and metabolic signals involved in increased NR message and protein turnover are not known but possible effectors include NO₃-, glutamine and asparagine. We conclude that plants grown in hydroponic culture have greater access to N than those grown in pots. Regardless of the culture method, CO₂ enrichment has a direct effect on NR mRNA stability.

Ferris, R., I. Nijs, T. Behaeghe, and I. Impens. 1996. Contrasting CO₂ and temperature effects on leaf growth of perennial ryegrass in spring and summer. *Journal of Experimental Botany* 47(301):1033-1043.

The effects of increased atmospheric carbon dioxide (CO₂) of 700 $\mu\text{mol mol}^{-1}$ and increased air temperature of +4 degrees C were examined in *Lolium perenne* L. cv. Vigor, growing in semi-controlled greenhouses. Leaf growth, segmental elongation rates (SER), water relations, cell wall (tensiometric) extensibility (%P) and epidermal cell lengths (ECL) were measured in expanding leaves in spring and summer. In elevated CO₂, shoot dry weight (SDW) increased in mid-summer. In both seasons, SDW decreased in elevated air temperatures with this reduction being greater in summer as compared to spring. Specific leaf area (SLA) decreased in elevated CO₂ and in CO₂ x temperature in both seasons. In spring, increased leaf extension and SER in elevated CO₂ were linked with increased ECL, %P and final leaf size whilst in summer all were reduced. In high temperature, leaf extension, SER, %P and final leaf size were reduced in both seasons. In elevated CO₂ x temperature, leaf extension, SER, %P, and ECL increased in spring, but final leaf size remained unaltered, whilst in summer all decreased. Mid-morning water potential did not differ with CO₂ or temperature treatments. Leaf turgor pressure increased in elevated CO₂ in spring and remained similar to the control in summer whilst solute potential decreased in spring and increased in summer. Contrasting seasonal growth responses of *L. perenne* in response to elevated CO₂ and temperature suggests pasture management may change in the future,

The grazing season may be prolonged, but whole season productivity may become more variable than today.

Ferris, R., I. Nijs, T. Behaeghe, and I. Impens. 1996. Elevated CO₂ and temperature have different effects on leaf anatomy of perennial ryegrass in spring and summer. *Annals of Botany* 78(4):489-497.

Mature second leaves of *Lolium perenne* L. cv. Vigor, were sampled in a spring and summer regrowth period. Effects of CO₂ enrichment and increased air temperature on stomatal density, stomatal index, guard cell length, epidermal cell density, epidermal cell length and mesophyll cell area were examined for different positions on the leaf and seasons of growth. Leaf stomatal density was smaller in spring but greater in summer in elevated CO₂ and higher in both seasons in elevated temperature and in elevated CO₂ x temperature relative to the respective controls. In spring, leaf stomatal index was reduced in elevated CO₂ but in summer it varied with position on the leaf. In elevated temperature, stomatal index in both seasons was lower at the tip/middle of the leaf but slightly higher at the base. In elevated CO₂ x temperature, stomatal index varied with position on the leaf and between seasons. Leaf epidermal cell density was higher in all treatments relative to controls except in elevated CO₂ (spring) and elevated CO₂ x temperature (summer), it was reduced at the leaf base. In all treatments, stomatal density and epidermal cell density declined from leaf tip to base, whilst guard cell length showed an inverse relationship, increasing towards the base. Leaf epidermal cell length and mesophyll cell area increased in elevated CO₂ in spring and decreased in summer. In elevated CO₂ x temperature leaf epidermal cell length remained unaltered in spring compared to the control but decreased in summer. Stomatal conductance was lower in all treatments except in summer in elevated CO₂ it was higher than in the ambient CO₂. These contrasting responses in anatomy to elevated CO₂ and temperature provide information that might account for differences in seasonal leaf area development observed in *L. perenne* under the same conditions. Ferris, R., and G. Taylor. 1993. Contrasting effects of elevated CO₂ on the root and shoot growth of 4 native herbs commonly found in chalk grassland. *New Phytologist* 125(4):855-866.

The aim of this study was to investigate the impact of ambient (345 $\mu\text{mol l}^{-1}$) and elevated (590 $\mu\text{mol l}^{-1}$) CO₂ on the root and shoot growth of four native chalk grassland herbs: *Sanguisorba minor* Scop. (salad burnet), *Lotus corniculatus* L. (birdsfoot trefoil), *Anthyllis vulneraria* L. (kidney vetch) and *Plantago media* L. (hoary plantain). Elevated CO₂ had contrasting effects on both shoot and root growth of the four species studied. Both leaf expansion and production were stimulated by elevated CO₂ for *S. minor*, *L. corniculatus* and *P. media*, whilst for *A. vulneraria*, only leaflet shape appeared to be altered by elevated CO₂, with the production of broader leaflets, compared with those produced in ambient CO₂. After 100 d shoot biomass was enhanced in elevated CO₂ for *S. minor* and *L. corniculatus*, whilst there was no effect of elevated CO₂ on shoot biomass for *A. vulneraria* or *P. media*. Contrasting effects of CO₂ were also apparent for measurements of specific leaf area (SLA), which

increased for *L. corniculatus*, decreased for *A. vulneraria* and remained unaltered for *S. minor* and *P. media* in elevated compared with ambient CO₂. Elevated CO₂ also had contrasting effects on both the growth and morphology of roots. The accumulation of root biomass was stimulated following exposure to elevated CO₂ for *S. minor* and *L. corniculatus* whilst there was no effect on root biomass for *A. vulneraria* or *P. media*. Root length was measured on three occasions during the 100 d and revealed that exposure to elevated CO₂ promoted root extension in *S. minor*, *L. corniculatus* and *P. media*, but not in *A. vulneraria*. Specific root length (SRL, length per unit dry weight) was increased in elevated CO₂ for one species, *P. media*, whilst the root to shoot ratio of all four species remained unchanged by CO₂. These results show that four native herbs differ in their response to CO₂, suggesting that the structure of this plant community may be altered in the future.

Ferris, R., and G. Taylor. 1994. Elevated CO₂, water relations and biophysics of leaf extension in 4 chalk grassland herbs. *New Phytologist* 127(2):297-307.

Diurnal measurements of leaf or leaflet extension, water relations and cell wall extensibility (ϕ) were made on young growing leaves of four chalk downland herbs (*Sanguisorba minor* Scop., *Lotus corniculatus* L., *Anthyllis vulneraria* L. and *Plantago media* L.) growing in controlled environment cabinets and exposed to either ambient or elevated CO₂. This study revealed differences in the effect of CO₂ and the control of leaf growth between the four species. Leaf extension rate (LER) increased significantly at night (average over 8 h) in elevated CO₂ for *S. minor*, *A. vulneraria* and *P. media* with a significant increase over the first 4 h of darkness for *S. minor*, *L. corniculatus* and *P. media*, whilst for *S. minor* and *P. media* average day-time LER (over 16 h) also increased significantly in elevated CO₂ as compared with ambient CO₂. Water potential (Psi), solute potential (Psi(s)), turgor pressure (P), yield turgor (Y) and the effective turgor for growth (Pe) were measured using psychrometers. Solute potentials of *S. minor*, *A. vulneraria* and *P. media* decreased significantly following exposure to elevated CO₂ with a significant reduction in Psi(s) during the day in *A. vulneraria*. Turgor pressure increased significantly in elevated CO₂ as compared with ambient CO₂ in *A. vulneraria* but there was no effect of elevated CO₂ on P in the other species. No effects of CO₂ on Psi, Y or Pe were observed. Leaf cell wall extensibility (ϕ) increased significantly in leaves of *S. minor*, *L. corniculatus* and *P. media* exposed to elevated CO₂, whereas in *A. vulneraria*, there was no effect of CO₂ on extensibility. These results suggest that the mechanism by which elevated CO₂ promotes leaf growth differs between species since in *S. minor*, *L. corniculatus* and *P. media*, CO₂ promoted growth through an influence on cell wall properties, whilst in *A. vulneraria*, higher values of P explain the increased leaf growth in elevated CO₂ for this species.

Ferris, R., and G. Taylor. 1994. Increased root-growth in elevated CO₂ - a biophysical analysis of root cell elongation. *Journal of Experimental Botany* 45(280):1603-1612.

A biophysical analysis of root expansion was conducted in four chalk downland herbs (*Sanguisorba minor* Scop., *Lotus corniculatus* L.,

Anthyllis vulneraria L. and *Plantago media* L.) exposed to either ambient or elevated CO₂ in controlled environment cabinets. Measurements of fine (F) and extra-fine (EF) root extension rate (RER), water relations, and cell wall tensiometric extensibility revealed differences in the diurnal pattern of root growth between species. After 35 d of exposure to elevated CO₂, RER of both F and EF roots increased significantly in darkness and on illumination for *S. minor*, whilst for *A. vulneraria* (EF roots only) and *L. corniculatus* a significant increase occurred at night whereas for *P. media* a significant increase occurred during the day. Cells measured in the zone of elongation were longer in all species exposed to elevated CO₂. Water potential (Psi), solute potential (Psi(s)), turgor pressure (P), yield turgor (Y) and effective turgor (Pe) were measured by stress-relaxation of excised root tips placed in psychrometers. Solute potentials decreased significantly for all species following exposure to elevated CO₂. In *S. minor* and *L. corniculatus*, P and Pe, respectively, were higher in elevated CO₂. No significant effects of CO₂ on Y were observed (not shown). Root cell wall tensiometric extensibility, measured as % plasticity, increased in all species exposed to elevated CO₂. These results suggest that root growth is enhanced following increased cell expansion and that increased P and cell wall tensiometric extensibility are both important for root growth in elevated CO₂.

Ferris, R., and G. Taylor. 1995. Contrasting effects of elevated CO₂ and water deficit on two native herbs. *New Phytologist* 131(4):491-501.

This study investigated the effects of carbon dioxide (CO₂) enrichment and soil water deficit on the water use efficiency (WUE) and growth of *Sanguisorba minor* Scop. (salad burnet) and *Anthyllis vulneraria* L. (kidney vetch), growing in controlled environments. Instantaneous WUE (IWUE) increased in both species in elevated CO₂, with a higher average increase in unwatered (UW) *A. vulneraria* over the drying cycle. Total plant WUE of *A. vulneraria* increased in elevated CO₂ and under water deficit: the UW plants in elevated CO₂ had higher WUE and reduced water loss. By contrast, there was only an effect of water supply on *S. minor*: total plant WUE increased and water loss decreased in the UW plants in both CO₂ treatments. Total apparent root length (ARL) of both species increased with CO₂ enrichment and in UW *S. minor* total ARL was increased. By contrast, for *A. vulneraria*, total ARL of UW plants increased in ambient CO₂, but decreased in elevated CO₂ as compared with well-watered (WW) plants. Shoot dry weight (SDW) and root dry weight increased in both species (WW and UW) with CO₂ enrichment. For UW *S. minor*, SDW decreased relative to WW plants in both CO₂ treatments. By contrast, ANOVA showed no significant effect of water supply on SDW of *A. vulneraria*. Leaflet length increased in both species in elevated CO₂ and decreased following drought. Cell wall tensiometric extensibility (%P) increased in expanding leaves of *S. minor* in elevated CO₂ and for both species %P decreased in the UW plants as compared with those WW. Leaf water potential (Psi) of both species was lower in growing leaves of WW plants in elevated CO₂. Water deficit reduced the Psi of growing leaves in both CO₂ treatments.

The different responses of these species suggest that in a drier, enriched CO₂ environment survival in a community might depend on their ability to maintain growth at the same time as conserving water.

Ferris, R., T.R. Wheeler, R.H. Ellis, and P. Hadley. 1999. Seed yield after environmental stress in soybean grown under elevated CO₂. *Crop Science* 39(3):710-718.

Episodes of high temperature and drought are predicted to occur more frequently under conditions of future climate change. This study investigated whether an episode of high air temperature (HT + 15 degrees C), water deficit (WD), or both (HTWD), for 8 d, had the same effects on the yield of soybean [Glycine max (L.) Merrill, cv. Fiskeby V] grown under either ambient (aCO₂); 360 μ mol mol⁻¹ CO₂ or elevated (eCO₂); 700 μ mol mol⁻¹ CO₂ CO₂ concentrations. Plants were grown in a glasshouse at either aCO₂ or at eCO₂ until 52 d after sowing (DAS). The 8-d stress treatments were then imposed before the plants were returned to their original environments. Across harvests, total biomass was 41% greater under eCO₂ than under aCO₂ but reduced by HT, WD, and HTWD under both CO₂ concentrations. The relative response of total biomass to HT, WD, and HTWD episodes was the same for plants grown under either aCO₂ or eCO₂. At maturity, seed dry weight and number per plant under eCO₂ were increased by an average of 32 and 22%, respectively, compared with aCO₂. The same parameters were reduced after HTWD by 29 and 30%, respectively, in aCO₂ and eCO₂. Seed filling was earlier under HT and HTWD. The rate of change in harvest index was unaltered by CO₂ while under HTWD, it decreased. Seed number explained 85% of the variation in yield, but yield was also related linearly to photosynthesis during seed filling, suggesting both are important determinants of yields under stress.

Ferris, R., T.R. Wheeler, P. Hadley, and R.H. Ellis. 1998. Recovery of photosynthesis after environmental stress in soybean grown under elevated CO₂. *Crop Science* 38(4):948-955.

Episodes of high temperature and water deficit may be more frequent under predicted future climates of warmer mean temperatures and elevated CO₂. This study investigated whether the effects of an episode of high air temperature (HT, 43 degrees C as a daily maximum), water deficit (WD), or both, had the same effect on the recovery of photosynthesis and on leaf water relations of soybean [Glycine max (L.) Merr., cv. Fiskeby V] grown at ambient CO₂ (aCO₂) or elevated CO₂ (eCO₂). An 8-d period of HT, WD, or both (HTWD) were imposed during early seed filling of soybean grown in glasshouses at either 362 or 685 μ mol mol⁻¹ CO₂. Photosynthesis (Amax), stomatal conductance (g(s)), and water relations were measured in fully expanded upper-canopy leaves. Immediately after the 8-d treatments at 60 d after sowing (DAS), Amax was reduced by 31, 48, and 64% in aCO₂ and by 28, 39, and 49% in eCO₂ under HT, WD, and HTWD, respectively, but no significant interactions were detected. At 60 DAS, g(s) was reduced by WD and HTWD in aCO₂ but not by HT while there was little change in g(s) by WD, HT, and HTWD under eCO₂. Amax fully recovered under WD in eCO₂ by 66 DAS, while Amax remained reduced under WD in aCO₂. Under each CO₂ concentration, almost

full recovery of Amax occurred under HT by 75 DAS but under HTWD Amax never attained control values. At 60 DAS, early morning leaf water potential (Psi) was lower after HT, WD, and HTWD and Amax was a negative function of Psi, at each CO₂ concentration. The results suggest that full recovery of Amax from WD was only possible under eCO₂, because at aCO₂, immediately after the stress episode, Psi was below the threshold for chloroplast damage.

Field, C.B., R.B. Jackson, and H.A. Mooney. 1995. Stomatal responses to increased co₂ - implications from the plant to the global scale. *Plant, Cell and Environment* 18(10):1214-1225.

Increased atmospheric CO₂ Often but not always leads to large decreases in leaf conductance. Decreased leaf conductance has important implications for a number of components of CO₂ responses, from the plant to the global scale. All of the factors that are sensitive to a change in soil moisture, either amount or timing, may be affected by increased CO₂. The list of potentially sensitive processes includes soil evaporation, run-off, decomposition, and physiological adjustments of plants, as well as factors such as canopy development and the composition of the plant and microbial communities. Experimental evidence concerning ecosystem-scale consequences of the effects of CO₂ on water use is only beginning to accumulate, but the initial indication is that, in water-limited areas, the effects of CO₂-induced changes in leaf conductance are comparable in importance to those of CO₂-induced changes in photosynthesis. Above the leaf scale, a number of processes interact to modulate the response of canopy or regional evapotranspiration to increased CO₂. While some components of these processes tend to amplify the sensitivity of evapotranspiration to altered leaf conductance, the most likely overall pattern is one in which the responses of canopy and regional evapotranspiration are substantially smaller than the responses of canopy conductance. The effects of increased CO₂ on canopy evapotranspiration are likely to be smallest in aerodynamically smooth canopies with high leaf conductances. Under these circumstances, which are largely restricted to agriculture, decreases in evapotranspiration may be only one-fourth as large as decreases in canopy conductance. Decreased canopy conductances over large regions may lead to altered climate, including increased temperature and decreased precipitation. The simulation experiments to date predict small effects globally, but these could be important regionally, especially

in combination with radiative (greenhouse) effects of increased CO₂.

Field, C.B., C.P. Lund, N.R. Chiariello, and B.E. Mortimer. 1997. CO₂ effects on the water budget of grassland microcosm communities. *Global Change Biology* 3(3):197-206.

Experimental grassland ecosystems, in microcosms 0.2 m in diameter and with a 0.95 m soil column, varied in their responses to elevated partial pressure of CO₂ (pCO₂) and altered moisture inputs. Ecosystems on moderately fertile sandstone soil and with a typical mix of moderately fast-growing sandstone species, responded to elevated pCO₂ with decreases in mid-season evapotranspiration of nearly 50%. This pattern reversed at the end of the growing season, and sandstone ecosystems under elevated pCO₂ continued active transpiration farther into the summer drought. The sandstone ecosystems appeared to convert mid-season water conservation into increased late-season growth. Effects of increased pCO₂ on ecosystem evapotranspiration were much smaller in ecosystems with very infertile serpentine soil and a diverse mixture of slow-growing serpentine species.

Field, C.D. 1995. Impact of expected climate-change on mangroves. *Hydrobiologia* 295(1-3):75-81.

There is a consensus of scientific opinion that the activities of man will cause a significant change in the global climate over the next hundred years. The rising level of carbon dioxide and other industrial gases in the atmosphere may lead to global warming with an accompanying rise in sea-level. Mangrove ecosystems grow in the intertidal zones in tropical and sub-tropical regions and are likely to be early indicators of the effects of climate change. The best estimates of predicted climate change in the literature are presented. It is suggested that a rise in mean sea-level may be the most important factor influencing the future distribution of mangroves but that the effect will vary dramatically depending on the local rate of sea-level rise and the availability of sediment to support reestablishment of the mangroves. The predicted rise in mean air temperature will probably be of little consequence to the development of mangroves in general but it may mean that the presence of mangroves will move further north and south, though this will depend on a number of additional factors. The effect of enhanced atmospheric CO₂ on the growth of mangroves is unknown at this time but that there is some evidence that not all species of mangroves will respond similarly. The socio-economic impacts of the effects of climate change on mangrove ecosystems may include increased risk of flooding, increased erosion of coast lines, saline intrusion and increased storm surges.

Fierro, A., N. Tremblay, and A. Gosselin. 1994. Supplemental carbon-dioxide and light improved tomato and pepper seedling growth and yield. *Hortscience* 29(3):152-154.

The experiment was conducted to determine the effects of CO₂ enrichment (900 µmol.liter⁻¹, 8 hours/day) in combination with supplementary lighting of 100 µmol.s⁻¹.m⁻² (16-h photoperiod) on tomato (*Lycopersicon esculentum* Mill.) and sweet pepper (*Capsicum annuum* L.) seedling growth in the greenhouse and subsequent yield in the field. Enrichment with CO₂ and supplementary lighting for almost-equal-to 3 weeks before transplanting increased accumulation of dry matter in shoots by almost-equal-to 50% compared with the control, while root dry weight increased 49% for tomato and 62% for pepper. Early yields increased by almost-equal-to 15% and 11% for tomato and pepper, respectively.

Figueira, A., and J. Janick. 1994. Optimizing carbon-dioxide and light levels during in-vitro culture of theobroma-cacao. *Journal of the American Society for Horticultural Science* 119(4):865-871.

In vitro culture of axillary cotyledonary shoots of *Theobroma cacao* L. (cacao) under increasing CO₂ concentration from ambient to 24,000 ppm (culture tube levels) significantly increased total shoot elongation, number of leaves, leaf area per explant, and shoot dry and fresh weight. Although light was necessary for the CO₂ response, the effect of various photon fluxes was not significant for the measured growth parameters. Net photosynthesis estimated on the basis of CO₂ depletion in culture tubes increased 3.5 times from 463 to 2639 ppm CO₂, and increased 1.5 times from 2639 to 14,849 ppm CO₂, but declined from 14,849 to 24,015 ppm CO₂. Ethylene concentration in culture vessels increased under enriched CO₂ conditions. Depletion of nutrients (fructose, K, Ca, Mg, and P) from the medium was increased under enriched CO₂ conditions.

Figueira, A., A. Whipkey, and J. Janick. 1991. Increased CO₂ and light promote invitro shoot growth and development of theobroma-cacao. *Journal of the American Society for Horticultural Science* 116(3):585-589.

Axillary shoots of cacao (*Theobroma cacao* L.), induced in vitro with cytokinins (BA or TDZ), elongated and produced leaves only in the presence of cotyledons and/or roots. Detached axillary shoots, which do not grow in vitro under conventional tissue culture protocols, rooted with auxin and developed normally in vivo. Detached axillary shoots from cotyledonary nodes and single-node cuttings from mature plants were induced to elongate and produce normal leaves in the presence of 20,000 ppm CO₂ and a photosynthetic photon flux density (PPFD) of 150 to 200 µmol.s⁻¹.m⁻². Subcultured nodal cuttings continued to elongate and produce leaves under elevated CO₂ and light levels, and some formed roots. Subculture of microcuttings under CO₂ enrichment could be the basis for a rapid system of micropropagation for cacao. Chemical names used: N- (phenylmethyl)-1H-purin-6-amine (BA); 1H-indole-3-butylric acid (IBA); alpha-naphthaleneacetic acid (NAA); thidiazuron (TDZ).

Finlayson, S.A., and D.M. Reid. 1996. The effect of CO₂ On ethylene evolution and elongation rate in roots of sunflower (*Helianthus annuus*)

seedlings. *Physiologia Plantarum* 98(4):875-881.

Both carbon dioxide and ethylene can affect the rate of root elongation. Carbon dioxide can also promote ethylene biosynthesis by enhancing the activity of 1-aminocyclopropane-1-carboxylic acid (ACC) oxidase. Since the amount of CO₂ in the soil air, and in the atmosphere surrounding roots held in enclosed containers, is known to vary widely, we investigated the effects of varying CO₂ concentrations on ethylene production by excised and intact sunflower roots (*Helianthus annuus* L. cv. Dahlgren 131). Seedlings were germinated in an aeroponic system in which the roots hung freely in a chamber and were misted with nutrient solution. This allowed for treatment, manipulation and harvest of undamaged and minimally disturbed roots. While exposure of excised roots to 0.5% CO₂ could produce a small increase in ethylene production (compared to roots in ambient CO₂), CO₂ concentrations of 2% and above always inhibited ethylene evolution. This inhibition of ethylene production by CO₂ was attributed to a reduction in the availability of ACC; however, elevated CO₂ had no effect on ACC oxidase activity. ACC levels in excised roots were depressed by CO₂ at a concentration of 2% (as compared to ambient CO₂), but n-malonyl-ACC (MACC) levels were not affected. Treating intact roots with 2% CO₂ inhibited elongation by over 50%. Maximum inhibition of elongation occurred 1 h after the CO₂ treatment began, but elongation rates returned to untreated values by 6 h. Supplying these same intact roots with 2% CO₂ did not alter ethylene evolution. Thus, in excised sunflower roots 2% CO₂ treatment reduces ethylene evolution by lowering the availability of ACC. Intact seedlings respond differently in that 2% CO₂ does not affect ethylene production in roots. These intact roots also temporarily exhibit a significantly reduced rate of elongation in response to 2% CO₂.

Firbank, L.G., A.R. Watkinson, L.R. Norton, and T.W. Ashenden. 1995. Plant-populations and global environmental-change - the effects of different temperature, carbon-dioxide and nutrient regimes on density-dependence in populations of *Vulpia ciliata*. *Functional Ecology* 9(3):432-441.

1. Monocultures of *Vulpia ciliata* spp. *ambigua* were subjected to a range of temperatures, CO₂, nutrient and density regimes in a factorial design housed within solar-domes. Temperature treatments were imposed at ambient and +3 degrees C levels, CO₂ at ambient and +340 ppm, and there were three levels of nutrients and eight levels of densities ranging from 156 to 31250 seeds m⁻². The abiotic treatments were imposed after emergence. 2. There was little mortality and this was unrelated to the treatments. Plants grew more quickly at the high temperature, high nutrient and low density regimes, and flowering was earlier at the high temperature regime. 3. At seed set, biomass per plant and seed production per plant were analysed by analysis of variance and by fitting mean yield- density models expanded to account for different environmental conditions. Biomass and fecundity were greatest at high temperature, high nutrient and low density regimes. Allocation of biomass to shoots was greater at the high temperatures, as were seed number/shoot biomass ratios. Any effects of CO₂ were negligible. The parameter *b* describing the nature of the relationship between seed production per plant and density was always less than unity but was greater at the higher temperature regime. The response to density was therefore undercompensating in all conditions, implying that populations would display monotonic damping to equilibrium densities. 4. Under proposed future environmental regimes, *V. ciliata* has the capacity for more rapid population growth from low levels and for a northwards range shift. However, if open ground is not maintained, its habitat may

become dominated by species that are more competitive or that have a higher rate of increase.

Fischer, B.U., M. Frehner, T. Hebeisen, S. Zanetti, F. Stadelmann, A. Luscher, U.A. Hartwig, G.R. Hendrey, H. Blum, and J. Nosberger. 1997. Source-sink relations in *Lolium perenne* L. as reflected by carbohydrate concentrations in leaves and pseudo-stems during regrowth in a free air carbon dioxide enrichment (FACE) experiment. *Plant, Cell and Environment* 20(7):945-952.

The effect of an elevated partial pressure of CO₂ (P-CO₂) on carbohydrate concentrations in source leaves and pseudostems (stubble) of *Lolium perenne* L., (perennial ryegrass) during regrowth was studied in a regularly defoliated grass sward in the field. The free air carbon dioxide enrichment (FACE) technology enabled natural environmental conditions to be provided. Two levels of nitrogen (N) supply were used to modulate potential plant growth. Carbohydrate concentrations in source leaves were increased at elevated P-CO₂, particularly at low N supply. Elevated leaf carbohydrate concentrations were related to an increased structural carbon (C) to N ratio and thus reflected an increased C availability together with a N- dependent sink limitation. Immediately after defoliation, apparent assimilate export rates (differences in the carbohydrate concentrations of young source leaves measured in the evening and on the following morning) showed a greater increase at elevated p(CO₂) than at ambient p(CO₂); however, replenishment of carbohydrate reserves was not accelerated. Distinct, treatment-dependent carbohydrate concentrations in pseudo-stems suggested an increasing degree of C-sink limitation from the treatment at ambient p(CO₂) with high N supply to that at elevated P-CO₂ With low N supply. During two growing seasons, no evidence of a substantial change in the response of the carbohydrate source in *L. perenne* to elevated p(CO₂) was found. Our results support the view that the response of *L. perenne* to elevated p(CO₂) is restricted by a C- sink limitation, which is particularly severe at low N supply.

Fischer, M., D. Matthies, and B. Schmid. 1997. Responses of rare calcareous grassland plants to elevated CO₂: a field experiment with *Gentianella germanica* and *Gentiana cruciata*. *Journal of Ecology* 85(5):681-691.

1 Endangered plant species may be particularly vulnerable to global change. We investigated differences in the behaviour of the rare calcareous grassland species *Gentiana cruciata* and *Gentianella germanica* under ambient (360 µl l⁻¹) and elevated CO₂ (600 µl l⁻¹) in a field experiment. 2 Rosettes of *G. germanica* and *G. cruciata* were planted into grassland plots with 29 other plant species. Each of the 30 rosettes of *G. germanica* in a plot represented a different maternal seed family, whereas *G. cruciata* was grown from a mixture of seeds from one field site. After overwintering, eight of the 12 plots were equipped with open-top chambers, four of which were run at ambient and four at elevated CO₂ concentrations; the remaining four plots were left without chambers. 3 CO₂ concentration did not significantly affect growth and survival of *G. cruciata*. Rosette diameter increased by 70% over 1 year. 4 Overall only 13.6% of transplanted *G. germanica* survived for 1 year. Elevated CO₂ reduced survival by 57% (this reduction was

only marginally significant due to large variation between plots) and seed set by 46%. Both these effects appeared to be mediated by competition from other species since survival and seed set were negatively correlated with total plot biomass at the time of fastest growth in June 1994 and at the time of fruit set in October, respectively. Compared with plots under ambient CO₂, population growth rate (based on survival and reproduction) was reduced by 56% under elevated CO₂. 5 There were no significant effects of elevated CO₂ on leaf characters in either species. 6 The sugar concentration of the nectar of *G. germanica* was increased by 36% under elevated CO₂ but its composition remained unchanged. 7 Significant interactions between the effects of seed family and CO₂ concentration on demographic parameters in *G. germanica* indicated large genetic variation in the response to elevated CO₂, which represents evolutionary potential. Although predictions based on mean responses are therefore unreliable, the majority of genotypes reacted negatively to elevated CO₂, suggesting that competitive exclusion and extinction of *G. germanica* would occur at many sites before populations could adapt to increased concentrations of CO₂.

Fiscus, E.L., and C.D. Reid. 1995. Pollutant ozone does not affect stomatal limitation to photosynthesis in soybean in ambient or elevated CO₂. *Plant Physiology* 108(2):63.

672

Fiscus, E.L., C.D. Reid, J.E. Miller, and A.S. Heagle. 1997. Elevated CO₂ reduces O₃ flux and O₃-induced yield losses in soybeans: Possible implications for elevated CO₂ studies. *Journal of Experimental Botany* 48(307):307-313.

Soybeans were grown for three seasons in open-top field chambers to determine (1) whether elevated CO₂ (360 Versus 700 $\mu\text{mol mol}^{-1}$) alleviates some of the yield loss due to pollutant O₃, (2) whether the partial stomatal closure resulting from chronic O₃ exposure (charcoal-filtered air versus 1.5 x ambient concentrations) is a cause or result of decreased photosynthesis, and (3) possible implications of CO₂/O₃ interactions to climate change studies using elevated CO₂. Leaf conductance was reduced by elevated CO₂, regardless of O₃ level, or by exposure to O₃ alone. As a result of these effects on conductance, high CO₂ reduced estimated midday O₃ flux into the leaf by an average of 50% in charcoal-filtered air and 35% in the high O₃ treatment. However, while exposure to O₃ reduced seed yields by 41% at ambient CO₂ levels, the yield reduction was completely ameliorated by elevated CO₂. The threshold midday O₃ flux for yield loss appears to be 20-30 $\text{nmol m}^{-2} \text{s}^{-1}$ in this study. Although elevated CO₂ increased total biomass production, it did not increase seed yields. A/C_i curves show a large reduction in the stomatal limitation to photosynthesis due to elevated CO₂, but no effect of O₃. These data demonstrate that (1) reduced conductance due to O₃ is the result, and not the cause, of reduced photosynthesis, (2) 700 $\mu\text{mol mol}^{-1}$ CO₂ can completely ameliorate yield losses due to O₃ within the limits of these experiments, and (3) some reports of increased yields under elevated CO₂ treatments may, at least in part, reflect the amelioration of unrecognized suppression of yield by O₃ or other stresses.

Fitter, A.H., J.D. Graves, J. Wolfenden, G.K. Self, T.K. Brown, D. Bogie, and T.A. Mansfield. 1997. Root production and turnover and carbon budgets of two contrasting grasslands under ambient and elevated atmospheric carbon dioxide concentrations. *New Phytologist* 137(2):247-255.

Monoliths of two contrasting vegetation types, a species-rich grassland on a brown earth soil over limestone and a species-poor community on a peaty gley, were transferred to solardomes and grown under ambient (350 $\mu\text{mol l}^{-1}$) and elevated (600 $\mu\text{mol l}^{-1}$) CO₂ for 2 yr. Shoot biomass was unaltered but root biomass increased by 40-50% under elevated CO₂. Root production was increased by elevated CO₂ in the peat soil, measured both as instantaneous and cumulative rates, but only the latter measure was increased in the limestone soil. Root growth was stimulated more at 6 cm depth than at 10 cm in the limestone soil. Turnover was faster under elevated CO₂ in the peat soil, but there was only a small effect on turnover in the limestone soil. Elevated CO₂ reduced nitrogen concentration in roots and might have increased mycorrhizal colonization. Respiration rate was correlated with N concentration, and was therefore lower in roots grown at elevated CO₂. Estimates of the C budget of the two communities, based upon root production and on net C uptake, suggest that C sequestration in the peat soil increases by c. 0.2 kg C $\text{m}^{-2} \text{yr}^{-1}$ (= 2 t ha yr^{-1}) under elevated CO₂.

Fitter, A.H., G.K. Self, J. Wolfenden, M.M.I. van Vuuren, T.K. Brown, L. Williamson, J.D. Graves, and D. Robinson. 1996. Root production and mortality under elevated atmospheric carbon dioxide. *Plant and Soil* 187(2):299-306.

An essential component of an understanding of carbon flux is the quantification of movement through the root carbon pool. Although estimates have been made using radiocarbon, the use of minirhizotrons provides a direct measurement of rates of root birth and death. We have measured root demographic parameters under a semi-natural grassland and for wheat. The grassland was studied along a natural altitudinal gradient in northern England, and similar turf from the site was grown in elevated CO₂ in solardomes. Root biomass was enhanced under elevated CO₂. Root birth and death rates were both increased to a similar extent in elevated CO₂, so that the throughput of carbon was greater than in ambient CO₂, but root half-lives were shorter under elevated CO₂ only under a *Juncus/Nardus* sward on a peaty gley soil, and not under a *Festuca* turf on a brown earth soil. In a separate experiment, wheat also responded to elevated CO₂ by increased root production, and there was a marked shift towards surface rooting: root development at a depth of 80-85 cm was both reduced and delayed. In conjunction with published results for trees, these data suggest that the impact of elevated CO₂ will be system-dependent, affecting the spatio-temporal pattern of root growth in some ecosystems and the rate of turnover in others. Turnover is also sensitive to temperature, soil fertility and other environmental variables, all of which are likely to change in tandem with atmospheric CO₂ concentrations. Differences in turnover and time and location of rhizodeposition may have a large effect on rates of carbon cycling.

Flagella, Z., R.G. Campanile, M.C. Stoppelli, A. De Caro, and N. Di Fonzo. 1998. Drought tolerance of photosynthetic electron transport under CO₂-enriched and normal air in cereal species. *Physiologia*

The quantum yield of photosynthetic electron transport (Phi PSII), evaluated by means of chlorophyll (Chl) fluorescence analysis, has proven to be a useful screening test for drought tolerance in durum wheat (*Triticum durum* Desf.). To explore the potential of this parameter further in detecting drought-tolerant genotypes, three cereal species were studied; Phi PSII measurements were carried out under two different gas mixtures, at three points of the induction curve (to obtain the maximal Phi PSII and both the transient and steady-state actual Phi PSII), and at three different water stress levels (moderate, severe and drastic). The species investigated were durum and bread wheat (*Triticum aestivum* L.) and barley (*Hordeum vulgare* L.); two cultivars per species, characterized by different levels of drought tolerance, were tested. The two gas mixtures used were normal air (21% O₂, 0.035% CO₂ in N₂) to monitor the whole photosynthetic process under physiological conditions, and CO₂ enriched-low O₂ air (1% O₂, 5% CO₂ in N₂) to monitor Phi PSII reduction under stress mainly related to Calvin cycle activity. When Phi PSII related to both assimilatory and non-assimilatory metabolism was evaluated, the cultivar differences observed under normal air were more representative of the agronomic performance upon drought stress than under high CO₂-low O₂ air. Maximal Phi PSII showed no difference among either cultivars, gas mixtures or stress levels, the efficiency of excitation capture being highly resistant to drought. The Phi PSII evaluated during the transient yielded predictable values in respect of drought tolerance for durum wheat and barley cultivars, highlighting the key role of regulatory processes such as the Mehler peroxidase reaction and possibly also cyclic electron transport, in preventing overreduction under stress. The results clearly show that when Chl fluorescence analysis is used as a parameter in plant breeding, different experimental conditions should be used depending on the physiological mechanism that is bred or selected for.

Flanagan, L.B., S.L. Phillips, J.R. Ehleringer, J. Lloyd, and G.D. Farquhar. 1994. Effect of changes in leaf water oxygen isotopic composition on discrimination against (coo)-o-18-o-16 during photosynthetic gas-exchange. *Australian Journal of Plant Physiology* 21(2):221-234.

Photosynthetic gas exchange measurements were combined with measurements of the carbon and oxygen stable isotopic composition of CO₂ after it passed over a leaf of *Phaseolus vulgaris* or *Senecio* spp. plants held in a controlled environment chamber. Calculations were then made of discrimination by the leaf against (CO₂)-C-13 and (COO)-O-18-O-16. Leaves were maintained at different vapour pressure gradients in order to generate a range of leaf water O-18/O-16 ratios. The O-18 content of leaf water increased when plants were exposed to higher vapour pressure deficits. The observed (COO)-O-18-O-16 discrimination values also increased with an increase in the leaf-air vapour pressure gradient and the associated change in leaf water 18/(OO)-O-16 values. In addition, the observed (COO)-O-18-O-16 discrimination values were strongly correlated with values predicted by a mechanistic model of isotopic fractionation.

1999. Analysis of the relative increase in photosynthetic O₂ uptake when photosynthesis in grapevine leaves is inhibited following low night temperatures and/or water stress. *Plant Physiology* 121(2):675-684.

We found similarities between the effects of low night temperatures (5 degrees C-10 degrees C) and slowly imposed water stress on photosynthesis in grapevine (*Vitis vinifera* L.) leaves. Exposure of plants growing outdoors to successive chilling nights caused light- and CO₂ saturated photosynthetic O₂ evolution to decline to zero within 5 d. Plants recovered after four warm nights. These photosynthetic responses were confirmed in potted plants, even when roots were heated. The inhibitory effects of chilling were greater after a period of illumination, probably because transpiration induced higher water deficit. Stomatal closure only accounted for part of the inhibition of photosynthesis. Fluorescence measurements showed no evidence of photoinhibition, but nonphotochemical quenching increased in stressed plants. The most characteristic response to both stresses was an increase in the ratio of electron transport to net O₂ evolution, even at high external CO₂ concentrations. Oxygen isotope exchange revealed that this imbalance was due to increased O₂ uptake, which probably has two components: photorespiration and the Mehler reaction. Chilling- and drought-induced water stress enhanced both O₂ uptake processes, and both processes maintained relatively high rates of electron flow as CO₂ exchange approached zero in stressed leaves. Presumably, high electron transport associated with O₂ uptake processes also maintained a high Delta pH, thus affording photoprotection.

Foley, J.A., S. Levis, I.C. Prentice, D. Pollard, and S.L. Thompson. 1998. Coupling dynamic models of climate and vegetation. *Global Change Biology* 4(5):561-579.

Numerous studies have underscored the importance of terrestrial ecosystems as an integral component of the Earth's climate system. This realization has already led to efforts to link simple equilibrium vegetation models with Atmospheric General Circulation Models through iterative coupling procedures. While these linked models have pointed to several possible climate- vegetation feedback mechanisms, they have been limited by two shortcomings: (i) they only consider the equilibrium response of vegetation to shifting climatic conditions and therefore cannot be used to explore transient interactions between climate and vegetation; and (ii) the representations of vegetation processes and land-atmosphere exchange processes are still treated by two separate models and, as a result, may contain physical or ecological inconsistencies. Here we present, as a proof concept, a more tightly integrated framework for simulating global climate and vegetation interactions. The prototype coupled model consists of the GENESIS (version 2) Atmospheric General Circulation Model and the IBIS (version 1) Dynamic Global Vegetation Model. The two models are directly coupled through a common treatment of land surface and ecophysiological processes, which is used to calculate the energy, water, carbon, and momentum fluxes between vegetation, soils, and the atmosphere. On one side of the interface, GENESIS simulates the physics and general circulation of the atmosphere. On the other side, IBIS predicts transient changes in the vegetation structure through changes in the carbon balance and competition among plants within terrestrial ecosystems. As an initial test of this modelling framework, we perform a 30 year simulation in which the coupled model is supplied with modern CO₂ concentrations, observed ocean temperatures, and modern insolation. In this exploratory study, we run the GENESIS atmospheric model at relatively coarse horizontal resolution (4.50

latitude by 7.5 degrees longitude) and IBIS at moderate resolution (2 degrees latitude by 2 degrees longitude). We initialize the models with globally uniform climatic conditions and the modern distribution of potential vegetation cover. While the simulation does not fully reach equilibrium by the end of the run, several general features of the coupled model behaviour emerge. We compare the results of the coupled model against the observed patterns of modern climate. The model correctly simulates the basic zonal distribution of temperature and precipitation, but several important regional biases remain. In particular, there is a significant warm bias in the high northern latitudes, and cooler than observed conditions over the Himalayas, central South America, and north-central Africa. In terms of precipitation, the model simulates drier than observed conditions in much of South America, equatorial Africa and Indonesia, with wetter than observed conditions in northern Africa and China. Comparing the model results against observed patterns of vegetation cover shows that the general placement of forests and grasslands is roughly captured by the model. In addition, the model simulates a roughly correct separation of evergreen and deciduous forests in the tropical, temperate and boreal zones. However, the general patterns of global vegetation cover are only approximately correct: there are still significant regional biases in the simulation. In particular, forest cover is not simulated correctly in large portions of central Canada and southern South America, and grasslands extend too far into northern Africa. These preliminary results demonstrate the feasibility of coupling climate models with fully dynamic representations of the terrestrial biosphere. Continued development of fully coupled climate-vegetation models will facilitate the exploration of a broad range of global change issues, including the potential role of vegetation feedbacks within the climate system, and the impact of climate variability and transient climate change on the terrestrial biosphere.

Fonseca, F., C.G. Bowsher, and I. Stulen. 1997. Impact of elevated atmospheric CO₂ on nitrate reductase transcription and activity in leaves and roots of *Plantago major*. *Physiologia Plantarum* 100(4):940-948.

Vegetative plants of an inbred line, A4, of *Plantago major* ssp. *pleiosperma* (L.) Pilger were grown at 350 $\mu\text{mol l}^{-1}$ or at elevated (700 $\mu\text{mol l}^{-1}$) CO₂ in non-limiting nutrient solution with nitrate. Both the relative growth rate (RGR) and the root to total plant weight ratio (RWR) were increased by elevated CO₂. However, the stimulation of both RGR and RWR was transient and did not last longer than 8 days. To investigate the physiological mechanisms involved in this stimulation, related changes in C/N metabolism were examined. In the roots soluble sugar concentration increased during the transient period of RGR stimulation (up to 23%), as did the root respiration rate. Changes in nitrogen metabolism were also restricted to this period and consisted of an increase in (1) in vivo and in vitro root nitrate reductase (EC 1.6.6.1) activity, (2) in vitro leaf nitrate reductase activity, (3) leaf and root nitrate reductase mRNA and (4) reduced nitrogen concentration in the roots. The elevated CO₂-related signal for the increase in nitrate reductase transcript levels in the roots is discussed in terms of the increased availability of soluble sugars. The results suggest that the short-term enhancement of root carbon and nitrogen metabolism may be responsible for the transient effect of elevated CO₂ on whole plant RGR.

Fonseca, F., J. DenHertog, and I. Stulen. 1996. The response of *Plantago major* ssp. *pleiosperma* to elevated CO₂ is modulated by the formation of secondary shoots. *New Phytologist* 133(4):627-635.

The effect of elevated CO₂ on the relative growth rate (RGR) of *Plantago major* ssp. *pleiosperma* was studied during the vegetative stage, in relation to plant development, by growing plants at 350 $\mu\text{mol l}^{-1}$ or at 700 $\mu\text{mol l}^{-1}$ CO₂ in non-limiting nutrient solution with nitrate. To minimize interference by the accumulation of non-structural carbohydrates in the interpretation of results, RGR was expressed on a f. wt basis (RGR(FW)), as were all plant weight ratios. Stimulation of the RGR(FW) of the whole plant by elevated CO₂ was transient, and did not last longer than 8 d. At the same time a transient increase in root weight ratio (RWR) was observed. In order to investigate whether the transient effect of elevated CO₂ on RGR(FW) was size-dependent, the data were plotted versus total f. wt (log(e) transformed). The transient period of stimulation of RGR(FW) and of RWR by elevated CO₂ was still found, but in both CO₂ treatments RGR(FW) decreased after a certain plant size had been reached. This size coincided with the stage at which secondary shoots started to develop, and was reached earlier in plants grown at elevated CO₂. The RGR of these secondary shoots (RGR(see)) was still increased when the period of whole plant stimulation of RGR(FW) had ended, indicating that the development of these new sinks took priority over a continuation of the stimulation of RWR. It is hypothesized that in this *Plantago* subspecies the response of the RGR(FW) of the whole plants to elevated CO₂ is modulated by the formation of secondary shoots. Apparently, partitioning of the extra soluble carbohydrates at elevated CO₂ to this tissue takes precedence over partitioning to the roots, resulting in a cessation of stimulation of plant RGR(FW) by elevated CO₂.

Fordham, M., J.D. Barnes, I. Bettarini, A. Polle, N. Slee, C. Raines, F. Miglietta, and A. Raschi. 1997. The impact of elevated CO₂ on growth and photosynthesis in *Agrostis canina* L. ssp. *monteluccii* adapted to contrasting atmospheric CO₂ concentrations. *Oecologia* 110(2):169-178.

The aim of this study was to characterise growth and photosynthetic capacity in plants adapted to long-term contrasting atmospheric CO₂ concentrations (C-a). Seeds of *Agrostis canina* L. ssp. *monteluccii* were collected from a natural CO₂ transect in central-western Italy and plants grown in controlled environment chambers at both ambient and elevated CO₂ (350 and 700 $\mu\text{mol mol}^{-1}$) in nutrient-rich soil. Seasonal mean C-a at the source of the plant material ranged from 610 to 451 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, derived from C-4 leaf stable carbon isotope discrimination ($\delta(13\text{C})$). Under chamber conditions, CO₂ enrichment stimulated the growth of all populations. However, plants originating from elevated C-a exhibited higher initial relative growth rates (RGRs) irrespective of chamber CO₂ concentrations and a positive relationship was found between RGR and C-a at the seed source. Seed weight was positively correlated with C-a, but differences in seed weight were found to explain no more than 34% of the variation in RGRs at elevated CO₂. Longer-term experiments (over 98 days) on two populations originating from the extremes of the transect (451 and 610 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) indicated that differences in growth between populations were maintained when plants were grown at both 350 and 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. Analysis of leaf material revealed an increase in the cell wall fraction (CWF) in plants grown at elevated CO₂, with plants originating from high C-a exhibiting constitutively lower levels but a variable response in terms of the degree of lignification. In vivo gas exchange measurements revealed

no significant differences in light and CO₂ saturated rates of photosynthesis and carboxylation efficiency between populations or with CO₂ treatment. Moreover, SDS-PAGE/LISA quantification of leaf ribulose biphosphate carboxylase/oxygenase (Rubisco) showed no difference in Rubisco content between populations or CO₂ treatments. These findings suggest that long-term adaptation to growth at elevated CO₂ may be associated with a potential for increased growth, but this does not appear to be linked with differences in the intrinsic capacity for photosynthesis.

Fournioux, J.C., and R. Bessis. 1993. Use of carbon-dioxide enrichment to obtain adult morphology of grapevine invitro. *Plant Cell Tissue and Organ Culture* 33(1):51-57.

A procedure has been developed for in vitro propagation of *Vitis vinifera* 'Pinot noir' from lateral-bud cuttings under high CO₂ concentration (1200 µmol mol⁻¹). Because of inhibition of rooting by CO₂, this procedure requires a rooting pre-culture of explants on medium with sucrose before the CO₂-enriched culture on sucrose-free medium. Shoot growth was enhanced by CO₂ enrichment as a result of both a higher rate of leaf production and greater internode elongation. Leaf expansion and tendril growth were promoted and better rooting was obtained. The more significant effect of CO₂ enrichment was to promote adult morphology with, in particular, the tendril pattern. Thus, for the first time, grapevine plants have been produced in vitro without typical juvenile characteristics. CO₂ enrichment appears to be an interesting process to improve the in vitro propagation of grapevines.

Fowler, D., J.N. Cape, M. Coyle, C. Flechard, J. Kuylensstierna, K. Hicks, D. Derwent, C. Johnson, and D. Stevenson. 1999. The global exposure of forests to air pollutants. *Water, Air, and Soil Pollution* 116(1-2):5-32.

The tall, aerodynamically rough surfaces of forests provide for the efficient exchange of heat and momentum between terrestrial surfaces and the atmosphere. The same properties of forests also provide for large potential rates of deposition of pollutant gases, aerosols and cloud droplets. For some reactive pollutant gases, including SO₂, HNO₃ and NH₃, rates of deposition may be large and substantially larger than onto shorter vegetation and is the cause of the so called "filtering effect" of forest canopies. Pollutant inputs to moorland and forest have been compared using measured ambient concentrations from an unpolluted site in southern Scotland and a more polluted site in south eastern Germany. The inputs of S and N to forest at the Scottish site exceed moorland by 16% and 31% respectively with inputs of 7.3 kg S ha⁻¹ y and 10.6 kg N ha⁻¹ y⁻¹. At the continental site inputs to the forest were 43% and 48% larger than over moorland for S and N deposition with totals of 53.6 kg S ha⁻¹ y⁻¹ and 69.5 kg N ha⁻¹ y⁻¹ respectively. The inputs of acidity to global forests show that in 1985 most of the areas receiving > 1 kg H⁺ ha⁻¹ y⁻¹ as S are in the temperate latitudes, with 8% of total global forest exceeding this threshold. By 2050, 17% of global forest will be receiving > 1 kg H⁺ ha⁻¹ as S and most of the increase is in tropical and sub-tropical countries. Forests throughout the world are also exposed to elevated concentrations of ozone. Taking 60 ppb O₃ as a concentration likely to be phytotoxic to sensitive forest species, a global model has been used to simulate the global exposure of forests to potentially phytotoxic O₃ concentrations for the years 1860, 1950, 1970, 1990 and 2100. The

model shows no exposure to concentrations in excess of 60 ppb in 1860, and of the 6% of global forest exposed to concentrations > 60 ppb in 1950, 75% were in temperate latitudes and 25% in the tropics. By 1990 24% of global forest is exposed to O₃ concentrations > 60 ppb, and this increases to almost 50% of global forest by 2100. While the uncertainty in the future pollution climate of global forest is considerable, the likely impact of O₃ and acid deposition is even more difficult to assess because of interactions between these pollutants and substantial changes in ambient CO₂ concentration, N deposition and climate over the same period, but the effects are unlikely to be beneficial overall.

Franchito, S.H., V.B. Rao, and R.R. da Silva. 1998. A parameterization of radiative fluxes suitable for use in a statistical-dynamical model. *Meteorology and Atmospheric Physics* 69(1-2):23-38.

A parameterization of shortwave and longwave radiation fluxes derived from detailed radiative transfer models is included in a global primitive equation statistical-dynamical model (SDM) with two bulk atmospheric layers. The model is validated comparing the model simulations with the observed mean annual and seasonal zonally averaged climate. The results show that the simulation of the shortwave and longwave radiation fluxes matches well with the observations. The SDM variables such as surface and 500hPa temperatures, zonal winds at 250hPa and 750 hPa, vertical velocity at 500 hPa and precipitation are also in good agreement with the observations. A comparison between the results obtained with the present SDM and those with the previous version of the model indicates that the model results improved when the parameterization of the radiative fluxes based on detailed radiative transfer models are included into the SDM. The SDM is used to investigate its response to the greenhouse effect. Sensitivity experiments regarding the doubling of CO₂ and the changing of the cloud amount and height are performed. In the case 2xCO₂ the model results are consistent with those obtained from GCMs, showing a warming of the climate system. An enhancement of the greenhouse effect is also noted when the cloud layer is higher. However, an increase of the cloud amount in all the latitude belts provokes an increase of the surface temperature near poles and a decrease in all the other regions. This suggests that the greenhouse effect overcomes the albedo effect in the polar latitudes and the opposite occurs in other regions. In all the experiments the changes in the surface temperature are larger near poles, mainly in the Southern Hemisphere.

Franck, V.M., B.A. Hungate, F.S. Chapin, and C.B. Field. 1997. Decomposition of litter produced under elevated CO₂: Dependence on plant species and nutrient supply. *Biogeochemistry* 36(3):223-237.

We investigated the effect of CO₂ concentration and soil nutrient availability during growth on the subsequent decomposition and nitrogen (N) release from litter of four annual grasses that differ in resource requirements and native habitat. *Vulpia microstachys* is a native grass found on California serpentine soils, whereas *Avena fatua*, *Bromus hordeaceus*, and *Lolium multiflorum* are introduced grasses restricted to more fertile sandstone soils (Hobbs & Mooney 1991). Growth in elevated CO₂ altered litter C:N ratio, decomposition, and N release, but the direction and magnitude of the changes differed among plant species and nutrient treatments. Elevated CO₂ had relatively

modest effects on C:N ratio of litter, increasing this ratio in *Lolium* roots (and shoots at high nutrients), but decreasing C:N ratio in *Avena* shoots. Growth of plants under elevated CO₂ decreased the decomposition rate of *Vulpia* litter, but increased decomposition of *Avena* litter from the high-nutrient treatment. The impact of elevated CO₂ on N loss from litter also differed among species, with *Vulpia* litter from high-CO₂ plants releasing N more slowly than ambient-CO₂ litter, whereas growth under elevated CO₂ caused increased N loss from *Avena* litter. CO₂ effects on N release in *Lolium* and *Bromus* depended on the nutrient regime in which plants were grown. There was no overall relationship between litter C:N ratio and decomposition rate or N release across species and treatments. Based on our study and the literature, we conclude that the effects of elevated CO₂ on decomposition and N release from litter are highly species-specific. These results do not support the hypothesis that CO₂ effects on litter quality consistently lead to decreased nutrient availability in nutrient-limited ecosystems exposed to elevated CO₂.

Frank, A.B., and A. Bauer. 1996. Temperature, nitrogen, and carbon dioxide effects on spring wheat development and spikelet numbers. *Crop Science* 36(3):659-665.

Spring wheat (*Triticum aestivum* L.) responds favorably to elevated atmospheric carbon dioxide concentration ([CO₂]) at optimum temperatures. Predictions are for air temperatures to increase as global [CO₂] increases. Since spring wheat grain yields generally decline as temperature increases, there is a need to understand the effects of both [CO₂] and temperature on spring wheat growth, development, and yield potential. Objectives were to evaluate combinations of [CO₂], air temperature, and applied N levels on leaf and apex development, spike components, tiller numbers, dry matter, plant height, and water use in spring wheat. 'Amidon' spring wheat was grown in controlled environment chambers at all combinations of 350, 650, and 950 $\mu\text{mol m}^{-2} \text{s}^{-1}$ [CO₂], 0, 100, and 300 kg N ha⁻¹, and 14/18 degrees C and 22/26 degrees C night/day air temperatures. Temperature affected the Haun stage by growth degree-days (GDD) relationship more than N or [CO₂]. The phyllochron in GDD was greater for plants grown at 22/26 degrees C (433 GDD) than at 14/18 degrees C (345 GDD). The Haun stage at apex double ridge and terminal spikelet increased as applied N and [CO₂] increased. Fertile spikelet numbers increased as [CO₂] and N level increased at 14/18 degrees C, but at 22/26 degrees C, spikelets increased as N increased and decreased as [CO₂] increased. Fertile spikelets were greatest at 14/18 degrees C and 650 $\mu\text{mol m}^{-2} \text{s}^{-1}$ [CO₂]. Results suggest that at elevated [CO₂] and adequate soil water, air temperature is more important than [CO₂] in controlling grain yield potential. Because wheat yield potential at higher temperatures decreased as [CO₂] increased, a northly shift in the spring wheat growing areas may occur if global temperatures increased in concert with [CO₂].

Fredeen, A.L., and C.B. Field. 1995. Contrasting leaf and ecosystem CO₂ and H₂O exchange in *Avena fatua* monoculture - growth at ambient and elevated CO₂. *Photosynthesis Research* 43(3):263-271.

Elevated CO₂ (ambient + 35 Pa) increased shoot dry mass production in *Avena fatua* by similar to 68% at maturity. This increase in shoot

biomass was paralleled by an 81% increase in average net CO₂ uptake (A) per unit of leaf area and a 65% increase in average A at the 'ecosystem' level per unit of ground area. Elevated CO₂ also increased 'ecosystem' A per unit of biomass. However, the products of total leaf area and light-saturated leaf A divided by the ground surface area over time appeared to lie on a single response curve for both CO₂ treatments. The approximate slope of the response suggests that the integrated light saturated capacity for leaf photosynthesis is similar to 10-fold greater than the 'ecosystem' rate. 'Ecosystem' respiration (night) per unit of ground area, which includes soil and plant respiration, ranged from -20 (at day 19) to -18 (at day 40) $\mu\text{mol m}^{-2} \text{s}^{-1}$ for both elevated and ambient CO₂ *Avena*. 'Ecosystem' below-ground respiration at the time of seedling emergence was similar to -10 $\mu\text{mol m}^{-2} \text{s}^{-1}$, while that occurring after shoot removal at the termination of the experiment ranged from -5 to -6 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Hence, no significant differences between elevated and ambient CO₂ treatments were found in any respiration measure on a ground area basis, though 'ecosystem' respiration on a shoot biomass basis was clearly reduced by elevated CO₂. Significant differences existed between leaf and 'ecosystem' water flux. In general, leaf transpiration (E) decreased over the course of the experiment, possibly in response to leaf aging, while 'ecosystem' rates of evapotranspiration (ET) remained constant, probably because falling leaf rates were offset by an increasing total leaf biomass. Transpiration was lower in plants grown at elevated CO₂, though variation was high because of variability in leaf age and ambient light conditions and differences were not significant. In contrast, 'ecosystem' evapotranspiration (ET) was significantly decreased by elevated CO₂ on 5 out of 8 measurement dates. Photosynthetic water use efficiencies (A/E at the leaf level, A/ET at the 'ecosystem' level) were increased by elevated CO₂. Increases were due to both increased A at leaf and 'ecosystem' level and decreased leaf E and 'ecosystem' ET.

Fredeen, A.L., G.W. Koch, and C.B. Field. 1995. Effects of atmospheric CO₂ enrichment on ecosystem CO₂ exchange in a nutrient and water limited grassland. *Journal of Biogeography* 22(2-3):215-219.

We have completed 3 years of a study aimed at understanding the impact of elevated atmospheric CO₂ on ecosystem properties of annual grasslands at the Jasper Ridge Biological Preserve, Stanford, CA, U.S.A. Measurements of net ecosystem CO₂ uptake were made on intact grassland (on serpentine and sandstone derived soils grown in open-top chambers since December 1991). We measured CO₂ exchange in the field with transparent Teflon-lined acrylic chambers coupled to an open gas exchange system. Net ecosystem CO₂ uptake for both the high productivity sandstone and the low productivity serpentine grassland communities ranged from 2 to 11 $\mu\text{mol m}^{-2} \text{s}^{-1}$ ground s⁻¹ in 1992 and 1993, similar to rates obtained with eddy covariance techniques on the sandstone and serpentine grasslands at Jasper Ridge in a previous study. There was a significant effect of elevated CO₂ on net ecosystem CO₂ uptake rate (40-48% increase in 1992 and 17-117% increase in 1993; ANOVA P = 0.018). Although elevated CO₂ consistently enhanced net ecosystem CO₂ uptake at the growth CO₂ concentrations, acclimation occurred such that elevated CO₂-grown ecosystems had reduced rates of CO₂ uptake relative to ambient CO₂-grown ecosystems at either ambient or elevated CO₂ measurement concentrations of CO₂. The reduction in ecosystem level photosynthetic capacity in elevated CO₂ treatments was accompanied by decreased foliar ribulose-bisphosphate carboxylase (rubisco) activity on a weight basis in the species dominant in both grassland communities. Decreases in rubisco activity resulted largely from increases in leaf mass per area in elevated CO₂ plants. In general, net ecosystem CO₂ uptake was positively correlated with peak biomass. However, the data suggest that biomass yield for a

given level of net ecosystem CO₂ uptake may be lower in elevated CO₂ chambers, especially in the higher productivity sandstone community.

Fredeen, A.L., G.W. Koch, and C.B. Field. 1998. Influence of fertilization and atmospheric CO₂ enrichment on ecosystem CO₂ and H₂O exchanges in single- and multiple-species grassland microcosms. *Environmental and Experimental Botany* 40(2):147-157.

This paper reports on measurements of net CO₂ and H₂O exchange from single- and multiple-species microcosms composed of California annual grassland species grown at either ambient or elevated (ambient + 36 Pa) CO₂. Microcosms consisted of grassland species grown in PVC tubes (similar to 0.95 m deep x 0.2 m diameter) containing similar to 45 kg of either serpentine or sandstone derived soil or parent material in open-top enclosures under ambient meteorological conditions. Half of the microcosms were left unfertilized (low nutrient) while the other half received an intermediate level of a slow-release (N,P,K) fertilizer (high nutrient). Gas exchange was performed by sealing individual microcosms within a transparent chamber (on clear sunny days) and coupling this to an open gas-exchange system. In fertilized single-species microcosms, elevated CO₂ consistently enhanced net 'ecosystem' CO₂ exchange (NCE) on a ground area basis in both early and late spring. Among unfertilized single-species microcosms, no significant trends or differences were observed in NCE between those grown at ambient versus elevated CO₂. The NCE in sandstone and serpentine multiple-species microcosms was monitored seasonally over a majority of the 1993-1994 growing season. Rates were largely unaffected by growth CO₂ or fertilization until after mid-February, 1994. Water-use efficiency (WUE = NCE/evapotranspiration (ET)) was generally enhanced by elevated CO₂, but this was primarily a result of enhancements in NCE as opposed to decreases in ET. Enhancements in NCE by elevated CO₂ in fertilized single-species microcosms at the growth-CO₂ concentration were partially explained by higher above-ground biomass in elevated CO₂ microcosms. However, ecosystem-level 'acclimation' occurred such that microcosms grown at elevated CO₂ consistently had lower NCE than ambient CO₂ treatments at a single measurement CO₂ concentration (ambient or elevated). The reduction in apparent ecosystem-level photosynthetic capacity in elevated CO₂ microcosms was accompanied by decreases in foliar Rubisco activity, such that NCE measured at ambient CO₂ was highly correlated ($r = 0.98$) with foliar Rubisco activity across the three single-species microcosms in which it was measured. Fredeen, A.L., J.T. Randerson, N.M. Holbrook, and C.B. Field. 1997. Elevated atmospheric CO₂ increases water availability in a water-limited grassland ecosystem. *Journal of the American Water Resources Association* 33(5):1033-1039.

Californian annual grassland on sandstone (moderately fertile) and serpentine (very infertile) soils at the Jasper Ridge Biological Preserve, Stanford, California, were exposed to ambient or elevated (ambient + 36 Pa CO₂) atmospheric CO₂ in open-top chambers since December 1991. We measured ecosystem evapotranspiration with open gas-exchange systems, and soil moisture with time-domain reflectometry (TDR) over 0-15 cm (serpentine) and 0-30 cm (sandstone) depths, at times of peak

above ground physiological activity. Evapotranspiration decreased by 12 to 63 percent under elevated CO₂ in three consecutive years in the sandstone ecosystem ($p = 0.053$, $p = 0.162$, $p = 0.082$ in 1992, 1993, and 1994, respectively). In correspondence with decreased evapotranspiration, late-season soil moisture reserves in the sandstone were extended temporally by 10 +/- 3 days in 1993 and by 28 +/- 11 days in 1994. The effect of elevated CO₂ on soil moisture was greater in the drier spring of 1994 (419 mm annual rainfall) than in 1993 (905 mm annual rainfall). In the serpentine ecosystem, evapotranspiration and soil moisture reserves were not clearly affected by elevated CO₂. Soil water may be conserved in drought-affected ecosystems exposed to elevated CO₂, but the amount of conservation appears to depend on the relative importance of transpiration and soil evaporation in controlling water flux.

Frederick, K.D. 1993. Climate-change impacts on water-resources and possible responses in the Mink region. *Climatic Change* 24(1-2):83-115.

The capacity to supply both instream and offstream water uses under alternative climate conditions and likely future changes in population, technology, and water-using practices are examined through an adaptation of the framework developed in the Second National Water Assessment. Two measures of the adequacy of water supplies - the availability of renewable supplies to provide for withdrawal and instream uses and the relation between desired instream flows and current streamflows - are used to examine the impact of the 1931-1940 analog climate (with and without CO₂ enrichment) on Missouri, Iowa, Nebraska, and Kansas (MINK). The impacts of the analog climate on water supplies are estimated from actual streamflow data and estimates of the differences in reservoir evaporation under the 1931-1940 analog and the 1951-1980 control climates. A modification of the Erosion Productivity Inventory Calculator (EPIC) model is used to estimate the impacts of the analog climate (with and without CO₂ enrichment) on irrigation water use. Water, which is already a scarce resource in the MINK region, would become much scarcer if the climate of the 1930s were to become the norm. Mean assessed total streamflow would drop to 69% of the control climate level for the Missouri River Basin, 71% for the Upper Mississippi, and 93% for the Arkansas. Even in the absence of climate change, MINK will have less water in the year 2030 than it does today because groundwater stocks are being depleted and increased upstream diversions would reduce surface flows into these states. Irrigation and instream uses such as navigation, hydroelectric power production, recreation, and fish and wildlife habitat would be most adversely impacted by the climate-induced changes in water supplies.

Freeman, C., R. Baxter, J.F. Farrar, S.E. Jones, S. Plum, T.W. Ashendon, and C. Stirling. 1998. Could competition between plants and microbes regulate plant nutrition and atmospheric CO₂ concentrations? *The Science of the Total Environment* 220(2-3):181-184.

It has been proposed that under high CO₂, soil microbes may outcompete plants for access to inorganic nutrients, leading to a negative feedback to the fertilising effects of that CO₂. However, tests of the hypothesis using radioisotope tracers indicate that, in the competition for inorganic nutrients, higher CO₂ concentrations may actually favour the plants rather than the microflora. The relatively lower microbial metabolism could, however, have an indirect adverse effect on plant nutrition by restricting nutrient cycling in soils, and has the potential to induce negative feedback to rising atmospheric CO₂ concentrations. Frehner, M., A. Luscher, T. Hebeisen, S. Zanetti, F. Schubiger, and M. Scalet. 1997. Effects of elevated partial pressure of carbon dioxide and season of the year on forage quality and cyanide concentration of *Trifolium repens* L. from a FACE experiment. *Acta Oecologica-International Journal of Ecology* 18(3):297-304.

Differently managed (cutting frequency and N fertilization) *Trifolium repens* monocultures were grown at 60 Pa and 35 Pa of pCO₂ (partial pressure of CO₂) in a Free Air Carbon dioxide Enrichment (FACE) array. The concentrations of cyanide, digestible organic matter, crude protein and net energy for lactation were measured at different harvests throughout the growing season. The average cyanide concentrations differed significantly in the years and the seasons within the year; however, the concentrations were not affected by CO₂. Digestible organic matter, crude protein and net energy for lactation differed significantly with the seasons of the year and cutting frequencies. While digestible organic matter and net energy for lactation were not affected by elevated pCO₂, the concentration of crude protein decreased from 288 g kg⁻¹ at ambient to 251 g kg⁻¹ at elevated pCO₂. Since the crude protein concentration in herbage from *Trifolium* monocultures was very high even at elevated CO₂, it is suggested that this decrease in crude protein concentration does not negatively affect forage quality. We conclude that, in *Trifolium* herbage, the seasons of the year and management practices are more decisive for forage quality than changes in pCO₂. We shall discuss how forage quality and cyanide intake by ruminants may, however, be affected by CO₂-induced shifts in the proportion of species in mixed plant communities.

Frick, J., S.S. Nielsen, and C.A. Mitchell. 1994. Yield and seed oil content response of dwarf, rapid-cycling brassica to nitrogen treatments, planting density, and carbon-dioxide enrichment. *Journal of the American Society for Horticultural Science* 119(6):1137-1143.

Effects of N level (15 to 30 mM), time of N increase (14 to 28 days after planting), and planting density (1163 to 2093 plants/m²) were determined for crop yield responses of dwarf, rapid-cycling brassica (*Brassica napus* L., CrGC 5-2, Genome: ACaacc). Crops were grown in solid-matrix hydroponic systems and under controlled-environment conditions, including nonsupplemented (ambient) or elevated CO₂ concentrations (998 ± 12 μmol mol⁻¹). The highest seed yield rate obtained (4.4 g.m⁻².day⁻¹) occurred with the lowest N level (15 mM) applied at the latest treatment time (day 28). In all trials, CO₂ enrichment reduced seed yield rate and harvest index by delaying the onset of flowering and senescence and stimulating vegetative shoot growth. The highest shoot biomass accumulation rate (55.5 g.m⁻².day⁻¹) occurred with the highest N level (30 mM) applied at the earliest

time (day 14). Seed oil content was not significantly affected by CO₂ enrichment. Maximum seed oil content (30% to 34%, dry weight basis) was obtained using the lowest N level (15 mM) initiated at the latest treatment time (day 28). In general, an increase in seed oil content was accompanied by a decrease in seed protein. Seed carbohydrate, moisture, and ash contents did not vary significantly in response to experimental treatments. Effects of N level and time of N increase were consistently significant for most crop responses. Planting density was significant only under elevated CO₂ conditions.

Friedlingstein, P., I. Fung, E. Holland, J. John, G. Brasseur, D. Erickson, and D. Schimel. 1995. On the contribution of CO₂ fertilization to the missing biospheric sink. *Global Biogeochemical Cycles* 9(4):541-556.

A gridded biospheric carbon model is used to investigate the impact of the atmospheric CO₂ increase on terrestrial carbon storage. The analysis shows that the calculated CO₂ fertilization sink is dependent not just on the mathematical formulation of the "beta factor" but also on the relative controls of net primary productivity (NPP), carbon residence times, and resource availability. The modeled evolution of the biosphere for the period 1850-1990 shows an increasing lag between NPP and the heterotrophic respiration. The time evolution of the modeled biospheric sink (i.e., difference between enhanced NPP and enhanced respiration) does not match that obtained by deconvolution of the ice core CO₂ time series. Agreement between the two is reasonable for the first half of the period, but during the recent decades the deconvoluted CO₂ increase is much too fast to be explained by the CO₂ fertilization effect only. Therefore other mechanisms than CO₂ fertilization should also contribute to the missing sink. Our results suggest that about two thirds to three fourths of the 1850-1990 integrated missing sink is due to the CO₂ greening of the biosphere. The remainder may be due to the increased level of nitrogen deposition starting around 1950.

Friedlingstein, P., G. Joel, C.B. Field, and I.Y. Fung. 1999. Toward an allocation scheme for global terrestrial carbon models. *Global Change Biology* 5(7):755-770.

The distribution of assimilated carbon among the plant parts has a profound effect on plant growth, and at a larger scale, on terrestrial biogeochemistry. Although important progress has been made in modelling photosynthesis, less effort has been spent on understanding the carbon allocation, especially at large spatial scales. Whereas several individual-level models of plant growth include an allocation scheme, most global terrestrial models still assume constant allocation of net primary production (NPP) among plant parts, without any environmental coupling. Here, we use the CASA biosphere model as a platform for exploring a new global allocation scheme that estimates allocation of photosynthesis products among leaves, stems, and roots depending on resource availability. The philosophy underlying the model is that-allocation patterns result from evolved responses that adjust carbon investments to facilitate capture of the most limiting resources, i.e. light, water, and mineral nitrogen. In addition, we allow allocation of NPP to vary in response to changes in atmospheric CO₂. The relative magnitudes of changes in NPP and resource-use efficiency control the response of root:shoot allocation. For ambient CO₂, the model produces realistic changes in above-ground allocation along productivity

gradients. In comparison to the CASA standard estimate using fixed allocation ratios, the new allocation scheme tends to favour root allocation, leading to a 10% lower global biomass. Elevated CO₂, which alters the balance between growth and available resources, generally leads to reduced water stress and consequently, decreased root:shoot ratio. The major exception is forest ecosystems, where increased nitrogen stress induces a larger root allocation.

Friend, A.D., and P.M. Cox. 1995. Modeling the effects of atmospheric CO₂ on vegetation atmosphere interactions. *Agricultural and Forest Meteorology* 73(3-4):285-295.

The effect of doubling atmospheric CO₂ concentration (C-a) on climate and vegetation is investigated using a combined climate-vegetation model. The vegetation model predicts the response of leaf area index, canopy transpiration (E(T)) and whole-plant carbon balance to changes in climate, soil moisture, and atmospheric CO₂ forcing. This model has been embedded in the UK Meteorological Office Single Column Model (SCM), which provides the climate feedback to the vegetation. The vegetation model uses an optimisation approach to predict stomatal resistance, a biochemical model to predict photosynthesis and a simple carbon balance model to predict leaf area. Respiration is calculated as a function of leaf area and vegetation height. Clouds are assumed to be radiatively passive in the SCM to avoid unrealistic feedbacks. Simulations were performed with the fully interactive vegetation-climate model for an Amazon location with the present-day value of C-a (1 x CO₂), and twice this value (2 x CO₂). In addition, two other types of simulation were performed at both CO₂ concentrations: one in which the vegetation component was forced only with 1 x CO₂, and one using a fixed surface resistance. The latter case is equivalent to simulations using most current general circulation models. In all the simulations, increased atmospheric CO₂ caused an increase in surface temperature owing to increased radiative forcing. With a fixed resistance, mean E(T) was increased by 5.6% and sensible heat flux was reduced by 3.8%. The fully interactive model had significant effects on the response of both climate and productivity to C-a. Increased C-a caused stomatal closure, which resulted in a reduction in mean E(T) of 25%. The effect of C-a on E(T) was amplified by the positive feedback resulting from the effect of increased air humidity deficit on stomatal resistance.

Fritschi, F.B., K.J. Boote, L.E. Sollenberger, and L.H. Allen. 1999. Carbon dioxide and temperature effects on forage establishment: tissue composition and nutritive value. *Global Change Biology* 5(7):743-753.

Atmospheric CO₂ concentration ([CO₂]) and temperature are likely to increase in the future and may change plant growth and composition characteristics. Rhizoma peanut (*Arachis glabrata* Benth.) and bahiagrass (*Paspalum notatum* Flugge) were grown on a natural field soil in temperature-gradient greenhouses to evaluate the effects of elevated [CO₂] and temperature on tissue composition and digestibility during the establishment year. Carbon dioxide levels were maintained at 365 (ambient) and 640 µmol L⁻¹ CO₂ L⁻¹ air. The temperature-gradient greenhouses were regulated to obtain air temperature sectors of 0.2, 1.5, 2.9, and 4.5 degrees C above ambient. Samples were taken of previously

undefoliated herbage at 57, 86, 121, 148, and 217 days after planting and entire plots were harvested at 218 days after planting. Elevated [CO₂] increased total nonstructural carbohydrate concentration in rhizoma peanut leaves by almost 50%. Rhizoma peanut leaf N concentration was 6% lower at elevated than at ambient [CO₂]. The N concentration in new rhizomes of rhizoma peanut was increased by high [CO₂], while the N concentration in bahiagrass was not affected by temperature or [CO₂]. No effects of [CO₂] and temperature were found on neutral detergent fibre in rhizoma peanut leaves or stems; however, elevated [CO₂] increased neutral detergent fibre in bahiagrass leaves. Only at season end was in vitro organic matter digestion of rhizoma peanut higher at ambient (623 g kg⁻¹) than at elevated [CO₂] (609 g kg⁻¹). Elevated [CO₂] had a greater effect on tissue composition of rhizoma peanut than of bahiagrass. These data suggest that elevated temperature and CO₂-induced changes in chemical composition of forage species adapted to humid subtropics will be relatively small, particularly for C4 species.

Fritschi, F.B., K.J. Boote, L.E. Sollenberger, L.H. Allen, and T.R. Sinclair. 1999. Carbon dioxide and temperature effects on forage establishment: photosynthesis and biomass production. *Global Change Biology* 5(4):441-453.

Concerns about climatic change have stimulated interest in the response of plants to increasing CO₂ concentration ([CO₂]), temperature, and their possible interactions. The purpose of this study was to determine the effects of elevated [CO₂] and air temperature on photosynthesis, development, and biomass production of rhizoma peanut (*Arachis glabrata* Benth.) and bahiagrass (*Paspalum notatum* Flugge) during the establishment year. Forages were grown in four temperature-gradient greenhouses on a natural Grossarenic Paleudult soil profile at temperatures of 0.2, 1.5, 2.9, and 4.5 degrees C above ambient, and at [CO₂] of 365 and 640 µmol L⁻¹ CO₂ L⁻¹ air. Elevated [CO₂] accelerated establishment and ground cover of both species. Leaf and canopy photosynthesis of both species increased at elevated [CO₂], with greater increases in rhizoma peanut than bahiagrass. Averaged across five sampling dates, total biomass production of rhizoma peanut and bahiagrass responded to elevated [CO₂] with a 52 and 9% increase, respectively. Increasing temperature enhanced biomass production of bahiagrass but not rhizoma peanut. Forage yield at the end of the growing season in CO₂-enriched treatments was increased over that in ambient [CO₂] treatments (385 vs. 318 g m⁻²) for rhizoma peanut and 376 vs. 321 g m⁻² for bahiagrass). Overall, the enhancement of rhizoma peanut under elevated [CO₂] was greater than that of bahiagrass; however, bahiagrass responded more positively to increasing temperature.

Fujii, N., M. Watanabe, Y. Watanabe, and N. Shimada. 1994. Relationship between oxalate synthesis and glycolate cycle in spinach. *Journal of the Japanese Society for Horticultural Science* 62(4):789-794.

The relationship between oxalate synthesis and glycolate pathway in spinach (*Spinacia oleracea* L. cv. Sunlight) was studied by exposing

seedling to 1,000 PPM CO₂-enriched atmosphere. It was observed that CO₂-enrichment increased the content of ascorbic acid but decreased that of oxalate. It was presumed that reducing the rate of glycolate synthesis would reduce the content of oxalate. Mature leaves of spinach grown under normal conditions, were fed with [2-C-14] glycolate and [1-C-14] ascorbic acid to compare their contribution as a precursor of oxalate. Using the values of the C-14 distribution to oxalate, photorespiratory glycolate metabolic rate and the turnover rate of ascorbic acid, the rate of oxalate synthesis was calculated. It was observed that glycolate was more efficient as a precursor of oxalate synthesis than it was for ascorbic acid. From these results, we postulate that the oxalate synthesis is closely related to the glycolate cycle.

Gahrooe, F.R. 1998. Impacts of elevated atmospheric CO₂ on litter quality, litter decomposability and nitrogen turnover rate of two oak species in a Mediterranean forest ecosystem. *Global Change Biology* 4(6):667-677.

Elevated CO₂ may affect litter quality of plants, and subsequently C and N cycling in terrestrial ecosystems, but changes in litter quality associated with elevated CO₂ are poorly known. Abscised leaf litter of two oak species (*Quercus cerris* L. and *a. pubescens* Willd.) exposed to long-term elevated CO₂ around a natural CO₂ spring in Tuscany (Italy) was used to study the impact of increasing concentration of atmospheric CO₂ on litter quality and C and N turnover rates in a Mediterranean-type ecosystem. Litter samples were collected in an area with elevated CO₂ (>500 ppm) and in an area with ambient CO₂ concentration (360 ppm). Leaf samples were analysed for concentrations of total C, N, lignin, cellulose, acid detergent residue (ADR) and polyphenol. The decomposition rate of litter was studied using a litter bag experiment (12 months) and laboratory incubations (3 months). In the laboratory incubations, N mineralization in litter samples was measured as well (125 days). Litter quality was expressed in terms of chemical composition and element ratios. None of the litter quality parameters was affected by elevated CO₂ for the two *Quercus* species. Remaining mass in *a. cerris* and *Q. pubescens* litter from elevated CO₂ was similar to that from ambient conditions. C mineralization in *Q. pubescens* litter from elevated CO₂ was lower than that from ambient CO₂, but the difference was insignificant. This effect was not observed for *Q. cerris*. N mineralization was higher from litter grown at elevated CO₂, but this difference disappeared at the end of the incubation. Litter of *a. pubescens* had a higher quality than *Q. cerris*, and indeed mineralized more rapidly in the laboratory, but not under field conditions.

Gallardo, A., and J. Merino. 1998. Soil nitrogen dynamics in response to carbon increase in a Mediterranean shrubland of SW Spain. *Soil Biology and Biochemistry* 30(10-11):1349-1358.

Most models predict that high atmospheric CO₂ concentrations will lead to an increase in the C-to-N ratio of litter production in terrestrial ecosystems. The effect of an increase in the soil C-to-N ratio on the nitrogen dynamics in a Mediterranean shrubland was simulated by mixing with the litter layer wood shavings with a high C-to-N ratio. Samples of mineral soil, taken subsequently eight times during 404 d, were analyzed for total C, total N, total soil carbohydrates, potential net N mineralization, potential net nitrification and microbial biomass-N. We found significant increases in the concentration of total carbohydrates, C-to-N ratio and microbial biomass N in amended soils

during the experiment, while potential net N mineralization rate and net nitrification rate significantly decreased; amounts of available nitrogen (NH₄⁺-N + NO₃-N) were unaffected by the amendment treatment. However, by the end of the experiment, no significant differences between amended and control soil samples were found. The total carbohydrates-to-K₂SO₄-extractable total-N ratio was the best predictor of both net mineralization rate and microbial biomass N, showing that the available C-to- available-N ratio is a better indicator of N dynamics than the total C to total N ratio. Our results support the hypothesis that increasing C availability in soils leads to a decrease in N availability for plants through the immobilization of N in microbial biomass and to an increase in the temporal heterogeneity of soil properties in a Mediterranean shrubland. Galtier, N., C.H. Foyer, E. Murchie, R. Alred, P. Quick, T.A. Voelker, C. Thepenier, G. Lasceve, and T. Betsche. 1995. Effects of light and atmospheric carbon-dioxide enrichment on photosynthesis and carbon partitioning in the leaves of tomato (*lycopersicon-esculentum* L) plants over-expressing sucrose- phosphate synthase. *Journal of Experimental Botany* 46:1335-1344.

