We investigate the response of soil microorganisms to atmospheric CO₂ and temperature change within model terrestrial ecosystems in the Ecotron. The model communities consisted of four plant species (*Cardamine hirsuta*, *Poa annua*, *Senecio vulgaris*, *Spergula arvensis*), four herbivorous insect species (two aphids, a leaf-miner, and a whitefly) and their parasitoids, snails, earthworms, woodlice, soil-dwelling Collembola (springtails), nematodes and soil microorganisms (bacteria, fungi, mycorrhizae and Protista). In two successive experiments, the effects of elevated temperature (ambient plus 2 degrees C) at both ambient and elevated CO₂ conditions (ambient plus 200 ppm) were investigated. A 40:60 sand:Surrey loam mixture with relatively low nutrient levels was used. Each experiment ran for 9 months and soil microbial biomass (C-mic and N-mic), soil microbial community (fungal and bacterial phospholipid fatty acids), basal respiration, and enzymes involved in the carbon cycling (xylanase, trehalase) were measured at depths of 0-2, 0-10 and 10-20 cm. In addition, root biomass and tissue C:N ratio were determined to provide information on the amount and quality of substrates for microbial growth. Elevated temperature under both ambient and elevated CO₂ did not show consistent treatment effects. Elevation of air temperature at ambient CO₂ induced an increase in C-mic of the 0-10 cm layer, while at elevated CO₂ total phospholipid fatty acids (PLFA) increased after the third generation. The metabolic quotient qCO₂ decreased at elevated temperature in the ambient CO₂ run. Xylanase and trehalase skewed no changes in both runs. Root biomass and C:N ratio were not influenced by elevated temperature in ambient CO₂. In elevated CO₂, however, elevated temperature reduced root biomass in the 0-10 cm and 30-40 cm layers and increased N content of roots in the deeper layers. The different response of root biomass and C:N ratio to elevated temperature may be caused by differences in the dynamics of root decomposition and/or in allocation patterns to coarse or fine roots (i.e. storage vs. resource capture functions). Overall, our data suggests that in soils of low nutrient availability, the effects of climate change on the soil microbial community and processes are likely to be minimal and largely unpredictable.

Kanechi, M., M. Ochi, M. Abe, N. Inagaki, and S. Maekawa. 1998. The effects of carbon dioxide enrichment, natural ventilation, and light intensity on growth, photosynthesis, and transpiration of cauliflower plantlets cultured in vitro photoautotrophically and photomixotrophically. *Journal of the American Society for Horticultural Science* 123(2):176-181.

The effects of natural ventilation and CO₂ enrichment during the rooting stage on the growth and the rates of photosynthesis and transpiration of in vitro cauliflower (*Brassica oleracea* L.) plantlets were investigated. In vitro plantlets were established in airtight or ventilated vessels with or without CO₂ supplied (approximate to 1200 µmol g L⁻¹) through gas permeable films attached to the vessel's cap for 15 days before

transplanting ex vitro. Leaves generated in vitro in ventilated vessels had a higher photosynthetic rate than those produced in airtight vessels, which lead to greater leaf expansion and shoot and root dry matter accumulation during in vitro culture and acclimatization. Enhanced photosynthesis in leaves of ventilated plantlets was positively correlated with chlorophyll content. Increasing photosynthetically active radiation from 70 to 200 µmol.m⁻².s⁻¹ enhanced the growth of in vitro plantlets under ventilated conditions but it depressed photosynthesis of the leaves grown photomixotrophically with sugar and CO₂ enrichment which might be due to the feedback inhibition caused by marked accumulations of sucrose and starch. Higher CO₂ levels during in vitro culture enhanced photosynthesis under photoautotrophic conditions, but inhibited it under photomixotrophic conditions. Fifteen days after transplanting ex vitro, high photosynthetic ability and stomatal resistance to transpiratory water loss of ventilated plantlets in vitro had important contributions to rooting and acclimatization. Our findings show that the ventilated culture is effective for accelerating photoautotrophic growth of plantlets by increasing photosynthesis, suggesting that, especially for plantlets growing in vitro without sugar, CO₂ enrichment may be necessary to enhance photosynthetic ability.

Kano, A., Y. Fukazawa, M. Aono, and K. Ohkawa. 1992. Effect of age of cuttings, propagation media, and cutting methods on rooting of *Stephanotis floribunda* Brongn. *Journal of the Japanese Society for Horticultural Science* 61(3):619-624.

The effects of cutting methods, cutting media, and age of cutting on rooting capacity of *Stephanotis floribunda* Brongn. were investigated to improve propagation efficiency. The effects of CO₂ enrichment and a new acclimatization technique for cutting were also tested. 1. Cuttings made from older shoots showed a higher rooting percentage than those made from younger ones. 2. Rockwool mats were found to be useful as a cutting medium for *S. floribunda*. 3. Cuttings with differentiated leaf buds showed higher rooting percentage than those without buds. 4. Rooting was stimulated by placing cuttings in a closed frame, especially when CO₂ concentration was high. 5. An acclimatization technique using a computer controlled fan was developed to decrease water stress during the acclimatization period.

Karban, R., and J.S. Thaler. 1999. Plant phase change and resistance to herbivory. *Ecology* 80(2):510-517.

All plants pass through a series of predictable developmental stages during their lives, called phase changes. The phase change from juvenile to adult leaves is known to be associated with changes in resistance against plant pathogens and herbivores in several species. Virtually nothing is known about changes in resistance associated with the transition from embryonic tissue to autotrophic tissue in seedlings. We studied the consequences of transitions from cotyledons to juvenile true leaves to adult true leaves in cotton seedlings (*Gossypium hirsutum*) for their resistance to spider mites (*Tetranychus urticae*). Mite populations grew much more rapidly on cotyledons than on true leaves. However, there was no detectable difference in the population growth of mites on juvenile vs. adult true leaves. We suggest that population growth of mites is positively affected by the high rates of photosynthesis of cotyledons relative to true leaves, or by some process or attribute correlated with photosynthesis. Conditions that caused increased rates of photosynthesis (exposure to light and elevated concentrations of CO₂) caused mite populations to increase. Greater mite population growth on

cotyledons was not associated with stored reserves in the cotyledons, as the mites did poorly on cotyledons kept in the dark. This study indicates that phase changes can have profound effects on plant resistance to herbivores. Because the seedling stage is so vulnerable to herbivory and so critical to understanding plant population dynamics, a broader consideration of phase changes associated with seedlings is warranted.

Karnosky, D.F., B. Mankovska, K. Percy, R.E. Dickson, G.K. Podila, J. Sober, A. Noormets, G. Hendrey, M.D. Coleman, M. Kubiske, K.S. Pregitzer, and J.G. Isebrands. 1999. Effects of tropospheric O₃ on trembling aspen and interaction with CO₂: Results from an O₃-gradient and a face experiment. *Water, Air, and Soil Pollution* 116(1-2):311-322.

Over the years, a series of trembling aspen (*Populus tremuloides* Michx.) clones differing in O₃ sensitivity have been identified from OTC studies. Three clones (216 and 271 [O₃ tolerant] and 259 [O₃ sensitive]) have been characterized for O₃ sensitivity by growth and biomass responses, foliar symptoms, gas exchange, chlorophyll content, epicuticular wax characteristics, and antioxidant production. In this study we compared the responses of these same clones exposed to O₃ under field conditions along a natural O₃ gradient and in a Free-Air CO₂ and O₃ Enrichment (FACE) facility. In addition, we examined how elevated CO₂ affected O₃ symptom development. Visible O₃ symptoms were consistently seen (5 out of 6 years) at two of the three sites along the O₃ gradient and where daily one-hour maximum concentrations were in the range of 96 to 125 ppb. Clonal differences in O₃ sensitivity were consistent with our OTC rankings. Elevated CO₂ (200 ppm over ambient and applied during daylight hours during the growing season) reduced visible foliar symptoms for all three clones from 31 to 96% as determined by symptom development in elevated O₃ versus elevated O₃ + CO₂ treatments. Degradation of the epicuticular wax surface of all three clones was found at the two elevated O₃ gradient sites. This degradation was quantified by a coefficient of occlusion which was a measure of stomatal occlusion by epicuticular waxes. Statistically significant increases in stomatal occlusion compared to controls were found for all three clones and for all treatments including elevated CO₂, elevated O₃, and elevated CO₂ + O₃. Our results provide additional evidence that current ambient O₃ levels in the Great Lakes region are causing adverse effects on trembling aspen. Whether or not elevated CO₂ in the future will alleviate some of these adverse effects, as occurred with visible symptoms but not with epicuticular wax degradation, is unknown.

We exposed trembling aspen (*Populus tremuloides* Michx.) clones differing in tropospheric ozone (O₃) tolerance in various open-top chamber studies for three growing seasons, and examined the effects of O₃, CO₂, and O₃ + CO₂ on growth and physiological processes. Ozone in the range of 80 ppm hr (Sum 00) per growing season decreased height, diameter, and stem and leaf biomass slightly in a tolerant clone

but severely in a sensitive clone. Elevated CO₂ (150 ppm over ambient) did not compensate for the O₃ effects. Antioxidant enzyme analysis showed elevated SOD levels in the tolerant clone but not in the sensitive clone following O₃ exposure. Northern blot analysis indicated that the chloroplastic and cytosolic Cu/Zn SOD's were significantly increased in response to O₃ in the tolerant but not the sensitive clone. Currently, we are conducting molecular analysis to determine the functional significance of SOD's in regulating O₃ tolerance in aspen. (C) 1997 Elsevier Science Ltd.

Karowe, D.N., D.H. Seimens, and T. Mitchell-Olds. 1997. Species-specific response of glucosinolate content to elevated atmospheric CO₂. *Journal of Chemical Ecology* 23(11):2569-2582.

The carbon/nutrient balance hypothesis has recently been interpreted to predict that plants grown under elevated CO₂ environments will allocate excess carbon to defense, resulting in an increase in carbon-based secondary compounds. A related prediction is that, because plant growth will be increasingly nitrogen-limited under elevated CO₂ environments, plants will allocate less nitrogen to defense, resulting in decreased levels of nitrogen-containing secondary compounds. We present the first evidence of decreased investment in nitrogen-containing secondary compounds for a plant grown under elevated CO₂. We also present evidence that plant response is species specific and is not correlated with changes in leaf nitrogen content or leaf carbon-nitrogen ratio. When three crucifers were grown at 724 ± 8 ppm CO₂, total foliar glucosinolate content decreased significantly for mustard, but not for radish or turnip. Glucosinolate content of the second and fourth young est mustard leaves decreased by 45% and 31%, respectively. In contrast, no significant change in total glucosinolate content was observed in turnip or radish leaves, despite significant decreases in leaf nitrogen content. Total glucosinolate content differed significantly among leaves of different age; however, the trend differed among species. For both mustard and turnip, glucosinolate content was significantly higher in older leaves, while the opposite was true for radish. No significant CO₂ x leaf age interaction was observed, suggesting that intraplant patterns of allocation to defense will not change for these species. Changes in nitrogen allocation strategy are likely to be species-specific as plants experience increasing atmospheric CO₂ levels. The ecological consequences of CO₂-induced changes in plant defensive investment remain to be investigated.