Photosynthetic carbon assimilation, carbon partitioning and foliar carbon budgets were measured in the leaves of transformed tomato plants expressing a maize sucrose-phosphate synthase (SPS) gene in addition to the native enzyme, and in untransformed controls. The maize SPS gene was expressed under control of either the promoter of the small subunit of ribulose 1,5-bisphosphate carboxylase (rbcS promoter; lines 2, 9 and 18) or the 35S promoter from cauliflower mosaic virus (CaMV promoter; line 13). The rate of sucrose synthesis was increased relative to that of starch and sucrose/starch ratios were higher throughout the photoperiod in the leaves of all plants expressing high SPS activity. The leaf carbon budget over the day/night cycle in air at low irradiance (180 μ mol photon m⁻² s⁻¹) was similar in all plants. Net photosynthesis measured in air and at elevated CO₂ (800-1500 μ mol l⁻¹) on whole plants grown in air at 400 μ mol m⁻² s⁻¹ irradiance was significantly increased in the high SPS expressors compared to the untransformed controls and was highest where SPS activity was greatest. At high CO₂ the stimulation of photosynthesis was more pronounced. We conclude that SPS activity is a major point of control of photosynthesis particularly under saturating light and CO₂.

Gao, K., Y. Aruga, K. Asada, T. Ishihara, T. Akano, and M. Kiyohara. 1991. Enhanced growth of the red alga porphyra-yezoensis ueda in high co₂ concentrations. *Journal of Applied Phycology* 3(4):355-362.

Leafy thalli of the red alga *Porphyra yezoensis* Ueda, initiated from conchospores released from free-living conchocelis, were cultured using aeration with high CO₂. It was found that the higher the CO₂ concentration, the faster the growth of the thalli. Aeration with elevated CO₂ lowered pH in dark, but raised pH remarkably in light with the thalli, because the photosynthetic conversion of HCO₃⁻ to OH⁻ and CO₂ proceeded much faster than the dissociation of hydrated CO₂ releasing

H⁺. Photosynthesis of the alga was found to be enhanced in the seawater of elevated dissolved inorganic carbon (DIC, CO₂ + HCO₃⁻ + CO₃⁻). It is concluded that the increased pH in the light resulted in the increase of DIC in the culture media, thus enhancing photosynthesis and growth. The relevance of the results to removal of atmospheric CO₂ by marine algae is discussed.

Gao, K., Y. Aruga, K. Asada, T. Ishihara, T. Akano, and M. Kiyohara. 1993. Calcification in the articulated coralline alga corallinapilulifera, with special reference to the effect of elevated CO₂ concentration. *Marine Biology* 117(1):129-132.

Calcification in *Corallina pilulifera* Postels et Ruprecht displayed diurnal variations in aerated (350 ppm CO₂) culture media, with faster rates during the light than during the dark period. Addition of CO₂ (air + 1250 ppm) inhibited calcification. This was attributable to the decreased pH resulting from CO₂ addition. Both photosynthesis and calcification were enhanced in seawater, with elevated dissolved inorganic carbon concentrations at a constant pH of 8.2.

Gao, K., Y. Aruga, K. Asada, and M. Kiyohara. 1993. Influence of enhanced CO₂ on growth and photosynthesis of the red algae *Gracilaria* sp and *G. chilensis*. *Journal of Applied Phycology* 5(6):563-571.

The influence of elevated CO₂ concentrations on growth and photosynthesis of *Gracilaria* sp. and *G. chilensis* was investigated in order to procure information on the effective utilization of CO₂. Growth of both was enhanced by CO₂ enrichment (air + 650 ppm CO₂, air + 1250 ppm CO₂), the enhancement being greater in *Gracilaria* sp. Both species increased uptake of NO₃⁻ with CO₂ enrichment. Photosynthetic inorganic carbon uptake was depressed in *G. chilensis* by pre-culture (15 days) with CO₂ enrichment, but little affected in *Gracilaria* sp. Mass spectrometric analysis showed that O₂ uptake was higher in the light than in the dark for both species and in both cases was higher in *Gracilaria* sp. The higher growth enhancement in *Gracilaria* sp. was attributed to greater depression of photorespiration by the enrichment of CO₂ in culture.

Gao, Q., and M. Yu. 1998. A model of regional vegetation dynamics and its application to the study of Northeast China Transect (NECT) responses to global change. *Global Biogeochemical Cycles* 12(2):329-344.

We developed a dynamic regional vegetation model to address problems of responses of regional vegetation to elevated ambient CO₂ and climatic change. The model takes into consideration both local ecosystem processes within a patch or grid cell, such as plant growth and death, and mass and energy flow, such as plant migration, across adjacent grid cells. The model is able to couple vegetation structure dynamics and primary production processes. The normalized differential vegetation index from meteorological satellite AVHRR was used to parameterize the model. Plant migration rates were derived based on

effective seedling distribution around parent plants. The model was applied to Northeast China Transect at a spatial resolution of 10 min latitude by 10 min longitude per grid cell and a temporal resolution of 1 month. The results indicated that with doubled CO₂ concentration, a 20% increase in precipitation and a 4 degrees C increase in temperature, the model predicted that net primary productivity (NPP) of *Larix* forests, conifer-broadleaf mixed forests, *Aneurolepidium chinense* steppes, *Stipa grandis* steppes, and wetland and salty meadows would decrease by 15% to 20%. However, NPP of deciduous broadleaf forests, woodland and shrubs, *Stipa baicalensis* meadow steppes, and desert grasslands would increase by 20% to 115%, as predicted by the model for the same climatic scenario. The average NPP of natural vegetation over the whole transect would decrease slightly, largely because of the compensation between the positive effects of increased CO₂ and precipitation and the negative effect of increased evapotranspiration induced by increased temperature.

Gao, Q., and X.S. Zhang. 1997. A simulation study of responses of the northeast China transect to elevated CO₂ and climate change. *Ecological Applications* 7(2):470-483.

The spatiotemporal variations of vegetation biomass of the ecological transect in northeast China were simulated. State variables of the model included green biomass and nongreen biomass of 12 vegetation categories and water contents of three soil layers. The simulated monthly green biomass was converted into NDVI, or Normalized Differential Vegetation Index of AVHRR (Advanced Very High Resolution Radiometry). A comparison between the modeled and the observed NDVI was made at 10' spatial resolution. Atmospheric CO₂ concentration and monthly precipitation were used as two driving variables for global change simulation. Effects of precipitation increments on percentage sunshine, relative humidity, radiation, evapotranspiration, and eventually soil water and plant growth, were considered. Two levels of CO₂ concentration (present, doubled) and seven levels of precipitation increments (0, 0.05, 0.1, 0.15, 0.2, 0.25, and 0.30) were prescribed for a total of 14 simulation runs. A steady-state solution was obtained for each simulation run. The results of simulation showed that with the present climate conditions, doubling atmospheric CO₂ concentration led approximately to a 20.3% increase in green biomass, 11.0% increase in nongreen biomass, 19.0% increase in green NPP, 12.8% increase in nongreen NPP, and 24.9% increase in overall average NPP at steady state. These increases go, respectively, to 32.9, 13.9, 30.0, 20.1, and 23.4% when a 30% precipitation increase was superimposed on the doubled CO₂ concentration.

Garcia, J.M. 1993. Effect of CO₂ in fruit storage atmosphere on olive oil quality. *Grasas Y Aceites* 44(3):169-174.

Olive fruits (*Olea europaea*, cv. "Picual") were stored at 5-degrees-C and

four different atmospheres (% CO₂/% O₂/%N₂: 0/21/78; 5/20/75; 10/19/71 and 20/17/63). At 5-degrees-C the enrichment of the fruit storage atmosphere with concentrations of CO₂ above 5% resulted in a linear increase of the acidity of extracted oils after 60 days of fruit storage time. This fact showed a strong relationship with the appearance of fruit decay. Simple refrigeration of fruits at 5-degrees-C for 60 days was sufficient to maintain the commercial quality of "virgin extra" in oil extracted from them. Oils obtained from fruits stored at 5-degrees-C in CO₂ enriched atmospheres showed lower peroxide index and UV absorbance (270 nm), but developed off-flavor. Therefore, greater-than-or-equal-to 5% CO₂ concentrations in storage atmosphere of olive fruits for oil production at 5-degrees-C must be avoided.

Garcia, J.M., and J. Streif. 1993. Quality and storage potential of pear .1. Influence of ca- storage and ulo-storage conditions. *Gartenbauwissenschaft* 58(1):36-41.

In a CA experiment the storage potential of different pear cultivars was investigated, especially the behaviour of the fruits against elevated CO₂ concentrations and/or ultra low oxygen (ULO). The following CA combinations were tested: < 1 % CO₂ + 3 % O₂; 3 % CO₂ + 3 % O₂; < 1 % CO₂ + 1 % O₂; 3 % CO₂ + 1 % O₂, and refrigerated storage at -1-degrees-C 'Packham's Triumph' showed the best storage potential of all tested cultivars followed by 'Conference' and 'Doyenne' du Comice. The keepability of 'General Leclerc' was only slightly improved by CA conditions compared with cold stored pears. CA storage of 'Alexander Lucas' and 'Bristol Cross' didn't show an obvious advantage because of high CO₂ damages. Therefore, CO₂ concentrations in CA storage of these two cultivars should be < 1 %. 'Conference' and 'General Leclerc' tolerate up to 2 % CO₂, 'Doyenne du Comice' and 'Packham's Triumph' up to 3 % CO₂. ULO conditions amplified the CO₂ damages in the CO₂ sensitive cultivars, but improved the keepability of 'Doyenne du Comice' and 'Packham's Triumph'.

Garcia, R.L., S.B. Idso, and B.A. Kimball. 1994. Net photosynthesis as a function of carbon-dioxide concentration in pine trees grown at ambient and elevated co₂. *Environmental and Experimental Botany* 34(3):337-341.

Pinus eldarica seedlings were grown in a field of Avondale loam at Phoenix, Arizona within transparent open-top enclosures maintained for 15 months at mean CO₂ concentrations of 402 and 788 $\mu\text{mol l}^{-1}$, after which whole-tree net photosynthetic rates were measured at a number of CO₂ concentrations ranging from ambient (360 $\mu\text{mol l}^{-1}$) to 3000 $\mu\text{mol l}^{-1}$. Rates of the low- CO₂-treatment trees saturated at approximately five times their ambient-concentration value; while rates of the high-CO₂- treatment trees rose linearly across the entire CO₂ range investigated to more than 10 times their value at 360 $\mu\text{mol l}^{-1}$. These findings suggest that long-term exposure to elevated CO₂ can increase the ability of trees with unrestricted root systems to respond positively to still higher CO₂ concentrations.

Garcia, R.L., S.B. Idso, G.W. Wall, and B.A. Kimball. 1994. Changes in net photosynthesis and growth of *pinus-eldarica* seedlings in response to atmospheric co₂ enrichment. *Plant, Cell and Environment* 17(8):971-978.

Pinus eldarica L. trees, rooted in the natural soil of an agricultural field at Phoenix, Arizona, were grown from the seedling stage in clear-plastic-wall open-top enclosures maintained at four different atmospheric CO₂ concentrations for 15 months. Light response functions were determined for one tree from each treatment by means of whole-tree net CO₂ exchange measurements at the end of this period, after which rates of carbon assimilation of an ambient-treatment tree were measured across a range of atmospheric CO₂ concentrations. The first of these data sets incorporates the consequences of both the CO₂-induced enhancement of net photosynthesis per unit needle area and the CO₂-induced enhancement of needle area itself (due primarily to the production of more needles), whereas the second data set reflects only the first of these effects. Hence the division of the normalized results of the first data set by the normalized results of the second set yields a representation of the increase in whole-tree net photosynthesis due to enhanced needle production caused by atmospheric CO₂ enrichment. In the solitary trees we studied, the relative contribution of this effect increased rapidly with the CO₂ concentration of the air to increase whole-tree net photosynthesis by nearly 50% at a CO₂ concentration approximately 300 $\mu\text{mol mol}^{-1}$ above ambient.

Garcia, R.L., S.P. Long, G.W. Wall, C.P. Osborne, B.A. Kimball, G.Y. Nie, P.J. Pinter, R.L. Lamorte, and F. Wechsung. 1998. Photosynthesis and conductance of spring-wheat leaves: field response to continuous free-air atmospheric CO₂ enrichment. *Plant, Cell and Environment* 21(7):659-669.

Spring wheat was grown from emergence to grain maturity in two partial pressures of CO₂ (pCO₂): ambient air of nominally 37 Pa and air enriched with CO₂ to 55 Pa using a free-air CO₂ enrichment (FACE) apparatus. This experiment was the first of its kind to be conducted within a cereal field without the modifications or disturbance of microclimate and rooting environment that accompanied previous studies. It provided a unique opportunity to examine the hypothesis that continuous exposure of wheat to elevated pCO₂ will lead to acclimatory loss of photosynthetic capacity. The diurnal courses of photosynthesis and conductance for upper canopy leaves were followed throughout the development of the crop and compared to model-predicted rates of photosynthesis. The seasonal average of midday photosynthesis rates was 28% greater in plants exposed to elevated pCO₂ than in controls and the seasonal average of the daily integrals of photosynthesis was 21% greater in elevated pCO₂ than in ambient air. The mean conductance at midday was reduced by 36%. The observed enhancement of photosynthesis in elevated pCO₂ agreed closely with that predicted from a mechanistic biochemical model that assumed no acclimation of photosynthetic capacity. Measured values fell below predicted only in the flag leaves in the mid afternoon before the onset of grain-filling and over the whole diurnal course at the end of grain-filling. The loss of enhancement at this final stage was attributed to the earlier senescence of flag leaves in elevated pCO₂. In contrast to some controlled-environment and field-enclosure studies, this field-scale study of wheat using free-air CO₂ enrichment found little evidence of acclimatory loss of photosynthetic capacity with growth in elevated pCO₂ and a significant and substantial increase in leaf photosynthesis throughout the life of the crop.

Gardner, S.D.L., G. Taylor, and C. Bosac. 1995. Leaf growth of hybrid poplar following exposure to elevated CO₂. *New Phytologist* 131(1):81-90.

Leaf extension was stimulated following exposure of three interamerican hybrid poplar clones (*Populus trichocarpa* x *P. deltoides*); 'Unal', 'Boelare', and 'Beaupre' and a euramerican clone 'Primo' (*Populus nigra* x *P. deltoides*) to elevated CO₂ in controlled environment chambers. For all three interamerican clones the evidence suggests that this was the result of increased leaf cell expansion associated with enhanced cell wall extensibility (WEx), measured as tensiometric increases in cell wall plasticity. For the interamerican clone 'Boelare', there was also a significant increase in cell wall elasticity following exposure to elevated CO₂ (P less than or equal to 0.001). The effect of elevated CO₂ in stimulating cell wall extensibility was confirmed in a detailed spatial analysis of extensibility made across the lamina of expanding leaves of the clone 'Boelare'. For two of the interamerican hybrids, 'Unal' and 'Beaupre', both leaf cell water potential (ψ) and turgor pressure (P) were lower in elevated than in ambient CO₂. By contrast, no significant effects on the cell wall properties or leaf water relations for the euramerican hybrid 'Primo' were observed following exposure to elevated CO₂, suggesting that the mechanism for increased leaf extension in elevated CO₂ differed, depending on clone. The cumulative total length of leaves of 'Boelare' grown in elevated CO₂ was significantly increased (P less than or equal to 0.05) and since leaf number was not significantly increased in any inter-american clone it is hypothesized that final leaf size was stimulated in elevated CO₂ for these clones. By contrast, there was no significant effect of CO₂ on cumulative total leaf length for the euramerican clone 'Primo', but leaf number was significantly increased by elevated CO₂. The measurements suggest that total tree leaf area was stimulated for a range of poplar hybrids exposed to elevated CO₂. Given the short rotation of a coppiced crop, it is likely that increased leaf areas will result in enhanced stemwood production when hybrid poplars are grown in the CO₂ concentrations predicted for the next century.

Gary, C., N. Bertin, J.S. Frossard, and J. Le Bot. 1998. High mineral contents explain the low construction cost of leaves, stems and fruits of tomato plants. *Journal of Experimental Botany* 49(318):49-57.

The construction cost of plant tissues is used in crop models to convert the products of photosynthesis into biomass. As for other greenhouse crops, tomato tissues are specific in that they have a high mineral content. The consequences of this accumulation of minerals on the construction cost of the tissues and the possible interactions with the physiological age of the organs and with the CO₂ concentration in the atmosphere was examined. For that purpose, three methods of estimating the construction cost were used and compared. Large quantities of minerals accumulated in the tissues of tomato plants (ranging from 0.05 in fruits to 0.26 g g⁻¹ DM in leaves). The subsequent dilution of the organic matter explained why the estimated construction cost of the dry matter (organic matter + minerals) was fairly low in comparison to that of other crop species. The construction cost was higher in fruits than in vegetative organs, partly because of a lower mineral content. It decreased by 7-12% from top to bottom of the canopy, following the increase in

the physiological age of the tissues. This ontogenic drift was partly explained by the accumulation of minerals in the older organs. In the conditions of CO₂ enrichment of a commercial greenhouse, no effect of CO₂ concentration on the mineral content and on the construction cost of tissues was observed. Such a variability of the construction cost of tomato plant tissues due to the accumulation of minerals or to the ontogeny questions the use of standard values in crop models.

Gay, A.P., and B. Hauck. 1994. Acclimation of *Lolium temulentum* to enhanced carbon-dioxide concentration. *Journal of Experimental Botany* 45(277):1133-1141.

Acclimation of single plants of *Lolium temulentum* to changing [CO₂] was studied on plants grown in controlled environments at 20 degrees C with an 8 h photoperiod. In the first experiment plants were grown at 135 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photosynthetic photon flux density (PPFD) at m^{-2} 415 $\mu\text{l l}^{-1}$ or 550 $\mu\text{l l}^{-1}$ [CO₂] with some plants transferred from the lower to the higher [CO₂] at emergence of leaf 4. In the second experiment plants were grown at 135 and 500 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD at 345 and 575 $\mu\text{l l}^{-1}$ [CO₂]. High [CO₂] during growth had little effect on stomatal density, total soluble proteins, chlorophyll a content, amount of Rubisco or cytochrome f. However, increasing [CO₂] during measurement increased photosynthetic rates, particularly in high light. Plants grown in the higher [CO₂] had greater leaf extension, leaf and plant growth rates in low but not in high light. The results are discussed in relation to the limitation of growth by sink capacity and the modifications in the plant which allow the storage of extra assimilates at high [CO₂].

Gebauer, R.L.E., J.F. Reynolds, and B.R. Strain. 1996. Allometric relations and growth in *Pinus taeda*: The effect of elevated CO₂ and changing N availability. *New Phytologist* 134(1):85-93.

Loblolly pine (*Pinus taeda* L.) seedlings were grown for 138 d at two CO₂ partial pressures (35 and 70 Pa CO₂) and four N solution concentrations (0.5, 1.5, 3.5 and 6.5 mM NH₄NO₃). Allometric regression analysis was used to determine whether patterns of biomass allocation among functionally distinct plant-parts were directly controlled by CO₂ and N availability or whether differences between treatments were the result of size-dependent changes in allocation. Both CO₂ and N availability affected growth of loblolly pine. Growth stimulation by CO₂ at nonlimiting N solution concentrations (3.5 and 6.5 mM NH₄NO₃) was c. 90%. At the lowest N solution concentration (0.5 mM NH₄NO₃), total plant biomass was still enhanced by 35% under elevated CO₂. Relative growth rates were highly correlated with net assimilation rates, whereas leaf mass ratio remained unchanged under the wide range of CO₂ and N solution concentrations. When differences in plant size were adjusted apparent CO₂ effects on biomass allocation among different plant parts disappeared, indicating that CO₂ only indirectly affected allocation through accelerated growth. N availability, by contrast, had a direct effect on biomass allocation, but primarily at the lowest N solution concentration (0.5 mM NH₄NO₃). Loblolly pine compensated for N limitation by increasing specific lateral root length and proportional biomass allocation to the lateral root system. The results emphasize the significance of distinguishing size-dependent effects on biomass allocation from functional adjustments

made in direct response to changing resource availability.

Gebauer, R.L.E., B.R. Strain, and J.P. Reynolds. 1998. The effect of elevated CO₂ and N availability on tissue concentrations and whole plant pools of carbon-based secondary compounds in loblolly pine (*Pinus taeda*). *Oecologia* 113(1):29-36.

We examined the extent to which carbon investment into secondary compounds in loblolly pine (*Pinus taeda* L.) is changed by the interactive effect of elevated CO₂ and N availability and whether differences among treatments are the result of size-dependent changes. Seedlings were grown for 138 days at two CO₂ partial pressures (35 and 70 Pa CO₂) and four N solution concentrations (0.5, 1.5, 3.5, and 6.5 mmol l⁻¹ NO₃NH₄) and concentrations of total phenolics and condensed tannins were determined four times during plant development in primary and fascicular needles, stems and lateral and tap roots. Concentrations of total phenolics in lateral roots and condensed tannins in tap roots were relatively high regardless of treatment. In the smallest seedlings secondary compound concentrations were relatively high and decreased in the initial growth phase. Thereafter condensed tannins accumulated strongly during plant maturation in all plant parts except in lateral roots, where concentrations did not change. Concentrations of total phenolics continued to decrease in lateral roots while they remained constant in all other plant parts. At the final harvest plants grown at elevated CO₂ or low N availability showed increased concentrations of condensed tannins in aboveground parts. The CO₂ effect, however, disappeared when size differences were adjusted for, indicating that CO₂ only indirectly affected concentrations of condensed tannins through accelerating growth. Concentrations of total phenolics increased directly in response to low N availability and elevated CO₂ in primary and fascicular needles and in lateral roots, which is consistent with predictions of the carbon-nutrient balance (CNB) hypothesis. The CNB hypothesis is also supported by the strong positive correlations between soluble sugar and total phenolics and between starch and condensed tannins. The results suggest that predictions of the CNB hypothesis could be improved if developmentally induced changes of secondary compounds were included.

Gedroc, J.J., K.D.M. McConnaughay, and J.S. Coleman. 1996. Plasticity in root shoot partitioning: Optimal, ontogenetic, or both? *Functional Ecology* 10(1):44-50.

1. We tested whether plants increase root:shoot ratios to compensate for limitations of below-ground resources in a manner consistent with optimal partitioning theory or whether the relative production of roots and shoots is controlled by species-specific developmental patterns. Individuals of two annual plant species, *Abutilon theophrasti* and *Chenopodium album*, were grown from seed in controlled greenhouse conditions under high- or low-nutrient regimes. Mid-way through the experiment, a sub-set of low-nutrient-grown plants were given high nutrient availability and a sub-set of high-nutrient-grown plants were transferred to a low nutrient environment. 2. Under continuous nutrient regimes: (1) high-nutrient-grown plants of both species grew faster and had a lower root:shoot ratio than low-nutrient-grown plants, consistent with optimal partitioning theory; (2) both species exhibited a substantial

amount of ontogenetic drift as root:shoot ratios decreased through ontogeny (subsequent to an initial increase in R/S shortly after germination); (3) allometric analyses revealed that increased allocation to roots occurred very early in ontogeny for both species, after which the relative growth of shoots exceeded that of roots in low-nutrient-grown plants compared to their high nutrient-grown counterparts - a result inconsistent with optimal partitioning theory. 3. Under temporally varying nutrient regimes: (1) growth substantially increased in low-nutrient-grown plants that were switched to a high-nutrient environment without a change in root:shoot partitioning; (2) there was no change in growth or partitioning when plants were switched from a high- to a low-nutrient regime. 4. We conclude that, for these annual species, root/shoot partitioning is partially consistent with optimal partitioning theory but that is also highly ontogenetically constrained. This constraint is evident both in substantive ontogenetic drift in partitioning and in the period during development that plasticity in partitioning can be expressed.

Geethakumari, V.L., and K. Shivashankar. 1991. Studies on organic amendment and CO₂ enrichment in ragi soybean intercropping systems. *Indian Journal of Agronomy* 36(2):202-206.

Organic amendment comprising of ragi husk and FYM mixed in 1:1 ratio by weight promoted organic carbon content and available P status of the soil. A level of 4 t/ha of organic amendment promoted the uptake of N significantly by both ragi and soybean. Availability of P and K were also favourably influenced. Uptake of nutrients by soybean was promoted by CO₂ enrichment. Available P status was higher in intercropped ragi and soybean as compared to pure crops but nutrient uptake was higher by pure crops.

Geiger, M., V. Haake, F. Ludewig, U. Sonnewald, and M. Stitt. 1999. The nitrate and ammonium nitrate supply have a major influence on the response of photosynthesis, carbon metabolism, nitrogen metabolism and growth to elevated carbon dioxide in tobacco. *Plant, Cell and Environment* 22(10):1177-1199.

The effect of elevated [CO₂] on biomass, nitrate, ammonium, amino acids, protein, nitrate reductase activity, carbohydrates, photosynthesis, the activities of Rubisco and Sig other Calvin cycle enzymes, and transcripts for Rubisco small subunit, Rubisco activase, chlorophyll a binding protein, NADP-glyceraldehyde-3-phosphate dehydrogenase, aldolase, transketolase, plastid fructose-1,6-bisphosphatase and ADP-glucose pyrophosphorylase was investigated in tobacco growing at 2, 6 and 20 mM nitrate and 1, 3 and 10 mM ammonium nitrate. (i) The growth stimulation in elevated [CO₂] was attenuated in intermediate and abolished in low nitrogen. (ii) Elevated [CO₂] led to a decline of nitrate, ammonium, amino acids especially glutamine, and protein in low nitrogen and a dramatic decrease in intermediate nitrogen, but not in high nitrogen. (iii) Elevated [CO₂] led to a decrease of nitrate reductase activity in low, intermediate and high ammonium nitrate and in intermediate nitrate, but not in high nitrate. (iii) At low nitrogen, starch increased relative to sugars. Elevated [CO₂] exaggerated this shift. ADP-glucose pyrophosphorylase transcript increased in low nitrogen, and in elevated [CO₂]. (iv) In high nitrogen, sugars rose in elevated [CO₂], but there was no acclimation of photosynthetic rate, only a small decrease of Rubisco and no decrease of other Calvin cycle enzymes and no decrease of the corresponding transcripts. In lower nitrogen, there was a marked acclimation of photosynthetic rate and a general decrease of Calvin cycle enzymes, even though sugar levels did not increase. The

decreased activities were due to a general decrease of leaf protein. The corresponding transcripts did not decrease except at very low nitrogen. (v) It is concluded that many of the effects of elevated $[CO_2]$ on nitrate metabolism, photosynthate allocation, photosynthetic acclimation and growth are due to a shift in nitrogen status.

Geiger, M., P. Walch-Liu, C. Engels, J. Harnecker, E.D. Schulze, F. Ludewig, U. Sonnewald, W.R. Scheible, and M. Stitt. 1998. Enhanced carbon dioxide leads to a modified diurnal rhythm of nitrate reductase activity in older plants, and a large stimulation of nitrate reductase activity and higher levels of amino acids in young tobacco plants. *Plant, Cell and Environment* 21(3):253-268.

Higher rates of nitrate assimilation are required to support faster growth in enhanced carbon dioxide. To investigate how this is achieved, tobacco plants were grown on high nitrate and high light in ambient and enhanced (700 $\mu\text{mol mol}^{-1}$) carbon dioxide. Surprisingly, enhanced carbon dioxide did not increase leaf nitrate reductase (NR) activity in the middle of the photoperiod. Possible reasons for this anomalous result were investigated. (a) Measurements of biomass, nitrate, amino acids and glutamine in plants fertilized once and twice daily with 12 mol m^{-3} nitrate showed that enhanced carbon dioxide did not lead to a nitrate limitation in these plants. (b) Enhanced carbon dioxide modified the diurnal regulation of NR activity in source leaves. The transcript for nia declined during the light period in a similar manner in ambient and enhanced carbon dioxide. The decline of the transcript correlated with a decrease of nitrate in the leaf, and was temporarily reversed after re-irrigating with nitrate in the second part of the photoperiod. The decline of the transcript was not correlated with changes of sugars or glutamine. NR activity and protein decline in the second part of the photoperiod, and NR is inactivated in the dark in ambient carbon dioxide. The decline of NR activity was smaller and dark inactivation was partially reversed in enhanced carbon dioxide, indicating that post-transcriptional or post-translational regulation of NR has been modified. The increased activation and stability of NR in enhanced carbon dioxide was correlated with higher sugars and lower glutamine in the leaves. (c) Enhanced carbon dioxide led to increased levels of the minor amino acids in leaves. (d) Enhanced carbon dioxide led to a large decrease of glycine and a small decrease of serine in leaves of mature plants. The glycine:serine ratio decreased in source leaves of older plants and seedlings. The consequences of a lower rate of photorespiration for the levels of glutamine and the regulation of nitrogen metabolism are discussed. (e) Enhanced carbon dioxide also modified the diurnal regulation of NR in roots. The nia transcript increased after nitrate fertilization in the early and the second part of the photoperiod. The response of the transcript was not accentuated in enhanced carbon dioxide. NR activity declined slightly during the photoperiod in ambient carbon dioxide, whereas it increased 2-fold in enhanced carbon dioxide. The increase of root NR activity in enhanced carbon dioxide was preceded by a transient increase of sugars, and was followed by a decline of sugars, a faster decrease of nitrate than in ambient carbon dioxide, and an increase of nitrite in the roots. (f) To interpret the physiological significance of these changes in nitrate metabolism, they were compared with the current growth rate of the plants. (g) In 4-5-week-old plants, the current rate of growth was similar in ambient and enhanced carbon dioxide (approximate to $0.4 \text{ g}^{-1} \text{ d}^{-1}$). Enhanced carbon dioxide only led to small changes of NR activity, nitrate decreased, and overall amino acids were not significantly increased. (h) Young seedlings had a high growth rate ($0.5 \text{ g}^{-1} \text{ d}^{-1}$) in ambient carbon dioxide, that was increased by another 20% in enhanced carbon dioxide. Enhanced carbon

dioxide led to larger increases of NR activity and NR activation, a 2-3-fold increase of glutamine, a 50% increase of glutamate, and a 2-3-fold increase in minor amino acids. It also led to a higher nitrate level. It is argued that enhanced carbon dioxide leads to a very effective stimulation of nitrate uptake, nitrate assimilation and amino acid synthesis in seedlings. This will play an important role in allowing faster growth rates in enhanced carbon dioxide at this stage.

GenoudGourichon, C., H. Sallanon, and A. Coudret. 1996. Effects of sucrose, agar, irradiance and CO_2 concentration during the rooting phase on the acclimation of *Rosa hybrida* plantlets to ex vitro conditions. *Photosynthetica* 32(2):263-270.

Plantlets of *Rosa hybrida* cv. Deladel Madame Delbard were grown in vitro under different CO_2 concentrations and irradiances. The medium was solid or liquid with or without sucrose. Morphological (shoot length, leaf number, leaf area, root number and root length) and photosynthetic parameters (photosynthesis/irradiance curves and phosphoenolpyruvate carboxylase and ribulose-1,5-bisphosphate carboxylase/oxygenase activities) were measured. Sucrose was necessary for root formation but not for root initiation. Culture in sucrose-free and liquid medium, under CO_2 enrichment and high photosynthetic photon flux density increased the photosynthetic abilities and improved acclimation of plantlets to ex vitro conditions even if these plants had no roots after the rooting initiation phase.

George, V., D. Gerant, and P. Dizengremel. 1996. Photosynthesis, Rubisco activity and mitochondrial malate oxidation in pedunculate oak (*Quercus robur* L.) seedlings grown under present and elevated atmospheric CO_2 concentrations. *Annales Des Sciences Forestieres* 53(2-3):469-474.

Pedunculate oak seedlings were grown at 350 and 700 $\mu\text{L L}^{-1}$ CO_2 in controlled chambers. After 130 days at elevated CO_2 , the biomass of the whole plant did not significantly increase. Photosynthesis, Rubisco activity, mitochondrial malate oxidation, carbohydrates and nitrogen contents were examined in the fourth growth flush. At 700 $\mu\text{L L}^{-1}$ CO_2 , the leaf net photosynthetic rate was 220% higher than at 350 $\mu\text{L L}^{-1}$ CO_2 . The decreased activity of Rubisco was accompanied by an accumulation of sucrose and glucose. The decreased oxidative capacity of crude leaf mitochondria from elevated CO_2 plants was driven by the lower nitrogen and protein contents rather than by the higher carbohydrates contents in the leaves. Nevertheless, direct effects of elevated CO_2 on the respiratory biochemistry cannot be excluded.

Gesch, R.W., K.J. Boote, J.C.V. Vu, L.H. Allen, and G. Bowes. 1998. Changes in growth CO₂ result in rapid adjustments of ribulose-1,5-bisphosphate carboxylase/oxygenase small subunit gene expression in expanding and mature leaves of rice. *Plant Physiology* 118(2):521-529.

The accumulation of soluble carbohydrates resulting from growth under elevated CO₂ may potentially signal the repression of gene activity for the small subunit of ribulose-1,5-bisphosphate carboxylase/oxygenase (rbcS). To test this hypothesis we grew rice (*Oryza sativa* L.) under ambient (350 μ mol L⁻¹) and high (700 μ mol L⁻¹) CO₂ in outdoor, sunlit, environment-controlled chambers and performed a cross-switching of growth CO₂ concentration at the late-vegetative phase. Within 24 h, plants switched to high CO₂ showed a 15% and 23% decrease in rbcS mRNA, whereas plants switched to ambient CO₂ increased 27% and 11% in expanding and mature leaves, respectively. Ribulose-1,5-bisphosphate carboxylase/oxygenase total activity and protein content 8 d after the switch increased up to 27% and 20%, respectively, in plants switched to ambient CO₂, but changed very little in plants switched to high CO₂. Plants maintained at high CO₂ showed greater carbohydrate pool sizes and lower rbcS transcript levels than plants kept at ambient CO₂. However, after switching growth CO₂ concentration, there was not a simple correlation between carbohydrate and rbcS transcript levels. We conclude that although carbohydrates may be important in the regulation of rbcS expression, changes in total pool size alone could not predict the rapid changes in expression that we observed.

Ghannoum, O., and J.P. Conroy. 1998. Nitrogen deficiency precludes a growth response to CO₂ enrichment in C-3 and C-4 Panicum grasses. *Australian Journal of Plant Physiology* 25(5):627-636.

We investigated the interaction of nitrogen (N) supply and CO₂ enrichment on the growth and photosynthesis of *Panicum laxum* (C-3), *P. coloratum* (C-4) and *P. antidotale* (C-4). Plants were grown at ambient CO₂ partial pressures (p(a)) of either 36 (low) or 71 (high) Pa, in potted soil supplied with 0 (low) or 60 (high) mg N kg⁻¹ soil week⁻¹. Elevated CO₂ enhanced total plant dry mass of all three species by approximately 28% under high N supply, but had no effect on biomass accumulation under N deficiency. CO₂ enrichment resulted in reductions of CO₂ assimilation rates (A; measured at comparable p(a)) of *P. laxum*, indicating acclimation of photosynthesis. This acclimation, which was more pronounced under N stress, was unrelated to changes in leaf N or non-structural carbohydrate concentrations, because neither were affected by CO₂ enrichment. In the C-4 grasses grown at low N, A were fully saturated at the current ambient p(a), whereas at high N, A increased slightly when CO₂ was raised to 71 Pa. N deficiency reduced the initial slope of the CO₂ response curve of A in *P. antidotale*, and this effect was more pronounced at high CO₂. In conclusion, the preclusion of a growth response to CO₂ enrichment by N deficiency was correlated with a strong inhibition of A in the C-3 species, and the saturation of A at below current atmospheric p(a) in C-4 species.

Ghannoum, O., K. Siebke, S. Von Caemmerer, and J.P. Conroy. 1998. The photosynthesis of young *Panicum* C-4 leaves is not C-3-like.

Plant, Cell and Environment 21(11):1123-1131.

Evidence is presented contrary to the suggestion that C-4 plants grow larger at elevated CO₂ because the C-4 pathway of young C-4 leaves has C-3-like characteristics, making their photosynthesis O₂-sensitive and responsive to high CO₂. We combined PAM fluorescence with gas exchange measurements to examine the O₂-dependence of photosynthesis in young and mature leaves of *Panicum antidotale* (C-4, NADP-ME) and *P. coloratum* (C4, NAD-ME), at an intercellular CO₂ concentration of 5 Pa. *P. laxum* (C-3) was used for comparison. The young C₄ leaves had COL and light response curves typical of C-4 photosynthesis. When the O₂-concentration was gradually increased between 2 and 40%, CO₂ assimilation rates (A) of both mature and young C-4 leaves were little affected, while the ratio of the quantum yield of photosystem II to that of CO₂ assimilation ($\Phi(\text{PSII})/\Phi(\text{CO}_2)$) increased more in young (up to 31%) than mature (up to 10%) C-4 leaves. A of C-3 leaves decreased by 1.3 and $\Phi(\text{PSII})/\Phi(\text{CO}_2)$ increased by 9-fold, over the same range of O₂-concentrations. Larger increases in electron transport requirements in young, relative to mature, C-4 leaves at low CO₂ are indicative of greater O₂-sensitivity of photorespiration. Photosynthesis modelling showed that young C-4 leaves have lower bundle sheath CO₂ concentration, brought about by higher bundle sheath conductance relative to the activity of the C-4 and C-3 cycles and/or lower ratio of activities of the C-4 to C-3 cycles.

Ghannoum, O., S. vonCaemmerer, E.W.R. Barlow, and J.P. Conroy. 1996. Effect of CO₂ enrichment on growth, morphology and gas exchange of a C-3 (*Panicum laxum*) and a C-4 (*Panicum antidotale*) grass grown at two irradiance levels. *Plant Physiology* 111(2):211.

Ghannoum, O., S. vonCaemmerer, E.W.R. Barlow, and J.P. Conroy. 1997. The effect of CO₂ enrichment and irradiance on the growth, morphology and gas exchange of a C-3 (*Panicum laxum*) and a C-4 (*Panicum antidotale*) grass. *Australian Journal of Plant Physiology* 24(2):227-237.

The effect of CO₂ enrichment and irradiance on the growth and gas exchange of two tropical grasses, *Panicum laxum* (C-3) and *Panicum antidotale* (C-4) were investigated. The two species were grown at either 350 (low) or 700 (high) μ mol L⁻¹ CO₂ concentration, under 40% (low) or 100% (high) of direct sunlight and supplied with ample water and nutrition. Elevated CO₂ enhanced plant dry weight at both irradiances in the C-3 species (1.41-fold and 1.71-fold increase at low and high light, respectively) but only at high light in the C-4 species (1.28 fold increase). CO₂ enrichment had no effect on the dry weight of *P. antidotale*, when stem development was suppressed by growth under artificial lighting. When measured at the CO₂ concentration at which they were grown, assimilation rates were similar in the low and high CO₂ grown plants, for both species. However, when measurements made at low CO₂ were compared, CO₂ assimilation rates of the high light, high CO₂ grown C-3 and C-4 species were lower than those of their low CO₂ grown counterparts. High CO₂ strongly reduced the stomatal conductance of both species, while it affected the Rubisco content (30% decrease) of the high light C-3 species only. This work shows clearly that C-4 species can respond to CO₂ enrichment under favourable growth conditions, and that acclimation to elevated CO₂ in pasture grasses does not necessarily involve accumulation of non-structural

carbohydrates or reduction of total N or soluble proteins in source leaves.

Gifford, R.M. 1992. Implications of the globally increasing atmospheric CO₂ concentration and temperature for the Australian terrestrial carbon budget - integration using a simple-model. *Australian Journal of Botany* 40(4-5):527-543.

A simple continentally aggregated model of the Australian terrestrial carbon budget (CQUESTA) integrates information on CO₂ and temperature effects and is applied to evaluating whether vegetation is absorbing anthropogenic CO₂. Information from the literature is used to parameterise CQUESTA. A standard set of parameters is adopted for exploratory purposes. Historical information is used to describe the average CO₂ concentration and temperature over the southern hemisphere from 1750 AD to the present. From the present to 2050 AD the 'business-as-usual' scenario described by the Intergovernmental Panel on Climate Change (IPCC) is applied. The standard parameterisation of the model suggests that the changing CO₂ concentration and temperature regime since 1750 AD has been causing continuous net sequestration of carbon into Australian live vegetation and soils. The present modelled rate of net sequestration is of a similar magnitude to CO₂ emissions from continental fossil fuel burning and land clearing combined. The rate of sequestration is predicted to continue to increase until 2050 AD and beyond if atmospheric CO₂ concentration and temperature continue to increase. However, there remains considerable experimental uncertainty about the correct parameterisation of the model. The findings have implications for policies on greenhouse effect gas emissions.

Gifford, R.M. 1994. The global carbon-cycle - a viewpoint on the missing sink. *Australian Journal of Plant Physiology* 21(1):1-15.

Atmospheric carbon budgets that ignore the possibility of terrestrial ecosystem responses to global atmospheric change do not balance; there is a 'missing sink' of about 0.4 - 4 Gt C yr⁻¹. This paper argues a case that mechanistically it is well within the bounds of possibility that increasing carbon storage in vegetation and soils in response to the globally increasing CO₂ concentration, temperature and nitrogen deposition can account for the missing C sink. Global warming conditions considered alone would be unlikely to cause most ecosystems to emit CO₂, because the N mineralised by any enhanced soil organic matter decomposition would be largely taken up by plants and reconverted into organic matter having a much higher C:N ratio than that in the soil. Models of the global terrestrial C cycle indicate that an extra 0.5 - 4 Gt C yr⁻¹ could well be being stored in soils and

vegetation today in response to the CO₂ fertilising effect, having regard for the interactions with growth restricting water, light and nitrogen levels. To obtain direct proof as to whether that this is happening or not is a major challenge.

Gifford, R.M. 1995. Whole plant respiration and photosynthesis of wheat under increased CO₂ concentration and temperature: Long-term vs short-term distinctions for modelling. *Global Change Biology* 1(6):385-396.

Short- and long-term effects of elevated CO₂ concentration and temperature on whole plant respiratory relationships are examined for wheat grown at four constant temperatures and at two CO₂ concentrations. Whole plant CO₂ exchange was measured on a 24 h basis and measurement conditions varied both to observe short-term effects and to determine the growth respiration coefficient (r(g))r dry weight maintenance coefficient (r(g)), basal (i.e. dark acclimated) respiration coefficient (r(b)), and 24 h respiration:photosynthesis ratio (R:P). There was no response of r(b) to short-term variation in CO₂ concentration. For plants with adequate N-supply, r(g) was unaffected by the growth-CO₂ despite a 10% reduction in the plant's N concentration (%N). However, r(m) was decreased 13%, and r(b) was decreased 20% by growth in elevated CO₂ concentration relative to ambient. Nevertheless, R:P was not affected by growth in elevated CO₂. Whole plant respiration responded to short-term variation of + 5 degrees C around the growth temperature with low sensitivity (Q(10) = 1.8 at 15 degrees C, 1.3 at 30 degrees C). The shape of the response of whole plant respiration to growth temperature was different from that of the short term response, being a slanted S-shape declining between 25 and 30 degrees C. While r(m) increased, r(g) decreased when growth temperature increased between 15 and 20 degrees C. Above 20 degrees C r(m) became temperature insensitive while r(g) increased with growth temperature. Despite these complex component responses, R:P increased only from 0.40 to 0.43 between 15 degrees and 30 degrees C growth temperatures. Giving the plants a step increase in temperature caused a transient increase in R:P which recovered to the pre-transient value in 3 days. It is concluded that use of a constant R:P with respect to average temperature and CO₂ concentration may be a more simple and accurate way to model the responses of wheat crop respiration to 'climate change' than the more complex and mechanistically dubious functional analysis into growth and maintenance components.

Gifford, R.M., J.L. Lutz, and D. Barrett. 1996. Global atmospheric change effects on terrestrial carbon sequestration: Exploration with a global C- and N-cycle model (CQUESTN). *Plant and Soil* 187(2):369-387.

A model of the interacting global carbon and nitrogen cycles (CQUESTN) is developed to explore the possible history of C-sequestration into the terrestrial biosphere in response to the global increases (past and possible future) in atmospheric CO₂ concentration, temperature and N-deposition. The model is based on published estimates of pre-industrial C and N pools and fluxes into vegetation, litter and soil compartments. It was found necessary to assign low estimates of N pools and fluxes to be compatible with the more firmly established C-cycle data. Net primary production was made responsive to phytomass N level, and to CO₂ and temperature deviation from preindustrial values with sensitivities covering the ranges in the

literature. Biological N-fixation could be made either unresponsive to soil C:N ratio, or could act to tend to restore the preindustrial C:N of humus with different N-fixation intensities. As for all such simulation models, uncertainties in both data and functional relationships render it more useful for qualitative evaluation than for quantitative prediction. With the N-fixation response turned off, the historic CO₂ increase led to standard-model sequestration into terrestrial ecosystems in 1995AD of 1.8 Ct C yr⁻¹. With N-fixation restoring humus C:N strongly, C sequestration was 3 Ct yr⁻¹ in 1995. In both cases C:N of phytomass and litter increased with time and these increases were plausible when compared with experimental data on CO₂ effects. The temperature increase also caused net C sequestration in the model biosphere because decrease in soil organic matter was more than offset by the increase in phytomass deriving from the extra N mineralised. For temperature increase to reduce system C pool size, the biosphere "leakiness" to N would have to increase substantially with temperature. Assuming a constant N-loss coefficient, the historic temperature increase alone caused standard-model net C sequestration to be about 0.6 Gt C in 1995. Given the disparity of plant and microbial C:N, the modelled impact of anthropogenic N-deposition on C-sequestration depends substantially on whether the deposited N is initially taken up by plants or by soil microorganisms. Assuming the latter, standard-model net sequestration in 1995 was 0.2 Ct C in 1995 from the N-deposition effect alone. Combining the effects of the historic courses of CO₂, temperature and N-deposition, the standard-model gave C-sequestration of 3.5 Ct in 1995. This involved an assumed weak response of biological N-fixation to the increased carbon status of the ecosystem. For N-fixation to track ecosystem C-fixation in the long term however, more phosphorus must enter the biological cycle. New experimental evidence shows that plants in elevated CO₂ have the capacity to mobilize more phosphorus from so-called "unavailable" sources using mechanisms involving exudation of organic acids and phosphatases.

Gil, M.I., D.M. Holcroft, and A.A. Kader. 1997. Changes in strawberry anthocyanins and other polyphenols in response to carbon dioxide treatments. *Journal of Agricultural and Food Chemistry* 45(5):1662-1667.

Carbon dioxide-enriched atmospheres are used to reduce the incidence and severity of decay and to extend the postharvest life of strawberries. The influence of CO₂ on the postharvest quality parameters of strawberries, particularly the stability of anthocyanins and other phenolic compounds, was investigated. Freshly harvested strawberries were placed in jars ventilated continuously with air or air enriched with 10%, 20%, or 40% CO₂ at 5 degrees C for 10 days. Samples were taken initially, and after 5 and 10 days of storage, and color (L* a* b* color space), pH, TA, TSS, and firmness were measured. Anthocyanins and other phenolics were analyzed by HPLC. Elevated CO₂ degraded internal color while air-treated fruit remained red. Internal and external tissues differed in composition and concentration of phenolic compounds. CO₂ had a minimal effect on the anthocyanin content of external tissues but induced a remarkable decrease in anthocyanin content of internal tissues. Factors, such as pH and copigmentation, that could explain this degradation are discussed.

Gilmanov, T.G., and W.C. Oechel. 1995. New estimates of organic matter reserves and net primary productivity of the North American

tundra ecosystems. *Journal of Biogeography* 22(4-5):723-741.

The reserves and fluxes of carbon in ecosystems of the circumpolar tundra biome should be among the most responsive to climatic change, including their transformation from a CO₂ sink to a CO₂ source with respect to the atmosphere. To estimate accurately the significance of Arctic tundra to global carbon stocks and balances, quantitative geographically referenced estimates of the masses and fluxes of carbon are needed. Although new empirically based estimates of reserves and productivity were recently obtained for the Eurasian part of the tundra biome using GIS technology, the figures currently used for carbon reserves and productivity of the North American tundra ecosystems are based on earlier expert estimates or large scale models based on data primarily for non-tundra areas. To obtain new more empirically based estimates of the reserves and fluxes of carbon in North American tundra ecosystems a set of records of North American tundra ecosystems was obtained from the Global Arctic/Alpine Climate/Soil/Plant Productivity Data Base (Global Change Research Group, San Diego State University). This data base contains phytomass, productivity, climatic and soil characteristics for nearly fifty tundra-type ecosystems studied during the past 30 years in Alaska and Northern Canada. This information was used to interpolate the necessary data for all the tundra cells (1 X 1 degree) of the simple GIS, based on the Global Vegetation Map and the FAO/UNESCO Soil Map of the World. By integrating the corresponding maps of phytomass and productivity the quantitative estimates of the reserves and productivity fluxes of organic matter in tundra ecosystems of North America and Greenland (4.12 x 10⁶ km² total area) were obtained: 2.26 Gt above-ground phytomass, 4.99 Gt total phytomass, 91.3 Gt soil organic matter of the active layer; 0.56 Gt/yr above-ground net primary production; 0.98 Gt/yr total net primary production. As an alternative means of determining the productivity totals for North American tundra ecosystems, the phenomenological model of the form: NPP=f(T,H,G), relating net primary production of tundra ecosystems to climatic, soil and vegetation factors, was applied to the GIS layers of mean annual temperature (T), soil organic matter content (H), and above-ground phytomass density (G) to produce a map of modelled NPP estimates for North American tundra ecosystems. The subroutine of spatial integration of the local production estimates takes into account geographical changes in the landscape composition (proportions of the zonal, meadow, mire and aquatic ecosystem types) and results in totals of 0.58 Gt/yr for above-ground and 1.16 Gt/yr for total net primary production of tundra ecosystems of North America and Greenland.

Gimenez, C., V.J. Mitchell, and D.W. Lawlor. 1992. Regulation of photosynthetic rate of 2 sunflower hybrids under water-stress. *Plant Physiology* 98(2):516-524.

The effect of short-term water stress on photosynthesis of two sunflower hybrids (*Helianthus annuus* L. cv Sungro-380 and cv SH-3622), differing in productivity under field conditions, was measured. The rate of CO₂ assimilation of young, mature leaves of SH-3622 under well-watered conditions was approximately 30% greater than that of Sungro-380 in bright light and elevated CO₂; the carboxylation efficiency was also larger. Growth at large photon flux increased assimilation rates of both hybrids. The changes in leaf composition, including cell numbers and sizes, chlorophyll content, and amounts of total soluble and ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) protein, and in Rubisco activity and amount of ribulose-1,5-bisphosphate (RuBP) were determined to assess the factors regulating the differences in assimilation of the hybrids at high and low water potentials. The amounts of chlorophyll, soluble protein, Rubisco protein and the initial activity of

Rubisco and its activation state did not differ significantly between hybrids. However, unstressed leaves of SH-3622 had more, smaller cells per unit area and 60% more RuBP per unit leaf area than that of Sungro-380. Water stress developing over 4 days decreased the assimilation of both hybrids similarly. Changes in the amounts of chlorophyll, soluble and Rubisco protein, and Rubisco activity and activation state were small and were not sufficient to explain the decrease in photosynthesis; neither was decreased stomatal conductance (or stomatal "patchiness"). Reduction of photosynthesis per unit leaf area from 25 to 5 micromoles CO₂ per square meter per second in both hybrids was caused by a decrease in the amount of RuBP from approximately 130 to 40 micromoles per square meter in SH-3622 and from 80 to 40 micromoles per square meter in Sungro. Differences between hybrids and their response to water stress is discussed in relation to control of RuBP regeneration.

Giordano, M., J.S. Davis, and G. Bowes. 1994. Organic-carbon release by dunalialla-salina (chlorophyta) under different growth-conditions of co₂, nitrogen, and salinity. *Journal of Phycology* 30(2):249-257.

Two strains of Dunalialla salina (Dunal) Teod., UTEX 1644 and UTEX 200, were cultured under different growth regimes, including 10 mM NO₃- or NH₄+, 1.5 or 3.0 M NaCl, and low (0.035%) or high (5%) CO₂ in air. The release of C-14-labeled dissolved organic carbon (DOC), expressed as a rate and as a percentage of photo synthetic (CO₂)-C-14, assimilation, was subsequently determined. The percentage of DOC released was inversely related to cell density in the assay medium, but photosynthesis on a per-cell basis was not. Release of DOC was low, in the range of 1-5% of photosynthesis, but during acclimation to growth on NH₄+, it rose to 11%. The presence of NH₄ rather than NO₃- in the growth medium increased the rate of release by both strains, but the percentage release was stimulated only in UTEX 200 cells, because their photosynthetic rate was depressed by NH₄+. For UTEX 1644, high, as compared to low, CO₂-grown cells, had somewhat higher rates and percentages of DOC release, but release from UTEX 200 cells was unaffected by the growth-CO₂. The rate of DOC release by high CO₂-grown cells was not enhanced at a low concentration of dissolved inorganic carbon, indicating that the released material did not originate from the photorespiratory pathway. The effects of NaCl on DOC release varied with strain and growth conditions. For UTEX 200, the cells in NO₃-, but not NH₄+, exhibited a doubling or more in percentage of release with a doubling in NaCl concentration, irrespective of growth-CO₂. With UTEX 1644 the low CO₂-grown cells showed the greatest enhancement in 3.0 M NaCl. Organic matter accumulated on the external surface of the cell membrane and constituted a well-defined cell-coat, which was more dense in NH₄ than in NO₃- grown cells. Microtubules, which may play a role in maintaining cell shape, were observed just below the plasma membrane. From a practical viewpoint, the presence of organic material in the hypersaline ponds of salt-works is detrimental to salt production. When D. salina cells become abundant in such ponds, the attendant, continuous release of DOC may make a significant contribution to the problem.

Gleadow, R.M., W.J. Foley, and I.E. Woodrow. 1998. Enhanced CO₂ alters the relationship between photosynthesis and defence in cyanogenic

Eucalyptus cladocalyx F. Muell. *Plant, Cell and Environment* 21(1):12-22.

The effect of elevated CO₂ and different levels of nitrogen on the partitioning of nitrogen between photosynthesis and a constitutive nitrogen-based secondary metabolite (the cyanogenic glycoside prunasin) was examined in Eucalyptus cladocalyx. Our hypothesis was that the expected increase in photosynthetic nitrogen-use efficiency of plants grown at elevated CO₂ concentrations would lead to an effective reallocation of available nitrogen from photosynthesis to prunasin. Seedlings were grown at two concentrations of CO₂ and nitrogen, and the proportion of leaf nitrogen allocated to photosynthesis, ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), protein and prunasin compared. Up to 20% of leaf nitrogen was allocated to the cyanogenic glycoside, although this proportion varied with leaf age, position and growth conditions. Leaf prunasin concentration, was strongly affected by nitrogen supply, but did not increase, on a dry weight basis, in the leaves from the elevated CO₂ treatments. However, the proportion of nitrogen allocated to prunasin increased significantly, in spite of a decreasing pool of leaf nitrogen, in the plants grown at elevated concentrations of CO₂. There was less protein in leaves of plants grown at elevated CO₂ in both nitrogen treatments, while the concentration of active sites of Rubisco only decreased in plants from the low-nitrogen treatment. These changes in leaf chemistry may have significant implications in terms of the palatability of foliage and defence against herbivores.

Gloser, J., and M. Bartak. 1994. Net photosynthesis, growth-rate and biomass allocation in a rhizomatous grass calamagrostis-epigejos grown at elevated co₂ concentration. *Photosynthetica* 30(1):143-150.

Young plants of Calamagrostis epigejos (L.) Roth were grown in controlled environments with two regimes of CO₂ in the air: normal (350 cm³ m⁻³) and elevated (700 cm³ m⁻³). The relative growth rate of plants grown at elevated CO₂ was increased by about 20 % in comparison with control plants cultivated at ambient CO₂ concentration. Partitioning of assimilates into roots (+ rhizomes) and shoots was the same in both treatments. Slightly lower values of specific leaf area, leaf mass ratio and leaf area ratio were found in the plants grown at elevated CO₂. The net photosynthetic rate (P-N) was measured gasometrically in plants from both treatments at 350 and 700 cm³ m⁻³ CO₂ in the leaf chamber. There were no significant differences between plants grown at either CO₂ concentration in their responses to radiation and CO₂ conditions during measurements, i.e., no regulation of photosynthetic

processes in response to elevated CO₂ was detectable. P-N at saturating irradiance and maximum apparent quantum yield of photosynthesis were always considerably higher at doubled CO₂ concentration during measurements.

Godbold, D.L., and G.M. Berntson. 1997. Elevated atmospheric CO₂ concentration changes ectomycorrhizal morphotype assemblages in *Betula papyrifera*. *Tree Physiology* 17(5):347-350.

Ectomycorrhizae are extremely diverse, with different species of fungi having very different physiologies and morphologies that, in turn, confer a range of different benefits to the host plant. To test the hypothesis that elevated CO₂ leads to changes in the assemblage of ectomycorrhizae associated with trees, we examined the number and frequency of ectomycorrhizal morphotypes colonizing roots of *Betula papyrifera* Marsh. saplings grown at an ambient or elevated (700 ppm) atmospheric CO₂ concentration for 24 weeks. Elevated CO₂ resulted in significant changes in the composition of the ectomycorrhizal assemblage toward morphotypes with a higher incidence of emanating hyphae and rhizomorphs. We conclude that *B. papyrifera* saplings will be able to support a more costly mycorrhization in future elevated-CO₂ atmospheres.

Godbold, D.L., G.M. Berntson, and F.A. Bazzaz. 1997. Growth and mycorrhizal colonization of three North American tree species under elevated atmospheric CO₂. *New Phytologist* 137(3):433-440.

We investigated the effect of elevated CO₂ on the growth and mycorrhizal colonization of three tree species native to north-eastern American forests (*Betula papyrifera* Marsh., *Pinus strobus* L. and *Tsuga canadensis* L. Carr). Saplings of the tree species were collected from Harvard Forest, Massachusetts, and grown in forest soil under ambient (c. 375 ppm) and elevated (700 ppm) atmospheric CO₂ concentrations for 27-35 wk. In all three species there was a trend to increasing whole-plant, total-root and fine-root biomass in elevated CO₂, and a significant increase in the degree of ectomycorrhizal colonization in *B. papyrifera* and *P. strobus*, but not in *T. canadensis*. However, in *T. canadensis* the degree of colonization with arbuscular mycorrhizas increased significantly. In both the ambient and elevated environments, on the roots of *B. papyrifera* and *P. strobus* 12 distinct ectomycorrhizal morphotypes were identified. Distinct changes in the ectomycorrhizal morphotype assemblage of *B. papyrifera* were observed under CO₂ enrichment. This change resulted in an increase in the frequency of ectomycorrhizas with a higher incidence of emanating hyphae and rhizomorphs, and resulted in a higher density of fungal hyphae in a root exclusion chamber.

Goettel, M.S., G.M. Duke, and D.W. Goerzen. 1997. Pathogenicity of *Ascosphaera larvis* to larvae of the alfalfa leafcutting bee, *Megachile rotundata*. *Canadian Entomologist* 129(6):1059-1065.

Laboratory assays and field surveys showed that *Ascosphaera larvis*

(Bissett) is a pathogen of alfalfa leafcutting bee larvae, capable of causing high mortality in commercial populations. In one population over 21% of bees were found to be infected by *A. larvis*. However, overall levels of the disease are low and it is unlikely that this pathogen poses an immediate threat to commercial leafcutting bee populations in Canada. The LD₅₀ was determined to be 1.9×10^5 spores/bee. Elevated levels of CO₂ are required for in vitro spore germination. The disease can easily be diagnosed within bee cells by X-ray radiography, thereby enabling disease levels to be monitored using conventional methods utilized by the industry to monitor leafcutting bee quality.

Goldewijk, K.K., J.G. Vanminnen, G.J.J. Kreileman, M. Vloedveld, and R. Leemans. 1994. Simulating the carbon flux between the terrestrial environment and the atmosphere. *Water, Air, and Soil Pollution* 76(1-2):199-230.

A Terrestrial C Cycle model that is incorporated in the Integrated Model to Assess the Greenhouse Effect (IMAGE 2.0) is described. The model is a geographically explicit implementation of a model that simulates the major C fluxes in different compartments of the terrestrial biosphere and between the biosphere and the atmosphere. Climatic parameters, land cover and atmospheric C concentrations determine the result of the dynamic C simulations. The impact of changing land cover patterns, caused by anthropogenic activities (shifting agriculture, de- and afforestation) and climatic change are modeled implicitly. Feedback processes such as CO₂ fertilization and temperature effects on photosynthesis, respiration and decomposition are modeled explicitly. The major innovation of this approach is that the consequences of climate change are taken into account instantly and that their results can be quantified on a global medium-resolution grid. The objectives of this paper are to describe the C cycle model in detail, present the linkages with other parts of the IMAGE 2.0 framework, and give an array of different simulations to validate and test the robustness of this modeling approach. The computed global net primary production (NPP) for the terrestrial biosphere in 1990 was 60.6 Gt C a⁻¹, with a global net ecosystem production (NEP) of 2.4 Gt C a⁻¹. The simulated C flux as result from land cover changes was 1.1 Gt C a⁻¹, so that the terrestrial biosphere in 1990 acted as a C sink of 1.3 Gt C a⁻¹. Global phytomass amounted 567.5 Gt C and the dead biomass pool was 1517.7 Gt C. IMAGE 2.0 simulated for the period 1970 - 2050 a global average temperature increase of 1.6-degrees-C and a global average precipitation increase of 0.1 mm/day. The CO₂ concentration in 2050 was 522.2 ppm. The computed NPP for the year 2050 is 82.5 Gt C a⁻¹, with a NEP of 8.1 Gt C a⁻¹. Projected land cover changes result in a C flux of 0.9 Gt C a⁻¹, so that the terrestrial biosphere will be a strong sink of 7.2 Gt C a⁻¹. The amount of phytomass hardly changed (600.7 Gt C) but the distribution over the different regions had. Dead biomass increased significantly to 1667.2 Gt C.

Gong, H., S. Nilsen, and J.F. Allen. 1993. Photoinhibition of photosynthesis *in vivo* - involvement of multiple sites in a photodamage process under CO₂-free and O₂-free conditions. *Biochimica Et Biophysica Acta* 1142(1-2):115-122.

Intact *Lemna gibba* plants were illuminated by photoinhibitory light in air, in air minus O₂, in air minus CO₂, and in pure N₂. In pure N₂, the degree of photoinhibition increased 3-5-times compared with that in air.

This high degree of photoinhibition is described as photodamage. Photodamage was found to constitute a syndrome, that is, it is due to inactivation of multiple sites. These sites include RC II component(s) from P680 to Q(A); the Q(B)-Site; and a component of PS I. In photodamage, the donor side of PS II and PS II excitation energy transfer remain unimpaired, but the size of the PS I antenna seems to decrease. Photodamage is distinguishable from photoinactivation. Photoinactivation occurred in air and could be attributed to inhibition of electron transport from Q(A)- to Q(B). During photoinactivation the D1 protein of RC II became degraded faster than the detectable inhibition of Q(B) reduction. The photoinhibition-induced rise in F0 occurred only during the process of photodamage but not during that of photoinactivation, and was a secondary event which arose as a consequence of photodamage. Atmospheric O₂ alleviated photodamage but increased photoinactivation. The light-induced D1 degradation and inhibition of Q(A) to Q(B) electron transfer were enhanced in vivo not only by O₂ but also by depletion of CO₂.

Gonzalez-Meler, M.A., M. RibasCarbo, J.N. Siedow, and B.G. Drake. 1996. Direct inhibition of plant mitochondrial respiration by elevated CO₂. *Plant Physiology* 112(3):1349-1355.

Doubling the concentration of atmospheric CO₂ often inhibits plant respiration, but the mechanistic basis of this effect is unknown. We investigated the direct effects of increasing the concentration of CO₂ by 360 μ mol L⁻¹ above ambient on O₂ uptake in isolated mitochondria from soybean (*Glycine max* L. cv Ransom) cotyledons. Increasing the CO₂ concentration inhibited the oxidation of succinate, external NADH, and succinate and external NADH combined. The inhibition was greater when mitochondria were preincubated for 10 min in the presence of the elevated CO₂ concentration prior to the measurement of O₂ uptake. Elevated CO₂ concentration inhibited the salicylhydroxamic acid-resistant cytochrome pathway, but had no direct effect on the cyanide-resistant alternative pathway. We also investigated the direct effects of elevated CO₂ concentration on the activities of cytochrome c oxidase and succinate dehydrogenase (SDH) and found that the activity of both enzymes was inhibited. The kinetics of inhibition of cytochrome c oxidase were time-dependent. The level of SDH inhibition depended on the concentration of succinate in the reaction mixture. Direct inhibition of respiration by elevated CO₂ in plants and intact tissues may be due at least in part to the inhibition of cytochrome c oxidase and SDH.

Gonzalez-Meler, M.A., and J.N. Siedow. 1999. Direct inhibition of mitochondrial respiratory enzymes by elevated CO₂: does it matter at the tissue or whole-plant level? *Tree Physiology* 19(4-5):253-259.

On average, a doubling in current atmospheric [CO₂] results in a 15 to 20% direct inhibition of respiration, although the variability associated with this value is large within and among species. Direct effects of CO₂ on respiration may also be relevant to tree canopies because of dynamic fluctuations between nighttime and daytime [CO₂] throughout the growing season. The mechanism by which CO₂ inhibits respiration is not known. A doubling of ambient [CO₂] inhibits the activity of the mitochondrial enzymes, cytochrome c oxidase and succinate

dehydrogenase. If inhibition of these enzymes is the only factor involved in the direct inhibition of respiration, the overall inhibition of specific respiration will be proportional to the control that such enzymes exert on the overall respiratory rate. We analyzed the effects of [CO₂] on respiration in an attempt to scale the direct effects of CO₂ on respiratory enzymes to the whole-plant level. Sensitivity analysis showed that inhibition of mitochondrial enzymes by doubling current atmospheric [CO₂] does not explain entirely the CO₂ inhibition of tissue or whole-plant respiration. We conclude that CO₂-dependent suppression of respiratory enzymatic activity will be minimal when cytochrome c oxidase inhibition is scaled up from the mitochondria to the whole tree and that the primary mechanism for the direct inhibitory effect remains to be identified.

Goodale, C.L., J.D. Aber, and E.P. Farrell. 1998. Predicting the relative sensitivity of forest production in Ireland to site quality and climate change. *Climate Research* 10(1):51-67.

Most model-based predictions of climate change effects on forest ecosystems have used either potential or static descriptions of vegetation and site, removing the effects of direct management or land use. In this paper we use a previously developed and validated model of carbon and water balances in forest ecosystems (PnET-II) to assess the relative sensitivity of forest production in Ireland to predicted climate change and to ambient variability in site quality. After validating the model against measured productivity for 2 sets of stands, we ran the model using existing variation in site quality, represented as differences in foliar N concentration, and also for predicted changes in climate and atmospheric CO₂. Resulting variations in productivity were compared with those due to potential errors in the specification of input parameters and to variation in current ambient climate across the region. The effects on net primary production (NPP) and wood production of either ambient variation in climate or predicted changes in temperature, precipitation and CO₂ are quite small (0 to 30%) relative to the effects of ambient variability in site quality (up to 400%). The range of possible variation in other user-specified physiological parameters resulted in changes of less than 10% in model predictions. We conclude that site-specific conditions and management practices result in a range of forest productivity that is much greater than any likely to be induced by climate change or CO₂ enrichment. We also suggest that it is essential to understand and map spatial variability in site quality, as well as to understand how the productive capacity of landscapes will change in response to management and pollution loading, if we are to predict the actual role that climate change will play in altering forest productivity and global biogeochemistry.

Goodfellow, J., D. Eamus, and G. Duff. 1997. Diurnal and seasonal changes in the impact of CO₂ enrichment on assimilation, stomatal conductance and growth in a long-term study of *Mangifera indica* in the wet-dry tropics of Australia. *Tree Physiology* 17(5):291-299.

We studied assimilation, stomatal conductance and growth of *Mangifera indica* L. saplings during long-term exposure to a CO₂-enriched

atmosphere in the seasonally wet-dry tropics of northern Australia. Grafted saplings of *M. indica* were planted in the ground in four air-conditioned, sunlit, plastic-covered chambers and exposed to CO₂ at the ambient or an elevated (700 $\mu\text{mol mol}^{-1}$) concentration for 28 months. Light-saturating assimilation ($A(\text{max})$), stomatal conductance ($g(s)$), apparent quantum yield (ϕ), biomass and leaf area were measured periodically. After 28 months, the CO₂ treatments were changed in all four chambers from ambient to the elevated concentration or vice versa, and $A(\text{max})$ and $g(s)$ were remeasured during a two-week exposure to the new regime. Throughout the 28-month period of exposure, $A(\text{max})$ and apparent quantum yield of leaves in the elevated CO₂ treatment were enhanced, whereas stomatal conductance and stomatal density of leaves were reduced. The relative impacts of atmospheric CO₂ enrichment on assimilation and stomatal conductance were significantly larger in the dry season than in the wet season. Total tree biomass was substantially increased in response to atmospheric CO₂ enrichment throughout the experimental period, but total canopy area did not differ between CO₂ treatments at either the first or the last harvest. During the two-week period following the change in CO₂ concentration, $A(\text{max})$ of plants grown in ambient air but measured in CO₂-enriched air was significantly larger than that of trees grown and measured in CO₂-enriched air. There was no difference in $A(\text{max})$ between trees grown and measured in ambient air compared to trees grown in CO₂-enriched air but measured in ambient air. No evidence of down-regulation of assimilation in response to atmospheric CO₂ enrichment was observed when rates of assimilation were compared at a common intercellular CO₂ concentration. Reduced stomatal conductance in response to atmospheric CO₂ enrichment was attributed to a decline in both stomatal aperture and stomatal density.

Gordon, D.C., M.M.I. VanVuuren, B. Marshall, and D. Robinson. 1995. Plant growth chambers for the simultaneous control of soil and air temperatures, and of atmospheric carbon dioxide concentration. *Global Change Biology* 1(6):455-464.

Many facilities for growing plants at elevated atmospheric concentrations of CO₂ ([CO₂]) neglect the control of temperature, especially of the soil. Soil and root temperatures in conventional, free-standing pots often exceed those which would occur in the field at a given air temperature. A plant growth facility is described in which atmospheric CO₂ can be maintained at different concentrations while soil and air temperatures mimic spatial and temporal patterns seen in the field. It consists of glasshouse-located chambers in which [CO₂] is monitored by an infra-red gas analyser and maintained by injection of CO₂ from a cylinder. Air is cooled by a heat exchange unit. Plants grow in soil in 1.2 m long containers that are surrounded by cooling coils and thermal insulation. Both [CO₂] and temperature are controlled by customized software. Air temperature is programmed to follow a sine function of diurnal time. Soil temperature at a depth of 0.55 m is programmed to be constant. Temperature at 0.1 m depth varies as a damped, lagged function of air temperature; that at 1.0 m as a similar function of the 0.55 m temperature. [CO₂] is maintained within 20 $\mu\text{mol mol}^{-1}$ of target concentrations during daylight. A feature of the

system is that plant material is labelled with a C-13 enrichment different from that of carbon in soil organic matter. The operation of the system is illustrated with data collected in an experiment with spring wheat (*Triticum aestivum* L., cv Tonic) grown at ambient [CO₂] and at [CO₂] 350 $\mu\text{mol mol}^{-1}$ greater than ambient.

Gordon, H.B., P.H. Whetton, A.B. Pittock, A.M. Fowler, and M.R. Haylock. 1992. Simulated changes in daily rainfall intensity due to the enhanced greenhouse-effect - implications for extreme rainfall events. *Climate Dynamics* 8(2):83-102.

In this study we present rainfall results from equilibrium 1 x - and 2 x CO₂ experiments with the CSIRO 4-level general circulation model. The 1 x CO₂ results are discussed in relation to observed climate. Discussion of the 2 x CO₂ results focuses upon changes in convective and non-convective rainfall as simulated in the model, and the consequences these changes have for simulated daily rainfall intensity and the frequency of heavy rainfall events. In doing this analysis, we recognize the significant shortcomings of GCM simulations of precipitation processes. However, because of the potential significance of any changes in heavy rainfall events as a result of the enhanced greenhouse effect, we believe a first examination of relevant GCM rainfall results is warranted. Generally, the model results show a marked increase in rainfall originating from penetrative convection and, in the mid-latitudes, a decline in large-scale (non-convective) rainfall. It is argued that these changes in rainfall type are a consequence of the increased moisture holding capacity of the warmer atmosphere simulated for 2 x CO₂ conditions. Related to changes in rainfall type, rainfall intensity (rain per rain day) increases in the model for most regions of the globe. Increases extend even to regions where total rainfall decreases. Indeed, the greater intensity of daily rainfall is a much clearer response of the model to increased greenhouse gases than the changes in total rainfall. We also find a decrease in the number of rainy days in the middle latitudes of both the Northern and Southern Hemispheres. To further elucidate these results daily rainfall frequency distributions are examined globally and for four selected regions of interest. In all regions the frequency of high rainfall events increases, and the return period of such events decreases markedly. If realistic, the findings have potentially serious practical implications in terms of an increased frequency and severity of floods in most regions. However, we discuss various important sources of uncertainty in the results presented, and indicate the need for rainfall intensity results to be examined in enhanced greenhouse experiments with other GCMs.

Gorissen, A. 1996. Elevated CO₂ evokes quantitative and qualitative changes in carbon dynamics in a plant/soil system: Mechanisms and implications. *Plant and Soil* 187(2):289-298.

It is hypothesized that carbon storage in soil will increase under an elevated atmospheric CO₂ concentration due to a combination of an increased net CO₂ uptake, a shift in carbon allocation pattern in the plant/soil system and a decreased decomposition rate of plant residues. An overview of several studies, performed in our laboratory, on the effects of elevated CO₂ on net carbon uptake, allocation to the soil and decomposition of roots is given to test this hypothesis. The studies included wheat, ryegrass and Douglas-fir and comprised both short-term and long-term studies. Total dry weight of the plants increased up to 62%, but depended on nutrient availability. These results were supported by the data on net (CO₂)-C-14 uptake. A shift in C-14-carbon

distribution from shoots to roots was found in perennial species, although this depended on nutrient availability. The decomposition experiments showed that roots cultivated at 700 $\mu\text{L L}^{-1}$ CO_2 were decomposed more slowly than those cultivated at 350 $\mu\text{L L}^{-1}$ CO_2 . Even after two growing seasons differences up to 13% were observed, although this was found to be dependent on the nitrogen level at which the roots were grown. Both an increased carbon allocation to the soil due to an increased carbon uptake, whether or not combined with a shift in distribution pattern, and a decreased decomposition of root residues will enhance the possibilities of carbon sequestration in soil, thus supporting our hypothesis. However, nutrient availability and the response of the soil microbial biomass (size and activity) play a major role in the processes involved and require attention to clarify plant/soil responses in the long term with regard to sustained stimulation of carbon input into soils and the decomposability of roots and rhizodeposition. Soil texture will also have a strong effect on decomposition rates as a result of differences in the protecting capacity for organic matter. More detailed information on these changes is needed for a proper use of models simulating soil carbon dynamics in the long term.

Gorissen, A., P.J. Kuikman, and H. Vandebeek. 1995. Carbon allocation and water-use in juvenile douglas-fir under elevated CO_2 . *New Phytologist* 129(2):275-282.

In this study the impact of an elevated CO_2 level on allocation of assimilates and water use efficiency of Douglas fir [*Pseudotsuga menziesii* (Mirb.) France] was investigated. Juvenile Douglas firs were exposed to a long-term treatment at 350 and 700 $\mu\text{L L}^{-1}$ CO_2 for 14 months and subsequently crosswise transferred to phytotrons for a short-term treatment with 350 and 700 $\mu\text{L L}^{-1}$ CO_2 for 4 wk in an atmosphere continuously labelled with $(\text{CO}_2)\text{-C-14}$. No interactive effects on total net uptake of $(\text{CO}_2)\text{-C-14}$ between long-term treatment and short-term treatment were observed. The short-term treatment with 700 $\mu\text{L L}^{-1}$ CO_2 increased the total net uptake of $(\text{CO}_2)\text{-C-14}$ by 22%, compared with the 350 $\mu\text{L L}^{-1}$ CO_2 treatment. The long-term pretreatment did not affect the total net uptake, suggesting that photosynthetic acclimation had not occurred. However, expressed per unit of needle mass a 14% reduction was observed in the trees pretreated at 700 $\mu\text{L L}^{-1}$ CO_2 . This was not because of a reduced sink strength of the root system. This reduced uptake per unit of needle mass after long-term treatment may have implications for carbon storage in forest ecosystems. The results showed that an initial growth stimulation can eventually be annulled by developing physiological or morphological adaptations. $(\text{CO}_2)\text{-C-14}$ the root/soil respiration increased in the short-term treatment with 700 $\mu\text{L L}^{-1}$ CO_2 , indicating a stimulated use of current carbon compounds either by roots or microorganisms. The water use efficiency during the short-term treatment with 700 $\mu\text{L L}^{-1}$ CO_2 increased by 32%, but was not affected by the long-term pretreatment. Water use per unit needle mass during the short-term treatment was decreased both by the short-term treatment and by the long-term pretreatment by about 15%. Some of the observed effects appeared to be persistent, such as decreased water use per unit needle mass, whereas others, stimulation of total net $(\text{CO}_2)\text{-C-14}$ uptake and water use efficiency, were transient.

Gorissen, A., P.J. Kuikman, J.H. vanGinkel, H. vandeBeek, and A.G. Jansen. 1996. ESPAS - An advanced phytotron for measuring carbon dynamics in a whole plant-soil system. *Plant and Soil* 179(1):81-87.

The use of carbon isotopes as tracers is essential for measuring carbon flows in an intact whole plant-soil system. Here, we describe an Experimental Soil Plant Atmosphere System (ESPAS) to perform pulse-labelling and steady-state labelling experiments with $(\text{CO}_2)\text{-C-13}$ and $(\text{CO}_2)\text{-C-14}$. The ESPAS facility is an environmental research tool that is used to measure the carbon fluxes from the atmosphere to the roots and into the soil and the microbial biomass and to study decomposition of plant residues and soil organic matter. The influence of environmental conditions in the atmosphere or in soil on the carbon allocation and turnover in the plant-soil ecosystem can be quantified. The design and the technical description of the phytotrons is presented and evidence is provided that the phytotrons are equivalent. For this purpose, *Triticum aestivum* plants were cultivated in the phytotrons for 39 days and shoot growth, root growth and water use were compared. No significant differences were observed for plant growth and water use. As an example of the practical application of the equipment, an experiment with elevated atmospheric CO_2 is presented. Data are given on the uptake of C-14 under ambient (350 $\mu\text{L L}^{-1}$) and elevated (700 $\mu\text{L L}^{-1}$) CO_2 in *Lolium perenne* and *Festuca arundinacea* and the distribution of C-14 among different plant-soil compartments i.e. shoot, root, root-soil respiration, and soil. We conclude that these phytotrons yield detailed information on gross carbon flows in a whole plant-soil system that can not be obtained without sensitive carbon tracers. Such data are important for proper calibration of simulation models on soil organic matter.

Gorny, J.R., and A.A. Kader. 1996. Controlled-atmosphere suppression of ACC synthase and ACC oxidase in 'Golden Delicious' apples during long-term cold storage. *Journal of the American Society for Horticultural Science* 121(4):751-755.

Prelimacteric 'Golden Delicious' apples (*Malus domestica* Borkh.) were stored at 0 degrees C in: air; air + 5% CO_2 ; 2% O_2 + 98% N_2 ; or 2% O_2 + 5% CO_2 + 93% N_2 , and sampled monthly for 4 months to investigate the mechanism(s) by which reduced O_2 and/or elevated CO_2 atmospheres inhibit C_2H_4 biosynthesis. Ethylene biosynthesis rates and in vitro ACS activity were closely correlated in all treatments, while in vitro ACO activity significantly increased over time regardless of the treatment. Only a small amount of C_2H_4 biosynthesis inhibition by lowered O_2 and/or elevated CO_2 atmospheres could be accounted for by suppressed induction of ACO activity. Western blot analysis demonstrated that apples held for 2 months in lowered O_2 and/or elevated CO_2 atmospheres had significantly reduced abundance of ACO protein, compared to fruit held in air. Northern blot analysis of ACS and ACO transcript abundance revealed that reduced O_2 and/or elevated CO_2 atmospheres delay induction and reduce the abundance of both transcripts. Reduced O_2 and/or elevated CO_2 atmospheres reduce

C2H4 biosynthesis by delaying and suppressing expression of ACS at the transcriptional level and by reducing the abundance of active ACO protein. Chemical names used: 1-aminocyclopropane-1-carboxylic acid (ACC), ACC synthase (ACS), ACC oxidase (ACO), ethylene (C2H4), S-adenosylmethionine (AdoMet).

Gorny, J.R., and A.A. Kader. 1996. Regulation of ethylene biosynthesis in climacteric apple fruit by elevated CO₂ and reduced O₂ atmospheres. *Postharvest Biology and Technology* 9(3):311-323.

Autocatalytic (System II) C₂H₄ biosynthesis in climacteric 'Golden Delicious' apples (*Malus domestica* Borkh) was effectively inhibited at 20 degrees C by atmospheres of 20% CO₂-enriched air (17% O₂ + 63% N₂) or 0.25% O₂ (balance N₂). In vitro 1-aminocyclopropane-1-carboxylic acid (ACC) synthase (ACC-S) activity of apples held in atmospheres of air + 20% CO₂ or 0.25% O₂ was significantly inhibited when compared to apples kept in air, and correlated well with fruit C₂H₄ production rates. In vivo and in vitro ACC oxidase (ACC-O) activity of fruit held in atmospheres of air, air + 20% CO₂ or 0.25% O₂ were similar when the assays were performed under standard assay conditions (i.e., in vivo assay performed in air, in vitro assay performed in air + 6% CO₂). However, if the in vivo or in vitro ACC-O enzyme activity assays were performed in an atmosphere of 0.25% O₂, ACC-O catalytic competency and activity were significantly reduced. When the in vivo or in vitro ACC-O enzyme activity assays were performed in an atmosphere of air + 20% CO₂, ACC-O enzyme activity was actually stimulated. These data indicate that elevated levels of CO₂ do not inhibit ACC-O catalytic competency. Western blot analysis revealed that ACC-O protein abundance was not significantly affected by any of the treatments tested, and only the 0.25% O₂ atmosphere significantly inhibited ACC-O activity. ACC-S activity was significantly reduced by atmospheres of air + 20% CO₂ or 0.25% O₂ but not via direct inhibition of ACC-S catalytic competency.

Gorny, J.R., and A.A. Kader. 1997. Low oxygen and elevated carbon dioxide atmospheres inhibit ethylene biosynthesis in preclimacteric and climacteric apple fruit. *Journal of the American Society for Horticultural Science* 122(4):542-546.