Karunaratne, C., G.A. Moore, R. Jones, and R. Ryan. 1997. Phosphine and its effect on some common insects in cut flowers. *Postharvest Biology and Technology* 10(3):255-262.

The most effective fumigant for insect disinfestation of cut flowers is currently methyl bromide, which will soon be unavailable in several countries. The toxicity of an alternative fumigant, phosphine (2% PH₃ and 98% N₂), was tested at 24 degrees C on adult greenhouse thrips (*Heliothrips haemorrhoidalis*), adult aphids (*Myzus persicae*) and lightbrown apple moth larvae (LBAM; *Epiphyas postvittana*). These are commonly found as insect pests on many cut flower crops. Thrips were exposed to phosphine concentrations ranging from 20-600 mu l/l for 1 or 2 h. All thrips were killed within 18 h of exposure after a treatment of 300 mu l/l phosphine for 2 h. Adult aphids and fifth instar LBAM larvae were more resistant to phosphine, and trials were therefore conducted using higher phosphine concentrations (> 500 mu l/l) combined with atmospheric (0.035%) or elevated (33%) CO₂. The most effective treatment for aphids was 1000 mu l/l phosphine +33% CO₂ for 4 h, which killed all insects within 36 h of exposure. Under atmospheric CO₂ levels, 92% of aphids were killed within 36 h after exposure to 1000 mu l/l phosphine for 6 h, with 100% kill attained after exposure to 5000-8000 mu l/l phosphine for 6 h. Elevated CO₂ levels did not improve the efficacy of phosphine on LBAM larvae. The optimal treatment was 2000-2500 mu l/l phosphine for 4 or 6 h, which killed 96 or 100% of the larvae, respectively. Under atmospheric CO₂ levels, 4000 mu l/l phosphine killed 74% of LBAM larvae after 4 h. and 94% after 6 h exposure. (C) 1997 Elsevier Science B.V.

Kasurinen, A., H.S. Helmisaari, and T. Holopainen. 1999. The influence of elevated CO₂ and O₃ on fine roots and mycorrhizas of naturally growing young Scots pine trees during three exposure years. *Global Change Biology* 5(7):771-780.

Young Scots pine trees naturally established at a pine heath were exposed to two concentrations of CO₂ (ambient and doubled ambient) and two O₃ regimes (ambient and doubled ambient) and their combination in open-top field chambers during growing seasons 1994, 1995 and 1996 (late May to 15 September). Filtered ozone treatment and chamberless control trees were also included in the treatment comparisons. Root in-growth cores were inserted to the undisturbed soil below the branch projection of each tree at the beginning of the fumigation period in 1994 and were harvested at the end of the fumigation periods in 1995 and 1996. Root biomasses were determined from different soil layers in the ingrowth cores, and the infection levels of different mycorrhizal types were calculated. Elevated O₃ and CO₂ did not have significant effects on the biomass production of Scots pine coarse (diameter >2 mm) or fine roots (diameter <2 mm) and roots of grasses and dwarf shrubs. Elevated O₃ caused a transient stimulation, observable in 1995, in the proportion of tuber-like mycorrhizas, total mycorrhizas and total short roots but this stimulation disappeared during the last study year. Elevated CO₂ did not enhance carbon allocation to root growth or mycorrhiza formation, although a diminishing trend in the mycorrhiza formation was observed. In the combination treatment increased CO₂ inhibited the transient stimulating effect of ozone, and a significant increase of old mycorrhizas was observed. Our conclusion is that doubled CO₂ is not able to increase carbon allocation to growth of fine roots or mycorrhizas in nutrient poor forest sites and realistically elevated ozone does not cause a measurable limitation to roots within a period of three exposure years.

Kaufman, Y.J., and M.D. Chou. 1993. Model simulations of the competing climatic effects of so₂ and co₂. *Journal of Climate* 6(7):1241-1252.

Sulfur dioxide-derived cloud condensation nuclei are expected to enhance the planetary albedo, thereby cooling the planet. This effect might counteract the global warming expected from enhanced greenhouse gases. A detailed treatment of the relationship between fossil fuel burning and the SO₂ effect on cloud albedo is implemented in a two-dimensional model for assessing the climate impact. Although there are large gaps in our knowledge of the atmospheric sources and sinks of sulfate aerosol, it is possible to reach some general conclusions. Using a conservative approach, results show that the cooling induced by the SO₂ emission can presently counteract 50% of the CO₂ greenhouse warming. Since 1980, a strong warming trend has been predicted by the model, 0.15-degrees-C, during the 1980-1990 period alone. The model predicts that by the year 2060 the SO₂ cooling reduces climate warming by 0.5-degrees-C or 25% for the Intergovernmental Panel on Climate Change (IPCC) business as usual (BAU) scenario and 0.2-degrees-C or 20% for scenario D (for a slow pace of fossil fuel burning). The hypothesis is examined that the different responses between the Northern Hemisphere (NH) and the Southern Hemisphere (SH) can be used to validate the presence of the SO₂-induced cooling. Despite the fact that most of the SO₂-induced cooling takes place in the Northern Hemispheric continents, the model-predicted difference in the temperature response between the NH and the SH of -0.2-degrees-C in 1980 is expected to remain about the same at least until 2060. This result is a combined effect of the much faster response of the continents than the oceans and of the larger forcing due to CO₂ than due to the SO₂. The climatic response to a complete filtering of SO₂ from the emission products in order to reduce acid rain is also examined. The result is a warming surge of 0.4-degrees-C in the first few years after the elimination of the SO₂ emission.

Ke, D.Y., E. Yahia, M. Mateos, and A.A. Kader. 1994. Ethanolic fermentation of Bartlett pears as influenced by ripening stage and atmospheric composition. *Journal of the American Society for Horticultural Science* 119(5):976-982.

Changes in fermentation volatiles and enzymes were studied in preclimacteric and postclimacteric 'Bartlett' pears (*Pyrus communis* L.) kept in air, 0.25% O₂, 20% O₂ + 80% CO₂, or 0.25% O₂ + 80% CO₂ at 20C for 1, 2, or 3 days. All three atmospheres resulted in accumulation of acetaldehyde, ethanol, and ethyl acetate. The postclimacteric pears had higher activity of pyruvate decarboxylase (PDC) and higher concentrations of fermentation volatiles than those of the preclimacteric fruit. For the preclimacteric pears, the 0.25% O₂ treatment dramatically increased alcohol dehydrogenase (ADH) activity, which was largely due to the enhancement of one ADH isozyme. Exposure to 20% O₂ + 80% CO₂ slightly increased ADH activity, but the combination of 0.25% O₂ + 80% CO₂ resulted in lower ADH activity than 0.25% O₂ alone. For the postclimacteric pears, the three atmospheres resulted in higher PDC and ADH activities than those of air control fruit. Ethanolic fermentation in 'Bartlett' pears could be induced by low O₂ and/or high CO₂ via 1) increased amounts of PDC and ADH;

2) PDC and ADH activation caused by decreased cytoplasmic pH; or 3) PDC and ADH activation or more rapid fermentation due to increased concentrations of their substrates (pyruvate, acetaldehyde, or NADH).

Ke, D.Y., L.L. Zhou, and A.A. Kader. 1994. Mode of oxygen and carbon-dioxide action on strawberry ester biosynthesis. *Journal of the American Society for Horticultural Science* 119(5):971-975.

'Chandler' strawberries (*Fragaria ananassa* Duck.) were kept in air, 0.25% O₂, 21% O₂ + 50% CO₂, or 0.25 O₂ + 50% CO₂ (balance N₂) at 5°C for 1 to 7 days to study the effects of controlled atmospheres (CAs) on volatiles and fermentation enzymes. Concentrations of acetaldehyde, ethanol, ethyl acetate, and ethyl butyrate were greatly increased, while concentrations of isopropyl acetate, propyl acetate, and butyl acetate were reduced by the three CA treatments compared to those of air-control fruit. The CA treatments enhanced activities of pyruvate decarboxylase (PDC) and alcohol dehydrogenase (ADH) but slightly decreased activity of alcohol acetyltransferase (AAT). The results indicate that the enhanced PDC and ADH activities by CA treatments cause ethanol accumulation, which in turn drives the biosynthesis of ethyl esters. The increased ethanol concentration also competes with other alcohols for carboxyl groups for esterification reactions. The reduced AAT activity and limited availability of carboxyl groups due to ethanol competition decrease production of other acetate esters.

Keith, H., R.J. Raison, and K.L. Jacobsen. 1997. Allocation of carbon in a mature eucalypt forest and some effects of soil phosphorus availability. *Plant and Soil* 196(1):81-99.

Pools and annual fluxes of carbon (C) were estimated for a mature *Eucalyptus pauciflora* (snowgum) forest with and without phosphorus (P) fertilizer addition to determine the effect of soil P availability on allocation of C in the stand. Aboveground biomass was estimated from allometric equations relating stem and branch diameters of individual trees to their biomass. Biomass production was calculated from annual increments in tree diameters and measurements of litterfall. Maintenance and construction respiration were calculated for each component using equations given by Ryan (1991a). Total belowground C flux was estimated from measurements of annual soil CO₂ efflux less the C content of annual litterfall (assuming forest floor and soil C were at approximate steady state for the year that soil CO₂ efflux was measured). The total C content of the standing biomass of the unfertilized stand was 138 t ha⁻¹, with approximately 80% aboveground and 20% belowground. Forest floor C was 8.5 t ha⁻¹. Soil C content (0-1 m) was 369 t ha⁻¹ representing 70% of the total C pool

in the ecosystem. Total gross annual C flux aboveground (biomass increment plus litterfall plus respiration) was 11.9 t ha⁻¹ and gross flux belowground (coarse root increment plus fine root production plus root respiration) was 5.1 t ha⁻¹. Total annual soil efflux was 7.1 t ha⁻¹, of which 2.5 t ha⁻¹ (35%) was contributed by litter decomposition. The short-term effect of changing the availability of P compared with C on allocation to aboveground versus belowground processes was estimated by comparing fertilized and unfertilized stands during the year after treatment. In the P-fertilized stand annual wood biomass increment increased by 30%, there was no evidence of change in canopy biomass, and belowground C allocation decreased by 19% relative to the unfertilized stand. Total annual C flux was 16.97 and 16.75 t ha⁻¹ yr⁻¹ in the unfertilized and P-fertilized stands, respectively. Therefore, the major response of the forest stand to increased soil P availability appeared to be a shift in C allocation; with little change in total productivity. These results emphasize that both growth rate and allocation need to be estimated to predict changes in fluxes and storage of C in forests that may occur in response to disturbance or climate change.

Keller, T., J. Guiot, and L. Tessier. 1997. Climatic effect of atmospheric CO₂ doubling on radial tree growth in south eastern France. *Journal of Biogeography* 24(6):857-864.

The climatic effect of a doubling of atmospheric CO₂ on radial growth of trees was studied in ten populations of three species in south eastern France using an Atmospheric General Circulation Model (AGCM) predicting a 3 degrees C increase of mean temperature and a light rise of precipitation. Results are based on empirical growth climate models, involving an Artificial Neural Network (ANN) technique. Only two of the studied populations, on the boundaries of their ecological area, are sensitive to the climatic variations. One is the larch (*Larix decidua* Mill.) population located at 2300m on elevation (near the timberline) which shows a radial growth increase. The other is the most southern French Scots pine (*Pinus sylvestris* L.) population which reacts with a severe growth rate reduction.