Autocatalytic C₂H₄ biosynthesis in preclimacteric apple fruit (*Malus domestica* Borkh, 'Golden Delicious') was prevented by storage in atmospheres of 20% CO₂-enriched air (17% O₂ + 63% N₂) or 0.25% O₂ (balance N₂). In preclimacteric fruit, both treatments inhibited C₂H₄ biosynthesis by suppressing expression of ACC synthase (ACC-S) at the mRNA level. ACC oxidase (ACC-O) mRNA abundance and in vitro enzyme activity also were impaired by these treatments. However, the conversion of ACC to C₂H₄ never became the rate limiting step in C₂H₄ biosynthesis, C₂H₄ biosynthesis also was effectively inhibited in climacteric apple fruit kept in air + 20% CO₂ or 0.25% O₂. Climacteric apples also exhibited suppressed expression of ACC-S at the mRNA level, while ACC-O transcript abundance, enzyme activity, and protein abundance were reduced only slightly. ACC-S is the key regulatory enzyme of C₂H₄ biosynthesis and is the major site at which elevated CO₂ and reduced O₂ atmospheres inhibit C₂H₄ biosynthesis, irrespective of fruit physiological maturity. Chemical names used: 1-aminocyclopropane-1-carboxylic acid (ACC).

Gouk, S.S., J. He, and C.S. Hew. 1999. Changes in photosynthetic capability and carbohydrate production in an epiphytic CAM orchid plantlet exposed to super-elevated CO₂. *Environmental and Experimental Botany* 41(3):219-230.

The effects on growth in super-elevated (1%) CO₂ in terms of photosynthetic capability and carbohydrate production were studied in an epiphytic CAM (Crassulacean acid metabolism) orchid plantlet, Mokara Yellow (*Arachnis hookeriana* x *Ascocenda* Madame Kenny). The growth of the plantlets was greatly enhanced after growing for 3 months at 1% CO₂ compared with the control plantlets (0.035% CO₂). CO₂ enrichment produced more than a 2-fold increase in dry matter production. The enhanced root growth at 1% CO₂ led to a higher root:shoot ratio. Plantlets grown at super-elevated CO₂ had higher F_v/F_m values, a higher photochemical quenching (q(P)) and a relatively lower non-photochemical quenching (q(N)). CO₂ at 1% appeared to enhance the utilization of captured light energy in the orchid plantlets. CO₂ enrichment also increased contents of soluble sugars (glucose and sucrose) and starch in the orchid plantlets. The extra starch formed under 1% CO₂ did not cause a disruption of the chloroplasts. Chlorophyll content was higher and a clear granal stacking was evident in young leaves and roots of plantlets grown at 1% CO₂. An extensive thylakoid system was observed in the young leaf chloroplasts of the CO₂-enriched plantlets indicating an improved development of the photosynthetic apparatus when compared to that of the control plantlets. The increased photosynthetic capacity and enhanced growth of the epiphytic roots under CO₂ enrichment would facilitate the generation of more photoassimilates and acquisition of essential resources, thereby increasing the survival rate of orchid plantlets under stressful field conditions. Gouk, S.S., J.W.H. Yong, and C.S. Hew. 1997. Effects of super-elevated CO₂ on the growth and carboxylating enzymes in an epiphytic CAM orchid plantlet. *Journal of Plant Physiology* 151(2):129-136.

Responses of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) and phosphoenolpyruvate carboxylase (PEPCase) to super-elevated CO₂ were determined along with dry mass production, chlorophyll, soluble protein and nocturnal malate increases (NMI) for an epiphytic Crassulacean acid metabolism (CAM) orchid plantlet, Mokara Yellow. After 8-month culture period, the total dry mass under super-elevated CO₂ was 170% higher than the plantlets grown in 0.03% CO₂; young leaf dry mass was 4-fold higher while the root dry mass increased 278% and 344% under 1% and 5% CO₂ respectively. Higher root:shoot ratio was observed under super-elevated CO₂; 0.22 in 0.03% CO₂, 0.32 in 1% CO₂ and 0.38 in 5% CO₂. The averaged increase in total young leaf area was 244% and 373% under 1% and 5% CO₂ respectively. Leaf

chlorophyll expressed per unit fresh weight was reduced under 5% CO₂ but it increased 19% and 67% in old and young leaves of 3-month plantlets under 1% CO₂. The root chlorophyll content increased 108% and 154% under 1%; and 5% CO₂ respectively. Soluble protein in young leaves increased 32% under 1% CO₂ and 75% under 5% CO₂, while the increase in root protein varied from 36% to 100%. The activities of Rubisco and PEPCase expressed per unit protein were reduced under super-elevated CO₂, particularly in 5% CO₂, the decreases ranged from 12% to 90% in Rubisco and 27% to 90% in PEPCase. Nevertheless, the leaf Rubisco:PEPCase ratio increased 110% to 362% under super-elevated CO₂. Increased NMI, ranged from 23% to 182% under super-elevated CO₂, contributed to the increased dry matter accumulation in Mokara plantlets. Throughout the 5-month culture period, the CO₂-enriched plantlets showed enhanced growth particularly under 1% CO₂ in terms of biomass production, chlorophyll, soluble protein and NMI despite a concomitant decrease in the activities of the carboxylating enzymes.

Goulart, B.L., P.E. Hammer, K.B. Evensen, W. Janisiewicz, and F. Takeda. 1992. Pyrrolnitrin, captan + benomyl, and high CO₂ enhance raspberry shelf-life at 0C or 18C. *Journal of the American Society for Horticultural Science* 117(2):265-270.

The effects of preharvest applications of pyrrolnitrin (a biologically derived fungicide) on postharvest longevity of 'Bristol' black raspberry (*Rubus occidentalis* L.) and 'Heritage' red raspberry [*R. idaeus* L. var. *strigosus* (Michx.) Maxim] were evaluated at two storage temperatures. Preharvest fungicide treatments were 200 mg pyrrolnitrin/liter, a standard fungicide treatment (captan + benomyl or iprodione) or a distilled water control applied 1 day before first harvest. Black raspberries were stored at 18 or 0 +/- 1C in air or 20% CO₂. Red raspberries were stored at the same temperatures in air only. Pyrrolnitrin-treated berries often had less gray mold (*Botrytis cinerea* Pers. ex Fr.) in storage than the control but more than berries treated with the standard fungicides. Storage in a modified atmosphere of 20% CO₂ greatly improved postharvest quality of black raspberries at both storage temperatures by reducing gray mold development. The combination of standard fungicide or pyrrolnitrin, high CO₂, and low temperature resulted in more than 2 weeks of storage with less than 5% disease on black raspberries; however, discoloration limited marketability after almost-equal-to 8 days under these conditions. Chemical names used: 3-chloro-4-(2'-nitro-3'-chlorophenyl)-pyrrole (pyrrolnitrin); N-trichloromethylthio-4-cyclohexene-1,2-dicarboximide (captan); methyl 1-(butylcarbonyl)-2-benzimidazolecarbamate (benomyl); 3-(3,5-dichlorophenyl)-N-(1-methylethyl)-2,4-dioxo-1-imidazolidinecarboxamide (Rovral, iprodione).

Graham, E.A., and P.S. Nobel. 1996. Long-term effects of a doubled atmospheric CO₂ concentration on the CAM species *Agave deserti*. *Journal of Experimental Botany* 47(294):61-69.

To examine the effects of a doubled atmospheric CO₂ concentration and other aspects of global climate change on a common CAM species native to the Sonoran Desert, *Agave deserti* was grown under 370 and 750 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ air and gas exchange was measured under various environmental conditions. Doubling the CO₂ concentration increased daily net CO₂ uptake by 49% throughout the 17 months and

decreased daily transpiration by 24%, leading to a 110% increase in water-use efficiency. Under the doubled CO₂ concentration, the activity of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) was 11% lower, phosphoenolpyruvate carboxylase was 34% lower, and the activated:total ratio for Rubisco was 25% greater than under the current CO₂ concentration. Less leaf epicuticular wax occurred on plants under the doubled CO₂ concentration, which decreased the reflectance of photosynthetic photon flux (PPF); the chlorophyll content per unit leaf area was also less. The enhancement of daily net CO₂ uptake by doubling the CO₂ concentration increased when the PPF was decreased below 25 $\mu\text{mol m}^{-2} \text{ d}^{-1}$, when water was withheld, and when day/night temperatures were below 17/12 degrees C. More leaves, each with a greater surface area, were produced per plant under the doubled CO₂ concentration. The combination of increased total leaf surface area and increased daily net CO₂ uptake led to an 88% stimulation of dry mass accumulation under the doubled CO₂ concentration. A rising atmospheric CO₂ concentration, together with accompanying changes in temperature, precipitation, and PPF, should increase growth and productivity of native populations of *A. deserti*.

Grams, T.E.E., S. Anegg, K.H. Haberle, C. Langebartels, and R. Matyssek. 1999. Interactions of chronic exposure to elevated CO₂ and O-3 levels in the photosynthetic light and dark reactions of European beech (*Fagus sylvatica*). *New Phytologist* 144(1):95-107.

Young trees of European beech (*Fagus sylvatica*) acclimated for one growing season to ambient (c. 367 $\mu\text{mol l}^{-1}$) or elevated CO₂ levels (c. 660 $\mu\text{mol l}^{-1}$) were exposed during the subsequent year to combinations of the same CO₂ regimes and ambient or twice-ambient ozone (O-3) levels (generated from the database of a rural site). By the end of June, before the development of macroscopic leaf injury, the raised O-3 levels had not affected the light and dark reactions of photosynthesis. However, acclimation to elevated CO₂ had resulted in lowered chlorophyll and nitrogen concentrations, whereas photosynthetic performance, examined over a wide range of parameters from light and dark reactions, remained unchanged or showed only slight reductions (e.g. apparent electron transport rate, ETR; apparent quantum yield of CO₂ gas exchange, $\Phi(\text{CO}_2)$; apparent carboxylation efficiency, CE; and photosynthetic capacity at light and CO₂ saturation, PC). In August, after the appearance of leaf necroses, plants grown under ambient CO₂ and twice-ambient O-3 conditions declined in both the photosynthetic light reactions (optimum electron quantum yield, Fv/Fm, non-photochemical energy quenching, NPQ, reduction state of Q(A), apparent electron quantum yield, $\Phi(\text{PSII})$, maximum electron transport rates) and the dark reactions as reflected by CE, $\Phi(\text{CO}_2)$, as well as the maximum CO₂ uptake rate (i.e. PC). CE, $\Phi(\text{CO}_2)$ and PC were reduced by c. 75, 40 and 75%, respectively, relative to plants exposed to ambient CO₂ and O-3 levels. By contrast, plants exposed to twice-ambient O-3 and elevated CO₂ levels maintained a photosynthetic performance similar to individuals grown either under ambient CO₂ and ambient O-3, or elevated CO₂ and ambient O-3 conditions. The long-term exposure to elevated CO₂ therefore tended to counteract adverse chronic effects of enhanced O-3 levels on photosynthesis. Possible reasons for this compensatory effect in *F. sylvatica* are discussed.

Grams, T.E.E., and R. Matyssek. 1999. Elevated CO₂ counteracts the limitation by chronic ozone exposure on photosynthesis in *Fagus sylvatica* L.: Comparison between chlorophyll fluorescence and leaf gas exchange. *Phyton-Annales Rei Botanicae* 39(4):31-39.

The interaction of elevated CO₂ and enhanced chronic ozone (O₃) impact was analysed throughout the growing season in the photosynthetic response (chlorophyll fluorescence and leaf gas exchange) of beech saplings (*Fagus sylvatica*) which had been acclimated to CO₂ supply during the year prior to the experiment. Both light and dark reactions (i.e. electron transport rate and photosynthetic capacity) of plants grown at ambient CO₂ and twice-ambient O₃ concentrations were distinctly reduced by August. The O₃-induced decline was counteracted by elevated CO₂ supply (i.e. ambient +300 ppm). Plants grown at high CO₂ supply and ambient or twice-ambient O₃ concentrations displayed a photosynthetic performance similar to plants exposed to ambient CO₂ and O₃ conditions. Responses in chlorophyll fluorescence were found to be consistent with those in leaf gas exchange.

Grant, R.F. 1998. Simulation in ecosys of root growth response to contrasting soil water and nitrogen. *Ecological Modelling* 107(2-3):237-264.

If mathematical models of plant growth are to perform reliably under diverse conditions of soil and climate, then the effects of these conditions on root growth must be represented. A mathematical model of root and mycorrhizal growth is proposed to represent the effects of soil and climate on growth using the hypothesis that a functional equilibrium exists among root axes and shoot branches. In this model access to growth resources (C, N, P, water) by different axes or branches depends upon (1) proximity of the axis or branch to the point of resource acquisition, and (2) the rate at which resources are consumed by the axis or branch in relation to that by other axes or branches. This model was coupled to a plant growth model as part of the ecosystem simulation model ecosys, and its sensitivity to changes in model parameters and soil boundary conditions was tested. Simulated root growth was less sensitive to changes in soil water and nitrogen than was simulated shoot growth. This lower sensitivity allowed the model to simulate changes in root:shoot ratios with changes in soil water and nitrogen that were consistent with those commonly reported in the literature. Changes in soil water also caused changes in vertical distributions of root length density to be simulated that were also consistent with those reported. Changes in root:shoot partitioning and in root density distributions allowed improved access by plants in the model to limiting growth resources. The root model was parameterized from basic root growth studies conducted independently of the model, and without reference to site-specific patterns of seasonal root growth. Consequently the model is likely to be of general value in the simulation of root growth under diverse soil conditions, although such generality needs to be established through further testing under different soils, climates and crops. The precision of some of the model parameters is uncertain and the sensitivity of the model to this uncertainty is discussed. (C) 1998 Elsevier Science B.V. All rights reserved.

Grant, R.F., T.A. Black, G. den Hartog, J.A. Berry, H.H. Neumann, P.D. Blanken, P.C. Yang, C. Russell, and I.A. Nalder. 1999. Diurnal and annual exchanges of mass and energy between an aspen-hazelnut forest and the atmosphere: Testing the mathematical model Ecosys with data from the BOREAS experiment. *Journal of Geophysical Research-Atmospheres* 104(D22):27699-27717.

There is much uncertainty about the net carbon (C) exchange of boreal forest ecosystems, although this exchange may be an important part of global C dynamics. To resolve this uncertainty, net C exchange has been measured at several sites in the boreal forest of Canada as part of the Boreal Ecosystem- Atmosphere Study (BOREAS). One of these sites is the Southern Old Aspen site at which diurnal CO₂ and energy (radiation, latent, and sensible heat) fluxes were measured during 1994 using eddy correlation techniques at different positions within a mixed 70 year old aspen-hazelnut forest. These measurements were used to test a complex ecosystem model "ecosys" in which mass and energy exchanges between terrestrial ecosystems and the atmosphere are simulated hourly under diverse conditions of soil, management, and climate. These simulations explained between 70% and 80% of diurnal variation in ecosystem CO₂ and energy fluxes measured during three 1 week intervals in late April, early June, and mid-July. Total annual CO₂ fluxes indicated that during 1994, aspen was a net sink of 540 (modeled) versus 670 (measured) g C m⁻² yr⁻¹, while hazelnut plus soil were a net source of 472 (modeled) versus 540 (measured) g C m⁻² yr⁻¹. The aspen-hazelnut forest at the BOREAS site was therefore estimated to be a net sink of about 68 (modeled) versus 130 (measured) g C m⁻² yr⁻¹ during 1994. Long-term simulations indicated that this sink may be larger during cooler years and smaller during warmer years because C fixation in the model was less sensitive to temperature than respiration. These simulations also indicated that the magnitude of this sink declines with forest age because respiration increases with respect to fixation as standing phytomass grows. Confidence in the predictive capabilities of ecosystem models at decadal or centennial timescales is improved by well-constrained tests of these models at hourly timescales.

Grant, R.F., R.L. Garcia, P.J. Pinter, D. Hunsaker, G.W. Wall, B.A. Kimball, and R.L. LaMorte. 1995. Interaction between atmospheric CO₂ concentration and water deficit on gas exchange and crop growth: Testing of ecosys with data from the Free Air CO₂ Enrichment (FACE) experiment. *Global Change Biology* 1(6):443-454.

Soil water deficits are likely to influence the response of crop growth and yield to changes in atmospheric CO₂ concentrations (C-a), but the extent of this influence is uncertain. To study the interaction of water deficits and C-a on crop growth, the ecosystem simulation model ecosys was tested with data for diurnal gas exchange and seasonal wheat growth measured during 1993 under high and low irrigation at C-a = 370 and 550 μmol mol⁻¹ in the Free Air CO₂ Enrichment (FACE) experiment near Phoenix, AZ. The model, supported by the data from canopy gas exchange enclosures, indicated that under high irrigation canopy conductance (g(c)) at C-a = 550 μmol mol⁻¹ was reduced to about 0.75 that at C-a = 370 μmol mol⁻¹, but that under low irrigation, g(c) was reduced less. Consequently when C-a was increased from 370 to 550 μmol mol⁻¹, canopy transpiration was reduced less, and net CO₂ fixation was increased more, under low irrigation than under high irrigation. The simulated effects of C-a and irrigation on diurnal gas exchange were also apparent on seasonal water use and grain yield. Simulated vs. measured seasonal water use by wheat under high irrigation was reduced by 6% vs. 4% at C-a = 550 vs. 370 μmol mol⁻¹, but that under low irrigation was increased by 3% vs. 5%. Simulated

vs. measured grain yield of wheat under high irrigation was increased by 16% vs. 8%, but that under low irrigation was increased by 38% vs. 21%. In ecosys, the interaction between C-a and irrigation on diurnal gas exchange, and hence on seasonal crop growth and water use, was attributed to a convergence of simulated $g(c)$ towards common values under both C-a as canopy turgor declined. This convergence caused transpiration to decrease comparatively less, but CO₂ fixation to increase comparatively more, under high vs. low C-a. Convergence of $g(c)$ was in turn attributed to improved turgor maintenance under elevated C-a caused by greater storage C concentrations in the leaves, and by greater rooting density in the soil.

Grant, R.F., B.A. Kimball, P.J. Pinter, G.W. Wall, R.L. Garcia, R.L. Lamorte, and D.J. Hunsaker. 1995. Carbon-dioxide effects on crop energy-balance - testing ecosys with a free-air CO₂ enrichment (FACE) experiment. *Agronomy Journal* 87(3):446-457.

Elevated CO₂ concentrations (C-e) have been observed to decrease short-term plant water use under controlled conditions by increasing stomatal resistance. The extent to which this decrease occurs over a growing season in the field is uncertain, however, because stomatal resistance is only one of many mechanisms that control water use. In this study, we tested the ecosystem simulation model ecosys, which reproduces an hourly energy balance through soil-vegetation systems under defined atmospheric boundary conditions, using energy exchange data measured as part of the Free-Air CO₂ Enrichment (FACE) experiment at C-e = 550 vs. 370 $\mu\text{mol mol}^{-1}$. The model reproduced reductions in measured upward latent heat fluxes that varied from -10 to +40 W m⁻², depending on atmospheric conditions. In the model, the primary effect of elevated C-e on latent heat fluxes was through canopy stomatal conductance. This effect was largely offset by secondary effects through canopy temperature that enabled the model to reproduce measured changes in sensible heat fluxes. The total effect simulated by ecosys of C-e = 550 vs. 370 $\mu\text{mol mol}^{-1}$ on evapotranspiration during the entire PACE experiment was a reduction of 7%. This reduction compares with one of 11% estimated from accumulated daily measurements of latent heat flux. In the model, the different effects of C-e on plant water use depend on atmosphere and soil boundary conditions, and are highly dynamic. Consequently the simulated C-e-water use relationship is likely to be site-specific. The use of models such as ecosys allows site-specific boundary conditions to be considered in the study of C-e effects on plant growth and water use.

Grant, R.F., G.W. Wall, B.A. Kimball, K.F.A. Frumau, P.J. Pinter, D.J. Hunsaker, and R.L. Lamorte. 1999. Crop water relations under different CO₂ and irrigation: testing of ecosys with the free air CO₂ enrichment (FACE) experiment. *Agricultural and Forest Meteorology* 95(1):27-51.

Increases in crop growth under elevated atmospheric CO₂ concentration (C-A) have frequently been observed to be greater under water-limited versus non-limited conditions. Crop simulation models used in climate change studies should be capable of reproducing such changes in growth

response to C-A with changes in environmental conditions. We propose that changes with soil water status in crop growth response to C-A can be simulated if stomatal resistance is considered to vary directly with air-leaf C-A gradient, inversely with leaf carboxylation rate, and exponentially with leaf turgor. Resistance simulated in this way increases with C-A relatively less, and CO₂ fixation increases with C-A relatively more, under water-limited versus non-limited conditions. As part of the ecosystem model ecosys, this simulation technique caused changes in leaf conductance and CO₂ fixation, and in canopy water potential, temperature and energy balance in a modelling experiment that were consistent with changes measured under 355 versus 550 $\mu\text{mol mol}^{-1}$ C-A and low versus high irrigation in a free air CO₂ enrichment (FACE) experiment on wheat. Changes with C-A in simulated crop water relations allowed the model to reproduce under 550 $\mu\text{mol mol}^{-1}$ C-A and low versus high irrigation a measured increase of 20 versus 10% in seasonal wheat biomass, and a measured decrease of 2 versus 5% in seasonal evapotranspiration. The basic nature of the processes simulated in this model is intended to enable its use under a wide range of soil, management and climate conditions. (C) 1999 Elsevier Science B.V. Grant, W.J.R., H.M. Fan, W.J.S. Downton, and B.R. Loveys. 1992. Effects of CO₂ enrichment on the physiology and propagation of 2 australasian ornamental plants, *Chamelacium-uncinatum* (schauer) X *chamelacium-floriferum* (ms) and *correa- schlehtendalii* (behr). *Scientia Horticulturae* 52(4):337-342.

Root formation on both *Chamelacium* and *Correa* cuttings maintained at high humidity in an enclosed fog tunnel was significantly enhanced when ambient CO₂ was increased from 350 to 800 μmbar . CO₂ enrichment resulted in decreased transpiration and increased water potential of cuttings implying an effect of CO₂ on stomatal conductance. CO₂ enrichment led to increased starch levels in cuttings of both species probably by raising the intercellular partial pressure of CO₂. Increased starch content with CO₂ enrichment was able to account for 70-90% of the dry weight increase in *Correa*, but only for 10-30% of the dry weight increase in *Chamelacium*. It is suggested that the stimulation of rooting associated with CO₂ enrichment probably derives from the improved water relations of the cuttings rather than from increased carbohydrate levels.

Grant, W.J.R., and B.R. Loveys. 1996. Controlling rootstock sprouts of *Agonis flexuosa* (Willd.) Sweet at ambient and elevated CO₂ by multiple applications of low concentration NAA. *Australian Journal of Experimental Agriculture* 36(5):619-624.

A method for grafting variegated scion material to green leafed *Agonis flexuosa* (Willd.) Sweet stock was developed to overcome the difficulty of striking cuttings. However sprouting of both seedling and cutting-grown *A. flexuosa* rootstocks was a significant problem. Microwedge grafting of actively growing leafy scions and stocks in fog at 32/22 degrees C gave 90-100% success and scion bud activity was stimulated within 2 weeks. Weekly or fortnightly spray applications of 100 mg NAA/L (naphthaleneacetic acid), starting at the time of grafting, gave effective sprout control whereas a single pregraft spray of 200 mg NAA/L was not effective. CO₂ enrichment of the fog environment was

investigated as a means of enhancing scion growth. CO₂ at 80 kPa increased scion dry weight (DW), leaf and branch numbers, but had no effect on rootstock sprout or stem DW or sprout numbers. Optimum NAA concentrations for rootstock sprout suppression under elevated CO₂ with fog, were 50-100 mg/L, which were not deleterious to scion shoot length, when sprayed on the stock portion only. Stock sprout numbers, scion leaf and branch numbers were negatively correlated with NAA concentration. Sprout growth at 100 mg NAA/L was about 5% of control sprout growth. Concentrations greater than or equal to 200 mg NAA/L caused leaf tip necrosis and excess stem callusing. Scion growth was inversely related to the degree of resprouting in control treatments.

Grashoff, C., P. Dijkstra, S. Nonhebel, A.H.C.M. Schapendonk, and S.C. VandeGeijn. 1995. Effects of climate change on productivity of cereals and legumes; model evaluation of observed year-to-year variability of the CO₂ response. *Global Change Biology* 1(6):417-428.

The effect of elevated [CO₂] on the productivity of spring wheat, winter wheat and faba bean was studied in experiments in climatized crop enclosures in the Wageningen Rhizolab in 1991-93. Simulation models for crop growth were used to explore possible causes for the observed differences in the CO₂ response. Measurements of the canopy gas exchange (CO₂ and water vapour) were made continuously from emergence until harvest. At an external [CO₂] of 700 $\mu\text{mol mol}^{-1}$, Maximum Canopy CO₂ Exchange Rate (CCFR_{max}) at canopy closure was stimulated by 51% for spring wheat and by 71% for faba bean. At the end of the growing season, above ground biomass increase at 700 $\mu\text{mol mol}^{-1}$ was 58% (faba bean), 35% (spring wheat) and 19% (winter wheat) and the harvest index did not change. For model exploration, weather data sets for the period 1975-88 and 1991-93 were used, assuming adequate water supply and [CO₂] at 350 and 700 $\mu\text{mol mol}^{-1}$. For spring wheat the simulated responses (35-50%) were at the upper end of the experimental results. In agreement with experiments, simulations showed smaller responses for winter wheat and larger responses for faba bean. Further model explorations showed that this differential effect in the CO₂ response may not be primarily due to fundamental physiological differences between the crops, but may be at least partly due to differences in the daily air temperatures during comparable stages of growth of these crops. Simulations also showed that variations between years in CO₂ response can be largely explained by differences in weather conditions (especially temperature) between growing seasons.

Graumlich, L.J. 1991. Sub-alpine tree growth, climate, and increasing CO₂ - an assessment of recent growth trends. *Ecology* 72(1):1-11.

LaMarche et al. (1984) hypothesized that recent trends of increasing ring widths in subalpine conifers may be due to the fertilizing effects of increased atmospheric CO₂. Five tree-ring series from foxtail pine (*Pinus balfouriana*), lodgepole pine (*P. murrayana*), and western juniper (*Juniperus occidentalis*) collected in the Sierra Nevada, California, were analyzed to determine if the temporal and spatial patterns of recent growth were consistent with the hypothesized CO₂-induced growth enhancement. Specifically, I address the following questions: (1) Can growth trends be explained solely in terms of climatic variation? (2) Are recent growth trends unusual with respect to long-term growth records? For three of the five sites, 20th-century growth variation can be adequately modeled as a function of climatic variation. For the

remaining two sites, trends in the residuals from the growth/climate models indicate systematic underestimation of growth during the past decade that could be interpreted as either CO₂ fertilization or as a response to extreme climatic events during the mid 1970s. At all five sites, current growth levels have been equalled or exceeded during some preindustrial periods. Taken together, these results do not indicate that CO₂-induced growth enhancement is occurring among subalpine conifers in the Sierra Nevada. While the results presented here offer no support for the hypothesized CO₂ fertilization effect, they do provide insights into the response of subalpine conifers to climatic variation. Response surfaces demonstrate that precipitation during previous winter and temperature during the current summer interact in controlling growth and that the response can be nonlinear. Although maximum growth rates occur under conditions of high winter precipitation and warm summers for all three species, substantial species-to-species variation occurs in the response to these two variables.

Graybill, D.A., and S.B. Idso. 1993. Detecting the aerial fertilization effect of atmospheric CO₂ enrichment in tree-ring chronologies. *Global Biogeochemical Cycles* 7(1):81-95.

The growth-promoting effects of the historical increase in the air's CO₂ content are not yet evident in tree-ring records where yearly biomass additions are apportioned among all plant parts. When almost all new biomass goes into cambial enlargement, however, a growth increase of 60% or more is observed over the past two centuries. As a result, calibration of tree-ring records of this nature with instrumental climate records may not be feasible because of such growth changes. However, climate signals prior to about the mid-19th century may yet be discovered by calibrating such tree-ring series with independently derived proxy climate records for those times.

Grayston, S.J., C.D. Campbell, J.L. Lutze, and R.M. Gifford. 1998. Impact of elevated CO₂ on the metabolic diversity of microbial communities in N-limited grass swards. *Plant and Soil* 203(2):289-300.

The impact of elevated atmospheric CO₂ on qualitative and quantitative changes in rhizosphere carbon flow will have important consequences for nutrient cycling and storage in soil, through the effect on the activity, biomass size and composition of soil microbial communities. We hypothesized that microbial communities from the rhizosphere of *Danthonia richardsonii*, a native C₃ Australian grass, growing at ambient and twice ambient CO₂ and varying rates of low N application (20, 60, 180 kg N ha⁻¹) will be different as a consequence of qualitative and quantitative change in rhizosphere carbon flow. We used the Biolog(TM) system to construct sole carbon source utilisation profiles of these communities from the rhizosphere of *D. richardsonii*. Biolog(TM) GN and MT plates, the latter to which more ecologically relevant root exudate carbon sources were added, were used to characterise the communities. Microbial communities from the rhizosphere of *D. richardsonii* grown for four years at twice ambient CO₂ had significantly greater utilisation of all carbon sources except those with a low C:N ratio (neutral and acidic amino acids, amides, N-heterocycles, long chain aliphatic acids) than communities from plants grown at ambient CO₂. This indicates a change in microbial community composition suggesting that under elevated CO₂ compounds with a higher C:N ratio were exuded. Enumeration of microorganisms, using

plate counts, indicated that there was a preferential stimulation of fungal growth at elevated CO₂ and confirmed that bacterial metabolic activity (C utilisation rates), not population size (counts), were stimulated by additional C flow at elevated CO₂. Nitrogen was an additional rate-limiting factor for microbial growth in soil and had a significant impact on the microbial response to elevated CO₂. Microbial populations were higher in the rhizosphere of plants receiving the highest N application, but the communities receiving the lowest N application were most active. These results have important implications for carbon turnover and storage in soils where changes in soil microbial community structure and stimulation of the activity of microorganisms which prefer to grow on rhizodeposits may lead to a decrease in the composition of organic matter and result in an accumulation of soil carbon.

Greaves, A.J., and J.G. Buwalda. 1996. Observations of diurnal decline of photosynthetic gas exchange in kiwifruit and the effect of external CO₂ concentration. *New Zealand Journal of Crop and Horticultural Science* 24(4):361-369.

The prevalence of diurnal decline of photosynthesis in field-grown kiwifruit (*Actinidia deliciosa* (A. Chev.) C.F. Liang et A.R. Ferguson var. *deliciosa* 'Hayward') and the effects of elevated CO₂ concentration during decline were studied. During the seasonal period from soon after fruit set to harvest, marked diurnal reductions of photosynthesis rate were found that could not be correlated with levels of photosynthetically active radiation (PAR), temperature, and transpiration. Declines of photosynthesis were observed only on clear days characterised by benign environmental conditions other than sustained irradiance at saturating or near saturating levels. Elevation of CO₂ concentration to 200 μ mol/mol above ambient during photosynthesis decline overcame the decline effect, allowing photosynthesis to track irradiance levels throughout the day. Possible mechanisms generating the diurnal decline and the alleviation by elevation of CO₂ concentration are discussed.

Greer, D.H., W.A. Laing, and B.D. Campbell. 1995. Photosynthetic responses of 13 pasture species to elevated CO₂ and temperature. *Australian Journal of Plant Physiology* 22(5):713-722.

Thirteen common pasture species, (eleven C-3 and two C-4), were grown in controlled environments at 12/7, 18/13 and 28/23 degrees C and at 350 and 700 ppm CO₂ to evaluate the effects of elevated CO₂ on their photosynthetic responses. Photosynthesis was measured at the growth temperatures and at both 350 and 700 ppm CO₂. In C-3 species, short-term (within minutes) increases in CO₂ had the greatest effect on photosynthesis, with an average of 50-60% higher rates in plants exposed to 700 ppm CO₂ at each temperature. However, there was a continuum of response between the C-3 species whereas C-4 species were unaffected by short-term changes in CO₂. There was also a long-term (4-8 weeks) response to high CO₂, with an average of about 40-50% higher rates of photosynthesis, with some response by C-4 species. Both short- and long-term responses were negatively correlated with the photosynthetic rate of each species at 350 ppm CO₂ and all species were less efficient at converting photosynthate to dry matter at elevated CO₂. These data show clearly that photosynthesis of these cool temperate pasture species can respond to elevated CO₂, especially at low temperatures. This will have consequences for predicting the potential effects of climate change, accompanied by rising CO₂, on pasture

ecosystems.

Gregor, H.D. 1992. The potential role of temperate forests as sinks for CO₂ - examples from the German environmental-policy against global warming. *Water, Air, and Soil Pollution* 64(1-2):197-212.

Among industrialized nations Germany ranks fourth in CO₂ emissions. Most of these originate from the use of fossil fuels. Based on reports of a parliamentary study commission, established in 1987, and other expert groups in Germany this article addresses possible environmental effects of increasing atmospheric CO₂, the sink potential of temperate forests and the influence of forest damage on this potential. A strategy for a 25 to 30% or 250 to 300 X 10⁶ t yr⁻¹ CO₂ emissions reduction by 2005 (which Germany has itself committed to) is described in which measures to enhance C sequestration by forests play an important role. Expansion of forest area, a further increase of C storage by appropriate management and the restoration and protection of forest health impaired by air pollution would result in an additional storage of 17 to 20 x 10⁶ t yr⁻¹ of CO₂, equaling 6 to 8% of the reduction target.

Gregory, K.M. 1996. Are paleoclimate estimates biased by foliar physiognomic responses to increased atmospheric CO₂? *Palaeogeography Palaeoclimatology Palaeoecology* 124(1-2):39-51.

Physiognomic analysis of fossil angiosperm leaves has provided an important quantitative database of Tertiary terrestrial paleoclimate. However, atmospheric CO₂ level, a critical control on plant growth, may have been higher in the Tertiary. It is thus crucial to investigate whether elevated CO₂ affects leaf physiognomy. In this study, leaves were collected from white oak (*Quercus alba* L.) seedlings grown in open-top growth chambers at Oak Ridge National Laboratory. The only physiognomic change noted is an increase in length to width ratio with increasing CO₂. In the literature, leaf size has been observed to increase, decrease or remain unchanged for woody C-3 species grown in elevated CO₂. Typically, one sees more variation due to microsite or phenotype than due to CO₂ level. By applying these observed physiognomic trends to two fossil floras, it is argued that estimates of mean annual temperature and growing season precipitation may be biased on the order of 1 degrees C and 20 cm, respectively. These are relatively small effects, as the values are similar to the standard errors of the regression models used to estimate paleoclimate. The lack of data, the variability of response to CO₂ associated with microsite and phenotype, and the question of whether observed short-term trends with elevated CO₂ are sustained make it impossible to propose a correction factor. Adequate sample size and sampling of several sites are the best way to attempt to compensate for CO₂ effects on a given fossil flora until response to CO₂ is better understood.

Gregory, P.J., J.A. Palta, and G.R. Batts. 1996. Root systems and root:mass ratio - Carbon allocation under current and projected atmospheric conditions in arable crops. *Plant and Soil* 187(2):221-228.

Roots of annual crop plants are a major sink for carbon particularly during early, vegetative growth when up to one-half of all assimilated carbon may be translocated belowground. Flowering marks a particularly important change in resource allocation, especially in determinate species, with considerably less allocation to roots and, depending on environmental conditions, there may be insufficient for maintenance. Studies with C-14 indicate the rapid transfer belowground of assimilates with typically 50% translocated in young cereal plants of which 50% is respired; exudation/rhizodeposition is generally <5% of the fixed carbon. Root:total plant mass decreases through the season and is affected by soil and atmospheric conditions. Limited water availability increased the allocation of C-13 to roots of wheat grown in columns so that at booting 0.38 of shoot C (ignoring shoot respiration) was belowground compared to 0.31 in well-watered plants. Elevated CO₂ (700 μ mol CO₂ mol⁻¹ air) increased the proportion of root:total mass by 55% compared with normal concentration, while increasing the air temperature by a mean of 3 degrees C decreased the proportion from 0.093 in the cool treatment to 0.055 in the warm treatment.

Grieb, B., U. Gross, E. Pleschka, B. Arnholdtschmitt, and K.H. Neumann. 1994. Embryogenesis of photoautotrophic cell-cultures of *daucus-carota* L. *Plant Cell Tissue and Organ Culture* 38(2-3):115-122.

In this paper photoautotrophic carrot (*Daucus carota* L.) suspension cultures are described which are able to produce somatic embryos. The development of somatic embryos, however, requires a sucrose supplement. Although an elevation of the CO₂ concentration up to 2.3% results in the same level of dry weight production as with sucrose in the medium, somatic embryos could not be observed. Results on the influence of sucrose on some aspects of the photosynthetic apparatus of cultured cells are discussed.

Gries, C., B.A. Kimball, and S.B. Idso. 1993. Nutrient-uptake during the course of a year by sour orange trees growing in ambient and elevated atmospheric carbon-dioxide concentrations. *Journal of Plant Nutrition* 16(1):129-147.

During the third year of a long-term carbon dioxide (CO₂) enrichment study, macro- and micro-nutrient concentrations in leaves and roots of sour orange trees were analyzed. Data for yearly courses of the macronutrients Ca, Mg, N, P, K, Na, and S and the micronutrients B, Cu, Fe, Mn, and Zn are presented. Significantly higher concentrations of N, K, Ca, and Mn were found in leaves of the control trees. The degree of difference varied seasonally: the greatest differences occurred in summer, whereas essentially no differences were found in spring and winter.

Griffin, K.L., J.T. Ball, and B.R. Strain. 1996. Direct and indirect effects of elevated CO₂ on whole-shoot respiration in ponderosa pine seedlings. *Tree Physiology* 16(1-2):33-41.

We determined the short-term direct and longterm indirect effects of CO₂ on apparent dark respiration (CO₂ efflux in the dark) in ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) seedlings grown in 35 or 70 Pa CO₂ partial pressure for 163 days in naturally lit, controlled-environment chambers. Two soil N treatments (7 and 107 ppm total N, low-N and high-N treatments, respectively) were imposed by watering half the plants every 2 weeks with 15/15/18 fertilizer (N,P,K) and the other half with demineralized water. Direct effects of ambient CO₂ partial pressure on apparent dark respiration were measured during short-term manipulations (from minutes to hours) of the CO₂ environment surrounding the aboveground portion of individual seedlings. Short-term increases in the ambient CO₂ partial pressure consistently resulted in significant decreases in CO₂ efflux of seedling in all treatments. Efflux of CO₂ decreased by 3 to 13% when measurement CO₂ partial pressure was increased from 35 to 70 Pa, and by 8 to 46% over the entire measurement range from 0 to 100 Pa. No significant interactions between the indirect effects of growth CO₂ partial pressure and the direct effects of the measurement CO₂ partial pressure were found. Seedlings grown in the high-N treatment were significantly less sensitive to short-term changes in CO₂ partial pressures than seedlings grown in the low-N treatment. Apparent respiration tended to decrease in seedlings grown in elevated CO₂, but the decrease was not significant. Nitrogen had a large effect on CO₂ efflux, increasing apparent respiration more than twofold on both a leaf area and a leaf or shoot mass basis. Both the direct and indirect effects of elevated CO₂ were correlated with changes in the C/N ratio. A model of cumulative CO₂ efflux for a 160-day period demonstrated that, despite a 49% increase in total plant biomass, seedlings grown in the high-N + high-CO₂ treatment lost only 2% more carbon than seedlings grown in the high-N + low-CO₂ treatment, suggesting increased carbon use efficiency in plants grown in elevated CO₂. We conclude that small changes in instantaneous CO₂ efflux, such as those observed in ponderosa pine seedlings, could scale to large changes in carbon sequestration.

Griffin, K.L., M.A. Bashkin, R.B. Thomas, and B.R. Strain. 1997. Interactive effects of soil nitrogen and atmospheric carbon dioxide on root/rhizosphere carbon dioxide efflux from loblolly and ponderosa pine seedlings. *Plant and Soil* 190(1):11-18.

We measured CO₂ efflux from intact root/rhizosphere systems of 155 day old loblolly (*Pinus taeda* L.) and ponderosa (*Pinus ponderosa* Dougl. ex Laws.) pine seedlings in order to study the effects of elevated atmospheric CO₂ on the below-ground carbon balance of coniferous tree seedlings. Seedlings were grown in sterilized sand culture, watered daily with either 1, 3.5 or 7 mM NH₄⁺, and maintained in an atmosphere of either 35 or 70 Pa CO₂. Carbon dioxide efflux (μ mol CO₂ plant⁻¹ s⁻¹) from the root/rhizosphere system of both species significantly increased when seedlings were grown in elevated CO₂, primarily due to large increases in root mass. Specific CO₂ efflux (μ mol CO₂ g root⁻¹ s⁻¹) responded to CO₂ only under conditions of adequate soil nitrogen availability (3.5 mM). Under these conditions, CO₂ efflux rates from loblolly pine increased 70% from 0.0089 to 0.0151 μ mol g⁻¹ s⁻¹ with elevated CO₂ while ponderosa pine responded with a 59% decrease, from 0.0187 to 0.0077 μ mol g⁻¹ s⁻¹. Although below ground CO₂ efflux from seedlings grown in either sub-optimal (1 mM) or supra-optimal (7 mM) nitrogen availability did not respond to CO₂, there was a significant nitrogen treatment effect. Seedlings grown in supra-optimal soil nitrogen had significantly increased specific CO₂ efflux rates, and significantly lower total biomass compared to either of the other two nitrogen treatments. These results indicate that carbon losses from the root/rhizosphere systems are responsive to environmental

resource availability, that the magnitude and direction of these responses are species dependent, and may lead to significantly different effects on whole plant carbon balance of these two forest tree species.

Griffin, K.L., and Y.Q. Luo. 1999. Sensitivity and acclimation of Glycine max (L.) Merr. leaf gas exchange to CO₂ partial pressure. *Environmental and Experimental Botany* 42(2):141-153.

Theoretical studies suggest that partitioning leaf photosynthetic responses to CO₂ partial pressures into two components, sensitivity and acclimation, facilitates both scaling-up photosynthetic responses and predicting global terrestrial carbon influx. Here, we experimentally examine these two components by growing soybean (Glycine max) in two CO₂ partial pressures, 35 and 70 Pa, and making a suite of ecophysiological measurements on expanding and fully expanded leaves. These CO₂ treatments resulted in a variety of acclimation responses, including changes in net photosynthetic rate and capacity, stomatal conductance, transpiration, and respiration. These responses were strongly dependent on leaf age. Despite the wide variety of acclimation responses, the experimentally derived photosynthetic sensitivity did not vary with CO₂ treatments or leaf age. In addition, the photosynthetic sensitivity to ambient CO₂ partial pressure was consistent with the sensitivity to intercellular CO₂ partial pressure, indicating little effect of stomatal conductance on photosynthetic sensitivity. This study supports the theoretical conclusion that photosynthetic sensitivity is independent of growth environment and leaf age, as well as photosynthetic acclimation, even though the latter varies with both environmental and developmental factors. Accordingly, photosynthetic sensitivity may be directly extrapolated from leaf to globe to predict the increment in terrestrial carbon influx stimulated by the yearly increase in atmospheric CO₂, whereas the acclimation component must be used to adjust the overall global estimate. Griffin, K.L., P.D. Ross, D.A. Sims, Y. Luo, J.R. Seemann, C.A. Fox, and J.T. Ball. 1996. EcoCELLs: Tools for mesocosm scale measurements of gas exchange. *Plant, Cell and Environment* 19(10):1210-1221.

We describe the use of a unique plant growth facility, which has as its centerpiece four 'EcoCELLs', or 5x7 m mesocosms designed as open-flow, mass-balance systems for the measurement of carbon, water and trace gas fluxes. This system is unique in that it was conceived specifically to bridge the gap between measurement scales during long-term experiments examining the function and development of model ecosystems. There are several advantages to using EcoCELLs, including (i) the same theory of operation as leaf level gas exchange systems, but with continuous operation at a much larger scale; (ii) the ability to independently evaluate canopy-level and ecosystem models; (iii) simultaneous manipulation of environmental factors and measurement of system-level responses, and (iv) maximum access to, and manipulation of, a large rooting volume. In addition to discussing the theory, construction and relative merits of EcoCELLs, we describe the calibration and use of the EcoCELLs during a 'proof of concept' experiment. This experiment involved growing soybeans under two

ambient CO₂ concentrations (similar to 360 and 710 $\mu\text{mol mol}^{-1}$). During this experiment, we asked 'How accurate is the simplest model that can be used to scale from leaf-level to canopy-level responses?' in order to illustrate the utility of the EcoCELLs in validating canopy-scale models.

Griffin, K.L., and J.R. Seemann. 1996. Plants, CO₂ and photosynthesis in the 21st century. *Chemistry & Biology* 3(4):245-254.

Human activity in the last 200 years has led to a marked increase in the level of CO₂ in the atmosphere. Plants sense increases in CO₂ levels and initially respond with an increase in photosynthetic rate, which may then slow as the plant adapts. This increase in photosynthetic rate may account in part for the 'disappearance' of an estimated 1.8 gigatons of carbon per year.

Griffin, K.L., D.A. Sims, and J.R. Seemann. 1999. Altered night-time CO₂ concentration affects the growth, physiology and biochemistry of soybean. *Plant, Cell and Environment* 22(1):91-99.

Soybean plants (Glycine max (L.) Merr. c. v. Williams) were grown in CO₂ controlled, natural-light growth chambers under one of four atmospheric CO₂ concentrations ([CO₂]): (1) 250 $\mu\text{mol mol}^{-1}$ 24 h d(-1) [250/250]; (2) 1000 $\mu\text{mol mol}^{-1}$ 24 h d(-1) [1000/1000]; (3) 250 $\mu\text{mol mol}^{-1}$ during daylight hours and 1000 $\mu\text{mol mol}^{-1}$ during nighttime hours [250/1000] or (4) 1000 $\mu\text{mol mol}^{-1}$ during daylight hours and 250 $\mu\text{mol mol}^{-1}$ during night-time hours [1000/250]. During the vegetative growth phase few physiological differences were observed between plants exposed to a constant 24 h [CO₂] (250/250 and 1000/1000) and those that were switched to a higher or lower [CO₂] at night (250/1000 and 1000/250), suggesting that the primary physiological responses of plants to growth in elevated [CO₂] is apparently a response to daytime [CO₂] only. However, by the end of the reproductive growth phase, major differences were observed. Plants grown in the 1000/250 regime, when compared with those in the 1000/1000 regime, had significantly more leaf area and leaf mass, 27% more total plant dry mass, but only 18% of the fruit mass. After 12 weeks of growth these plants also had 19% higher respiration rates and 32% lower photosynthetic rates than the 1000/1000 plants. As a result the ratio of carbon gain to carbon loss was reduced significantly in the plants exposed to the reduced night-time [CO₂]. Plants grown in the opposite switching environment, 250/1000 versus 250/250, showed no major differences in biomass accumulation or allocation with the exception of a significant increase in the amount of leaf mass per unit area. Physiologically, those plants exposed to elevated night-time [CO₂] had 21% lower respiration rates, 14% lower photosynthetic rates and a significant increase in the ratio of carbon gain to carbon loss, again when compared with the 250/250 plants. Biochemical differences also were found. Ribulose-1,5-bisphosphate carboxylase/ oxygenase concentrations decreased in the 250/1000 treatment compared with the 250/250 plants, and phosphoenolpyruvate carboxylase activity decreased in the 1000/250 compared with the 1000/1000 plants. Glucose, fructose and to a lesser extent sucrose concentrations also were reduced in the 1000/250 treatment compared with the 1000/1000 plants. These results

indicate that experimental protocols that do not maintain elevated CO₂ levels 24 h d⁻¹) can have significant effects on plant biomass, carbon allocation and physiology, at least for fast-growing annual crop plants. Furthermore, the results suggest some plant processes other than photosynthesis are sensitive to [CO₂] and under ecologically relevant conditions, such as high night-time [CO₂], whole plant carbon balance can be affected.

Griffin, K.L., R.B. Thomas, and B.R. Strain. 1993. Effects of nitrogen supply and elevated carbon-dioxide on construction cost in leaves of *pinus-taeda* (L) seedlings. *Oecologia* 95(4):575-580.

Seedlings of loblolly pine (*Pinus taeda* L.) were grown under varying conditions of soil nitrogen and atmospheric carbon dioxide availability to investigate the interactive effects of these resources on the energetic requirements for leaf growth. Increasing the ambient CO₂ partial pressure from 35 to 65 Pa increased seedling growth only when soil nitrogen was high. Biomass increased by 55% and photosynthesis increased by 13% after 100 days of CO₂ enrichment. Leaves from seedlings grown in high soil nitrogen were 7.0% more expensive on a g glucose g⁻¹ dry mass basis to produce than those grown in low nitrogen, while elevated CO₂ decreased leaf cost by 3.5%. Nitrogen and CO₂ availability had an interactive effect on leaf construction cost expressed on an area basis, reflecting source-sink interactions. When both resources were abundant, leaf construction cost on an area basis was relatively high (81.8 +/- 3.0 g glucose m⁻²) compared to leaves from high nitrogen, low CO₂ seedlings (56.3 +/- 3.0 g glucose m⁻²) and low nitrogen, low CO₂ seedlings (67.1 +/- 2.7 g glucose m⁻²). Leaf construction cost appears to respond to alterations in the utilization of photoassimilates mediated by resource availability.

Griffin, K.L., W.E. Winner, and B.R. Strain. 1995. Growth and dry-matter partitioning in loblolly and ponderosa pine-seedlings in response to carbon and nitrogen availability. *New Phytologist* 129(4):547-556.

We grew loblolly pine (*Pinus taeda* L.) and ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) seedlings in a factorial experiment with two CO₂ partial pressures (35 and 70 Pa) and two nitrogen treatments (1.0 and 3.5 mM NH₄⁺) for one growing season in a 'common garden' experiment designed to examine the extent that dry matter and nitrogen accumulation and partitioning are environmentally controlled. Ponderosa pine seedlings grown in 35 Pa CO₂ and 3.5 mM NH₄⁺ showed symptoms of nitrogen toxicity, characterized by greatly reduced growth, and moderately reduced total plant N. With the exception of this treatment combination, there were no significant differences between species in total plant dry matter or total plant nitrogen, suggesting that responses of growth to environmental conditions were stronger than heritable responses. There were however large differences in dry matter and N partitioning between the two species. Increases in leaf mass were largest in loblolly pine, whilst ponderosa pine tended to have higher root:shoot (R:S) ratios. R:S ratio of loblolly increased in response to C availability and decreased in response to N availability, whilst R: S ratio of ponderosa pine was much less responsive to resource availability.

Total plant N varied with N supply, and N partitioning was related to plant growth and carbon partitioning. Carbon and N were interactive, such that an increase in the accumulation of either resource was always accompanied by an increase in the other. Over several seasons the different patterns of resource acquisition and biomass allocation that we observed in a uniform environment could potentially result in different growth rates at most resource levels. In the first season, contrary to our expectations, heritable differences in growth rate did not appear.

Griffin, K.L., W.E. Winner, and B.R. Strain. 1996. Construction cost of loblolly and ponderosa pine leaves grown with varying carbon and nitrogen availability. *Plant, Cell and Environment* 19(6):729-739.

We grew loblolly and ponderosa pine seedlings in a factorial experiment with two CO₂ partial pressures (35 and 70 Pa), and two nitrogen treatments (1.0 and 3.5 mol m⁻³ NH₄⁺), for one growing season to examine the effects of carbon and nitrogen availability on leaf construction cost. Growth in elevated CO₂ reduced leaf nitrogen concentrations by 17 to 40%, and increased C:N by 22 to 68%. Elevated N availability increased leaf N concentrations and decreased C:N. Non-structural carbohydrates increased in high-CO₂-grown loblolly seedlings, except in fascicles from low N, and in ponderosa primary and fascicle leaves grown in high N. In loblolly, increases in starch were nearly 2-fold greater than the increases in soluble sugars. In ponderosa, only the soluble sugars were affected by CO₂. Leaf construction cost (g glucose g⁻¹ dm) varied by 9.3% across all treatments. All of the variation in loblolly leaf construction cost could be explained by changes in non-structural carbohydrates. A model of the response of construction cost to changes in the mass of different biochemical fractions suggests that the remainder of the variation in ponderosa, not explained by non-structural carbohydrates, is probably attributable to changes in lignin, phenolic or protein concentrations.

Griffiths, B.S., K. Ritz, N. Ebbelwhite, and G. Dobson. 1999. Soil microbial community structure: Effects of substrate loading rates. *Soil Biology and Biochemistry* 31(1):145-153.

A fuller understanding of the interactions which affect rhizosphere microbial community structure requires experimental manipulation of the individual components of that interaction (e.g. amount and composition of exudate, soil moisture and soil nutrient status). We describe an experiment where a synthetic root exudate was applied continuously to a soil held at constant water potential. The solution contained compounds characteristic of root exudates (fructose, glucose, sucrose, succinic acid, malic acid, arginine, serine and cysteine), which were added at a range of concentrations. After 14 d of such substrate addition, a central portion of soil, known to be influenced by the added substrate, was removed for analysis. Microbial community structure of this central core was determined by the broad-scale measurements; community DNA hybridisation and % G + C profiling, and phospholipid-fatty acid analysis (PLFA). The trend was that microbial community structure changed consistently as substrate loading increased, and that fungi dominated over bacteria at high substrate loading rates. The DNA and the PLFA analyses both indicated that there was a coherent gradient of changes with increased substrate loading. This may have arisen as a consequence of the competitive ability of soil microorganisms being

dependent on the quantity of available substrate. (C) 1998 Elsevier Science Ltd. All rights reserved.

Griffiths, B.S., K. Ritz, N. Ebbelwhite, E. Paterson, and K. Killham. 1998. Ryegrass rhizosphere microbial community structure under elevated carbon dioxide concentrations, with observations on wheat rhizosphere. *Soil Biology and Biochemistry* 30(3):315-321.

The structure of microbial communities in the rhizospheres of ryegrass and wheat, growing at an elevated atmospheric CO₂ concentration, was investigated using broad-scale DNA techniques. Community DNA hybridisation and %G + C base profiling by thermal denaturation assess changes at the whole microbial community level. DNA analysis of the rhizosphere of ryegrass grown in soil microcosms for 28 or 42 d, showed only minor differences between plants grown at 450 or 720 μ l CO₂ l⁻¹. In a second experiment with ryegrass, 5 of 10 replicate microcosms were pulse labelled with (CO₂)-C-14 and 5 simultaneously sampled for DNA analysis. Carbon partitioning below ground showed changes due to the elevated CO₂, notably an increased proportion of fixed carbon in non-microbial biomass residue in the rhizosphere. There was again no effect of elevated CO₂ on rhizosphere microbial community structure. Community DNA hybridisation indicated that the rhizosphere communities under ambient and elevated CO₂ were 86% similar (unlikely to be a biologically relevant change), with indistinguishable %G + C profiles. Wheat was grown to maturity (129 d) in a different soil microcosm design, and rhizosphere microbial communities from plants grown at 350 and 700 μ l CO₂ l⁻¹ were identical according to the DNA analyses. In these experiments rhizosphere microbial community structure at the broad scale was unaffected by the interactions occurring below ground as a result of elevated concentrations of CO₂. RossFraser, R.E. Spencer, F. Sutton, D.E. Tasker, P.C. Thorpe, and J. Whitehouse. 1997. Integrated screening validates primary axes of specialisation in plants. *Oikos* 79(2):259-281.

Standardised procedures have been used to measure 67 traits in 43 common plants of the British flora. This paper provides an interpretation of the most consistent patterns in the resulting matrix by means of correlation, ordination and classification analyses. Only a weak coupling was observed between attributes of the regenerative and established phases of the life history. However, within each phase, attributes were strongly aggregated into sets and a high proportion of the variation between species coincided with a single axis. Attributes of the established phase displayed remarkably consistent trends, with a strong 'Axis 1' being identified by three different multivariate methods. There was a marked correlation between foliar concentrations of N, P, K, Ca and Mg, high concentrations of which coincided with the capacity for rapid growth in productive conditions and an inability to sustain yield

under limiting supplies of nutrients. A diverse array of other traits, less immediately involving mineral nutrients, were also entrained in Axis 1; these included life history, root and shoot foraging, the morphology, longevity, tensile strength and palatability of leaves, and the decomposition rate of leaf litter. This pattern occurred in both monocotyledons and dicotyledons and appeared to reflect a tradeoff between attributes conferring an ability for high rates of resource acquisition in productive habitats and those responsible for retention of resource capital in unproductive conditions. The second axis of variation evident in the established phase was related to phylogeny and distinguished between monocotyledons and dicotyledons on the basis of a diverse set of traits including genome size, cell size, root and shoot foraging characteristics and vascular tissues. A third axis was detected in which ephemerals and perennials were separated by differences in attributes such as breeding system, leaf decomposition rate and a set of traits reflecting the small stature of many short-lived plants. In the regenerative phase, the leading axis was clearly related to the widely recognised tradeoff between seed size and seed number and was consistent with current understanding of seed banks, and with modern theories explaining species coexistence in terms of complementary responses to temporal and spatial variation in vegetation gap dynamics. The data provide strong evidence of functional integration between evolutionary specialisations in root and shoot and support Donald's unified theory of competitive ability. The data are not consistent with theories of functional types based upon evolutionary tradeoffs in allocation between root and shoot. We suggest that the evidence assembled here and elsewhere in the current literature points to the existence of primary functional types, including those recognised by Ramenskii and Grime. These functional types can be reconciled with the individuality of plant ecologies in the field and provide an effective basis for interpretation and prediction at various scales from the plant community to regional floras. There are particular opportunities for prediction of successional trajectories, the role of herbivores in vegetation succession and the response of vegetation to eutrophication and extreme climatic events. It is also suggested that aspects of this investigation may provide a Darwinian underpinning for Odum's theory of ecosystem maturation.

Grimm, A.G., and J. Fuhrer. 1992. The response of spring wheat (*Triticum aestivum* L.) to ozone at higher elevations .1. Measurement of ozone and carbon-dioxide fluxes in open-top field chambers. *New Phytologist* 121(2):201-210.

The flux of O₃ was determined in open-top chambers (OTC) used to investigate its effect on spring wheat (*Triticum aestivum* L., cv. Albis) in 1989 and 1990. The experimental site was located at 900 m above sea level at Zimmerwald, near Bern (Switzerland). The aims were to evaluate the use of OTCs for O₃ flux measurements under field conditions, to assess the role of stomata in controlling the O₃ fluxes, and to establish a quantitative relationship between radiation-weighted O₃ concentrations and O₃ flux. Measurements were carried out from full expansion of flag leaves until the onset of senescence. Ozone flux was determined by mass balance using the concentrations of O₃ measured at the inlet and outlet of the OTC. The CO₂ exchange rate was corrected for soil-borne CO₂ and used as a reference. Measurements of temperature, photosynthetically active radiation (PAR), saturated water vapour pressure deficit (SVPD), and boundary layer conductance were used to describe the microclimate inside OTCs. In the warmer microclimate in 1989, the plant canopy was characterized by a smaller leaf area index (LAI) than in 1990, while the fluxes of O₃ and CO₂ during daytime were generally larger in 1989. The diurnal patterns of

fluxes of O₃ and CO₂ in OTCs supplied with unfiltered air were similar. It is estimated that O₃ absorption via the stomata contributed 50-70 % of its total flux. Identical relationships between leaf conductance for O₃ measured by porometry and leaf conductance calculated from O₃ flux were found in both years, but measured leaf conductance during daytime was generally smaller in 1990 than in 1989. The results indicate that stomatal conductance largely controlled O₃ flux, and that the canopy structure has an influence on the overall conductance of the canopy. Different linear functions were obtained for the relationship between radiation-weighted O₃ concentration and O₃ flux, using data from OTCs supplied with either charcoal-filtered air, unfiltered air or unfiltered air enriched with O₃ (two levels). These relationships form the basis for the calculation of mean O₃ fluxes which can be used as an exposure index in the exposure-response analysis.

Grimmer, C., T. Bachfischer, and E. Komor. 1999. Carbohydrate partitioning into starch in leaves of *Ricinus communis* L.-grown under elevated CO₂ is controlled by sucrose. *Plant, Cell and Environment* 22(10):1275-1280.

Ricinus communis plants were grown under normal (350 ppm) and elevated (700 ppm) CO₂ atmosphere and the growth and carbohydrate status of leaf 2 (first leaf above the pair of primary leaves) was studied. Elevated carbon dioxide stimulated the growth of leaves 1.7-fold. The glucose and fructose concentrations exhibited the same diurnal rhythm under both growth conditions. The sucrose concentrations stayed relatively constant and at 700 ppm were one-third higher than at 350 ppm. The starch content increased steadily during the day and disappeared overnight at 350 ppm CO₂, but remained partially in plants at 700 ppm CO₂. Consequently at 700 ppm CO₂, the leaves accumulated starch continuously over their life time. The rate of starch synthesis was correlated to the activity of ADP- glucose pyrophosphorylase, which was related to the sucrose concentration in the leaf. It is concluded that sucrose controls the expression of ADP-glucose pyrophosphorylase, leading to a shift of carbohydrate partitioning into starch when more sucrose is produced than consumed or exported, a situation which is especially pertinent at elevated CO₂. These results show that the previously experimentally observed transcriptional regulation of starch synthesis by sucrose occurs in vivo in the daily life of a leaf.

Grimmer, C., and E. Komor. 1999. Assimilate export by leaves of *Ricinus communis* L. growing under normal and elevated carbon dioxide concentrations: the same rate during the day, a different rate at night. *Planta* 209(3):275-281.

Castor bean (*Ricinus communis* L.) plants were grown for 5-7 weeks in a controlled environment at 350 μ mol l⁻¹ or 700 μ mol l⁻¹ CO₂. Carbon assimilation, assimilate deposition, dark respiration and assimilate mobilization were measured in leaves 2, 3 and 4 (counted from the base of the plant), and a balance sheet of carbon input and export was elaborated for both CO₂ concentrations. Carbon dioxide assimilation was nearly constant over the illumination period, with only a slight depression occurring at the end of the day in mature source leaves, not in young source leaves. Assimilation was ca. 40% higher at 700 μ mol l⁻¹ than at 350 μ mol l⁻¹ CO₂. The source leaves increased steadily in weight per unit area during the first 3 weeks, more at 700 μ mol l⁻¹ than at 350 μ mol l⁻¹ CO₂. On top of an irreversible weight increase, there was a large gain in dry weight during the day, which was reversed during the night. This reversible weight gain was constant over the life time of the leaf and ca. 80% higher at 700 μ mol l⁻¹ than at 350 μ mol l⁻¹. Most of it was due to carbohydrates. The carbon content (as a percentage) was not altered by the CO₂ treatment. Respiration was 25% higher in high-CO₂ plants when based on leaf area, but the same when based on dry weight. The rate of carbon export via the phloem was the same during the daytime in plants grown at 350 μ mol l⁻¹ and 700 μ mol l⁻¹ CO₂. During the night the low-CO₂ plants had only 50% of the daytime export rate, in contrast to the high-CO₂ plants which maintained the high export rate. It was concluded that the phloem loading system is saturated during the daytime in both CO₂ regimes, whereas during the night the assimilate supply is reduced in plants in the normal CO₂ concentration. Two-thirds of the carbon exported from the leaves was permanently incorporated as plant dry matter in the residual plant parts. This "assimilation efficiency" was the same for both CO₂ regimes. It is speculated that under 350 μ mol l⁻¹ CO₂ the growing *Ricinus* plant operates at sink limitation during the day and at source limitation during the night.

Grobelaar, N., W.M. Chou, and T.C. Huang. 1992. Effect of CO₂, O₂, DCMU, FCCP, and DL-glyceraldehyde on the nitrogenase activity of *Synechococcus* RF-1. *Botanical Bulletin of Academia Sinica* 33(2):167-174.

Elevated atmospheric CO₂ concentrations drastically inhibit nitrogenase activity of the unicellular *Synechococcus* RF-1 but stimulate photosynthetic CO₂ assimilation. The inhibitory effect on nitrogenase activity is stronger in the light than in the dark. During three hours, 1% CO₂ in air can reduce nitrogenase activity in the light by about 50% compared to that in unenriched air. The inhibitory effect of elevated CO₂ concentrations on nitrogenase activity persists for many hours after the organism has been returned to air not enriched with CO₂. The nitrogenase activity of heterocystous cyanobacteria, generally, does not appear to be affected by 5% CO₂ in the air. DCMU strongly enhanced nitrogenase activity and inhibited the assimilation of CO₂ by *Synechococcus* RF-1 in the light, and elevated atmospheric O₂ concentrations reduced the nitrogenase activity, especially in the dark. DL-glyceraldehyde at a concentration of 19.4 mM strongly inhibited nitrogenase activity, dark respiration, and photosynthesis. FCCP had no effect on dark respiration but depressed nitrogenase activity and photosynthesis of *Synechococcus* RF-1. The inhibitory effect of FCCP on nitrogenase activity was stronger in the dark than in the light.

Grodzinski, B., J.R. Jiao, and E.D. Leonardos. 1998. Estimating photosynthesis and concurrent export rates in C-3 and C-4 species at ambient and elevated CO₂. *Plant Physiology* 117(1):207-215.

The ability of 21 C-3 and C-4 monocot and dicot species to rapidly export newly fixed C in the light at both ambient and enriched CO₂ levels was compared. Photosynthesis and concurrent export rates were estimated during isotopic equilibrium of the transport sugars using a steady-state (CO₂)-C-14-labeling procedure. At ambient CO₂ photosynthesis and export rates for C-3 species were 5 to 15 and 1 to 10 $\mu\text{mol C m}^{-2} \text{ s}^{-1}$, respectively, and 20 to 30 and 15 to 22 $\mu\text{mol C m}^{-2} \text{ s}^{-1}$, respectively, for C-4 species. A linear regression plot of export on photosynthesis rate of all species had a correlation coefficient of 0.87. When concurrent export was expressed as a percentage of photosynthesis, several C-3 dicots that produced transport sugars other than Suc had high efflux rates relative to photosynthesis, comparable to those of C-4 species. At high CO₂ photosynthetic and export rates were only slightly altered in C₃ species, and photosynthesis increased but export rates did not in all C₃ species. The C-3 species that had high efflux rates relative to photosynthesis at ambient CO₂ exported at rates comparable to those of C-4 species on both an absolute basis and as a percentage of photosynthesis. At ambient CO₂ there were strong linear relationships between photosynthesis, sugar synthesis, and concurrent export. However, at high CO₂ the relationships between photosynthesis and export rate and between sugar synthesis and export rate were not as strong because sugars and starch were accumulated.

Grodzinski, B., L. Woodrow, E.D. Leonardos, M. Dixon, and M.J. Tsujita. UNKNOWN YEAR. Plant responses to short- and long-term exposures to high carbon dioxide levels in closed environments. *Natural and Artificial Ecosystems* :203-211.

When higher plants are exposed to elevated levels of CO₂ for both short- and long-term periods photosynthetic C-gain and photoassimilate export from leaves are generally increased. Water use efficiency is increased on a leaf area basis. During long-term exposures, photosynthesis rates on leaf and whole plant bases are altered in a species specific manner. The most common pattern in C-3 plants is an enhanced rate of whole plant photosynthesis in a well irradiated canopy. Nevertheless, in some herbaceous species prolonged exposure to high CO₂ results in remobilization of nitrogenous reserves (i.e., leaf protein degradation) and reduced rates of mature leaf photosynthesis when assayed at ambient CO₂ and O-2 levels. Both short- and long-term exposures to those CO₂ levels (i.e., 100 to 2,000 $\mu\text{mol l}^{-1}$) which modify photosynthesis and export, also modify both endogenous ethylene gas (C₂H₄) release, and substrate, 1- aminocyclopropane-1-carboxylic acid (ACC), saturated C₂H₄ release rates from irradiated leaves. Photosynthetically active canopy leaves contribute most of the C₂H₄ released from the canopy. Prolonged growth at high CO₂ results in a persistent increase in the rate of endogenous C₂H₄ release from leaves which can, only in part, be attributed to the increase of the endogenous pools of C₂H₄ pathway intermediates (e.g., methionine, M-ACC, and ACC). The capacity for increasing the rate of C₂H₄ release in response to short-term exposures to varying CO₂ levels does not decline after prolonged growth at high CO₂. When leaves, whole plants, and model canopies of tomato plants are exposed to exogenous C₂H₄ a reduction in the rate of photosynthesis can, in each case, be attributed to the classical effects of C₂H₄ on plant development and morphology. The effect of C₂H₄ on CO₂ gas exchange of plant canopies is shown to be dependent on the canopy leaf area index.

Groninger, J.W., K.H. Johnsen, J.R. Seiler, R.E. Will, D.S. Ellsworth, and C.A. Maier. 1999. Elevated carbon dioxide in the atmosphere - What might it mean for loblolly pine plantation forestry? *Journal of Forestry* 97(7):4-10.

Research with loblolly pine suggests that projected increases in atmospheric CO₂ concentration will accelerate early growth and could result in shorter rotation length, reduced time until first commercial thinning, higher optimal planting density, and possibly higher maximum stocking level in managed stands. We discuss some of the physiological processes and stand dynamics that underlie these changes, as well as silvicultural strategies that may serve to ensure sustainability of intensively managed forest systems in the face of increasing CO₂ and possible climate change.

Groninger, J.W., J.R. Seiler, S.M. Zedaker, and P.C. Berrang. 1995. Effects of elevated CO₂, water-stress, and nitrogen level on competitive interactions of simulated loblolly-pine and sweetgum stands. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 25(7):1077-1083.

Loblolly pine (*Pinus taeda* L.) and sweetgum (*Liquidambar styraciflua* L.) were grown in mixed stands and in monocultures at 2.54 X 2.54 cm spacing in controlled-environment chambers. Treatments consisted of present (ambient) and projected future (ambient + 400 ppm) carbon dioxide (CO₂) concentrations, drought-stressed, and well-watered conditions, and low (20 kg N/ha) and high (474 kg N/ha) nitrogen application rates. After two accelerated growing cycles, total biomass of both species was significantly greater under elevated CO₂. No significant interactions between CO₂ concentration and water availability, nitrogen availability, or stand type were observed. Competitive interactions between loblolly pine and sweetgum were strongly influenced by water availability, but not CO₂ concentration. Assessment of species response to CO₂ was dependent upon growth in monoculture or mixture. Under low water availability, data from monocultures suggested that sweetgum had a stronger growth response to elevated CO₂ concentrations than loblolly pine. In contrast, results from mixed-species stands showed that the competitive status of loblolly pine and sweetgum did not change under the high CO₂ concentration. These results underscore the value of growing co-occurring species in mixed stands under varying levels of multiple resources for the determination of relative performance under future environments.

Groninger, J.W., J.R. Seiler, S.M. Zedaker, and P.C. Berrang. 1996. Effects of CO₂ concentration and water availability on growth and gas exchange in greenhouse-grown miniature stands of Loblolly Pine and Red Maple. *Functional Ecology* 10(6):708-716.

1. The study assesses the effects of atmospheric CO₂ concentration and water availability on stand development and photosynthetic characteristics of Loblolly Pine (*Pinus taeda*) and Red Maple (*Acer rubrum*). Miniature stands of these species were grown from seed in monoculture and in a 50:50 replacement mixture for two accelerated growing seasons. 2. Both species had greater biomass under the higher

levels of CO₂ and water availability. Biomass of Loblolly Pine seedlings in mixed stands exceeded that in monocultures, while the opposite was true for Red Maple. No significant treatment interactions were detected for total biomass. Significant main effects for water and stand type were detected for stem height of Loblolly Pine. CO₂, water and stand type interactions were observed for height of Red Maple. 3. Net photosynthetic rates were measured on miniature stand canopies and constituent seedlings from these stands. Both species exhibited higher photosynthetic rates under elevated CO₂. However, expression of photosynthesis on a leaf mass or soil area basis affected conclusions regarding the role of water availability on stand-level response to elevated CO₂.

Groninger, J.W., J.R. Seiler, S.M. Zedaker, and P.C. Berrang. 1996. Photosynthetic response of loblolly pine and sweetgum seedling stands to elevated carbon dioxide, water stress, and nitrogen level. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 26(1):95-102.

Seedling stands of loblolly pine (*Pinus taeda* L.) and sweetgum (*Liquidambar styraciflua* L.) were grown in monoculture or mixed stands for two growing cycles in controlled-environment chambers. Treatments consisted of ambient (408 ppm) and elevated (806 ppm) CO₂ concentrations, water-stressed and well-watered conditions, and low (20 kg N/ha) and high (215 kg N/ha) nitrogen application rates. Photosynthesis rates were measured under ambient and elevated CO₂ concentrations for both whole stands and individual seedlings from these stands. Significant interactions between CO₂ and water suggested that elevated CO₂ concentration compensated for low water availability in individually measured loblolly pine and in whole seedling stands regardless of stand type. Expressing photosynthesis on a soil area versus a leaf-mass basis influenced the photosynthetic rankings of the three stand types relative to one another. Net photosynthetic rates per unit leaf mass were 390 and 880% higher in individually measured seedlings than in whole monoculture stands for loblolly pine and sweetgum, respectively. Lower photosynthetic contributions from lower canopy leaves in whole seedling stands compared with the upper canopy leaves used in individual-seedling measurements were thought to be responsible for lower photosynthetic rates in seedling stands. These results suggest that photosynthetic response is influenced by canopy dynamics that are unaccounted for by individual-seedling measurements of photosynthesis. Differences in photosynthetic response between loblolly pine and sweetgum stands and individuals are thought to be largely due to species-specific differences in canopy light extinction characteristics.

Gross, U., F. Gilles, L. Bender, P. Berghofer, and K.H. Neumann. 1993. The influence of sucrose and an elevated CO₂ concentration on photosynthesis of photoautotrophic peanut (*arachis-hypogaea* L.) cell-cultures. *Plant Cell Tissue and Organ Culture* 33(2):143-150.

Using photoautotrophic cells of *Arachis hypogaea* (L.) growing at ambient CO₂, it was shown that exogenous sucrose supplied to the liquid medium reduced (CO₂)-C-14 fixation (supplied as NaH(CO₃)-C-14). This was mostly due to a reduced labelling in P-esters, and to a

lesser extent, in the serine/glycine moiety. However, radioactivity in the neutral sugar fraction was increased upon supplement of exogenous sucrose. The reduced labelling of P-esters and serine/glycine agrees with a lower concentration and specific activity of Rubisco in the sucrose supplied treatments as compared to the control. Following a transfer into a sugar free nutrient medium the concentration and activity of Rubisco is increased. The concentration of PEPCase was not influenced by sucrose application, although its specific activity was increased. At elevated CO₂ concentration (2.34% v/v) the Rubisco concentration and specific activity was at the same level as in the control (0.03% V/V CO₂). However, the concentration and the specific activity of PEPCase was increased and dry weight increase was about 8-9-fold higher than at ambient CO₂.

Grossman, S., T. Kartschall, B.A. Kimball, D.J. Hunsaker, R.L. LaMorte, R.L. Garcia, G.W. Wall, and P.J. Pinter. 1995. Simulated responses of energy and water fluxes to ambient atmosphere and free-air carbon dioxide enrichment in wheat. *Journal of Biogeography* 22(4-5):601-609.

Increased ambient carbon dioxide has been associated with CO₂-induced stomatal closure which affects growth and evapotranspiration of crop canopies. This results in changes of the energy balance components of the soil-plant-atmosphere system. The agroecosystem wheat model DEMETER was linked to a soil-vegetation-atmosphere-transfer module which includes the energy balance of the crop canopy and the energy balance of the soil surface. Thus, it was possible to calculate evapotranspiration, canopy temperature and the changed ratio of sensible and latent heat fluxes in response to elevated atmospheric CO₂ concentrations. The free-air carbon dioxide enrichment (FACE) technique provided a largely undisturbed regime for atmospheric exchange. During the FACE wheat experiment at Maricopa in 1992-93, the effects of elevated atmospheric CO₂ concentrations on energy balance and evapotranspiration of the wheat canopy at about 350-370 $\mu\text{mol/mol}$ (control) and 550 $\mu\text{mol/mol}$ (FACE) were investigated. The recorded data were used for model validation. Diurnal trends of all energy balance components and the canopy temperature were simulated for FACE and control conditions using hourly weather data. Results were compared with the observed data on 16 March 1993. Simulated cumulative seasonal evapotranspiration was found in good accordance to the observed one. Consistent with observations, the simulations suggest that there was a small reduction in evapotranspiration of about 4%. Of course, with the observed increases in growth, there were even larger increases in water use efficiency.

Grossman-Clarke, S., B.A. Kimball, D.J. Hunsaker, S.P. Long, R.L. Garcia, T. Kartschall, G.W. Wall, P.J. Pinter, F. Wechsung, and R.L. LaMorte. 1999. Effects of elevated atmospheric CO₂ on canopy transpiration in senescent spring wheat. *Agricultural and Forest Meteorology* 93(2):95-109.

The seasonal course of canopy transpiration and the diurnal courses of latent heat flux of a spring wheat crop were simulated for atmospheric CO₂ concentrations of 370 and 550 $\mu\text{mol/mol}$ (-1). The hourly weather data, soil parameters and the irrigation and fertilizer treatments of the Free-Air Carbon Dioxide Enrichment wheat experiment in Arizona (1992-1993) were used to drive the model. The simulation results were tested against field measurements with special emphasis on the period

between anthesis and maturity. A model integrating leaf photosynthesis and stomatal conductance was scaled to canopy level in order to be used in the wheat growth model. The simulated intercellular CO₂ concentration, C_i, was determined from the ratio of C_i to the CO₂ concentration at the leaf surface, C_s, the leaf-to-air specific humidity deficit and a possibly unfulfilled transpiration demand. After anthesis, the measured assimilation rates of the flag leaves decreased more rapidly than their stomatal conductances, leading to a rise in the C_i/C_s ratio. In order to describe this observation, an empirical model approach was developed which took into account the leaf nitrogen content for the calculation of the C_i/C_s ratio. Simulation results obtained with the new model version were in good agreement with the measurements. If changes in the C_i/C_s ratio in accordance with the decrease in leaf nitrogen content during leaf senescence were not considered in the model, simulations revealed an underestimation of the daily canopy transpiration of up to 20% and a decrease in simulated seasonal canopy transpiration by 10%. The measured reduction in the seasonal sum of canopy transpiration and soil evaporation owing to CO₂ enrichment, in comparison, was only about 5%. (C) 1999 Elsevier Science B.V. All rights reserved.

Grotenhuis, T.P., and B. Bugbee. 1997. Super-optimal CO₂ reduces seed yield but not vegetative growth in wheat. *Crop Science* 37(4):1215-1222.

Although terrestrial atmospheric CO₂ levels will not reach 1000 μmol mol⁻¹ (0.1%) for decades, CO₂ levels in growth chambers and greenhouses routinely exceed that concentration. CO₂ levels in life support systems in space can exceed 10 000 μmol mol⁻¹ (1%). Numerous studies have examined CO₂ effects up to 1000 μmol mol⁻¹, but biochemical measurements indicate that the beneficial effects of CO₂ can continue beyond this concentration. We studied the effects of near-optimal (approximate to 1200 μmol mol⁻¹) and super-optimal CO₂ levels (2400 μmol mol⁻¹) on yield of two cultivars of hydroponically grown wheat (*Triticum aestivum* L.) in 12 trials in growth chambers. Increasing CO₂ from sub-optimal to near-optimal (350-1200 μmol mol⁻¹) increased vegetative growth by 25% and seed yield by 15% in both cultivars. Yield increases were primarily the result of an increased number of heads per square meter. Further elevation of CO₂ to 2500 μmol mol⁻¹ reduced seed yield by 22% ($P < 0.001$) in cv. Veery-10 and by 15% ($P < 0.001$) in cv. USU-Apogee. Super-optimal CO₂ did not decrease the number of heads per square meter, but reduced seeds per head by 10% and mass per seed by 11%. The toxic effect of CO₂ was similar over a range of light levels from half to full sunlight. Subsequent trials revealed that super-optimal CO₂ during the interval between 2 wk before and after anthesis mimicked the effect of constant super-optimal CO₂. Furthermore, near-optimal CO₂ during the same interval mimicked the effect of constant near-optimal CO₂. Nutrient concentration of leaves and heads was not affected by CO₂. These results suggest that super optimal CO₂ inhibits some process that occurs near the time of seed set resulting in decreased seed set, seed mass, and yield.

Grotenhuis, T., J. Reuveni, and B. Bugbee. UNKNOWN YEAR. Super-optimal CO₂ reduces wheat yield in growth chamber and

greenhouse environments. *Life Sciences: Life Support Systems Studies-I :1901-1904.*

Seven growth chamber trials (six replicate trials using 0.035, 0.12, and 0.25 % CO₂ in air and one trial using 0.12, 0.80, and 2.0% CO₂ in air) and three replicate greenhouse trials (0.035, 0.10, 0.18, 0.26, 0.50, and 1.0% CO₂ in air) compare the effects of super-optimal CO₂ on the seed yield, harvest index, and vegetative growth rate of wheat (*Triticum aestivum* L. cvs. USU-Apogee and Veery-10). Plants in the growth chamber trials were grown hydroponically under fluorescent lamps, while the greenhouse trials were grown under sunlight and high pressure sodium lamps and in soilless media. Plants in the greenhouse trials responded similarly to those in the growth chamber trials; maximum yields occurred near 0.10 and 0.12 % CO₂ and decreased significantly thereafter. This research indicates that the toxic effects of elevated CO₂ are not specific to only one environment and has important implications for the design of bio-regenerative life support systems in space, and for the future of terrestrial agriculture. Grulke, N.E., J.L. Hom, and S.W. Roberts. 1993. Physiological adjustment of 2 full-sib families of ponderosa pine to elevated CO₂. *Tree Physiology* 12(4):391-401.

Seeds from two full-sib families of ponderosa pine (*Pinus ponderosa*) with known differences in growth rates were germinated and grown in an ambient (350 μmol l⁻¹) or elevated (700 μmol l⁻¹) CO₂ concentration. Gas exchange at both ambient and elevated CO₂ concentrations was measured 1, 6, 39, and 112 days after the seed coat was shed. Initial stimulation of CO₂ exchange rate (CER) by elevated CO₂ was large (> 100%). On Day 1, CER of seedlings grown in elevated CO₂ and measured at ambient CO₂ was significantly lower than the CER of seedlings grown and measured at ambient CO₂, indicating physiological adjustment of the seedlings exposed to elevated CO₂. Physiological acclimation to elevated CO₂ was complete by Day 39 when there was no significant difference in CER between seedlings grown and measured at ambient CO₂ and seedlings grown and measured at elevated CO₂. After 4 months, the light response of seedlings in the two treatments was determined at both ambient and elevated CO₂. Light compensation point, CER at light saturation, and apparent quantum efficiency of seedlings grown and measured at ambient CO₂ were not significantly different from those of seedlings grown and measured at elevated CO₂. With a short-term increase in CO₂, CER at light saturation (5.16 ± 0.52 versus 3.13 ± 0.30 μmol CO₂ m⁻² s⁻¹) and apparent quantum efficiency (0.082 ± 0.011 versus 0.045 ± 0.003 μmol CO₂ μmol⁻¹ quanta) were significantly increased. Leaf C/N ratio was significantly increased in the elevated CO₂ treatment. There were few significant differences between families for any response to elevated CO₂. Under the experimental conditions, high growth rate was not correlated with a greater response to elevated CO₂.

Gruters, U. 1999. On the role of wheat stem reserves when source-sink balance is disturbed by elevated CO₂. *Journal of Applied Botany-Angewandte Botanik* 73(1-2):55-62.

Spring wheat (*Triticum aestivum* L. cv. Minaret) was exposed to 360 and 680 $\mu\text{mol mol}^{-1}$ CO_2 in open top chambers during the vegetation periods of 1994/1995. In 1994 fractionated harvests were carried out at weekly intervals from the onset of stem elongation. At final harvest CO_2 enhanced aboveground biomass and yield by 49.7 and 43.2%, respectively. From all plant organs stem dry weights showed the largest increases under doubled CO_2 , whereas leaf-blade dry weights increased only slightly. Since stems are known as sites of intermediary carbohydrate-storage, carbohydrate composition was analysed in the internodes of the main stem. Carbohydrates were determined as fructans, sucrose and reducing sugars. CO_2 stimulated the amounts per organ of all components, but fructans showed the largest increases. Fructan accumulation lasted about one week longer and remobilisation was faster under elevated CO_2 . The results are consistent with current knowledge, that temporary storage pools accommodate source photosynthate supply to sink demand and suggested a predominant role of the intermediary stem reserves, when source-sink relations are changed under elevated CO_2 . The contribution of the main stem reserves to the main stem yield was also enhanced by elevated CO_2 (6.1-8.7% compared to 10.0-14.2%). In 1995 growth and yield increase due to elevated CO_2 (50.6 and 53%) was comparable to 1994. A functional growth analysis of the stem dry weight was carried out in this year. There was only a slightly longer accumulation phase in response to elevated CO_2 . Combined stem reserves contributed 12-18% to the final grain yield thereby contradicting the suggestions based on the results of the year 1994.

Guak, S., D.M. Olszyk, L.H. Fuchigami, and D.T. Tingey. 1998. Effects of elevated CO_2 and temperature on cold hardiness and spring bud burst and growth in Douglas-fir (*Pseudotsuga menziesii*). *Tree Physiology* 18(10):671-679.

We examined effects of elevated CO_2 and temperature on cold hardiness and bud burst of Douglas-fir (*Pseudotsuga menziesii* (Mirb.) France) seedlings. Two-year-old seedlings were grown for 2.5 years in semi-closed, sunlit chambers at either ambient or elevated (ambient + approximate to 4 degrees C) air temperature in the presence of an ambient or elevated (ambient + approximate to 200 ppm) CO_2 concentration. The elevated temperature treatment delayed needle cold hardening in the autumn and slowed dehardening in the spring. At maximum hardiness, trees in the elevated temperature treatment were less hardy by about 7 degrees C than trees in the ambient temperature treatment. In general, trees exposed to elevated CO_2 were slightly less hardy during hardening and dehardening than trees exposed to ambient CO_2 . For trees in the elevated temperature treatments, date to 30% burst of branch terminal buds was advanced by about 6 and 15 days in the presence of elevated CO_2 and ambient CO_2 , respectively. After bud burst started, however, the rate of increase in % bud burst was slower in the elevated temperature treatments than in the ambient temperature treatments. Time of bud burst was more synchronous and bud burst was completed within a shorter period in trees at ambient temperature (with and without elevated CO_2) than in trees at elevated temperature. Exposure to elevated temperature reduced final % bud burst of both leader and branch terminal buds and reduced growth of the leader shoot. We conclude that climatic warming will influence the physiological processes of dormancy and cold hardiness development in Douglas-fir growing in the relatively mild temperate region of western Oregon, reducing bud burst and shoot growth.

Guehl, J.M., C. Picon, G. Aussenac, and P. Gross. 1994. Interactive effects of elevated CO_2 and soil drought on growth and transpiration efficiency and its determinants in 2 european forest tree species. *Tree Physiology* 14(7-9):707-724.

The responses of growth and transpiration efficiency (W = biomass accumulation/water consumption) to ambient and elevated atmospheric CO_2 concentrations (350 and 700 $\mu\text{mol mol}^{-1}$, respectively) were investigated under optimal nutrient supply in well-watered and in drought conditions in two temperate-forest tree species: *Quercus petraea* Liebl. and *Pinus pinaster* Ait. Under well-watered conditions, doubling the CO_2 concentration for one growing season increased biomass growth by 138% in *Q. petraea* and by 63% in *P. pinaster*. In contrast, under drought conditions, elevated CO_2 increased biomass growth by only 47% in *Q. petraea* and had no significant effect on biomass growth in *P. pinaster*. Transpiration efficiency was higher in *Q. petraea* than in *P. pinaster* in all treatments. This difference was linked (i) to lower carbon isotope discrimination ($\Delta^{13}\text{C}$), and thus lower values of the intercellular/ambient CO_2 concentration ($c(i)/c(a)$) ratio, in *Q. petraea*, (ii) to lower values of leaf mass ratio (LMR, leaf mass/whole plant mass), which we suggest was positively related to the proportion of daytime carbon fixation lost by respiration (PHI), in *Q. petraea*, and (iii) to slightly lower C concentrations in *Q. petraea* than in *P. pinaster*. The CO_2 -promoted increase in W was higher in *Q. petraea* (+80%) than in *P. pinaster* (+50%), and the difference was associated with a more pronounced decrease in PHI in response to elevated CO_2 in *Q. petraea* than in *P. pinaster*, which could be linked with the N dilution effect observed in *Q. petraea*. Because PHI also directly affects growth, the CO_2 -induced enhancement of PHI in *Q. petraea* is a crucial determinant of the growth stimulation observed in this species. Leaf gas exchange regulation was not the only factor involved in the responses of growth and W to elevated CO_2 and drought, other physiological processes that have crucial roles include carbon and N allocation and respiration.

Gunderson, C.A., R.J. Norby, and S.D. Wullschlegel. 1993. Foliar gas-exchange responses of 2 deciduous hardwoods during 3 years of growth in elevated CO_2 - no loss of photosynthetic enhancement. *Plant, Cell and Environment* 16(7):797-807.

Responses of photosynthesis and stomatal conductance were monitored throughout a 3-year field exposure of *Liriodendron tulipifera* (yellow-poplar) and *Quercus alba* (white oak) to elevated concentrations of atmospheric CO_2 . Exposure to atmospheres enriched with +150 and +300 $\mu\text{mol mol}^{-1}$ CO_2 increased net photosynthesis by 12-144% over the course of the study. Net photosynthesis was consistently higher at +300 than at +150 $\mu\text{mol mol}^{-1}$ CO_2 . The effect of CO_2 enrichment on stomatal conductance was limited, but instantaneous leaf-level water use efficiency increased significantly. No decrease in the responsiveness of photosynthesis to CO_2 enrichment over time was detected, and the responses were consistent throughout the canopy and across successive growth flushes and seasons. The relationships between internal CO_2 concentration and photosynthesis (e.g. photosynthetic capacity and carboxylation efficiency) were not altered by growth at elevated concentrations of CO_2 . No alteration in the timing of leaf senescence or abscission was detected, suggesting that the seasonal duration of effective gas-exchange was unaffected by CO_2 treatment. These results are consistent with data previously reported for these species in controlled-environment studies, and suggest that leaf-level photosynthesis does not down-regulate in these species as a result of acclimation to CO_2 enrichment in the field. This sustained enhancement of photosynthesis provides the opportunity for increased growth and carbon storage by trees as the atmospheric concentration of CO_2 rises, but many additional factors interact in determining whole-plant and forest responses to global change.

Gunderson, C.A., and S.D. Wullschleger. 1994. Photosynthetic acclimation in trees to rising atmospheric CO₂ - a broader perspective. *Photosynthesis Research* 39(3):369-388.

Analysis of leaf-level photosynthetic responses of 39 tree species grown in elevated concentrations of atmospheric CO₂ indicated an average photosynthetic enhancement of 44% when measured at the growth [CO₂]. When photosynthesis was measured at a common ambient [CO₂], photosynthesis of plants grown at elevated [CO₂] was reduced, on average, 21% relative to ambient-grown trees, but variability was high. The evidence linking photosynthetic acclimation in trees with changes at the biochemical level is examined, along with anatomical and morphological changes in trees that impact leaf- and canopy- level photosynthetic response to CO₂ enrichment. Nutrient limitations and variations in sink strength appear to influence photosynthetic acclimation, but the evidence in trees for one predominant factor controlling acclimation is lacking. Regardless of the mechanisms that underlie photosynthetic acclimation, it is doubtful that this response will be complete. A new focus on adjustments to rising [CO₂] at canopy, stand, and forest scales is needed to predict ecosystem response to a changing environment.

Gunn, S., S.J. Bailey, and J.F. Farrar. 1999. Partitioning of dry mass and leaf area within plants of three species grown at elevated CO₂. *Functional Ecology* 13:3-11.

1. We tested the hypothesis that the net partitioning of dry mass and dry mass:area relationships is unaltered when plants are grown at elevated atmospheric CO₂ concentrations. 2. The total dry mass of *Dactylis glomerata*, *Bellis perennis* and *Trifolium repens* was higher for plants in 700 compared to 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ when grown hydroponically in controlled- environment cabinets. 3. Shoot:root ratios were higher and leaf area ratios and specific leaf areas lower in all species grown at elevated CO₂. Leaf mass ratio was higher in plants of *B. perennis* and *D. glomerata* grown at elevated CO₂. 4. Whilst these data suggest that CO₂ alters the net partitioning of dry mass and dry mass:leaf area relationships, allometric comparisons of the components of dry mass and leaf area suggest at most a small effect of CO₂. CO₂ changed only two of a total of 12 allometric coefficients we calculated for the three species: v relating shoot to root dry mass was higher in *D. glomerata*, whilst v relating leaf area to total dry mass was lower in *T. repens*. 5. CO₂ alone has very little effect on partitioning when the size of the plant is taken into account.

GunthardtGoerg, M.S. 1997. Leaf and shoot formation of young spruce and beech exposed to elevated CO₂. *Acta Oecologica-International Journal of Ecology* 18(3):335-341.

Sixteen open-top chambers (divided into two halves each containing either calcareous or acidic soil) were supplied in four combinations with either 366 or 550 $\mu\text{mol CO}_2 \text{ L}^{-1}$, and either 2.5 or 25 kg N ha⁻¹ y⁻¹ (ammonium nitrate by irrigation). The development of young spruce (*Picea abies*) and beech (*Fagus sylvatica*) trees planted in the chambers together with understory plants will be studied over four years. The presented data are preliminary results from the first year of this experiment and refer to 64 spruce and 64 beech trees from two different Swiss spruce and beech provenances; two trees each per soil type, sampled in July and September in each chamber. Specific current-year spruce needle length (length/dry mass) was reduced by elevated CO₂ due to an increase in dry mass. Beech specific leaf area was only temporarily reduced in July. Elevated CO₂ induced an earlier autumnal leaf discoloration. Total current-year shoot length per spruce and total number of leaves per beech tree were not influenced by the first year treatment with elevated CO₂. N deposition had no effect on these parameters, but soil type influenced spruce needle colour. Spruce, in contrast to beech, may therefore profit from elevated CO₂ (when other resources are unlimited) by increasing shoot and needle dry mass.

GwynnJones, D., J.A. Lee, and T.V. Callaghan. 1997. Effects of enhanced UV-B radiation and elevated carbon dioxide concentrations on a sub-Arctic forest heath ecosystem. *Plant Ecology* 128(1-2):242-249.

An experiment is described which studies the effects of enhanced UV-B radiation (simulating a 15% reduction in the Ozone layer) and elevated atmospheric concentrations of CO₂ (600 ppm) on the dwarf shrub layer of a sub-arctic forest heath ecosystem at Abisko, North Sweden. The experimental treatments were first applied in 1993, and have covered most of the snow-free season (late May to early September) 1993-1995. Effects of the treatments on the four dwarf shrub species have been recorded largely using non-destructive measures (*Vaccinium uliginosum*, *Vaccinium myrtillus* - deciduous species and *Vaccinium vitis-idaea* and *Empetrum hermaphroditum* - evergreen species). Effects of the treatments on stem growth and leaf thickness have so far been small, although CO₂ treatments initially stimulated stem extension in *Vaccinium myrtillus* 1993 and depressed growth in *V. vitis idaea* in 1994 and *E. hermaphroditum* during 1995. UV-B treatments stimulated fruit production in *V. myrtillus* in both 1994 and 1995, but there was no effect on reproductive phenology. There were also marked effects of UV-B treatments on insect herbivory in the deciduous dwarf shrubs; with leaf area loss being greater than the control in the UV-B treatment in *V. myrtillus* and less in *V. uliginosum*. The results point to the possibility of important effects of the treatments on physiological and chemical processes within the plants. The ecological results of such effects may not be immediately apparent, but may be far reaching, pointing to the need for long-term in situ experimentation in predicting the effects of these global change variables.

Habash, D.Z., M.A.J. Parry, S. Parmar, M.J. Paul, S. Driscoll, J. Knight, J.C. Gray, and D.W. Lawlor. 1996. The regulation of

component processes of photosynthesis in transgenic tobacco with decreased phosphoribulokinase activity. *Photosynthesis Research* 49(2):159-167.

Tobacco plants (*Nicotiana tabacum* L.) transformed with an inverted cDNA encoding ribulose 5-phosphate kinase (phosphoribulokinase, PRK; EC 2.7.1.19) were employed to study the in vivo relationship between photosynthetic electron transport and the partitioning of electron transport products to major carbon metabolism sinks under conditions of elevated ATP concentrations and limited ribulose 1,5-bisphosphate (RuBP) regeneration. Simultaneous measurements of room temperature chlorophyll fluorescence and CO₂ gas exchange were conducted on intact leaves. Under ambient CO₂ concentrations and light intensities above those at which the plants were grown, transformants with only 5% of PRK activity showed 'down-regulation' of PS II activity and electron transport in response to a decrease in net carbon assimilation when compared to wild-type. This was manifested as a decline in the efficiency of PS II electron transport ($\Phi(\text{PS II})$), an increase in dissipation of excess absorbed light in the antennae of PS II and a decline in : total linear electron transport ($J(1)$), electron transport dedicated to carbon assimilation ($J(A)$) and electron transport allocated to photorespiration ($J(L)$). The transformants showed no alteration in the Rubisco specificity factor measured in vitro and calculated in vivo but had a relatively smaller ratio of RuBP oxygenation to carboxylation rates ($v(o)/v(c)$), due to a higher CO₂ concentration at the carboxylation site (C-c). The relationship between $\Phi(\text{PS II})$ and $\Phi(\text{CO}_2)$ was similar in transformants and wild-type under photorespiratory conditions demonstrating no change in the intrinsic relationship between PS II function and carbon assimilation, however, a novel result of this study is that this similar relationship occurred at different values of quantum flux, $J(1)$, $J(A)$, $J(L)$ and $v(o)/v(c)$ in the transformant. For both wild-type and transformants, an assessment was made of the possible presence of a third major sink for electron transport products, beside RuBP oxygenation and carboxylation, the data provided no evidence for such a sink.

Habash, D.Z., M.J. Paul, M.A.J. Parry, A.J. Keys, and D.W. Lawlor. 1995. Increased capacity for photosynthesis in wheat grown at elevated CO₂ - the relationship between electron-transport and carbon metabolism. *Planta* 197(3):482-489.

Spring wheat (*Triticum aestivum* L.) was grown under optimal nutrition for six weeks at 700 and 350 $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ and simultaneous measurements of photosystem-II (PSII) chlorophyll fluorescence and gas exchange were conducted on intact attached leaves. Plants grown at elevated CO₂ had double the concentration of CO₂ at the carboxylation site (C-c) despite a lowered stomatal ($g(s)$) and mesophyll ($g(m)$) conductance compared with ambient-grown plants. Plants grown at elevated CO₂ had a higher relative quantum yield of PSII electron transport ($\Phi(\text{PSII})$) and a higher relative quantum yield of CO₂ fixation ($\Phi(\text{CO}_2)$). The higher $\Phi(\text{PSII})$ was due to a larger proportion of open PSII centres, estimated by the coefficient of photochemical quenching of fluorescence ($q(p)$), with no change in the efficiency of light harvesting and energy transduction by open PSII centres ($F(v)/F(m)$). Analysis of the relationship between $\Phi(\text{PSII})$ and $\Phi(\text{CO}_2)$ conducted under various CO₂ and O₂ concentrations showed that the higher $\Phi(\text{CO}_2)$ for a given $\Phi(\text{PSII})$ in leaves developed under elevated CO₂ was similar to that obtained in leaves upon a partial reduction in photorespiration. Calculation of the allocation of photosynthetic electron-transport products to CO₂ and O₂ showed that for leaves

developed in elevated CO₂, there was an increase in both total linear electron flow and electron flow to CO₂ and a decrease in electron flow to O₂. Plants developed under elevated CO₂ showed positive acclimation manifested by a higher $\Phi(\text{CO}_2)$ when measured under ambient CO₂ and higher assimilation rates in A/C-i curves. Initial and total activity of ribulose-1,5-bisphosphate carboxylase-oxygenase (Rubisco EC 4.1.1.39) measured in vitro increased by 16 and 15% respectively in leaves from plants grown in elevated CO₂, which was in agreement with a 15% higher in vivo carboxylation efficiency. It is concluded that growth of spring wheat at elevated CO₂ enhances photosynthesis due to a change in the balance of component processes manifested as an increased capacity for carbon fixation, total electron transport and Rubisco activity, and a concomitant partial reduction of photorespiration.

Hadley, P., G.R. Batts, R.H. Ellis, J.L.L. Morison, S. Pearson, and T.R. Wheeler. 1995. Temperature-gradient chambers for research on global environment change. 2. a twin-wall tunnel system for low-stature, field-grown crops using a split heat-pump. *Plant, Cell and Environment* 18(9):1055-1063.

A temperature gradient chamber (TGC) is described which enables elevated CO₂ concentrations and a dynamic temperature gradient to be imposed on field crops throughout their life cycle under standard husbandry. Air is circulated through two double-walled polyethylene-covered tunnels connected to a split heat pump system to give a near-linear temperature gradient along each tunnel. Solar energy gain along each tunnel and exchange with outer tunnel air flow contribute to the temperature gradient and also produce diurnal and seasonal temperature fluctuations corresponding to ambient conditions. Mean temperature gradients of between 3 and 5 degrees C have been recorded throughout the growing seasons of crops of lettuce, carrot, cauliflower and winter wheat. Elevated or present CO₂ concentrations are maintained in each of two pairs of tunnels throughout the cropping season using pure CO₂ injected through motorized needle valves. This system can realistically simulate aspects of the effects of projected future environmental change on crop growth, development and yield, and in particular the possible interaction of the effects of increased CO₂ and temperature.

Hager, C., G. Wurth, and G.H. Kohlmaier. 1999. Biomass of forest stands under climatic change: a German case study with the Frankfurt biosphere model (FBM). *Tellus Series B-Chemical and Physical Meteorology* 51(2):385-401.

In this contribution, we perform a case study of the German forests. We couple the Frankfurt biosphere model (FBM) with a model of the age class development (AGEDYN). The coupled model is applied to simulate the temporal development of carbon pools in German forests under the influence of climate change taking into account changes in the age class structure. In the base case, the growth of forest stands is simulated using a temporally averaged climate dataset, being representative for the contemporary climate conditions. To assess the sensitivity of forest growth to changes in environmental conditions, the FBM is run in several scenarios. In these simulations the effects both of climate change and of the direct effect of increased levels of atmospheric CO₂ on photosynthesis (CO₂ fertilization) on forest growth are assessed. In another simulation run with the FBM both effects - climate change and CO₂ fertilization are combined. In simulations under present day's

climate conditions a good agreement is gained between simulation results and statistical data of the present standing stock carbon density of Germany's forests. A pure climate change leads to a decrease of the annual increments as well as to the climax standing stocks. The negative effect of climate change alone is overcompensated by enhanced photosynthesis in the simulations with combined climate change and CO₂ fertilization. In the transient case, the coupled model is used in two scenarios describing first a continuation of present day's climate conditions and second a transient climate change from present conditions (1990) to 2 x CO₂ conditions in 2090. Here, the simulations indicate that changes in the forest's age class structure can have a stronger influence on the future carbon balance of the forests in the considered region than the combined effect of climate change and CO₂ fertilization.

Hakala, K. 1998. Growth and yield potential of spring wheat in a simulated changed climate with increased CO₂ and higher temperature. *European Journal of Agronomy* 9(1):41-52.

The effects of climatic change on the growth, yield and nitrogen content of spring wheat (*Triticum aestivum* L., cv. Polkka) were studied from 1992 to 1994. The crop was sown directly in the field, at a normal sowing density. Leaf canopies were exposed to CO₂ concentrations of 700 $\mu\text{l l}^{-1}$ and temperatures 3 degrees C higher than ambient throughout the growing season. CO₂ concentrations were elevated in open-top chambers 3m in diameter. Temperatures were elevated in an automatically controlled greenhouse built over the experimental field. To simulate conditions predicted for a future warmer climate, the wheat crop was sown 2-3 weeks earlier in the elevated temperature (future warmer climate) than in the ambient temperature treatment (present climate). In the elevated temperature experiment, the average temperatures and development rates were not increased during the period from sowing to anthesis, but from anthesis to maturity, both temperatures and development rates were increased. The small increase in the development rate after anthesis at elevated temperatures in 1992 and 1994 did not affect the grain weight, but the considerable increase in development rate in 1993 was accompanied by a decrease in grain weight. CO₂ enrichment had no effect on development rate. The total biomass at harvest was significantly higher in CO₂ enrichment in both temperature treatments. Although the mean increase in grain yield was not significant, the yields tended to be higher in CO₂ enrichment. The magnitude of the increase in biomass and grain yield in CO₂ enrichment ranged from about 5 to 60%. The increase in yield was mainly attributed to an increase in the number of ear-bearing shoots m^{-2} . Seed number per main shoot and seed weight were in general not increased with CO₂ enrichment unless these were exceptionally low in the ambient CO₂ conditions (in 1993). The harvest index was decreased at elevated temperatures, but there was no significant effect of CO₂ enrichment. There was a small (7%) but significant decrease in the nitrogen content of the grain in CO₂ enrichment at ambient temperatures. (C) 1998 Elsevier Science B.V.

Hakala, K., and T. Mela. 1996. The effects of prolonged exposure to elevated temperatures and elevated CO₂ levels on the growth, yield and dry matter partitioning of field-sown meadow fescue. *Agricultural and Food Science in Finland* 5(3):285-298.

Field-sown meadow fescue (*Festuca pratensis*, cv. Kalevi) stands were exposed to elevated temperatures (+3 degrees C) and elevated CO₂ (700 ppm) levels in two experiments conducted in 1992-1993 (experiment 1) and in 1994-1995 (experiment 2). Total aboveground yield was, on average, 38% higher at elevated than at ambient temperatures. At ambient temperatures elevated CO₂ increased the number of tillers by 63% in 1992, 24% in 1993, 90% in 1994 and 14% in 1995. At elevated temperatures, the increase in tiller number in elevated CO₂ was seen only in the first growing seasons after sowing. The total yield in a growing season was about 10% higher in elevated CO₂ in experiment 1. In experiment 2 the yield was more than 20% higher in elevated CO₂ at elevated temperatures, whereas at ambient temperatures the rise in CO₂ level had no effect on the yield; the root biomass, however, increased by more than 30%. In elevated CO₂ at ambient temperatures the root biomass also increased in experiment 1, but at elevated temperatures there was no consistent change. The soluble carbohydrate content of above-ground biomass was 5-48% higher in elevated CO₂ at most of the measuring times during the growing season, but the nitrogen content did not show a clear decrease. The reasons for the lack of a marked increase in biomass in elevated CO₂ despite a 40-60% increase in photosynthesis are discussed.

Hakala, K., T. Mela, H. Laurila, and T. Kaukoranta. 1996. Arrangement of experiments for simulating the effects of elevated temperatures and elevated CO₂ levels on field-sown crops in Finland. *Agricultural and Food Science in Finland* 5(1):25-47.

The experimental plants: spring wheat, winter wheat, spring barley, meadow fescue, potato, strawberry and black currant were sown or planted directly in the field, part of which was covered by an automatically controlled greenhouse to elevate the temperature by 3 degrees C. The temperature of the other part of the field (open field) was not elevated, but the field was covered with the same plastic film as the greenhouse to achieve radiation and rainfall conditions comparable to those in the greenhouse. To elevate the CO₂ concentrations, four open top chambers (OTC) were built for the greenhouse, and four for the open field. Two of these, both in the greenhouse and in the open field, were supplied with pure CO₂ to elevate their CO₂ level to 700 ppm. The temperatures inside the greenhouse followed accurately the desired level. The relative humidity was somewhat higher in the greenhouse and in the OTC:s than in the open field, especially after the modifications in the ventilation of the greenhouse and in the OTC:s in 1994. Because the OTC:s were large (3 m in diameter), the temperatures inside them differed very little from the surrounding air temperature. The short-term variation in the CO₂ concentrations in the OTC:s with elevated CO₂ was, however, quite high. The control of the CO₂ concentrations improved each year from 1992 to 1994, as the CO₂ supplying system was modified. The effects of the experimental conditions on plant growth and phenology are discussed.

Hall, D.O., D.S. Ojima, W.J. Parton, and J.M.O. Scurlock. 1995. Response of temperate and tropical grasslands to CO₂ and climate change. *Journal of Biogeography* 22(2-3):537-547.

Under a recent SCOPE collaborative project, longterm data from eleven tropical and temperate grassland sites were used (a) to validate the CENTURY model of plant-soil ecosystems and (b) to model climate

change and CO₂ effects for thirty-one temperate and tropical grassland sites, representing seven ecoregions of the world. Model calibration and testing showed that soil carbon and nitrogen dynamics can be well simulated for the grassland biome worldwide, over a wide range of climate and soil types. The interannual response of above ground biomass and plant residue to variation in climate resulted in a good correspondence between simulated and observed dynamics on a monthly basis. These results are useful for analysis and description of grassland carbon dynamics, and as a reference point for testing predictions of net primary production (NPP) and biomass dynamics from levels of more physiologically based models. Prediction of plant and soil organic matter C and N dynamics requires knowledge of climate, soil texture, N inputs and fire and grazing patterns. CENTURY simulations of climate change and CO₂ effects showed increased NPP for climate change alone, except in cold desert steppe regions, and CO₂ increased production everywhere. Climate changes, predominantly a warming of these ecosystems, caused soil carbon to decrease overall, especially in cold desert and temperate steppes. Increased production due to elevated CO₂ tended to ameliorate soil carbon losses and tropical savannas were actually soil carbon sinks. Climate change alone projected a carbon loss of 3-4 Pg after 50 years, and 1-2 Pg for the combined climate change and CO₂ simulated effects. We analysed the dynamic response of some of the major CENTURY output parameters (e.g. NPP, soil organic matter, N mineralization and decomposition) for their sensitivity to climate change and increasing CO₂ for one of the two general circulation models (GFHI scenario). This analysis was limited to a subset of five well-known study sites, representing five of the seven ecoregions.

Hall, J.M., E. Paterson, and K. Killham. 1998. The effect of elevated CO₂ concentration and soil pH on the relationship between plant growth and rhizosphere denitrification potential. *Global Change Biology* 4(2):209-216.

The effect of CO₂ concentration on plant growth and the size of the rhizosphere denitrifier population was investigated for ryegrass grown at 3 different soil pH values (pH 4.3, 5.9 and 7.0). Soil microcosms were planted with ryegrass and maintained under constant growth conditions

at either ambient (450ppm) or elevated (720ppm) CO₂ concentration. At harvest, the rhizosphere soil was collected and subjected to a potential denitrification assay to provide an estimate of the size of the denitrifier population present. Ryegrass dry matter production varied across the pH range studied and contrary to other studies, elevated CO₂ concentration did not consistently increase growth. Plant growth was reduced by approximate to 35% and 23% at pH 4.3 and pH 5.9, respectively, under elevated CO₂ concentration. At pH 7.0, however, plant growth was increased by approximate to 45% under elevated CO₂. Potential denitrification rates within the rhizosphere followed a similar pattern to plant growth in the different treatments, suggesting that plant growth and the size of denitrifier population within the rhizosphere are coupled. This study investigates the relationship between plant growth and rhizosphere denitrification potential, thereby providing an estimate of the size of the denitrifier population under increased CO₂ concentration and soil pH.

Halloy, S.R.P., and A.F. Mark. 1996. Comparative leaf morphology spectra of plant communities in New Zealand, the Andes and the European Alps. *Journal of the Royal Society of New Zealand* 26(1):41-78.

Leaf morphology of native vegetation has often been interpreted as a sensitive indicator of environmental conditions, presumably as a result of natural selection. If environmental pressures act as a selective force on community leaf morphology, then we would expect a high degree of similarity in similar environments, regardless of biogeographic origin of the flora. A comparative study of full regional floras of alpine vascular plants was undertaken to test the sensitivity of leaf morphology to macro-environmental conditions. Five alpine sites and one lowland (control) site were selected in southern New Zealand spanning 1.5 degrees latitude and 2323 m. Three sites with equivalent alpine environments were selected in South America across a 60 degrees latitudinal and 4200 m altitudinal span with subtropical forest used as a control. A further alpine site from the European Alps was included as an outlier. Twenty leaf parameters were obtained for 2143 taxonomic entities x sites. Both the mean and the frequency distribution of leaf size and shape parameters were distinctive for each locality. Several morphological trends were found. Means of New Zealand contiguous low-alpine and high-alpine site pairs differed in: length -33%, width -14%, length/width -20%, leaf area -44%, entire margin -2% (variable), coriaceousness -18%, folded +22%, pubescence +40%. At higher elevations, leaves become smaller but rounder, considerably softer, are more often folded into crypts or similar structures and are more often pubescent. These changes corresponded to reductions of 2-3 degrees C in mean annual air temperature, c. 10% in mean minimum relative humidity and 7% in CO₂ partial pressure. Despite the biogeographic and environmental differences, New Zealand and South American low-alpine sites were consistently similar in their morphological parameters and consistently different from high-alpine sites (except in Tierra del Fuego). High alpine sites were also consistently similar across the Pacific. Several parameters were found to have multimodal frequency distributions that were not significantly different in widely separate localities with different floras. The results suggest that plant community morphology is an emergent property, the magnitude of which is environmentally constrained.

Ham, J.M., C.E. Owensby, and P.I. Coyne. 1993. Technique for measuring air-flow and carbon-dioxide flux in large, open-top chambers. *Journal of Environmental Quality* 22(4):759-766.

Open-Top Chambers (OTCs) are commonly used to evaluate the effect of CO₂, O₃, and other trace gases on vegetation. A study was conducted to develop and test a new technique for measuring forced air flow and net CO₂ flux from OTCs. Experiments were performed with a 4.5-m diam. OTC that had a sealed floor and a specialized air delivery system. Air flow through the chamber was computed with the Bernoulli equation using measurements of the pressure differential between the air delivery ducts and the chamber interior. An independent measurement of air flow was made simultaneously to calibrate and verify the accuracy of the Bernoulli relationship. The CO₂ flux density was calculated as the product of chamber air flow and the difference in CO₂ concentration between the air entering and exhausting from the OTC (C(in) - C(out)). Accuracy of the system was evaluated by releasing CO₂ within the OTC at known rates to emulate respiration from the field surface. Data were collected with OTCs at ambient and elevated CO₂ (almost-equal-to 700 $\mu\text{mol mol}^{-1}$). Results showed that the Bernoulli equation, with a flow coefficient of 0.7, accurately measured air flow in the OTC to within $\pm 5\%$ regardless of flow rate and air duct geometry. Experiments in ambient OTCs showed that CO₂ flux density ($\mu\text{mol m}^{-2} \text{ s}^{-1}$), computed from 2-min averages of air flow and C(in) - C(out), was typically within $\pm 10\%$ of actual flux, provided that the exit air velocity at the top of the OTC was greater than 0.6 m s⁻¹. Obtaining the same level of accuracy in CO₂-enriched OTCs, however, required a critical exit velocity near 1.2 m s⁻¹ to minimize the incursion of ambient air and prevent contamination of the exit gas sample. When flux data were integrated over time to estimate daily CO₂ flux ($\mu\text{mol m}^{-2} \text{ d}^{-1}$), actual and measured values agreed to within $\pm 2\%$ for both ambient and CO₂-enriched chambers, suggesting that accurate measurements of daily net C exchange are possible with this technique.

Ham, J.M., C.E. Owensby, P.I. Coyne, and D.J. Bremer. 1995. Fluxes of CO₂ and water-vapor from a prairie ecosystem exposed to ambient and elevated atmospheric CO₂. *Agricultural and Forest Meteorology* 77(1-2):73-93.

Increasing concentrations of atmospheric CO₂ may alter the carbon and water relations of prairie ecosystems. A C-4-dominated tallgrass prairie near Manhattan, KS, was exposed to 2x ambient CO₂ concentrations using 4.5 m-diameter open-top chambers. Whole-chamber net CO₂ exchange (NCE) and evapotranspiration (ET) were continuously monitored in CO₂-enriched and ambient (no enrichment) plots over a 34-d period encompassing the time of peak biomass in July and August, 1993. Soil-surface CO₂ fluxes were measured with a portable surface chamber, and sap flow (water transport in xylem) in individual grass culms was monitored with heat balance techniques. Environmental measurements were used to determine the effect of CO₂ on the surface energy balance and canopy resistances to vapor flux. In 1993, frequent rainfall kept soil water near field capacity and minimized plant water stress. Over the 34-d measurement period, average daily NCE (canopy photosynthesis - soil and canopy respiration) was 9.3 g CO₂ m⁻² in the ambient treatment and 11.4 g CO₂ m⁻² under CO₂ enrichment. However, differences in NCE were caused mainly by delayed senescence in the CO₂-enriched plots at the end of the growing season. At earlier stages of growth, elevated CO₂ had no effect on NCE. Soil-surface CO₂ fluxes typically ranged from 0.4 to 0.66 mg CO₂ m⁻² s⁻¹, but were slightly greater in the CO₂-enriched chambers. CO₂ enrichment reduced daily ET by 22%, reduced sap flow by 18%, and increased canopy resistance to vapor flux by 24 s m⁻¹. Greater NCE and lower ET resulted in higher daytime water use efficiency (WUE) under CO₂

enrichment vs. ambient (9.84 vs. 7.26 g CO₂ kg⁻¹ H₂O). However, record high precipitation during the 1993 season moderated the effect of WUE on plant growth, and elevated CO₂ had no effect on peak aboveground biomass. CO₂-induced stomatal closure also affected the energy balance of the surface by reducing latent heat flux (LE), thereby causing a consequent change in sensible heat flux (H). The daytime Bowen ratio (H/LE) for the study period was near zero for the ambient treatment and 0.21 under CO₂ enrichment.

Hamerlynck, E.P., C.A. McAllister, A.K. Knapp, J.M. Ham, and C.E. Owensby. 1997. Photosynthetic gas exchange and water relation responses of three tallgrass prairie species to elevated carbon dioxide and moderate drought. *International Journal of Plant Science* 158(5):608-616.

Undisturbed tallgrass prairie was exposed to ambient and elevated (twice-ambient) levels of atmospheric CO₂ and experimental dry periods. Seasonal and diurnal midday leaf water potential (Psi(leaf)), net photosynthesis (A(net)), and stomatal conductance (g(s)) responses of three tallgrass prairie growth forms—a C-4 grass, *Andropogon gerardii*; a broad-leaved woody C, shrub, *Symphoricarpos orbiculatus*; and a C-3 perennial forb, *Salvia pitcheri*—were assessed. Psi(leaf) in *A. gerardii* and *S. orbiculatus* was higher under elevated CO₂, regardless of soil moisture, while Psi(leaf) in *S. pitcheri* responded only to drought. Elevated CO₂ always stimulated A(net) in the C-3 species, while *A. gerardii* A(net) increased only under dry conditions. However, A(net) under elevated CO₂ in the C-3 species declined with drought but not in the C-grass. Under wet conditions, g(s) reduced in elevated CO₂ for all species. During dry periods, g, at elevated CO₂, was sometimes higher than in ambient CO₂. Our results support claims that elevated CO₂ will stimulate tallgrass prairie productivity during dry periods and possibly reduce temporal and spatial variability in productivity in these grasslands.

Hanba, Y.T., E. Wada, M. Osaki, and T. Nakamura. 1996. Growth and delta C-13 responses to increasing atmospheric carbon dioxide concentrations for several crop species. *Isotopes in Environmental and Health Studies* 32(1):41-54.

The responses of plant growth and carbon isotope discrimination (Delta) to elevated atmospheric CO₂ concentrations for several crop species (lettuce: *Lactuca sativa* L.; corn: *Zea mays* L. var. P3540; wheat: *Triticum aestivum* L. var. Haruyutaka; and soybean: *Glycine max* (L.) Merr. var. Kitamusume) were investigated. Shoot relative growth rate was used to indicate plant growth, and delta(13)C value of leaf materials in corn (C4 species) was used to calculate Delta for C3 species. Plant growth was stimulated by enriched CO₂, while Delta remained almost constant as CO₂ concentration changed. Delta showed interspecific difference, and the plant species of larger Delta had larger relative growth rates. Relative growth rates of the plants of larger Delta were stimulated by CO₂ enrichment more than those of the plants of smaller Delta. We propose that plant Delta could be a possible parameter to assess the interspecific difference of plant response to the increasing atmospheric CO₂ concentrations.

Handel, M.D., and J.S. Risbey. 1992. An annotated-bibliography on the greenhouse-effect and climate change. *Climatic Change* 21(2):97-253.

The literature on climate change from an enhanced greenhouse effect is large and growing rapidly. The problems considered are increasingly interdisciplinary. For these reasons many workers will find useful pointers to the literature in the fields interacting with, but outside of, their own. We present here an annotated bibliography on issues relating to changes in the concentrations of Earth's greenhouse gases. The areas covered include theory and numerical modelling of climate change; cycles involving carbon dioxide and other radiatively important trace gases; observations of climate change and the problems associated with those observations; paleoclimatology as it relates to previous changes in the greenhouse gases; the impacts on and interactions with managed and natural ecosystems from climate change; policy issues related to climate change and to the limitation of climate change; history of the study of the greenhouse effect; and some other causes of climate change. Selection of papers has been made to facilitate rapid introduction to most of the important issues and findings in an area. Over 600 articles, reports, and books are discussed.

Hanninen, H. 1995. Effects of climatic-change on trees from cool and temperate regions - an ecophysiological approach to modeling of bud burst phenology. *Canadian Journal of Botany-Revue Canadienne De Botanique* 73(2):183-199.

A framework is presented for meddling bud burst phenology of trees from the cool and temperate regions. Three ecophysiological aspects affecting the timing of bud burst are considered: (i) effects of environmental factors on the rest status of the bud, (ii) effect of rest status on the ability for bud burst, and (iii) direct effect of air temperature on the rate of development towards bud burst. Any model for bud burst phenology can be presented within the framework with three submodels, each of them addressing one of the corresponding three ecophysiological aspects. A total of 96 hypothetical models were synthesized by combining submodels presented in the literature. The models were tested in two experiments with saplings of *Pinus sylvestris* L. growing in experimental chambers at their natural site in eastern Finland. In the first experiment, air temperature and (or) concentration of atmospheric CO₂ was elevated. Elevation of the air temperature hastened bud burst, whereas elevation of the concentration of CO₂ did not affect it. Several models accurately predicted the timing of bud burst for natural conditions but too early for bud burst at the elevated temperatures. This finding suggests that (i) the risk of a premature bud

burst with subsequent frost damage, as a result of climatic warming, was overestimated in a recent simulation study, and (ii) bud burst observations in natural conditions alone are not sufficient for the testing of these mechanistic models. Several models did predict the timing of bud burst accurately for all treatments, but none of them obtained sufficiently strong support from the findings to stand out as superior or uniquely correct. In the second experiment a photoperiod submodel for rest break was tested by exposing the saplings to short-day conditions. The short-day treatment had only a minor effect on the timing of bud burst. These results demonstrated the importance of the concept of model realism: the accuracy of a model can be lost in new conditions (e.g., global warming), unless the model correctly addresses the essential ecophysiological aspects of the regulation of timing of bud burst.

Hanson, J.D., B.B. Baker, and R.M. Bourdon. 1993. Comparison of the effects of different climate change scenarios on rangeland livestock production. *Agricultural Systems* 41(4):487-502.

The effect of climate change on plant and livestock production in the Great Plains of North America is an important issue. The purpose of this study was to modify an existing rangeland ecosystem model and to simulate a cow/calf production system under different climate scenarios. The project required the capability of simulating rangeland livestock production under different ambient CO₂ concentrations, temperatures and precipitation patterns. Climate change scenarios were created from three general circulation models (GCMs): GISS (Goddard Institute for Space Studies model), GFDL (Geophysical Fluid Dynamic Laboratory model), and UKMO (United Kingdom Meteorological Office model). Results from the GCMs were used to modify the climate record for a site in northeastern Colorado. Concomitantly, modifications were made to the SPUR model to help predict the effect of predicted climate change on selected variables of the range/livestock ecosystem. Simulation runs showed that predicted climate change will affect plant and animal production for rangelands. Changes in production were more closely related to changes in temperature and precipitation than to enhanced [CO₂] alone. The effect of climate change on livestock production was very complex and results were dependent on the particular GCM scenario being simulated.

Hao, X.M., B.A. Hale, and D.P. Ormrod. 1997. The effects of ultraviolet-B radiation and carbon dioxide on growth and photosynthesis of tomato. *Canadian Journal of Botany-Revue Canadienne De Botanique* 75(2):213-219.

Tomato (*Lycopersicon esculentum* Mill.) plants were exposed, in controlled environments with 2.7 W/(m².day) background ultraviolet-B (UV-B) radiation from fluorescent and incandescent lamps, to ambient (380 μmol L⁻¹) or elevated (600 μmol L⁻¹) CO₂ combined with a total of 7.2 or 13.1 kJ/(m².day) UV-B radiation to determine effects on growth and photosynthesis. Ten consecutive days of exposure to the higher level of UV-B significantly reduced total and stem dry weight, leaf area, and plant height compared with the lower level. Only leaf area and plant height were significantly reduced after 19 consecutive days of exposure. To investigate whether plants recover from UV-B damage, the UV-B exposures were halted for 3 days after 19 days of UV-B exposure and then restarted for a further 2 days. The largest reduction in plant growth was found after 3 days with no UV-B followed by 2 days of the higher level of UV-B. Plants did not recover from UV-B damage during

the 3 days with background UV-B. Significant CO₂×UV-B interactions were detected on stem dry weight after 10 consecutive days of the higher level of UV-B and on total dry weight, leaf dry weight, stem dry weight, and plant height after 3 days with no UV-B followed by 2 days of the higher level of UV-B. The higher dose of enhanced UV-B resulted in more severe damage at 600 μ mol L⁻¹ CO₂ than at ambient CO₂. The higher level of UV-B did not affect the leaf net photosynthesis rate on a leaf area basis, although this UV-B level may have inhibited tomato growth through reducing the photosynthetic area. UV-absorbing compounds in leaves in the highest UV-B radiation level for 19 days were greater than for leaves with the lower dose. These UV-absorbing compounds in the higher UV-B dose diminished more than in the lower dose plants during the 3 days without UV-B. The UV-absorbing compounds maintained by plants exposed to the highest level of UV-B radiation may have protected plants from UV-B damage, particularly between 10 and 19 consecutive days of exposure.

Hao, Y.Y., and R.E. Brackett. 1993. Influence of modified atmosphere on growth of vegetable spoilage bacteria in media. *Journal of Food Protection* 56(3):223-228.

Six gas mixtures (CO₂/O₂/N₂: 0/5/95, 0/10/90, 5/10/85, 5/20/75, 10/5/85, and 10/20/70) and air were used to investigate the effect of modified atmosphere (MA) on growth of four vegetable spoilage bacteria. In addition, we determined the ability of the MA which most inhibited spoilage bacteria to reduce spoilage in bell peppers inoculated with the respective bacteria. In general, MA did not significantly affect growth of the bacteria tested. Growth of *Erwinia*, *Pseudomonas*, *Xanthomonas*, and Pepper # 15 (a pectinolytic *Pseudomonas*) at 10 and 20-degrees-C was not significantly affected regardless of gas mixtures. At 5-degrees-C, growth of *Erwinia*, *Xanthomonas*, and Pepper # 15 was slightly reduced by some gas mixtures (CO₂/O₂/N₂: 0/5/95, 0/10/90, and 10/5/85; 10/5/85; 0/5/95 and 10/5/85, respectively). Modified atmosphere containing 10% CO₂, 5% O₂, and 85% N₂ did not reduce the ability of bacteria tested to grow at elevated concentrations of sodium chloride. In addition, this MA composition did not change the percentage of bell peppers spoiled by test bacteria inoculated. However, overall visual quality was enhanced by MA.

Harley, P.C., R.B. Thomas, J.F. Reynolds, and B.R. Strain. 1992. Modeling photosynthesis of cotton grown in elevated CO₂. *Plant, Cell and Environment* 15(3):271-282.

Cotton plants were grown in CO₂-controlled growth chambers in atmospheres of either 35 or 65 Pa CO₂. A widely accepted model of C₃ leaf photosynthesis was parameterized for leaves from both CO₂ treatments using non-linear least squares regression techniques, but in order to achieve reasonable fits, it was necessary to include a phosphate limitation resulting from inadequate triose phosphate utilization. Despite the accumulation of large amounts of starch (> 50 g m⁻²) in the high CO₂ plants, the photosynthetic characteristics of leaves in both treatments were similar, although the maximum rate of Rubisco activity (V_c(max)), estimated from A versus C(i) response curves measured at 29-degrees-C, was almost-equal-to 10% lower in leaves from plants grown in high CO₂. The relationship between key model parameters and total leaf N was linear, the only difference between CO₂ treatments

being a slight reduction in the slope of the line relating V_c(max) to leaf N in plants grown at high CO₂. Stomatal conductance of leaves of plants grown and measured at 65 Pa CO₂ was approximately 32% lower than that of plants grown and measured at 35 Pa. Because photosynthetic capacity of leaves grown in high CO₂ was only slightly less than that of leaves grown in 35Pa CO₂, net photosynthesis measured at the growth CO₂, light and temperature conditions was approximately 25% greater in leaves of plants grown in high CO₂, despite the reduction in leaf conductance. Greater assimilation rate was one factor allowing plants grown in high CO₂ to incorporate 30% more biomass during the first 36 d of growth.

Harrison, K., W. Broecker, and G. Bonani. 1993. A strategy for estimating the impact of CO₂ fertilization on soil carbon storage. *Global Biogeochemical Cycles* 7(1):69-80.

As soils are a likely candidate for the so-called missing carbon sink, we explore the possible impact of CO₂ fertilization on the global humus inventory. For any given greening-induced enhancement of plant growth, the increase in soil carbon inventory will depend on the spectrum of turnover times with respect to oxidation. Here we develop estimates of carbon turnover rates based on soil radiocarbon measurements.

Harrison, P.A., and R.E. Butterfield. 1996. Effects of climate change on Europe-wide winter wheat and sunflower productivity. *Climate Research* 7(3):225-241.

Spatially explicit crop models were developed from mechanistic principles to investigate the regional impacts of climate change. The approach highlights the spatial variability of crop responses to altered environmental conditions. The mechanistic nature of the models allows some confidence to be placed in the results that are produced under climate change scenarios. Two crop models have been constructed and applied across a large European region: EuroWheat (winter wheat) and EuroSunfl (sunflower). Model results were compared with observed phenology and yield across a variety of scales and found to capture the current spatial variability in wheat and sunflower productivity. Climate change scenarios from both equilibrium and transient general circulation model experiments were applied to each crop model. Wheat yields are predicted to increase throughout Europe for all climate change scenarios. Conversely, water-limited sunflower yields decrease in most regions and scenarios. More positive effects are predicted for winter wheat than sunflower due to a lower sensitivity to increased temperature and a higher sensitivity to elevated concentrations of CO₂. The lowest yield increases for wheat and the largest yield decreases for sunflower are found in western Europe, whilst the most positive responses for both crops occur in central and eastern Europe. Predictions for southern Europe are highly sensitive both within the region and between the scenarios. The old generation of equilibrium climate change scenarios gives the worst predictions (lowest yield increases or highest yield decreases). More beneficial responses are observed for the new generation of transient scenarios for both wheat and sunflower. Area averaged results for Europe, based on the United Kingdom Meteorological Office transient experiment (UKTR), indicate a rate of increase in winter wheat yields of 0.2 t ha⁻¹ decade⁻¹ up to the 2020s

and 0.36 t ha⁻¹ decade⁻¹ beyond. Smaller changes are predicted for sunflower: a rate of decrease of 0.05 t ha⁻¹ decade⁻¹ up to the 2020s followed by an increase of 0.05 t ha⁻¹ decade⁻¹.

Hartz, T.K., A. Baameur, and D.B. Holt. 1991. Carbon-dioxide enrichment of high-value crops under tunnel culture. *Journal of the American Society for Horticultural Science* 116(6):970-973.

The feasibility of field-scale CO₂ enrichment of vegetable crops grown under tunnel culture was studied with cucumber (*Cucumis sativus* L. cv. Dasher II, summer squash (*Cucurbita pepo* L. cv. Gold Bar), and tomato (*Lycopersicon esculentum* Mill. cv. Bingo) grown under polyethylene tunnels. The drip irrigation system was used to uniformly deliver a CO₂-enriched air stream independent of irrigation. Carbon dioxide was maintained between 700 and 1000- μ l.liter⁻¹ during daylight hours. Enrichment began immediately after crop establishment and continued for almost-equal to 4 weeks. At the end of the treatment phase, enrichment had significantly increased plant dry weight in the 2 years of tests. This growth advantage continued through harvest, with enriched cucumber, squash, and tomato plots yielding 30%, 20%, and 32% more fruit, respectively, in 1989. In 1990, cucumber and squash yields were increased 20%, and 16%, respectively. As performed, the expense of CO₂ enrichment represented less than a 10% increase in total preharvest costs. A similar test was conducted on fall-planted strawberries (*Fragaria X ananassa* Duch. cvs. Irvine and Chandler). Carbon dioxide enrichment under tunnel culture modestly increased 'Irvine' yields but did not affect 'Chandler'.

Harvey, L.D.D. 1996. Development of a risk-hedging CO₂-emission policy .2. Risks associated with measures to limit emissions, synthesis, and conclusions. *Climatic Change* 34(1):41-71.

This paper is Part II of a two-part series in which the risks associated with unrestrained greenhouse-gas emissions, and with measures to limit emissions, are reviewed. A sustained limitation of global CO₂ emissions requires global population stabilization, a reduction in per capita emissions in the developed world, and a limitation of the increase in per capita emissions in the developing world. Reducing or limiting per capita emissions requires a major effort to improve the efficiency with which energy is transformed and used; urban development which minimizes the need for the private automobile and facilitates district heating, cooling, and cogeneration systems; and accelerated development of renewable energy. The following risks associated with these efforts to limit CO₂ emissions are reviewed here: (i) resources might be diverted from other urgent needs; (ii) economic growth might be reduced; (iii) reduction measures might cost more than expected; (iv) early action might cost more than later action; (v) reduction measures might have undesired side effects; (vi) reduction measures might require heavy-handed government intervention; and (vii) reduction measures might not work. With gradual implementation of a diversified portfolio of measures, these risks can be greatly reduced. Net risk is further reduced by the fact that a number of non-climatic benefits would result from measures to limit CO₂ emissions. Based on the review of risks associated with measures to limit emissions here, and the review of the risks associated with unrestrained emissions presented in Part I, it is concluded that a reasonable near-term (20-30 year) risk hedging

strategy is one which seeks to stabilize global fossil CO₂ emissions at the present (early 1990's) level. This in turn implies an emission reduction of 26% for industrialized countries as a whole and 40-50% for Canada and the USA if developing country emissions are to increase by no more than 60%, which in itself would require major assistance from the industrialized countries. The effectiveness of global CO₂-emission stabilization in slowing down the buildup of atmospheric CO₂ is enhanced by the fact that the airborne fraction (ratio of annual atmospheric CO₂ increase to total annual anthropogenic emissions) decreases if emissions are stabilized, whereas it increases if emissions continue to grow exponentially. The framework and conclusions presented here are critically compared with so-called optimization frameworks.

Harwood, K.G., J.S. Gillon, A. Roberts, and H. Griffiths. 1999. Determinants of isotopic coupling of CO₂ and water vapour within a *Quercus petraea* forest canopy. *Oecologia* 119(1):109-119.

Concentration and isotopic composition ($\delta^{13}\text{C}$ and $\delta^{18}\text{O}$) of ambient CO₂ and water vapour were determined within a *Quercus petraea* canopy, Northumberland, UK. From continuous measurements made across a 36-h period from three heights within the forest canopy, we generated mixing lines (Keeling plots) for $\delta^{13}\text{C}$ (CO₂)-C-13, $\delta^{18}\text{O}$ (COO)-O-18-O-16 and $\delta^{18}\text{O}$ (H₂O)-O-18, to derive the isotopic composition of the signal being released from forest to atmosphere. These were compared directly with measurements of different respective pools within the forest system, i.e. $\delta^{13}\text{C}$ of organic matter input for $\delta^{13}\text{C}$ (CO₂)-C-13 $\delta^{18}\text{O}$ Of exchangeable water for $\delta^{18}\text{O}$ (COO)-O-18-O-16 and transpired water vapour for $\delta^{18}\text{O}$ (H₂O)-O-18. [CO₂] and $\delta^{13}\text{C}$ (CO₂)-C-13 showed strong coupling, where the released CO₂ was, on average, 4 per mil enriched compared to the organic matter of plant material in the system? suggesting either fractionation of organic material before eventual release as soil-respired CO₂, or temporal differences in ecosystem discrimination. $\delta^{18}\text{O}$ (COO)-O-18-O-16 was less well coupled to [CO₂], probably due to the heterogeneity and transient nature of water pools (soil, leaf and moss) within the forest. Similarly, $\delta^{18}\text{O}$ (H₂O)-O-18 was less coupled to [H₂O], again reflecting the transient nature of water transpired to the forest, seen as uncoupling during times of large changes in vapour pressure deficit. The $\delta^{18}\text{O}$ of transpired water vapour, inferred from both mixing lines at the canopy scale and direct measurement at the leaf level, approximated that of source water, confirming that an isotopic steady state held for the forest integrated over the daily cycle. This demonstrates that isotopic coupling of CO₂ and water vapour within a forest canopy will depend on absolute differences in the isotopic composition of the respective pools involved in exchange and on the stability of each of these pools with time.

Haszpra, L. 1999. On the representativeness of carbon dioxide measurements. *Journal of Geophysical Research-Atmospheres* 104(D21):26953-26960.

On the basis of the measurements at two monitoring sites located close to each other (220 km) in plain regions in Hungary, the representativeness of low-elevation continental CO₂ measurements is

estimated. It is shown that under such conditions only the measurements carried out in the early afternoon hours can be considered as regionally representative for the CO₂ content of the planetary boundary layer (PBL). Filtering the data in this way, it is calculated that the characteristic CO₂ mixing ratio in the PBL may be about 2.5 ppm higher over this part of Europe than at the Mauna Loa Observatory (National Oceanic and Atmospheric Administration), Hawaii.

Hattenschwiler, S., S. Buhler, and C. Korner. 1999. Quality, decomposition and isopod consumption of tree litter produced under elevated CO₂. *Oikos* 85(2):271-281.

Rising atmospheric CO₂ is expected to alter plant tissue quality which in turn could affect litter quality, decomposition, and carbon and nutrient turnover. We tested this hypothesis using leaf litter of beech (*Fagus sylvatica*) and branchlets (wood + bark) of spruce (*Picea abies*) produced under contrasting CO₂ concentrations in model ecosystems. Both types of litter produced under elevated CO₂ had significantly lower N concentrations, but showed no CO₂-related differences in carbon and lignin concentrations. Decomposition rates (mass loss) assessed in a natural temperate forest were significantly slower in litter produced at high CO₂. However, this effect became stronger in beech leaves but gradually disappeared in spruce branchlets over the 331-d exposure period. Irrespective of CO₂ treatment beech leaf litter lost 16% of its initial N content. Spruce branchlets produced at low CO₂ lost 50% of their initial N content, and those produced at high CO₂ lost 26%. Two isopod species representing native macro-decomposers consumed 36% more of the high CO₂-produced beech litter than they did of low CO₂-produced beech litter. Only small, and non-significant increases in consumption of high CO₂-produced spruce branchlets were observed. Isopods feeding on high CO₂ litter also produced more feces than those feeding litter from low CO₂. Our results indicate that CO₂-induced litter quality changes influence only certain stages of decomposition, and that these stages differ between different litter types. Inhibitory effects of elevated CO₂, however, may be compensated by the positive feed-back of intensified "litter processing" of low quality litter by macro-decomposers. Consequently, the entire cycle of litter production and decomposition must be included in the analysis of the potential effects of rising CO₂ on litter decomposition. This includes both micro- and macro-decomposer specific effects.

Hattenschwiler, S., and C. Korner. 1996. Effects of elevated CO₂ and increased nitrogen deposition on photosynthesis and growth of understory plants in spruce model ecosystems. *Oecologia* 106(2):172-180.

We studied the effects of-atmospheric CO₂ enrichment (280, 420 and 560 $\mu\text{mol CO}_2\text{ L}^{-1}$) and increased N deposition (0.30 and 90 $\text{kg ha}^{-1}\text{ year}^{-1}$) on the spruce-forest understory species *Oxalis acetosella*, *Homogyne alpina* and *Rubus hirtus*. Clones of these species formed the ground cover in nine 0.7 m^2 model ecosystems with 5-year-old *Picea abies* trees (leaf area index of approx. 2.2). Communities grew on natural forest soil in a simulated montane climate. Independently of N deposition, the rate of light-saturated net photosynthesis of leaves grown and measured at 420 $\mu\text{mol CO}_2\text{ L}^{-1}$ was higher in *Oxalis* and in *Homogyne*, but was not significantly different in *Rubus* compared to

leaves grown and measured at the pre-industrial CO₂ concentration of 280 $\mu\text{mol CO}_2\text{ L}^{-1}$. Remarkably, further CO₂ enrichment to 560 $\mu\text{mol CO}_2\text{ L}^{-1}$ caused no additional increase of CO₂ uptake. With increasing CO₂ supply concentrations of non-structural carbohydrates in leaves increased and N concentrations decreased in all species, whereas N deposition had no significant effect on these traits. Above-ground biomass and leaf area production were not significantly affected by elevated CO₂ in the more vigorously growing species *O. acetosella* and *R. hirtus*, but the "slow growing" *H. alpina* produced almost twice as much biomass and 50% more leaf area per plant under 420 $\mu\text{mol CO}_2\text{ L}^{-1}$ compared to 280 $\mu\text{mol CO}_2\text{ L}^{-1}$ (again no further stimulation at 560 $\mu\text{mol CO}_2\text{ L}^{-1}$). In contrast, increased N addition stimulated growth in *Oxalis* and *Rubus* but had no effect on *Homogyne*. In *Oxalis* (only) biomass per plant was positively correlated with microhabitat quantum flux density at low CO₂, but not at high CO₂ indicating carbon saturation. On the other hand, the less shade-tolerant *Homogyne* profited from CO₂ enrichment at all understory light levels facilitating its spread into more shady micro-habitats under elevated CO₂. These species-specific responses to CO₂ and N deposition will affect community structure. The non-linear responses to elevated CO₂ of several of the traits studied here suggest that the largest responses to rising atmospheric CO₂ are under way now or have already occurred and possible future responses to further increases in CO₂ concentration are likely to be much smaller in these understory species.

Hattenschwiler, S., and C. Korner. 1996. System-level adjustments to elevated CO₂ in model spruce ecosystems. *Global Change Biology* 2(4):377-387.

Atmospheric carbon dioxide enrichment and increasing nitrogen deposition are often predicted to increase forest productivity based on currently available data for isolated forest tree seedlings or their leaves. However, it is highly uncertain whether such seedling responses will scale to the stand level. Therefore, we studied the effects of increasing CO₂ (280, 420 and 560 $\mu\text{mol CO}_2\text{ L}^{-1}$) and increasing rates of wet N deposition (0, 30 and 90 $\text{kg ha}^{-1}\text{ year}^{-1}$) on whole stands of 4-year-old spruce trees (*Picea abies*). One tree from each of six clones, together with two herbaceous understory species, were established in each of nine 0.7 m^2 model ecosystems in nutrient poor forest soil and grown in a simulated montane climate for two years. Shoot level light-saturated net photosynthesis measured at growth CO₂ concentrations increased with increasing CO₂, as well as with increasing N deposition. However, predawn shoot respiration was unaffected by treatments. When measured at a common CO₂ concentration of 420 $\mu\text{mol CO}_2\text{ L}^{-1}$ 37% down-regulation of photosynthesis was observed in plants grown at 560 $\mu\text{mol CO}_2\text{ L}^{-1}$. Length growth of shoots and stem diameter were not affected by CO₂ or N deposition. Bud burst was delayed, leaf area index (LAI) was lower, needle litter fall increased and soil CO₂ efflux increased with increasing CO₂. N deposition had no effect on these traits. At the ecosystem level the rate of net CO₂ exchange was not significantly different between CO₂ and N treatments. Most of the responses to CO₂ studied here were non-linear with the most significant differences between 280 and 420 $\mu\text{mol CO}_2\text{ L}^{-1}$ and relatively small changes between 420 and 560 $\mu\text{mol CO}_2\text{ L}^{-1}$. Our results suggest that the lack of above-ground growth responses to elevated CO₂ is due to the combined effects of physiological down-regulation of photosynthesis at the leaf level, allometric adjustment at the canopy level (reduced LAI), and increasing strength of below-ground carbon sinks. The non-linearity of treatment effects further suggests that major responses of coniferous forests to atmospheric CO₂ enrichment might already be under way and that future responses may be comparatively smaller.

Hattenschwiler, S., and C. Körner. 1997. Annual CO₂ budget of spruce model ecosystems in the third year of exposure to elevated CO₂. *Acta Oecologica-International Journal of Ecology* 18(3):319-325.

Clones of 4-year-old spruce trees (*Picea abies*) were grown in competition in model ecosystems with nutrient-poor natural forest soil and natural understory vegetation and were exposed to three CO₂ concentrations (280, 420 and 560 μmol mol⁻¹) for three years. Diurnal net ecosystem CO₂ uptake (NECd), nocturnal net ecosystem CO₂ loss (NECn) and soil CO₂ efflux were measured repeatedly in the third year of CO₂ exposure and were used to estimate an annual ecosystem CO₂ budget. The CO₂ induced stimulation of NECd varied over the year with no measurable stimulation in spring and fall but a high mid-season CO₂ stimulation. Respiratory losses of whole ecosystems and soil CO₂ efflux alone were both progressively increased with increasing CO₂, thus counteracting the CO₂ stimulation of photosynthesis per unit ground area. Consequently, the annual net ecosystem CO₂ uptake was only moderately and non-linearly stimulated by CO₂ (+8% = 84 g C m⁻² a⁻¹) at 420 and +9% = 90 g C m⁻² a⁻¹) at 560 compared to 280 μmol CO₂ mol⁻¹). We conclude that the rising atmospheric CO₂ concentration may lead to an increase in annual net ecosystem carbon gain of rather nutrient-poor spruce communities. Our results further suggest that CO₂ fertilization effects may be greatest under current CO₂ concentration and that relative increases of net ecosystem CO₂ uptake will become relatively smaller as atmospheric CO₂ will continue to rise.

Hattenschwiler, S., and C. Körner. 1997. Growth of autotrophic and root-hemiparasitic understory plants under elevated CO₂ and increased N deposition. *Acta Oecologica-International Journal of Ecology* 18(3):327-333.

Effects of atmospheric CO₂ enrichment (280, 420 and 560 μmol CO₂ mol⁻¹) and increased N deposition (0, 30 and 90 kg ha⁻¹ a⁻¹) on *Oxalis acetosella*, *Homogyne alpina*, and *Melampyrum sylvaticum*, growing in model ecosystems beneath spruce stands, were studied. Aboveground biomass in the less-shade-tolerant *Homogyne* and in the annual hemiparasite *Melampyrum* was strongly increased with increasing CO₂, but not in the more shade-adapted *Oxalis*. In contrast, increased N deposition stimulated growth in *Oxalis*, but had no effect on *Homogyne* and *Melampyrum*. Due to spruce canopy closure *Homogyne* became light limited and its survivorship was strongly correlated with spruce canopy LAI in the second year of the experiment. Our results suggest, that elevated CO₂ facilitates the expansion of *Homogyne* into less favourable micro-habitats (deeper shade) and that increasing N deposition enables more vigorously growing species like *Oxalis* to increase in abundance. Growth of the hemiparasite *Melampyrum* was stimulated indirectly by increased heterotrophic carbon supply (carbon isotope data) from the host (*Picea abies*), and thus, this species may also increase in abundance with increasing CO₂. However, possible indirect effects (canopy feedbacks) make predictions of long-term understory development difficult.

Hattenschwiler, S., and C. Körner. 1998. Biomass allocation and

canopy development in spruce model ecosystems under elevated CO₂ and increased N deposition. *Oecologia* 113(1):104-114.

Ecosystem-level experiments on the effects of atmospheric CO₂ enrichment and N deposition on forest trees are urgently needed. Here we present data for nine model ecosystems of spruce (*Picea abies*) on natural nutrient-poor montane forest soil (0.7 m²) of ground and 350 kg weight). Each system was composed of six 7-year-old (at harvest) trees each representing a different genotype, and a herbaceous understory layer (three species). The model ecosystems were exposed to three different CO₂ concentrations (280, 420, 560 μmol l⁻¹) and three different rates of wet N deposition (0, 30, 90 kg ha⁻¹ year⁻¹) in a simulated annual course of Swiss montane climate for 3 years. The total ecosystem biomass was not affected by CO₂ concentration, but increased with increasing N deposition. However, biomass allocation to roots increased with increasing CO₂ leading to significantly lower leaf mass ratios (LMRs) and leaf area ratios (LARs) in trees grown at elevated CO₂. In contrast to CO₂ enrichment, N deposition increased biomass allocation to the aboveground plant parts, and thus LMR and LAR were higher with increasing N deposition. We observed no CO₂ x N interactions on growth, biomass production, or allocation, and there were also no genotype x treatment interactions. The final leaf area index (LAI) of the spruce canopies was 19% smaller at 420 and 27% smaller at 560 than that measured at 280 μmol CO₂ l⁻¹, but was not significantly altered by increasing N deposition. Lower LAIs at elevated CO₂ largely resulted from shorter branches (less needles per individual tree) and partially from increased needle litterfall. Independently of N deposition, total aboveground N content in the spruce communities declined with increasing CO₂ (-18% at 420 and -31% at 560 compared to 280 μmol CO₂ l⁻¹). N deposition had the opposite effect on total above ground N content (+18% at 30 and +52% at 90 compared to 0 kg N ha⁻¹ year⁻¹). Our results suggest that under competitive conditions on natural forest soil, atmospheric CO₂ enrichment may not lead to higher ecosystem biomass production, but N deposition is likely to do so. The reduction in LAI under elevated CO₂ suggests allometric down-regulation of photosynthetic carbon uptake at the canopy level. The strong decline in the tree nitrogen mass per unit ground area in response to elevated CO₂ may indicate CO₂-induced reductions of soil N availability.

Hattenschwiler, S., F. Miglietta, A. Raschi, and C. Körner. 1997. Morphological adjustments of mature *Quercus ilex* trees to elevated CO₂. *Acta Oecologica-International Journal of Ecology* 18(3):361-365.

It is still not known whether mature forest trees respond to increasing atmospheric CO₂ concentrations in similar ways as seedlings do. Mature Mediterranean oaks (*Quercus ilex*) growing in a CO₂ enriched atmosphere around natural CO₂ vents since the seedling stage showed a moderate, age dependent increase in stem biomass production, but had significantly lower biomass of 6-year-old branches, decreased branching, and lower leaf area per unit branch biomass, compared to control trees at a nearby unenriched site. Our data indicate that trees in natural forest stands morphologically adjust to increasing CO₂ and reduce CO₂ induced initial growth stimulations. Allometric adjustments such as reduction in leaf area may be regarded as a "down-regulation" of canopy photosynthesis and may be an effective mechanism for saving water.

Hattenschwiler, S., F. Miglietta, A. Raschi, and C. Korner. 1997. Thirty years of in situ tree growth under elevated CO₂: a model for future forest responses? *Global Change Biology* 3(5):463-471.

Rising concentrations of atmospheric carbon dioxide have been predicted to stimulate the growth of forest trees. However, long-term effects on trees growing to maturity and to canopy closure while exposed to elevated CO₂ have never been examined. We compared tree ring chronologies of Mediterranean *Quercus ilex* which have been continuously exposed to elevated CO₂ (around 650 $\mu\text{mol mol}^{-1}$) since they were seedlings, near two separate natural CO₂ springs with those from trees at nearby ambient-CO₂ 'control' sites. Trees grown under high CO₂ for 30 years (1964-93) showed a 12% greater final radial stem width than those growing at the ambient-CO₂ control sites. However, this stimulation was largely due to responses when trees were young. By the time trees were 25-30 y old the annual difference in tree ring width between low and high CO₂ grown trees had disappeared. At any given tree age, elevated CO₂ had a relatively greater positive effect on tree ring width in years with a dry spring compared to years with more rainfall between April and May. This indicates a beneficial effect of elevated CO₂ on tree water relations under drought stress. Our data suggest that the early regeneration phase of forest stands can be accelerated in CO₂-enriched atmospheres and that maximum biomass per land area may be reached sooner than under lower CO₂ concentrations. In our study, high CO₂ grown *Q. ilex* trees reached the same stem basal area at the age of 26 y as control trees at 29 y, i.e. three years earlier (faster turnover of carbon?). Reliable predictions of the future development of forests need to account for the variable responses of trees over their entire lifetime. Such responses to elevated CO₂ can presently only be assessed at such unique field sites.

Hattenschwiler, S., and C. Schaffellner. 1999. Opposing effects of elevated CO₂ and N deposition on *Lymantria monacha* larvae feeding on spruce trees. *Oecologia* 118(2):210-217.

The effects of elevated atmospheric CO and increased wet N deposition on leaf quality and insect herbivory were evaluated in nine model ecosystems composed of 7-year-old spruce trees (*Picea abies*) and three understorey species established on natural forest soil. Each model ecosystem was grown in a simulated montane climate, and was exposed to one of three CO₂ concentrations (280, 420, and 560 $\mu\text{l l}^{-1}$) and to one of three levels of N deposition (0, 30, and 90 kg ha⁻¹ year⁻¹) for 3 years. In the 3rd year of the experiment second to third instars of the nun moth (*Lymantria monacha*) were allowed to feed directly on current-year needles of top canopy branches of each tree for 13 days. Specific leaf area (SLA), water content, and N concentration decreased in needles exposed to elevated CO₂, whereas the concentrations of starch, condensed tannins, and total phenolics increased. Increased N deposition had no significant effect on SLA, and water content, but the concentrations of starch, condensed tannins, and total phenolics decreased, and sugar and N concentrations increased. Despite higher relative consumption rates (RCRs) larvae consumed 33% less N per unit larval biomass and per day at the two high CO₂ treatments, compared to those feeding on 280 $\mu\text{l l}^{-1}$ -needles, but they maintained similar N accumulation rates due to increased N utilization efficiencies (NUE). However, over the 12-day experimental period larvae gained less N overall and reached a 35% lower biomass in the two high-CO₂ treatments compared to those at 280 $\mu\text{l l}^{-1}$. The effects of increased N deposition on needle quality and insect performance were generally opposite to those of CO enrichment, but were lower in magnitude. We conclude that altered needle quality in response to elevated CO₂ will impair the growth and development of *L. monacha* larvae. Increasing N

deposition may mitigate these effects, which could lead to altered insect herbivore distributions depending on regional patterns of N deposition.

Hattenschwiler, S., F.H. Schweingruber, and C. Korner. 1996. Tree ring responses to elevated CO₂ and increased N deposition in *Picea abies*. *Plant, Cell and Environment* 19(12):1369-1378.

Four- to seven-year-old spruce trees (*Picea abies*) were exposed to three CO₂ concentrations (280, 420 and 560 $\mu\text{mol m}^{-3}$) and three rates of wet N deposition (0, 30 and 90 kg ha⁻¹ year⁻¹) for 3 years in a simulated montane forest climate. Six trees from each of six clones were grown in competition in each of nine 100 x 70 x 36 cm model ecosystems with nutrient-poor natural forest soil. Stem discs were analysed using X-ray densitometry. The radial stem increment was not affected by [CO₂] but increased with increasing rates of N deposition. Wood density was increased by [CO₂], but decreased by N deposition. Woodstarch concentration increased, and wood nitrogen concentration decreased with increasing [CO₂], but neither was affected by N deposition. The lignin concentration in wood was affected by neither [CO₂] nor N deposition. Our results suggest that, under natural growth conditions, rising atmospheric [CO₂] will not lead to enhanced radial stem growth of spruce, but atmospheric N deposition will, and in some regions is probably already doing so. Elevated [CO₂], however, will lead to denser wood unless this effect is compensated by massive atmospheric N deposition. It can be speculated that greater wood density under elevated [CO₂] may alter the mechanical properties of wood, and higher ratios of C/N and lignin/N in wood grown at elevated [CO₂] may affect nutrient cycles of forest ecosystems.

Hatton, T.J., J. Walker, W.R. Dawes, and F.X. Dunin. 1992. Simulations of hydroecological responses to elevated CO₂ at the catchment scale. *Australian Journal of Botany* 40(4-5):679-696.

A spatially explicit hydroecological landscape model of water, carbon and energy balances (Topog-IRM) is described. The landscape is envisaged as a catchment forested with a single stratum comprising *Eucalyptus maculata* trees. The model was used to simulate the direct effects of a 2X elevation in atmospheric carbon dioxide at two levels of nitrogen on catchment water yield, soil moisture status and tree growth. Experimental results used to parameterise the model are detailed. Key features of the model are (1) an ability to scale hydrological processes at the catchment scale in three dimensions, and (2) a means to integrate multiple factors/stresses on plant growth. The effects of CO₂ on catchment hydrology (water yield or soil moisture content) and forest growth (expressed as leaf area index, LAI) were modelled for a 2-year period, and contrasted with the effects of added nitrogen. Results were expressed as totals for the catchment or spatially distributed across the catchment. For the total catchment, water yield increased in the order: high CO₂ with low N, high CO₂ with high N, ambient CO₂ with low N, ambient CO₂ with high N. LAI increased from 3.3 to 5.7 in the order: ambient CO₂ with low N, ambient CO₂ with high N, high CO₂ with low N, high CO₂ with high N. These results agree with previous data. New findings are: (1) with elevated CO₂ a new equilibrium in transpiration is established in which leaf area increases offset decreases in stomatal

conductance; (2) the addition of nitrogen increases transpiration without any indication of a new equilibrium being reached during the simulated period; (3) the spatial distribution of soil moisture changes, presenting a new resource base for spatial changes to species composition and growth rates. The major hydroecological responses to elevated CO₂ are seen as increased maximum upper canopy leaf area, increased litter inputs, especially at times of drought (hence changed fire regimes), changes in the composition of the understorey (hence litter composition, soil microfauna, and the spatial expression of biological diversity) and a slight increase in water yield.

Hausler, R.E., P.J. Lea, and R.C. Leegood. 1994. Control of photosynthesis in barley leaves with reduced activities of glutamine-synthetase or glutamate synthase .2. Control of electron-transport and co₂ assimilation. *Planta* 194(3):418-435.

Heterozygous plants of barley (*Hordeum vulgare* L. cv. Maris Mink) with activities of chloroplastic glutamine synthetase (GS) between 47% and 97% of the wild-type and ferredoxin- dependent glutamate synthase (Fd-GOGAT) activities down to 63% of the wild-type have been used to study the control of photosynthetic fluxes. Rates of CO₂ assimilation measured over a range of intercellular CO₂ concentrations and photon flux densities (PFDs) were little different in the wild-type and a mutant with 47% GS, although total activities of ribulose-1, 5- bisphosphate carboxylase/oxygenase (Rubisco) decreased by about 20% with a decrease in GS to 50% of the wild-type. The quantum efficiencies of photosystem II electron transport (Phi PSII) and CO₂ assimilation (Phi CO₂) were determined. Phi PSII was lower than expected in mutants with 50% less GS under conditions which enhance the photorespiratory flux, but were identical to the wildtype under non-photorespiratory conditions, suggesting that at high rates of photorespiration the electron requirement for net CO₂ assimilation declines in plants with decreased GS. This discrepancy in the electron requirement between the wild-type and the 47% GS mutant was enhanced at high temperatures and low CO₂, conditions which favour oxygenation by Rubisco. Photochemical and non- photochemical chlorophyll a fluorescence quenching as well as the quantum efficiency of excitation-energy capture by open photosystem II reaction centres were differentially affected in mutants with less GS relative to the wild-type when CO₂ was lowered or the PFD was varied. The quantum efficiencies of electron transport in photosystems I and II were closely correlated under a range of PFDs and CO₂ concentrations, confirming that the rate of linear electron transport was much lower in plants with less GS. It is shown that GS exerts considerable control (flux control coefficients between 0.5 and 1.0) on the electron requirement for CO₂ assimilation at high fluxes of photorespiration relative to CO₂ assimilation. Apart from the control of GS on protein and Rubisco contents, GS in the wild-type has also some direct positive control on CO₂ assimilation. However, negative control on CO₂ assimilation was found in mutants with 50% less GS. These data, taken with the data on electron requirements for CO₂ assimilation, suggest that CO₂-fixing processes other than that catalysed by Rubisco, such as carboxylation of phosphoenolpyruvate, or an inhibition of photorespiration (e.g. glycine decarboxylation), may contribute to the observed CO₂ exchange and photosystem II electron transport in plants with less GS. In the 63%-Fd-GOGAT mutant, rates of CO₂ assimilation were appreciably lower than in the wild-type under a range of PFDs and CO₂ concentrations, which largely reflected lower contents of Rubisco in the Fd- GOGAT mutants. Assimilation of CO₂ was inhibited appreciably at high CO₂ concentrations. There was little difference in the electron requirement for CO₂ assimilation between the wild-type and mutants with less Fd-GOGAT, although there were indications that a

triose-phosphate/glycerate-3-phosphate shuttle or cyclic electron transport operates to balance ATP generation and NADP reduction. The latter was supported by a curvilinear relationship of photosystem I and II electron transport in the 63% Fd-GOGAT mutant. A positive control is exerted by Fd-GOGAT on the amounts of protein and Rubisco and on CO₂ assimilation.

Havstrom, M., T.V. Callaghan, and S. Jonasson. 1993. Differential growth-responses of *Cassiope tetragona*, an arctic dwarf-shrub, to environmental perturbations among 3 contrasting high sites and sub-arctic sites. *Oikos* 66(3):389-402.

Three populations of *Cassiope tetragona* (Ericaceae) were subjected to in situ environmental perturbations simulating predictions of global warming. The populations were selected to represent different parts of the range of the species, one growing in a high arctic coastal heath at Ny-Alesund (Svalbard, northern part of the species' range), one at a subarctic fellfield at 1150 m a.s.l. at Abisko, Swedish Lapland, and one in a subarctic tree-line heath at 450 m a.s.l. at Abisko, southern part of the species' range. The manipulations included nutrient addition, shading and two levels of temperature enhancement using passive greenhouses. The micrometeorological effects of the shading treatment was similar to that of a mountain birch canopy and the temperature enhancement treatments had the desired effect to increase the average air temperature by 2-4-degrees-C. Greenhouses which had a gap between the soil and the greenhouse plastic were particularly successful in creating the desired climatic perturbation without causing extreme maximum temperatures or other unwanted side-effects. The environmental manipulations caused strikingly different responses in the vegetative growth pattern of main shoots of *C. tetragona* among the three populations: at the subarctic tree-line heath, nutrient addition caused a substantial increase in growth, whereas it was the temperature enhancement treatments that caused increases, although smaller, at the subarctic fellfield and the high arctic heath sites. At the high arctic site, we also found growth reduced in response to shading, but at the subarctic sites, and particularly at the tree-line heath site, shading caused a marked etiolation of the shoots. Hence, different factors seem to produce very different responses in the vegetative growth of *C. tetragona* in different parts of its geographical range. We conclude that competition for nutrients and light are the main limiting factors for the growth of *Cassiope tetragona* near the lower distributional limit (LODIL) of the species, but that temperature is the main limiting factor in the northern parts of its range, and at high altitudes in the southern parts of its range. We also suggest that the direct effect of predicted future climatic warming on the growth of *Cassiope tetragona* will increase towards the north, whereas a possible indirect effect of increasing nutrient availability following a temperature increase will be the main effect in the southern and lower parts of its range. These responses could, however, be modified by shading from other species responding to environmental change by increased growth.

Haxeltine, A., and I.C. Prentice. 1996. A general model for the light-use efficiency of primary production. *Functional Ecology* 10(5):551-561.

1. Net primary production (NPP) by terrestrial ecosystems appears to be proportional to absorbed photosynthetically active radiation (APAR) on a seasonal and annual basis. This observation has been used in 'diagnostic' models that estimate NPP from remotely sensed vegetation indices. In 'prognostic' process-based models carbon fluxes are more commonly integrated with respect to leaf area index assuming invariant leaf photosynthetic parameters. This approach does not lead to a proportional relationship between NPP and APAR. However, leaf nitrogen content and Rubisco activity are known to vary seasonally and with canopy position, and there is evidence that this variation takes place in such a way as to nearly optimize total canopy net photosynthesis. 2. Using standard formulations for the instantaneous response of leaf net photosynthesis to APAR, we show that the optimized canopy net photosynthesis is proportional to APAR. This theory leads to reasonable values for the maximum (unstressed) light-use efficiency of gross and net primary production of C-3 plants at current ambient CO₂, comparable with empirical estimates for agricultural crops and forest plantations. 3. By relating the standard formulations to the Collatz-Farquhar model of photosynthesis, we show that a range of observed physiological responses to temperature and CO₂ can be understood as consequences of the optimization. These responses include the CO₂ fertilization response and stomatal closure in C-3 plants, the increase of leaf N concentration with decreasing growing season temperature, and the downward acclimation of leaf respiration and N content with increasing ambient CO₂. The theory provides a way to integrate diverse experimental observations into a general framework for modelling terrestrial primary production.