Kellogg, E.A., E.J. Farnsworth, E.T. Russo, and F. Bazzaz. 1999. Growth responses of C-4 grasses of contrasting origin to elevated CO₂. *Annals of Botany* 84(3):279-288.

Nine grass species representing three independent origins of the C-4 photosynthetic pathway were grown at ambient (350 ppm) and elevated (700 ppm) CO₂ and were harvested after flowering. *Setaria* and *Arundinella* are both members of the subfamily Panicoideae, and represent a single origin of the pathway. *Aristida* and *Stipagrostis* are sister genera in the subfamily Aristidoideae (formerly classified in subfamily Arundinoideae), and represent a second origin. *Sporobolus*, a member of the subfamily Chloridoideae, represents the third. By investigating two genera each within Panicoideae and Aristidoideae, we test the hypothesis that genera sharing the same origin of C-4 respond similarly. To explore variation among congeneric species, five species of *Setaria* were also examined to test the hypothesis that congeneric species have similar responses. Plant height and numbers of tillers, branches and inflorescences were measured, both over time and at final harvest. Biomass of roots, shoots, and inflorescences was also measured. Members of the Aristidoideae were generally significantly larger in

elevated CO₂, as indicated by measurements of biomass and plant height, whereas representatives of the Panicoideae varied considerably in their response. The two subfamilies differed significantly in their responses to elevated CO₂ and this effect outweighed any effect of CO₂ alone. Sporobolus, though equally distantly related to Panicoideae and Aristidoideae, had a CO₂ response similar to that of some panicoid species. Even within the genus Setaria, some species were significantly smaller at elevated than at ambient CO₂, whereas others were larger. This may reflect diversity in internal regulation rather than acclimation or changes in source-sink allocation of carbon. The variation complicates any prediction of responses of C-4 plants to future atmospheric change. Comparison of closely related species, however, may well lead to intriguing new insights into how regulatory pathways of CO₂ assimilation are modified during evolution. Kellomaki, S., T. Karjalainen, and H. Vaisanen. 1997. More timber from boreal forests under changing climate? *Forest Ecology and Management* 94(1-3):195-208.

The effects of increases in temperature, precipitation and atmospheric CO₂ concentration on timber yields from stands of Scots pine (*Pinus sylvestris* L.) in southern Finland (61 degrees N) are addressed. The assessment is based on simulations using a process-based model in which temperature, precipitation, and atmospheric CO₂ are among the main drivers linking the dynamics of the tree stands directly and indirectly with the changing climate. These factors control photosynthesis, respiration, transpiration and the uptake of nitrogen and water, with consequent effects on the growth and development of tree stands. The timing of thinnings and the length of the rotation were related to the dynamics of the tree stand in compliance with the thinning rules applied in practical forestry. The simulations indicated that an increase in precipitation of 9 mm per decade alone did not affect timber yields. However, a temperature increase of 0.4 degrees C per decade, and the combination of temperature and precipitation increases would increase timber yields by 10% during one rotation. An elevation in the concentration of atmospheric CO₂ by 33 $\mu\text{mol mol}^{-1}$ per decade alone would increase removals of timber by 20%, and a combination of increases in temperature, precipitation and CO₂ concentration would increase removals by 30%. A rise in precipitation did not have any effect on the length of the rotation, but the other combinations shortened the rotation; by 9 years in the case of elevating temperature, by 17 years in the case of elevating atmospheric CO₂ concentration, and by 23 years in the case of the combined elevation of temperature, precipitation, and CO₂ concentration due to more rapid tree growth and development. These changes can be expected to affect the supply of timber and also the profitability of forestry. (C) 1997 Elsevier Science B.V.

Kellomaki, S., and H. Vaisanen. 1997. Modelling the dynamics of the forest ecosystem for climate change studies in the boreal conditions. *Ecological Modelling* 97(1-2):121-140.

This paper summarizes a forest ecosystem model developed for assessing the effects of climate change on the functioning and structure of boreal coniferous forests under the assumption that temperature and

precipitation are the basic dimensions of the niche occupied by any one tree species. Special attention is paid to specifying weather patterns to a level representing the time constant of different physiological and ecological processes relevant to the regeneration, growth and death of trees. The long-term dynamics of the forest ecosystem have been coupled with climatic factors at the level of mechanisms, e.g., photosynthesis and respiration, in terms of the energy flow through the ecosystem. Furthermore, hydrological and nutrient cycles couple the dynamics of the forest ecosystem with climate change through soil processes representing the thermal and hydraulic properties of the soil and the decomposition of litter and humus with the mineralization of nutrients. Simulations for southern Finland (62 degrees N) and northern Finland (66 degrees N) indicated that a transient increase in temperature by 4 degrees C over a period of 100 years could substantially increase soil temperature and reduce soil moisture in forest ecosystems dominated by Scots pine. At the same time, the temperature increase could enhance photosynthetic production and consequent stemwood growth in southern Finland by about 8% and in northern Finland by about 19%. Given the current temperature but elevating CO₂ concentration, the increase in photosynthesis in southern Finland could be about 23% and in northern Finland about 21%, but the concurrent elevation in temperature and CO₂ concentration increased photosynthesis by about 32% in southern Finland and by about 40% in northern Finland. Transpiration decreased by as much as 10-20% under the changing climate with the consequence that water-use efficiency increased by as much as 25-45%, the higher values representing southern Finland. Kellomaki, S., H. Vaisanen, and T. Kolstrom. 1997. Model computations on the effects of elevating temperature and atmospheric CO₂ on the regeneration of Scots pine at the timber line in Finland. *Climatic Change* 37(4):683-708.

Based on model computations, the regeneration of Scots pine (*Pinus sylvestris* L.) was studied at the northern timber line in Finland (70 degrees N) in relation to elevating temperature and atmospheric CO₂. If a transient increase of 4 degrees C was assumed during the next 100 years, the length of growing season increased from the current 110-120 days to 150-160 days. This was associated with ca. 5 degrees C increase in the soil temperature over June-August with larger variability in temperature and deeper freezing of the soil due to the reduced depth and duration of the snow cover. At the same time, the moisture content of the surface soil decreased ca. 10% and was more variable, due to less infiltration of water into the soil as a consequence of the enhanced evapotranspiration and deeper freezing of the soil. The temperature elevation alone, or combined with elevating CO₂, increased flowering and the subsequent seed crop of Scots pine with a decrease in the frequency of zero crops. In both cases, temperature elevation substantially increased the success of regeneration in terms of the number of seedlings produced after each seed crop. The increasing number of mature seeds was mainly responsible for the enhanced regeneration, but increasing soil temperature also increased the success of regeneration. The soil moisture was seldom limited for seed germination. In terms of the density of seedling stands, and the height and diameter growth of the seedlings, the establishment of a seedling stand was substantially improved under the combined elevation of temperature and CO₂ in such a way that the temperature increased the number of mature seeds and enhanced germination of seeds and CO₂ increased seedling growth. Even under the changing climatic conditions, however, the growth of the seedling stands was slow, which indicated that the northward advance of the timber line would probably be very slow, even though regeneration was no longer a limiting factor.

Kellomaki, S., and K.Y. Wang. 1996. Photosynthetic responses to needle water potentials in Scots pine after a four-year exposure to elevated CO₂ and temperature. *Tree Physiology* 16(9):765-772.

Effects of needle water potential ($\psi(1)$) on gas exchange of Scots pine (*Pinus sylvestris* L.) grown for 4 years in open-top chambers with elevated temperature (ET), elevated CO₂ (EC) or a combination of elevated temperature and CO₂ (EC + ET) were examined at a high photon flux density (PPFD), saturated leaf to air water vapor pressure deficit (VPD) and optimal temperature (T). We used the Farquhar model of photosynthesis to estimate the separate effects of $\psi(1)$ and the treatments on maximum carboxylation efficiency (V-c, V-max), ribulose-1,5-bisphosphate regeneration capacity (J), rate of respiration in the light (R(d)), intercellular partial pressure of CO₂ (C_i) and stomatal conductance (G(s)). Depression of CO₂ assimilation rate at low $\psi(1)$ was the result of both stomatal and non-stomatal limitations on photosynthetic processes; however, stomatal limitations dominated during short-term water stress ($\psi(1) < -1.2$ MPa), whereas nonstomatal limitations dominated during severe water stress. Among the nonstomatal components, the decrease in J contributed more to the decline in photosynthesis than the decrease in Long-term elevation of CO₂ and temperature led to differences in the maximum values of the parameters, the threshold values of $\psi(1)$ and the sensitivity of the parameters to decreasing $\psi(1)$. The CO₂ treatment decreased the maximum values of V-c, V-max J and R(d) but significantly increased the sensitivity of V-c, V-max J and R(d) to decreasing $\psi(1)$ ($P < 0.05$). The effects of the ET and EC + ET treatments on V-c, V-max J and R(d) were opposite to the effects of the EC treatment on these parameters. The values of G(s), which were measured simultaneously with maximum net rate of assimilation (A(max)), declined in a curvilinear fashion as $\psi(1)$ decreased. Both the EC + ET and ET treatments significantly decreased the sensitivity of G(s) to decreasing $\psi(1)$. We conclude that, in the future, acclimation to increased atmospheric CO₂ and temperature could increase the tolerance of Scots pine to water stress.

Kellomaki, S., and K.Y. Wang. 1997. Effects of elevated O-3 and CO₂ concentrations on photosynthesis and stomatal conductance in Scots pine. *Plant, Cell and Environment* 20(8):995-1006.

Naturally regenerated Scots pines (*Pinus sylvestris* L.), aged 28-30 years old, were grown in open-top chambers and subjected in situ to three ozone (O-3) regimes, two concentrations of CO₂, and a combination of O-3 and CO₂ treatments from 15 April to 15 September for two growing seasons (1994 and 1995). The gas exchanges of current-year and 1-year-old shoots were measured, along with the nitrogen content of needles. In order to investigate the factors underlying modifications in photosynthesis, five parameters linked to photosynthetic performance and three to stomatal conductance were determined. Elevated O-3 concentrations led to a significant decline in the CO₂ compensation point (I*), maximum RuP2-saturated rate of carboxylation (V-*emax*), maximum rate of electron transport (J(max)) maximum stomatal conductance (g(smax)) and sensitivity of stomatal conductance to changes in leaf-to-air vapour pressure difference (partial derivative g(s)/partial derivative D-v) in both shoot-age classes. However, the effect of elevated O-3 concentrations on the respiration rate in light (R-d) was dependent on shoot age. Elevated CO₂ (700 $\mu\text{mol mol}^{-1}$) significantly decreased J(max) and g(smax) but increased R-d in 1-year-

old shoots and the partial derivative(s)/partial derivative D-v in both shoot-age classes. The interactive effects of O-3 and CO₂ on some key parameters (e.g. V-*emax* and J(max)) were significant. This may be closely related to regulation of the maximum stomatal conductance and stomatal sensitivity induced by elevated CO₂. As a consequence, the injury induced by O-3 was reduced through decreased ozone uptake in 1-year-old shoots, but not in the current-year shoots. Compared to ambient O-3 concentration, reduced O-3 concentrations (charcoal-filtered air) did not lead to significant changes in any of the measured parameters. Compared to the control treatment, calculations showed that elevated O-3 concentrations decreased the apparent quantum yield by 35% and by 18%, and the maximum rate of photosynthesis by 21% and by 29% in the current-year and 1-year-old shoots, respectively. Changes in the nitrogen content of needles resulting from the various treatments were associated with modifications in photosynthetic components.