Hdider, C., L.P. Vezina, and Y. Desjardins. 1994. Short-term studies of (no₃-)-n-15 and (nh₄+) -n-15 uptake by micropropagated strawberry shoots cultured with or without co₂ enrichment. *Plant Cell Tissue and Organ Culture* 37(2):185-191.

The uptake of (NO₃-)-N-15 and (NH₄+) -N-15 has been examined in 5-, 10- and 28-day-old micropropagated strawberry (*Fragaria x ananassa* Duch. cv. Kent) shoots rooted in one-half strength Murashige and Skoog (MS) liquid medium on cellulose plugs (Sorbarods). The results indicated that the plantlets absorbed both NO₃- and NH₄+ during the culture with a greater uptake of NH₄+ at 5 days of culture. Furthermore, a pronounced reduction in NO₃- and NH₄+ uptake at 10 and 28 days of culture was observed within 6 h of the short-term uptake study. This reduction could be explained by the low CO₂ concentration in test tubes during the photoperiod, since no reduction in nitrogen uptake occurred in the CO₂ enriched condition. The results are interpreted as an indication of the important role for photosynthetic CO₂ fixation in the process of nitrogen uptake by the plantlets during the rooting stage.

He, P., K.P. Bader, A. Radunz, U. Kahmann, G.H. Ruppel, and G.H. Schmid. 1998. Gas exchange characteristics in leaves of the Euphorbiaceae *Aleurites montana* as consequence of growth under 700 ppm CO₂ in air - A study on photosynthesis and photorespiration in the Chinese tung-oil tree. *Zeitschrift Fur Naturforschung C-A Journal of Biosciences* 53(3-4):151-158.

Three months old plants of the Chinese tung-oil tree *Aleurites montana* (Euphorbiaceae) were cultivated for 4 months in air containing 700 ppm

CO₂. These plants, which grow substantially better in the CO₂-enriched atmosphere, were analyzed by mass spectrometry for photosynthesis and photorespiration together with control plants grown all the time in normal (350 ppm CO₂) air. Thereafter part of the plants was subjected for two weeks to 0.3 ppm SO₂ in the atmosphere and again analyzed for photosynthesis and photorespiration. *Aleurites montana* exhibits a strongly CO₂-dependent photosynthesis which partially explains the observed stimulatory effect of 700 ppm CO₂ on growth of the plant. In control plants grown in normal air, photorespiration measured simultaneously with photosynthesis via the uptake of O-18(2) in the light, is much lower than in C-3-plants like tobacco (He et al, 1995, *Z. Naturforsch.* 50c, 781-788). In *Aleurites* grown in 700 ppm CO₂, however, photorespiration is completely absent in contrast to tobacco when grown under 700 ppm CO₂. In tobacco, photorespiration is not inhibited to the extent of the in vitro experiments in which plants grown at 350 ppm CO₂ are measured under the increased CO₂ content of 700 ppm. Gas exchange measurements carried out by mass spectrometry show that the ratio of O-2 evolved to CO₂ fixed is about 0.5. Apparently, part of the CO₂ fixed is channelled into a metabolic path without concomitant O-2-evolution. Although the plant has no succulent appearance (its leaves somehow resemble maple leaves) apparently a Crassulacean type metabolism is performed. When *Aleurites* plants grown all the time in normal air with 350 ppm, are exposed for two weeks to 0.3 ppm SO₂ the treatment completely inhibits this CO₂-fixing portion which is tentatively attributed to a Crassulacean type of metabolism. This is demonstrated by a normal C-3-type ratio O-2 evolved/CO₂ fixed of 1. When *Aleurites* plants, grown for 4 months in a CO₂-enriched atmosphere of 700 ppm CO₂, are subjected for two weeks to 0.3 ppm SO₂, the features of control plants show up again. When these plants are tested under 350 ppm CO₂ the Crassulacean type CO₂-fixation apparently is not inhibited by SO₂. Photorespiration, although low is present in the same activity as in the controls. Seemingly, an increased level of CO₂ in air tends to alleviate the impact of the SO₂ at least in the Chinese lung-oil tree.

He, P., K.P. Bader, A. Radunz, and G.H. Schmid. 1995. Consequences of high CO₂-concentrations in air on growth and gas-exchange rates in tobacco mutants. *Zeitschrift Fur Naturforschung C-A Journal of Biosciences* 50(11-12):781-788.

Wild type tobacco *N. tabacum* var. John William's Broadleaf and the tobacco aurea mutant Su/su were permanently grown under 700 ppm CO₂ in air. In comparison to plants grown under 350 ppm CO₂ in air but under otherwise identical conditions growth was substantially enhanced. Gas exchange measurements carried out by mass spectrometry show that the rate of photosynthesis in the wild type and in the mutant is increased by more than 100%. The photorespiratory rate in the wild type measured; as O-18(2)- uptake in the light in the "700 ppm CO₂-plants" is not reduced to the extent expected or deduced from experiments in which the 350 ppm system responds under in vitro conditions to 700 ppm CO₂. An analysis of the induction kinetics of room temperature fluorescence kinetics of the adapted (700 ppm CO₂) system and the control system (350 ppm CO₂) under various CO₂-partial pressures shows that permanent growth under the elevated CO₂-partial pressure leads to a structural modification of the photosynthetic apparatus.

He, P., A. Radunz, K.P. Bader, and G.H. Schmid. 1996. Influence of CO₂ and SO₂ on growth and structure of photosystem II of the Chinese

tung-oil tree *Aleurites montana*. *Zeitschrift Fur Naturforschung C-A Journal of Biosciences* 51(7-8):441-453.

Three months old plants of the Chinese tung-oil tree *Aleurites montana* were cultivated for 4 months in air containing an increased amount of 700 ppm CO₂. During the exposure to 700 ppm CO₂ the plants exhibited a considerably stronger growth (30- 40%) in comparison to the control plants (grown in normal air). In these CO₂-plants during the entire analyzing period the amount of soluble proteins, of soluble sugars and the chlorophyll content were lower than in control plants. The protein content, referred to leaf area, increased during this time in both plant types by approx. 50% but with a different time course. The increase is faster in CO₂-plants compared to control plants, and ends up with similar values in both plants after 4 months. No difference is seen between sun and shade leaves. The chlorophyll content in both sun and shade leaves is 20% lower in CO₂-plants. Whereas the chlorophyll content in sun leaves stays constant during development, it has increased in shade leaves by 20% at the end of the 4 months period. The content of soluble sugars is lower in CO₂-plants compared to control plants. The difference is bigger in sun leaves than in shade leaves. The ribulose 1.5-bisphosphate carboxylase/oxygenase content almost doubles within the experimentation period, but seems to be subject to large variations. CO₂-plants contain in general less ribulose 1.5- bisphosphate carboxylase/oxygenase than control plants. The content of coupling factor of photophosphorylation is 20% lower in CO₂-plants when compared to control plants and remains during development more constant in CO₂-plants. The molecular structure of the photosystem II-complex undergoes under the influence of the increased CO₂-content a quantitative modification. The light harvesting complex (LHCP) and the extrinsic peptide with the molecular mass of 33 kDa increase in CO₂-plants. Gassing with SO₂ (0.3 ppm in air) leads to a strong damage of the plants. The damaging influence is already seen after 6 days and leads to a partial leaf-shedding of the tree. In the visually still intact remaining leaves the chlorophyll content referred to unit leaf area decreases by 63%, that of soluble sugars by 65%, the content of soluble proteins and that of Rubisco decrease by 26% and 36% respectively. The light harvesting complex and the chlorophyll-binding peptides (43 and 47 kDa) increase whereas the extrinsic peptides decrease. It looks as if the simultaneous application of SO₂ (0.3 ppm) and increased CO₂ (700 ppm) relieves the damaging effect of SO₂. Plant growth does not exhibit a difference in comparison to control plants. Soluble proteins and chlorophyll increase by 27% and 33% and the ribulose 1.5-bisphosphate carboxylase/oxygenase content as well as that of soluble sugars increases by 18 respectively 14%. The peptide composition of photosystem II shows a quantitative modification. The LHCP increases and the chlorophyll-binding peptides and the peptides with a molecular mass smaller than 24 kDa are reduced. The quantity of extrinsic peptides appears unchanged. Ribulose 1,5- bisphosphate carboxylase/oxygenase and the CF1-complex of *Aleurites* are immunochemically only partially identical to the corresponding enzymes of *Nicotiana tabacum* as demonstrated by tandem-cross-immune electrophoresis.

He, X.Q., Y.H. Lin, J.X. Lin, and Y.X. Hu. 1998. Relationship between stomatal density and the changes of atmospheric CO₂ concentrations. *Chinese Science Bulletin* 43(11):928-930.

The relationship between the stomatal density of five woody plants endemic to China, i.e. *Eucommia ulmoides*, *Quercus liaotungensis*, *Q. glandulifera* var. *brevipetiolata*, *Cyclocarya paliurus* and *Ficus heteromorpha*, and the atmospheric CO₂ concentrations was studied by observations on leaves of the herbarium-stored specimens(1920s-

1990s). The results showed that the stomatal density in *Eucommia ulmoides*, *Quercus liaotungensis* and *Q. glandulifera* var. *brevipetiolata* decreased significantly in response to the elevated atmospheric CO₂ concentrations, while in *Cyclocarya paliurus* it decreased slightly and in *Ficus heteromorpha* there were no responses.

He, Y., X.S. Yang, D.R. Miller, G.R. Hendrey, K.F. Lewin, and J. Nagy. 1996. Effects of face system operation on the micrometeorology of a loblolly pine stand. *Transactions of the Asae* 39(4):1551-1556.

The effects of the gas injection operation on air movement in the loblolly pine stand at the Duke Forest prototype BNL-FACE User Facility were investigated. The micrometeorological conditions were measured using three-dimensional sonic anemometers in the center of the FACE ring at two heights, one just above the canopy (median height of the canopy = 9 m) at 11.6 m and another at 6.8 m above the ground where the canopy was the most dense. While the micrometeorological parameters were sampled continuously at 10 Hz, the gas injection system was turned alternatively on and off every 5 min for about 100 h. The analyses indicated that the system operation had little effect on the micrometeorology processes above the canopy. There were small magnitude but detectable changes in some of the micrometeorological parameters within the canopy, primarily during stable atmospheric conditions, in response to this 5-min alternation. The gas injection operation created a slightly diverging windfield in the top half of the canopy in the enclosed stand. A slight dampening of the vertical wind and air temperature fluctuations was detected. No detectable effects on the mean, or accumulated, heat and momentum fluxes at the measurement locations were found. In general, the system was shown to cause minimal disturbances to the natural environment compared to traditional carbon dioxide (CO₂) enrichment facilities and it provides a better alternative for long-term ecological studies.

He, Z.L., S. von Caemmerer, G.S. Hudson, G.D. Price, M.R. Badger, and T.J. Andrews. 1997. Ribulose-1,5-bisphosphate carboxylase/oxygenase activase deficiency delays senescence of ribulose-1,5-bisphosphate carboxylase/oxygenase but progressively impairs its catalysis during tobacco leaf development. *Plant Physiology* 115(4):1569-1580.

Transgenic tobacco (*Nicotiana tabacum* L. cv W38) plants with an antisense gene directed against the mRNA of ribulose-1,5- biphosphate carboxylase/oxygenase (Rubisco) activase grew more slowly than wild-type plants in a CO₂-enriched atmosphere, but eventually attained the same height and number of leaves. Compared with the wild type, the anti-activase plants had reduced CO₂ assimilation rates, normal contents of chlorophyll and soluble leaf protein, and much higher Rubisco contents, particularly in older leaves. Activase deficiency greatly delayed the usual developmental decline in Rubisco content seen in wild-type leaves. This effect was much less obvious in another transgenic tobacco with an antisense gene directed against chloroplast-located glyceraldehyde-3-phosphate dehydrogenase, which also had reduced photosynthetic rates and delayed development. Although Rubisco carbamylation was reduced in the anti-activase plants, the reduction was not sufficient to explain the reduced photosynthetic rate of older anti-activase leaves. Instead, up to a 10-fold reduction in the catalytic turnover rate of carbamylated Rubisco *in vivo* appeared to be the main cause. Slower catalytic turnover by carbamylated Rubisco was particularly obvious in high-CO₂-grown leaves but was also detectable in air-grown leaves. Rubisco activity measured immediately after rapid

extraction of anti-activase leaves was not much less than that predicted from its degree of carbamylation, ruling out slow release of an inhibitor from carbamylated sites as a major cause of the phenomenon. Nor could substrate scarcity or product inhibition account for the impairment. We conclude that activase must have a role in vivo, direct or indirect, in promoting the activity of carbamylated Rubisco in addition to its role in promoting carbamylation.

Heagle, A.S., F.L. Booker, J.E. Miller, W.A. Pursley, and L.A. Stefanski. 1999. Influence of daily carbon dioxide exposure duration and root environment on soybean response to elevated carbon dioxide. *Journal of Environmental Quality* 28(2):666-675.

Little is known about effects of daily CO₂ enrichment duration and root environment on plant response to elevated CO₂. Two experiments were performed, with Essex soybean (*Glycine max* L. Merr.) in open-top field chambers to address these questions. In one experiment, effects of 12 and 24 h d(-1) exposures to double-ambient CO₂ were compared for plants grown in 14 L pots that were either insulated to moderate soil temperature or not insulated. Although never significant statistically, trends at some growth stages suggested that nighttime CO₂ enrichment contributed to growth and yield. Plants grew and yielded more in insulated than noninsulated pots, but there were no significant CO₂ enrichment X insulation interactions. In the second experiment, response to approximately 1.3, 1.6, and 1.9 times ambient CO₂ was compared for plants grown in the ground or 14 L pots. Enhancement of photosynthesis, growth, and yield by CO₂ enrichment was similar in pots and in the ground. Linear responses to different CO₂ concentrations were significant for all yield components in both root environments, whereas quadratic responses were significant for plants in pots but not for plants in the ground. Tests of proportionality of response for yield components showed no evidence of significant differences between plants in pots and in the ground except weight per 100 seeds. Seed yield enhancement at 1.9 times ambient CO₂ was 36% for plants in pots and 33% for plants in the ground. Overall, proportional response of soybean to CO₂ enrichment was relatively uniform in spite of large differences in baseline growth and yield.

Heagle, A.S., R.L. Brandenburg, J.C. Burns, and J.E. Miller. 1994. Ozone and carbon-dioxide effects on spider-mites in white clover and peanut. *Journal of Environmental Quality* 23(6):1168-1176.

Effects of O₃ and/or elevated CO₂ on two-spotted spider mites (*Tetranychus urticae* Koch) grown on an O₃-sensitive and an O₃-resistant clone of white clover (*Trifolium repens* L.) were measured in greenhouse and field experiments. Peanut (*Arachis hypogaea* L.) 'NC-9' was used in one greenhouse study with O₃. In field studies, O₃ treatments were charcoal filtered air (CF), nonfiltered air (NF), and two NF treatments with O₃ added for 12 h d(-1) at proportions of approximate to 1.25 and 1.50 times the ambient O₃ concentration. In greenhouse studies, constant amounts of O₃ were added to CF for 6 h d(-1) to achieve mean concentrations ranging from 5 to 100 nL L(-1). For the greenhouse O₃ X CO₂ experiment, CO₂ concentrations were ambient and approximately twice-ambient for 24 h d(-1). Plants were exposed to O₃ and/or CO₂ for approximate to 7 d before infestation

with mites; daily exposures continued for 14 to 28 d to allow reproduction for at least two generations. Leaves were sampled to count eggs, larvae, nymphs, and adults. Ozone caused more chlorosis and necrosis on the O₃-sensitive clover clone (NC-S) than on the O₃-resistant clone (NC-R). Carbon dioxide enrichment increased shoot growth of both clones by approximate to 33%. Statistical analyses indicated significant O₃ effects in some experiments and nonsignificant O₃ effects in others. A trend toward increased mite populations with increased O₃ occurred, however, on NC-S in all trials. No consistent trends occurred with NC-R. With peanut, a significant linear increase in mite population occurred with increased O₃. Carbon dioxide enrichment increased the rate of population increase on both clover clones, but more so on NC-R. At 22 to 28 d after infestation, the total population in the twice-ambient CO₂ treatment was 65% greater than in the ambient treatment for NC-R and 22% greater than in the ambient treatment for NC-S. There were no statistically significant interactive effects between CO₂ and O₃ on mite population growth. The apparent clone effects on mite population response to O₃ and CO₂ strongly suggest that responses were mediated through the host plants.

Heagle, A.S., J.E. Miller, and F.L. Booker. 1998. Influence of ozone stress on soybean response to carbon dioxide enrichment: I. Foliar properties. *Crop Science* 38(1):113-121.

Tropospheric O₃ can cause foliar injury, decreased growth, and decreased yield, whereas CO₂ enrichment generally causes opposite effects. Little is known about plant response to mixtures of O₃ and CO₂. Open-top field chambers were used to determine if foliar responses of soybean [*Glycine max* (L.) Merr.] to CO₂ enrichment are affected by O₃ stress and vice versa. Plants were grown in 14-L pots and exposed to four CO₂ and three O₃ concentrations in 12 combinations. The CO₂ treatments were ambient (366 µL L(-1)) and three treatments with CO₂ added for 24 h d(-1) at approximately 1.3, 1.6, and 2.0 times ambient. The O₃ treatments were charcoal-filtered air (CF), nonfiltered air (NF), and NF with O₃ added for 12 h d(-1) (NF+), resulting in seasonal concentrations of approximately 20, 46, and 75 nL L(-1). Foliar effects of CO₂ enrichment were dependent on the amount of stress caused by O₃. In the CF treatment, plants were not stressed by O₃, and CO₂ enrichment caused chlorosis and decreased chlorophyll. In the IVF and NF+ treatments, plants were stressed by O₃, and CO₂ enrichment suppressed chlorosis and increased chlorophyll. Ozone decreased specific leaf weight, increased foliar N and C, and decreased C/N ratios, whereas CO₂ caused opposite responses for these measures. Ozone increased foliar S and B but did not affect P or K concentrations. Conversely, CO₂ enrichment suppressed foliar S, B, P, and K concentrations. These interactions between O₃ and CO₂ emphasize a need to consider the amount of plant stress caused by O₃ in studies to measure effects of CO₂ enrichment.

Heagle, A.S., J.E. Miller, F.L. Booker, and W.A. Pursley. 1999. Ozone stress, carbon dioxide enrichment, and nitrogen fertility interactions in cotton. *Crop Science* 39(3):731-741.

Ozone (O-3) in the troposphere can cause plant stress leading to foliar injury and suppressed growth and yield, whereas elevated CO₂ generally enhances growth and yield. Numerous studies have been performed to determine effects of O-3 and CO₂ separately, but relatively few have been performed to determine if O-3 can affect plant response to CO₂ or vice versa. Open-top field chambers were used to determine if such interactions occur for cotton (*Gossypium hirsutum* L.), which is relatively sensitive to O-3. Nitrogen nutrition is especially important in cotton production so N nutrition was included as an experimental factor. Plants were grown in 14-L pots at low, medium, and high soil N levels and exposed to three CO₂ and two or three O-3 treatments in all combinations during two seasons. The CO₂ treatments were ambient (370 μ mol L⁻¹) and two treatments with CO₂ added for 24 h d⁻¹ at approximately 1.5 and 2.0 times ambient. In 1995, the O-3 treatments were charcoal filtered air (CF), and nonfiltered air (NF) with O-3 added for 12 h d⁻¹ (NF+). In 1996, a NF treatment was also included to represent ambient O-3 conditions. The CF, NF, and NF+ treatments resulted in seasonal O-3 concentrations of approximately 23, 51, and 75 nL L⁻¹. Carbon dioxide enrichment generally stimulated growth and yield whereas O-3 exposure suppressed growth and yield. Stimulation induced by CO₂ increased as O-3 stress increased. For example, in 1995 at medium N, the percentage increase in yield caused by doubling CO₂ in CF air was 0%, but was 52% in NF+ air. Comparable values for 1996 were 23% in CF air and 140% in NF+ air. These interactions occurred for a range of soil N levels, and were probably caused by CO₂-induced prevention of O-3 stress. The results emphasize the need to consider O-3 x CO₂ interactions to ensure correct interpretation of cause-effect relationships in CO₂ enrichment studies with crops that are sensitive to O-3.

Heagle, A.S., J.E. Miller, and W.A. Pursley. 1998. Influence of ozone stress on soybean response to carbon dioxide enrichment: III. Yield and seed quality. *Crop Science* 38(1):128-134.

Ozone in the troposphere can cause plant stress, whereas elevated CO₂ generally causes positive responses. Little is known of how these gases interact to affect plant response. Interactive effects on yield and seed quality of soybean [*Glycine max* (L.) Merr.] grown in 14-L pots were measured in open-top field chambers. Essex was tested in 1993, and Essex, Holladay, and NK 6955 were tested in 1994. Plants were exposed from emergence to maturity to four CO₂ levels (ambient and 1.3, 1.6, and 2.0 times ambient) and three O-3 levels (0.4, 0.9, and 1.5 times ambient) in 12 combinations. Increasing O-3 suppressed growth and yield, whereas CO₂ enrichment stimulated growth and yield. Carbon dioxide-induced stimulation was greater for plants stressed by O-3 than for non stressed plants. For example, CO₂ at 2.0 times ambient increased 2-yr mean seed yield of Essex by 16, 24, and 81% at O-3 levels of 0.4, 0.9, and 1.5 times ambient, respectively. Effects of O-3 and CO₂ on seed oil content were variable with numerous cultivar differences. Seed protein content was never affected. Elevated O-3 suppressed oleic acid content in seeds, whereas CO₂ increased it; the nature of the O-3 x CO₂ interaction for oleic acid was similar to that observed for most yield measures. Carbon dioxide-induced stimulation of plants stressed by O-3 was apparently caused partly by amelioration of O-3 stress. Interactions between O-3 and CO₂ must be considered for proper interpretation of cause-effect relationships in CO₂ enrichment studies.

Heagle, A.S., J.E. Miller, D.E. Sherrill, and J.O. Rawlings. 1993.

Effects of ozone and carbon-dioxide mixtures on 2 clones of white clover. *New Phytologist* 123(4):751-762.

The effects of mixtures of ozone and carbon dioxide on growth and physiology of an O₃-sensitive (NC-S) and an O₃-resistant (NC-R) clone of white clover (*Trifolium repens* L.) were determined. The experiment was performed in a greenhouse with O₃ treatments of 5 and 82 nL L⁻¹ (ppb) for 6 h d⁻¹ and CO₂ treatments of 380 (ambient), 490,600, and 710 μ mol L⁻¹ (ppm) for 24 h d⁻¹. Enrichment with CO₂ decreased foliar gas exchange (measured as stomatal resistance) of NC-R more than that of NC-S whereas O₃ decreased gas exchange of NC-S more than that of NC-R. Ozone caused extensive foliar injury of NC-S but caused only slight injury of NC-R. CO₂ enrichment suppressed O₃-induced foliar injury of NC-S as measured after 4 wk of exposure, but this effect diminished after 8 wk of exposure. CO₂ enrichment decreased the relative chlorophyll content (mg of chlorophyll mg⁻¹ of leaf tissue sampled) but not the total chlorophyll (total chlorophyll in the leaves sampled). There were no O₃ x CO₂ interactions for foliar chlorophyll. High concentrations of CO₂ caused reddening of new leaves near the end of the 8 wk exposure period. CO₂ enrichment decreased foliar concentrations of N, P, K, S, Cu, B, and Fe, increased foliar concentrations of Mn, but did not affect Zn, Ca, or Mg. Ozone exposure did not modify the CO₂ effects on foliar nutrient concentration. Ozone decreased growth of NC-S but not NC-R while CO₂ enrichment stimulated growth of both clones. The highest CO₂ concentration appeared to decrease the effects of O₃ on growth of NC-S. However, except for a transitory effect on foliar injury, there was no evidence that CO₂ at concentrations less than the highest used in this study, will protect white clover from the effects of tropospheric O₃.

Heath, J. 1998. Stomata of trees growing in CO₂-enriched air show reduced sensitivity to vapour pressure deficit and drought. *Plant, Cell and Environment* 21(11):1077-1088.

Stomatal conductance (g(s)) and photosynthetic rate (A) were measured in young beech (*Fagus sylvatica*), chestnut (*Castanea sativa*) and oak (*Quercus robur*) growing in ambient or CO₂-enriched air. In oak, g(s) was consistently reduced in elevated CO₂. However, in beech and chestnut, the stomata of trees growing in elevated CO₂ failed to close normally in response to increased leaf-to-air vapour pressure deficit (LAVPD). Consequently, while g(s) was reduced in elevated CO₂ on days with low LAVPD, on warm sunny days (with correspondingly high LAVPD) g(s) was unchanged or even slightly higher in elevated CO₂. Furthermore, during drought, g(s) of beech and chestnut was unresponsive to [CO₂], over a wide range of ambient LAVPD, whereas in oak g(s) was reduced by an average of 50% in elevated CO₂. Stimulation of A by elevated CO₂ in beech and chestnut was restricted to days with high irradiance, and was greatest in beech during drought. Hence, most of the additional carbon gain in elevated CO₂ was made at the expense of water economy, at precisely those times (drought, high evaporative demand) when water conservation was most important. Such effects could have serious consequences for drought tolerance, growth and, ultimately, survival as atmospheric [CO₂] increases.

Heath, J., and G. Kerstiens. 1997. Effects of elevated CO₂ on leaf gas exchange in beech and oak at two levels of nutrient supply: Consequences for sensitivity to drought in beech. *Plant, Cell and Environment* 20(1):57-67.

Beech (*Fagus sylvatica* L.) and pedunculate oak (*Quercus robur* L.) were grown from seed for two whole seasons at two CO₂ concentrations (ambient and ambient + 250 $\mu\text{mol mol}^{-1}$) with two levels of soil nutrient supply. Measurements of net leaf photosynthetic rate (A) and stomatal conductance (g(s)) of well-watered plants were taken over both seasons; a drought treatment was applied in the middle of the second growing season to a separate sample of beech drawn from the same population. The net leaf photosynthetic rate of well-watered plants was stimulated in elevated CO₂ by an average of 75% in beech and 33% in oak; the effect continued through both growing seasons at both nutrient levels. There were no interactive effects of CO₂ concentration and nutrient level on A or g(s) in beech or oak. Stomatal conductance was reduced in elevated CO₂ by an average of 34% in oak, but in beech there were no significant reductions in g(s) except under cloudy conditions (-22% in elevated CO₂). During drought, there was no effect of CO₂ concentration on g(s) in beech grown with high nutrients, but for beech grown with low nutrients, g(s) was significantly higher in elevated CO₂, causing more rapid soil drying. With high nutrient supply, soil drying was more rapid at elevated CO₂ due to increased leaf area. It appears that beech may substantially increase whole-plant water consumption in elevated CO₂, especially under conditions of high temperature and irradiance when damage due to high evaporative demand is most likely to occur, thereby putting itself at risk during periods of drought.

Heath, J., G. Kerstiens, and M.T. Tyree. 1997. Stem hydraulic conductance of European beech (*Fagus sylvatica* L.) and pedunculate oak (*Quercus robur* L.) grown in elevated CO₂. *Journal of Experimental Botany* 48(312):1487-1489.

Over two seasons in c. 600 ppm CO₂, oak had lower stomatal conductance in CO₂-enriched compared to ambient air. Beech showed no response to CO₂ concentration on sunny days. Mirroring this pattern, exposure to elevated CO₂ reduced whole-shoot hydraulic conductance per unit leaf area in oak, but not in beech.

Hebeisen, T., A. Luscher, and J. Nosberger. 1997. Effects of elevated atmospheric CO₂ and nitrogen fertilisation on yield of *Trifolium repens* and *Lolium perenne*. *Acta Oecologica-International Journal of Ecology* 18(3):277-284.

Trifolium repens L. and *Lolium perenne* L. were grown in monocultures and bi-species mixture in a Free Air Carbon Dioxide Enrichment (FACE) experiment at elevated (60 Pa) and ambient (35 Pa) CO₂ partial pressure (pCO₂) for two years. The effects of nitrogen fertilisation (10 and 42 g N m⁻² a⁻¹ in 1993; 14 and 56 g N m⁻² a⁻¹ in 1994) on the growth response to pCO₂ were investigated in frequently defoliated (7 cuts in 1993; 8 cuts in 1994) swards. The yield of *Trifolium* in monocultures increased by 22% when grown at elevated pCO₂. In contrast, the yield of *Lolium* monocultures was not affected (2%) by elevated pCO₂, whereas *Lolium* increased its root mass considerably. The consequence of these interspecific differences in the CO₂ response

was an increase in the proportion of *Trifolium* in the mixed swards from 39% at ambient to 50% at elevated pCO₂. However, the proportion of the species was more strongly affected by N fertilisation than by elevated pCO₂. Based on these 2' results, we conclude that the species proportion in managed grassland may change as the CO₂ concentration increases. However, an adapted management may, at least partially, counteract such CO₂ induced changes in the proportion of the species.

Hebeisen, T., A. Luscher, S. Zanetti, B.U. Fischer, U.A. Hartwig, M. Frehner, G.R. Hendrey, H. Blum, and J. Nosberger. 1997. Growth response of *Trifolium repens* L. and *Lolium perenne* L. as monocultures and bi-species mixture to free air CO₂ enrichment and management. *Global Change Biology* 3(2):149-160.

Trifolium repens L. and *Lolium perenne* L. were grown in monocultures and bi-species mixture in a Free Air Carbon Dioxide Enrichment (FACE) experiment at elevated (60 Pa) and ambient (35 Pa) CO₂ partial pressure (pCO₂) for three years. The effects of defoliation frequencies (4 and 7 cuts in 1993; 4 and 8 cuts in 1994/95) and nitrogen fertilization (10 and 42 g m⁻² y⁻¹ N in 1993; 14 and 56 g m⁻² y⁻¹ in 1994/95) on the growth response to pCO₂ were investigated. There were significant interspecific differences in the CO₂ responses during the first two years, while in the third growing season, these interspecific differences disappeared. Yield of *T. repens* in monocultures increased in the first two years by 20% when grown at elevated pCO₂. This CO₂ response was independent of defoliation frequency and nitrogen fertilization. In the third year, the CO₂ response of *T. repens* declined to 11%. In contrast, yield of *L. perenne* monocultures increased by only 7% on average over three years at elevated pCO₂. The yield response of *L. perenne* to CO₂ changed according to defoliation frequency and nitrogen fertilization, mainly in the second and third year. The ratio of root/yield of *L. perenne* increased under elevated pCO₂, low N fertilizer rate, and frequent defoliation, but it remained unchanged in *T. repens*. We suggest that the more abundant root growth of *L. perenne* was related to increased N limitation under elevated pCO₂. The consequence of these interspecific differences in the CO₂ response was a higher proportion of *T. repens* in the mixed swards at elevated pCO₂. This was evident in all combinations of defoliation and nitrogen treatments. However, the proportion of the species was more strongly affected by N fertilization and defoliation frequency than by elevated pCO₂. Based on these results, we conclude that the species proportion in managed grassland may change as the CO₂ concentration increases. However, an adapted management could, at least partially, counteract such CO₂ induced changes in the proportion of the species. Since the availability of mineral N in the soil may be important for the species' responses to elevated pCO₂, more long-term studies, particularly of processes in the soil, are required to predict the entire ecosystem response.

Hedges, L.V., J. Gurevitch, and P.S. Curtis. 1999. The meta-analysis of response ratios in experimental ecology. *Ecology* 80(4):1150-1156.

Meta-analysis provides formal statistical techniques for summarizing the results of independent experiments and is increasingly being used in ecology. The response ratio (the ratio of mean outcome in the experimental group to that in the control group) and closely related measures of proportionate change are often used as measures of effect

magnitude in ecology. Using these metrics for meta-analysis requires knowledge of their statistical properties, but these have not been previously derived. We give the approximate sampling distribution of the log response ratio, discuss why it is a particularly useful metric for many applications in ecology, and demonstrate how to use it in meta-analysis. The meta-analysis of response-ratio data is illustrated using experimental data on the effects of increased atmospheric CO₂ on plant biomass responses.

Heifetz, P.B., A. Lers, D.H. Turpin, N.W. Gillham, J.E. Boynton, and C.B. Osmond. 1997. *dr* and *spr/sr* mutations of *Chlamydomonas reinhardtii* affecting D1 protein function and synthesis define two independent steps leading to chronic photoinhibition and confer differential fitness. *Plant, Cell and Environment* 20(9):1145-1157.

The effects of introduced chloroplast gene mutations affecting D1 synthesis, turnover and function on photosynthesis, growth and competitive ability were examined in autotrophic cultures of *Chlamydomonas reinhardtii* (Chlorophyta) adapted to low or high irradiance. Few discernible effects were evident when the mutants were grown in low light (LL, 70 $\mu\text{mol m}^{-2} \text{s}^{-1}$). The herbicide-resistant *psbA* mutation Ser(264) $\rightarrow$ Ala (*dr*) slowed electron transfer and accelerated D1 degradation in cells grown under high light (HL, 600 $\mu\text{mol m}^{-2} \text{s}^{-1}$). The maximum rate of light- and CO₂-saturated photosynthesis, cell growth rate and competitive ability in the *dr* mutant were reduced compared to wild type under HL. However, the wild-type rate of D1 synthesis in *dr* was adequate to compensate for accelerated D1 degradation. 16S rRNA mutations conferring resistance to streptomycin and spectinomycin (*spr/sr*) that altered chloroplast ribosome structure and assembly were used to inhibit chloroplast protein synthesis. In *spr/sr* cells grown under HL, D1 synthesis was reduced by 40-60% compared to wild type and D1 degradation was accelerated, leading to a 4-fold reduction in D1 pool size. The reduced D1 levels were accompanied by an elevation of F_o and a decline in F_v/F_m, quantum yield and maximum rate of CO₂-saturated photosynthesis. Chemostat experiments showed that the growth rate and competitive ability of *spr/sr* were reduced against both wild type and *dr*.

Heilman, J.L., D.R. Cobos, F.A. Heinsch, C.S. Campbell, and K.J. McInnes. 1999. Tower-based conditional sampling for measuring ecosystem-scale carbon dioxide exchange in coastal wetlands. *Estuaries* 22(3A):584-591.

Long-term measurements of CO₂ exchange between coastal wetlands and the atmosphere are necessary to improve our understanding of the role these ecosystems play in the global carbon cycle, and the response of these systems to environmental change. We conducted research to adapt and evaluate tower-based conditional sampling as a method for measuring net CO₂ exchange (NCE) at the ecosystem scale on a continuous basis. With conditional sampling, NCE is determined from the product of the standard deviation of vertical wind velocity, the difference in CO₂ concentration between updrafts and downdrafts in the constant flux portion of the boundary layer above the surface, and an empirical coefficient. We constructed a system that used a sonic anemometer to measure vertical wind velocity (*w*) and control a high-speed three-way valve that diverted air from updrafts and down, drafts into separate sample lines, depending on the direction of *w*. An infrared

gas analyzer was used to measure the concentration difference. The conditional sampling system was installed and tested in a marsh in the Nueces River Delta near Corpus Christi, Texas, as part of a long-term study of effects of freshwater inflow on CO₂ flux. System accuracy was evaluated by comparing conditional sampling measurements of water vapor flux with independent estimates obtained with the Bowen ratio method. Average daily flux estimates for the two methods agreed to within 13%. Measurements showed that freshwater inflow due to flooding of the Nueces River increased NCE by increasing CO₂ assimilation and decreasing CO₂ efflux. Over a 65-d period, daily NCE varied from a maximum gain of 0.16 mol CO₂ m⁻² d⁻¹ during flooding to a maximum loss of - 0.14 mol CO₂ m⁻² d⁻¹ when the marsh dried. Our study showed that conditional sampling was well suited for quantifying CO₂ exchange in coastal wetlands on a diel, daily, and seasonal basis.

Heineke, D., F. Kauder, W. Frommer, C. Kuhn, B. Gillissen, F. Ludewig, and U. Sonnewald. 1999. Application of transgenic plants in understanding responses to atmospheric change. *Plant, Cell and Environment* 22(6):623-628.

Acclimation of plants to an increase in atmospheric carbon dioxide concentration is a well described phenomenon. It is characterized by an increase in leaf carbohydrates and a degradation of ribulose 1,5-bisphosphate carboxylase protein (Rubisco) leading in the long term to a lower rate of CO₂ assimilation than expected from the kinetic constants of Rubisco. This article summarizes studies with transgenic plants grown in elevated pCO₂ which are modified in their capacity of CO₂ fixation, of sucrose and starch synthesis, of triosephosphate and sucrose transport and of sink metabolism of sucrose. These studies show that a feedback accumulation of carbohydrates in leaves play only a minor role in acclimation, because leaf starch synthesis functions as an efficient buffer for photoassimilates. There is some evidence that in elevated pCO₂, plants grow faster and senescence is induced earlier.

Heissner, A. 1996. A simple model of greenhouse climate for short term control of temperature, air humidity, and CO₂ concentration. *Gartenbauwissenschaft* 61(6):289-300.

A simple greenhouse climate model was designed for short term control of temperature, air humidity, and CO₂ concentration. The model is based on the balances of thermal energy, water vapour, and carbon dioxide and is represented by a system of three nonlinear differential equations of the first order. The reaction of the canopy is taken into consideration through empirical models of CO₂ gas exchange and transpiration of tomato plants. Model inputs are the meteorological conditions in the open (temperature, air humidity, CO₂ concentration, global radiation, and wind velocity), the temperature of the ground surface in the greenhouse, and the temperature on the greenhouse cover as well as four control variables (heating, ventilation, CO₂ enrichment, and moistening of the air). Measurements were carried out in two greenhouses with glass and plastic film cover under conditions of ventilation to estimate model quantities and to test the suitability of the

model fort prognosis. By means of simulations possibilities for the comparison of control strategies were demonstrated.

Hemming, J.D.C., and R.L. Lindroth. 1999. Effects of light and nutrient availability on aspen: Growth, phytochemistry, and insect performance. *Journal of Chemical Ecology* 25(7):1687-1714.

This study explored the effect of resource availability on plant phytochemical composition within the framework of carbon- nutrient balance (CNB) theory. We grew quaking aspen (*Populus tremuloides*) under two levels of light and three levels of nutrient availability and measured photosynthesis, productivity, and foliar chemistry [water, total nonstructural carbohydrates (TNC), condensed tannins, and phenolic glycosides]. Gypsy moths (*Lymantria dispar*) and forest tent caterpillars (*Malacosoma disstria*) were reared on foliage from each of the treatments to determine effects on insect performance. Photosynthetic rates increased under high light, but were not influenced by nutrient availability. Tree growth increased in response to both the direct and interactive effects of light and nutrient availability. Increasing light reduced foliar nitrogen, while increasing nutrient availability increased foliar nitrogen. TNC levels were elevated under high light conditions, but were not influenced by nutrient availability. Starch and condensed tannins responded to changes in resource availability in a manner consistent with CNB theory; levels were highest under conditions where tree growth was limited more than photosynthesis (i.e., high light-low nutrient availability). Concentrations of phenolic glycosides, however, were only moderately influenced by resource availability. In general, insect performance varied relatively little among treatments. Both species performed most poorly on the high light-low nutrient availability treatment. Because phenolic glycosides are the primary factor determining aspen quality for these insects, and because levels of these compounds were minimally affected by the treatments, the limited response of the insects was not surprising. Thus, the ability of CNB theory to accurately predict allocation to defense compounds depends on the response of specific allelochemicals to changes in resource availability. Moreover, whether allelochemicals serve to defend the plant depends on the response of insects to specific allelochemicals. Finally, in contrast to predictions of CNB theory, we found substantial allocation to storage and defense compounds under conditions in which growth was carbon-limited (e.g., low light), suggesting a cost to defense in terms of reduced growth.

Hendrey, G.R., D.S. Ellsworth, K.F. Lewin, and J. Nagy. 1999. A free-air enrichment system for exposing tall forest vegetation to elevated atmospheric CO₂. *Global Change Biology* 5(3):293-309.

A free-air CO₂ enrichment (FACE) system was designed to permit the experimental exposure of tall vegetation such as stands of forest trees to elevated atmospheric CO₂ concentrations ([CO₂](a)) without enclosures that alter tree microenvironment. We describe a prototype FACE system currently in operation in forest plots in a maturing loblolly pine (*Pinus taeda* L.) stand in North Carolina, USA. The system uses feedback control technology to control [CO₂] in a 26 m diameter forest plot that is over 10 m tall, while monitoring the 3D plot volume to characterize the whole-stand CO₂ regime achieved during enrichment. In the second summer season of operation of the FACE system, atmospheric CO₂ enrichment was conducted in the forest during all daylight hours for 96.7% of the scheduled running time from 23 May to 14 October with a preset target [CO₂] of 550 $\mu\text{mol mol}^{-1}$, approximate to 200 $\mu\text{mol mol}^{-1}$ above ambient [CO₂]. The system provided spatial and temporal control of [CO₂] similar to that reported for open-top chambers over trees, but without enclosing the vegetation. The daily average daytime [CO₂] within the upper forest canopy at the centre of the FACE plot was 552 $\pm$ 9 $\mu\text{mol mol}^{-1}$ (mean $\pm$ SD). The FACE system maintained 1-minute average [CO₂] to within $\pm$ 110 $\mu\text{mol mol}^{-1}$ of the target [CO₂] for 92% of the operating time. Deviations of [CO₂] outside of this range were short-lived (most lasting < 60 s) and rare, with fewer than 4 excursion events of a minute or longer per day. Acceptable spatial control of [CO₂] by the system was achieved, with over 90% of the entire canopy volume within $\pm$ 10% of the target [CO₂] over the exposure season. CO₂ consumption by the FACE system was much higher than for open-top chambers on an absolute basis, but similar to that of open-top chambers and branch bag chambers on a per unit volume basis. CO₂ consumption by the FACE system was strongly related to windspeed, averaging 50 g CO₂ m⁻³ h⁻¹ for the stand for an average windspeed of 1.5 m s⁻¹ during summer. The [CO₂] control results show that the free-air approach is a tractable way to study long-term and short-term alterations in trace gases, even within entire tall forest ecosystems. The FACE approach permits the study of a wide range of forest stand and ecosystem processes under manipulated [CO₂](a) that were previously impossible or intractable to study in true forest ecosystems.

Hendrey, G.R., and B.A. Kimball. 1994. The face program. *Agricultural and Forest Meteorology* 70(1-4):3-14.

A large, cooperative, integrated experimental program utilizing free-air CO₂ enrichment (FACE) is being conducted to expose plants to elevated concentrations of CO₂. The goals are to evaluate the effects of increasing atmospheric CO₂ on plants and ecosystems and, in the long run, to contribute to the evaluation of terrestrial plant feedback regulation on the rate of change of CO₂ in the atmosphere. Having no walls, the FACE system allows plants to be grown under realistic microclimate and CO₂ conditions expected to prevail in the mid-twenty-first century. Data obtained under such conditions are needed for validation of models being developed to predict the effects of increasing CO₂ and changing climate variables on plants, ecosystems, agricultural productivity and water resources. Setup costs for the FACE systems used in these experiments are similar to the costs of field chamber systems. Although annual operating costs are about three times the cost of field chambers, FACE plots are relatively large, leading to an economy of scale, so that per unit of treated plant material, FACE systems are the least expensive approach for well-integrated field experiments. These features have provided an incentive to conduct comprehensive FACE experiments with many cooperating scientists working together to measure numerous plant, soil and micrometeorological parameters, as described in the collection of papers in this special issue of 'Agricultural

and Forest Meteorology'.

899

Hendrey, G.R., K.F. Lewin, and J. Nagy. 1993. Free air carbon-dioxide enrichment - development, progress, results. *Vegetatio* 104:17-31.

Credible predictions of climate change depend in part on predictions of future CO₂ concentrations in the atmosphere. Terrestrial plants are a large sink for atmospheric CO₂ and the sink rate is influenced by the atmospheric CO₂ concentration. Reliable field experiments are needed to evaluate how terrestrial plants will adjust to increasing CO₂ and thereby influence the rate of change of atmospheric CO₂. Brookhaven National Laboratory (BNL) has developed a unique Free-Air CO₂ Enrichment (FACE) system for a cooperative research program sponsored by the U.S. Department of Energy and U.S. Department of Agriculture, currently operating as the FACE User Facility at the Maricopa Agricultural Center (MAC) of the University of Arizona. The BNL FACE system is a tool for studying the effects of CO₂ enrichment on vegetation and natural ecosystems, and the exchange of carbon between the biosphere and the atmosphere, in open-air settings without any containment. The FACE system provides stable control of CO₂ at 550 ppm $\pm$ 10%, based on 1-min averages, over 90% of the time. In 1990, this level of control was achieved over an area as large as 380 m², at an annual operating cost of \$668 m⁻². During two field seasons of enrichment with cotton (*Gossypium hirsutum*) as the test plant, enrichment to 550 ppm CO₂ resulted in significant increases in photosynthesis and biomass of leaves, stems and roots, reduced evapotranspiration, and changes in root morphology. In addition, soil respiration increased and evapotranspiration decreased.

Hendrey, G.R., S.P. Long, I.F. McKee, and N.R. Baker. 1997. Can photosynthesis respond to short-term fluctuations in atmospheric carbon dioxide? *Photosynthesis Research* 51(3):179-184.

Rapid and irregular variations of atmospheric CO₂ concentrations ($c(a)$) occur in nature but are often very much more pronounced and frequent when artificially enriching CO₂ concentrations in simulating the future atmosphere. Therefore, there is the danger that plant responses at elevated CO₂ in fumigation experiments might reflect the increased frequency and amplitude of fluctuation in concentration as well as the increase in average concentration. Tests were conducted to determine whether the photosynthetic process could sense such fluctuations in $c(a)$. Instantaneous chlorophyll fluorescence ($F-t$) was monitored for wheat leaves (*Triticum aestivum* cv. Hereward) exposed to $c(a)$ oscillating symmetrically by 225 $\mu\text{mol mol}^{-1}$ about a $c(a)$ set point concentration of 575 or 650 $\mu\text{mol mol}^{-1}$. No $F-t$ response was detected to half-cycle step changes in $c(a)$ lasting less than two seconds, but at half-cycles of two seconds or longer, the response of $F-t$ was pronounced. In order to determine the in vivo linear electron transport rate (J) the O₂ concentration was maintained at 21 mmol mol^{-1} to eliminate photorespiration. J which is directly proportional to the rate of CO₂ uptake under these conditions, was not significantly changed at half-cycles of 30 s or less but was decreased by half-cycles of 60 s or longer. It was inferred that if duration of an oscillation is less than 1 minute and is symmetrical with respect to mean CO₂ concentration, then there is no effect on current carbon uptake, but oscillations of 1 minute or more decrease photosynthetic CO₂ uptake in wheat.

Hendrix, D.L., J.R. Mauney, B.A. Kimball, K. Lewin, J. Nagy, and G.R. Hendrey. 1994. Influence of elevated CO₂ and mild water-stress on nonstructural carbohydrates in field-grown cotton tissues. *Agricultural and Forest Meteorology* 70(1-4):153-162.

Root, stem and leaf tissues, from cotton plants exposed to CO₂ at ambient (370 $\mu\text{mol mol}^{-1}$ (control)) or elevated (550 $\mu\text{mol mol}^{-1}$ (FACE; free-air carbon dioxide enrichment)) levels in the field during the 1990 and 1991 growing seasons, were analyzed for nonstructural carbohydrates (glucose, fructose, sucrose and starch). Besides the FACE treatment, these plants were also exposed to two irrigation levels: 100% and 67% replacement of evapotranspiration. FACE had a greater effect upon cotton plant nonstructural carbohydrates than did irrigation treatments. Leaf carbohydrate content was increased by FACE, but this increase was much more pronounced in the stems and roots. Starch and soluble sugars in leaves in FACE plots tended to be consistently greater than in control leaves, without much change in carbohydrate content during the growing season. In contrast, root and stem, starch and soluble sugar pools were strongly increased by FACE and fluctuated strongly during the growing season. In both seasons, stem and taproot nonstructural carbohydrate content passed through a minimum during periods of heavy boll set. The fluctuations in stem and root carbohydrate content were therefore probably caused by the varying metabolic demands of the developing plant. These results suggest that a significant effect of CO₂ enrichment on starch-accumulating plants is an increase of nonstructural carbohydrate, especially starch, in nonleaf storage pools. This buildup occurs somewhat independently of the water status of the plant, and these enlarged pools can be drawn upon by the growing plant to maintain growth during periods of high metabolic demand.

Hendry, M.J., C.A. Mendoza, R.A. Kirkland, and J.R. Lawrence. 1999. Quantification of transient CO₂ production in a sandy unsaturated zone. *Water Resources Research* 35(7):2189-2198.

Temporal and spatial respiration rates were determined in a 5.7-m thick, sandy, unsaturated zone over a 550-day period using measured CO₂ concentrations, CO₂ fluxes to the atmosphere, moisture contents, and temperatures. Cyclical patterns in CO₂ concentrations were measured in duplicate nests of nine gas samplers. Maximum CO₂ gas concentrations occurred during the summer (0.85-1.22%), and minimum concentrations occurred during the winter (0.04-0.24%). CO₂ gas concentrations decreased with increasing depth during the summer and increased with depth during the winter. A one-dimensional finite element model was developed to quantify transient respiration rates through the unsaturated zone. The model was calibrated to the measured CO₂ concentrations. Temperature and moisture content variations were represented with an analytical expression and linear interpolation of field-measured values, respectively, in the model. Simulation results provided very good approximations to the field-measured CO₂ concentrations, but predicted CO₂ fluxes to the atmosphere were higher than measured. Respiration rates ranged from 5 $\mu\text{g C g}^{-1}\text{d}^{-1}$ in the soil horizon during the summer to about $<10(-4) \mu\text{g C g}^{-1}\text{d}^{-1}$ in unsaturated sections of the C horizon. A sensitivity analysis showed that the respiration rates in the C horizon must be $<10(-3) \mu\text{g C g}^{-1}\text{d}^{-1}$ and that the majority of the elevated CO₂ concentrations in this thick unsaturated zone are the result of respiration in the soil horizon. Overall, roots contribute about 75% of the CO₂ in the summer months. O₂ gas, microbial analyses, and the distribution of root biomass supported this conclusion. These

observations also imply that although microorganisms are present in subsurface environments their in situ activity in this sandy unsaturated zone may be very low.

Henning, F.P., C.W. Wood, H.H. Rogers, G.B. Runion, and S.A. Prior. 1996. Composition and decomposition of soybean and sorghum tissues grown under elevated atmospheric carbon dioxide. *Journal of Environmental Quality* 25(4):822-827.

It has been hypothesized that changes in both quantity and quality of plant residue inputs to soils as atmospheric carbon dioxide (CO₂) concentration increases may alter carbon (C) and nitrogen (N) turnover rates and pool sizes. We determined the effect of elevated atmospheric CO₂ on plant tissue quality, and flow modifications in tissue quality affect C and N mineralization. Soybean [C-3; Glycine max (L.) Merr. cv. Stonewall] and sorghum [C-4; Sorghum bicolor (L.) Moen, cv. Savanna 5] were grown under elevated (704.96 ± 0.33 μmol CO₂ mol⁻¹) and ambient (357.44 ± 0.12 μmol CO₂ mol⁻¹) atmospheric CO₂ in open-top chambers. Leaf and stem tissues were separated from harvested plants and analyzed for C, N, lignin, and cellulose. Tissues were applied to Norfolk loamy sand (fine-loamy, siliceous, thermic Typic Kandudult) and aerobically incubated for 70-d to determine C and N mineralization, C turnover, relative N mineralization, and C/N mineralized. Elevated CO₂ had no effect on plant residue C concentration, but N concentration of soybean leaves and stems and sorghum stems was reduced; however, CO₂ enrichment increased C/N ratio and lignin concentration for only sorghum stems and soybean leaves, respectively. Source of plant residue (i.e., produced under either elevated or ambient CO₂) had no impact on soil C turnover, relative N mineralization, cumulative C and N mineralization, and C/N mineralized. These data suggest that increasing atmospheric CO₂ will have little effect on composition or decomposition of field crop residues. Thus, since CO₂ enrichment results in increased photosynthetic C fixation, the possibility exists for increased soil C storage under field crops in an elevated CO₂ world.

Herbert, D.A., E.B. Rastetter, G.R. Shaver, and G.I. Agren. 1999. Effects of plant growth characteristics on biogeochemistry and community composition in a changing climate. *Ecosystems* 2(4):367-382.

Vegetation growth characteristics influence ecosystem biogeochemistry and must be incorporated in models used to project biogeochemical responses to climate variations. We used a multiple-element limitation model (MEL) to examine how variations in nutrient use efficiency (NUE) and net primary production to biomass ratio (nPBR) affect changes in ecosystem C stocks after an increase in temperature and atmospheric CO₂. nPBR influences the initial rates of response, but the magnitude and direction of long-term responses are determined NUE. MEL was used to simulate responses to climate change in communities composed of two species differing in nPBR and/or NUE. When only nPBR differed between the species, the high-nPBR species outgrew the low-nPBR species early in the simulations, but the shift in dominance was transitory because of secondary N limitations. High-NUE and were therefore favored under elevated CO₂. Increased temperature stimulated N release from soil organic matter (SOM) and therefore favored low-NUE species. The combined release from C and N limitation under the

combination of increased temperature and elevated CO₂ favored high-NUE species. High C:N litter from high-NUE species limited the N-supply rate from SOM, which favors the dominance of the high-NUE species in the short term. However, in the long term increased litter production resulted in SOM accumulation, which reestablished a N supply rate favorable to the reestablishment and dominance of the low-NUE species. Conditions then reverted to a state favorable to the high-NUE species.

Herbst, M., and G. Hormann. 1998. Predicting effects of temperature increase on the water balance of beech forest - An application of the 'KAUSHA' model. *Climatic Change* 40(3-4):683-698.

The water balance model 'KAUSHA' (Halldin, 1989) was applied to a 100-year-old beech (*Fagus sylvatica* L.) forest in northern Germany. Overall, a satisfying agreement between modelled evapotranspiration values and independent micrometeorological measurements (Bowen ratio energy balance method) could be observed, although for rainy days KAUSHA showed a tendency to overestimate evapotranspiration. The model was used to predict the effects of a climate warming on the water budgets of the forest. It is shown that a temperature increase of 2 degrees C due to a rising CO₂ content of the atmosphere will not change the yearly totals of evapotranspiration significantly, but could have serious effects on the soil water balance during the vegetation period. Because under climate change conditions a higher amount of the available soil water has already been evaporated in winter and spring, soil water content will limit the transpiration of the trees from July to September much more strongly. Therefore, the yield of beech forest might also suffer from drought effects. It can be concluded that a better knowledge of the seasonal distribution of rainfall under climate change conditions is indispensable for predicting effects of rising temperatures and CO₂ concentrations on ecosystems.

Herrick, J.D., and R.B. Thomas. 1999. Effects of CO₂ enrichment on the photosynthetic light response of sun and shade leaves of canopy sweetgum trees (*Liquidambar styraciflua*) in a forest ecosystem. *Tree Physiology* 19(12):779-786.

To investigate whether sun and shade leaves respond differently to CO₂ enrichment, we examined photosynthetic light response of sun and shade leaves in canopy sweetgum (*Liquidambar styraciflua* L.) trees growing at ambient and elevated (ambient + 200 μmol⁻¹) atmospheric CO₂ in the Brookhaven National Laboratory/Duke University Free Air CO₂ Enrichment (FACE) experiment. The sweetgum trees were naturally established in a 15-year-old forest dominated by loblolly pine (*Pinus taeda* L.). Measurements were made in early June and late August 1997 during the first full year of CO₂ fumigation in the Duke Forest FACE experiment. Sun leaves had a 68% greater leaf mass per unit area, 63% more leaf N per unit leaf area, 27% more chlorophyll per unit leaf area and 77% greater light-saturated photosynthetic rates than shade leaves. Elevated CO₂ strongly stimulated light-saturated photosynthesis of sun and shade leaves in June and August; however, the relative photosynthetic enhancement by elevated CO₂ for sun leaves was more than double the relative enhancement of shade leaves. Elevated CO₂

stimulated apparent quantum yield by 30%. but there was no interaction between CO₂ and leaf position. Daytime leaf-level carbon gain extrapolated from photosynthetic light response curves indicated that sun leaves were enhanced 98% by elevated CO₂, whereas shade leaves were enhanced 41%. Elevated CO₂ did not significantly affect leaf N per unit area in sun or shade leaves during either measurement period. Thus, the greater CO₂ enhancement of light-saturated photosynthesis in sun leaves than in shade leaves was probably a result of a greater amount of nitrogen per unit leaf area in sun leaves. A full understanding of the effects of increasing atmospheric CO₂ concentrations on forest ecosystems must take account of the complex nature of the light environment through the canopy and how light interacts with CO₂ to affect photosynthesis.

Herrmann, B., and U. Feller. 1998. CO₂, light and temperature influence senescence and protein degradation in wheat leaf segments. *Physiologia Plantarum* 103(3):320-326.

Effects of environmental conditions influencing photosynthesis and photorespiration on senescence and net protein degradation were investigated in segments from the first leaf of young wheat (*Triticum aestivum* cv. Arina) plants. The segments were floated on H₂O at 25, 30 or 35 degrees C in continuous light (PAR: 50 or 150 $\mu\text{mol m}^{-2}\text{s}^{-1}$) in ambient air and in CO₂-depleted air. Stromal enzymes, including phosphoglycolate phosphatase, glutamine synthetase, ferredoxin-dependent glutamate synthase, phosphoribulokinase, and the peroxisomal enzyme, glycolate oxidase, were detected by SDS-PAGE followed by immunoblotting with specific antibodies. In general, the net degradation of proteins and chlorophylls was delayed in CO₂-depleted air. However, little effect of CO₂ on protein degradation was observed at 25 degrees C under the lower level of irradiance. The senescence retardation by the removal of CO₂ was most pronounced at 30 degrees C and at the higher irradiance. The stromal enzymes declined in a coordinated manner. Immunoreactive fragments from the degraded polypeptides were in most cases not detectable. However, an insolubilized fragment of glycolate oxidase accumulated in vivo, especially at 25 degrees C in the presence of CO₂. Detection of this fragment was minimal after incubation at 30 degrees C and completely absent on blots from segments kept at 35 degrees C. In CO₂-depleted air, the fragment was only weakly detectable after incubation at 25 degrees C. The results from these investigations indicate that environmental conditions that influence photosynthesis may interfere with senescence and protein catabolism in wheat leaves.

Hertstein, U., J. Colls, F. Ewert, and M. van Oijen. 1999. Climatic conditions and concentrations of carbon dioxide and air pollutants during 'ESPACE-wheat' experiments. *European Journal of Agronomy* 10(3-4):163-169.

A major objective of the ESPACE-wheat programme was to perform by means of open-top chambers (OTCs) 'standardised' experimental investigations of spring wheat responses to increased atmospheric CO₂ and O₃ concentrations and to other environmental stresses at different locations in Europe, representing a broad range of different climatic

conditions. From 1994 to 1996 a total number of 25 OTC experiments were carried out. In addition, four growth chamber experiments focusing on key physiological processes of wheat growth in CO₂-enriched air were performed. According to the specific needs for subsequent modelling purposes, environmental data were collected during experiments, i.e. air temperature, global radiation, humidity and trace gas concentrations. In the present paper results of these measurements are summarised. It was shown, that the OTC-experiments covered a considerable range of growing season mean-air-temperatures (13.0-23.4 degrees C) and global irradiances (10.8-18.1 MJ m⁻² d⁻¹), the most important driving variables for crop growth simulation models. Mean concentrations of CO₂ and O₃ in ambient air and in different treatments illustrated the observed variability of trace gas exposures between different experiments. Implications for subsequent analyses of biological response data are discussed. (C) 1999 Elsevier Science B.V. All rights reserved.

Hertstein, U., A. Fangmeier, and H.J. Jager. 1996. ESPACE-wheat (European Stress Physiology and Climate Experiment-project 1: Wheat): Objectives, general approach, and first results. *Journal of Applied Botany-Angewandte Botanik* 70(5-6):172-180.

The "European Stress Physiology and Climate Experiment - project 1: wheat" (acronym: ESPACE-wheat) is funded by the EU since 1994. In the present paper the projects goals, the general methodological approach, and a summary of the experimental work performed in 1994 and 1995 are described. Main objectives of the project are 1) to investigate experimentally the sensitivity of wheat growth, development and productivity to changes in CO₂ concentration, climatic variables and other physiological stresses, 2) to use experimental data for extension, improvement and validation of process-based wheat growth simulation models, and 3) to use models for assessments of the influences on crops of climatic change, increasing CO₂ concentration and additional physiological stresses in Europe. Most experimental investigations are being performed by means of open-top chambers (OTC's) according to a common standard protocol to meet specific data requirements for model construction and validation. ESPACE-wheat OTC-experiments in 1994 and 1995 are summarized and the principal methods of data evaluation are presented by analyzing responses of grain yield and aboveground biomass of spring wheat, cv. Minaret, to CO₂ enrichment and other factors varied in experiments at different sites. The mean observed CO₂-doubling responses was about 1.4, i.e. grain yield and biomass production were increased by about 40% compared to growth in ambient CO₂ concentration. However, there was a large variability of responses between sites and years. Results are discussed with respect to modeling attempts.

Hew, C.S., S.E. Hin, J.W.H. Yong, S.S. Gouk, and M. Tanaka. 1995. In-vitro CO₂ enrichment of cam orchid plantlets. *Journal of Horticultural Science* 70(5):721-736.

Increased growth of an in vitro-propagated CAM orchid hybrid Mokara 'White' was obtained using a novel method of CO₂ enrichment in an optimized photoautotrophic open system compared with the conventional closed system of culture. The optimization process for the open system involved the manipulation of external CO₂ concentrations (0.03%, 1% and 10%), sucrose requirements, light intensities (80 and 200 $\mu\text{mol m}^{-2}\text{s}^{-1}$) and the venting of headspace ethylene from the culture vessels. The physiological basis for increased growth in these CAM orchid plantlets after three months was attributed to the direct

effects of elevated CO₂ resulting in higher CAM activity for the plantlets and to the elevated CO₂ present in the system which might interact with the ethylene present thereby reducing the inhibition of growth of plantlets due to ethylene.

Heyworth, C.J., G.R. Iason, V. Temperton, P.G. Jarvis, and A.J. Duncan. 1998. The effect of elevated CO₂ concentration and nutrient supply on carbon-based plant secondary metabolites in *Pinus sylvestris* L. *Oecologia* 115(3):344-350.

This study investigated changes in carbon-based plant secondary metabolite concentrations in the needles of *Pinus sylvestris* saplings, in response to longterm elevation of atmospheric CO₂, at two rates of nutrient supply. Experimental trees were grown for 3 years in eight open-top chambers (OTCs), four of which were maintained at ambient (similar to 350 $\mu\text{mol mol}^{-1}$) and four at elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations, plus four open air control plots. Within each of these treatments, plants received either high (7.0 g N m⁻² year⁻¹) added) or low (no nutrients added) rates of nutrient supply for two years. Needles from lateral branches were analysed chemically for concentrations of condensed tannins and monoterpenes. Biochemical determinations of cellulase digestibility and protein precipitating capacity of their phenolic extracts were made because of their potential of importance in ecological interactions between pine and other organisms including herbivores and decomposers. Elevated CO₂ concentration caused an increase ($P < 0.05$) in dry mass per needle, tree height and the concentration of the monoterpene α -pinene, but there were no direct effects of CO₂ concentration on any of the other chemical measurements made. High nutrient availability increased cellulase digestibility of pine needles. There was a significant negative effect of the OTCs on protein precipitating capacity of the needle extracts in comparison to the open-air controls. Results suggest that predicted changes in atmospheric CO₂ concentration will be insufficient to produce large changes in the concentration of condensed tannins and monoterpenes in Scots pine. Processes which are influenced by these compounds, such as decomposition and herbivore food selection; along with their effects on ecosystem functioning, are therefore unlikely to be directly affected through changes in these secondary metabolites.

Hibberd, J.M., P. Richardson, R. Whitbread, and J.F. Farrar. 1996. Effects of leaf age, basal meristem and infection with powdery mildew on photosynthesis in barley grown in 700 $\mu\text{mol mol}^{-1}$ CO₂. *New Phytologist* 134(2):317-325.

The rate of net photosynthesis in the second leaf of barley was higher in 700 than 350 $\mu\text{mol mol}^{-1}$ CO₂ when measured in the CO₂ concentration in which the plants were grown, but the magnitude of this difference decreased as the leaf aged. Infection by powdery mildew accelerated the decline in net photosynthesis of leaves grown in either 350 or 700 $\mu\text{mol mol}^{-1}$ CO₂. A/C-i curves allowed the reduction in net photosynthesis of plants exposed to 700 $\mu\text{mol mol}^{-1}$ CO₂ or after infection by powdery mildew to be related to changes in the carboxylation efficiency or in the regeneration of ribulose 1,5-bisphosphate. The carboxylation efficiency declined in plants exposed to 700 $\mu\text{mol mol}^{-1}$ CO₂. In plants infected with powdery mildew, the reduction in net photosynthesis was associated with both reduced carboxylation efficiency and reduced ability to regenerate ribulose 1,5-

bisphosphate. Reduced carboxylation efficiency of the second leaf of plants grown in 700 $\mu\text{mol mol}^{-1}$ CO₂ was not associated with a reduction in the concentration of rubisco within the leaf. In contrast to the presence of a close exogenous sink, leaf age had large effects on the acclimation of photosynthesis to 700 $\mu\text{mol mol}^{-1}$ CO₂.

Hibberd, J.M., R. Whitbread, and J.F. Farrar. 1996. Carbohydrate metabolism in source leaves of barley grown in 700 $\mu\text{mol mol}^{-1}$ CO₂ and infected with powdery mildew. *New Phytologist* 133(4):659-671.

Soluble carbohydrate accumulated faster in second leaf blades of barley when plants were grown in 700 $\mu\text{mol mol}^{-1}$ CO₂ rather than 350 $\mu\text{mol mol}^{-1}$ CO₂. Infection of the second leaf blade by powdery mildew had no effect on the concentration of soluble carbohydrate until 6 d after inoculation when it was lower than in controls. The accumulation of soluble carbohydrate in the second leaf of uninfected plants grown in 700 $\mu\text{mol mol}^{-1}$ CO₂ was due largely to earlier and faster accumulation of fructan. TLC showed that the series of fructan was not different in plants grown in 700 $\mu\text{mol mol}^{-1}$ CO₂ relative to plants grown in 350 $\mu\text{mol mol}^{-1}$ CO₂, neither did infection by powdery mildew affect the series of fructan present in the second leaf blade. The rate constant for phloem loading obtained by compartmental analysis of C-14 efflux from the leaf blade was not reduced in plants grown in 700 $\mu\text{mol mol}^{-1}$ CO₂, indicating that carbohydrate accumulation was not caused by reduced ability of the leaf to export carbon.

Hibberd, J.M., R. Whitbread, and J.F. Farrar. 1996. Effect of 700 $\mu\text{mol mol}^{-1}$ CO₂ and infection with powdery mildew on the growth and carbon partitioning of barley. *New Phytologist* 134(2):309-315.

The dry weight of barley plants in 700 $\mu\text{mol mol}^{-1}$ CO₂ was increased by 19 d after planting relative to plants grown in 350 $\mu\text{mol mol}^{-1}$ CO₂. Infection of the second leaf by powdery mildew led to reduced growth rates in both 350 and 700 $\mu\text{mol mol}^{-1}$ CO₂, but the reduction in growth was transitory in 350 $\mu\text{mol mol}^{-1}$ CO₂. Neither the allometric coefficient k between shoot and root, nor the leaf weight ratio, was altered by growth in 700 $\mu\text{mol mol}^{-1}$ CO₂ or by infection with powdery mildew. The number of tillers produced increased per plant but not per unit d. wt in 700 $\mu\text{mol mol}^{-1}$ CO₂. The growth response of barley to increased concentrations of CO₂ and/or to infection with powdery mildew was not associated with alterations in net carbon partitioning, so a change in the ratio of photosynthetic to non-photosynthetic tissue, contributed to neither the growth response of barley to 700 $\mu\text{mol mol}^{-1}$ CO₂ nor to infection with powdery mildew. The increase in the growth rate of barley in 700 $\mu\text{mol mol}^{-1}$ CO₂ and the reduction in the growth rate after infection occurred at the same time as increased and reduced rates of net photosynthesis respectively.

Hibberd, J.M., R. Whitbread, and J.F. Farrar. 1996. Effect of elevated concentrations of CO₂ on infection of barley by *Erysiphe graminis*. *Physiological and Molecular Plant Pathology* 48(1):37-53.

Although there was no difference in the percentage of powdery mildew conidia that germinated on the second leaf of barley plants grown in either 350 or 700 ppm CO₂, the percentage of conidia that progressed to produce colonies was lower in plants grown in 700 than in 350 ppm CO₂. The lower percentage of conidia producing hyphae in 700 ppm CO₂ was due to a higher proportion of the spores being arrested at the appressorial stage. The reduction in penetration of spores in 700 ppm CO₂ was due neither to 700 ppm CO₂ per se, nor to ontogenetic changes in the host tissue. Removing the epicuticular waxes from the surface of the leaf had no effect on the development of conidia on the surface of leaves in 350 or 700 ppm CO₂, showing that increased epicuticular waxes were not causing the increased resistance to primary penetration of powdery mildew in 700 ppm CO₂. We relate reduced rates of primary penetration in barley grown in 700 ppm CO₂ to higher rates of net photosynthesis allowing increased mobilisation of resources into resistance including the production of papillae and accumulation of silicon at the sites of appressorial penetration. Established colonies of powdery mildew grew faster in 700 ppm CO₂ than in 350 ppm CO₂, coincident with accumulation of host carbohydrate in the source leaf.

Hibbs, D.E., S.S. Chan, M. Castellano, and C.H. Niu. 1995. Response of red alder seedlings to CO₂ enrichment and water- stress. *New Phytologist* 129(4):569-577.

Red alder (*Alnus rubra* Bong.) is a nitrogen-fixing pioneer tree species of the Pacific Northwest of North America. We investigated the response of different seed sources of red alder to elevated atmospheric CO₂ and to varied levels of water stress. Seeds were stratified, germinated and grown for up to 147 d under ambient (350 μ l l⁻¹) or elevated (700 μ l l⁻¹) CO₂. There were no significant interactions of seed source latitude with either treatment, although seedlings from more northerly sources were larger. Elevated CO₂ and low moisture stress resulted in larger plants with more leaf area; effects of the two factors appeared additive. Effects of both factors on biomass allocation, including root:shoot ratios, were small or nonsignificant. Elevated CO₂ decreased specific nitrogenase activity and generally increased photosynthesis (A) and stomatal conductance (g). The ratio A:g, potential water use efficiency, also increased when plants were under water stress. Elevated CO₂ appears to improve drought tolerance in red alder. Overall, these results indicate that red alder would benefit in total plant growth from increased ambient CO₂ and could tolerate changes in precipitation.

Hikosaka, K. 1997. Modelling optimal temperature acclimation of the photosynthetic apparatus in C-3 plants with respect to nitrogen use. *Annals of Botany* 80(6):721-730.

A new hypothesis for temperature acclimation by the photosynthetic apparatus is presented. An optimization model is developed to examine effects of changes in the organization of photosynthetic components on leaf photosynthesis under various growth temperatures where the photosynthetic apparatus is not damaged. In this model, photosynthetic

rate is limited either by the capacity of ribulose biphosphate carboxylase (RuBPCase) to consume ribulose biphosphate (RuBP), or by the capacity of RuBP regeneration. For temperature dependence of the RuBPCase activity, data from *Spinacia oleracea* L., which have a temperature optimum of 30 degrees C, are used. For temperature dependence of the capacity of RuBP regeneration, two contrasting curves that have temperature optima of 30 degrees C (*Eucalyptus pauciflora* Sieb. ex Spreng) and 40 degrees C (*Larrea divaricata* Cav.) are applied. The temperature dependence of each process is fixed for respective species, but the rate of each process varies with changes in the amounts of components. The cost of proteins, in terms of nitrogen, required to carry out each process is calculated when nitrogen is partitioned differently among photosynthetic components. The optimal nitrogen partitioning that maximizes daily photosynthesis at a given temperature is obtained. The predicted temperature optimum of the photosynthetic rate in *Larrea divaricata* exhibits large shifts with changes in target temperature, while shifts are negligible in *Eucalyptus pauciflora*. It is suggested that the shift in temperature optimum of photosynthetic rate is large when the temperature dependences of the capacities of RuBPCase and RuBP regeneration differ from each other. Hikosaka, K., and T. Hirose. 1998. Leaf and canopy photosynthesis of C-3 plants at elevated CO₂ in relation to optimal partitioning of nitrogen among photosynthetic components: theoretical prediction. *Ecological Modelling* 106(2-3):247-259.

Effects of changes in the organization of photosynthetic components on leaf photosynthesis under contrasting atmospheric CO₂ conditions (35 and 70 Pa) are evaluated using an optimization model, in which the photosynthetic rate is limited either by the capacity of ribulose biphosphate carboxylase (RuBPCase) to consume ribulose biphosphate (RuBP) or by the capacity of RuBP regeneration. The nitrogen cost of photosynthetic components to carry out each process is calculated for the optimal partitioning of nitrogen among the components. The model predicts that nitrogen allocation to the components carrying out RuBP regeneration should be increased with reduction in allocation to RuBPCase to maximize daily photosynthesis at 70 Pa CO₂. At a temperature of 25 degrees C, doubling the current CO₂ level increases daily photosynthesis by 60% with optimal reallocation of the nitrogen partitioning while the increase without reallocation of nitrogen is 40%. However, at lower growth irradiance, the advantage in daily photosynthesis due to the reallocation decreases with increasing nitrogen content. The ratio of photosynthesis at 70 Pa to that at 35 Pa increases with increasing temperature. The effects of CO₂ levels on photosynthesis of a canopy in which nitrogen is optimally allocated among leaf layers are also examined. At 25 degrees C, canopy photosynthesis at the doubled CO₂ level is predicted to increase 60 and 40% with and without the optimization of nitrogen partitioning among photosynthetic components, respectively. Doubling the CO₂ level does not affect the optimal nitrogen distribution among leaf layers in the canopy irrespective of optimization of nitrogen partitioning among photosynthetic components. Hileman, D.R., G. Huluka, P.K. Kenjige, N. Sinha, N.C. Bhattacharya, P.K. Biswas, K.F. Lewin, J. Nagy, and G.R. Hendrey. 1994. Canopy photosynthesis and transpiration of field-grown cotton exposed to free-air CO₂ enrichment (FACE) and differential irrigation. *Agricultural and Forest Meteorology* 70(1-4):189-207.

Growth, yield and leaf photosynthetic rates of cotton (*Gossypium hirsutum* L.) all respond strongly to CO₂ enrichment, but the gas exchange of whole cotton canopies grown under elevated CO₂ has not been investigated. We compared the effects of CO₂ enrichment on both single-leaf and whole-canopy photosynthetic rates in cotton. We also determined whole-canopy photosynthetic and transpiration rates in cotton in response to CO₂ enrichment and differential irrigation. Field-grown cotton was exposed to either 550 $\mu\text{mol mol}^{-1}$ of CO₂ using the free-air carbon dioxide enrichment (FACE) system or to 370 $\mu\text{mol mol}^{-1}$ in control plots. In the second year of the experiment, half of each plot received reduced levels of irrigation. Rates of photosynthesis and stomatal conductance of single leaves were determined using a portable photosynthesis system and a portable steady-state porometer, respectively. Rates of whole-canopy photosynthesis and transpiration were determined using a custom-built chamber (about 1 m x 1 m). Midday net photosynthesis rates of both leaves and canopies were 19-41% higher in the CO₂-enriched plots than in control plots. The CO₂ effect on leaf photosynthesis was greatest in July, whereas the CO₂ effect on canopy photosynthesis was greatest in June and decreased thereafter as mutual shading of leaves and the amount of non-photosynthetic biomass increased. Midday stomatal conductance values of leaves were 13-44% greater in control plants than in CO₂-enriched plants. Except for late in the second season, canopy transpiration rates were not affected by the CO₂ treatment because the decrease in stomatal conductance was offset by an increase in plant size. Differential irrigation led to no significant differences in either canopy photosynthesis or transpiration, possibly because differential irrigation was applied only during the second half of the season. It appears that cotton crops grown in a future, higher-CO₂ climate may have increased photosynthetic rates, but water requirements may not be reduced.

Hirose, T., D.D. Ackerly, M.B. Traw, and F.A. Bazzaz. 1996. Effects

of CO₂ elevation on canopy development in the stands of two co-occurring annuals. *Oecologia* 108(2):215-223.

Elevated CO₂ may increase dry mass production of canopies directly through increasing net assimilation rate of leaves and also indirectly through increasing leaf area index (LAI). We studied the effects of CO₂ elevation on canopy productivity and development in monospecific and mixed (1:1) stands of two co-occurring C-3 annual species, *Abutilon theophrasti* and *Ambrosia artemisiifolia*. The stands were established in the glasshouse with two CO₂ levels (360 and 700 $\mu\text{mol l}^{-1}$) under natural light conditions. The planting density was 100 per m² and LAI increased up to 2.6 in 53 days of growth. Root competition was excluded by growing each plant in an individual pot. However, interference was apparent in the amount of photons absorbed by the plants and in photon absorption per unit leaf area. Greater photon absorption by *Abutilon* in the mixed stand was due to different canopy structures: *Abutilon* distributed leaves in the upper layers in the canopy while *Ambrosia* distributed leaves more to the lower layers. CO₂ elevation did not affect the relative performance and light interception of the two species in mixed stands. Total aboveground dry mass was significantly increased with CO₂ elevation, while no significant effects on leaf area development were observed. CO₂ elevation increased dry mass production by 30-50%, which was mediated by 35-38% increase in the net assimilation rate (NAR) and 37-60% increase in the nitrogen use efficiency (NUE, net assimilation rate per unit leaf nitrogen). Since there was a strong overall correlation between LAI and aboveground nitrogen and no significant difference was found in the regression of LAI against aboveground nitrogen between the two CO₂ levels, we hypothesized that leaf area development was controlled by the amount of nitrogen taken up from the soil. This hypothesis suggests that the increased LAI with CO₂ elevation observed by several authors might be due to increased uptake of nitrogen with increased root growth.

Hirose, T., D.D. Ackerly, M.B. Traw, D. Ramseier, and F.A. Bazzaz. 1997. CO₂ elevation, canopy photosynthesis, and optimal leaf area index. *Ecology* 78(8):2339-2350.

We studied the effects of CO₂ elevation on leaf and canopy photosynthesis and optimal leaf area index (LAI) for stands of the annual species *Abutilon theophrasti* and *Ambrosia artemisiifolia*. Leaf photosynthesis was modeled as a function of photosynthetic photon flux density (PPFD) and nitrogen content per unit leaf area (N-L). There was a curvilinear relationship between the light-saturated rates of leaf photosynthesis (P-max) and N-L. CO₂ elevation significantly increased P-max as a function of N, in both species. Dark respiration (R-d) was linearly correlated with N-L. CO₂ elevation slightly but significantly increased R-d in *Abutilon*, while it had no significant effect on R-d in *Ambrosia*. The initial slope of a light-response curve was determined from quantum yield ($\phi(\text{abs})$) multiplied by leaf absorptance and then calibrated against N-L. Daily canopy photosynthesis, calculated by integration of leaf photosynthesis with the actual distribution of leaf area, leaf N, and PPFD within a canopy, showed fairly good agreement with the canopy photosynthesis estimated from growth analysis. CO₂ elevation increased canopy photosynthesis by 30-50%. Based on the leaf photosynthesis model for *Abutilon*, we calculated daily canopy photosynthesis for a given LAI and N availability, in which N was assumed to be distributed optimally within a leaf canopy to maximize daily canopy photosynthesis. An optimal LAI to maximize daily canopy photosynthesis was obtained for each level of N availability and this optimum increased with increasing N availability. Contrary to the often predicted increase in LAI with CO₂ elevation, the optimum LAI did not

increase at high CO₂ when N availability was limited. Two factors were suggested to be involved in counteracting the increase in LAI in a high-CO₂ world. One is the higher $\phi(\text{abs})$ of plants grown in elevated CO₂, which makes leaves in the canopy more N limited, favors higher N-L and thus lowers optimal LAI. The other is the higher R-d in elevated CO₂, which leads to higher light compensation points, and lowers optimal LAI.

Hirose, T., and F.A. Bazzaz. 1998. Trade-off between light- and nitrogen-use efficiency in canopy photosynthesis. *Annals of Botany* 82(2):195-202.

If the light-use efficiency (LUE) of species in a canopy is constant, canopy photosynthesis (CP) is proportional to the number of photons (Φ) absorbed by the canopy ($CP = LUE \times \Phi$). Likewise, if nitrogen-use efficiency (NUE) is constant, canopy photosynthesis is proportional to the amount of total leaf nitrogen (LN) ($CP = NUE \times LN$). We applied these concepts to monospecific and mixed (1:1) stands of annuals (*Abutilon theophrasti* and *Ambrosia artemisiifolia*) at two stages, established in an ambient (360 $\mu\text{mol l}^{-1}$) or elevated (700 $\mu\text{mol l}^{-1}$) CO₂ atmosphere. In both CO₂ concentrations, across the two species, daily canopy photosynthesis gave strong linear regressions with zero intercepts both against the number of absorbed photons and against total leaf nitrogen in the canopy. Doubling CO₂ increased LUE by 20-80 % and NUE by 20-100 %. LUE tended to be higher in *Ambrosia* than in *Abutilon*, and also higher in the later stage of canopy development than in the younger stage. Interference by *Abutilon* increased the LUE of *Ambrosia*. On the other hand, NUE tended to be higher in *Abutilon* than in *Ambrosia*, and to be higher in younger than in later stages. Interference by *Abutilon* decreased the NUE of *Ambrosia*. Thus, there are trade-offs (negative correlations) between LUE and NUE, which result from differences in leaf nitrogen per unit leaf area and from differences in leaf area development in the canopy. LUE increased with increasing leaf nitrogen concentration, while NUE increased with increasing light availability in the canopy. (C) 1998 Annals of Botany Company.

Hirschel, G., C. Korner, and J.A. Arnone. 1997. Will rising atmospheric CO₂ affect leaf litter quality and in situ decomposition rates in native plant communities? *Oecologia* 110(3):387-392.

Though field data for naturally senesced leaf litter are rare, it is commonly assumed that rising atmospheric CO₂ concentrations will reduce leaf litter quality and decomposition rates in terrestrial ecosystems and that this will lead to decreased rates of nutrient cycling and increased carbon sequestration in native ecosystems. We generally found that the quality of naturally senesced leaf litter (i.e. concentrations of C, N and lignin; C:N, lignin:N) of a variety of native plant species produced in alpine, temperate and tropical communities maintained at elevated CO₂ (600-680 $\mu\text{mol l}^{-1}$) was not significantly different from that produced in similar communities maintained at current ambient CO₂ concentrations (340-355 $\mu\text{mol l}^{-1}$). When this litter was allowed to decompose in situ in a humid tropical forest in Panama (*Cecropia peltata*, *Elettaria cardamomum*, and *Ficus benjamina*, 130 days exposure) and in a lowland temperate calcareous grassland in

Switzerland (*Carex flacca* and a graminoid species mixture; 261 days exposure), decomposition rates of litter produced under ambient and elevated CO₂ did not differ significantly. The one exception to this pattern occurred in the high alpine sedge, *Carex curvula*, growing in the Swiss Alps. Decomposition of litter produced in situ under elevated CO₂ was significantly slower than that of litter produced under ambient CO₂ (14% vs. 21% of the initial litter mass had decomposed over a 61-day exposure period, respectively). Overall, our results indicate that relatively little or no change in leaf litter quality can be expected in plant communities growing under soil fertilities common in many native ecosystems as atmospheric CO₂ concentrations continue to rise. Even in situations where small reductions in litter quality do occur, these may not necessarily lead to significantly slower rates of decomposition. Hence in many native species in situ litter decomposition rates, and the time course of decomposition, may remain relatively unaffected by rising CO₂.

Hobbie, J.E., B.L. Kwiatkowski, E.B. Rastetter, D.A. Walker, and R.B. McKane. 1998. Carbon cycling in the Kuparuk basin: Plant production, carbon storage, and sensitivity to future changes. *Journal of Geophysical Research-Atmospheres* 103(D22):29065-29073.

The Marine Biological Laboratory General Ecosystem Model was calibrated for an arctic tussock tundra system using data from long-term observations and experiments at Toolik Lake, Alaska. These experiments include the effects of changes in temperature, light, CO₂, and nutrients, so the model could be applied to five regions comprising the entire Kuparuk River basin. Net primary production, averaged for the entire basin, was 92 g C m⁻² yr⁻¹. A 150 year simulation of carbon storage under a doubling of CO₂ (slow ramp-up) and a temperature increase of 3.5 degrees C gave an estimate of +400 g C m⁻² when soil moisture increased and +500 g C m⁻² when soil moisture decreased. Drier soils stimulated decomposition producing an increase in nitrogen availability; the increased N led to increased net primary production. If this result is applicable to other arctic ecosystems, then it is unlikely that warming will enhance carbon loss to the atmosphere to further enhance warming.

Hocking, P.J., and C.P. Meyer. 1991. Carbon-dioxide enrichment decreases critical nitrate and nitrogen concentrations in wheat. *Journal of Plant Nutrition* 14(6):571-584.

Atmospheric carbon dioxide (CO₂) levels are increasing. In a glasshouse experiment with wheat grown at 5 levels of nitrate (NO₃) supply, CO₂ enrichment (1500 cm³/m³) substantially decreased critical concentrations of NO₃-N and total-N in stem bases and leaves. For example, critical NO₃-N concentrations in stem bases at Feekes Stages 1.5, 5, and 10.3, were 4.5, 2.0, and 2.0 mg/g dry wt, respectively, for CO₂-enriched plants, compared with 7.5, 6.2 and 6.4 mg/g dry wt, respectively, for control plants grown at the ambient level of CO₂. However, concentrations of NO₃-N in the rooting medium required to produce maximum dry matter accumulation by CO₂-enriched plants were similar to those of control plants at the three growth stages. Critical concentrations of NO₃-N and total-N declined with time in stem bases and leaves of plants grown at both ambient and elevated CO₂ levels, but the decline was greater for CO₂-enriched plants. It was concluded that diagnostic criteria based on current critical N concentrations may

become invalid as the atmospheric level of CO₂ increases.

Hocking, P.J., and C.P. Meyer. 1991. Effects of CO₂ enrichment and nitrogen stress on growth, and partitioning of dry-matter and nitrogen in wheat and maize. *Australian Journal of Plant Physiology* 18(4):339-356.

Atmospheric CO₂ levels are increasing, but little is known about how this will affect tissue concentrations and the partitioning of agriculturally important nutrients such as nitrogen (N) within crop plants. To investigate this, a glasshouse experiment was conducted in which wheat, a C3 species, and maize, a C4 species, were grown for 8 weeks at high CO₂ (1500 cm³ m⁻³) on N supplies ranging from deficient (0.5 mol m⁻³) to more than adequate for maximum growth (25 mol m⁻³). Wheat responded to both CO₂ enrichment and N supply; maize responded only to N supply. CO₂-enriched wheat produced about twice the dry matter of control plants at all levels of N supply. Tiller and ear numbers were increased by CO₂ enrichment irrespective of N supply. Enriched wheat plants had a lower Leaf Area Ratio but higher Net Assimilation Rate and Relative Growth Rate than control plants. There was no effect of CO₂ enrichment on specific leaf weight. The enriched plants had lower shoot to root dry matter ratios than the controls at 6 mol m⁻³ N and higher. Shoot to root dry matter ratios of both wheat and maize increased with increasing N supply. CO₂-enriched wheat plants accumulated more N than the controls but the proportional increase in N content was not as great as that in dry matter, with the result that concentrations of total-N and nitrate-N were lower in all organs of enriched plants, including ears. Nitrate reductase activity was lower in enriched than in control wheat plants. N-use efficiency by wheat was increased by CO₂ enrichment. From a practical point of view, the study indicates that critical total-N and NO₃-N concentrations used to diagnose the N status of wheat will need to be reassessed as global CO₂ levels increase. Elevated CO₂ may also reduce the protein content of grain and thus the baking quality of hard wheats.

Hoddinott, J., and R. Scott. 1996. The influence of light quality and carbon dioxide enrichment on the growth and physiology of seedlings of three conifer species. 1. Growth responses. *Canadian Journal of Botany-Revue Canadienne De Botanique* 74(3):383-390.

Plant growth responds to light quality, as evaluated by the red/far-red (R/FR) quantum flux ratio, and to the level of CO₂. *Pinus banksiana*, *Picea mariana* and *Picea glauca* seedlings were raised at 350, 700, or 1050 µmol L⁻¹ CO₂ and high or low R/FR ratios and growth was measured over a 16-week growth period. Far-red rich light enhanced the whole plant and height relative growth rates of *Pinus banksiana*. The three species showed species specific responses in plant organ relative growth rates and partitioning ratios. On the basis of their biomass partitioning the species would be ranked *Pinus banksiana* < *Picea mariana* < *Picea glauca* for shade tolerance. In commercial operations, seedlings grown for outplanting are selected, in part, on the basis of plant form as described by the stem height/diameter ratio. More desirable ratios were obtained at ambient CO₂ concentrations for *Pinus banksiana* and *Picea mariana* in red rich light and for *Picea glauca* in far-red rich light.

Hoddinott, J., and R. Scott. 1996. The influence of light quality and carbon dioxide enrichment on the growth and physiology of seedlings of three conifer species. 2. Physiological responses. *Canadian Journal of Botany-Revue Canadienne De Botanique* 74(3):391-402.

Pinus banksiana, *Picea mariana*, and *Picea glauca* were grown at 350, 700, or 1050 µmol L⁻¹ CO₂ and either high or low red/far-red quantum flux ratios. After a 16-week, long day growth period, seedlings were subjected sequentially to short daylengths, then short days with low temperatures. Various physiological parameters were determined at the end of each treatment phase to monitor how those treatments influenced the onset of seedling dormancy. After the long day treatments, high ratios increased the total chlorophyll content and reduced the original level of chlorophyll fluorescence and the shoot total nonstructural carbohydrate content in very shade-intolerant *Pinus banksiana*. In shade-tolerant *Picea mariana*, high CO₂ levels caused the main effects on these parameters while neither light quality or CO₂ had significant effects on them in shade-tolerant *Picea glauca*. Short days and low temperature induced a proportional increase in the partitioning of total nonstructural carbohydrate to the roots in all species and produced other species and treatment-specific responses.

Hodge, A. 1996. Impact of elevated CO₂ on mycorrhizal associations and implications for plant growth. *Biology and Fertility of Soils* 23(4):388-398.

The impact of increasing concentrations of atmospheric CO₂ upon plant physiology has been widely investigated. Plant, and in particular root, growth is nearly always enhanced as a direct consequence of CO₂ enrichment, with C-3 species generally more responsive than C-4 species. Such alterations in plant productivity will have consequence for below-ground processes and increased carbon allocation to the roots may favour symbiotic relationships. This paper discusses the current information available for the consequences of these changes upon mycorrhizal relationships. Generally mycorrhizal plants grown under CO₂ enrichment show enhanced phosphorus uptake but nitrogen uptake is unaffected. This increased nutrient uptake is not correlated with increased mycorrhizal colonization of the roots. Similarly root exudation does not increase under CO₂ enrichment but qualitative differences have yet to be assessed. However, it is predicted that total rhizodeposition of materials will increase as will litter inputs, although mineral and biochemical alterations to these plant derived inputs may occur. The consequences of such changes within the rhizosphere are discussed and future research priorities identified.

Hodge, A., and P. Millard. 1998. Effect of elevated CO₂ on carbon partitioning and exudate release from *Plantago lanceolata* seedlings.

Plantago lanceolata L. seedlings were grown in sand microcosm units over a 43-day experimental period under two CO₂ regimes (800 or 400 $\mu\text{mol mol}^{-1}$) to investigate the effect of elevated atmospheric CO₂ concentration on carbon partitioning and exudate release. Total organic carbon (TOC) content of the collected exudate material was measured throughout the experimental period. After 42 days growth the seedlings were labelled with [C-14]-CO₂ and the fate of the label within the plant and its release by the roots monitored. Elevated CO₂ significantly (P less than or equal to 0.001) enhanced shoot, root and total dry matter production although the R:S ratio was unaltered, suggesting no alteration in press carbon partitioning. The cumulative release of TOC (in mg C) over 0-42 days was unaltered by CO₂ treatment however, when expressed as a percentage of net assimilated C, ambient-grown plants released a significantly (P less than or equal to 0.001) higher percentage from their roots compared to elevated CO₂-grown plants (i.e. 8 vs 3%). The distribution of C-14-label was markedly altered by CO₂ treatment with significantly (P less than or equal to 0.001) greater per cent label partitioned to the roots under elevated CO₂. This indicates increased partitioning of recent assimilate belowground under elevated CO₂ treatment although there was no significant difference in the percentage of C-14-label released by the roots. Comparison of plant C budgets based on C-14-pulse-chase methodology and TOC measurements is discussed.

Hodge, A., E. Paterson, S.J. Grayston, C.D. Campbell, B.G. Ord, and K. Killham. 1998. Characterisation and microbial utilisation of exudate material from the rhizosphere of *Lolium perenne* grown under CO₂ enrichment. *Soil Biology and Biochemistry* 30(8-9):1033-1043.

The effects of elevated atmospheric CO₂ concentration on alterations, both qualitatively and quantitatively, of exuded compounds from the roots of *Lolium perenne* seedlings were investigated by growing plants in a sterilised sand microcosm unit. In addition, the effect of CO₂ treatment on carbon substrate utilisation of microbial populations extracted from the rhizosphere of *L. perenne* seedlings grown in soil microcosm units was examined and alterations on microbial activity and diversity assessed using a commercially-available redox-based sole C source utilisation test (Biolog(R)) including additional exudate compounds. Both types of microcosm units (sand and soil) were maintained at specific growth conditions under two CO₂ regimes (450 and 720 $\mu\text{mol mol}^{-1}$). Growth of *L. perenne* seedlings from both types of microcosm units was enhanced under elevated atmospheric CO₂ although the root-to-shoot ratios were not significantly altered, indicating no gross change in dry matter partitioning. Cumulative total organic carbon (TOC) release in the exudate material over the duration of the experiment was significantly (P less than or equal to 0.05) higher from ambient-grown seedlings despite a significant (P less than or equal to 0.05) increase in the dry weight of roots of the elevated CO₂ grown seedlings as determined at harvest. Over the individual sampling periods TOC release was significantly (P less than or equal to 0.05) higher from elevated CO₂ grown seedlings on only one occasion (21 d). Qualitative differences, measured between d 1-6 and 14-18, also occurred with elevated CO₂ treatment decreasing the amount of phenolic acids and total sugars at the latter sampling period compared to ambient CO₂ seedlings. Total numbers of bacteria were significantly (P less than or equal to 0.05) decreased under elevated CO₂ although culturable numbers significantly (P less than or equal to 0.05) increased. This increase in culturable microorganisms may explain the faster carbon source utilisation rates of the elevated CO₂ treatment. No change in morphotypes of microbial colonies were observed suggesting a

quantitative difference due to elevated CO₂ treatment only. (C) 1998 Elsevier Science Ltd. All rights reserved.

Hoen, H.F., and B. Solberg. 1994. Potential and economic-efficiency of carbon sequestration in forest biomass through silvicultural management. *Forest Science* 40(3):429-451.

This paper has two main objectives: First, to discuss in principle some vital methodological issues which have to be considered when analyzing how preferable measures in forestry are to decrease the atmospheric concentration of greenhouse gases (GHGs). Economic evaluation of the flow of carbon in and out of the atmosphere is discussed, related particularly to two important problems: (1) the determination of the utility of reducing the quantity of CO₂ in the atmosphere at a given point in time; and (2) the intertemporal evaluation of a flow of atmospheric CO₂ reductions. The marginal cost, measured as the change in net present value, is proposed as a proper measure for ranking of alternative projects. Secondly, a case study is reported. The case study is based on forest-level optimization with a model estimating carbon flows related to forest biomass growth and decay, linked to a long-range forest management planning (LFMP) model. Alternative stand treatment schedules are simulated, and the forest management problem is solved by linear programming in a model I type LFMP model for the county of Buskerud, with a forest area of 574,000 ha. The potential for increasing the net carbon sequestration related to timber production by changes in the forest management over a time period of 30 yr is studied. A total of 253 stand treatment schedules was calculated for the 40 stand types, allowing for the following stand treatment options, (1) continued growth, (2) release thinnings of young growth, (3) thinning, (4) fertilization, (5) clear felling, (6) clear felling with retention of seed trees, and (7) planting or natural regeneration depending on the felling regime. The study shows that there is a significant potential for increasing the present value of the flow of net CO₂ fixations (NPV(CO₂)) by changing the forest management on the productive forest area of Buskerud. Compared with the NPV(CO₂) obtained when the net present value of the timber cash flow (NPV(NOK)) for the area is maximized (BASE problem), an increase between 8.4%-17.9% in NPV(CO₂) can be obtained. The potential for increasing the NPV(CO₂) depends on the real rate of discount. The corresponding decrease in the NPV(NOK) lies between 8.1% and 14.9%. The results further indicate that a large proportion of the increase in NPV(CO₂) can be obtained by changes in forest management at a moderate marginal cost. If we assume that 80% of the maximum potential increase in NPV(CO₂) is obtained, this gives a yearly increase (30-yr annuity) in net CO₂ fixation in the range from 145,000 to 250,000 tons (depending on the real rate of discount and assumptions about fertilization) by changing the management of the 574,000 ha of productive forestland in Buskerud, compared to the current forest management practice (BASE problem). Obtaining 80% of the maximum potential increase in NPV(CO₂) imposes a decrease in the NPV(NOK) in the range of 22% to 65% of the total potential difference in NPV(NOK) between the BASE problem and the NPV(CO₂) maximizing problem. The annual decrease (30-yr annuity) in NPV(NOK) corresponding to the 80% of the maximum potential NPV(CO₂) increase, is ranging between 7.6 and 25 million NOK. The results indicate that at a RRD of 4%, 5%, and 7% p.a., 80% of the increase in NPV(CO₂) can be reached at a marginal cost (shadow price) below 150 NOK (21/US\$) per ton NPV(CO₂). Measured per ton C, the corresponding marginal cost is 551 NOK (79 US\$) per ton C. For RRDs at 3% p.a. and 2% p.a., the marginal costs are significantly higher, but relaxing the NPV(CO₂) constraint to 60% of the total increase brings the marginal costs down and below half of this level (59 NOK or 8 US\$ per ton NPV(CO₂)) for 3% p.a. and to a comparable level (182 NOK or 26

US\$ per ton NPV(CO₂)) for 2% p.a. These results are related to changes in the management of the forested area in even-aged stands and do not take into account measures such as afforestation of marginal agricultural land or changes of tree species. Fertilization, avoiding release thinning in young growth, and changes in clear felling priorities were the most cost-efficient changes in stand treatment management in order to increase the net CO₂ fixation.

Hogan, K.P., I. Fleck, R. Bungard, J.M. Cheeseman, and D. Whitehead. 1997. Effect of elevated CO₂ on the utilization of light energy in *Nothofagus fusca* and *Pinus radiata*. *Journal of Experimental Botany* 48(311):1289-1297.

Red beech (*Nothofagus fusca* (Hook. F.) Oerst.; Fagaceae) and radiata pine (*Pinus radiata* D. Don; Pinaceae) were grown for 16 months in large open-top chambers at ambient (37 Pa) and elevated (66 Pa) atmospheric partial pressure of CO₂, and in control plots (no chamber). Summer-time measurements showed that photosynthetic capacity was similar at elevated CO₂ (light and CO₂-saturated value of 17.2 $\mu\text{mol m}^{-2} \text{s}^{-1}$) for beech, 13.5 $\mu\text{mol m}^{-2} \text{s}^{-1}$ for pine), plants grown at ambient CO₂ (beech 21.0 $\mu\text{mol m}^{-2} \text{s}^{-1}$, pine 14.9 $\mu\text{mol m}^{-2} \text{s}^{-1}$) or control plants grown without chambers (beech 23.2 $\mu\text{mol m}^{-2} \text{s}^{-1}$, pine 12.9 $\mu\text{mol m}^{-2} \text{s}^{-1}$). However, the higher CO₂ partial pressure had a direct effect on photosynthetic rate, such that under their respective growth conditions, photosynthesis for the elevated CO₂ treatment (measured at 70 Pa CO₂ partial pressure: beech 14.1 $\mu\text{mol m}^{-2} \text{s}^{-1}$ pine 10.3) was greater than in ambient (measured at 35 Pa CO₂: beech 9.7 $\mu\text{mol m}^{-2} \text{s}^{-1}$, pine 7.0 $\mu\text{mol m}^{-2} \text{s}^{-1}$) or control plants (beech 10.3 $\mu\text{mol m}^{-2} \text{s}^{-1}$, pine 7.2 $\mu\text{mol m}^{-2} \text{s}^{-1}$). Measurements of chlorophyll fluorescence revealed no evidence of photodamage in any treatment for either species. the quantity of the photoprotective xanthophyll cycle pigments and their degree of de-epoxidation at midday did not differ among treatments for either species. The photochemical efficiency of photosystem II (yield) was lower in control plants than in chamber-grown plants, and was higher in chamber plants at ambient than at elevated CO₂. These results suggest that at lower (ambient) CO₂ partial pressure, beech plants may have dissipated excess energy by a mechanism that does not involve the xanthophyll cycle pigments.

Hogan, K.P., A.P. Smith, and L.H. Ziska. 1991. Potential effects of elevated CO₂ and changes in temperature on tropical plants. *Plant, Cell and Environment* 14(8):763-778.

Very little attention has been directed at the responses of tropical plants to increases in global atmospheric CO₂ concentrations and the potential climatic changes. The available data, from greenhouse and laboratory studies, indicate that the photosynthesis, growth and water use efficiency of tropical plants can increase at higher CO₂ concentrations. However, under field conditions abiotic (light, water or nutrients) or biotic (competition or herbivory) factors might limit these responses. In general, elevated atmospheric CO₂ concentrations seem to increase plant tolerance to stress, including low water availability, high or low temperature, and photoinhibition. Thus, some species may be able to extend their ranges into physically less favourable sites, and biological interactions may become relatively more important in determining the distribution and abundance of species. Tropical plants may be more

narrowly adapted to prevailing temperature regimes than are temperate plants, so expected changes in temperature might be relatively more important in the tropics. Reduced transpiration due to decreased stomatal conductance could modify the effects of water stress as a cue for vegetative or reproductive phenology of plants of seasonal tropical areas. The available information suggests that changes in atmospheric CO₂ concentrations could affect processes as varied as plant/herbivore interactions, decomposition and nutrient cycling, local and geographic distributions of species and community types, and ecosystem productivity. However, data on tropical plants are few, and there seem to be no published tropical studies carried out in the field. Immediate steps should be undertaken to reduce our ignorance of this critical area.

Hogan, K.P., D. Whitehead, J. Kallarackal, J.G. Buwalda, J. Meekings, and G.N.D. Rogers. 1996. Photosynthetic activity of leaves of *Pinus radiata* and *Nothofagus fusca* after 1 year of growth at elevated CO₂. *Australian Journal of Plant Physiology* 23(5):623-630.

Radiata pine (*Pinus radiata* D. Don) and red beech (*Nothofagus fusca* (Hook.f.) Oerst.) were grown for over 1 year at elevated (ELEV, 64 Pa) and ambient (AMB, 38 Pa) CO₂ partial pressure in open-top chambers. Springtime measurements of overwintering leaves showed that light- and CO₂-saturated photosynthetic rates (A_{max}) of pine leaves were similar for the two treatments (AMB: 6.7 $\pm$ 1.08 $\mu\text{mol m}^{-2} \text{s}^{-1}$, mean $\pm$ 1 s.e.; ELEV: 6.6 $\pm$ 0.47) but, for beech leaves, A_{max} was greater for AMB plants (8.8 $\pm$ 0.90 $\mu\text{mol m}^{-2} \text{s}^{-1}$) than for ELEV plants (6.10 $\pm$ 0.71). Summertime measurements of leaves grown that spring showed that for pine, A_{max} was similar in the two CO₂ treatments (AMB 14.9 $\mu\text{mol m}^{-2} \text{s}^{-1}$ $\pm$ 0.80; ELEV: 13.5 $\pm$ 1.9) while, for beech, A_{max} was higher in AMB plants (21.0 $\pm$ 1.1) than in ELEV plants (17.2 $\pm$ 1.9), although the difference was not statistically significant. These results indicate downregulation of photosynthetic capacity of beech but not pine. V_{cmax} did not differ between treatments within species, suggesting that there was no acclimation of rubisco activity. Triose phosphate utilisation limitation may have contributed to the downregulation of A_{max} in beech. For pine, photosynthesis at treatment CO₂ partial pressures was greater in ELEV plants in both spring and summer. For beech measured at treatment CO₂ partial pressures, photosynthesis was greater in ELEV plants in summer, but was similar between treatments in the springtime.

Holbrook, G.P., J. Hansen, K. Wallick, and T.M. Zinnen. 1993. Starch accumulation during hydroponic growth of spinach and basil plants under carbon-dioxide enrichment. *Environmental and Experimental Botany* 33(2):313-321.

The effects of CO₂ enrichment, photoperiod duration, and inorganic phosphate levels on growth and starch accumulation by spinach and basil plants were studied in a commercial hydroponic facility. During a 3-week growth period, both species exhibited increased whole-plant fresh weight as a result of an increase in atmospheric CO₂ concentration from 400 to 1500 $\mu\text{mol l}^{-1}$. However, basil leaves exhibited a 1.5- to 2-fold greater increase in specific leaf weight (SLW), and accumulated starch to much greater levels than did leaves of spinach. At 1500 $\mu\text{mol CO}_2\text{l}^{-1}$, starch accounted for up to 38% of SLW with basil compared to < 10%

of SLW with spinach. The maximum ratio of starch/chlorophyll was 55.0 in basil leaves vs 8.0 in spinach leaves. High ratio values were associated with the appearance of chlorotic symptoms in leaves of basil grown under CO₂ enrichment (WALLICK and ZINNEN (1990) Plant Disease 74, 171-173), whereas spinach did not exhibit chlorosis. Increasing inorganic phosphate concentrations from 0.7 to 1.8 mM in the hydroponic medium did not appreciably affect leaf starch accumulation in either species. Starch accumulation in basil leaves was not consistently related to the duration of the photoperiod. However, photoperiod-induced changes in leaf starch levels were much greater in basil than spinach. The results clearly indicate that different horticultural crops can show diverse responses to CO₂ enrichment, and thus highlight the need to develop individual growth strategies to optimize production quality of each species.

Holcroft, D.M., M.I. Gil, and A.A. Kader. 1998. Effect of carbon dioxide on anthocyanins, phenylalanine ammonia lyase and glucosyltransferase in the arils of stored pomegranates. *Journal of the American Society for Horticultural Science* 123(1):136-140.

Wonderful' Pomegranates (*Punica granatum* L.) were placed in jars ventilated continuously with air or air enriched with 10 or 20 kPa CO₂ at 10 degrees C for 6 weeks. Samples were taken initially and after 1, 2, 4, and 6 weeks, and postharvest quality attributes were measured. The arils of the pomegranates stored in air were deeper red than the initial controls and than those stored in CO₂-enriched atmospheres. This increased color was associated with increased anthocyanin concentration. Arils from fruit stored in air enriched with 10 kPa CO₂ had a lower anthocyanin concentration than air-stored fruit, and atmospheres enriched with 20 kPa CO₂ had even lower levels, possibly from suppressed anthocyanin biosynthesis. Anthocyanin concentration correlated well with the activity of phenylalanine ammonia lyase but not with glucosyltransferase activity. Moderate CO₂ atmospheres (10 kPa) prolong the storage life and maintain quality of pomegranates, including adequate red color intensity of the arils.

Holcroft, D.M., and A.A. Kader. 1999. Carbon dioxide-induced changes in color and anthocyanin synthesis of stored strawberry fruit. *Hortscience* 34(7):1244-1248.

Anthocyanin concentrations increased in both external and internal tissues of 'Selva' strawberries (*Fragaria xananassa* Duch.) stored in air at 5 degrees C for 10 days, but the increase was lower in fruit stored in air enriched with 10 or 20 kPa CO₂. Flesh red color was less intense in CO₂ storage than in air storage. Activities of phenylalanine ammonia lyase (PAL) and UDP glucose : flavonoid glucosyltransferase (GT) decreased during storage, with decreases being greater in both external and internal tissues of strawberry fruit stored in air + 20 kPa CO₂ than in those kept in air. Activities of both PAL and GT in external tissues of strawberries stored in air + 10 kPa CO₂ were similar to those in fruit stored in air, while enzyme activities in internal tissues more closely resembled those from fruit stored in air + 20 kPa CO₂. Phenolic compounds increased during storage but were not affected by the storage atmosphere. The pH increased and titratable acidity decreased during storage; these effects were enhanced in internal tissues by the CO₂ treatments, and may in turn have influenced anthocyanin expression.

Holland, E.A., A.R. Townsend, and P.M. Vitousek. 1995. Variability in temperature regulation of CO₂ fluxes and N mineralization from 5 hawaiian soils - implications for a changing climate. *Global Change Biology* 1(2):115-123.

We examined the possibility that microbial adaptation to temperature could affect rates of CO₂, N₂O and CH₄ release from soils. Laboratory incubations were used to determine the functional relationship between temperature and CO₂, N₂O and CH₄ fluxes for five soils collected across an elevational range in Hawaii. Initial rates of CO₂ production and net N mineralization increased exponentially from 15 degrees C to 55 degrees C; initial rates of CH₄ and N₂O release were more complex. No optimum temperature (in which rates decline at higher and lower temperatures) was apparent for any of the gases, but respiration declined with time at higher temperatures, suggesting rapid depletion of readily available substrate. Mean Q(10)s for respiration varied from 1.4 to 2.0, a typical range for tropical soils. The functional relationship between CO₂ production and temperature was consistent among all five soils, despite the substantial differences in mean annual temperature, soils, and land-use among the sites. Temperature responses of N₂O and CH₄ fluxes did not follow simple Q(10) relationships suggesting that temperature functions developed for CO₂ release from heterotrophic respiration cannot be simply extrapolated. Expanding this study to tropical heterotrophic respiration, the flux is more sensitive to changes in Q(10) than to changes in temperature on a per unit basis: the partial derivative with respect to temperature is 2.4 Gt C . degrees C⁻¹, with respect to Q(10) it is 3.5 Gt C . Q(10) unit⁻¹. Therefore, what appears to be minor variability might still produce substantial uncertainty in regional estimates of gas exchange.

Hollander, B., and H. Krug. 1991. Effects of high CO₂ concentrations on vegetable species .1. Symptoms, ranges of injuries, and reactions of species. *Gartenbauwissenschaft* 56(5):193-205.

To test the reactions of various vegetable species to high CO₂-concentrations, the plants were treated with 1-3% technical CO₂ day and night for 10-42 days in growth chambers (table 1). The development of CO₂ injury symptoms as well as growth rates were noted and measured. With exception of spinach and sweet pepper, which showed no symptoms in the range tested, CO₂ injuries occurred in the form of morphological alterations (epinastic and hyponastic rolling of the leaves, crisping, reduction and thickening of the leaf lamina), chlorosis (marginal or in areas between the veins), necrosis, wilting, drying up and browning of the veins (kohlrabi). The symptoms mentioned varied between the species and between the cultivars. The injuries occurred at young leaves only (beans), at older leaves (kohlrabi) or at all leaves (fig. 1-5, table 6). Moreover, high CO₂-concentrations caused a remarkable reduction of growth (fig. 6). Ensuring favourable growth conditions the cold-season species tolerated concentrations of 1% CO₂ for 4-6 weeks showing only week (radish var. niger, kohlrabi, corn salad) or no significant growth reductions (radish, var. sativus, lettuce). Light injuries and morphological alterations were identifiable after 2-3 weeks. Higher concentrations caused stronger growth reductions, injuries appeared after 1 week using 2% CO₂ and after 2-3 days using 3% CO₂. The warm-season species tested reacted more sensitive. Cucumbers tolerated 1% CO₂ for 2-3 weeks, using 2% CO₂ wilting and driving injuries occurred already after 1 day table 2). In case of disturbances of the water status of the plants by transplanting, top dressing or sharp decrease of air

humidity cucumber wilted with 1% CO₂ already after a few days. Equal reactions were observed with radish, var. sativus. With tomatoes strong injuries of the leaves causing leaf death were observed after 7 days with 1% CO₂ and after 5 days with 2% CO₂. Bush beans reacted by a distinct reduction of leaf area growth and by chlorotic discolorations.

Hollander, B., and H. Krug. 1992. Effects of high CO₂-concentrations on vegetable species .2. Growth, CO₂-gas-exchange and stomata resistance. *Gartenbauwissenschaft* 57(1):32-43.

In the climatic conditions tested the growth of young cucumber plants (3-7 leaf stage) was slightly promoted as well by day as by continuous enrichment with 5000- μ mol/l CO₂ compared to the control (400- μ mol/l CO₂). A definite effect of enrichment during the night was not evident. The analysis of the growth components and gas exchange measurements revealed, that CO₂ enrichment during the day as well as during day and night increased net assimilation rate and dark respiration distinctly. Enrichment during the night showed no effect on net assimilation rate and increased dark respiration only slightly. The specific leaf area was strongly reduced by the high CO₂ concentration, but leaf weight ratio was rarely changed. By these morphogenetic effects growth promotion by an increased net assimilation rate was diminished. Continuous CO₂ enrichment to cucumber plants with CO₂ concentrations greater-than-or-equal-to 1000- μ mol/l decreased stomata resistance. This effect increased with higher CO₂ concentrations and longer treatments. The stomata remained open even at night and at low air humidity. Also with CO₂ enrichment up to 5000- μ mol/l during the day or during the night only the stomata remained wider open than in the control plants. The reaction of stomata to high CO₂-concentrations is reversible. The regeneration proceeds all the faster as lower the proceeding concentration and shorter the exposition. The actions of high CO₂-concentrations on stomata movement of cucumbers were confirmed with other species.

Homma, K., H. Nakagawa, T. Horie, H. Ohnishi, H.Y. Kim, and M. Ohnishi. 1999. Energy budget and transpiration characteristics of rice grown under elevated CO₂ and high temperature conditions as determined by remotely sensed canopy temperatures. *Japanese Journal of Crop Science* 68(1):137-145.

The effects of elevated CO₂ concentration and high temperatures on transpiration and gaseous diffusive resistances of rice canopy were investigated. Akihikari and IR36 cultivars were grown under two CO₂ concentrations ([CO₂], 365 and 700 μ mol L⁻¹) X three temperatures (29.8, 30.4 and 32.5 degrees C on average over the experimental period), created by two Temperature Gradient Chambers. From 2 August (panicle initiation) to 22 August (booting), measurements were made of dry and wet bulb temperatures, canopy surface temperatures (T_c) and net radiation along with evapotranspiration (E) measurements by microlysimeters. Aerodynamic resistance (r_a), obtained from the measured E and microclimate data, showed a fairly constant value (11.7 s m⁻¹). Then, r_a, T_c and microclimates data were substituted into energy budget equations to obtain E and canopy resistance (r_c). In all plots, calculated E was in good agreement with measurement by lysimeters, and r_c reached minimum values (r_{c,min}) at solar radiation above 500 W m⁻². Elevated [CO₂] at the lowest temperature plot

increased r_{c,min} by 40-49% and T_c by 1.4- 1.6 degrees C and it reduced E by 14-16% of those under ambient CO₂ conditions. With the rising growth temperature, these effects of elevated [CO₂] drastically decreased. The observed r_{c,min} responses to temperature and [CO₂] seemed to have reflected a long-term acclimation of rice to these environments. These results indicate that anticipated global warming significantly reduces the advantageous effects of elevated [CO₂] on plant water use.

Hopkins, D.W., J.A. Chudek, E.A. Webster, and D. Barraclough. 1997. Following the decomposition of ryegrass labelled with C-13 and N-15 in soil by solid-state nuclear magnetic resonance spectroscopy. *European Journal of Soil Science* 48(4):623-631.

Investigating the biogeochemistry of plant material decomposition in soil has been restricted by difficulties extracting and identifying organic compounds. In this study the decomposition of C-13- and N-15-labelled *Lolium perenne* leaves mixed with mineral soil has been investigated over 224 days of incubation under laboratory conditions. Decomposition was followed using short-term rates of CO₂ evolution, the amounts of C-13 and N-15 remaining were determined by mass spectrometry, and C-13 and N-15 solid-state nuclear magnetic resonance (NMR) spectroscopy was used to characterize chemically the plant material as it decomposed. After 224 days 48% of the added C-13 had been lost with a rapid period of CO₂ evolution over the first 56 days. The fraction of cross-polarization magic angle spinning (CP MAS) C-13 NMR spectra represented by O-alkyl-C signal probably in carbohydrates (chemical shift, 60-90 p.p.m.) declined from 60 to 20% of the spectrum (chemical shift, 0-200 p.p.m.) over 224 days. The rate of decline of the total C-13 exceeded that of the 60-90 p.p.m. signal during the first 56 days and was similar thereafter. The fraction of the CP MAS C-13 NMR spectra represented by the alkyl- and methyl-C (chemical shift, 10-45 p.p.m.) signal increased from 5 to 14% over the first 14 days and was 19% after 224 days. CP MAS C-13 NMR of C-13- and N-15-L. *perenne* contained in 100- μ m aperture mesh bags incubated in the soil for 56 days indicated that the remaining material was mainly carbohydrate but there was an increase in the alkyl- and methyl- C associated with the bag's contents. After 224 days incubation of the labelled C-13- and N-15-L. *perenne* mixed with the soil, 40% of the added N-15 had been lost. Throughout the incubation there was only one signal centred around 100 p.p.m, detectable in the CP MAS N-15 NMR spectra. This signal corresponded to amide N-15 in peptides and may have been of plant or microbial origin or both. Although there had been substantial interaction between the added N-15 and the soil microorganisms, the associated redistribution of N-15 from plant to microbial tissues occurred within the amide region. The feasibility of following some of the component processes of plant material decomposition in soil using NMR has been demonstrated in this study and evidence that microbial synthesis contributes to the increase in alkyl- and methyl-C content of soil during decomposition has been represented.

Horie, T., H. Nakagawa, J. Nakano, K. Hamotani, and H.Y. Kim. 1995. Temperature-gradient chambers for research on global environment change .3. a system designed for rice in kyoto, japan. *Plant, Cell and Environment* 18(9):1064-1069.

Synthesis and validation of crop models for assessment of the impact

of elevated atmospheric CO₂ concentration and anticipated global warming on crop production require crop response data obtained under field-like conditions. The temperature gradient chamber (TGC) with the facility for CO₂ enrichment allows the creation of various CO₂ and temperature regimes for crops over the entire growth period with relatively inexpensive construction and running costs. The TGC develops a temperature gradient along its longitudinal axis using solar energy during the day and heating at night while maintaining the natural diurnal cycle. The temperature gradient and the CO₂ concentration in the TGC are regulated by computer control of the air ventilation rate through the TGC and of the CO₂ release rate. Longitudinal gradients of CO₂ concentration and water vapour pressure deficit of air in the TGC were generally less than 5% and ± 0.2 kPa, respectively. A CO₂ enrichment experiment on rice in the TGC showed that a doubling of the CO₂ concentration markedly enhanced crop dry matter production. Temperature had less effect on dry matter production, although panicle dry weight was greatly decreased at higher temperature as a result of high-temperature-induced sterility of rice spikelets. Since rice spikelets are most sensitive to high temperature at the moment of flowering, and their flowering habit is highly synchronized with the diurnal courses of environmental conditions, the TGC is a useful tool in understanding rice responses to changes in atmosphere and temperature.

Horn, M.E., and J.M. Widholm. 1994. Photoautotrophic growth of soybean cells in suspension-culture .3. Characterization of carbon fixation products under high and low CO₂ levels. *Plant Cell Tissue and Organ Culture* 39(3):239-244.

A photoautotrophic soybean suspension culture (SB-P) was used to study CO₂ assimilation while exposed to elevated or ambient CO₂ levels. These studies showed that under elevated CO₂ (5% v/v) malate is the dominant fixation product, strongly suggesting that phosphoenolpyruvate carboxylase (PEPCase) is the primary enzyme involved in carbon fixation in these cells under their normal growth conditions. Citrate and [aspartate + glutamate] were also significant fixation products during fifteen minutes of exposure to (CO₂)-C-14. During the ten minute unlabeled CO₂ chase however, C-14-malate continued to increase while citrate and [aspartate + glutamate] declined. Fixation of (CO₂)-C-14 under ambient CO₂ levels (0.037%) showed a very different product pattern as 3-phosphoglycerate was very high in the first one to two minutes followed by increases in [serine + glycine] and [aspartate + glutamate]. Hexose phosphates were also quite high initially but then declined relatively rapidly. Thus, the carbon fixation pattern at ambient CO₂ levels resembles somewhat that seen in C3 leaf cells while that seen at elevated CO₂ levels more closely resembles that of a C-4 plant. The initial fixation product of C-3 plants, 3-PGA, was never detectable under high CO₂ conditions. These data suggest that an in vitro photoautotrophic system would be suitable for studying carbon fixation physiology during photosynthetic and non- photosynthetic growth.

Hostetler, S.W., and F. Giorgi. 1995. Effects of a 2-times-CO₂ climate on 2 large lake systems - pyramid lake, Nevada, and Yellowstone lake, Wyoming. *Global and Planetary Change* 10(1-4):43-54.

The possible effects of trace-gas induced climatic changes on Pyramid and Yellowstone Lakes are assessed using a model of lake temperature. The model is driven by 3 1/2 years of hourly meteorological data obtained directly from the output of doubled-CO₂ experiments (2 x

CO₂) conducted with a regional climate model nested in a general circulation model. The regional atmospheric model is the climate version of the National Center for Atmospheric Research/Pennsylvania State University mesoscale model, MM4. Average annual surface temperature of Pyramid Lake for the 2 X CO₂ climate is 15.5 $\pm$ 5.4 degrees C ($\pm$ 1 sigma), 2.8 degrees C higher than the control. Annual overturn of the lake ceases as a result of these higher temperatures for the 2 x CO₂ climate. Evaporation increases from 1400 mm yr⁻¹ in the control to 1595 mm yr⁻¹ in the 2 X CO₂ simulation, but net water supplied to the Pyramid Lake basin increases from -6 mm yr⁻¹ in the control to +27 mm yr⁻¹ in the 2 x CO₂ simulation due to increased precipitation. For the open water periods, the average annual surface temperature of Yellowstone Lake is 13.2 $\pm$ 5.1 degrees C for the 2 x CO₂ climate, a temperature 1.6 degrees C higher than the control. The annual duration of ice cover on the lake is 152 days in the 2 X CO₂ simulation, a reduction of 44 days relative to the control. Warming of the lake for the 2 x CO₂ climate is mostly confined to the near-surface. Simulated spring overturn for the 2 X CO₂ climate occurs earlier in the year and fall overturn later than in the control. Evaporation increases from 544 mm yr⁻¹ to 600 mm yr⁻¹ in the 2 X CO₂ simulation, but net water supplied to the Yellowstone Lake basin increases from +373 mm yr⁻¹ in the control to +619 mm yr⁻¹ due to increased precipitation. The effects of these climatic changes suggest possible deterioration of water quality and productivity in Pyramid Lake and possible enhancement of productivity in Yellowstone Lake.

Houghton, R.A. 1996. Converting terrestrial ecosystems from sources to sinks of carbon. *Ambio* 25(4):267-272.

It may be possible to sequester carbon in forests and forest products, but to date global trends in land management have resulted in a release of terrestrial carbon to the atmosphere. Over 100 PgC were released between 1850 and 1980, and during the 1980s global changes in land use (predominantly deforestation) caused a net release of 1.6 PgC yr⁻¹, about 25% of the total emissions of carbon dioxide from human activities and about 15% of the enhanced radiative forcing. Management practices that could change this release of terrestrial carbon to an accumulation include (i) a halt to deforestation; (ii) an expansion in the land area of forests; (iii) an increase in the stocks of carbon in existing forests; (iv) more efficient harvest and greater use of wood in long-lasting products; and (v) the substitution of wood fuels for fossil fuels. However, the rate of global warming needs management as well. Unless the warming is gradual enough to avoid widespread mortality of forests, the additional releases of carbon caused by the warming itself, through increased respiration, decay, and fires, may cancel the intended effects of forest management.

Houpis, J.L.J., P.D. Anderson, J.C. Pushnik, and D.J. Ansel. 1999. Among-provenance variability of gas exchange and growth in response to long-term elevated CO₂ exposure. *Water, Air, and Soil Pollution* 116(1-2):403-412.

Genetic variability can have profound effects on the interpretation of results from elevated CO₂ studies, and future forest management decisions. Information on which varieties are best suited to future atmospheric conditions is needed to develop future forest management practices. A large-scale screening study of the effects of elevated CO₂

on 15 half-sibling sources of genetically superior ponderosa pine (*Pinus ponderosa* Dougl ex P. Laws.) is presented. These sources represent multiple elevations and latitudes throughout California. Among-provenance variability in the effects of elevated CO₂ on gas exchange and growth, and their correlation with geographic origin were investigated in ponderosa pine seedlings subjected to ambient or elevated CO₂ concentrations (525 $\mu\text{mol mol}^{-1}$ CO₂, and 700 $\mu\text{mol mol}^{-1}$ CO₂) for more than two years in open-top chambers. Substantial among-provenance variability in growth response to elevated CO₂ was evident, with 8 sources demonstrating no significant growth response to elevated CO₂ while 7 sources responded positively. For all sources, elevated CO₂ increased photosynthesis (ranging from 19% increase at 525 $\mu\text{mol mol}^{-1}$ CO₂ to 49% increase at 700 $\mu\text{mol mol}^{-1}$ CO₂). A modest correlation existed between geographic origin and above ground growth response to elevated CO₂.

Howden, S.M., G.M. McKeon, L. Walker, J.O. Carter, J.P. Conroy, K.A. Day, W.B. Hall, A.J. Ash, and O. Ghannoum. 1999. Global change impacts on native pastures in south-east Queensland, Australia. *Environmental Modelling & Software* 14(4):307-316.

Increases in atmospheric concentrations of greenhouse gases such as carbon dioxide (CO₂) are likely to impact on grazing industries through direct effects on plant growth and through possible changes in climate. Assessment of the likely direction and magnitude of these impacts requires development of appropriate modelling capacities linked with experimental work. This paper documents the adaptation of an existing soil-pasture-livestock model, GRASP, to simulate system responses to changes in CO₂. The adapted model is then used to compare these responses under current climate and CO₂ conditions with four possible future scenarios: (1) doubled CO₂; (2) doubled CO₂ and increased temperature; (3) as in the previous scenario but with a drier climate; and (4) as in (2) but with a wetter climate. These studies suggest that CO₂ changes alone are likely to have beneficial effects, with increased pasture growth, increased and less variable liveweight gain, and increased ground cover. However, subsoil drainage is likely to increase. Growth responses to CO₂ are likely to be greater in drier years than in wetter years partly due to nitrogen limitations in the soils of the region. Increases in temperature in combination with CO₂ further increased animal production due to the increased number of growing days in the cooler months. The increased rainfall scenario had few additional positive effects but further increased subsoil drainage. In contrast, the drier scenario had reduced plant and animal production when compared with current conditions even though seasonal transpiration efficiency was increased by 20% due to increased CO₂. Hu, S.J., M.K. Firestone, and F.S. Chapin. 1999. Soil microbial feedbacks to atmospheric CO₂ enrichment. *Trends in Ecology and Evolution* 14(11):433-437.

Increased atmospheric CO₂ concentration often stimulates plant photosynthesis, enhances carbon (C) allocation belowground, increases plant nutrient uptake and improves the efficiency of plant water use. Recent studies suggest that microbial responses to CO₂-induced alterations in soil C, water and nutrient availability play an important role in determining ecosystem feedback to CO₂ elevation. However, to date, most of the published results have been obtained from short-term experiments or from studies using high-nutrient or disturbed soils. Information on microbial responses to CO₂-induced changes in natural and/or mature ecosystems with nutrient limitations is critical to predict changes in terrestrial ecosystem C storage under future CO₂ scenarios.

Huang, B.R., J.W. Johnson, and D.S. NeSmith. 1997. Responses to root-zone CO₂ enrichment and hypoxia of wheat genotypes differing in waterlogging tolerance. *Crop Science* 37(2):464-468.

Knowledge of wheat (*Triticum aestivum* L.) responses to CO₂ and O₂ in the root environment could improve understanding of the mechanisms of waterlogging tolerance and thus help develop waterlogging-tolerant wheat plants. This experiment was designed to investigate the responses to elevated CO₂ and hypoxia of two wheat genotypes, Bayles and Savannah, which differ in waterlogging tolerance. Plants were grown in a growth chamber in nutrient solutions. Nutrient solutions were bubbled with ambient air (control), N-2 containing 5 kPa O₂ and ambient CO₂ (hypoxia), N-2 containing 10 kPa CO₂ and ambient O₂ (high CO₂, ambient O₂), and N-2 containing 10 kPa CO₂ and 5 kPa O₂ (high CO₂, low O₂). Hypoxia alone had adverse effects on net photosynthesis (P-n), stomatal conductance (g(s)), water relations, leaf chlorophyll (chl) content, and shoot and root growth. The effects were greater for waterlogging-sensitive Bayles. When compared with the aerated control, the combination of elevated CO₂ and hypoxia caused significant reductions in P-n, g(s), leaf water potential, and leaf chl content for Bayles, and in shoot and root growth for both Bayles and Savannah. Photosynthetic rate and leaf chl content of Savannah were increased when roots of hypoxic plants were exposed to elevated CO₂, but this was not true for Bayles. Root-zone CO₂ enrichment at ambient O₂ had no significant effects on shoot growth, but reduced root growth in both genotypes. The results showed that CO₂ enrichment under root hypoxia can alleviate some negative effects of hypoxia on P-n, leaf chl content, and shoot growth, the effect being larger for waterlogging-tolerant Savannah.

Huang, Y.S., F.A. Street-Perrott, R.A. Perrot, P. Metzger, and G. Eglinton. 1999. Glacial-interglacial environmental changes inferred

from molecular and compound-specific $\delta^{13}\text{C}$ analyses of sediments from Sacred Lake, Mt. Kenya. *Geochimica et Cosmochimica Acta* 63(9):1383-1404.

Molecular Stratigraphic analyses, including lipid distributions and compound-specific $\delta^{13}\text{C}$ measurements, have been performed at 15 levels in a sediment core from Sacred Lake, Mt. Kenya, a high-altitude (2350 m a.s.l.) freshwater lake with a record extending from the last glacial (>40,000 cal. yr BP) through the present interglacial; Terrestrial and aquatic organic-matter sources were independently assessed using source-specific biomarkers. $\delta^{13}\text{C}$ values of long-chain n-alkyl lipids from terrestrial higher plants exhibit large glacial to interglacial shifts: those from the last glacial maximum (LGM) (-20 to -18 parts per thousand) indicate a terrestrial vegetation dominated by C-4 grasses or sedges, whereas those from the early Holocene (-34 to -27 parts per thousand) reflect recolonization of the catchment area by C-3 plants, consistent with a rapid rise in the upper treeline. Specific algal biomarkers, including five unsaturated hydrocarbons of novel structure ascribed to the microalga *Botryococcus braunii*, were abundant, as confirmed by scanning electronic microscopy (SEM). An extreme $\delta^{13}\text{C}$ shift of over 25 parts per thousand is displayed by the algal biomarkers, an elevated value of -5.1 parts per thousand at the last glacial maximum (LGM) contrasting with a minimum value of -30.3 parts per thousand at the beginning of the Holocene. A major change in the molecular distributions of the algal biomarkers parallels this large $\delta^{13}\text{C}$ shift, with acyclic isoprenoid hydrocarbons dominating the last glacial and cyclic isoprenoid hydrocarbons the Holocene. The low atmospheric partial pressure of CO_2 ($p\text{CO}_2$) at the LGM would favour photosynthetic organisms possessing CO_2 -concentrating mechanisms, including terrestrial C-4 grasses and freshwater green algae. Hence, glacial/interglacial changes in $p\text{CO}_2$, and in the $\text{CO}_2:\text{O}_2$ ratio in particular, had a significant impact on both terrestrial and aquatic ecosystems on Mt. Kenya, in addition to the effects of climate and local environmental factors. Copyright (C) 1999 Elsevier Science Ltd.

Hufton, C.A., R.T. Besford, and A.R. Wellburn. 1996. Effects of NO ($+\text{NO}_2$) pollution on growth, nitrate reductase activities and associated protein contents in glasshouse lettuce grown hydroponically in winter with CO_2 enrichment. *New Phytologist* 133(3):495-501.

Winter hydroponic growth of several lettuce cultivars under glass showed considerable inhibition (up to 47%) of growth after 6 wk exposure to concentrations of NO ($+\text{NO}_2$; 450 nl l⁻¹) in total) typical of emissions from propane burners used for direct heating and CO_2 enrichment. After a further 4 wk under similar conditions, however, these growth depressions were replaced by a swing into benefit so that, by harvest, pollutant-exposed lettuces were bigger and had faster assimilation rates than those growing in clean CO_2 -enriched air. This adaptation may partly be explained by enhanced use of NO_2 -derived N by lettuce leaves, a consequence of increased nitrate reductase (NaR) activities and amounts of associated NaR proteins, despite adequate nitrate also being available in the hydroponic fluid. Rates of NaR activity in the roots, by contrast, were depressed by NO ($+\text{NO}_2$) pollution. NaR activities were highest in early afternoon in clean or polluted air but these daily patterns did not coincide with the content of NaR-associated proteins determined by ELISA. Other mechanisms of modulating NaR activity must therefore be responsible.

Hughes, L., and F.A. Bazzaz. 1997. Effect of elevated CO_2 on interactions between the western flower thrips, *Frankliniella occidentalis* (Thysanoptera: Thripidae) and the common milkweed, *Asclepias syriaca*. *Oecologia* 109(2):286-290.

We measured the effect of elevated CO_2 on populations of the western flower thrips, *Frankliniella occidentalis* and on the amount of leaf damage inflicted by the thrips to one of its host plants, the common milkweed, *Asclepias syriaca*. Plants grown at elevated CO_2 had significantly greater aboveground biomass and C:N ratios, and significantly reduced percentage nitrogen. The number of thrips per plant was not affected by CO_2 treatment, but the density of thrips (numbers per gram aboveground biomass), was significantly reduced at high CO_2 . Consumption by thrips, expressed as the amount of damaged leaf area per capita, was significantly greater at high CO_2 , and the amount of leaf area damaged by thrips was increased by 33%. However overall leaf area at elevated CO_2 increased by 62%, more than compensating for the increase in thrips consumption. The net outcome was that plants at elevated CO_2 had 3.6 times more undamaged leaf area available for photosynthesis than plants at ambient CO_2 , even though they had only 1.6 times the overall amount of leaf area. This study highlights the need for measuring the effects of herbivory at the whole-plant level and also the importance of taking herbivory into account when predicting plant responses to elevated CO_2 .

Huluka, G., D.R. Hileman, P.K. Biswas, K.F. Lewin, J. Nagy, and G.R. Hendrey. 1994. Effects of elevated CO_2 and water-stress on mineral concentration of cotton. *Agricultural and Forest Meteorology* 70(1-4):141-152.

Projected increases in atmospheric CO_2 concentrations may alter mineral and protein levels in plant tissues, systematically affecting growth, nutrient cycling and utilization, residue decomposition, and insect-plant interactions in the future. The free-air CO_2 enrichment (FACE) system provided an opportunity to monitor seasonal trends in nutrient status and crude protein content of cotton (*Gossypium hirsutum* L. cv. Deltapine 77) grown in a natural field setting without the limitations often imposed by growth chambers or reduced rooting volumes. In 1990, plants were exposed to two levels of atmospheric CO_2 (FACE, almost-equal-to 550 $\mu\text{mol mol}^{-1}$ and CONTROL, almost-equal-to 370 $\mu\text{mol mol}^{-1}$) and two irrigation regimes (100% and 75% replacement of evapotranspiration) beginning in early July. Cotton leaves, stem, and roots were sampled at different times during the season and analyzed for C, N, Ca, K, Mg, P, Cu, Fe, Mn, Zn, B, Mo, Si and protein. The N and protein concentrations of leaves, stems and roots were significantly lower in FACE plants than in CONTROL plants, but C:N ratios were higher for the FACE plants than the CONTROL plants. Some other elements were significantly affected by CO_2 enrichment, but not for all dates and all plant tissues. There were no significant effects in any of the data because of the irrigation treatment or the irrigation- CO_2 interaction. Reductions in tissue N and protein concentrations and the increases in the C:N with CO_2 enrichment have important implications for agricultural and natural systems and demand additional research.

Humphries, S.W., and S.P. Long. 1995. Wimovac - a software package for modeling the dynamics of plant leaf and canopy photosynthesis. *Computer Applications in the Biosciences* 11(4):361-371.

The ability to predict net carbon exchange and production of vegetation in response to predicted atmospheric and climate change is critical to assessing the potential impacts of these changes. Mathematical models provide an important tool in the study of whole plant, canopy and ecosystem responses to global environmental change. Because this requires prediction beyond experience, mechanistic rather than empirical models are needed. The uniformity and strong understanding of the photosynthetic process, which is the primary point of response of plant production to global atmospheric change, provides a basis for such an approach. Existing modelling systems have been developed primarily for expert modellers and have not been easily accessible to experimentalists, managers and students. Here we describe a modular modelling system operating within Windows to provide this access. WIMOVAC (Windows Intuitive Model of Vegetation response to Atmosphere and Climate Change) is designed to facilitate the modelling of various aspects of plant photosynthesis with particular emphasis on the effects of global climate change. WIMOVAC has been designed to run on IBM PC-compatible computers running Microsoft Windows. The package allows the sophisticated control of the simulation processes for photosynthesis through a standardized Windows user interface and provides automatically formatted results as either tabulated data or as a range of customizable graphs. WIMOVAC has been written in Microsoft Visual Basic, to facilitate the rapid development of user-friendly modules within the familiar Windows framework, while allowing a structured development. The highly interactive nature of controls adopted by WIMOVAC makes it suitable for research, management and educational purposes.

Hungate, B.A., J. Canadell, and F.S. Chapin. 1996. Plant species mediate changes in soil microbial N in response to elevated CO₂. *Ecology* 77(8):2505-2515.

The effect of elevated CO₂ on plant-microbial interactions and nitrogen (N) cycling is critical to predicting plant growth responses to elevated CO₂, because plant growth is often N-limited. We investigated whether the effects of elevated CO₂ on plant-microbial N dynamics differed among six annual plant species: three European grasses that have invaded California grasslands, and one grass and two forbs native to California serpentine grassland. Elevated CO₂ altered plant N pools and (NH₄⁺)-N-15 uptake, but the direction and magnitude of the changes were species dependent. The introduced grasses showed increased plant N pools and (NH₄⁺)-N-15 uptake, whereas the native species showed smaller increases or even decreases in plant N pools and N-15(4)+ uptake. Under nutrient enrichment, soil microbial N and (NH₄⁺)-N-15 uptake differed among soils with different plant species, but they were not affected by elevated CO₂. At low nutrients, elevated CO₂ altered soil microbial N and (NH₄⁺)-N-15 uptake, but the direction and magnitude of the changes were species dependent. The changes in soil microbial N were positively correlated with changes in the plant N pool, suggesting that there was no trade-off in N uptake between plants and microbes. These results also suggest that plant species composition will partly determine the direction of changes in soil N cycling in response to elevated CO₂.

Hungate, B.A., F.S. Chapin, H. Zhong, E.A. Holland, and C.B. Field. 1997. Stimulation of grassland nitrogen cycling under carbon dioxide enrichment. *Oecologia* 109(1):149-153.

Nitrogen (N) limits plant growth in many terrestrial ecosystems, potentially constraining terrestrial ecosystem response to elevated CO₂. In this study, elevated CO₂ stimulated gross N mineralization and plant N uptake in two annual grasslands. In contrast to other studies that have invoked increased C input to soil as the mechanism altering soil N cycling in response to elevated CO₂, increased soil moisture, due to decreased plant transpiration in elevated CO₂, best explains the changes we observed. This study suggests that atmospheric CO₂ concentration may influence ecosystem biogeochemistry through plant control of soil moisture.

Hungate, B.A., P. Dijkstra, D.W. Johnson, C.R. Hinkle, and B.G. Drake. 1999. Elevated CO₂ increases nitrogen fixation and decreases soil nitrogen mineralization in Florida scrub oak. *Global Change Biology* 5(7):781-789.

We report changes in nitrogen cycling in Florida scrub oak in response to elevated atmospheric CO₂ during the first 14 months of experimental treatment. Elevated CO₂ stimulated above-ground growth, nitrogen mass, and root nodule production of the nitrogen-fixing vine, *Galactia elliptica* Nuttall. During this period, elevated CO₂ reduced rates of gross nitrogen mineralization in soil, and resulted in lower recovery of nitrate on resin lysimeters. Elevated CO₂ did not alter nitrogen in the soil microbial biomass, but increased the specific rate of ammonium immobilization (NH₄⁺ immobilized per unit microbial N) measured over a 24-h period. Increased carbon input to soil through greater root growth combined with a decrease in the quality of that carbon in elevated CO₂ best explains these changes. These results demonstrate that atmospheric CO₂ concentration influences both the internal cycling of nitrogen (mineralization, immobilization, and nitrification) as well as the processes that regulate total ecosystem nitrogen mass (nitrogen fixation and nitrate leaching) in Florida coastal scrub oak. If these changes in nitrogen cycling are sustained, they could cause long-term feedbacks to the growth responses of plants to elevated CO₂. Greater nitrogen fixation and reduced leaching could stimulate nitrogen-limited plant growth by increasing the mass of labile nitrogen in the ecosystem. By contrast, reduced nitrogen mineralization and increased immobilization will restrict the supply rate of plant-available nitrogen, potentially reducing plant growth. Thus, the net feedback to plant growth will depend on the balance of these effects through time.

Hungate, B.A., E.A. Holland, R.B. Jackson, F.S. Chapin, H.A. Mooney, and C.B. Field. 1997. The fate of carbon in grasslands under carbon dioxide enrichment. *Nature* 388(6642):576-579.

The concentration of carbon dioxide (CO₂) in the Earth's atmosphere is rising rapidly(1), with the potential to alter many ecosystem processes. Elevated CO₂ often stimulates photosynthesis(2), creating the possibility that the terrestrial biosphere will sequester carbon in response to rising atmospheric CO₂ concentration, partly offsetting emissions from fossil-

fuel combustion, cement manufacture, and deforestation(3,4). However, the responses of intact ecosystems to elevated CO₂ concentration, particularly the below-ground responses, are not well understood. Here we present an annual budget focusing on below-ground carbon cycling for two grassland ecosystems exposed to elevated CO₂ concentrations. Three years of experimental CO₂ doubling increased ecosystem carbon uptake, but greatly increased carbon partitioning to rapidly cycling carbon pools below ground. This provides an explanation for the imbalance observed in numerous CO₂ experiments, where the carbon increment from increased photosynthesis is greater than the increments in ecosystem carbon stocks. The shift in ecosystem carbon partitioning suggests that elevated CO₂ concentration causes a greater increase in carbon cycling than in carbon storage in grasslands.

Hungate, B.A., R.B. Jackson, C.B. Field, and F.S. Chapin. 1996. Detecting changes in soil carbon in CO₂ enrichment experiments. *Plant and Soil* 187(2):135-145.

After four growing seasons, elevated CO₂ did not significantly alter surface soil C pools in two intact annual grasslands. However, soil C pools in these systems are large compared to the likely changes caused by elevated CO₂. We calculated statistical power to detect changes in soil C, using an approach applicable to all elevated CO₂ experiments. The distinctive isotopic signature of the fossil-fuel-derived CO₂ added to the elevated CO₂ treatment provides a C tracer to determine the rate of incorporation of newly-fixed C into soil. This rate constrains the size of the possible effect of elevated CO₂ on soil C. Even after four years of treatment, statistical power to detect plausible changes in soil C under elevated CO₂ is quite low. Analysis of other elevated CO₂ experiments in the literature indicates that either CO₂ does not affect soil C content, or that reported CO₂ effects on soil C are too large to be a simple consequence of increased plant carbon inputs, suggesting that other mechanisms are involved, or that the differences are due to chance. Determining the effects of elevated CO₂ on total soil C and long-term C storage requires more powerful experimental techniques or experiments of longer duration.

Hungate, B.A., C.P. Lund, H.L. Pearson, and F.S. Chapin. 1997. Elevated CO₂ and nutrient addition alter soil N cycling and N trace gas fluxes with early season wet-up in a California annual grassland. *Biogeochemistry* 37(2):89-109.

We examined the effects of growth carbon dioxide (CO₂) concentration and soil nutrient availability on nitrogen (N) transformations and N trace gas fluxes in California grassland microcosms during early-season wet-up, a time when rates of N transformation and N trace gas flux are high. After plant senescence and summer drought, we simulated the first fall rains and examined N cycling. Growth at elevated CO₂ increased root

production and root carbon:nitrogen ratio. Under nutrient enrichment, elevated CO₂ increased microbial N immobilization during wet-up, leading to a 43% reduction in gross nitrification and a 55% reduction in NO emission from soil. Elevated CO₂ increased microbial N immobilization at ambient nutrients, but did not alter nitrification or NO emission. Elevated CO₂ did not alter soil emission of N₂O at either nutrient level. Addition of NPK fertilizer (1:1:1) stimulated N mineralization and nitrification, leading to increased N₂O and NO emission from soil. The results of our study support a mechanistic model in which elevated CO₂ alters soil N cycling and NO emission: increased root production and increased C:N ratio in elevated CO₂ stimulate N immobilization, thereby decreasing nitrification and associated NO emission when nutrients are abundant. This model is consistent with OUT basic understanding of how C availability influences soil N cycling and thus may apply to many terrestrial ecosystems.

Hunsaker, D.J., G.R. Hendrey, B.A. Kimball, K.F. Lewin, J.R. Mauney, and J. Nagy. 1994. Cotton evapotranspiration under field conditions with CO₂ enrichment and variable soil-moisture regimes. *Agricultural and Forest Meteorology* 70(1-4):247-258.

The CO₂ concentration of the atmosphere is predicted to double by the next century, and this is expected to increase significantly the growth and yield of many important agricultural crops. One consequence of larger and more vigorous plants may be increased crop evapotranspiration (ET) and irrigation water requirements. The objective of this work was to determine ET of cotton (*Gossypium hirsutum* L. cv. 'Deltapine 77') grown under ambient (about 370 μmol mol⁻¹) and enriched (550 μmol mol⁻¹) CO₂ concentrations for both well-watered and water-stress irrigation managements. Studies were conducted in 1990 and 1991 within a large, drip-irrigated cotton field in central Arizona. Cotton ET was measured during the growing seasons using a soil water balance, based on neutron gauge soil water measurements. ET, for periods from 7 to 14 days, was not significantly different between ambient and enriched CO₂ treatments at the 0.05 probability level, and the total seasonal ET for the CO₂ treatments varied by 2% or less in either year. However, water-stress treatments, which were initiated on 3 July (day of year (DOY) 184) in 1990 and on 20 May (DOY 128) in 1991, had significantly lower (P < 0.05) ET than well-watered treatments starting at the end of July in 1990 and in early July in 1991 when the plants were about 75-90 days old. The result that CO₂ enrichment to 550 μmol mol⁻¹ did not significantly change the ET of cotton was consistent with the results of co-investigators who measured ET in the same experiments using stem flow gauges and an energy balance. This result implies that irrigation water use would not have to be increased to produce cotton in a future high-CO₂ world. However, if a concomitant change in climate occurs, such as global warming, cotton evapotranspiration may change in response to the changed weather condition.

Hunsaker, D.J., B.A. Kimball, P.J. Pinter, R.L. LaMorte, and G.W. Wall. 1996. Carbon dioxide enrichment and irrigation effects on wheat evapotranspiration and water use efficiency. *Transactions of the Asae* 39(4):1345-1355.

Evapotranspiration (ET) and water use efficiency were evaluated for two spring wheat crops, grown in a drip-irrigated field under ambient (about 370 μmol mol⁻¹) and enriched (550 μmol mol⁻¹) carbon dioxide

(CO₂) concentrations during the 1992-1993, and 1993-1994, Free-Air CO₂ Enrichment (FACE) experiments in central Arizona. CO₂-enriched (FACE) and ambient CO₂ (CONTROL) treatments were replicated in four circular plots, 25 m in diameter, and well-watered (WET) and water-stressed (DRY) irrigation treatments were imposed on one-half of each plot. Wheat ET, measured over discrete time periods of several days by a soil water balance, was significantly higher for WET than DRY irrigation treatments after the first week in March in both years. Differences in ET between CO₂ treatments during the season were generally small, although there was a consistent trend towards decreased ET for the FACE over CONTROL under the well-watered irrigation regime. The two-year average reduction in seasonal ET owing to the FACE treatment was about 5% under WET irrigation and was consistent with the results from two parallel investigations that used an energy balance and sap flow measurements. Under the DRY irrigation treatment, seasonal ET was 5 and 0.9% higher for the FACE treatment in the first and second years, respectively. Water use efficiency (grain yield per unit seasonal ET) was significantly higher for FACE treatments; 15 and 24% higher than CONTROL under DRY irrigation, and 13 and 18% higher than CONTROL under WET irrigation. The results indicate that irrigation requirements for fully irrigated wheat may be slightly lower in the future high-CO₂ environment.

Hunt, H.W., E.T. Elliott, J.K. Detling, J.A. Morgan, and D.X. Chen. 1996. Responses of a C-3 and a C-4 perennial grass to elevated CO₂ and temperature under different water regimes. *Global Change Biology* 2(1):35-47.

An experiment was carried out to determine the effects of elevated CO₂, elevated temperatures, and altered water regimes in native shortgrass steppe. Intact soil cores dominated by *Bouteloua gracilis*, a C-4 perennial grass, or *Pascopyrum smithii*, a C-3 perennial grass, were placed in growth chambers with 350 or 700 µmol L⁻¹ atmospheric CO₂, and under either normal or elevated temperatures. The normal regime mimicked field patterns of diurnal and seasonal temperatures, and the high-temperature regime was 4 degrees C warmer. Water was supplied at three different levels in a seasonal pattern similar to that observed in the field. Total biomass after two growing seasons was 19% greater under elevated CO₂, with no significant difference between the C-3 and C-4 grass. The effect of elevated CO₂ on biomass was greatest at the intermediate water level. The positive effect of elevated CO₂ on shoot biomass was greater at normal temperatures in *B. gracilis*, and greater at elevated temperatures in *P. smithii*. Neither root-to-shoot ratio nor production of seed heads was affected by elevated CO₂. Plant tissue N and soil inorganic N concentrations were lower under elevated CO₂, but no more so in the C-3 than the C-4 plant. Elevated CO₂ appeared to increase plant N limitation, but there was no strong evidence for an increase in N limitation or a decrease in the size of the CO₂ effect from the first to the second growing season. Autumn samples of large roots plus crowns, the perennial organs, had 11% greater total N under elevated CO₂, in spite of greater N limitation.

Hunt, H.W., J.A. Morgan, and J.J. Read. 1998. Simulating growth and root-shoot partitioning in prairie grasses under elevated atmospheric CO₂ and water stress. *Annals of Botany* 81(4):489-501.

We constructed a model simulating growth, shoot-root partitioning, plant nitrogen (N) concentration and total nonstructural carbohydrates in perennial grasses. Carbon (C) allocation was based on the concept of a functional balance between root and shoot growth, which responded to variable plant C and N supplies. Interactions between the plant and environment were made explicit by way of variables for soil water and soil inorganic N. The model was fitted to data on the growth of two species of perennial grass subjected to elevated atmospheric CO₂ and water stress treatments. The model exhibited complex feedbacks between plant and environment, and the indirect effects of CO₂ and water treatments on soil water and soil inorganic N supplies were important in interpreting observed plant responses. Growth was surprisingly insensitive to shoot-root partitioning in the model, apparently because of the limited soil N supply, which weakened the expected positive relationship between root growth and total N uptake. Alternative models for the regulation of allocation between shoots and roots were objectively compared by using optimization to find the least squares fit of each model to the data. Regulation by various combinations of C and N uptake rates, C and N substrate concentrations, and shoot and root biomass gave nearly equivalent fits to the data, apparently because these variables were correlated with each other. A partitioning function that maximized growth predicted too high a root to shoot ratio, suggesting that partitioning did not serve to maximize growth under the conditions of the experiment (C) 1998 *Annals of Botany Company*.

Hunt, H.W., M.J. Trlica, E.F. Redente, J.C. Moore, J.K. Detling, T.G.F. Kittel, D.E. Walter, M.C. Fowler, D.A. Klein, and E.T. Elliott. 1991. Simulation-model for the effects of climate change on temperate grassland ecosystems. *Ecological Modelling* 53(3-4):205-246.

We studied the responses of temperate grasslands to climate change using a grassland ecosystem model which simulates seasonal dynamics of shoots, roots, soil water, mycorrhizal fungi, saprophytic microbes, soil fauna, inorganic nitrogen, plant residues and soil organic matter. Forty-year simulations were made for several climate change scenarios. The model was driven with observed weather and with combinations of elevated atmospheric CO₂, elevated temperature, and either increased or decreased precipitation. Precipitation and CO₂ level accounted for most of the variation among climate change treatments in the responses of soil, plants, animals and microbes. Elevated temperature extended the growing season but depressed photosynthesis in the summer, with little net effect on annual primary production. Doubling CO₂ (1) caused persistent increases in primary production, in spite of greater nitrogen limitation, and (2) led to greater storage of carbon in plant residues and soil organic matter. The increased carbon storage was not great enough to keep pace with the present rate of increase in atmospheric CO₂.

Hunt, R., and J.H.C. Cornelissen. 1997. Components of relative growth rate and their interrelations in 59 temperate plant species. *New Phytologist* 135(3):395-417.

Three groups of species (21 herbaceous monocotyledons, 22 herbaceous dicotyledons and 16 woody dicotyledons), including representatives of a wide range of natural habitats and life forms in inland Britain, were grown in the seedling phase in a resource-rich controlled environment and assessed over a 14-day period (21 d in the case of woody species). Mean values of relative growth rate (RGR), Unit leaf rate (ULR), leaf area ratio (LAR), leaf weight fraction (LWF), specific leaf area (SLA), and the root-shoot allometric coefficient were derived. In herbaceous species, the grand mean RGR was 0.20 d⁻¹, comparable to values previously recorded. For woody species, the mean was 0.09 d⁻¹. An existing assumption linking high RGR to high allocation to photosynthetic biomass was upheld by comparisons made between groups. Within groups, however, no pattern of this kind could be demonstrated. When photosynthetically active radiation was increased from 125 to 250 $\mu\text{mol m}^{-2} \text{s}^{-1}$, ULR was increased almost pro rata. The parallel response in RGR was only slight, being offset by considerable reductions in LAR. The apparent mean quantum yield for photosynthesis in herbaceous species (whole-plant d. wt basis) was 0.60 g mol⁻¹. There was no significant dependence of RGR on ULR in any of the three groups of species, although the absolute magnitude of ULR declined in the order: herbaceous monocotyledons > herbaceous dicotyledons > woody dicotyledons. In all three groups, RGR was strongly dependent upon LAR but no differences emerged in absolute scale of LAR. The absolute scale of mean LWF decreased from herbaceous to woody species, but the dependence of LAR on LWF strengthened. Groups showed no systematic differences in magnitude of SLA, but the correlation of LAR with SLA was strong throughout. Multiple regression showed that the leading determinants of RGR were ULR and SLA in herbaceous species and LWF in woody species. Principal components analyses (PCA) on each of the three groups explained at least 77% of variation and agreed closely with an optimal (non-hierarchical) classification. Only six cluster 'types' were recognized out of the 16 theoretically possible combinations of 'high' or 'low' values of the four growth parameters. Strong evidence of evolutionary trade-offs emerged, most strikingly in that high RGR was never seen in combination with low SLA. The morphological/physiological types identified by an all-groups PCA separated woody from the herbaceous species, but dicotyledons were almost congruent with the monocotyledons. The non-growth-analytical attributes most strongly correlated with mean RGR were percentage yield at a low level of mineral nutrients, leaf nitrogen concentration, and seed weight. It was concluded that mean RGR plays a central role in the identification of pathways of evolutionary specialization in herbaceous species.

Hunt, R., D.W. Hand, M.A. Hannah, and A.M. Neal. 1991. Response to CO₂ enrichment in 27 herbaceous species. *Functional Ecology* 5(3):410-421.

CO₂-enrichment experiments were performed on 25 British native species of widely differing ecology. Two crops, one C3 (sunflower) and one C4 (maize), were also included. The background regime involved full-light, glasshouse conditions, non-limiting supplies of water and mineral nutrients and a daytime mean temperature of 18-degrees-C. Four CO₂ treatments were maintained at nominal concentrations of 350, 500, 650 or 800 v.p.m. over a 56-day period. Hyperbolic functions were fitted to yield vs CO₂ concentration. The functions were then used to generate

predictions of Q540/350 (the quotient of present yield under the CO₂ regime predicted for the year 2050) and Q700/350 (the quotient of present yield predicted for a doubling of ambient CO₂ concentration). Values of Q540/350 for whole-plant dry weight ranged from below 1.01 to 1.49, the upper values being at least similar in magnitude to those already observed in C3 crops. The mean value of whole-plant Q700/350 for 11 species of near-competitive strategy was 1.43. Four species of stress-tolerant or ruderal strategy had a mean Q700/350 of only 1.05. High CO₂ responsiveness was common only within the competitive strategy and its close relations. The fitted Q540/350 for species of the pure strategy was 1.38. In the centre of the strategic range the fitted value was 1.12, and at the far extreme, the value for species of ruderal or stress-tolerant strategy was only 1.03.

976

Hunt, R., D.W. Hand, M.A. Hannah, and A.M. Neal. 1993. Further responses to co₂ enrichment in british herbaceous species. *Functional Ecology* 7(6):661-668.

1. CO₂-enrichment experiments have been performed on 15 British herbaceous species of widely differing ecology. The conditions of growth were very similar to those used in a previous study and involved full-light glasshouse conditions, non-limiting supplies of water and mineral nutrients and a daytime mean temperature of 18 degrees C. Four CO₂ treatments were maintained (350, 500, 650 or 800 vpm) over periods of 49 or 52 days. 2. Hyperbolic functions were fitted to yield vs CO₂ concentration. The functions were used to generate predictions of Q(540/350) (the quotient of the 'present' yield which is predicted for the CO₂ regime expected by the year 2050) and Q(700/350) (the quotient predicted for a doubling of the present ambient CO₂ concentration). Values of Q(540/350) for whole-plant dry weight ranged from below 1.00 to 1.19. The mean Value of whole-plant Q(700/350) for eight species of 'competitive' functional type was 1.13. Six species of 'stress-tolerant' or 'ruderal' type had a mean Q(700/350) Of only 1.07. 3. The new data support and amplify an earlier conclusion that high CO₂ responsiveness is normal only within the competitive functional type (or 'strategy') and its close relations. A simplified and more broadly based general prediction now gives a fitted percentage increase after approximately 7 weeks' growth of 27% for species of broadly competitive strategy. In the centre of the range of functional types the fitted values now range from 13 to 20%, and at the far extremes, the value for species of either the ruderal or the stress-tolerant type is now 6%. The gradient of this response is statistically significant, but less steep than that previously reported.

977

Hunt, R., D.W. Hand, M.A. Hannah, and A.M. Neal. 1995. Temporal and nutritional influences on the response to elevated co₂ in selected british grasses. *Annals of Botany* 75(2):207-216.

To investigate the duration of the CO₂ response and its interaction with mineral nutrition, CO₂-enrichment experiments were performed on four British grasses of differing ecology and functional type: *Arrhenatherum elatius* (L.) Beauv., *Festuca ovina* L., *Festuca rubra* L. and *Poa annua* L. Naturally-lit, glasshouse cabinets were used, with a non-limiting water supply and a daytime mean temperature of 18 degrees C. Two CO₂ treatments were maintained at nominal concentrations of 350 and 700 vpm and were combined factorially with two levels of balanced mineral nutrition at conductivities of 0.1 and 1 mS cm⁻¹. Harvests took place at planting-out, and at 16, 37 and 58 d thereafter. Fitted curves were used to derive instantaneous values of total dry weight, relative growth rate (RGR), shoot weight fraction (SWF) and unit shoot rate (USR) for all combinations of species, CO₂ level, nutrient level and time of harvesting. At the higher nutrient level there was a reasonably close

agreement with previous estimates of the CO₂ response in the four species. The response, if any, most often arose from an increase in USR being accompanied by a less than proportionate decline in SWF. Responses were sustained throughout the period studied. At the lower nutrient level, all species showed a CO₂ response initially, but this declined at a rate which was inversely related to the CO₂-responsiveness of the species at the higher nutrient level. The underlying ontogenetic drift appeared to be markedly towards adjustment in SWF and away from that of USR. However, this drift was retarded, suspended or even reversed by low-nutrient conditions and/or by high CO₂ responsiveness in the species itself.

Huntley, B. 1995. Plant-species response to climate-change - implications for the conservation of European birds. *Ibis* 137:S127-S138.

Wildlife conservation faces new and extreme challenges in adapting to the accelerating dynamics of a world responding to global change. The Quaternary record shows that migration has been the usual response of organisms to environmental change. This record also reveals that forecast future climate changes are of a magnitude and in a direction unprecedented in recent earth history: the rate of these changes is likely also to surpass that of any comparable change during the last 2.4 million years. The relationship between a species' geographical distribution and present climate may be modelled by a surface representing the probability of encountering that species under given combinations of climate conditions. This 'climate response surface' then may be used to simulate potential future distributions of the species in response to forecast climate scenarios. Such simulations reveal the magnitude of the impacts of these forecast climate changes. Although to date this approach has been applied in Europe only to plants, it promises to be valuable also for other groups of organisms, including birds. Some bird species, however, may respond more directly to either habitat structure or presence of specific food plants; such factors may be incorporated into the models when required. The magnitude of likely vegetation changes necessitates a global approach to conservation if there is to be any hope of long-term success. Successful conservation of global biodiversity will depend upon conservation of the global environment and limitation of the human population much more than upon parochial efforts to conserve locally rare organisms or habitats.

Huntley, B., P.M. Berry, W. Cramer, and A.P. McDonald. 1995. Modelling present and potential future ranges of some European higher plants using climate response surfaces. *Journal of Biogeography* 22(6):967-1001.

It is hypothesized that the principal features of higher plant distributions at continental scales are determined by the macroclimate. Bioclimate data have been computed on a 50 km grid across Europe. Along with published maps of higher plant distributions based upon the same grid, these data have been used to derive climate response surfaces that model the relationship between a species' distribution and the present climate. Eight species representative of a variety of phytogeographic patterns have been investigated. The results support the hypothesis that the European distributions of all eight species are principally determined by macroclimate and illustrate the nature of the climatic constraints upon each species. Simulated future distributions in equilibrium with 2 x CO₂ climate scenarios derived from two alternative GCMs show that all of

the species are likely to experience major shifts in their potential range if such climatic changes take place. Some species may suffer substantial range and population reductions and others may face the threat of extinction. The rate of the forecast climate changes is such that few, if any, species may be able to maintain their ranges in equilibrium with the changing climate. In consequence, the transient impacts upon ecosystems will be varied but often may lead to a period of dominance by opportunist, early-successional species. Our simulations of potential ranges take no account of such factors as photoperiod or the direct effects of CO₂, both of which may substantially alter the realized future equilibrium.

Hurry, V., M. Tobiaeson, S. Kromer, P. Gardestrom, and G. Oquist. 1995. Mitochondria contribute to increased photosynthetic capacity of leaves of winter rye (*Secale cereale* L.) following cold-hardening. *Plant, Cell and Environment* 18(1):69-76.