Kellomaki, S., and K.Y. Wang. 1997. Effects of elevated O-3 and CO₂ on chlorophyll fluorescence and gas exchange in Scots pine during the third growing season. *Environmental Pollution* 97(1-2):17-27.

Naturally regenerated, 30-year-old Scots pines (*Pinus Sylvestris* L.) were grown in open-top chambers and exposed in situ to doubled ambient O-3, doubled ambient CO₂ and a combination of elevated O-3 and CO₂ from 15 April to 15 September for three growing seasons (1994-1996). To examine the effects of O-3 and/or CO₂ on photosynthesis, chlorophyll a fluorescence and gas exchange were measured simultaneously. Doubled ambient O-3 significantly decreased the rates of photosynthesis at all levels of photon flux density. This was related mainly to a significant decrease in the photochemical efficiency of photosystem II (PS II) and the rate of whole electron transport, rather than to a decrease in stomatal conductance. When measurements were made at doubled ambient concentration of CO₂ (700 $\mu\text{mol mol}^{-1}$), doubled ambient CO₂ treatment did not lead to a significant change in the intrinsic capacity of photosynthesis, as manifested by no changes in PS II, the rate of electron transport, the maximal rate of photosynthesis and the apparent quantum yield of CO₂ assimilation. However, elevated CO₂ increased the sensitivity of stomatal conductance to light and decreased maximal stomatal conductance. When O-3 and CO₂ were combined, the O-3-induced decrease in photosynthesis rate was reduced significantly by a high concentration of CO₂. This may be partly related to the decrease in stomatal conductance induced by the high concentration of CO₂. The complete mechanism behind this interaction is, however, still unclear. Kellomaki, S., and K.Y. Wang. 1997. Effects of long-term CO₂ and temperature elevation on crown nitrogen distribution and daily photosynthetic performance of Scots pine. *Forest Ecology and Management* 99(3):309-326.

Single Scots pines (*Pinus sylvestris* L.), aged 20-25 years, were grown in open-top chambers and exposed to elevated temperature (Elev. T), elevated CO₂ (Elev. C) and a combination of elevated CO₂ and temperature (Elev. C + T) for 3 years. The vertical distribution of needle

nitrogen concentration was measured simultaneously with gas exchange of attached shoots. Based on the measurements, the dependencies on needle nitrogen concentrations of four photosynthetic parameters, i.e., RuP2 (ribulose 1,5-bisphosphate)-saturated rate of carboxylation (V_{cmax}), maximum potential electron transport ($J(\text{max})$), the rate of respiration in the light (R_d) and light-use-efficiency factor (δ), were determined. Using a crown multilayer model, the performance of daily crown photosynthesis in Scots pine was predicted. Compared to the control treatment, the mean concentration of nitrogen in the foliage decreased by 20% and by 17% for trees grown under Elev. C and under Elev. C + T, respectively, but increased by 4% for trees grown under Elev. T. However, the total content of foliage nitrogen per unit ground area increased by 25% for trees grown under Elev. C, by 19% for trees grown under Elev. C + T and by 6% for trees grown under Elev. T; these were due to the increase in the total needle area index. Regressions showed that the foliage grown under Elev. C and Elev. C + T had steeper slopes representing the responses of V_{cmax} , and R_d and δ to leaf nitrogen concentrations, while Elev. C + T and Elev. T had steeper slopes representing the response of $J(\text{max})$ to needle nitrogen concentrations. Predictions showed that, on a typical sunny day, the daily total of crown photosynthesis increased 22% and 27%, separately for Elev. C and Elev. C + T, and by only 9% for Elev. T alone. Furthermore, the increased daily crown photosynthesis, resulting from treatments involving elevated CO_2 , can be attributed mainly to an increase in the ambient CO_2 concentration and the needle area index, while modification of the intrinsic photosynthetic capacity had only a marginal effect. Based on the current pattern of crown nitrogen allocation, the prediction showed also that the relationship between daily crown photosynthesis and crown nitrogen content was strongly dependent on the daily incident PAR and air temperature. The CO_2 -elevated treatments led to an increase in the sensitivity of daily crown photosynthesis to changes in crown nitrogen content, daily incident PAR and temperature, while the temperature-elevated treatment had the opposite effect on the sensitivity. Kellomaki, S., and K.Y. Wang. 1997. Photosynthetic responses of Scots pine to elevated CO_2 and nitrogen supply: Results of a branch-in-bag experiment. *Tree Physiology* 17(4):231-240.

Naturally seeded Scots pine (*Pinus sylvestris* L.) trees, age 25-30 years, were subjected to two soil-nitrogen-supply regimes and to elevated atmospheric CO_2 concentrations by the branch-in-bag method from April 15 to September 15 for two or three years. Gas exchange in detached shoots was measured in a diffuse radiation field. Seven parameters associated with photosynthetic performance and two describing stomatal conductance were determined to assess the effects of treatments on photosynthetic components. An elevated concentration of CO_2 did not lead to a significant downward regulation in maximum carboxylation rate (V_{cmax}) or maximum electron transport rate ($J(\text{max})$), but it significantly decreased light-saturated stomatal conductance ($g(\text{sat})$) and increased minimum stomatal conductance ($g(\text{min})$). Light-saturated rates of CO_2 assimilation were higher (24-31%) in shoots grown and measured at elevated CO_2 concentration than in shoots grown and measured under ambient CO_2 concentration, regardless of treatment time or nitrogen-supply regime. High soil-nitrogen supply significantly increased photosynthetic capacity, corresponding to significant increases in V_{cmax} and $J(\text{max})$. However, the combined elevated CO_2 + high nitrogen-supply treatment did not enhance the photosynthetic response above that observed in the elevated CO_2 treatment alone.

Kellomaki, S., and K.Y. Wang. 1998. Daily and seasonal CO_2 exchange in Scots pine grown under elevated O-3 and CO_2 : experiment and simulation. *Plant Ecology* 136(2):229-248.

Starting in early spring of 1994, naturally regenerated, 30-year-old Scots pine (*Pinus sylvestris* L.) trees were grown in open-top chambers and exposed in situ to doubled ambient O-3, doubled ambient CO_2 and a combination of O-3 and CO_2 from 15 April to 15 September. To investigate daily and seasonal responses of CO_2 exchange to elevated O-3 and CO_2 , the CO_2 exchange of shoots was measured continuously by an automatic system for measuring gas exchange during the course of one year (from 1 January to 31 December 1996). A process-based model of shoot photosynthesis was constructed to quantify modifications in the intrinsic capacity of photosynthesis and stomatal conductance by simulating the daily CO_2 exchange data from the field. Results showed that on most days of the year the model simulated well the daily course of shoot photosynthesis. Elevated O-3 significantly decreased photosynthetic capacity and stomatal conductance during the whole photosynthetic period. Elevated O-3 also led to a delay in onset of photosynthetic recovery in early spring and an increase in the sensitivity of photosynthesis to environmental stress conditions. The combination of elevated O-3 and CO_2 had an effect on photosynthesis and stomatal conductance similar to that of elevated O-3 alone, but significantly reduced the O-3 induced depression of photosynthesis. Elevated CO_2 significantly increased the photosynthetic capacity of Scots pine during the main growing season but slightly decreased it in early spring and late autumn. The model calculation showed that, compared to the control treatment, elevated O-3 alone and the combination of elevated O-3 and CO_2 decreased the annual total of net photosynthesis per unit leaf area by 55% and 38%, respectively. Elevated CO_2 increased the annual total of net photosynthesis by 13%.

Kellomaki, S., and K.Y. Wang. 1998. Growth, respiration and nitrogen content in needles of Scots pine exposed to elevated ozone and carbon dioxide in the field. *Environmental Pollution* 101(2):263-274.

Single Scots pine (*Pinus sylvestris* L.) trees, aged 30 years, were grown in open-top chambers and exposed to two atmospheric concentrations of ozone (O-3; ambient and elevation) and carbon dioxide (CO_2) as single variables or in combination for 3 years (1994-96). Needle growth, respiration and nitrogen content were measured simultaneously over the period of needle expansion. Compared to ambient treatment (33 nmol mol⁻¹ O-3 and 350 $\mu\text{mol mol}^{-1}$ CO_2) doubled ambient O-3 (69 nmol mol⁻¹) significantly reduced the specific growth rates (SGRs) of the needles in the early stage of needle expansion and needle nitrogen concentration (N-1) in the late stage, but increased apparent respiration rates (ARRs) in the late stage. Doubled ambient CO_2 (about 650 $\mu\text{mol mol}^{-1}$) significantly increased maximum SGR but reduced ARR and N-1 in the late stage of needle expansion. The changes in ARR induced by the different treatments may be associated with treatment-induced changes in needle growth, metabolic activities and turnover of nitrogenous compounds. When ARR was partitioned into its two functional components, growth and maintenance respiration, the results

showed that neither doubled ambient O₃ nor doubled ambient CO₂ influenced the growth respiration coefficients (R-g). However, doubled ambient O₃ significantly increased the maintenance respiration coefficients (R-m) regardless of the needle development stage, while doubled ambient CO₂ significantly reduced R-m only in the late stage of needle expansion. The increase in R-m under doubled ambient O₃ conditions appeared to be related to an increase in metabolic activities, whereas the decrease in R-m under doubled ambient CO₂ conditions may be attributed to the reduced N-I and turnover rate of nitrogenous compounds per unit. The combination of elevated O₃ and CO₂ had very similar effects on growth, respiration and N-I to doubled ambient O₃ alone, but the interactive mechanism of the two gases is still not clear. Kellomaki, S., and K.Y. Wang. 1998. Sap flow in Scots pines growing under conditions of year-round carbon dioxide enrichment and temperature elevation. *Plant, Cell and Environment* 21(10):969-981.

Starting in 1996, individual trees of Scots pine (*Pinus sylvestris* L.) aged 30 years were grown in closed-top chambers and exposed to normal ambient conditions (CON), elevated CO₂ (Elev. C), elevated temperature (Elev. T) and a combination of elevated CO₂ and temperature (Elev. C + T). Using the constant- power heat balance method, sap flow was monitored simultaneously in a total of 16 trees, four for each treatment, over a 32 d period (after the completion of needle expansion and branch elongation in 1997). An overall variation in diurnal sap flow totals (F-t) was evident during the period of measurement (days 167-198, 1997) regardless of the treatments, with a range from 0.15 to 2.82 kg tree⁻¹ d⁻¹. Elev. C reduced F-t by 4.1-13.7% compared with CON on most days (P varies from 0.042 to 0.108), but slightly increased it on some days (P greater than or equal to 0.131), depending on the weather conditions. Although the decrease in F-t caused by Elev. C was statistically significant on only a few days (P < 0.042), the cumulative F-t, for the 32 d decreased by 14.4% (P = 0.047), indicating that Elev. C may have an important influence on seasonal water use of the Scots pine. Analysis of the diurnal courses of sap flow combined with corresponding weather factors indicated that the CO₂-induced decrease in F-t could be largely attributed to an increase in stomatal sensitivity to vapour pressure deficit (VPD), whereas the CO₂- induced increase in F-t related to an increase in stomatal sensitivity to low light levels. Elev. T increased F-t by 11.2- 35.6% throughout the measuring period and the cumulative F-t for the 32 d by 32.5% (P = 0.019), which could be largely attributed to the temperature-induced increase in current-year needle area and decrease in stomatal sensitivity to high levels of VPD. There were no significant interactive effects of CO₂ and temperature on sap flow, so that Elev. C + T had approximately the same F-t as Elev. T and similar diurnal patterns of sap flow, suggesting that the temperature factor played a dominant role in the case of Elev. C + T.

Kellomaki, S., and K.Y. Wang. 1999. Short-term environmental controls of heat and water vapour fluxes above a boreal coniferous forest: model computations compared with measurements by eddy

correlation. *Ecological Modelling* 124(2-3):145-173.

Eddy correlation and stern how measurements were coupled with detailed microclimate and soil measurements made in a boreal Scots pine forest in the late growing season of 1998 to determine sensible and latent heat fluxes from the soil and the canopy separately. A 'resistance/energy' model is constructed and parametrized in order to reproduce the dynamics of water and heat exchange between the soil, the canopy and the atmosphere as a part of a larger forest ecosystem model (FinnFor; Kellomaki and Vaisanen, 1997). Unique features of the present model are that (1) energy flux equations are expressed in terms of conceptual resistances and their solutions are obtained by closing two surface energy budget equations defined separately for canopy and soil surface; (2) the forest canopy is divided into shaded and sunlit fractions in the radiation transfer submodel and the canopy resistance submodels; (3) a numerical integrating solutions are derived separately for net radiation absorption in the canopy, bulk canopy resistance and the bulk aerodynamic resistances of the forest; and (4) iterative determinations of canopy water potential based on a classical one-dimensional water flow model enable the model to represent explicitly the interaction between the above-ground and the below-ground water dynamics. The model is validated against 19-day flux measurements. In general, the total system sensible heat flux (H), total system latent heat flux (lambda E), canopy latent heat flux (lambda E-c), and soil surface heat flux (G(s)) computed by the model matched well with the measured data. Based on 1/2 h flux measurements, daily lambda E varied from 0.50-7.38 MW m⁻², H from 0.64-8.3 MW m⁻²; and lambda E-c from 0.30-6.93 MW m⁻². The Bowen ratio (H/lambda E) ranged from -4.5 to 9.8, but 82% of the values for the Bowen ratio were within 0.5-2.5. The model computations showed that daily lambda E-c and H-c accounted for 21-64% and 43-66% of the daily total system flux, respectively. Daily soil latent heat (lambda E_s) and soil sensible heat (H-s) fluxes accounted for 0.02-4.5% and 0.05-7.6%, respectively, and the daily energy storage within the canopy (S-c) and G(s) accounted for 0.1-7.2% and 0.8-5.6%, respectively. Plotting of 1/2 h flux data against a single environmental factor indicated that a 68% change in lambda E-c and a 72% change in H-c can be explained by a change in canopy radiation absorption (R-nc) at the 5% probability level. The high correlation between the canopy fluxes and R-nc could be related to the moderate weather conditions and high soil water content during the selected days, whereas lambda E- s, H-s, S-c and G(s) give no significant correlation with R-n. As expected, lambda E-c was strongly dependent on canopy resistance (r(cs)), but less impact on aerodynamic resistances during most of the measuring time. The proportion of energy partitioning in H and lambda E exhibited a clear diurnal trend and was mainly controlled by the system total resistance and the vapour pressure deficit, but less related to changes in soil water content. Kelly, D.W., P.R. Hicklenton, and E.G. Reekie. 1991. Photosynthetic response of geranium to elevated co₂ as affected by leaf age and time of co₂ exposure. *Canadian Journal of Botany-Revue Canadienne De Botanique* 69(11):2482-2488.

Geranium plants were grown from seed in chambers maintained at 350 or 1000-mu-L-L-1 CO₂. Photopsynthesis as affected by leaf age and by leaf position was determined. Elevated CO₂ enhanced photosynthesis to the greatest extent in middle-aged leaves; very young leaves exhibited little enhancement, and net photosynthesis in the oldest leaves was depressed by elevated CO₂. Temporary increases in net photosynthesis (relative to leaves developed at high CO₂) resulted when young leaves grown at 350-mu-L-L-1 CO₂ were switched to 1000-mu-L-L-1 CO₂.

Leaves switched later in development exhibited permanent enhancement. Middle-aged leaves exhibited a temporary depression followed by permanent enhancement. Leaves developed at high CO₂ and switched to low CO₂ did not exhibit any photosynthetic depression relative to plants grown continuously at low CO₂. Similarly, leaves developed at low CO₂ switched to high CO₂ for various lengths of time, and returned to low CO₂ showed no photosynthetic depression. Leaves developed at low CO₂ and switched to high CO₂ exhibited increases in specific leaf weight and leaf thickness. The increase in leaf thickness was proportional to length of time spent at high CO₂. High CO₂ depressed the rate at which stomata developed but did not affect final stomatal density. Results suggest that photosynthesis at low CO₂ was limited by CO₂ regardless of developmental environment, whereas photosynthesis at high CO₂ was limited by the developmental characteristics of the leaf. Further, both biochemical and structural modifications appear to be involved in this response. Because of the very different responses of young versus old leaves, future studies should be careful to consider leaf age in assessing response to elevated CO₂.

Kemp, P.R., D.G. Waldecker, C.E. Owensby, J.F. Reynolds, and R.A. Virginia. 1994. Effects of elevated CO₂ and nitrogen-fertilization pretreatments on decomposition on tallgrass prairie leaf-litter. *Plant and Soil* 165(1):115-127.

Standing dead and green foliage litter was collected in early November 1990 from *Andropogon gerardii* (C-4), *Sorghastrum nutans* (C-4), and *Poa pratensis* (C-3) plants that were grown in large open-top chambers under ambient or twice ambient CO₂ and with or without nitrogen fertilization (45 kg N ha⁻¹). The litter was placed in mesh bags on the soil surface of pristine prairie adjacent to the growth treatment plots and allowed to decay under natural conditions. Litter bags were retrieved at fixed intervals and litter was analyzed for mass loss, carbon chemistry, and total Kjeldahl nitrogen and phosphorus. The results indicate that growth treatments had a relatively minor effect on the initial chemical composition of the litter and its subsequent rate of decay or chemical composition. This suggests that a large indirect effect of CO₂ on surface litter decomposition in the tallgrass prairie would not occur by way of changes in chemistry of leaf litter. However, there was a large difference in characteristics of leaf litter decomposition among the species. *Poa* leaf litter had a different initial chemistry and decayed more rapidly than C-4 grasses. We conclude that an indirect effect of CO₂ on decomposition and nutrient cycling could occur if CO₂ induces changes in the relative aboveground biomass of the prairie species.

Kennedy, A.D. 1995. Antarctic terrestrial ecosystem response to global environmental-change. *Annual Review of Ecology and Systematics* 26:683-704.

Geographical isolation and climatic constraints are responsible for the low biodiversity and structural simplicity of the antarctic terrestrial ecosystem. Under projected scenarios of global change, both limiting factors may be released. Alien species immigration is likely to be facilitated as modified ocean and atmospheric circulation introduce exotic water- and air-borne propagules from neighboring continents.

Elevated temperature, UV radiation, CO₂, and precipitation will combine additively and synergistically to favor new trajectories of community development. It can be predicted that existing patterns of colonization, recruitment, succession, phenology and mortality will be perturbed with concomitant effects for ecosystem function through changes in biomass, trophodynamics, nutrient cycling, and resource partitioning. Soil propagule banks will play an important role through founder effects. Uniquely in Antarctica, many of the short-term consequences of global change will depend on the ecophysiological relationships of cryptogamic plants. However, in the long term, climatic warming will favor an increase in phanerogamic biomass since these species are currently excluded by the low cumulative degree-days > 0 degrees C. It has been suggested that antarctic communities may be particularly vulnerable to global change: Their slow rate of development and restricted gene flow limit response to new conditions. However, vulnerability must be defined with respect to both the direction and rate of change and it is likely that some perturbations will enhance the complexity and productivity of the biota, with negative feedback to the global carbon cycle. The chapter concludes with a discussion of institutional issues surrounding this topic.

Kennedy, A.D. 1995. Simulated climate-change - are passive greenhouses a valid microcosm for testing the biological effects of environmental perturbations. *Global Change Biology* 1(1):29-42.

This paper considers the use of passive greenhouse apparatus in field experiments investigating the biological consequences of climate change. The literature contains many accounts of such experiments claiming relevance of greenhouse treatment effects to global change scenarios. However, inadequacies in microclimate monitoring, together with incomplete understanding of greenhouse modes of action, cast doubt upon such claims. Here, treatment effects upon temperature (magnitude, range, variation, rates of change), moisture (humidity, precipitation, soil water content), light (intensity, spectral distribution), gas composition, snow cover, and wind speed are reviewed in the context of Intergovernmental Panel on Climate Change (IPCC) predictions. It is revealed that greenhouses modify each of these potentially limiting factors in a complex and interactive manner, but that the relationship between this modification and forecast conditions of climate change is poor. Interpretation of biological responses, and their extrapolation to predictive models, is thus unreliable. In order that future greenhouse experiments may overcome criticisms of artefact and lack of rigour, two amendments to methodology are proposed: (1) objective-orientated design of greenhouse apparatus (2) multiple controls addressing individual environmental factors. The importance of a priori testing of microclimate treatment effects is stressed.

Kennedy, A.D. 1995. Temperature effects of passive greenhouse apparatus in high- latitude climate-change experiments. *Functional Ecology* 9(2):340-350.

1. Passive greenhouse apparatus is commonly used to investigate the in situ biological response of terrestrial communities to global warming. 2. Although close conformity of greenhouse treatment effects to general circulation model (GCM) scenarios is widely claimed, no proof of such

a relationship has yet been published. 3. Here, the relationship between passive greenhouse thermal environment and future climate conditions is considered using temperature data collected from within and without greenhouses deployed in the maritime Antarctic. It is revealed that in terms of thermal extremes, diel and annual variation, and overall distribution across the temperature spectrum, such apparatus achieves only poor simulation of GCM forecasts. 4. During summer, greenhouses induce an amplified daily range of temperatures, elevated maxima and accelerated rates of change. 5. During spring and autumn, diel temperature variation continues inside the greenhouses while snow cover protects the controls. 6. During winter, an inverse treatment effect occurs, in which the relative depth of snow cover causes lower temperatures in greenhouses than in controls. 7. These treatment effects differ significantly from GCM climate predictions. Changes recorded in the composition, structure and function of greenhouse biota may thus be artefacts of the methodology. 8. Thorough a priori testing of greenhouse treatment effects is recommended for future climate change studies that are to be conducted in environments subject to seasonal snowfall, solar elevation and day length.