Cold-hardening of winter rye (*Secale cereale* L. cv. Musketeer) increased dark respiration from -2.2 to -3.9 $\mu\text{mol O}_2 \text{ m}^{-2} \text{ s}^{-1}$ and doubled light- and CO₂-saturated photosynthesis at 20 degrees C from 18.1 to 37.0 $\mu\text{mol O}_2 \text{ m}^{-2} \text{ s}^{-1}$. We added oligomycin at a concentration that specifically inhibits oxidative phosphorylation to see whether the observed increase in dark respiration reflected an increase in respiration in the light, and whether this contributed to the enhanced photosynthesis of cold-hardened leaves. Oligomycin inhibited light- and CO₂-saturated rates of photosynthesis in non-hardened and cold-hardened leaves by 14 and 25%, respectively, and decreased photochemical quenching of chlorophyll a fluorescence to a greater degree in cold-hardened than in non-hardened leaves. These data indicate an increase both in the rate of respiration in the light, and in the importance of respiration to photosynthesis following cold-hardening. Analysis of metabolite pools indicated that oligomycin inhibited photosynthesis by limiting regeneration of ribulose-1,5-bisphosphate. This limitation was particularly severe in cold-hardened leaves, and the resulting low 3-phosphoglycerate pools led to a feed-forward inhibition of sucrose-phosphate synthase activity. Thus, it does not appear that oxidative phosphorylation supports the increase in photosynthetic O₂ evolution following cold-hardening by increasing the availability of cytosolic ATP. The data instead support the hypothesis that the mitochondria function in the light by using the reducing equivalents generated by non-cyclic photosynthetic electron transport.

Hussain, M.W., L.H. Allen, and G. Bowes. 1999. Up-regulation of sucrose phosphate synthase in rice grown under elevated CO₂ and temperature. *Photosynthesis Research* 60(2-3):199-208.

Rice (*Oryza sativa* L. cv. IR-30) was grown season-long in outdoor, controlled-environment chambers at 33 Pa CO₂ with day/night/paddy-water temperatures of 28/21/25 degrees C, and at 66 Pa CO₂ with five different day/night/paddy-water temperature regimes (25/18/21, 28/21/25, 31/24/28, 34/27/31 and 37/30/34 degrees C). Sucrose phosphate synthase (SPS) activities in leaf extracts at 21, 48 and 81 days after planting (DAP) were assayed under saturating and selective (limiting) conditions. Diel SPS activity data indicated that rice SPS was light regulated; with up to 2.2-fold higher rates during the day.

Throughout the growth season, leaf SPS activities were up-regulated in the CO₂-enriched plants, averaging 20 and 12% higher than in ambient-CO₂ grown plants in selective and saturating assays, respectively. Similarly, SPS activities increased 2.4% for each 1 degrees C rise in growth temperature from 25 to 34 degrees C, but decreased 11.5% at 37 degrees C. Leaf sucrose content was higher, and mirrored SPS activity better, than starch, although starch was more responsive to CO₂ treatment. Leaf sucrose and starch contents were significantly higher throughout the season in plants at elevated CO₂, but the N content averaged 6.5% lower. Increasing growth temperatures from 25 to 37 degrees C caused a linear decrease (62%) in leaf starch content, but not in sucrose. Consequently, the starch:sucrose ratio declined with growth temperature. The data are consistent with the hypothesis that the up-regulation of leaf SPS may be an acclimation response of rice to optimize the utilization and export of organic-C with the increased rates of inorganic-C fixation in elevated CO₂ or temperature growth regimes.

Hutchin, P.R., M.C. Press, J.A. Lee, and T.W. Ashenden. 1995. Elevated concentrations of CO₂ may double methane emissions from mires. *Global Change Biology* 1(2):125-128.

The potential impact of an increase in methane emissions from natural wetlands on climate change models could be very large. We report a profound increase in methane emissions from cores of mire peat and vegetation as a direct result of increasing the CO₂ concentration from 355 to 550 $\mu\text{mol mol}^{-1}$ (a 60% increase). Increased CH₄ fluxes were observed throughout the four month period of study. Seasonal variation in CH₄ flux, consistent with that seen in the field, was observed under both ambient and elevated CO₂. Under ambient CO₂ methane fluxes rose from 0.02 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in May to 0.11 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in July before declining again in August. Under elevated CO₂, methane fluxes were at least 100% greater throughout the experiment, rising from 0.05 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in May to a peak of 0.27 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in July. The stimulation of CH₄ emissions was accompanied by a 100% increase in rates of photosynthesis from 4.6 (± 0.3) under ambient CO₂ to 9.3 (± 0.7) $\mu\text{mol m}^{-2} \text{s}^{-1}$. Root and shoot biomass were unaffected.

Valentini, R.L. Victoria, and C.J. Vorosmarty. 1998. Biospheric aspects of the hydrological cycle - Preface. *Journal of Hydrology* 213(1-4):1-21.

The Core Project Biospheric Aspects of the Hydrological Cycle (BAHC) of the International Geosphere Biosphere Programme (IGBP) addresses the biospheric aspects of the hydrological cycle through experiments and modelling of energy, water, carbon dioxide and sediment fluxes in the soil-vegetation-atmosphere system at a variety of spatial and temporal scales. Active regulation of water, energy and carbon dioxide fluxes by the vegetation make it an important factor in regulating the Earth's hydrological cycle and in the formation of the climate. Consequently,

human induced conversion of vegetation cover is an important driver for climate change. A number of recent studies, discussed in this paper, emphasise the importance of the terrestrial biosphere for the climate system. Initially, these studies demonstrate the influence of the land surface on tropical weather and climate, revealing the mechanisms, acting at various scales, that connect increasing temperatures and decreasing rainfall to large-scale deforestation and other forms of land degradation. More recently, the significance of the land surface processes for water cycle and for weather and climate in temperate and boreal zones was demonstrated. In addition the terrestrial biosphere plays a significant role in the carbon dioxide fluxes and in global carbon balance. Recent work suggests that many ecosystems both in the tropics and in temperate zones may act as a substantial sink for carbon dioxide, though the temporal variability of this sink strength is yet unclear. Further, carbon dioxide uptake and evaporation by vegetation are intrinsically coupled leading to Links and feedbacks between land surface and climate that are hardly explored yet. Earth's vegetation cover and its changes owing to human impact have a profound influence on a lateral redistribution of water and transported constituents, such as nutrients and sediments, and acts therefore as an important moderator of Earth's biogeochemical cycles. In the BAHC science programme, the importance of studying the influence of climate and human activities on mobilisation and river-borne transport of constituents is explicitly articulated. The terrestrial water and associated material cycles are studied as highly dynamic in space and time, and reflect a complex interplay among climatic forcing, topography, land cover and vegetation dynamics. Despite a large progress in our understanding of how the terrestrial biosphere interacts with Earth's and climate system and with the terrestrial part of its hydrological cycle, a number of basic issues still remain unresolved. Limited to the scope of BAHC, the paper briefly assesses the present status and identifies the most important outstanding issues, which require further research. Two, arguably most important outstanding issues are identified: a limited understanding of natural variability, especially with respect to seasonal to inter-annual cycles, and of a complex ecosystem behaviour resulting from multiple feedbacks and multiple coupled biogeochemical cycles within the overall climate system. This leads to two major challenges for the future science agenda related to global change research. First, there is a need for a strong multidisciplinary integration of research efforts in both modelling and experiments, the latter extending to inter-annual timescales. Second, the ever increasing complexity in characterisation and modelling of the climate system, which is mainly owing to incorporation of the biosphere's and human feedbacks, may call for a new approach in global change impact studies. Methodologies need to be developed to identify risks to, and vulnerability of environmental systems, taking into account all important interactions between atmospheric, ecological and hydrological processes at relevant scales. With respect to the influence of climate and human activities on mobilisation and river-borne transport of constituents, the main issues for the future are related to declining availability and quality of ground data for quantity and quality of water discharge. Such assessments presented in this paper, in combination with community wide science evaluation, has lead to an update of the science agenda for BAHC, a summary of which is provided in the appendix. Huxman, K.A., S.D. Smith, and D.S. Neuman. 1999. Root hydraulic conductivity of *Larrea tridentata* and *Helianthus annuus* under elevated CO₂. *Plant, Cell and Environment* 22(3):325-330.

While investigations into shoot responses to elevated atmospheric CO₂

are extensive, few studies have focused on how an elevated atmospheric CO₂ environment might impact root functions such as water uptake and transport. Knowledge of functional root responses may be particularly important in ecosystems where water is limiting if predictions about global climate change are true. In this study we investigated the effect of elevated CO₂ on the root hydraulic conductivity (L-p) of a C-3 perennial, *Lawea tridentata*, and a C-3 annual, *Helianthus annuus*. The plants were grown in a glasshouse under ambient (360 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) CO₂. The L-p through intact root systems was measured using a hydrostatic pressure-induced flow system. Leaf gas exchange was also determined for both species and leaf water potential ($\psi(\text{leaf})$) was determined in L, *tridentata*. The L-p of L, *tridentata* roots was unchanged by an elevated CO₂ growth environment. Stomatal conductance ($g(s)$) and transpiration (E) decreased and photosynthetic rate ($A(\text{net})$) and $\psi(\text{leaf})$ increased in L, *tridentata*. There were no changes in biomass, leaf area, stem diameter or root : shoot (R : S) ratio for L, *tridentata*. In H, *annuus*, elevated CO₂ induced a nearly two-fold decrease in root L-p. There was no effect of growth under elevated CO₂ on $A(\text{net})$, $g(s)$, E, above- and below-ground dry mass, R : S ratio, leaf area, root length or stem diameter in this species. The results demonstrate that rising atmospheric CO₂ can impact water uptake and transport in roots in a species-specific manner. Possible mechanisms for the observed decrease in root L-p in H, *annuus* under elevated CO₂ are currently under investigation and may relate to either axial or radial components of root L-p.

Huxman, T.E., E.P. Hamerlynck, D.N. Jordan, K.J. Salsman, and S.D. Smith. 1998. The effects of parental CO₂ environment on seed quality and subsequent seedling performance in *Bromus rubens*. *Oecologia* 114(2):202-208.

Seeds were collected and compared from parent plants of *Bromus rubens* L. (Poaceae), an exotic Mojave Desert annual grass, grown in ambient (360 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ to determine if parental CO₂ growth conditions affected seed quality. Performance of seeds developed on the above plants was evaluated to determine the influence of parental CO₂ growth conditions on germination, growth rate, and leaf production. Seeds of B. *rubens* developed oil parents grown in elevated CO₂ had a larger pericarp surface area, higher C:N ratio, and less total mass than ambient-developed seeds. Parental CO₂ environment did not have an effect on germination percentage or mean germination timer as determined by radicle emergence. Seedlings from elevated-CO₂-developed seeds had a reduced relative growth rate and achieved smaller final mass over the same growth period. Elevated-CO₂-developed seeds had smaller seed reset-yes than ambient seeds, as determined by growing seedlings in sterile media and monitoring senescence. It appears that increased seed C:N ratios associated with plants grown under elevated CO₂ may have a major effect on seed quality (morphology, nutrition) and seedling performance (e.g., growth rate and leaf production). Since the invasive success of B. *rubens* is primarily due to its ability to rapidly germinate, increase leaf area and maintain a relatively high growth rate compared to native annuals and perennial grasses, reductions in seed quality and seedling performance in elevated CO₂ may have significant impacts on future community composition in the Mojave Desert.

Huxman, T.E., E.P. Hamerlynck, M.E. Loik, and S.D. Smith. 1998.

Gas exchange and chlorophyll fluorescence responses of three southwestern *Yucca* species to elevated CO₂ and high temperature. *Plant, Cell and Environment* 21(12):1275-1283.

The ability of seedlings to tolerate temperature extremes is important in determining the distribution of perennial plants in the arid south-western USA, and the manner in which elevated CO₂ impacts the ability of plants to tolerate high temperatures is relatively unknown. Whereas the effects of chronic high temperature (30-38 degrees C) and elevated CO₂ are comparatively well understood, little research has assessed plant performance in elevated CO₂ during extreme (> 45 degrees C) temperature events. We exposed three species of *Yucca* to 360 and 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ for 8 months, then 9 d of high temperature (up to 53 degrees C) to evaluate the impacts of elevated CO₂ on the potential for photosynthetic function during external high temperature. Seedlings of a coastal C-3 species (*Yucca whipplei*), a desert C-3 species (*Yucca brevifolia*), and a desert CAM species (*Yucca schidigera*), were used to test for differences among functional groups. In general, *Yuccas* exposed to elevated CO₂ showed decreases in carboxylation efficiency as compared with plants grown at ambient before the initiation of high temperature. The coastal species (*Y. whipplei*) showed significant reductions (33%) in CO₂ saturated maximum assimilation rate ($A(\text{max})$), but the desert species (*Y. brevifolia* and *Y. schidigera*) showed no such reductions in $A(\text{max})$. Stomatal conductance was lower in elevated CO₂ as compared with ambient throughout the temperature event; however, there were species-specific differences over time. Elevated CO₂ enhanced photosynthesis in *Y. whipplei* at high temperatures for a period of 4 d, but not for *Y. brevifolia* or *Y. schidigera*. Elevated CO₂ offset photoinhibition (measured as F-v/F-m) in *Y. whipplei* as compared with ambient CO₂, depending on exposure time to high temperature. Stable F-v/F-m in *Y. whipplei* occurred in parallel with increases in the quantum yield of photosystem II ($\Phi \text{ PSII}$) at high temperatures in elevated CO₂. The value of $\Phi \text{ PSII}$ remained constant or decreased with increasing temperature in all other treatment and species combinations. This suggests that the reductions in F-v/F-m resulted from thermal energy dissipation in the pigment bed for *Y. brevifolia* and *Y. schidigera*. The greater efficiency of photosystem II in *Y. whipplei* helped to maintain photosynthetic function at high temperatures in elevated CO₂. These patterns are in contrast to the hypothesis that high temperatures in elevated CO₂ would increase the potential for photoinhibition. Our results suggest that elevated CO₂ may offset high-temperature stress in coastal *Yucca*, but not in those species native to drier systems. Therefore, in the case of *Y. whipplei*, elevated CO₂ may allow plants to survive extreme temperature events, potentially relaxing the effects of high temperature on the establishment in novel habitats.

Huxman, T.E., E.P. Hamerlynck, B.D. Moore, S.D. Smith, D.N. Jordan, S.F. Zitzer, R.S. Nowak, J.S. Coleman, and J.R. Seemann. 1998. Photosynthetic down-regulation in *Larrea tridentata* exposed to elevated atmospheric CO₂: interaction with drought under glasshouse and field (FACE) exposure. *Plant, Cell and Environment* 21(11):1153-1161.

The photosynthetic response of *Larrea tridentata* Cav., an evergreen Mojave Desert shrub, to elevated atmospheric CO₂ and drought was examined to assist in the understanding of how plants from water-limited ecosystems will respond to rising CO₂. We hypothesized that photosynthetic down-regulation would disappear during periods of water limitation, and would, therefore, likely be a seasonally transient event. To test this we measured photosynthetic, water relations and fluorescence responses during periods of increased and decreased mater

availability in two different treatment implementations: (1) from seedlings exposed to 360, 550, and 700 $\mu\text{mol mol}^{-1}$ CO_2 in a glasshouse; and (2) from intact adults exposed to 360 and 550 $\mu\text{mol mol}^{-1}$ CO_2 at the Nevada Desert FACE (Free Air CO_2 Enrichment) Facility. FACE and glasshouse well-watered *Larrea* significantly down-regulated photosynthesis at elevated CO_2 , reducing maximum photosynthetic rate ($A(\text{max})$), carboxylation efficiency (CE), and Rubisco catalytic sites, whereas droughted *Larrea* showed a differing response depending on treatment technique. $A(\text{max})$ and CE were lower in droughted *Larrea* compared with well-watered plants, and CO_2 had no effect on these reduced photosynthetic parameters. However, Rubisco catalytic sites decreased in droughted *Larrea* at elevated CO_2 . Operating C_i increased at elevated CO_2 in droughted plants, resulting in greater photosynthetic rates at elevated CO_2 as compared with ambient CO_2 . In well-watered plants, the changes in operating C_i , CE and $A(\text{max})$ resulted in similar photosynthetic rates across CO_2 treatments. Our results suggest that drought can diminish photosynthetic down-regulation to elevated CO_2 in *Larrea*, resulting in seasonally transient patterns of enhanced carbon gain. These results suggest that water status may ultimately control the photosynthetic response of desert systems to rising CO_2 .

Hymus, G.J., D.S. Ellsworth, N.R. Baker, and S.P. Long. 1999. Does free-air carbon dioxide enrichment affect photochemical energy use by evergreen trees in different seasons? A chlorophyll fluorescence study of mature loblolly pine. *Plant Physiology* 120(4):1183-1191.

Previous studies of the effects of growth at elevated CO_2 on energy partitioning in the photosynthetic apparatus have produced conflicting results. The hypothesis was developed and tested that elevated CO_2 increases photochemical energy use when there is a high demand for assimilates and decreases usage when demand is low. Modulated chlorophyll a fluorescence and leaf gas exchange were measured on needles at the top of a mature, 12-m loblolly pine (*Pinus taeda* L.) forest. Trees were exposed to ambient CO_2 or ambient plus 20 Pa CO_2 using free-air CO_2 enrichment. During April and August, periods of shoot growth, light-saturated photosynthesis and linear electron transport were increased by elevated CO_2 . In November, when growth had ceased but temperatures were still moderate, CO_2 treatment had no significant effect on linear electron transport. In February, when low temperatures were likely to inhibit translocation, CO_2 treatment caused a significant decrease in linear electron transport. This coincided with a slower recovery of the maximum photosystem II efficiency on transfer of needles to the shade, indicating that growth in elevated CO_2 induced a more persistent photoinhibition. Both the summer increase and the winter decrease in linear electron transport in elevated CO_2 resulted from a change in photochemical quenching, not in the efficiency of energy transfer within the photosystem II antenna. There was no evidence of any effect of CO_2 on photochemical energy sinks other than carbon metabolism. Our results suggest that elevated CO_2 may increase the effects of winter stress on evergreen foliage.

1993. Characterization and induction of the activity of 1-aminocyclopropane-1-carboxylate oxidase in the wounded mesocarp tissue of cucurbita-maxima. *Plant and Cell Physiology* 34(5):667-671.

1-Aminocyclopropane-1-carboxylate (ACC) oxidase (ethylene-forming enzyme) was isolated from wounded mesocarp tissue of Cucurbita maxima (winter squash) fruit, and its enzymatic properties were investigated. The enzyme required Fe^{2+} and ascorbate for its activity as well as ACC and O_2 as substrates. The in vitro enzyme activity was enhanced by CO_2 . The apparent K_m value for ACC was 175 μM under atmospheric conditions. The enzyme activity was inhibited by sulfhydryl inhibitors and divalent cations such as Co^{2+} , Cu^{2+} , and Zn^{2+} . ACC oxidase activity was induced at a rapid rate by wounding in parallel with an increase in the rate of ethylene production. The exposure of excised discs of mesocarp to 2,5-norbornadiene (NBD), an inhibitor of ethylene action, strongly suppressed induction of the enzyme, and the application of ethylene significantly accelerated the induction of the activity of ACC oxidase in the wounded mesocarp tissue. These results suggest that endogenous ethylene produced in response to wounding may function in promoting the induction of ACC oxidase.

Idso, C.D., S.B. Idso, and R.C. Balling. 1998. The urban CO_2 dome of Phoenix, Arizona. *Physical Geography* 19(2):95-108.

Air temperatures, relative humidities, and atmospheric carbon dioxide concentrations were measured at a height of 2 m at approximate 1.6-km intervals prior to sunrise and in the middle of the afternoon on five days in January along a number of different transects through the extended metropolitan area of Phoenix, Arizona. Spatially interpolated maps of the data indicate the presence of an "urban CO_2 dome" that reaches concentrations as high as 555 ppmv in the city center and decreases to a value of approximately 370 ppmv on the outskirts of the city at this time of year. Pre-dawn CO_2 values inside the dome are considerably higher than mid-afternoon values, suggesting that solar-induced convective mixing and the photosynthetic uptake of CO_2 by urban vegetation may play significant roles in diurnally redistributing the anthropogenically produced CO_2 that, together with that produced by plant respiration, accumulates near the ground during the night and early morning hours. Temperature and relative humidity appear to have little influence on either the concentration or location of the CO_2 dome, but variations in wind speed and direction at times may disrupt the pattern that develops under normally fair conditions. The high CO_2 concentrations within the dome may help to ameliorate the deleterious effects of urban air pollution on vegetation growing within the city. Together with the urban heat island phenomenon, they may also provide a natural laboratory for studying the effects of contemporaneous warming and atmospheric CO_2 enrichment within the context of predicted future global change.

This paper presents a detailed analysis of several hundred plant carbon

exchange rate (CER) and dry weight (DW) responses to atmospheric CO₂ enrichment determined over the past 10 years. It demonstrates that the percentage increase in plant growth produced by raising the air's CO₂ content is generally not reduced by less than optimal levels of light, water or soil nutrients, nor by high temperatures, salinity or gaseous air pollution. More often than not, in fact, the data show the relative growth-enhancing effects of atmospheric CO₂ enrichment to be greatest when resource limitations and environmental stresses are most severe.

Idso, S.B. 1992. Net photosynthesis - corrections required of leaf chamber measurements. *Agricultural and Forest Meteorology* 58(1-2):35-42.

Direct measurements of trunk and branch volumes and fine-root biomass confirm that the growth rate of sour orange trees supplied with an extra 300 cm³ of CO₂ m⁻³ of air is approximately 2.8 times greater than that of similar trees growing in ambient air. Net CO₂ exchange measurements made on individual leaves over three 24 h periods in May, June and July 1990, however, suggest a relative growth enhancement for the CO₂-enriched trees of the order of five to seven, which is clearly impossible on the basis of the direct growth measurements. It is shown that this discrepancy is due to a problem inherent in the act of enclosing a leaf in a leaf chamber, but that its effects can be removed by means of a simple correction procedure.

Idso, S.B. 1997. The poor man's biosphere, including simple techniques for conducting CO₂ enrichment and depletion experiments on aquatic and terrestrial plants. *Environmental and Experimental Botany* 38(1):15-38.

This paper reports the results of a 3-year experimental program designed to develop an inexpensive, low-technology approach for conducting

atmospheric CO₂ enrichment and depletion studies of aquatic and terrestrial plants. It begins by demonstrating the effectiveness of a number of simple techniques for creating a wide range of sub-and supra-ambient atmospheric CO₂ concentrations in a set of low-cost experimental enclosures. It then describes the utilization of this approach in a variety of experiments that lead to the derivation of CO₂-growth response relationships for a common terrestrial plant and for both a submerged and a floating aquatic species. Finally, it provides a description of a simple procedure for obtaining accurate assessments of atmospheric CO₂ concentrations in such experiments. (C) 1997 Elsevier Science B.V.

Idso, S.B. 1998. CO₂-induced global warming: a skeptic's view of potential climate change. *Climate Research* 10(1):69-82.

Over the course of the past 2 decades, I have analyzed a number of natural phenomena that reveal how Earth's near-surface air temperature responds to surface radiative perturbations. These studies all suggest that a 300 to 600 ppm doubling of the atmosphere's CO₂ concentration could raise the planet's mean surface air temperature by only about 0.4 degrees C. Even this modicum of warming may never be realized, however, for it could be negated by a number of planetary cooling forces that are intensified by warmer temperatures and by the strengthening of biological processes that are enhanced by the same rise in atmospheric CO₂ concentration that drives the warming. Several of these cooling forces have individually been estimated to be of equivalent magnitude, but of opposite sign, to the typically predicted greenhouse effect of a doubling of the air's CO₂ content, which suggests to me that little net temperature change will ultimately result from the ongoing buildup of CO₂ in Earth's atmosphere. Consequently, I am skeptical of the predictions of significant CO₂-induced global warming that are being made by state-of-the-art climate models and believe that much more work on a wide variety of research fronts will be required to properly resolve the issue.

Idso, S.B., and R.C. Balling. 1992. United-states drought trends of the past century. *Agricultural and Forest Meteorology* 60(3-4):279-284.

One of the primary concerns about potential global change is that the steadily rising CO₂ content of earth's atmosphere may lead to significant increases in the severity and frequency of drought, especially in the agricultural heartland of the USA (Manabe et al., 1981; Gleick, 1987;

Manabe and Wetherald, 1986, 1987, McCabe et al., 1990). This consequence has been postulated to result from minor changes in the atmospheric supply of moisture (precipitation) and major changes in the atmospheric demand for moisture (potential evapotranspiration), as a result of increased surface temperatures. Waggoner (1989), for example, has shown how a 10% drop in precipitation can lead to a 46% increase in the frequency of drought; while Rind et al. (1990) have demonstrated that CO₂-induced global warming, if it occurs as projected, could raise the frequency of severe drought in the USA from 5 to 50% by the year 2050. If drought is truly this responsive to changes in precipitation and potential evapotranspiration, and there is little reason to believe it is not, it could serve as a sensitive indicator of global warming and as a reliable test for identifying its onset. Hence, as the effective CO₂ content of the atmosphere has already risen by nearly 50% above its pre-industrial level (Michaels, 1990; Houghton et al., 1990), studies of drought trends of the past century might even now provide evidence for the reality of global warming. However, there are three separate factors that could complicate this simple test.

Idso, S.B., K.E. Idso, R.L. Garcia, B.A. Kimball, and J.K. Hooper. 1995. Effects of atmospheric CO₂ enrichment and foliar methanol application on net photosynthesis of sour orange tree (citrus- aurantium, rutaceae) leaves. *American Journal of Botany* 82(1):26-30.

Foliar spray applications of 40% aqueous methanol were made to sunlit leaves of sour orange trees that had been grown continuously in clear-plastic-wall open-top enclosures maintained out-of-doors at Phoenix, Arizona, for over 5.5 years in ambient air of approximately 400 $\mu\text{mol mol}^{-1}$ CO₂ and in air enriched with CO₂ to a concentration of approximately 700 $\mu\text{mol mol}^{-1}$. No unambiguous effects of the methanol applications were detected in net photosynthesis measurements made on foliage in either of the two CO₂ treatments. The 75% increase in CO₂ however, raised the upper-limiting leaf temperature for positive net photosynthesis by approximately 7 °C, which resulted in a 75% enhancement in net photosynthesis at a leaf temperature of 31 °C, a 100% enhancement at a leaf temperature of 35 °C, and a 200% enhancement at 42 °C.

Idso, S.B., and B.A. Kimball. 1991. Downward regulation of photosynthesis and growth at high CO₂ levels - no evidence for either phenomenon in 3-year study of sour orange trees. *Plant Physiology* 96(3):990-992.

Numerous photosynthesis and growth measurements of sour orange (Citrus aurantium L.) trees maintained in ambient air and air enriched with an extra 300 microliters per liter of CO₂ have revealed the CO₂-enriched trees to have consistently sequestered approximately 2.8 times more carbon than the control trees over a period of three full years. Under field conditions in the natural environment, plants may not experience the downward regulation of photosynthetic capacity typically observed in long-term CO₂ enrichment experiments with plants growing in pots.

Idso, S.B., and B.A. Kimball. 1991. Effects of 2 and a half years of atmospheric CO₂ enrichment on the root density distribution of 3-year-old sour orange trees. *Agricultural and Forest Meteorology* 55(3-4):345-349.

Eight sour orange trees planted directly into the ground at Phoenix, Arizona, as small seedlings in July 1987 have been enclosed by four clear-plastic-wall, open-top chambers since November of that year, half of which have been continuously supplied with a CO₂ enriched atmosphere consisting of an extra 300 $\text{cm}^3 \text{CO}_2 \text{m}^{-3}$ of air. Extensive soil coring of the trees' root zones conducted in July 1990 indicated that two and a half years of growth under these conditions produced a fine root biomass enhancement of 175% in the CO₂ enriched trees. This growth enhancement is of the same order of magnitude as our previously reported results for net photosynthesis and trunk and branch volumes for these trees.

Idso, S.B., and B.A. Kimball. 1992. Aboveground inventory of sour orange trees exposed to different atmospheric CO₂ concentrations for 3 full years. *Agricultural and Forest Meteorology* 60(1-2):145-151.

Sour orange trees have been grown from the seedling stage out-of-doors at Phoenix, Arizona in clear-plastic-wall, open-top enclosures for 3.5 years. For the last 3 years of this period, half of the trees have been continuously exposed to air enriched with an extra 300 $\text{cm}^3 \text{CO}_2 \text{m}^{-3}$ of air. Inventories of all aboveground plant parts conducted at the conclusions of the second and third years of the study reveal that the total number of branches per tree, the total number of leaves per tree, and the total trunk plus branch volume per tree can all be adequately inferred from measurements of trunk cross-sectional area. They also reveal a sustained beneficial impact of atmospheric CO₂ enrichment. After 3 full years of differential CO₂ exposure, the CO₂-enriched trees had nearly 100% more branches, 75% more leaves, approximately 160% more trunk and branch volume, and 190% more trunk, branch and fruit rind volume than the ambient-treatment trees.

Idso, S.B., and B.A. Kimball. 1992. Effects of atmospheric CO₂ enrichment on photosynthesis, respiration, and growth of sour orange trees. *Plant Physiology* 99(1):341-343.

Numerous net photosynthetic and dark respiratory measurements were made over a period of 4 years on leaves of 24 sour orange (Citrus aurantium) trees; 8 of them growing in ambient air at a mean CO₂ concentration of 400 microliters per liter, and 16 growing in air enriched with CO₂ to concentrations approaching 1000 microliters per liter. Over this CO₂ concentration range, net photosynthesis increased linearly with CO₂ by more than 200%, whereas dark respiration decreased linearly to only 20% of its initial value. These results, together with those of a comprehensive fine-root biomass determination and two independent above-ground trunk and branch volume inventories, suggest that a doubling of the air's current mean CO₂ concentration of 360 microliters per liter would enhance the growth of the trees by a factor of 3.8.

Idso, S.B., and B.A. Kimball. 1992. Seasonal fine-root biomass development of sour orange trees grown in atmospheres of ambient and elevated CO₂ concentration. *Plant, Cell and Environment* 15(3):337-341.

Sour orange trees have been grown from the seedling stage out-of-doors at Phoenix, Arizona, USA, in open-top enclosures with clear plastic walls for 3.5 years. For the last 3 years of this period, half of the trees have been continuously exposed to air enriched with CO₂ to 300- μ mol mol⁻¹ above the ambient concentration. At 2-month intervals over the last 12 months, we have determined the fine-root biomass in the top 0.4 m of the soil profile beneath the trees. Results from both treatments define a single relationship between fine-root biomass and trunk cross-sectional area. The data also show the CO₂-enriched trees to have approximately 2.3 times more fine-root biomass in this soil layer than the trees grown in ambient air.

Idso, S.B., and B.A. Kimball. 1993. Effects of atmospheric CO₂ enrichment on net photosynthesis and dark respiration rates of 3 Australian tree species. *Journal of Plant Physiology* 141(2):166-171.

Net photosynthesis and dark respiration rates of leaves of three Australian tree species exposed to a range of atmospheric CO₂ concentrations were measured throughout the summer of 1991. For all three species - the Australian bottle tree (*Brachychiton populneum* (Schott.) R. Br.) and two eucalyptus (*Eucalyptus microtheca* F. Muell. and *E. polyanthemus* Schauer) - dark respiration dropped by approximately 50 % for a 360 to 720 μ L/L doubling of the air's CO₂ concentration, while net photosynthesis rose by a factor of two. These results were not significantly different from results obtained previously for the common sour orange tree (*Citrus aurantium* L.).

Idso, S.B., and B.A. Kimball. 1993. Tree growth in carbon-dioxide enriched air and its implications for global carbon cycling and maximum levels of atmospheric CO₂. *Global Biogeochemical Cycles* 7(3):537-555.

In the longest carbon dioxide enrichment experiment ever conducted, well-watered and adequately fertilized sour orange tree seedlings were planted directly into the ground at Phoenix, Arizona, in July 1987 and continuously exposed, from mid-November of that year, to either ambient air or air enriched, with an extra 300 ppmv of CO₂ in clear-plastic-wall open-top enclosures. Only 18 months later, the CO₂-enriched trees had grown 2.8 times larger than the ambient-treated trees; and they have maintained that productivity differential to the present day. This tremendous growth advantage is due to two major factors: a CO₂-induced increase in daytime net photosynthesis and a CO₂-induced reduction in nighttime dark respiration. Measurements of these physiological processes in another experiment have shown three Australian tree species to respond similarly; while an independent study of the atmosphere's seasonal CO₂ cycle suggests that all earth's trees, in the mean, probably share this same response. A brief review of the plant science literature outlines how such a large growth response to atmospheric CO₂ enrichment might possibly be maintained in light of resource limitations existing in nature. Finally, it is noted that a CO₂ "fertilization effect" of this magnitude should substantially slow the rate at which anthropogenic carbon dioxide would otherwise accumulate in the atmosphere, possibly putting an acceptable upper limit on the level to which the CO₂ content of the air may ultimately rise.

Idso, S.B., and B.A. Kimball. 1994. Effects of atmospheric CO₂ enrichment on biomass accumulation and distribution in *eldarica* pine trees. *Journal of Experimental Botany* 45(280):1669-1672.

Eight *Eldarica* pine tree (*Pinus eldarica* L.) seedlings planted directly into the ground at Phoenix, Arizona within four clear-plastic-wall open-top enclosures were grown for a period of 2 years at mean atmospheric CO₂ concentrations of 408, 554, 680, and 812 μ mol L⁻¹. Biomass accumulations in needles, branches and boles were all linear functions of CO₂ over this concentration range. For a 75% increase in ambient CO₂, i.e. for an increase from 400-700 μ mol L⁻¹, the trees experienced a 3.42-fold increase in total above-ground biomass; while for a CO₂ concentration doubling from 400-800 μ mol L⁻¹, they experienced a 4.23-fold increase. Bore biomass responded similarly. Needle biomass, however, increased by a smaller amount (2.84-fold and 3.45-fold, respectively, for 400-700 and 400-800 μ mol L⁻¹ increases in CO₂); while branch biomass was increased considerably more (by 4.73-fold and 5.97-fold for corresponding increases in CO₂).

Idso, S.B., and B.A. Kimball. 1994. Effects of atmospheric CO₂ enrichment on regrowth of sour orange trees (*Citrus aurantium* rutaceae) after coppicing. *American Journal of Botany* 81(7):843-846.

Sixteen sour orange tree (*Citrus aurantium* L.) seedlings were grown out-of-doors at Phoenix, Arizona, in eight clear-plastic-wall open-top enclosures maintained at four different atmospheric CO₂ concentrations for a period of 2 years. Over the last year of this period, the trees were coppiced five times. The amount of dry matter harvested at each of these cuttings was a linear function of the atmospheric CO₂ concentration to which the trees were exposed. For a 75% increase in atmospheric CO₂ from 400 to 700 μ mol liter⁻¹ (1), total aboveground biomass rose, in the mean, by a factor of 3.19; while for a 400 to 800 μ mol liter⁻¹ doubling of the air's CO₂ content, it rose by a factor of 3.92. The relative summer (mean air temperature of 32.8 C) response to CO₂ was about 20% greater than the relative winter (mean air temperature of 16.4 C) response.

Idso, S.B., and B.A. Kimball. 1997. Effects of long-term atmospheric CO₂ enrichment on the growth and fruit production of sour orange trees. *Global Change Biology* 3(2):89-96.

In July of 1987, we planted eight 30-cm-tall sour orange tree seedlings in a field of Avondale loam at Phoenix, Arizona and enclosed them in pairs in clear-plastic-wall open-top chambers. Since 18 November of that year, we have continuously pumped ambient air of approximate to 400 ppmv [CO₂] through two of these enclosures, while through the other two we have continuously pumped air of approximate to 700 ppmv [CO₂]. By the end of the second year of the study, the trunk plus branch volume of the [CO₂]-enriched trees was approximate to 2.75 times greater than that of the ambient-treatment trees. Three years later, this factor had dropped to approximate to 2.0; but the decline in the [CO₂]-enriched/ambient-treatment ratio of trunk plus branch volume was nearly perfectly offset by the relative fruit production advantage enjoyed by the [CO₂]-enriched trees over that period. In Years 6, 7 and 8, however, there was a moderate drop in total productivity enhancement. This decline may be a delayed acclimation response, or it could be due to enhanced self-shading in the [CO₂]-enriched trees or to the fact that, starting early in Year 6, many branches of the [CO₂]-enriched trees grew all the way to the walls of their enclosures, so that many blossoms and young fruit were destroyed by intermittent physical trauma produced by the action of wind against the taut plastic in that year and in all succeeding years. Hence, we will have to maintain our experiment for several more years for this lateral growth obstruction to occur to the same degree in the ambient-air chambers as it has in the [CO₂]-enriched chambers, in order to determine the long-term equilibrium effects of atmospheric [CO₂] enrichment in a spatially confined environment.

Idso, S.B., B.A. Kimball, D.E. Akin, and J. Kridler. 1993. A general relationship between CO₂-induced reductions in stomatal conductance and concomitant increases in foliage temperature. *Environmental and Experimental Botany* 33(3):443-446.

Simultaneous measurements of the temperatures and stomatal conductances of leaves of sour orange trees growing in normal and CO₂-enriched air, together with similar data for water hyacinths and cotton, suggest that a plant's foliage temperature response to atmospheric CO₂-enrichment is directly proportional to its degree of stomatal closure, i.e. that plants that experience a greater stomatal closure in response to atmospheric CO₂ enrichment experience a greater warming of their foliage. The data also suggest that this primary relationship may be modified by CO₂-induced changes in leaf chlorophyll content that may have implications for global climate change.

Idso, S.B., B.A. Kimball, and S.G. Allen. 1991. CO₂ enrichment of sour orange trees - 2.5 years into a long-term experiment. *Plant, Cell and Environment* 14(3):351-353.

Eight sour orange trees have been grown from seedling stage in the field at Phoenix, Arizona, U.S.A., in four identically-vented, open-top, clear-plastic-wall chambers for close to 2.5 years. Half of the chambers have

been maintained at ambient atmospheric CO₂ concentrations over this period, while half of them have been maintained at 300 ppm (300-μmol CO₂ per mol air) above ambient. Initially, the trees in each treatment were essentially identical; but in less than 2 years, the trunks of the CO₂-enriched trees had become twice as large as their ambient-treatment counterparts. After 2 full years of growth, the enriched trees had 79% more leaves, 56% more primary branches with 172% more volume, 70% more secondary branches with 190% more volume, and 240% more tertiary branches with 855% more volume. In addition, the CO₂-enriched trees also had fourth-, fifth- and sixth-order branches, while the ambient-treatment trees had no branches above third order. Total trunk plus branch volume of the CO₂-enriched trees was 2.79 times that of the ambient-treatment trees after 2 full years of growth.

Idso, S.B., B.A. Kimball, and S.G. Allen. 1991. Net photosynthesis of sour orange trees maintained in atmospheres of ambient and elevated CO₂ concentration. *Agricultural and Forest Meteorology* 54(1):95-101.

Eight sour orange trees planted directly into the ground at Phoenix, Arizona, as small seedlings in July 1987 have been enclosed by four clear-plastic-wall, open-top chambers since November of that year. Half of the trees have been continuously supplied with a CO₂-enriched atmosphere consisting of an extra 300 cm³ of CO₂ per m³ of air. Data from a comprehensive inventory of all above-ground plant parts at the conclusion of two full years of growth under these conditions have revealed that the net effect of the CO₂-enriched air was to more than double the normal production of biomass over that time interval. Here we report net photosynthesis measurements made throughout the last summer of the period, which suggest that the primary impetus for this large growth response was an equivalent enhancement of the net photosynthetic rates of the CO₂-enriched trees.

Idso, S.B., B.A. Kimball, and D.L. Hendrix. 1993. Air-temperature modifies the size-enhancing effects of atmospheric CO₂ enrichment on sour orange tree leaves. *Environmental and Experimental Botany* 33(2):293-299.

Every other month for a period of 2 years, leaf area and dry weight measurements were made on the foliage of sour orange trees growing in ambient air and in air enriched with an extra 300 μmol/l CO₂. Leaf starch content measurements were made at approximate 2-month intervals for a period of 1 year. The data demonstrated that all three plant parameters were significantly increased by atmospheric CO₂ enrichment, except in the coldest portion of the year. A plot of the ratio of CO₂-enriched leaf dry weight to ambient-treatment leaf dry weight against the mean air temperature of the preceding month revealed this relationship with temperature to be linear. The relationship shows atmospheric CO₂ enrichment to have a negligible effect on leaf dry weight at a mean air temperature of approximately 5-degrees-C. At a mean air temperature of 35-degrees-C, however, it shows individual CO₂-enriched leaves of our experiment to weigh 40% more than their ambient-treatment counterparts. This phenomenon helps to explain the vastly different effects of atmospheric CO₂ enrichment that have been reported for a number of diverse ecosystems.

Idso, S.B., B.A. Kimball, and D.L. Hendrix. 1996. Effects of atmospheric CO₂ enrichment on chlorophyll and nitrogen concentrations of sour orange tree leaves. *Environmental and Experimental Botany* 36(3):323-331.

Since 18 November 1987, eight sour orange (*Citrus aurantium* L.) trees have been maintained under well watered and fertilized conditions within four clear-plastic-wall open-top enclosures, two of which have been continuously supplied with ambient air of approximately 400 $\mu\text{mol l}^{-1}$ CO₂ and two of which have been supplied with air enriched to approximately 700 $\mu\text{mol l}^{-1}$ CO₂. At weekly intervals throughout years 4-7 of this long-term experiment, we measured chlorophyll contents of 60 leaves on each of the trees with a hand-held chlorophyll meter that was specifically calibrated for our study. At bi-monthly intervals, we also measured the areas, dry weights and nitrogen contents of 68 leaves from each tree. Expressed on a per-unit-leaf-area basis, leaves from the CO₂-enriched trees contained 4.8% less chlorophyll and nitrogen than leaves from the trees exposed to ambient air. Because of their greater leaf numbers, however, the CO₂-enriched trees contained 75% more total chlorophyll and nitrogen than the ambient-treatment trees; the total productivity of the CO₂-enriched trees was 175% greater. Consequently, although per-unit-leaf-area chlorophyll and nitrogen contents were slightly lowered by atmospheric CO₂ enrichment in our experiment, their use efficiencies were greatly enhanced.

Idso, S.B., B.A. Kimball, G.W. Wall, R.L. Garcia, R. Lamorte, P.J. Pinter, J.R. Mauney, G.R. Hendrey, K. Lewin, and J. Nagy. 1994. Effects of free-air CO₂ enrichment on the light response curve of net photosynthesis in cotton leaves. *Agricultural and Forest Meteorology* 70(1-4):183-188.

Daytime measurements of leaf CO₂ exchange rates in a free-air CO₂ enrichment (FACE) experiment reveal that at photosynthetically active radiation (PAR) flux rates in excess of 1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$, cotton leaves exposed to an atmospheric CO₂ concentration of approximately 500 $\mu\text{mol mol}^{-1}$ exhibit net photosynthetic rates about 30% greater than those for leaves of similar plants growing in ambient air. As PAR flux rates drop below this value, the stimulatory effect of elevated CO₂ rises, suggesting that the relative benefits of atmospheric CO₂ enrichment will be greater for shaded cotton leaves than for those exposed to full sunlight.

Idso, S.B., G.W. Wall, and B.A. Kimball. 1993. Interactive effects of atmospheric CO₂ enrichment and light-intensity reductions on net photosynthesis of sour orange tree leaves. *Environmental and Experimental Botany* 33(3):367-375.

In a long-term study of the effects of a 300 $\mu\text{mol l}^{-1}$ enrichment of the air's CO₂ content on the growth of sour orange trees, a comprehensive set of net photosynthesis and light intensity data was obtained. From these measurements we derived single-leaf light response curves, which together with complementary leaf area index data allowed us to derive full-canopy light response curves. The results showed our 85% enhancement of the air's CO₂ content to more than double canopy net photosynthesis at full sunlight. Our analysis demonstrated that the positive direct effect of atmospheric CO₂ enrichment on net photosynthesis more than compensated for the negative self-shading

effect produced by the CO₂-induced proliferation of leaf area.

Igamberdiev, A.U., and I.V. Zbrovskaya. 1994. The effect of light, carbon nutrition, and salinity on the oxidative-metabolism of *Wolffia arrhiza*. *Russian Journal of Plant Physiology* 41(2):208-214.

The effects of varying conditions of carbon nutrition (sucrose and an inorganic source of carbon in the growth medium), light, and salinity on oxidative metabolism were studied in *Wolffia arrhiza* (L.) Hork. ex Wimmer. In cells grown on 1% sucrose, the level of the cyanide-resistant (CO₂)-C-14 evolution from 1,4-C-14-succinate as a respiratory substrate was considerably higher than in autotrophically grown plants. When the medium was enriched in inorganic carbon (CO₂ or bicarbonate), the rate of metabolism of glucose and other respiratory substrates diminished, and total protein and chlorophyll content decreased. Light incubation enhanced glucose metabolism two- to threefold, whereas succinate transformation was increased by a factor of 1.5 to 2, with a concomitant rise in the electron flow via the cyanide-resistant pathway. Inhibition of the photorespiratory metabolism with α -hydroxypyridine-2-methanesulfonate slowed down glucose and succinate metabolism. NaCl activated glycolate metabolism in autotrophically grown plants and did not influence the rates of glucose and succinate transformation. In contrast, under photoheterotrophic (mixotrophic) growth conditions on sucrose, NaCl added to the cultivation medium led to a considerably higher (three- to fourfold) (CO₂)-C-14 evolution from 1,4-C-14-succinate and 1-C-14-glucose. The authors conclude that the adaptation of *Wolffia* plants to different environmental conditions is accompanied by changes in the metabolic fluxes via cyanide-resistant oxidase, along the glycolate pathway, and other oxidative pathways. These changes conform to the alterations in enzyme activities participating in the oxidative metabolism.

Igamberdiev, A.U., G.Q. Zhou, G. Malmberg, and P. Gardestrom. 1997. Respiration of barley protoplasts before and after illumination. *Physiologia Plantarum* 99(1):15-22.

Respiratory O₂ consumption was investigated in dark-adapted barley (*Hordeum vulgare* L. cv. Gunilla) protoplasts and after illumination for 10 min at high and very low CO₂ in the presence of respiratory and photorespiratory inhibitors. In dark-adapted protoplasts no difference was observed between inhibitor treatments in high and very low CO₂. The respiratory rate increased somewhat after illumination and a difference in response to inhibitors was in some cases observed between high and very low CO₂. Thus, the operation of the mitochondrial electron transport chain is affected following a period of active photosynthesis. In all situations tested, oligomycin inhibited respiratory O₂ uptake indicating that respiration of mitochondria in protoplasts is not strictly ADP limited. Antimycin A inhibited respiration more in dark-adapted protoplasts than after illumination whereas SHAM gave the opposite response. Rotenone inhibited respiration both in dark-adapted protoplasts (about 30%) and after illumination where the inhibition was much greater in very low CO₂ (50%) than in high CO₂ (10%). After illumination in very low CO₂, SHAM + rotenone inhibited respiration almost completely (70%). Photorespiratory inhibitors had very small effect on O₂ consumption in darkness. After illumination the effect of aminoacetonitrile (AAN) was also very low whereas α -hydroxypyridine-2-methane sulphonate (HPMS) in photorespiratory conditions inhibited O₂ uptake much stronger (35%). The addition of glyoxylate enhanced respiration in the presence of HPMS up to the

control level suggesting that alternative pathways of glyoxylate conversion might be operating. The differences in inhibitor responses may reflect fine mechanisms for the regulation of energetic balance in the plant cell which consists of switching from electron transport coupled to ATP production to non-coupled transport. Photorespiratory flux is also very flexible, and the suppression of glycine decarboxylation can induce bypass reactions of glyoxylate metabolism.

Imai, K., and M. Okamoto. 1991. Effects of temperature on CO₂ dependence of gas exchanges in C₃ and C₄ crop plants. *Japanese Journal of Crop Science* 60(1):139-145.

The effects of elevated CO₂ in the atmosphere and the accompanied temperature rise predicted for the future on gas exchanges of two summer C₃ (rice, soybean) and two C₄ (Japanese millet, finger millet) crop plants were examined. Plants were grown in artificially illuminated growth cabinets under 350 and 500- $\mu\text{mol mol}^{-1}$ ambient CO₂ (C(a)) and were measured for rates of CO₂ exchange (CER) and transpiration (E) of leaves at 23, 28 and 33-degrees-C in terms of C(a) (0-500- $\mu\text{mol mol}^{-1}$). The responses of CER to C(a) were slightly lower in plants grown in high C(a) than those in normal C(a) and were largely influenced by temperature. The promotive effect of elevating C(a) on CER was larger at higher temperatures, especially in C₄ crop plants. With the rise of C(a), the E in C₄ crop plants decreased more than in C₃ crop plants and it was correlated with the decrease in stomatal conductance to CO₂ transfer. The water use efficiency (WUE) of leaves increased with the rise in C(a) but the effect of temperature on WUE was unclear. It is concluded that, within limits, under high C(a), C₄ crop plants expand their photosynthetic capacity in an environment of high temperature.

Imichen, K., V. Wiemken, and A. Wiemken. 1995. Shoots, roots and ectomycorrhiza formation of pine-seedlings at elevated atmospheric carbon-dioxide. *Plant, Cell and Environment* 18(6):703-707.

The effect of elevated atmospheric CO₂ concentration on the growth of shoots, roots, mycorrhizas and extraradical mycorrhizal mycelia of pine (*Pinus silvestris* L.) was examined. Two and a half-month-old seedlings were inoculated axenically with the mycorrhizal fungus *Pisolithus tinctorius* (Pers.) by a method allowing rapid mycorrhiza formation in Petri dishes. The plants were then cultivated for 3 months in growth chambers with daily concentrations of 350 and 600 $\mu\text{mol mol}^{-1}$ CO₂ during the day. Whereas plants harvested after 1 and 2 months did not differ appreciably between ambient and increased CO₂ concentrations, after 3 months they developed a considerably higher root biomass (+57%) at elevated CO₂, but did not increase significantly in root length. The mycorrhizal fungus *Pisolithus tinctorius*, which depended entirely on the plant assimilates in the model system, grew much faster at increased CO₂: 3 times more mycorrhizal root clusters were formed and the extraradical mycelium produced had twice the biomass at elevated as at ambient CO₂. No difference in shoot biomass was found between the two treatments after 91d. However, since the total water consumption of seedlings was similar in the two treatments, the water use efficiency was appreciably higher for the seedlings at increased CO₂ because of the higher below-ground biomass.

Ineson, P., M.F. Cotrufo, R. Bol, D.D. Harkness, and H. Blum. 1996. Quantification of soil carbon inputs under elevated CO₂:C-3 plants in a C-4 soil. *Plant and Soil* 187(2):345-350.

The objective of this investigation was to quantify the differences in soil carbon stores after exposure of birch seedlings (*Betula pendula* Roth.) over one growing season to ambient and elevated carbon dioxide concentrations. One-year-old seedlings of birch were transplanted to pots containing 'C-4 soil' derived from beneath a maize crop, and placed in ambient (350 $\mu\text{mol L}^{-1}$) and elevated (600 $\mu\text{mol L}^{-1}$) plots in a free-air carbon dioxide enrichment (FACE) experiment. After 186 days the plants and soils were destructively sampled, and analysed for differences in root and stem biomass, total plant tissue and soil C contents and $\delta^{13}\text{C}$ values. The trees showed a significant increase (+50%) in root biomass, but stem and leaf biomasses were not significantly affected by treatment. C isotope analyses of leaves and fine roots showed that the isotopic signal from the ambient and elevated CO₂ supply was sufficiently distinct from that of the 'C-4 soil' to enable quantification of net root C input to the soil under both ambient and elevated CO₂. After 186 days, the pots under ambient conditions contained 3.5 g of C as intact root material, and had gained an additional 0.6 g C added to the soil through root exudation/turnover; comparable figures for the pots under elevated CO₂ were 5.9 g C and 1.5 g C, respectively. These data confirm the importance of soils as an enhanced sink for C under elevated atmospheric CO₂ concentrations. We propose the use of 'C-4 soils' in elevated CO₂ experiments as an important technique for the quantification of root net C inputs under both ambient and elevated CO₂ treatments.

Ineson, P., P.A. Coward, and U.A. Hartwig. 1998. Soil gas fluxes of N₂O, CH₄ and CO₂ beneath *Lolium perenne* under elevated CO₂: The Swiss free air carbon dioxide enrichment experiment. *Plant and Soil* 198(1):89-95.

Fluxes of nitrous oxide, methane and carbon dioxide were measured from soils under ambient (350 $\mu\text{mol L}^{-1}$) and enhanced (600 $\mu\text{mol L}^{-1}$) carbon dioxide partial pressures (pCO₂) at the 'Free Air Carbon Dioxide Enrichment' (FACE) experiment, Eidgenossische Technische Hochschule (ETH), Eschikon, Switzerland in July 1995, using a GC housed in a mobile laboratory. Measurements were made in plots of *Lolium perenne* maintained under high N input. During the data collection period N fertiliser was applied at a rate of 14 g m⁻² of N. Elevated pCO₂ appeared to result in an increased (27%) output of N₂O, thought to be the consequence of enhanced root-derived available soil C, acting as an energy source for denitrification. The climate, agricultural practices and soils at the FACE experiment combined to give rise to some of the largest N₂O emissions recorded for any terrestrial ecosystem. The amount of CO₂-C being lost from the control plot was higher (10%) than for the enhanced CO₂ plot, and is the reverse of that predicted. The control plot oxidised consistently more CH₄ than the enhanced plot, oxidising 25.5 $\pm$ 0.8 $\mu\text{g m}^{-2} \text{hr}^{-1}$ of CH₄ for the control plot, with an average of 8.5 $\pm$ 0.4 $\mu\text{g m}^{-2} \text{hr}^{-1}$ of CH₄ for the enhanced CO₂ plot. This suggests that elevated pCO₂ may lead to a feedback whereby less CH₄ is removed from the atmosphere. Despite the limited nature of the current study (in time and space), the observations made here on the interactions of elevated pCO₂ and soil trace gas release suggest that significant interactions are occurring. The feedbacks involved could have importance at the global scale.

Ingstad, T., O. Hellgren, H. Hessel Dahl, and A.B.L. Ingstad. 1996. Methods and applications to control the uptake rate of carbon. *Physiologia Plantarum* 98(3):667-676.

Methods to control carbon and nutrient uptake at different availability of carbon were tested on plants of birch (*Betula pendula* Roth.) and tomato (*Lycopersicon esculentum* Mill. cv. Solentos). The present paper accounts for the methods and the possibility to maintain steady-state, i.e., a long-term and stable physiological state of acclimated plants. Steady-state comprises, by definition, equality between constant relative growth rates, and relative uptake rates of carbon and nutrients. Two methods were tested. The first, not previously applied, method (a), was based on a constant relative addition rate of carbon, R(AC). In the second method (b), a constant concentration of CO₂ in the air, c(a), was used to attain non-limiting conditions. The methods are analogous to those used by us to control plant nutrition, and the generality of fluxes to quantify supply as well as uptake and growth was verified. Thus, different R(AC) resulted suited in clear-cut responses, from strong reduction to non-limitation of uptake and growth, whereas different c(a) levels in the range 100 to 700 ppm had comparatively small effects, with an unclear causality. Non-limiting conditions were achieved at c(a) greater than or equal to 200 ppm. Effects reported in the literature have been based upon the control of c(a), similarly to method (b), whereas results comparable to those obtained with method (a) are lacking. Transpiration rate increased rapidly at c(a) < 200 ppm CO₂, and at low R(AC) levels, less than or equal to 0.1 day⁻¹, wilting tendencies were observed. Elevated c(a) 500 or 700 ppm, did not increase the relative growth rate (R(G)) but reduced transpiration and increased both nitrogen productivity (growth rate per unit of nitrogen in the plant) and transpiration productivity (growth rate per unit of water transpired by the plant). Obviously, effects of c(a) may be due to changed transpiration rate rather than to changed quantitative availability of CO₂. Relative uptake (R(OC)) and growth (R(G)) rates were closely equal to the R(AC) applied (R(AC) approximate to R(UC) approximate to R(G)); i.e., the purely mathematical conditions defining steady-state were fulfilled. This unambiguous and straightforward test of reliability confirms that experimental artefacts did not produce uncontrolled or unintended effects, so that the new technique allows an accurate control of CO₂ uptake and plant growth. The results add to previous databases and reference systems, where limiting conditions grade and classify plant performance as deviations from maximum growth. Evidently, methodology in experimentation and in evaluation of plant responses, can be based upon unifying concepts and general theories.

Ingvardsen, C., and B. Veierskov. 1994. Response of young barley plants to CO₂ enrichment. *Journal of Experimental Botany* 45(279):1373-1378.

Barley (*Hordeum vulgare* L. cv. Digger) was grown for 22 d in enclosed chambers with a CO₂ enrichment of 35, 155, 400 or 675 µmol CO₂ mol⁻¹. CO₂ enrichment increased photosynthetic capacity in the plants grown at either of the two highest levels of pCO₂. A CO₂ enrichment of 675 µmol CO₂ caused a significant increment of shoot dry weight, whereas no changes were observed in fresh weight, chlorophyll or protein levels. At a light intensity of 860 µmol m⁻² s⁻¹ CO₂ enrichment caused photosynthetic capacity to increase by 250%, whereas no effect was observed at 80 µmol m⁻² s⁻¹. Over time, photosynthesis decreased by 70% independent of CO₂. A time-dependent increase in the level of extractable fructose was observed whereas total extractable carbohydrate only changed slightly.

Innes, J.L. 1994. Climatic sensitivity of temperature forests. *Environmental Pollution* 83(1-2):237-243.

Climatic change and associated global changes are of major interest to foresters, both in terms of forest ecology and of future forest production. Predicting the likely effects of global change on forests is extremely difficult due to the critical lack of information on regional changes in meteorological factors relevant to forests. However, existing models of forest production and forest distribution fail to take adequate account of what is already known. Climate and carbon dioxide concentrations have shown substantial changes over the last 100 years. Although the rate of change is likely to increase, recent proposed and implemented control strategies, together with better climatic models, are tending to suggest that the rate of change will be less than initially thought. This means that past changes may provide an increasingly useful source of information. In particular, information on the impact on forests of both long-term climate change and short-term climatic events is rapidly increasing. Such information should be built into future forest response models.

Insam, H., E. Baath, M. Berreck, A. Frostegard, M.H. Gerzabek, A. Kraft, F. Schinner, P. Schweiger, and G. Tschuggnall. 1999. Responses of the soil microbiota to elevated CO₂ in an artificial tropical ecosystem. *Journal of Microbiological Methods* 36(1-2):45-54.

Plants in artificial tropical ecosystems were grown under ambient (340 µmol l⁻¹) and elevated (610 µmol l⁻¹) atmospheric CO₂ for 530 d under low-nutrient conditions on a substrate free of organic C. At the end of the experiment a number of soil chemical and microbiological variables were determined. Although we found no changes in total soil organic matter under elevated CO₂, we did find that after physical fractionation the amount of organic C in the supernatant (< 0.2 µm) and the amount of water extractable organic C (WEOC) was lower under elevated CO₂. The extractable optical density (OD) indicated a higher degree of humification for the elevated than for the ambient CO₂ samples (P = 0.032). Microbial biomass C was not significantly altered under high CO₂, but total bacterial counts were significantly higher. The microbial biomass C-to-N ratio was also higher at elevated (15.0) than at ambient CO₂ (10.0). The number of mycorrhizal spores was lower at high CO₂, but ergosterol contents and fungal hyphal lengths were not significantly affected. Changes were found neither in community level physiological profiles (CLPPs) nor in the structural attributes (phospholipid fatty acids, PLFAs) of the microbial community. Overall, the effects on the soil microbiota were small, perhaps as a result of the low nutrient supply and low organic matter content of the soil used in our study. The few significant results showing changes in specific, though relatively minor, organic matter pools may point to possible long-term changes of the more major pools. Furthermore, the data suggest increased competition between plants and microbes for N at high CO₂.

Inubushi, K., W.G. Cheng, and K. Chander. 1999. Carbon dynamics in submerged soil microcosms as influenced by elevated CO₂ and temperature. *Soil Science and Plant Nutrition* 45(4):863-872.

A 45-d incubation experiment was conducted under controlled laboratory conditions to study the interactive effects of elevated CO₂ and temperature on the dynamics of microbial biomass C and organic C in hooded paddy soil microcosms amended or unamended with rice straw. The microcosms with the two treatments were transferred separately to four growth chambers to incubate them under 16 h/8 h light and dark conditions. Two of the growth chambers set at 25 and 35 degrees C provided a continuous flow of elevated CO₂ (equivalent to 800 μ mol L⁻¹). Similarly the other two growth chambers were run under near ambient CO₂ (400 μ mol L⁻¹) conditions at each of the two temperatures. The amounts of soluble carbon, microbial biomass C, chlorophyll-type compounds, and organic C in the surface (0-1 cm) and sub-surface (below 1 cm) soil layers were measured at 15, 30, and 45 d after incubation. The amount of soluble carbon in the straw-amended soil gradually decreased throughout the incubation period, while no significant differences were detected among the four different conditions. The interactive effects of both elevated CO₂ and temperature were found to be positive in terms of the size of the microbial biomass in surface soil, although no significant differences were detected in the subsurface. However, the amount of total soil organic C was larger in the soils incubated at a lower temperature. The amounts of chlorophyll-type compounds doubled in the surface soil when the soils were incubated under elevated CO₂ conditions, indicating that the higher incubation concentration of CO₂ promoted the growth of algae in surface soil.

Ioslovich, I., I. Seginer, P.O. Gutman, and M. Borshchevsky. 1995. Suboptimal CO₂ enrichment of greenhouses. *Journal of Agricultural Engineering Research* 60(2):117-136.

Greenhouse CO₂ enrichment in warm climates is restricted by the need to ventilate, leading some growers to intermittent enrichment, where enrichment and ventilation alternate several times an hour. This strategy relies on the heat and CO₂ capacity of the system, characterized by a heating time constant of the order of 10 min, during which period ventilation may be suspended. It is shown that, for slowly changing weather, the optimal CO₂ enrichment is basically not intermittent (bang-bang control), but rather quasi steady state (smoothly varying singular control). As the disturbance (weather) frequency increases, the quasi steady-state (QSS) solution becomes less and less optimal. Nevertheless, due to the difficulties involved in implementing a truly optimal control (the need for accurate weather forecast and high control fluxes), the sub-optimal QSS control may be a better choice. We chose to try a controller which aims to follow the QSS temperature and CO₂ setpoints at all disturbance frequencies. The performance of this controller for high disturbance frequencies is a few per cent lower than the truly optimal solution, but over the whole season this effect may not be significant. On the other hand, the controller is likely to be more robust. Implementation of the QSS solution requires simultaneous ventilation and enrichment, properly balanced.

Islam, K.R., C.L. Mulchi, and A.A. Ali. 1999. Tropospheric carbon dioxide or ozone enrichments and moisture effects on soil organic carbon quality. *Journal of Environmental Quality* 28(5):1629-1636.

Carbon, as an active component of organic matter, has considerable effects on soil quality and productivity. The objective of this study was to examine the effect of climate change variables on soil organic C (C-T) quality in an agroecosystem. Wheat (*Triticum aestivum* L.) and soybean [*Glycine max* (L.) Merr] plants were grown in 3 m in diam, open-top field chambers and exposed to charcoal-filtered (CF) air at 350 μ mol L⁻¹ CO₂ L⁻¹; CF air + 150 μ mol L⁻¹ CO₂ L⁻¹; nonfiltered (NF) air + 35 nL O₃ L⁻¹; and NF air + 35 nL O₃ L⁻¹ + 150 μ mol L⁻¹ CO₂ L⁻¹ at two soil moisture levels from 1994 to 1996. The 150 μ mol L⁻¹ CO₂ L⁻¹ addition was 18 h d⁻¹ and the 35 nL O₃ L⁻¹ was 7 h d⁻¹ from April until late October. In response to treatments, the CT contents did not change significantly; however, particulate, oxidizable, dissolved, humic (C-HA) and fulvic (C-FA) acid, and carbohydrate C pools increased in soils under CO₂ enrichment and well-watered conditions but decreased under O₃ stress compared with soils under CF ambient air quality. Tropospheric CO₂ enrichment and well-watered condition increased, and O₃ stress decreased the log optical density slope for both C-HA and C-FA fractions more than CF ambient air and restricted moisture treatment. Also, the E-465/E-665 ratios of both C-HA and C-FA fractions were higher for the CO₂ enrichment and smaller for the O₃ stress compared With CF ambient air quality. Results suggest that tropospheric CO₂ enrichment and well-watered conditions may favor an accumulation of low molecular weight and more aliphatic quality of C and O₃ stress favor high molecular weight and more aromatic quality of C.

Islam, M.S., T. Matsui, and Y. Yoshida. 1995. Effect of preharvest carbon dioxide enrichment on the postharvest quality of tomatoes. *Journal of the Japanese Society for Horticultural Science* 64(3):649-655.

The effect of preharvest application of elevated CO₂ throughout the fruit growing period on organic acid, sugar content, acid invertase activity (beta-fructofuranoside fructohydrolase, EC 3.2.1.26), and color quality in tomato (*Lycopersicon esculentum* Mill. cv. Momotaro) fruit during storage at 20 degrees C was determined. The CO₂-enriched tomato fruits contained significantly lower concentrations of citric, malic and oxalic acids, but had significantly higher reducing sugars and acid invertase activity at harvest and during storage. The concentration of these acids decreased with storage, whereas the activity of acid invertase and reducing sugar contents increased in the treated fruits; they were relatively constant in the control fruits. Furthermore, the elevated CO₂ resulted in a deeper red color during storage.

Islam, M.S., T. Matsui, and Y. Yoshida. 1996. Effect of carbon dioxide enrichment on physico-chemical and enzymatic changes in tomato fruits at various stages of maturity. *Scientia Horticulturae* 65(2-3):137-149.

The influence of CO₂ enrichment on fruit growth, firmness and colour, together with its effect on the concentrations of ascorbic acid, organic acids and sugars, and the activities of sucrose synthase (SS) (UDP glucose: D-fructose 2- glucosyltransferase, E. C. 2, 4, 1, 13) and sucrose phosphate synthase (SPS) (UDP glucose: D-fructose-6-phosphate 2- glucosyltransferase, E. C. 2. 4. 1. 14) were determined at various stages of maturity in fruits of tomato (*Lycopersicon esculentum* Mill. cv. Momotaro), CO₂ enriched tomatoes had lower amounts of citric, malic and oxalic acids, and higher amounts of ascorbic acid, fructose, glucose and sucrose synthase activity than the control. Elevated CO₂ enhanced fruit growth and colouring during development. Citric acid was the primary organic acid followed by malic and oxalic acids. The concentration of organic acids (mg g⁻¹ fresh weight) and of ascorbic acid (mg 100g⁻¹ fresh weight) increased with the maturity of fruits; their maximum concentrations were found at the pink stage of ripening, but declined slightly at the red stage. The amount of reducing sugars (mg g⁻¹ fresh weight) increased with the advancement of maturity, with fructose being the predominant sugar. The decrease in SS activity was accompanied by an increase in the concentrations of reducing sugars. There were no significant differences in fruit firmness, sucrose concentration and SPS activity between the treatments. The SPS activity did not change, but remained relatively constant throughout fruit development. The results also suggest that SS levels correlated positively with sucrose concentration but negatively with the concentration of reducing sugars.

Israel, A.A., and P.S. Nobel. 1994. Activities of carboxylating enzymes in the cam species opuntia- ficus-indica grown under current and elevated co₂ concentrations. *Photosynthesis Research* 40(3):223-229.

Responses of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) and phosphoenolpyruvate carboxylase (PEPCase) to an elevated atmospheric CO₂ concentration were determined along with net CO₂ uptake rates for the Crassulacean acid metabolism species *Opuntia ficus-indica* growing in open-top chambers. During the spring 13 months after planting, total daily net CO₂ uptake of basal and first-order daughter cladodes was 28% higher at 720 than at 360 μ l CO₂ l⁻¹ (-1). The enhancement, caused mainly by higher CO₂ assimilation during the early part of the night, was also observed during late summer (5 months after planting) and the following winter. The activities of Rubisco and PEPCase measured in vitro were both lower at the elevated CO₂ concentration, particularly under the more favorable growth conditions in the spring and late summer. Enzyme activity in second-order daughter cladodes increased with cladode age, becoming maximal at 6 to 10 days. The effect of elevated CO₂ on Rubisco and PEPCase activity declined with decreasing irradiance, especially for Rubisco. Throughout the 13-month observation period, *O. ficus-indica* thus showed increased CO₂ uptake when the atmospheric CO₂ concentration was doubled despite lower activities of both carboxylating enzymes.

Israel, D.W., T.W. Rufty, and J.D. Cure. 1990. Nitrogen and phosphorus nutritional interactions in a CO₂ enriched environment. *Journal of Plant Nutrition* 13(11):1419-1433.

Nonnodulated soybean plants (*Glycine max.* [L.] Merr. 'Lee') were

supplied with nutrient solutions containing growth limiting concentrations of N or P to examine effects on N- and P-uptake efficiencies (mg nutrient accumulated/gdw root) and utilization efficiencies in dry matter production (gdw/mg nutrient). Nutritional treatments were imposed in aerial environments containing either 350 or 700- μ l/l atmospheric CO₂ to determine whether the nutrient interactions were modified when growth rates were altered. Nutrient-stress treatments decreased growth and N- and P-uptake and utilization efficiencies at 27 days after transplanting (DAT) and seed yield at maturity (98 DAT). Atmospheric CO₂ enrichment increased growth and N- and P-utilization efficiencies at 27 DAT and seed yield in all nutritional treatments and did not affect N- and P-uptake efficiencies at 27 DAT. Parameter responses to nutrient stress at 27 DAT were not altered by atmospheric CO₂ enrichment and vice versa. Nutrient-stress treatments lowered the relative seed yield response to atmospheric CO₂ enrichment. Decreased total-N uptake by P- stressed plants was associated with both decreased root growth and N-uptake efficiency of the roots. Nitrogen-utilization efficiency was also decreased by P-stress. This response was associated with decreased plant growth as total-N uptake and plant growth were decreased to the same extent by P stress resulting in unaltered tissue N concentrations. In contrast, decreased total P-uptake by N-stressed plants was associated with a restriction in root growth as P-uptake efficiency of the roots was unaltered. This response was coupled with an increased root-to-shoot dry weight ratio; thus shoot and wholeplant growth were decreased to a much greater extent than total-P uptake which resulted in elevated P concentrations in the tissue. Therefore, P-utilization efficiency was markedly reduced by N stress.

Isutsa, D.K., M.P. Pritts, and K.W. Mudge. 1994. Rapid propagation of blueberry plants using ex-vitro rooting and controlled acclimatization of micropropagules. *Hortscience* 29(10):1124-1126.

A protocol is presented that enables a propagator to produce field-sized blueberry transplants within 6 months of obtaining microshoots from tissue culture. The protocol involves subjecting microshoots to ex vitro rooting in a fog chamber under 100 μ mol.m⁻².s⁻¹ photosynthetic photon flux for 7 weeks, transferring plants to a fog tunnel for 2 weeks, then to a greenhouse for 7 more weeks. Plant survival and rooting of cultivars Berkeley (*Vaccinium corymbosum* L.) and Northsky (*Vaccinium angustifolium* x *corymbosum*) were near 100% under these conditions. Plantlets in fog chambers receiving 100 μ mol.m⁻².s⁻¹ grew rapidly, while those at lower irradiance levels grew more slowly, and supplemental CO₂ enhanced growth only at 50 μ mol.m⁻².s⁻¹. Growth rates slowed when plants were moved into the fog tunnel; but by the end of 16 weeks, plants that were under high irradiance in the fog chamber had root systems that were 15 to 30 times larger than plants under low irradiance. Within 6 months, these plants were 30 to 60 cm tall and suitable for field planting.

Ito, J., S. Hasegawa, K. Fujita, S. Ogasawara, and T. Fujiwara. 1999. Effect of CO₂ enrichment on fruit growth and quality in Japanese pear (*Pyrus serotina* reheder cv. Kosui). *Soil Science and Plant Nutrition* 45(2):385-393.

Six year-old Japanese pear (*Pyrus serotina* Reheder cv. Kosui) trees

grafted on *P. serotina* cv. Nihonyamanashi were grown in containers filled with Granite Regosol under glasshouse conditions. At different stages of fruit growth, pear trees were exposed to an elevated CO₂ concentration (130 Pa CO₂) along with a control (35 Pa CO₂). For one group of plants, CO₂ enrichment was applied for 79 d from 52 d after full bloom (DAB) to fruit maturity (long-term CO₂ enrichment) and for another group the same treatment was applied for 35 d from 96 DAB to fruit maturity (short-term CO₂ enrichment). The effects of the elevated CO₂ concentration on vegetative growth, mineral contents, and fruit production and quality were examined. Long-term CO₂ enrichment enhanced vegetative growth, without any significant effect on the mineral contents in either flower bud or fruit except for a remarkable increase in the K content. Long-term CO₂ enrichment increased the fruit size and fresh weight, but had no significant effect on the fruit quality. On the other hand, the short-term CO₂ enrichment did not induce any significant change in the fruit size but increased the fruit sugar concentration. Along with the reduction of the sorbitol concentration in fruit, the fructose and sucrose concentrations increased and these changes occurred earlier at elevated CO₂ than at ambient CO₂ concentrations. From these results, we concluded that the effect of CO₂ enrichment on fruit growth varies depending upon the growth stages of fruit: during the initial and fruitlet stages when fruit expansion occurs, CO₂ enrichment increases the fruit size, whereas, during maturation when fruit expansion has slowed down and sugar accumulation in fruit is active, it increases the fruit sugar concentration.

Iverson, L.R., and A.M. Prasad. 1998. Predicting abundance of 80 tree species following climate change in the eastern United States. *Ecological Monographs* 68(4):465-485.

Projected climate warming will potentially have profound effects on the earth's biota, including a large redistribution of tree species. We developed models to evaluate potential shifts for 80 individual tree species in the eastern United States. First, environmental factors associated with current ranges of tree species were assessed using geographic information systems (GIS) in conjunction with regression tree analysis (RTA). The method was then extended to better understand the potential of species to survive and/or migrate under a changed climate. We collected, summarized, and analyzed data for climate, soils, land use, elevation, and species assemblages for >2100 counties east of the 100th meridian. Forest Inventory Analysis (FIA) data for >100000 forested plots in the East provided the tree species range and abundance information for the trees. RTA was used to devise prediction rules from current species-environment relationships, which were then used to replicate the current distribution as well as predict the future potential distributions under two scenarios of climate change with twofold increases in the level of atmospheric CO₂. Validation measures prove the utility of the RTA modeling approach for mapping current tree importance values across large areas, leading to increased confidence in the predictions of potential future species distributions. With our analysis of potential effects, we show that roughly 30 species could expand their range and/or weighted importance at least 10%, while an additional 30 species could decrease by at least 10%, following equilibrium after a changed climate. Depending on the global change scenario used, 4-9 species would potentially move out of the United States to the north. Nearly half of the species assessed (36 out of 80) showed the potential for the ecological optima to shift at least 100 km to the north, including seven that could move >250 km. Given these potential future distributions, actual species redistributions will be controlled by migration rates possible through fragmented landscapes.

Iverson, L.R., A. Prasad, and M.W. Schwartz. 1999. Modeling potential future individual tree-species distributions in the eastern United States under a climate change scenario: a case study with *Pinus virginiana*. *Ecological Modelling* 115(1):77-93.

We are using a deterministic regression tree analysis model (DISTRIB) and a stochastic migration model (SHIFT) to examine potential distributions of similar to 66 individual species of eastern US trees under a 2 x CO₂ climate change scenario. This process is demonstrated for Virginia pine (*Pinus virginiana*). USDA Forest Service Forest Inventory and Analysis data for more than 100 000 plots and nearly 3 million trees east of the 100th meridian were analyzed and aggregated to the county level to provide species importance values for each of more than 2100 counties. County-level data also were compiled on climate, soils, land use, elevation, and spatial pattern. Regression tree analysis (RTA) was used to devise prediction rules from current species-environment relationships, which were then used to replicate the current distribution and predict the potential future distributions under two scenarios of climate change (2 x CO₂). RTA allows different variables to control importance value predictions at different regions, e.g. at the northern versus southern range limits of a species. RTA outputs represent the potential 'environmental envelope' shifts required by species, while the migration model predicts the more realistic shifts based on colonization probabilities from varying species abundances within a fragmented landscape. The model shows severely limited migration in regions of high forest fragmentation, particularly when the species is low in abundance near the range boundary. These tools are providing mechanisms for evaluating the relationships among various environmental and landscape factors associated with tree-species importance and potential migration in a changing global climate. Iwasaki, I., N. Kurano, and S. Miyachi. 1996. Effects of high-CO₂ stress on photosystem II in a green alga, *Chlorococcum littorale*, which has a tolerance to high CO₂. *Journal of Photochemistry and Photobiology B-Biology* 36(3):327-332.

A green alga, *Chlorococcum littorale*, is known to have a tolerance to high CO₂ conditions. By a sudden change from stir to high CO₂, PSII activity of *C. littorale* decreased temporarily and then recovered, while PSI activity showed the opposite change (Pesheva et al., *Plant Cell Physiol*, 35 (1994) 379-387). To investigate the efficiency of energy captured by open PSII reaction centers, the quenching of chlorophyll fluorescence of intact cells of *C. littorale* was analyzed. The data obtained are compared with those obtained with cells of *Stichococcus bacillaris* which has little tolerance to high CO₂. Activities of photosynthetic oxygen evolution of the intact cells and DCIP photoreduction with the crude membrane fraction of *C. littorale* decreased within 1-2 days, and after about 4 days both activities recovered and/or were elevated to higher levels than those in the air conditions. During this temporal decrease in these activities, the effective quantum yield of PSII also lowered to about 50% of that in air. The values of F_v/F_m transiently decreased indicating photoinhibition in PSII. Such fluorescence quenching parameters recovered after about 4 days. On the other hand, the activities of PSII and other photosynthetic characteristics did not recover in *S. bacillaris*.

Jablonski, L.M. 1997. Responses of vegetative and reproductive traits to elevated CO₂ and nitrogen in *Raphanus* varieties. *Canadian Journal of Botany-Revue Canadienne De Botanique* 75(4):533-545.

The relationships between the responses to elevated CO₂ of the vegetative and reproductive phase were investigated in radish, used as a test system. The hypothesis that an increase in nonfoliar vegetative storage capacity promotes reproductive output was tested. Three cultivars of *Raphanus sarivus* and the wild, *Raphanus raphanistrum*, differing in root to shoot ratios, were grown under two levels of CO₂ and two levels of nitrogen fertilization. Varieties possessed different strategies of carbon storage and showed distinct responses to CO₂ at each vegetative harvest time. Vegetative sinks of hypocotyls, petioles, and young blades were enhanced by CO₂. Nitrogen promoted vegetative shoot growth, but did not enhance the reproductive response to CO₂. By the end of the reproductive phase, varieties did not differ in total biomass. Reproductive response to CO₂ may have been limited by the lack of an effect on the timing of flowering. Correlations in CO₂ enhancement ratios were examined in 12 traits of each phase. Only vegetative total leaf area correlated with reproductive mass. Foliar starch correlated with decreased abortion. Enhancements in vegetative biomass did not correlate with any reproductive response. Detailed studies of the reproductive phase are needed to understand the whole-plant response to elevated CO₂.

Jach, M.E., and R. Ceulemans. 1999. Effects of elevated atmospheric CO₂ on phenology, growth and crown structure of Scots pine (*Pinus sylvestris*) seedlings after two years of exposure in the field. *Tree Physiology* 19(4-5):289-300.

Three-year-old Scots pine (*Pinus sylvestris* L.) seedlings were grown for two years in the ground in open-top chambers supplied with either an ambient or elevated (ambient + 400 $\mu\text{mol mol}^{-1}$) CO₂ concentration. Phenological observations and measurements of height and stem diameter growth, absolute and relative growth rates, starch and soluble carbohydrate concentrations of the needles, and crown structure and needle properties were made at frequent intervals throughout the two growing seasons. Elevated CO₂ significantly advanced the date of bud burst in both years. The increase in total needle area in response to elevated CO₂ was accounted for by longer shoots and an increase in individual needle area in the first year, and by an increase in the number and length of shoots in the second year. Stem diameter and tree height were enhanced more by the elevated CO₂ treatment in the first year than in the second, indicating a decreased effect of CO₂ on growth over time. This was confirmed by a study of absolute and relative growth rates of leader shoots. During the first growing season of CO₂ enrichment, mean weekly relative growth rates over the growing season (RGR(m)) were significantly enhanced. During the second year, RGR(m) in ambient

CO₂ closely matched that in elevated CO₂.

Jackson, R.B., Y. Luo, Z.G. Cardon, O.E. Sala, C.B. Field, and H.A. Mooney. 1995. Photosynthesis, growth and density for the dominant species in a CO₂-enriched grassland. *Journal of Biogeography* 22(2-3):221-225.

Although increased atmospheric CO₂ frequently increases short-term photosynthetic rates, longer-term photosynthetic responses are more variable. Plant size, reproduction and ecosystem carbon gain are determined, in part, by such photosynthetic responses. Here we examine photosynthetic regulation for the dominant species in a grassland exposed to elevated CO₂ and examine whether the observed photosynthetic responses contribute to changes in growth, reproduction and plant density in the same grassland. *Avena barbata* in the field showed little evidence of photosynthetic downregulation with elevated CO₂ at the end of the growing season (differences between treatments <10%). Glasshouse studies also showed little evidence for downregulation of photosynthesis measured at various light and intercellular CO₂ concentrations. Although specific leaf mass (leaf mass per unit leaf area) for *Avena* increased 20% in the field with elevated CO₂, leaf nitrogen concentrations decreased 25%, resulting in an 11% reduction in leaf N on a leaf-area basis. For the relatively wet 1993 growing season, *Avena barbata* increased its size and reproduction approximately 30% in elevated CO₂, with a 21% decrease in population density. For the relatively dry 1994 season *Avena* density was almost doubled in elevated CO₂, but increases in individual size and reproduction with CO₂ were small (6-18%). The primary effect of CO₂ in the drier year appears to have been greater *Avena* survival, rather than increased individual size.

Jackson, R.B., and H.L. Reynolds. 1996. Nitrate and ammonium uptake for single- and mixed-species communities grown at elevated CO₂. *Oecologia* 105(1):74-80.