Kerslake, J.E., S.J. Woodin, and S.E. Hartley. 1998. Effects of carbon dioxide and nitrogen enrichment on a plant- insect interaction: the quality of *Calluna vulgaris* as a host for *Operophtera brumata*. *New Phytologist* 140(1):43-53.

Calluna vulgaris L. (Hull) is not one of the usual hosts of the winter moth, *Operophtera brumata* L., but outbreaks have caused extensive damage to heather moorland in Scotland in recent years. This study investigated the potential role of environmental change in such outbreaks by rearing *O. brumata* larvae on *C. vulgaris* plants grown in open-top chambers for 20 months with enriched CO₂ (600 ppm) and nitrogen supply (average 52.5 kg N ha⁻¹ yr⁻¹) in factorial combination. This prolonged exposure to elevated CO₂ caused no change in shoot growth, photosynthesis or foliar C:N ratio of *C. vulgaris*, even with increased N supply, indicating that the absence of response was not due to N limitation. Increased N supply itself resulted in increased shoot growth and a decrease in tissue C:N ratio. Phenolic content did not change in response to either CO₂ or N enrichment, contrary to the predictions of the carbon/nutrient balance hypothesis. In line with the absence of plant response, there was no effect of CO₂ on the development of *Operophtera brumata* on *C. vulgaris*, and so continued increase in atmospheric CO₂ concentration is unlikely to affect directly *O. brumata* outbreaks on heather moorland. *Operophtera brumata* showed increased larval development, growth rate and pupal weight on N-treated plants, correlated both to the decrease in foliar C:N ratio, and to the increase in shoot extension which was predictive of survivorship. Thus, increased atmospheric N deposition, or increased rates of mineralization in a warmer environment, might increase the severity of *O. brumata* outbreaks on *C. vulgaris*. Since the combination of high N availability and disturbance of heather canopy by herbivory is known to result in increased dominance of grasses, it is suggested that this could lead to further degradation of moorland in upland Britain.

Kerstiens, G. 1995. Cuticular water permeance of european trees and shrubs grown in polluted and unpolluted atmospheres, and its relation to stomatal response to humidity in beech (*fagus-sylvatica* L.). *New Phytologist* 129(3):495-503.

Cuticular water permeance (P) of astomatous adaxial surfaces of intact leaves was determined in *Acer pseudoplatanus* L., *Betula pubescens* Ehrh., *Corylus avellana* L., *Fagus sylvatica* L. and *Prunus avium* L. Water evaporating from the stomata-bearing abaxial leaf surface could not reach the moisture analyzer and the values of P presented here are therefore free from errors that often arise from unintentional inclusion of residual stomatal transpiration. Plants were exposed from before bud-break for several months to 20-50 ppb SO₂ (*Fagus*), a combination of 50-60 ppb SO₂ and 50-60 ppb NO₂ (*Betula*), 300- 400 ppb NO (*Acer*, *Corylus*, *Fagus*), regular ozone episodes of up to 120 ppb (*Fagus*, *Prunus*), or an elevated level of CO₂ (600 ppm for 2 yr; *Acer*, *Fagus*). Permeances were in the range 0.6- 2.9 x 10⁻⁵ m s⁻¹ and were unaffected by most treatments. In *Prunus*, P increased slightly but significantly in the NO treatment. In *Corylus* and *Fagus*, P was sometimes found to be reduced by fumigation with NO, but not always. *Betula* leaves grown under elevated SO₂ and NO₂ showed higher values of P only if they were visibly damaged. Minimum conductances (g/min) estimated from water loss rates of both sides of detached hypostomatous leaves were higher than P, and were more strongly affected by treatments. In these cases, the most probable explanation is some damage to stomatal function resulting in a reduced ability to close after leaf excision. Effects of growing conditions and time of year on P were found, which allowed a hypothetical interaction between P and stomatal sensitivity to air humidity to be tested in beech. No unambiguous indication of such a relationship was found.

Kerstiens, G. 1997. Why is increasing shade-tolerance of trees correlated with increasing stimulation of growth by elevated CO₂? *Plant Physiology* 114(3):371.

1146

Kerstiens, G. 1998. Shade-tolerance as a predictor of responses to elevated CO₂ in trees. *Physiologia Plantarum* 102(3):472-480.

Evidence from 10 studies comparing angiosperm trees and 5 studies comparing conifers or differing shade-tolerance was analysed. The number of intraphyletic comparisons in which the more shade-tolerant species showed the greater relative increase of biomass in elevated CO₂ was significantly higher than would be expected by chance alone. It is suggested that more shade-tolerant species are inherently better disposed, in terms of plant architecture and partitioning of biomass and nitrogen, to utilise resources (light, water, nutrients) that are potentially limiting in elevated CO₂ and that these traits are responsible for the interaction between shade-tolerance and CO₂ concentration. Compared with less shade-tolerant angiosperm trees, more shade-tolerant angiosperm species generally have a lower leaf area ratio in ambient CO₂ and show a smaller relative reduction in elevated CO₂. Furthermore, leaf nitrogen content is usually lower in more shade-tolerant angiosperm species and tends to be more strongly reduced by

elevated CO₂ in those species. Within angiosperm trees, more shade-tolerant species showed a stronger stimulation of net leaf photosynthetic rate in most experiments, but this trend was not significant.

Kerstiens, G., and C.V. Hawes. 1994. Response of growth and carbon allocation to elevated CO₂ in young cherry (*Prunus avium* L.) saplings in relation to root environment. *New Phytologist* 128(4):607-614.

The hypothesis that inadequate rooting volume may reduce the growth stimulation by elevated CO₂ in potted tree seedlings and saplings was tested experimentally and by surveying the literature. One-year-old cherry saplings were grown for one season in naturally lit growth chambers in eight combinations of CO₂ concentration (ambient; ambient + 250 ppm) and root environment (four types). The latter included (1) moderately restrictive pot volume (4 l) in combination with two levels of fertilizer addition (1a, 1b); (2) 10 l pots with total fertilizer content per pot as in treatment 1a, and (3) 20 l pots with five plants sharing five times the space and nutrient resources of treatment 1a. Plants were harvested in April, May, June, August and September. The overall mean effect of high CO₂ plant dry mass by the end of the season was +24%. Interactive effects of root environments and CO₂ concentrations on dry mass were not significant at the 5% level, but repeated measurements of basal stem diameter of individual plants indicated a significant impact of root environment on the response to CO₂. Overall growth enhancement by elevated CO₂ did not differ significantly between harvests, but it tended to increase during the season in those root environments which restricted growth in ambient CO₂ most strongly (1a and 3). The hypothesis was rejected for this experiment. Leaf area and stem height were not affected by any treatment. The variation of carbon allocation to roots and shoots with plant size was very similar in all treatments. Plants grew faster in elevated CO₂ very early in the season, and this resulted in small but significant differences between seasonal patterns of biomass partitioning in ambient and elevated CO₂. A survey of 33 studies on growth responses of 47 tree species to elevated CO₂ (600-800 ppm) showed that the relative change in biomass was not related to the ratio of plant biomass and pot volume found in either ambient or elevated CO₂. We conclude that there is no evidence that inadequate pot volume had a negative impact on the stimulation of growth of tree species in elevated CO₂.

Kerstiens, G., J. Townend, J. Heath, and T.A. Mansfield. 1995. Effects of water and nutrient availability on physiological- responses of woody species to elevated CO₂. *Forestry* 68(4):303-315.

The growth responses to elevated CO₂ found in experiments are highly variable and depend on other experimental parameters such as irrigation, fertilization, light regime, etc. As yet, the strength or even the sign of most interactions is all but impossible to predict from first principles. Experiments in ambient and CO₂-enriched ambient air (+250 p.p.m.) have been conducted in specially adapted greenhouses (Solardomes) at Lancaster University for the past four seasons on Sitka spruce (*Picea sitchensis* (Bong.) Carr.), wild cherry (*Prunus avium* L.), beech (*Fagus sylvatica* L.) and pedunculate oak (*Quercus robur* L.). These experiments are reviewed together with other published studies on interactive effects

of elevated CO₂ and water and nutrient supply on physiological processes, in particular gas exchange, in tree species. It is often assumed that drought tolerance will increase in elevated CO₂ because of a suppression of stomatal conductance and an increase in instantaneous water use efficiency. There is, however, some evidence that such effects could be more than offset in beech by CO₂-induced increases in leaf area. It is tentatively suggested that in beech, drought tolerance could already have been reduced by the increase in atmospheric CO₂ over the last century.

Keutgen, N., K. Chen, and F. Lenz. 1997. Responses of strawberry leaf photosynthesis, chlorophyll fluorescence and macronutrient contents to elevated CO₂. *Journal of Plant Physiology* 150(4):395-400.

Gas exchange, chlorophyll fluorescence parameters, and macronutrient contents were investigated in young (< 3 weeks), medium (4 - 6 weeks) and old (7 - 9 weeks) strawberry leaves growing at 300, 450, 600, 750, and 300 ppm CO₂. An increase of the CO₂ level to 600 ppm promoted leaf net photosynthesis, but a further rise led to a decrease of net CO₂ assimilation. The reduction of net photosynthetic rate was less distinct in young leaves exposed to CO₂ levels above 600 ppm for less than 3 weeks, indicating that the reduction might depend on the period of exposition or leaf age. Transpiration and stomatal conductance were significantly affected by leaf age, but not by CO₂ concentrations. Medium leaves were characterised by a higher transpiration rate and stomatal conductance than young and old ones. In leaves growing at high CO₂ levels Chl a and b contents as well as the a/b ratio decreased. The contents of N, P, K, Ca and Mg were lower in leaves growing at high CO₂ concentrations than in those at low ones. An elevated CO₂ level above 750 ppm led to a general macronutrient deficiency and was accompanied by a distinct decrease of optimal quantum yield, due to a rise of basal fluorescence, and an increase of non- photochemical energy dissipation in old leaves.

Kickert, R.N., G. Tonella, A. Simonov, and S.V. Krupa. 1999. Predictive modeling of effects under global change. *Environmental Pollution* 100(1-3):87-132.

The status of computer simulation models from around the world for evaluating the possible ecological, environmental, and societal consequences of global change is presented in this paper. In addition, a

brief synopsis of the state of the science of these impacts is included. Issues considered include future changes in climate and patterns of land use for societal needs. Models discussed relate to vegetation (e.g. crop), soil, bio-geochemistry, water, and wildlife responses to conventional, forecasted changes in temperature and precipitation. Also described are models of these responses, alone and interactively, to increased CO₂, other air pollutants and UV-B radiation, as the state of the science allows. Further, models of land-use change are included. Additionally, global multiple sector models of environment, natural resources, human population dynamics, economics, energy, and political relations are reviewed for integrated impact assessment. To the extent available, information on computer software and hardware requirements is presented for the various models. The paper concludes with comments about using these technologies as they relate to ecological risk assessment for policy decision analysis. Such an effort is hampered by considerable uncertainties with the output of existing models, because of the uncertainties associated with input data and the definitions of their dose-response relationships. The concluding suggestions point the direction for new developments in modeling and analyses that are needed for the 21st century. (C) 1999 Elsevier Science Ltd. All rights reserved.

Kicklighter, D.W., M. Bruno, S. Donges, G. Esser, M. Heimann, J. Helfrich, F. Ift, F. Joos, J. Kaduk, G.H. Kohlmaier, A.D. McGuire, J.M. Melillo, R. Meyer, B. Moore, A. Nadler, I.C. Prentice, W. Sauf, A.L. Schloss, S. Sitch, U. Wittenberg, and G. Wurth. 1999. A first-order analysis of the potential role of CO₂ fertilization to affect the global carbon budget: a comparison of four terrestrial biosphere models. *Tellus Series B-Chemical and Physical Meteorology* 51(2):343-366.

We compared the simulated responses of net primary production, heterotrophic respiration, net ecosystem production and carbon storage in natural terrestrial ecosystems to historical (1765 to 1990) and projected (1990 to 2300) changes of atmospheric CO₂ concentration of four terrestrial biosphere models: the Bern model, the Frankfurt Biosphere Model (FBM), the High-Resolution Biosphere Model (HRBM) and the Terrestrial Ecosystem Model (TEM). The results of the model intercomparison suggest that CO₂ fertilization of natural terrestrial vegetation has the potential to account for a large fraction of the so-called "missing carbon sink" of 2.0 Pg C in 1990. Estimates of this potential are reduced when the models incorporate the concept that CO₂ fertilization can be limited by nutrient availability. Although the model estimates differ on the potential size (126 to 461 Pg C) of the future terrestrial sink caused by CO₂ fertilization, the results of the four models suggest that natural terrestrial ecosystems will have a limited capacity to act as a sink of atmospheric CO₂ in the future as a result of physiological constraints and nutrient constraints on NPP. All the spatially explicit models estimate a carbon sink in both tropical and northern temperate regions, but the strength of these sinks varies over time. Differences in the simulated response of terrestrial ecosystems to CO₂ fertilization among the models in this intercomparison study reflect the fact that the models have highlighted different aspects of the effect of CO₂ fertilization on carbon dynamics of natural terrestrial ecosystems including feedback mechanisms. As interactions with nitrogen fertilization, climate change and forest regrowth may play an important role in simulating the response of terrestrial ecosystems to CO₂ fertilization, these factors should be included in future analyses. Improvements in spatially explicit data sets, whole-ecosystem experiments and the availability of net carbon exchange measurements across the globe will also help to improve future evaluations of the role

of CO₂ fertilization on terrestrial carbon storage.

Kim, H.Y., T. Horie, H. Nakagawa, and K. Wada. 1996. Effects of elevated CO₂ concentration and high temperature on growth and yield of rice. *Japanese Journal of Crop Science* 65(4):634-643.

Phenological development, biomass production and the related growth characteristics of rice (cv Akihikari) in canopy were measured over the entire growth period under different CO₂ concentrations and air temperature regimes in temperature gradient chambers (TGCs), in order to clarify the effects of anticipated global climate change on rice production. The TGC is a plastic tunnel with the dimensions of 26m in length, 2.05m in width and 1.7m in height in which air was ventilated at varying rates to create a 4 degrees C temperature gradient along its longitudinal axis. Two TGCs were used for this experiment; one was kept at ambient CO₂ (congruent to 350 mu LL(-1)) concentration and the other at 690 mu LL(-1) throughout the entire growth period. CO₂ x temperature treatments were applied to potted rice plants displaced in TGC at the density of 20 hills m(-2) in 1991, and on transplanted plants on soil bed in TGC at 25 hills m(-2) in 1992. In both years, a sufficient amount of nutrition was applied in split. The nearly doubled CO₂ concentration (690 mu LL(-1)) accelerated phenological development of rice toward heading with more pronounced effects at higher temperatures. The number of days to heading of elevated CO₂ plants at 30 degrees C was 11% less than that of ambient CO₂ plants. The elevated CO₂ concentration remarkably promoted both total and productive tiller numbers, whereas it gave a negligibly small effect on plant height. Also, the elevated CO₂ concentration gave minor effects on leaf area index except at the initial growth stage, coinciding with the previous workers' results. The elevated CO₂ concentration markedly promoted crop dry matter production, on which temperature appeared to give negligibly small effects. The relative enhancement rate by the doubled CO₂ on crop dry weight at maturity was estimated to be 24% as average over the entire temperature range (26 similar to 30 degrees C) in both years. The insensitive temperature response in the enhancement rate was contrary to previous workers' results. This is considered to be due to previous workers' results being based on largely isolated plants where radiation might less limit the growth than in the present experiment in the canopy condition.

Kim, H.Y., T. Horie, H. Nakagawa, and K. Wada. 1996. Effects of elevated CO₂ concentration and high temperature on growth and yield of rice. 2. The effect on yield and its components of Akihikari rice. *Japanese Journal of Crop Science* 65(4):644-651.

Yield and its component organs of rice (cv. Akihikari) were examined for populations grown under two different CO₂ concentrations (350 and 690 mu LL(-1)) x four temperature regimes in temperature gradient chambers (TGCs) in two cropping seasons of 1991 and 1992. The temperature treatments ranged 27.2 similar to 31.1 degrees C in 1991 and 26.0 similar to 29.3 degrees C in 1992 on average over the entire growth period. The relative yield increases by nearly doubling the CO₂ concentration under the lowest temperature conditions were 40% and 22% in 1991 and 1992, respectively. These yield increases were mainly attributable to the increased spikelet number per unit area by elevated CO₂, whereas the CO₂ effects on ripening percentage and weight of single grain mass were relatively small. The difference in the CO₂

enhancement rate in the spikelet number and hence in the yield between the two years was considered to reflect the difference in the nitrogen (N) application rate, as total amounts of N applied were 24 g m⁻² in 1991 and 12 g m⁻² in 1992. With the increase in temperature, yields at ambient and elevated CO₂ concentrations decreased drastically with a more pronounced reduction with elevated CO₂, resulting in no CO₂ enrichment effect on rice yield at higher temperatures. The yield decline at higher temperatures was primarily due to an increase in the number of sterile spikelets and slightly due to the increase in imperfectly ripened grains. The spikelet sterility was most closely related to the daily maximum temperature averaged over the flowering period.

Kimball, B.A., R.L. LaMorte, P.J. Pinter, G.W. Wall, D.J. Hunsaker, F.J. Adamsen, S.W. Leavitt, T.L. Thompson, A.D. Matthias, and T.J. Brooks. 1999. Free-air CO₂ enrichment and soil nitrogen effects on energy balance and evapotranspiration of wheat. *Water Resources Research* 35(4):1179-1190.

In order to determine the likely effects of the increasing atmospheric CO₂ concentration on future evapotranspiration, ET, plots of field-grown wheat were exposed to concentrations of 550 $\mu\text{mol/mol}$ CO₂ (or 200 $\mu\text{mol/mol}$ above current ambient levels of about 360 $\mu\text{mol/mol}$) using a free-air CO₂ enrichment (FACE) facility. Data were collected for four growing seasons at ample water and fertilizer (high N) and for two seasons when soil nitrogen was limited (low N). Measurements were made of net radiation, R_n; soil heat flux; air and soil temperatures; canopy temperature, T_s; and wind speed. Sensible heat flux was calculated from the wind and temperature measurements. ET, that is, latent heat flux, was determined as a residual in the energy balance. The FACE treatment increased daytime T_s about 0.6 degrees and 1.1 degrees C at high and low N, respectively. Daily total R_n was reduced by 1.3% at both levels of N. Daily ET was consistently lower in the FACE plots, by about 6.7% and 19.5% for high and low N, respectively.

Effects of free-air CO₂ enrichment on energy-balance and evapotranspiration of cotton. *Agricultural and Forest Meteorology* 70(1-4):259-278.

The effects of free-air CO₂ enrichment (FACE) at 550 $\mu\text{mol/mol}$ on the energy balance and evapotranspiration, ET, of cotton (*Gossypium hirsutum* L.) were investigated. Latent heat flux, λET , was calculated as the residual in an energy balance approach from determinations of net radiation, R_n, minus surface soil heat flux, G₀, minus sensible heat flux, H. R_n was directly measured. G₀ was determined from measurements with soil heat flux plates at 10 mm depth, corrected for temperature changes in the soil above. H was determined from measurements of air temperature with aspirated psychrometers, of foliage temperature with IR thermometers, and of wind speed with cup anemometers. Under ambient CO₂ (control) conditions (about 370 $\mu\text{mol/mol}$), the λET from the energy balance approach agreed fairly well with values from several other methods, including the Bowen ratio method, lending credence to the technique. However, the results had an uncertainty of the order of 20% associated with the R_n measurements. Therefore, an apparent increase in ET of about 13% in the FACE plots was judged insignificant. The

conclusion that any effects of CO₂ enrichment to 550 $\mu\text{mol/mol}$ on the ET of cotton were too small to be detected was consistent with the results of other investigators who determined ET in the same experiment using stem flow gauges and the soil water balance.

Kimball, B.A., and J.R. Mauney. 1993. Response of cotton to varying CO₂, irrigation, and nitrogen - yield and growth. *Agronomy Journal* 85(3):706-712.

The CO₂ concentration of the atmosphere is increasing and is expected to double sometime near the middle of the next century. To determine the effects of such a CO₂ increase on cotton (*Gossypium hirsutum* L.) growth and productivity, a series of experiments from 1983 through 1987 were conducted with open-top CO₂-enriched field chambers at ample as well as limiting levels of water and N at Phoenix, AZ. Comparisons with open-field plots showed that there was a significant chamber effect, amounting to a 30% average increase in growth inside, but under dry conditions in 1985, the situation was reversed. No significant effects of CO₂ on harvest index, root-shoot ratio, or lint percentage were found, so the primary effect of elevated CO₂ was to produce plants that were larger. Comparing the results of 500 and 650 $\mu\text{mol/mol}$ CO₂ treatments, the increments of growth from ambient (about 350 $\mu\text{mol/mol}$) to 500 $\mu\text{mol/mol}$ were not significantly different from increments from 500 to 650 $\mu\text{mol/mol}$. No statistically significant interactions were detected between CO₂ level and either irrigation or nitrogen level, even when these variables were sufficiently low enough to limit growth. However, under well-maintained water stress conditions, the growth response to CO₂ tended to be somewhat larger than under normal irrigation levels. Averaging over all the data available from these experiments, seed cotton yield (lint plus seed) and above-ground biomass were increased by 60 and 63%, respectively, by CO₂ enrichment to 650 $\mu\text{mol/mol}$.

Kimball, B.A., J.R. Mauney, F.S. Nakayama, and S.B. Idso. 1993. Effects of increasing atmospheric CO₂ on vegetation. *Vegetatio* 104:65-75.