Sustained increases in plant production in elevated CO₂ depend on adequate belowground resources. Mechanisms for acquiring additional soil resources include increased root allocation and changes in root morphology or physiology. CO₂ research to date has focused almost exclusively on changes in biomass and allocation. We examined physiological changes in nitrate and ammonium uptake in elevated CO₂, hypothesizing that uptake rates would increase with the amount of available CO₂. We combined our physiological estimates of nitrogen uptake with measurements of root biomass to assess whole root-system rates of nitrogen uptake. Surprisingly, physiological rates of ammonium uptake were unchanged with CO₂, and rates of nitrate uptake actually decreased significantly ($P < 0.005$). Root biomass increased 23% in elevated CO₂ ($P < 0.005$), but almost all of this increase came in fertilized replicates. Rates of root-system nitrogen uptake in elevated CO₂ increased for ammonium in nutrient-rich soil ($P < 0.05$) and were unchanged for nitrate ($P > 0.80$). Root-system rates of nitrogen uptake were more strongly correlated with physiological uptake rates than with root biomass in unamended soil, but the reverse was true in fertilized replicates. We discuss nitrogen uptake and changes in root biomass in the context of root nutrient concentrations (which were generally

unchanged with CO₂) and standing pools of belowground plant nitrogen. In research to date, there appears to be a fairly general increase in root biomass with elevated CO₂, and little evidence of up-regulation in root physiology.

Jackson, R.B., O.E. Sala, C.B. Field, and H.A. Mooney. 1994. CO₂ alters water-use, carbon gain, and yield for the dominant species in a natural grassland. *Oecologia* 98(3-4):257-262.

Global atmospheric CO₂ is increasing at a rate of 1.5-2 ppm per year and is predicted to double by the end of the next century. Understanding how terrestrial ecosystems will respond in this changing environment is an important goal of current research. Here we present results from a field study of elevated CO₂ in a California annual grassland. Elevated CO₂ led to lower leaf-level stomatal conductance and transpiration (approximately 50%) and higher mid-day leaf water potentials (30-35%) in the most abundant species of the grassland, *Avena barbata* Brot. Higher CO₂ concentrations also resulted in greater midday photosynthetic rates (70% on average). The effects of CO₂ on stomatal conductance and leaf water potential decreased towards the end of the growing season, when *Avena* began to show signs of senescence. Water-use efficiency was approximately doubled in elevated CO₂, as estimated by instantaneous gas-exchange measurements and seasonal carbon isotope discrimination. Increases in CO₂ and photosynthesis resulted in more seeds per plant (30%) and taller and heavier plants (27% and 41%, respectively). Elevated CO₂ also reduced seed N concentrations (9%).

Jackson, R.B., O.E. Sala, J.M. Paruelo, and H.A. Mooney. 1998. Ecosystem water fluxes for two grasslands in elevated CO₂: a modeling analysis. *Oecologia* 113(4):537-546.

The need to combine data from CO₂ field experiments with climate data remains urgent, particularly because each CO₂ experiment cannot run for decades to centuries. Furthermore, predictions for a given biome need to take into account differences in productivity and leaf area index (LAI) independent of CO₂-derived changes. In this study, we use long-term weather records and field data from the Jasper Ridge CO₂ experiment in Palo Alto, California, to model the effects of CO₂ and climate variability on ecosystem water fluxes. The sandstone and serpentine grasslands at Jasper Ridge provide a range of primary productivity and LAI, with the sandstone as the more productive system. Modeled soil water availability agreed well with published observations of time-domain reflectometry in the CO₂ experiment. Simulated water fluxes based on 10-year weather data (January 1985-December 1994) showed that the sandstone grassland had a much greater proportion of water movement through plants than did the serpentine; transpiration accounted for approximately 30% of annual fluxes in the sandstone and only 10% in the serpentine. Although simulated physiological and biomass changes were similar in both grasslands, the consequences of elevated CO₂ were greater for the sandstone water budget. Elevated CO₂ increased soil drainage by 20% in the sandstone, despite an approximately one-fifth increase in plant biomass; in the serpentine, drainage increased by <10% and soil evaporation was unchanged for the same simulated biomass change. Phenological changes, simulated by a 15-day lengthening of the growing season, had minimal impacts on the water budget. Annual variation in the timing and amount of rainfall was important for water fluxes in both grasslands. Elevated CO₂ increased

sandstone drainage > 50 mm in seven of ten years, but the relative increase in drainage varied from 10% to 300% depending on the year. Early-season transpiration in the sandstone decreased between 26% and 41%, with elevated CO₂ resulting in a simulated water savings of 54-76 mm. Even in years when precipitation was similar (e.g., 505 and 479 mm in years 3 and 4), the effect of CO₂ varied dramatically. The response of grassland water budgets to CO₂ depends on the productivity and structure of the grassland, the amount and timing of rainfall, and CO₂-induced changes in physiology. In systems with low LAT, large physiological changes may not necessarily alter total ecosystem water budgets dramatically.

Jacob, J., C. Greitner, and B.G. Drake. 1995. Acclimation of photosynthesis in relation to rubisco and nonstructural carbohydrate contents and in-situ carboxylase activity in *Scirpus olneyi* grown at elevated CO₂ in the field. *Plant, Cell and Environment* 18(8):875-884.

Stands of *Scirpus olneyi*, a native saltmarsh sedge with C-3 photosynthesis, had been exposed to normal ambient and elevated atmospheric CO₂ concentrations (C-a) in their native habitat since 1987. The objective of this investigation was to characterize the acclimation of photosynthesis of *Scirpus olneyi* stems, the photosynthesizing organs of this species, to long-term elevated C-a treatment in relation to the concentrations of Rubisco and non-structural carbohydrates. Measurements were made on intact stems in the field under existing natural conditions and in the laboratory under controlled conditions on stems excised in the field early in the morning. Plants grown at elevated C-a had a significantly higher (30-59%) net CO₂ assimilation rate (A) than those grown at ambient C-a when measurements were performed on excised stems at the respective growth C-a. However, when measurements were made at normal ambient C-a, A was smaller (45-53%) in plants grown at elevated C-a than in those grown at ambient C-a. The reductions in A at normal ambient C-a, carboxylation efficiency and in situ carboxylase activity were caused by a decreased Rubisco concentration (30-58%) in plants grown at elevated C-a; these plants also contained less soluble protein (39-52%). The Rubisco content was 43 to 58% of soluble protein, and this relationship was not significantly altered by the growth CO₂ concentrations. The Rubisco activation state increased slightly, but the in situ carboxylase activity decreased substantially in plants grown at elevated C-a. When measurements were made on intact stems in the field, the elevated C-a treatment caused a greater stimulation of A (100%) and a smaller reduction in carboxylation efficiency (which was not statistically significant) than when measurements were made on excised stems in the laboratory. The possible reasons for this are discussed. Plants grown at elevated C-a contained more non-structural carbohydrates (25-53%) than those grown at ambient C-a. Plants grown at elevated C-a appear to have sufficient sink capacity to utilize the additional carbohydrates formed during photosynthesis. Overall, our results are in agreement with the hypothesis that elevated C-a leads to an increased carbohydrate concentration and the ensuing acclimation of the photosynthetic apparatus in C-3 plants results in a reduction in the protein complement, especially Rubisco, which reduces the photosynthetic capacity in plants grown at elevated C-a, relative to plants grown at normal ambient C-a. Nevertheless, when compared at their respective growth C-a, *Scirpus olneyi* plants grown at

elevated C-a in their native habitat maintained a substantially higher rate of photosynthesis than those grown at normal ambient C-a even after 8 years of growth at elevated C-a.

Jacoby, G.C., and R.D. DArrigo. 1997. Tree rings, carbon dioxide, and climatic change. *Proceedings of the National Academy of Sciences of the United States of America* 94(16):8350-8353.

Tree rings have been used in various applications to reconstruct past climates as well as to assess the effects of recent climatic and environmental change on tree growth. In this paper we briefly review two ways that tree rings provide information about climate change and CO₂: (i) in determining whether recent: warming during the period of instrumental observations is unusual relative to prior centuries to millennia, and thus might be related to increasing greenhouse gases; and (ii) in evaluating whether enhanced radial growth has taken place in recent decades that appears to be unexplained by climate and might instead be due to increasing atmospheric CO₂ or other nutrient fertilization. It is found that a number of tree-ring studies from temperature-sensitive settings indicate unusual recent warming, although there are also exceptions al. certain sires, The present tree-ring evidence for a possible CO₂ fertilization effect under natural environmental conditions appears to be very limited.

Jalil, A., and R.M. Carlson. 1993. Potassium uptake by marianna plum under limited oxygen and elevated carbon-dioxide levels in the root atmosphere. *Journal of Plant Nutrition* 16(4):723-737.

Potassium (K) uptake rates were determined for Marianna 2624 rootstocks with 'French' prune scions using th nutrient solution depletion technique. The nutrient solutions were bubbled with factorial combinations of nitrogen (N₂), oxygen (O₂), and carbon dioxide (CO₂) to create treatment root atmospheres with O₂ ranging from 0.01 to 0.10

m³/m³ and CO₂ ranging from 0 to 0.05 m³/m³. The K⁺ uptake rate was more susceptible to O₂ deprivation than to elevated CO₂ in the root atmosphere. Decreasing O₂ levels from 0.10 M³/M³ decreased K⁺ uptake in a hyperbolic fashion to no net uptake at 0.01 M³/M³ O₂. Increasing root atmosphere CO₂ from 0 to 0.05 M³/M³ had a small depressing effect on net K⁺ influx from 60 μM K⁺ solutions at 0.10 and 0.05 M³/M³ O₂, but no effect when O₂ was 0.025 or 0.01 M³/M³. Elevating CO₂ decreased K_m for the net K⁺ influx rate at 0.10 and 0.05 M³/M³ O₂. Increased pH buffering from higher HCO₃ concentration at the plasma membrane surface was suggested to explain the CO₂ effect on K_m.

Jansen, D.M. 1990. Potential rice yields in future weather conditions in different parts of asia. *Netherlands Journal of Agricultural Science* 38(4):661-680.

Future climate change is expected to vary between regions, with possible different effects on crop growth. Various sites in Asia were selected to represent major rice growing environments. Historic weather data of these sites were adapted to possible changes in temperature and in CO₂ level, to mimic climate change. Potential rice yields at present, and for the years 2020 and 2100 were calculated with a crop growth simulation model. Simulated yields rose in low and middle temperature change scenarios, but decreased in the high temperature scenario. Effects were stronger in the year 2100, when also regional differences became clear: more than elsewhere, yields were affected by high temperatures between 10 and 35-degrees-N. Water use efficiency decreased in the high temperature scenario irrespective of CO₂ scenario, and increased otherwise.

Janssens, I.A., M. Crookshanks, G. Taylor, and R. Ceulemans. 1998. Elevated atmospheric CO₂ increases fine root production, respiration, rhizosphere respiration and soil CO₂ efflux in Scots pine seedlings. *Global Change Biology* 4(8):871-878.

In this study, we investigated the impact of elevated atmospheric CO₂ (ambient + 350 μmol mol⁻¹) on fine root production and respiration in Scots pine (*Pinus sylvestris* L.) seedlings. After six months exposure to elevated CO₂, root production measured by root in-growth bags, showed significant increases in mean total root length and biomass, which were more than 100% greater compared to the ambient treatment. This increased root length may have lead to a more intensive soil exploration. Chemical analysis of the roots showed that the roots in the elevated treatment accumulated more starch and had a lower C/N-ratio. Specific root respiration rates were significantly higher in the elevated treatment and this was probably attributed to increased nitrogen concentrations in the roots. Rhizospheric respiration and soil CO₂ efflux were also enhanced in the elevated treatment. These results clearly indicate that under elevated atmospheric CO₂ root production and development in Scots pine seedlings is altered and respiratory carbon losses through the root system are increased.

Jarvis, A.J., T.A. Mansfield, and W.J. Davies. 1999. Stomatal behaviour, photosynthesis and transpiration under rising CO₂. *Plant, Cell and Environment* 22(6):639-648.

The literature reports enormous variation between species in the extent of stomatal responses to rising CO₂. This paper attempts to provide a framework within which some of this diversity can be explained. We describe the role of stomata in the short-term response of leaf gas exchange to increases in ambient CO₂ concentration by developing the recently proposed stomatal model of Jarvis and Davies (1998). In this model stomatal conductance is correlated with the functioning of the photosynthetic system so that the effects of increases in CO₂ on stomata are experienced through changes in the rate of photosynthesis in a simple and mechanistically transparent way. This model also allows us to consider the effects of evaporative demand and soil moisture availability on stomatal responses to photosynthesis and therefore provides a means of considering these additional sources of variation. We emphasize that the relationship between the rate of photosynthesis and the internal CO₂ concentration and also drought will have important effects on the relative gains to be achieved under rising CO₂.

Jarvis, P.G. 1995. The role of temperate trees and forests in CO₂ fixation. *Vegetatio* 121(1-2):157-174.

The global flask network data indicate that the temperate and boreal forests of the northern hemisphere are a significant sink for anthropogenic CO₂. Bowen ratio and eddy covariance technology have been used to measure the net CO₂ exchange of deciduous and coniferous forest. Some results from an earlier study on spruce with the Bowen ratio technique are presented. New technology that has been developed to measure fluxes continuously by forest stands is described and data are presented to show the net exchange flux of CO₂ by temperate forests. These data support the hypothesis that temperate and boreal forests are significant sinks for carbon dioxide. An extensive programme of experimental impact studies is being carried out by a network of 12 laboratories in Europe funded by the European Commission. Parallel studies are in progress in North America and elsewhere. These studies indicate that doubling the atmospheric CO₂ concentration results in increases in tree biomass of 30-40%. Interactions with nutrition are particularly significant. If nitrogen is added at a commensurate rate, the overall effect is that trees grow larger more quickly in elevated CO₂ than in ambient air but they are essentially very similar in structure and physiology. However, if nutrients are in short supply, developmental and physiological changes occur. Then elevated CO₂ causes changes in dry mass allocation to roots, in phenology of bud burst and set, in photosynthesis, in respiration, and in tree water relations. These changes are exaggerated in low nutrition situations. Process-based models have been developed to scale-up from leaf and tree to the stand scale. These models contain explicit description of processes affected by CO₂, and are parameterised using the data collected in the impact studies. It is concluded that forests in the temperate and boreal region can effectively contribute to the removal of anthropogenic CO₂ from the atmosphere and that tree growth and production of long-lived wood products should be encouraged as a major contribution towards off-setting the greenhouse effect caused by the burning of fossil fuels.

Jauhainen, J., and J. Silvola. 1999. Photosynthesis of *Sphagnum fuscum* at long-term raised CO₂ concentrations. *Annales Botanici Fennici* 36(1):11-19.

Rate of net photosynthesis in *Sphagnum fuscum* (Schimp.) Klinggr. was measured during long-term (50-122 days), and subsequently during short-term (1/2 h), exposure to 350, 700, 1000 or 2000 ppm CO₂ concentrations. Raised CO₂ concentrations caused a general increase in the rate of net photosynthesis, increasing the rate of photosynthesis at light saturation and causing a given rate of net CO₂ exchange to be reached at lower light fluxes. The relative increase in the rate of net photosynthesis by increasing radiation fluxes was independent of the CO₂ treatment. The rates of net photosynthesis at enhanced CO₂ concentrations gradually decreased compared to rates found with the 350 ppm treatment and this acclimation was also noticed during short-term exposure to all four CO₂ concentrations. At 2000 ppm of CO₂, the depression of net photosynthesis at high water contents, found at lower CO₂ concentrations, was removed. Observed rates of net photosynthesis indicated that water-use efficiency of *Sphagnum* was not coupled with constant long-term CO₂ concentrations.

Jauhainen, J., J. Silvola, K. Tolonen, and H. Vasander. 1997. Response of *Sphagnum fuscum* to water levels and CO₂ concentration. *Journal of Bryology* 19:391-400.

Sphagnum fuscum samples collected from an ombrotrophic bog were grown in a greenhouse at six water levels (0, 5, 10, 15, 25 and 30 cm) below the capitulum level and in four concentrations of CO₂ (350, 700, 1000 and 2000 ppm). The cores of *S. fuscum* were treated for 87 days and length increment was measured by the plastic strip method and by innate time markers. Water content of the shoot, dry mass of the capitulum, dry mass per unit length of stem and production of dry mass were measured at the end of the experiment. The water content, capitulum dry mass, dry mass per unit length of stem, length increment and dry mass production differed markedly for *S. fuscum* grown in different water levels. With lower water levels, the water content of the shoot decreased and the dry mass of both the capitulum and unit length of stem increased. The total length increment was highest when the water level was at or near the capitulum level (0-10 cm). No clear trend in dry mass production on an areal basis could be found due to uncoupled responses in length increment and stem dry mass at the experimental water levels. Neither capitulum dry mass nor dry mass per unit length of stem showed distinct trends in *S. fuscum* grown at different ambient CO₂ concentrations. Some increase in length increment and in dry mass production was detected at CO₂ concentrations above 350 ppm, but this effect appeared only at high water levels. It is suggested that the low response in length increment and production to CO₂ concentration resulted in part from insufficient moisture for photosynthesis at the lower water levels. Also, the possibility of increased nonstructural production is discussed.

Jauhainen, J., H. Vasander, and J. Silvola. 1994. Response of *Sphagnum-fuscum* to N deposition and increased CO₂. *Journal of Bryology* 18:83-96.

The length increment and production of *Sphagnum fuscum* with enhanced nitrogen deposition (0, 10, 30 and 100 kg N ha⁻¹ yr⁻¹) and CO₂ concentration (350, 700, 1000 and 2000 ppm) were measured. The experiment was carried out in the glasshouse, where *S. fuscum* was grown with the water table maintained at 10 cm below the moss surface for 120 d. For length growth, 10 kg N ha⁻¹ yr⁻¹: and for biomass production, 30 kg N ha⁻¹ yr⁻¹ were found to be the optimal loads. A load of 100 kg N ha⁻¹ yr⁻¹ inhibited elongation and biomass production almost completely. An increased CO₂ concentration reduced length increment slightly, but it did not have a significant effect on biomass production. However, above ambient CO₂ concentrations increased capitulum density and stem dry mass per unit length. In addition, increased CO₂ concentration accelerated relative growth in *Sphagnum* carpets when these also received additional nitrogen. The study highlights the high degree of spatial variability that occurs within *Sphagnum fuscum*. Differences in growth and biomass production between samples, not found in natural conditions, emerged during the experiment. On the basis of our results, the present nitrogen deposition load in Southern Finland (ca 6-10 kg N ha⁻¹ yr⁻¹) is quite suitable for the growth and production of *S. fuscum*. If N deposition increased substantially, differences in the vitality of the species might be expected.

Jauhiainen, J., H. Vasander, and J. Silvola. 1998. Nutrient concentration in *Sphagna* at increased N-deposition rates and raised atmospheric CO₂ concentrations. *Plant Ecology* 138(2):149-160.

Sphagnum fuscum, *S. magellanicum*, *S. angustifolium* and *S. warnstorffii* were treated with N deposition rates (0, 10, 30 and 100 kg ha⁻¹ a⁻¹) and with four atmospheric CO₂ concentrations (350, 700, 1000 and 2000 ppm) in greenhouse for 71-120 days. Thereafter, concentrations of total N, P, K, Ca and Mg in the capitulae of the *Sphagna* were determined. The response of each species to N deposition was related to ecological differences. With increasing N deposition treatments, moss N concentrations increased and higher N:P- ratios were found, the increase being especially clear at the highest N load. *Sphagnum fuscum*, which occupies ombrotrophic habitats, was the most affected by the increased nitrogen load and as a consequence the other elements were decreased. Oligotrophic *S. magellanicum*, wide nutrient status tolerant *S. angustifolium* and meso-eutrophic *S. warnstorffii* tolerated better increased N deposition, though there were increased concentrations of Ca and Mg in *S. warnstorffii* and Mg in *S. magellanicum*. Nitrogen and P concentrations decreased with raised CO₂ concentrations, except for *S. magellanicum*. This seems to be the first time this kind of response in nutrient concentrations to enhanced CO₂ concentration has been shown to exist in bryophytes. The concentration of K clearly decreased in *S. fuscum* as did the concentration of Mg in the other *Sphagna* with increasing CO₂. *Sphagnum angustifolium* and *S. magellanicum*, which are the less specialized species, were the least affected by the CO₂ treatments.

Jenkinson, D.S., D.E. Adams, and A. Wild. 1991. Model estimates of CO₂ emissions from soil in response to global warming. *Nature* 351(6324):304-306.

ONE effect of global warming will be to accelerate the decomposition

of soil organic matter, thereby releasing CO₂ to the atmosphere, which will further enhance the warming trend 1- 7. Such a feedback mechanism could be quantitatively important, because CO₂ is thought to be responsible for approximately 55% of the increase in radiative forcing arising from anthropogenic emissions of gases to the atmosphere 8, and there is about twice as much carbon in the top metre of soil as in the atmosphere 9. Here we use the Rothamsted model for the turnover of organic matter in soil 3 to calculate the amount of CO₂ that would be released from the world stock of soil organic matter if temperatures increase as predicted, the annual return of plant debris to the soil being held constant. If world temperatures rise by 0.03-degrees-C yr⁻¹ (the increase considered as most likely by the Intergovernmental Panel on Climate Change 8), we estimate that the additional release of CO₂ from soil organic matter over the next 60 years will be 61 x 10¹⁵ gC. This is approximately 19% of the CO₂ that will be released by combustion of fossil fuel during the next 60 years if present use of fuel continues unabated.

Jiang, W.B., A. Lers, E. Lomaniec, and N. Aharoni. 1999. Senescence-related serine protease in parsley. *Phytochemistry* 50(3):377-382.

During leaf senescence protein degradation is enhanced. In order to obtain information on the enzymes involved in this process, a study was initiated to identify and characterize proteases whose activity is elevated in artificially senescing parsley leaves. A 70-kDa serine protease (EC 3.4.21) was identified by an activity gel assay. This protease activity, which is low in young leaves, was found to increase considerably in parallel to the advance of senescence and the reduction in the protein content of the leaves. A high correlation between the progress of senescence and the increase in the activity of the 70 kDa serine protease was demonstrated. Treatments with CO₂ or gibberellic acid, which retard senescence, reduced the protease's activity, whereas acceleration of senescence with ethylene enhanced it. (C) 1998 Elsevier Science Ltd. Jiao, J., P. Goodwin, and B. Grodzinski. 1999. Inhibition of photosynthesis and export in geranium grown at two CO₂ levels and infected with *Xanthomonas campestris* pv. *Pelargonii*. *Plant, Cell and Environment* 22(1):15-25.

The effects of CO₂ enrichment on growth of *Xanthomonas campestris* pv. *pelargonii* and the impact of infection on the photosynthesis and export of attached, intact, 'source' leaves of geranium (*Pelargonium x domesticum*, 'Scarlet Orbit Improved') are reported. Two experiments were performed, one with plants without flower buds, and another with plants which were flowering. Measurements were made on healthy and diseased leaves at the CO₂ levels (35 Pa or 90 Pa) at which the plants were grown. There were no losses of chlorophyll, or any signs of visible chlorosis or necrosis due to infection. Lower numbers of bacteria were

found in leaves at high CO₂, suggesting growth at elevated CO₂ created a less favourable condition in the leaf for bacterial growth. Although high CO₂ lowered the bacterial number in infected leaves, reductions in photosynthesis and export were greater than at ambient CO₂. The capacity of infected source leaves to export photoassimilates at rates observed in the controls was reduced in both light and darkness. In summary, the severity of infection on source leaf function by the bacteria was increased, rather than reduced by CO₂ enrichment, underscoring the need for further assessment of plant diseases and bacterial virulence in plants growing under varying CO₂ levels.

Jiao, J.R., and B. Grodzinski. 1998. Environmental influences on photosynthesis and carbon export in greenhouse roses during development of the flowering shoot. *Journal of the American Society for Horticultural Science* 123(6):1081-1088.

Photosynthesis and concurrent export rates of expanded leaves on the flowering shoot of *Rosa hybrida* L. 'Samantha' were measured at three stages of shoot and flower bud development. At 35 and 90 Pa CO₂ photosynthesis and concurrent export rates of the upper expanded leaves were greater at Stage 3 (i.e., when petal color of the flower bud was visible) than at the two earlier stages of shoot and flower development. The optimum for leaf photosynthesis and concurrent export at ambient CO₂ and saturating irradiance were approximate to 25 degrees C. Export was more sensitive to increased temperature than was carbon fixation. For example, at 40 degrees C photosynthesis was 40% lower while the export rate during photosynthesis was reduced by 80%. Increasing the photon fluence flux rate from 200 to 1000 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ PAR increased the photosynthetic rate and the concurrent export rate at 35 and 90 Pa CO₂, but the increase in export was proportionally greater than that of photosynthesis. At 35 Pa CO₂, the rate of C export during photosynthesis increased from 31 to 59% of the concurrent C fixation rate. At 90 Pa CO₂, export during photosynthesis increased from 38 to 62% of the photosynthesis rate. The importance of irradiance on translocation processes was further demonstrated by comparing the disappearance of label during the feed period and during an extended night period. Plants grown at each CO₂ level exported about three times as much of the C-14 fixed during a 2-hour feed period in the light as during a subsequent 15-hour dark chase period. The nighttime export and respiration rates of leaves which had been exposed to elevated CO₂ levels during the feed were higher than those rates observed at ambient CO₂. However, at the end of the chase period, the leaves of plants which had been exposed to CO₂ enrichment during the feed also retained more C-14 than did the leaves of the plants which were at ambient CO₂. Thus, although more C-14 was fixed and exported under high CO₂, the same proportion of labelled assimilates were exported, respired, and retained in the dark as at ambient CO₂.

Jiao, J., M.J. Tsujita, and B. Grodzinski. 1991. Influence of radiation and CO₂ enrichment on whole plant net CO₂ exchange in roses. *Canadian Journal of Plant Science* 71(1):245-252.

At three stages of flowering shoot development, varying the irradiance and CO₂ levels had a similar effect on the whole-plant net CO₂ exchange rate (NCER) of Samantha rose plants. At 22-degrees-C, the NCER was saturated at 1000- $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ photosynthetically active

radiation (PAR). The duration of the light period was also important in determining daily carbon (C) gain. When roses were exposed to a constant daily radiant energy dose of 17.6- $\mu\text{mol}\cdot\text{m}^{-2}$ provided either as a 12-h irradiation interval at 410- $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ PAR or 24 h of irradiation at 204- $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$ PAR, the plants exposed to 24 h of continuous irradiation at the lower photon flux density retained 80% more C. Under saturating irradiance, the net photosynthetic rate at an enriched (1000- $\mu\text{L}\cdot\text{L}^{-1}$) CO₂ level was almost double that at ambient (350- $\mu\text{L}\cdot\text{L}^{-1}$) CO₂. However, plants grown at ambient and enriched CO₂ levels had similar whole-plant NCERs when compared at the same assay CO₂ level. Under CO₂ enrichment the flower stem was longer and thicker but the flower bud size at harvest was not significantly different to that of roses grown at the ambient CO₂ level.

Jiao, J., M.J. Tsujita, and B. Grodzinski. 1991. Influence of temperature on net CO₂ exchange in roses. *Canadian Journal of Plant Science* 71(1):235-243.

The effect of temperature on net CO₂ exchange of source and sink tissues of the flowering shoots and of whole plants was examined using single-stemmed Samantha roses. At all stages of shoot development, the optimal temperature range for whole-plant carbon (C) gain at saturating irradiance and ambient CO₂ level was between 20-degrees and 25-degrees-C, narrower than the temperature range for optimal leaf net photosynthesis. Dark respiration increased more dramatically than photosynthesis with temperatures between 15 and 35-degrees-C. At 25-degrees-C, C loss due to respiration from the flower bud at colour bud stage accounted for 45% of the C loss of the flowering shoot. At low irradiance levels (e.g. 200- $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) whole-plant net photosynthesis was greater at 16-degrees than at 22-degrees-C because of a greater reduction in respiration. Lowering the night temperature from 27 to 17-degrees-C also increased daily C gain due to a reduction in the C lost at night. Whole-plant net photosynthesis of plants grown and measured at enriched (1000 +/- 100- $\mu\text{L}\cdot\text{L}^{-1}$) CO₂ was greater than that of plants grown and measured at ambient (350 +/- 50- $\mu\text{L}\cdot\text{L}^{-1}$) level at temperatures between 15-degrees and 35-degrees-C. Furthermore, the optimal temperatures for whole-plant net photosynthesis in CO₂ enrichment was higher than at ambient CO₂ level.

Jifon, J.L., A.L. Friend, and P.C. Berrang. 1995. Species mixture and soil-resource availability affect the root- growth response of tree seedlings to elevated atmospheric CO₂. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 25(5):824-832.

The effects of CO₂ enrichment on root proliferation of loblolly pine (*Pinus taeda* L.) and sweetgum (*Liquidambar styraciflua* L.) seedlings were studied under varied water and nitrogen (N) regimes and in competitive interaction. Seedlings of each species were grown from seed as monocultures or as 50:50 pine- sweetgum mixtures in 22-L pots filled with forest soil. Seedlings were exposed to either ambient (400 ppm) or CO₂-enriched (ambient plus 400 ppm) air for 32 weeks in continuously stirred tank reactors. Detailed sampling of very fine roots (<0.5 mm diam.) showed a general increase (up to 2-fold) in root length density (RLD, $\text{cm}\cdot\text{cm}^{-3}$) with elevated CO₂; however, the effects of CO₂ on RLD differed according to species, culture type, water, and N availability. In monoculture, low water with low N conditions produced the largest RLD responses to elevated CO₂: 75% increase for sweetgum

and 31% increase for pine. In mixed culture, by contrast, the largest RLD responses to CO₂ were observed under high water, high N regimes: pine showed a 110% increase and sweetgum a 96% increase. The total RLD of the standing crop in mixture under elevated CO₂, high water, and high N was 2.6 cm³ compared with 1.6 cm³ in ambient CO₂, with sweetgum accounting for >75% of the total RLD in both cases. These findings suggest that resource-rich rather than resource-poor soil environments could be the circumstances under which belowground interference from sweetgum would intensify in pine-sweetgum mixtures with rising atmospheric CO₂.

Jitla, D.S., G.S. Rogers, S.P. Seneweera, A.S. Basra, R.J. Oldfield, and J.P. Conroy. 1997. Accelerated early growth of rice at elevated CO₂ - Is it related to developmental changes in the shoot apex? *Plant Physiology* 115(1):15-22.

The influence of elevated CO₂ on the development of the shoot apex and on subsequent vegetative growth and grain yield was investigated using rice (*Oryza sativa* L. cv Jarrah) grown in flooded soil at either 350 or 700 µL CO₂ L⁻¹. At 8 d after planting (DAP), elevated CO₂ increased the height and diameter of the apical dome and lengths of leaf primordia and tiller buds but had no effect on their numbers. By 16 DAP, there were five tiller buds in the apex at 700 µL CO₂ L⁻¹ compared with only three tiller buds at 350 µL CO₂ L⁻¹. These changes in development of the shoot apex at high CO₂ were forerunners to faster development of the vegetative shoot at elevated CO₂ between 11 and 26 DAP as evidenced by increases in the relative growth rates of the shoot and tillers. Accelerated development at high CO₂ was responsible for the 42% increase in tiller number at the maximum tillering stage and the 57% enhancement of grain yield at the final harvest. The link between high CO₂ effects on development during the first 15 DAP and final tiller number and grain yield was demonstrated by delaying exposure of plants to high CO₂ for 15 d. The delay totally inhibited the tillering response to high CO₂, and the increase in grain yield of 20% arose from a greater number of grains per panicle. Consequently, it can be concluded that accelerated development in the shoot apex early in development is crucial for obtaining maximum increases in grain yield at elevated atmospheric CO₂ concentrations.

John-McKay, M.E., and B. Colman. 1997. Variation in the occurrence of external carbonic anhydrase among strains of the marine diatom *Phaeodactylum tricornutum* (Bacillariophyceae). *Journal of Phycology* 33(6):988-990.

Eleven different strains of *Phaeodactylum tricornutum* Bohlin were obtained from three culture collections and were examined for the presence of external and internal carbonic anhydrase (CA). Cells of all strains, grown in standing culture at alkaline pH and low dissolved inorganic carbon had internal CA, but only eight were found to have external CA. External CA activity was reduced when cultures were bubbled with air and was completely repressed when they were grown on 5% CO₂. Expression of external CA activity appears to be regulated by CO₂ concentration in the growth medium, but within one species, there appears to be a variation in occurrence of external CA and consequently in the mode of inorganic carbon acquisition.

Johnsen, K.H. 1993. Growth and ecophysiological responses of black spruce seedlings to elevated CO₂ under varied water and nutrient additions. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 23(6):1033-1042.

Two controlled-environment studies examined growth and ecophysiological responses of black spruce (*Picea mariana* (Mill.) B.S.P.) seedlings to elevated CO₂ under varied water and nutrient additions. Growth analyses were conducted followed by measurements of gas exchange, xylem pressure potential and foliar N concentrations. Growth under elevated CO₂ (700 ppm) increased final seedling dry weights by 20-48% compared with seedling growth under ambient CO₂ (350 ppm). Percent increases in seedling dry weight were greater under drought versus well-watered conditions and higher versus lower nutrient additions. Seedlings grown under elevated CO₂ displayed higher water use efficiency than seedlings grown under ambient CO₂. This was apparent based upon instantaneous gas exchange as well as xylem potential pressure measurements. Elevated CO₂-induced stimulation of relative growth rate was greatest shortly after seedling emergence and decreased with increased seedling size. Acclimation of net photosynthesis was observed and was reversible. Analyses using allometric principles indicate net photosynthetic acclimation resulted from: (i) growth-induced nutrient dilution; (ii) a decrease in foliar N levels not owing to dilution; and (iii) a decrease in net photosynthetic activity.

Johnsen, K.H., and J.E. Major. 1998. Black spruce family growth performance under ambient and elevated atmospheric CO₂. *New Forests* 15(3):271-281.

Seedlings from 20 families of black spruce (*Picea mariana* (Mill.) B.S.P.), representing a large range in field productivity, were subjected to a greenhouse retrospective test under ambient (409 ppm - year 1, 384 ppm - year 2) and high (686 ppm - year 1, 711 ppm - year 2) atmospheric CO₂ environments. After one and two growth cycles, seedling height and diameter growth significantly increased under elevated CO₂. At the end of the experiment, seedlings grown under high CO₂ had a mean above-ground dry weight of 48.77 g as compared to 26.36 g for seedlings grown under ambient atmospheric CO₂. Families were a significant source of variation for all growth parameters. Although the family x CO₂ environment interaction was not a statistically significant source of variation in the analysis of variance, the correlation between greenhouse and IS-year field height growth was weaker (r = 0.29, p = 0.2177) under elevated CO₂ compared to ambient CO₂ (r = 0.51, p = 0.0223) following the first growth cycle. However, following the second growth cycle, greenhouse-field correlations were similar between the two CO₂ environments (ambient CO₂: r = 0.55, p

= 0.0115; elevated CO₂: $r = 0.56$, $p = 0.0101$). Thus, with this set of families, growth performance ranking after two years appears relatively stable under ambient and elevated CO₂.

Johnsen, K.H., and J.R. Seiler. 1996. Growth, shoot phenology and physiology of diverse seed sources of black spruce .1. Seedling responses to varied atmospheric CO₂ concentrations and photoperiods. *Tree Physiology* 16(3):367-373.

We conducted a greenhouse experiment to determine: (1) if diverse provenances of black spruce (*Picea mariana* (Mill.) B.S.P.) respond similarly in growth, phenology and physiology to an approximately 300 ppm increase in atmospheric CO₂ concentration, and (2) the influence of photoperiod on both provenance and provenance x CO₂ interaction effects. Seedlings from provenances that originated from the Yukon (63 degrees 34' N, 135 degrees 55' W), British Columbia (58 degrees 47' N, 123 degrees 38' W), Alberta (52 degrees 22' N, 115 degrees 15' W), Newfoundland (50 degrees 54' N, 56 degrees 06' W) and Ontario (48 degrees 59' N, 80 degrees 38' W and 45 degrees 10' N, 77 degrees 10' W) were subjected to growth analysis in greenhouse growth chambers supplied with 712 +/- 93 (SD) ppm CO₂ (elevated) or 394 +/- 59 ppm CO₂ (ambient). Seedlings from Provenances 7000 and 6901 were also subjected to an extended photoperiod treatment and periodically measured for shoot and root gas exchange. In response to a natural photoperiod, southern provenances grew more, broke and set bud later, and partitioned more biomass to shoot versus root than northern provenances. These differences among provenances were influenced by the extended photoperiod treatment but not by the elevated CO₂ treatment. Averaged across all provenances, elevated CO₂ increased seedling final weights by 55%; however, the elevated CO₂ treatment had no effect on the provenance differences in any measured trait. We conclude that the large differences in physiology, phenology and growth among these diverse provenances of black spruce were expressed similarly in both ambient and elevated atmospheric CO₂ concentrations.

Johnson, B.G., B.A. Hale, and D.P. Ormrod. 1996. Carbon dioxide and ozone effects on growth of a legume-grass mixture. *Journal of Environmental Quality* 25(4):908-916.

Atmospheric carbon dioxide (CO₂) and photochemical ozone (O₃) have been increasing in the biosphere and will continue to do so with further industrialization and burning of fossil fuels. The purpose of this study was to examine the interaction of CO₂ and O₃ on plant growth and aboveground competition using a forage mixture of alfalfa (*Medicago sativa* L.) and timothy (*Phleum pratense* L.). Mixtures were grown at two CO₂ levels (350 and 700 µmol/L) in controlled environment chambers and exposed to four weekly O₃ episodes of 8-h duration with peak daily concentrations of 0.03, 0.08, 0.13, or 0.18 µmol/L on Days (d) 21, 28, 35, and 42 after seeding. Roots of individual plants were in separate containers. The plants were harvested 2 d after the final O₃ exposure. Total dry biomass of alfalfa and timothy was 50 and 40%, respectively, greater at 700 than at 350 µmol/L CO₂ with low O₃. Increasing peak O₃ concentration decreased alfalfa shoot dry biomass at 700 µmol/L CO₂ but not at 350 µmol/L and decreased root dry biomass at both CO₂ levels. In timothy, intermediate O₃ levels reduced shoot growth but the highest level of O₃ resulted in more shoot growth in the mixture at both CO₂ levels. Partitioning of dry matter to alfalfa roots was strongly retarded by increasing O₃, particularly in the CO₂-enriched

environment, while timothy root growth was unaffected by O₃. The enhancement of timothy shoot biomass is, the mixture by exposure to the highest level of O₃ at either CO₂ level could not be fully explained by changes in competition between timothy and alfalfa in relation to differential O₃ tolerance.

Johnson, D.W. 1999. Simulated nitrogen cycling response to elevated CO₂ in *Pinus taeda* and mixed deciduous forests. *Tree Physiology* 19(4-5):321-327.

Interactions between elevated CO₂ and N cycling Introduction were explored with a nutrient cycling model (NuCM, Johnson et al. 1993, 1995) for a *Pinus taeda* L. site at Duke University, North Carolina, and a mixed deciduous site at Walker Branch, Tennessee. The simulations tested whether N limitation would prevent growth increases in response to elevated CO₂, and whether growth responses to CO₂ in N-limited systems could be facilitated by increasing the biomass/N ratio (reducing N concentration) or increasing litter N mineralization, or both. Nitrogen limitation precluded additional growth when target growth rates and litterfall were increased (simulating potential response to elevated CO₂) at the Duke University site. At the Walker Branch site, increasing target growth and litterfall caused a 7% increase in growth. Reducing foliar N concentrations reduced growth because of N limitation created by reduced litter quality (C:N ratio), reduced decomposition and increased N accumulation on the forest floor. These effects were most pronounced at the Duke University site, because the forest floor N turnover rate was lower than at the Walker Branch site. Reducing wood N concentration allowed prolonged increases in growth because of greater biomass/N; however, N uptake was reduced, allowing greater N immobilization on the forest floor and in soil. Increased N mineralization caused increased growth at the Duke University site, but not at the Walker Branch site. These simulations pose the counterintuitive hypothesis that increased biogeochemical cycling of N (as a result of increased litterfall N) causes reduced growth in an N-limited system because of increased accumulations of N on the forest floor and in soil. Translocation of N from senescing leaves before litterfall mitigates this response by allowing the trees to retain a greater proportion of N taken up rather than recycle it back to the forest floor and soil where it can be immobilized. Eliminating N translocation at Walker Branch changed the direction as well as the magnitude of the responses in three of the four scenarios simulated. Because the NuCM model does not currently allow translocation in coniferous species, the effects of translocation on N cycling in the Duke University simulations are not known.

Johnson, D.W., and J.T. Ball. 1990. Environmental-pollution and impacts on soils and forests nutrition in north-america. *Water, Air, and Soil Pollution* 54:3-20.

The effects of acid deposition, excess N deposition, and elevated CO₂ on forest soils and nutrition in North America are reviewed. While there remains the possibility that acid deposition and excess N deposition are contributing to declines in red spruce, sugar maple, and southern pines, clear-cut cause and effects are still not evident. Climate is clearly a major factor in red spruce decline in the northeastern U.S., but air pollution may contribute. There is some evidence that soil solution Al may be approaching deleterious levels in southeastern red spruce forests. Lack of proper management may be a major factor in the sugar maple and southern pine declines, but once again, air pollution as a potential

contributor cannot be ignored. Nutrient budget analyses and discoveries of soils base cation depletion in certain sites suggest that base cation status is declining in forests of the southeastern U.S., but thus far, base cation deficiencies are uncommon. Recent research has revealed that there are more cases of N-saturated forests in North America than was previously suspected. These systems are characterized by high rates of soil N mineralization, high atmospheric N inputs, low uptakes, or some combination of these factors. Soil leaching and Al mobilization in such systems is often dominated by nitrate. However, the geographical extent of these types of systems is limited, and the traditional view that most forest ecosystems are N limited remains valid, especially where forest management is intensive. The limited information available on tree response to CO₂ suggests N-deficient plants often grow faster with elevated CO₂, whereas P-deficient plants often do not. Research is needed to 1) determine if the differences in response between N- and P-deficient plants is common, 2) the responses of plants deficient in other nutrients to elevated CO₂, and 3) the interactions of CO₂ increase, nutrient deficiencies, climate change.

Johnson, D.W., J.T. Ball, and R.F. Walker. 1997. Effects of CO₂ and nitrogen fertilization on vegetation and soil nutrient content in juvenile ponderosa pine. *Plant and Soil* 190(1):29-40.

This paper summarizes the data on nutrient uptake and soil responses in open-top chambers planted with ponderosa pine (*Pinus ponderosa* Laws.) treated with both N and CO₂. Based upon the literature, we hypothesized that 1) elevated CO₂ would cause increased growth and yield of biomass per unit uptake of N even if N is limiting, and 2) elevated CO₂ would cause increased biomass yield per unit uptake of other nutrients only by growth dilution and only if they are non-limiting. Hypothesis 1 was supported only in part: there were greater yields of biomass per unit N uptake in the first two years of growth but not in the third year. Hypothesis 2 was supported in many cases: elevated CO₂ caused growth dilution (decreased concentrations but not decreased uptake) of P, S, and Mg. Effects of elevated CO₂ on K, Ca, and B concentrations were smaller and mostly non-significant. There was no evidence that N responded in a unique manner to elevated CO₂, despite its unique role in rubisco. Simple growth dilution seemed to explain nutrient responses in almost all cases. There were significant declines in soil exchangeable K⁺, Ca²⁺, Mg²⁺ and extractable P over time which were attributed to disturbance effects associated with plowing. The only statistically significant treatment effects on soils were negative effects of elevated CO₂ on mineralizable N and extractable P, and positive effects of both N fertilization and CO₂ on exchangeable Al³⁺. Soil exchangeable K⁺, Ca²⁺, and Mg²⁺ pools remained much higher than vegetation pools, but extractable P pools were lower than vegetation pools in the third year of growth. There were also large losses of both native soil N and fertilizer N over time. These soil N losses could account for the observed losses in exchangeable K⁺, Ca²⁺, Mg²⁺ if N was nitrified and leached as NO₃⁻.

Johnson, D.W., T. Ball, and R.F. Walker. 1995. Effects of elevated CO₂ and nitrogen on nutrient-uptake in ponderosa pine-seedlings. *Plant*

and Soil 169:535-545.

This paper reports on the results of a controlled-environment study on the effects of CO₂ (370, 525, and 700 $\mu\text{mol mol}^{-1}$) and N [0, 200, and 400 $\mu\text{g N g soil}^{-1}$] as (NH₄)SO₄] on ponderosa pine (*Pinus ponderosa*) seedlings. Based upon a review of the literature, we hypothesized that N limitations would not prevent a growth response to elevated CO₂. The hypothesis was not supported under conditions of extreme N deficiency (no fertilizer added to a very poor soil), but was supported when N limitations were less severe but still suboptimal (lower rate of fertilization). The growth increases in N-fertilized seedlings occurred mainly between 36 and 58 weeks without any additional N uptake. Thus, it appeared that elevated CO₂ allowed more efficient use of internal N reserves in the previously-fertilized seedlings, whereas internal N reserves in the unfertilized seedlings were insufficient to allow this response. Uptake rates of other nutrients were generally proportional to growth. Nitrogen treatment caused reductions in soil exchangeable K⁺, Ca²⁺, and Mg²⁺ (presumably because of nitrification and NO₃⁻ leaching) but increases in extractable P (presumably due to stimulation of phosphatase activity). The results of this and other seedling studies show that elevated CO₂ causes a reduction in tissue N concentration, even under N-rich conditions. The unique response of N is consistent with the hypothesis that the efficiency of Rubisco increases with elevated CO₂. These results collectively have significant implications for the response of mature, N-deficient forests to elevated CO₂.

Johnson, D., D. Geisinger, R. Walker, J. Newman, J. Vose, K. Elliot, and T. Ball. 1994. Soil pCO₂, soil respiration, and root activity in CO₂-fumigated and nitrogen-fertilized ponderosa pine. *Plant and Soil* 165(1):129-138.

The purpose of this paper is to describe the effects of CO₂ and N treatments on soil pCO₂, calculated CO₂ efflux, root biomass and soil carbon in open-top chambers planted with *Pinus ponderosa* seedlings. Based upon the literature, it was hypothesized that both elevated CO₂ and N would cause increased root biomass which would in turn cause increases in both total soil CO₂ efflux and microbial respiration. This hypothesis was only supported in part: both CO₂ and N treatments caused significant increases in root biomass, soil pCO₂, and calculated CO₂ efflux, but there were no differences in soil microbial respiration measured in the laboratory. Both correlative and quantitative comparisons of CO₂ efflux rates indicated that microbial respiration contributes little to total soil CO₂ efflux in the field. Measurements of soil pCO₂ and calculated CO₂ efflux provided inexpensive, non-invasive, and relatively sensitive indices of belowground response to CO₂ and N treatments.

Johnson, D.W., R.B. Thomas, K.L. Griffin, D.T. Tissue, J.T. Ball, B.R. Strain, and R.F. Walker. 1998. Effects of carbon dioxide and nitrogen on growth and nitrogen uptake in ponderosa and loblolly pine. *Journal of Environmental Quality* 27(2):414-425.

The purpose of this paper is to summarize the results of a series of greenhouse and open-top chamber studies on the effects of N and elevated atmospheric CO₂ on ponderosa and loblolly pine (*Pinus ponderosa* Laws, and *P. taeda* L.) to evaluate common patterns of

response. Growth response to elevated CO₂ ranged from zero to more than 1000%, depending largely upon N status. In both species, growth response to CO₂ was greater under moderate N deficiency than under extreme N deficiency or N sufficiency/excess. Elevated CO₂ generally caused lowered tissue N concentrations in many (but not all) cases, which in turn resulted in smaller increases in N uptake than in biomass. Growth response to N ranged from -50 (in ponderosa pine) to more than 1000%, depending upon the N status of the control medium. Growth response to N was enhanced by elevated CO₂ when N was in the extreme deficiency range but not when N was in the moderate deficiency range. In two separate studies, ponderosa pine responded negatively to high N inputs, and in each case this response was mitigated by elevated CO₂. Collectively, these results show that (i) N deficiency is a continuum rather than a step function, (ii) responses to elevated CO₂ vary across this continuum of N deficiency, and (iii) elevated CO₂ greatly enhances growth response to N additions when N is initially in the extremely deficient range.

Johnson, D.W., R.F. Walker, and J.T. Ball. 1995. Combined effects of nitrogen and elevated CO₂ on soils from controlled environment studies. *Water, Air, and Soil Pollution* 85(3):1551-1556.

This paper describes the effects of elevated CO₂ and N fertilization on soils planted with ponderosa pine (*Pinus Ponderosa*) seedlings in short-term greenhouse studies. The high degree of homogeneity in the soils used allowed sensitive evaluation of soil changes in response to treatments. Elevated CO₂ had no detectable effect upon soil N availability, but both CO₂ and N fertilization caused significant changes in soil available (NH₄F/HCl-extractable) P. Some of these changes could be accounted for by plant uptake, some were apparently due to differences in P immobilization (biotic or abiotic). N fertilization caused reductions in exchangeable K, Ca and Mg which could not be accounted for by plant uptake and were probably due to increased leaching. None of the reductions in soil available nutrients observed were of sufficient magnitude to cause nutrient deficiencies over the approximate 1-year duration of these studies.

Johnson, D.W., R.F. Walker, and J.T. Ball. 1995. Lessons from lysimeters - soil N release from disturbance compromises controlled environment study. *Ecological Applications* 5(2):395-400.

A controlled environment study of the effects of carbon dioxide (CO₂) and nitrogen (N) on growth of ponderosa pine seedlings produced results contradictory to those obtained in the field with the same species, soil, and treatments. In the controlled environment study, there was a significant negative growth response to N fertilization, whereas in the field there was a significant positive response to N. The difference was due to high rates of native N mineralization after soil disturbance during potting. This was evident from soil solution NO₃⁻ concentrations that peaked at approximately 5000 µmol/L in the unfertilized pots and 20 000 µmol/L in the fertilized pots. These concentrations are orders of magnitude greater than those typically observed in the field. The effects of soil disturbance on N mineralization and nitrification need to be carefully considered before initiating controlled environment studies. The results of this study show that excessive N mineralization caused by soil disturbance can seriously compromise the results of controlled environment studies

Johnson, H.B., H.W. Polley, and H.S. Mayeux. 1993. Increasing CO₂ and plant-plant interactions - effects on natural vegetation. *Vegetatio* 104:157-170.

Plant species and functional groups of species show marked differences in photosynthesis and growth in relation to rising atmospheric CO₂ concentrations through the range of the 30 % increase of the recent past and the 100 % increase since the last glaciation. A large shift was found in the compositional mix of 26 species of C₃'s and 17 species of C₄'s grown from a native soil seed bank in a competitive mode along a CO₂ gradient that approximated the CO₂ increase of the past 150 years and before. The biomass of C₃'s increased from near zero to 50 % of the total while that of the C₄'s was reduced 25 % as CO₂ levels approached current ambient. The proposition that acclimation to rising CO₂ will largely negate the fertilization effect of higher CO₂ levels on C₃'s is not supported. No signs of photosynthetic acclimation were evident for *Avena sativa*, *Prosopis glandulosa*, and *Schizachyrium scoparium* plants grown in subambient CO₂. The effects of changing CO₂ levels on vegetation since the last glaciation are thought to have been at least as great, if not greater, than those which should be expected for a doubling of current CO₂ levels. Atmospheric CO₂ concentrations below 200 ppm are thought to have been instrumental in the rise of the C₄ grasslands of North America and other extensive C₄ grasslands and savannas of the world. Dramatic invasion of these areas by woody C₃ species are accompanying the historical increase in atmospheric CO₂ concentration now in progress.

Johnson, L.C., G.R. Shaver, A.E. Giblin, K.J. Nadelhoffer, E.R. Rastetter, J.A. Laundre, and G.L. Murray. 1996. Effects of drainage and temperature on carbon balance of tussock tundra microcosms. *Oecologia* 108(4):737-748.

We examined the importance of temperature (7 degrees C or 15 degrees C) and soil moisture regime (saturated or field capacity) on the carbon (C) balance of arctic tussock tundra microcosms (intact blocks of soil and vegetation) in growth chambers over an 81-day simulated growing season. We measured gaseous CO₂ exchanges, methane (CH₄) emissions, and dissolved C losses on intact blocks of tussock (*Eriophorum vaginatum*) and in tussock (moss-dominated). We hypothesized that under increased temperature and/or enhanced drainage, C losses from ecosystem respiration (CO₂ respired by plants and heterotrophs) would exceed gains from gross photosynthesis causing tussock tundra to become a net source of C to the atmosphere. The field capacity moisture regime caused a decrease in net CO₂ storage (NEP) in tussock tundra microcosms. This resulted from a stimulation of ecosystem respiration (probably mostly microbial) with enhanced drainage, rather than a decrease in gross photosynthesis. Elevated temperature alone had no effect on NEP because CO₂ losses from increased ecosystem respiration at elevated temperature were compensated by increased CO₂ uptake (gross photosynthesis). Although CO₂ losses from ecosystem respiration were primarily limited by drainage, CH₄ emissions, in contrast, were dependent on temperature. Furthermore, substantial dissolved C losses, especially organic C, and important microhabitat differences must be considered in estimating C balance for the tussock tundra system. As much as similar to 20% of total C fixed in photosynthesis was lost as dissolved organic C. Tussocks

stored similar to 2x more C and emitted 5x more methane than intertussocks. In spite of the limitations of this microcosm experiment, this study has further elucidated the critical role of soil moisture regime and dissolved C losses in regulating net C balance of arctic tussock tundra.

Johnson, R.H., and D.E. Lincoln. 1991. Sagebrush carbon allocation patterns and grasshopper nutrition - the influence of CO₂ enrichment and soil mineral limitation. *Oecologia* 87(1):127-134.

Artemisia tridentata seedlings were grown under carbon dioxide concentrations of 350 and 650- μ l l⁻¹ and two levels of soil nutrition. In the high nutrient treatment, increasing CO₂ led to a doubling of shoot mass, whereas nutrient limitation completely constrained the response to elevated CO₂. Root biomass was unaffected by any treatment. Plant root/shoot ratios declined under carbon dioxide enrichment but increased under low nutrient availability, thus the ratio was apparently controlled by changes in carbon allocation to shoot mass alone. Growth under CO₂ enrichment increased the starch concentrations of leaves grown under both nutrient regimes, while increased CO₂ and low nutrient availability acted in concert to reduce leaf nitrogen concentration and water content. Carbon dioxide enrichment and soil nutrient limitation both acted to increase the balance of leaf storage carbohydrate versus nitrogen (C/N). The two treatment effects were significantly interactive in that nutrient limitation slightly reduced the C/N balance among the high-CO₂ plants. Leaf volatile terpene concentration increased only in the nutrient limited plants and did not follow the overall increase in leaf C/N ratio. Grasshopper consumption was significantly greater on host leaves grown under CO₂ enrichment but was reduced on leaves grown under low nutrient availability. An overall negative relationship of consumption versus leaf volatile concentration suggests that terpenes may have been one of several important leaf characteristics limiting consumption of the low nutrient hosts. Digestibility of host leaves grown under the high CO₂ treatment was significantly increased and was related to high leaf starch content. Grasshopper growth efficiency (ECI) was significantly reduced by the nutrient limitation treatment but co-varied with leaf water content.

Johnston, K.M., and O.J. Schmitz. 1997. Wildlife and climate change: Assessing the sensitivity of selected species to simulated doubling of atmospheric CO₂. *Global Change Biology* 3(6):531-544.

We explored, using computer simulations, the sensitivity of four mammal species (elk, *Cervus canadensis*; white-tailed deer, *Odocoileus virginianus*; Columbian ground squirrel, *Spermophilus columbianus*; and chipmunk, *Tamias striatus*) within the continental USA to the effect of anticipated levels of global climate change brought about by a doubling of atmospheric CO₂. Sensitivity to the direct effects of climate change were evaluated using a climate-space approach to delineate the range of thermal conditions tolerable by each species. Sensitivity to indirect effects were evaluated by quantifying the association of each species to the current vegetation distribution within the continental USA and using this association to assess whether wildlife species distributions might shift in response to vegetation shifts under climate change. Results

indicate that altered thermal conditions alone should have little or no effect on the wildlife species' distributions as physiological tolerance to heat load would allow them to survive. Analyses of the effects of vegetation change indicate that deer and chipmunks should retain their current distributions and possibly expand westward in the USA. For Elk and ground squirrels, there is a possibility that their current distributions would shrink and there is little possibility that each species would spread to new regions. This work emphasizes that the distributions of the four mammalian species are likely to be influenced more by vegetation changes than by thermal conditions. Future efforts to understand the effects of global change on wildlife species should focus on animal-habitat and climate-vegetation linkages.

Joles, D.W., A.C. Cameron, A. Shirazi, P.D. Petracek, and R.M. Beaudry. 1994. Modified-atmosphere packaging of heritage red raspberry fruit - respiratory response to reduced oxygen, enhanced carbon- dioxide, and temperature. *Journal of the American Society for Horticultural Science* 119(3):540-545.

'Heritage' raspberries (*Rubus idaeus* L.) were sealed in low- density polyethylene packages and stored at 0, 10, and 20C during Fall 1990 and 1991 to study respiratory responses under modified atmospheres. A range of steady-state O₂ and CO₂ partial pressures were achieved by varying fruit weight in packages of a specific surface area and film thickness. Film permeability to O₂ and CO₂ was measured and combined with surface area and film thickness to estimate total package permeability. Rates of O₂ uptake and CO₂ production and respiratory quotient (RQ) were calculated using steady-state O₂ and CO₂ partial pressures, total package permeability, and fruit weight. The O₂ uptake rate decreased with decreasing O₂ partial pressure over the range of partial pressure studied. The Michaelis-Menten equation was used to model O₂ uptake as a function of O₂ partial pressure and temperature. The apparent K(m) (K_{1/2}) remained constant (5.6 kPa O₂) with temperature, while Q₁₀ was estimated to be 1.9. RQ was modeled as a function of O₂ partial pressure and temperature. Headspace ethanol increased at RQs >1.3 to 1.5. Based on RQ, ethanol production, and flavor, we recommend that raspberries be stored at O₂ levels above 4 kPa at 0C, 6 kPa at 10C, and 8 kPa at 20C. Steady-state CO₂ partial pressures of 3 to 17 kPa had little or no effect on O₂ uptake or headspace ethanol partial pressures at 20C.

Jones, C.G., and S.E. Hartley. 1999. A protein competition model of phenolic allocation. *Oikos* 86(1):27-44.

We present a Protein Competition Model (PCM) for predicting total phenolic allocation and concentration in leaves of terrestrial higher plants. In contrast to predictions based on the carbon composition of end products, the PCM is based on metabolic origins of pathway constituents, alternative fates of pathway precursors, and biochemical regulatory mechanisms. Protein and phenolic synthesis compete for the common, limiting resource phenylalanine, so protein and phenolic allocation are inversely correlated. Phenolic allocation can be predicted from the effects of development, inherent growth rate and environment on leaf functions that create competing demands for proteins or phenolics. We present the model general principles. We predict phenolic concentrations as leaves develop; in inherently fast versus slow growing species; and in response to the environment (nitrogen, light, phosphorus, heat shock, herbivore and pathogen injury, and carbon dioxide). Because

predictions generally fit observed patterns, we argue that, for phenylalanine-derived phenolics, the mechanistically distinctive PCM complements the Growth Differentiation and Resource Availability Hypotheses, and is a viable, testable alternative to the Carbon Nutrient Balance Hypothesis.

Jones, M.B., J.C. Brown, A. Raschi, and F. Miglietta. 1995. The effects on arbutus-unedo L of long-term exposure to elevated CO₂. *Global Change Biology* 1(4):295-302.

Arbutus unedo is a sclerophyllous evergreen, characteristic of Mediterranean coastal scrub vegetation. In Italy, trees of A. unedo have been found close to natural CO₂ vents where the mean atmospheric carbon dioxide concentration is about 2200 $\mu\text{mol mol}^{-1}$. Comparisons were made between trees growing in elevated and ambient CO₂ concentrations to test for evidence of adaptation to long-term exposure to elevated CO₂. Leaves formed at elevated CO₂ have a lower stomatal density and stomatal index and higher specific leaf area than those formed at ambient CO₂, but there was no change in carbon to nitrogen ratios of the leaf tissue. Stomatal conductance was lower at elevated CO₂ during rapid growth in the spring. In mid-summer, under drought stress, stomatal closure of all leaves occurred and in the autumn, when stress was relieved, the conductance of leaves at both elevated and ambient CO₂ increased. In the spring, the stomatal conductance of the new flush of leaves at ambient CO₂ was higher than the leaves at elevated CO₂, increasing instantaneous water use efficiency at elevated CO₂. Chlorophyll fluorescence measurements suggested that elevated CO₂ provided some protection against photoinhibition in mid-summer. Analysis of A/C-i curves showed that there was no evidence of either upward or downward regulation of photosynthesis at elevated CO₂. It is therefore anticipated that A. unedo will have higher growth rates as the ambient CO₂ concentrations increase.

Jones, M.B., and M. Jongen. 1996. Sensitivity of temperate grassland species to elevated atmospheric CO₂ and the interaction with temperature and water stress. *Agricultural and Food Science in Finland* 5(3):271-283.

The annual cycle of growth of many temperate grasses is limited by low temperatures during the winter and spring and water stress during the summer. Climate change, induced by increase in the concentration of greenhouse gases in the atmosphere, can affect the growth and community structure of temperate grasslands in two ways. The first is directly through changes in atmospheric concentration of CO₂ and the second is indirectly through changes in temperature and rainfall. At higher latitudes, where growth is largely temperature limited, it is probable that the direct effects of enhanced CO₂ will be less than at low latitudes. However, interactions with increasing temperature and water stress are complex. Temperate grasslands range from intensively managed monocultures of sown species to species-rich natural and semi-natural communities whose local distributions are controlled by variations in soil type and drainage. The different species can show marked differences in their responses to increasing CO₂ concentrations,

rising temperatures and water stress. This will probably result in major alterations in the community structure of temperate grasslands in the future. In addition to impacts on primary productivity and community structure, a long-term effect of elevated CO₂ on grasslands is likely to be a significant increase in soil carbon storage. However, this may be counteracted by increases in temperature.

Jones, M.B., M. Jongen, and T. Doyle. 1996. Effects of elevated carbon dioxide concentrations on agricultural grassland production. *Agricultural and Forest Meteorology* 79(4):243-252.

Open-top chambers have been used on a field-grown perennial ryegrass (*Lolium perenne*) sward to investigate the long-term responses to elevated CO₂ concentrations. A concentration of 2 x ambient CO₂ increased annual harvestable yield by about 20%, but the proportional stimulation was not constant throughout the growing season nor from one season to the next. Other effects of elevated CO₂ were an increase in carbon/nitrogen ratio of tissues and a decrease in specific leaf area and canopy conductance. There was no effect of CO₂ on the digestibility of the harvested grass. It is likely that climate change during the next century will lead to significant increases in agricultural grassland production in northern Europe. Production will be stimulated by a direct fertiliser effect due to the increasing CO₂ concentration of the atmosphere.

Jones, M.H., J.T. Fahnestock, D.A. Walker, M.D. Walker, and J.M. Welker. 1998. Carbon dioxide fluxes in moist and dry arctic tundra during season: Responses to increases in summer temperature and winter snow accumulation. *Arctic and Alpine Research* 30(4):373-380.

Climate-induced environmental changes are likely to have pronounced impacts on CO₂ flux patterns in arctic ecosystems. We initiated a long-term experiment in 1994 in moist tussock and dry heath tundra in arctic Alaska in which we increased summer air temperature (ca. 2 degrees C) and increased winter snow accumulation (shortening the growing season approximately 4 wk). During the 1996 snow-free season, we measured ecosystem CO₂ flux weekly in order to quantify net carbon gain or loss from these systems. Over the duration of the snow-free season, both dry heath and moist tussock tundra exhibited a net loss of carbon to the atmosphere, ranging from 12 to 81 g C m⁻² depending upon experimental treatment. Elevated summer temperatures accelerated net CO₂ loss rates over ambient temperatures in both deep and ambient snow treatments, and increased the total amount of carbon emitted during the snow-free season by 26 to 38% in ambient snow plots and by 112 to 326% in deep snow plots. Increased snow accumulation had less impact on CO₂ flux than did warming, and snow effects on total carbon loss were not consistent between the two temperature regimes. Ecosystem respiration exceeded assimilation on most sampling dates throughout the season. These data, coupled with winter carbon losses recently demonstrated in the same ecosystems, indicate that the moist and dry arctic ecosystems we examined are currently net sources of atmospheric carbon on an annual basis, and that anticipated global warming may increase carbon losses from these systems.

Jones, M.H., S.E. Macdonald, and G.H.R. Henry. 1999. Sex- and habitat-specific responses of a high arctic willow, *Salix arctica*, to experimental climate change. *Oikos* 87(1):129-138.

Dioecious plant species and those occupying diverse habitats may present special analytical problems to researchers examining effects of climate change. Here we report the results from two complementary studies designed to determine the importance of sex and habitat on gas exchange and growth of male and female individuals of a dioecious, circumpolar willow, *Salix arctica*, in the Canadian High Arctic. In field studies, male and female willows from dry and wet habitats were subjected to passively enhanced summer temperature (similar to 1.3 degrees C) using small open-top chambers over three years. Peak season gas exchange varied significantly by willow sex and habitat. Overall net assimilation was higher in the dry habitat than in the wet, and higher in females than in males. In the dry habitat, net assimilation of females was enhanced by experimental warming, but decreased in males. In the wet habitat, net assimilation of females was substantially depressed by experimental warming, while males showed an inconsistent response. Development and growth of male and female catkins were enhanced by elevated temperature more than leaf fascicles, but leaf fascicle development and growth varied more between the two habitats, particularly in males. In a controlled environment study, male and female willows from these same wet and dry habitats were grown in a 2x2 factorial experiment including 1 x or 2 x ambient [CO₂] and 5 or 12 degrees C. The sexes responded very differently to the experimental treatments, but we found no effect of original habitat. Net assimilation in males was affected by the interaction of temperature and CO₂, but in females by CO₂ only. Our results demonstrate (a) significant intraspecific and intersexual differences in arctic willow physiology and growth, (b) that these differences are affected by environmental conditions expected to accompany global climate change, and (c) that sex- and habitat-specific responses should be explicitly accounted for in studies of dioecious species.

Jones, P., L.M. Collins, and K.T. Ingram. 1995. Open-top chambers for field studies of crop response to elevated CO₂ and temperature. *Transactions of the Asae* 38(4):1195-1201.

A new design for Open Top Chambers (OTCs) is described. In addition to providing CO₂ controls as do several other existing OTCs, the system is designed to provide elevated temperature control. To provide a more natural vertical microclimate profile, the newly designed system pulls air down through the chamber and out the bottom rather than injecting air at the bottom and venting it out the top of the chamber. A prototype was constructed and performance tests were conducted. Over a 24-h test period with a CO₂ concentration setpoint of 660 ppm, individual measurements of concentration taken every 5 min averaged 660.5 ppm with a standard deviation of 26.6 ppm. Temperature controls were tested over 24-h periods for two different setpoints-ambient +4 degrees C and ambient +6 degrees C. For the two test periods the average chamber temperature measurements were 3.98 degrees and 5.99 degrees C above ambient, respectively. Twenty chambers based on the prototype design were constructed and installed at the International Rice Research Institute, Los Banos, Philippines. As intended, the chambers are currently being used to conduct research on rice crop response to elevated CO₂ and temperature.

Jones, T.H., L.J. Thompson, J.H. Lawton, T.M. Bezemer, R.D. Bardgett, T.M. Blackburn, K.D. Bruce, P.F. Cannon, G.S. Hall, S.E. Hartley, G. Howson, C.G. Jones, C. Kampichler, E. Kandeler, and D.A. Ritchie. 1998. Impacts of rising atmospheric carbon dioxide on model terrestrial ecosystems. *Science* 280(5362):441-443.

In model terrestrial ecosystems maintained for three plant generations at elevated concentrations of atmospheric carbon dioxide, increases in photosynthetically fixed carbon were allocated below ground, raising concentrations of dissolved organic carbon in soil. These effects were then transmitted up the decomposer food chain. Soil microbial biomass was unaffected, but the composition of soil fungal species changed, with increases in rates of cellulose decomposition. There were also changes in the abundance and species composition of Collembola, fungal-feeding arthropods. These results have implications for long-term feedback processes in soil ecosystems that are subject to rising global atmospheric carbon dioxide concentrations.

Jongen, M., P. Fay, and M.B. Jones. 1996. Effects of elevated carbon dioxide and arbuscular mycorrhizal infection on *Trifolium repens*. *New Phytologist* 132(3):413-423.

Trifolium repens L. cv. aran was grown for 58 d at ambient (350 µmol mol⁻¹) and elevated (700 µmol mol⁻¹) atmospheric CO₂, with and without the arbuscular mycorrhizal fungus *Glomus mosseae* (Nicol. & Gerd.) Gerd. St Trappe cv. YV. Plant biomass, mycorrhizal infection, non-structural carbohydrates, C, N and P content were examined. Elevated CO₂ (a) significantly increased above- and below-ground biomass, (b) decreased specific leaf area and specific root length, (c) decreased tissue %N and increased the C:N ratio, and (d) significantly increased total non-structural carbohydrates. Inoculating *T. repens* with *Glomus mosseae* (a) significantly increased above- and below-ground biomass, (b) increased the total root length and total leaf area, and (c) significantly decreased tissue %P. Evidence of an increased influence of mycorrhiza on the P nutrition of *T. repens* at elevated CO₂ was found in the 22% increase in leaf total P (P less than or equal to 0.05) of mycorrhizal plants grown at elevated CO₂ compared with nonmycorrhizal plants. No significant interactions were found between CO₂ and mycorrhiza treatments. The proportion of *T. repens* root length colonized by *Glomus mosseae* was not affected by CO₂ concentration. The percentage mycorrhizal infection was 29% at ambient CO₂ and 35% at elevated CO₂. However, exposure to elevated CO₂ significantly increased the total mycorrhizal root length from 3.4 to 6.1 m per plant. The results show little evidence that the role of arbuscular mycorrhiza in the growth and nutrition of *T. repens* would increase if atmospheric CO₂ were to increase as predicted.

Jongen, M., and M.B. Jones. 1998. Effects of elevated carbon dioxide on plant biomass production and competition in a simulated neutral grassland community. *Annals of Botany* 82(1):111-123.

Using open-top chambers, four prominent species (*Lolium perenne*, *Cynosurus cristatus*, *Holcus lanatus* and *Agrostis capillaris*) of Irish neutral grasslands were grown at ambient and elevated (700 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ for a period of 8 months. The effects of interspecific competition on plant responses to CO₂ enrichment were investigated by growing the species in a four-species mixture. The results indicate that the species differ in their ability to respond to elevated CO₂. CO₂-enrichment had the largest effect on the biomass production of *H. lanatus*, but substantial stimulations in biomass production were also found for the other three species. The CO₂-stimulation of biomass production for *H. lanatus* was accompanied by increased tillering. In addition, reductions in specific leaf area were found for all species. Exposure to elevated CO₂ increased the community biomass of the four-species mixture. This increase can be mainly attributed to a significant increase in the biomass of *H. lanatus* at elevated CO₂. No statistically-significant changes in species composition of community biomass were found. However, *H. lanatus* did increase its share of community biomass at each of the harvests, with the other three species, mainly *L. perenne*, suffering losses in their shares at elevated CO₂. The results show that: (1) the species varied in their response to elevated CO₂; and (2) species composition in natural plant communities is likely to change at elevated CO₂, but these changes may occur rather slowly. Much longer periods of exposure to elevated atmospheric CO₂ may be required to permit detection of significant changes in species composition. (C) 1998 Annals of Botany Company.

Jongen, M., M.B. Jones, T. Hebeisen, H. Blum, and G. Hendrey. 1995. The effects of elevated CO₂ concentrations on the root-growth of *lolium-perenne* and *trifolium-repens* grown in a FACE system. *Global Change Biology* 1(5):361-371.

Lolium perenne and *Trifolium repens* were grown in a Free Air CO₂ Enrichment (FACE) system at elevated (600 $\mu\text{mol mol}^{-1}$) and ambient (340 $\mu\text{mol mol}^{-1}$) carbon dioxide concentrations during a whole growing season. Using a root ingrowth bag technique the extent to which CO₂ enrichment influenced the growth of *L. perenne* and *T. repens* roots under two contrasting nutrient regimes was examined. Root ingrowth bags were inserted for a fixed time into the soil in order to trap roots. It was also possible to follow the mortality of roots in bags inserted for different time intervals. Root ingrowth of both *L. perenne* and *T. repens* increased under elevated CO₂ conditions. In *L. perenne*, root ingrowth decreased with increasing nutrient fertilizer level, but for *T. repens* the root ingrowth was not affected by the nutrient application rate. Besides biomass measurements, root length estimates were made for *T. repens*. These showed an increase under elevated CO₂ concentrations. Root decomposition appeared to decrease under elevated CO₂ concentrations. A possible explanation for this effect is the observed changes in tissue composition, such as the increase in the carbon:nitrogen ratio in roots of *L. perenne* at elevated CO₂ concentrations.

Jordan, D.N., S.F. Zitzer, G.R. Hendrey, K.F. Lewin, J. Nagy, R.S. Nowak, S.D. Smith, J.S. Coleman, and J.R. Seeman. 1999. Biotic, abiotic and performance aspects of the Nevada Desert Free-Air CO₂ Enrichment (FACE) Facility. *Global Change Biology* 5(6):659-668.

Arid and semiarid climates comprise roughly 40% of the earth's terrestrial surface. Deserts are predicted to be extremely responsive to global change because they are stressful environments where small absolute changes in water availability or use represent large proportional changes. Water and carbon dioxide fluxes are inherently coupled in plant growth. No documented global change has been more substantial or more rapid than the increase in atmospheric CO₂. Free Air CO₂ Enrichment (FACE) technology permits manipulation of CO₂ in intact communities without altering factors such as light intensity or quality, humidity or wind. The Nevada Desert FACE Facility (NDFF) consists of three 491 m² plots in the Mojave Desert receiving 550 $\mu\text{mol L}^{-1}$ CO₂, and six ambient plots to assess both CO₂ and fan effects. The shrub community was characterized as a *Larrea-Ambrosia-Lycium* species complex. Data are reported through 12 months of operation.

Julkunentiitto, R., J. Tahvanainen, and J. Silvola. 1993. Increased CO₂ and nutrient status changes affect phytomass and the production of plant defensive secondary chemicals in *salix-myrsinifolia* (salix). *Oecologia* 95(4):495-498.

The effect of CO₂ enrichment (700 and 1050 ppm) on phytomass, soluble sugars, leaf nitrogen and secondary chemicals of three *Salix myrsinifolia* clones was studied in plants cultivated at very poor (sand seedlings) and moderate (peat seedlings) nutrient availability and under low illumination. The total shoot phytomass production of sand seedlings was less than 10% of that of the peat seedlings. Carbon dioxide increased the total shoot phytomass of peat seedlings. When the ambient carbon supply was doubled (to 700 ppm) the growth of sand seedlings was slightly enhanced but 1050 ppm CO₂ gave growth figures similar to those at the control CO₂ level. Leaf nitrogen content and total soluble sugar contents were significantly higher in peat seedlings than in sand seedlings. Leaf nitrogen showed a decreasing trend in relation to CO₂ increase. On the other hand, CO₂ did not have any clear-cut effect on total sugars. At the control CO₂ level the content of salicortin, which is a dynamic phenolic, was higher in the peat seedlings than in the sand seedlings, but salicin showed the opposite trend. CO₂ enrichment considerably decreased these phenolics in the peat seedlings. At the control CO₂ level, the content of more static phenolics, such as proanthocyanidins, was higher in sand seedlings. An increased carbon supply considerably increased static phenolics in the peat seedlings. Willow defence against generalist herbivores is moderately decreased by enhancement of atmospheric carbon dioxide.

Kainulainen, P., J.K. Holopainen, and T. Holopainen. 1998. The influence of elevated CO₂ and O₃ concentrations on Scots pine needles: changes in starch and secondary metabolites over three exposure years. *Oecologia* 114(4):455-460.

Scots pine (*Pinus sylvestris* L.) trees, aged about 20 years old, growing on a natural pine heath were exposed to two concentrations of CO₂ (ambient CO₂ and double-ambient CO₂) and two O₃ regimes (ambient O₃ and double-ambient O₃) and their combination in open-top chambers during growing seasons 1994, 1995 and 1996. Concentrations of foliar starch and secondary compounds are reported in this paper. Starch concentrations remained unaffected by elevated CO₂ and/or O₃ concentrations during the first 2 study years. But in the autumn of the last study year, a significantly higher concentration of starch was found in current-year needles of trees exposed to elevated CO₂ compared with ambient air. There were large differences in concentrations of starch and

secondary compounds between individual trees. Elevated concentrations of CO₂ and/or O₃ did not have any significant effects on the concentrations of foliar total monoterpenes, total resin acids or total phenolics. Significantly higher concentrations of monoterpenes and resin acids and mostly lower concentrations of starch were found in trees growing without chambers than in those growing in open-top chambers, while there were no differences in concentrations of total phenolics between trees growing without or in chambers. The results suggest that elevated concentrations of CO₂ might increase foliar starch concentrations in Scots pine, while secondary metabolites remain unaffected. Realistically elevated O₃ concentrations do not have clear effects on carbon allocation to starch and secondary compounds even after 3 exposure years.

Kajfezbogataj, L., and A. Hocevar. 1994. Assessment of climate-change effects on productivity of beech stand in slovenia using simulation methods. *Agricultural and Forest Meteorology* 72(1-2):47-56.

On the basis of observed climatic trends in Slovenia obtained from 142 years of meteorological observation in Ljubljana (Slovenia) 15 climatic scenarios for the next 60 years are constructed regarding temperature rise and various levels of increasing CO₂ concentration. Yearly gross primary production of 80 year old beech stand (*Fagus sylvatica*) is simulated in daily scale by the PERUN 3 model for healthy trees assuming no water stress. The influence of increased CO₂ concentration on physiological processes is assessed over enhanced maximal photosynthesis, lower compensation point and increased stomatal resistance. Results of the simulation, giving decreased primary production of beech stand under the mentioned assumption, are discussed.

Kaji, H., M. Ueno, T. Ikebe, and Y. Osajima. 1993. Effects of low o₂ and elevated co₂ concentrations on the quality of matsutake [*tricholoma-matsutake* (s ito et imai) sing] during storage. *Bioscience Biotechnology and Biochemistry* 57(3):363-366.

Matsutake [*Tricholoma matsutake* (S. ITO et IMAI) SING.] was stored under conditions of low O₂ and elevated CO₂ concentrations. The storage conditions were as follows: with an O₂ concentration of 2.5+/-0.5%, the CO₂ concentrations were 5%, 10%, 15%, and 20%, and relative humidity (RH) was about 100%; with an O₂ concentration of 2.0+/-0.5%, the CO₂ concentrations were 0%, 5%, 10%, and 15%, and RH was about 100%; the storage temperature was 1.0+/-0.1-degrees-C. The fruit was also stored in air and under 100% N₂ as controls. Quality factors such as 'neto' (slimy microbial flora which develop on the moist surface of the fruiting body), weight loss, whiteness, firmness, and off-odor were measured. The development of neto and browning (loss of whiteness) of the inner stipe were suppressed for more than 14 days, except with storage under 100% N₂. Storage in air and under 0% or a high concentration (> 10%) of CO₂ caused an early development of off-odor, compared to storage under 5% and 10% CO₂. In air, the development of mold was observed after 14 days. Under a low O₂ concentration and 5% to 10% CO₂, the quality factors of matsutake were most retained, and the fruit was still acceptable after 14 days of storage. A weight decrease of the fruit was recognized as the CO₂ concentration was increased.

Kalina, J., and R. Ceulemans. 1997. Clonal differences in the response of dark and light reactions of photosynthesis to elevated atmospheric CO₂ in poplar. *Photosynthetica* 33(1):51-61.

Two hybrid poplar (*Populus*) clones (i.e., fast growing clone Beaupre and slow growing clone Robusta) were grown for two years from cuttings at close spacings in open top chambers (OTCs) under ambient (AC) and elevated [EC = AC + 350 μ mol(CO₂) mol(-1)] CO₂ treatments. For clone Beaupre no down-regulation of photosynthesis was observed. Two years of growing under EC resulted in an increase in quantum yield of photosystem 2 (PS2), steady state irradiance saturated rate of net photosynthesis (P-Nmax), chlorophyll (Chl) content, and ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBPC) activity for this clone. We suppose that under nonlimiting conditions of nitrogen and phosphorus content the response to EC was by building up light-harvesting complexes of PS2 and increasing photochemical efficiency of PS2. Due to a high rate of the primary reactions of photosynthesis and a high RuBPCO activity the end product of the response to EC was an increase in P-Nmax and a larger saccharides content. The Robusta clone showed a depression in the primary reactions of photosynthesis under EC. We found a decrease in quantum yield of PS2, Chl and phosphorus contents, and in RuBPCO activity. However, an increase in P-Nmax, saccharides content and Chi a/b ratio was observed. We speculate (1) that the phosphorus deficiency in combination with an increase in CO₂ concentrations may lead to a potential damage of the assimilation apparatus of the primary reactions of photosynthesis and to a decrease in photochemical efficiency of PS2; (2) that the primary target of "down-regulation" takes place at PS2 for irradiances above 150 μ mol m(-2) s(-1).

Kampichler, C., E. Kandeler, R.D. Bardgett, T.H. Jones, and L.J. Thompson. 1998. Impact of elevated atmospheric CO₂ concentration on soil microbial biomass and activity in a complex, weedy field model ecosystem. *Global Change Biology* 4(3):335-346.

Although soil organisms play an essential role in the cycling of elements in terrestrial ecosystems, little is known of the impact of increasing atmospheric CO₂ concentrations on soil microbial processes. We determined microbial biomass and activity in the soil of multitrophic model ecosystems housed in the Ecotron (NERC Centre for Population Biology, Ascot, UK) under two atmospheric CO₂ concentrations (ambient vs. ambient + 200 ppm). The model communities consist of four annual plant species which naturally co-occur in weedy fields and disturbed ground throughout southern England, together with their herbivores, parasitoids and soil biota. At the end of two experimental runs lasting 9 and 4.5 months, respectively, root dry weight and quality showed contradictory responses to elevated CO₂ concentrations, probably as a consequence of the different time-periods (and hence number of plant generations) in the two experiments. Despite significant root responses no differences in microbial biomass could be detected. Effects of CO₂ concentration on microbial activity were also negligible. Specific enzymes (protease and xylanase) showed a significant decrease in activity in one of the experimental runs. This could be related to the higher C:N ratio of root tissue. We compare the results with data from the literature and conclude that the response of complex communities cannot be predicted on the basis of oversimplified experimental set-ups.