The increasing atmospheric CO₂ concentration probably will have significant direct effects on vegetation whether predicted changes in climate occur or not. Averaging over many prior greenhouse and growth chamber studies, plant growth and yield have typically increased more than 30%, with a doubling of CO₂ concentration. Such a doubling also causes stomatal conductance to decrease about 37% which typically increases leaf temperatures more than 1-degree-C, and which may decrease evapotranspiration, although increases in leaf area counteract the latter effect. Interactions between CO₂ and climate variables also appear important. In one study the growth increase from near-doubled

CO₂ ranged from minus 60% at 12- degrees-C to 0% at 19-degrees-C to plus 130% at 34-degrees-C, suggesting that if the climate warms, the average growth response to doubled CO₂ could be consistently higher than the 30% mentioned above. Even when growing in nutrient-poor soil, the growth response to elevated CO₂ has been large, in contrast to nutrient solution studies which showed little response. Several studies have suggested that under water-stress, the CO₂ growth stimulation is as large or larger than under wellwatered conditions. Therefore, the direct CO₂ effect will compensate somewhat, if not completely, for a hotter drier climate. And if any climate change is small, then plant growth and crop yields will probably be significantly higher in the future high-CO₂ world.

Kimball, B.A., P.J. Pinter, R.L. Garcia, R.L. LaMorte, G.W. Wall, D.J. Hunsaker, G. Wechsung, F. Wechsung, and T. Kartschall. 1995. Productivity and water use of wheat under free-air CO₂ enrichment. *Global Change Biology* 1(6):429-442.

A free-air CO₂ enrichment (FACE) experiment was conducted at Maricopa, Arizona, on wheat from December 1992 through May 1993. The FACE apparatus maintained the CO₂ concentration, [CO₂], at 550 $\mu\text{mol mol}^{-1}$ across four replicate 25-m- diameter circular plots under natural conditions in an open field. Four matching Control plots at ambient [CO₂] (about 370 $\mu\text{mol mol}^{-1}$) were also installed in the field. In addition to the two levels of [CO₂], there were ample (Wet) and limiting (Dry) levels of water supplied through a subsurface drip irrigation system in a strip, split-plot design. Measurements were made of net radiation, R(n); soil heat flux, G(o); soil temperature; foliage or surface temperature; air dry and wet bulb temperatures; and wind speed. Sensible heat flux, H, was calculated from the wind and temperature measurements. Latent heat flux, λET , and evapotranspiration, ET, were determined as the residual in the energy balance. The FACE treatment reduced daily total R(n) by an average 4%. Daily FACE sensible heat flux, H, was higher in the FACE plots. Daily latent heat flux, λET , and evapotranspiration, ET, were consistently lower in the FACE plots than in the Control plots for most of the growing season, about 8% on the average. Net canopy photosynthesis was stimulated by an average 19 and 44% in the Wet and Dry plots, respectively, by elevated [CO₂] for most of the growing season. No significant acclimation or down regulation was observed. There was little above-ground growth response to elevated [CO₂] early in the season when temperatures were cool. Then, as temperatures warmed into spring, the FACE plants grew about 20% more than the Control plants at ambient [CO₂], as shown by above-ground biomass accumulation. Root biomass accumulation was also stimulated about 20%. In May the FACE plants matured and senesced about a week earlier than the Controls in the Wet plots. The FACE plants averaged 0.6 degrees C warmer than the Controls from February through April in the well-watered plots, and we speculate that this temperature rise contributed to the earlier maturity. Because of the acceleration of senescence, there was a shortening of the duration of grain filling, and consequently, there was a narrowing of the final biomass and yield differences. The 20% mid-season growth advantage of FACE shrunk to about an 8% yield advantage in the Wet plots, while the yield differences between FACE and Control remained at about 20% in the Dry plots.

King, A.W., W.R. Emanuel, S.D. Wullschlegel, and W.M. Post. 1995. In search of the missing carbon sink - a model of terrestrial

biospheric response to land-use change and atmospheric CO₂. *Tellus Series B-Chemical and Physical Meteorology* 47(4):501-519.

Estimates of the net exchange of carbon between the terrestrial biosphere and the atmosphere may be too large because the models of carbon release from changes in land use do not allow for enhanced carbon assimilation by the terrestrial biosphere in response to increasing atmospheric CO₂. We address this deficiency with a model of terrestrial biosphere that includes both ecosystem response to land-use perturbation and vegetation response to atmospheric CO₂. Model inputs specify the areas affected by land-use change since 1700. The carbon dynamics of the affected areas are described by an area distribution function for vegetation carbon density and a compartment model of carbon in vegetation, litter, and soil. Vegetation growth is modeled as the difference between net primary production (NPP) and mortality. NPP, the net flux of carbon from atmosphere to vegetation, is a logistic function of vegetation carbon density. The response of NPP to atmospheric CO₂ is modeled with three response functions: a logarithmic, a rectangular-hyperbolic, and a response function derived from a biochemical model of C-3 photosynthesis. The response functions are parameterized by ecosystem type with data from CO₂ exposure experiments. Elevated CO₂ affects the NPP of both undisturbed and recovering ecosystems. We use the model to test the hypothesis that the CO₂ enhancement of terrestrial NPP explains the historical missing carbon sink of the global carbon cycle budget. Our estimates of the biosphere's CO₂ enhanced carbon flux are much smaller than the reconstructed missing carbon sink. We conclude that our model results do not support the hypothesis.

King, A.W., W.M. Post, and S.D. Wullschlegel. 1997. The potential response of terrestrial carbon storage to changes in climate and atmospheric CO₂. *Climatic Change* 35(2):199-227.

We use a georeferenced model of ecosystem carbon dynamics to explore the sensitivity of global terrestrial carbon storage to changes in atmospheric CO₂ and climate. We model changes in ecosystem carbon density, but we do not model shifts in vegetation type. A model of annual NPP is coupled with a model of carbon allocation in vegetation and a model of decomposition and soil carbon dynamics. NPP is a function of climate and atmospheric CO₂ concentration. The CO₂ response is derived from a biochemical model of photosynthesis. With no change in climate, a doubling of atmospheric CO₂ from 280 ppm to 560 ppm enhances equilibrium global NPP by 16.9%; equilibrium global terrestrial ecosystem carbon (TEC) increases by 14.9%. Simulations with no change in atmospheric CO₂ concentration but changes in climate from five atmospheric general circulation models yield increases in global NPP of 10.0-14.8%. The changes in NPP are very nearly balanced by changes in decomposition, and the resulting changes in TEC range from an increase of 1.1% to a decrease of 1.1%. These results are similar to those from analyses using bioclimatic biome models that simulate shifts in ecosystem distribution but do not model changes in carbon density within vegetation types. With changes in both climate and a doubling of atmospheric CO₂, our model generates increases in NPP of 30.2-36.5%. The increases in NPP and litter inputs to the soil more than compensate for any climate stimulation of decomposition and lead to increases in global TEC of 15.4-18.2%.

King, D.A. 1995. Equilibrium-analysis of a decomposition and yield model applied to pinus-radiata plantations on sites of contrasting fertility. *Ecological Modelling* 83(3):349-358.

Recent models of growth and nutrient cycling relate forest productivity to canopy photosynthesis, as influenced by the effect of nutrient cycling on foliar nitrogen concentration. A useful approach for analysing the impact of elevated CO₂ or altered nitrogen inputs on production is to consider model solutions where recycling leaves, fine roots, litter and soil organic pools of intermediate turnover time are in equilibrium, while tree stems and recalcitrant humus are accumulating or releasing carbon and nitrogen. This equilibrium analysis, employed by the Generic Decomposition and Yield (G'DAY) model, was applied to Pinus radiata plantations growing on an infertile site in Australia and a fertile site in New Zealand. Predicted productivities and foliar nitrogen concentrations were substantially lower than observed for the young (12-year-old) stands, particularly for the fertile site. The model predictions were closer to values expected for older stands late in the commercial rotation cycle when reduced wood production rates reduce the net nitrogen requirements for growth. These results underscore the importance of the net release of nitrogen from soil organic matter early in the life of a stand and suggest that care should be taken in using equilibrium analyses to estimate the impacts of elevated [CO₂] on forest production.

King, J.S., R.B. Thomas, and B.R. Strain. 1996. Growth and carbon accumulation in root systems of Pinus taeda and Pinus ponderosa seedlings as affected by varying CO₂, temperature and nitrogen. *Tree Physiology* 16(7):635-642.

It has been hypothesized that increasing atmospheric CO₂ concentration enhances accumulation of carbon in fine roots, thereby altering soil carbon dynamics and nutrient cycling. To evaluate possible changes to belowground pools of carbon and nitrogen in response to elevated CO₂, an early and a late successional species of pine (Pinus taeda L. and Pinus ponderosa Dougl. ex Laws, respectively) were grown from seed for 160 days in a 35 or 70 Pa CO₂ partial pressure at low or high temperature (30-year weekly mean and 30 year weekly mean + 5 degrees C) and a soil solution nitrogen concentration of 1 or 5 mM NH₄NO₃ at the Duke University Phytotron. Seedlings were harvested at monthly intervals and growth parameters of the primary root, secondary root and tap root fractions evaluated. Total root biomass of P. ponderosa showed a positive CO₂ response (105% increase) (P = 0.0001) as a result of significant increases in all root fractions in the elevated CO₂ treatment, but all other main effects and interactions were insignificant. In P. taeda, there were significant interactions between CO₂ and temperature (P = 0.04) and CO₂ and nitrogen (P = 0.04) for total root biomass. An allometric analysis indicated that modulation of the secondary root fraction was the main response of the trees to altered environmental conditions. In P. ponderosa, there was an increase in the secondary root fraction relative to the primary and tap root fractions under conditions of low temperature. In P. taeda, there was a shift in carbon accumulation to the secondary roots relative to the primary roots under low temperature and low nitrogen. Neither species exhibited shifts in carbon accumulation in response to elevated CO₂. We conclude that both species have the potential to increase belowground biomass substantially in response to rising atmospheric CO₂ concentration, and this response is sensitive to temperature and nitrogen in P. taeda. Both species displayed small shifts in belowground carbon accumulation in response to altered temperature and nitrogen that may have substantial ecosystem consequences over time.

King, J.S., R.B. Thomas, and B.R. Strain. 1997. Morphology and tissue quality of seedling root systems of Pinus taeda and Pinus ponderosa as affected by varying CO₂, temperature, and nitrogen. *Plant and Soil* 195(1):107-119.

Rising atmospheric carbon dioxide, nitrogen deposition and warmer temperatures may alter the quantity and quality of plant-derived organic matter available to soil biota, potentially altering rates of belowground herbivory and decomposition. Our objective was to simulate future growth conditions for an early successional (loblolly) and late successional (ponderosa) species of pine to determine if the physical and chemical properties of the root systems would change. Seedlings were grown for 160 days in greenhouses at the Duke University Phytotron at 35 or 70 Pa CO₂ partial pressure, ambient or ambient +5 degrees C temperature, and 1 or 5 mM NH₄(4)O(3). Roots from harvested seedlings were analyzed for changes in surface area, specific root length, mass, total nonstructural carbohydrates (TNC), and concentrations of macronutrients. Surface area increased in both species under elevated CO₂, due primarily to increases in root length, and this response was greatest (+138%) in loblolly pine at high temperature. Specific root length decreased in loblolly pine at elevated CO₂ but increases in mass more than compensated for this, resulting in net increases in total length. TNC was unaffected and nutrient concentrations decreased only slightly at elevated CO₂, possibly from anatomical changes to the root tissues. We conclude that future growth conditions will enhance soil exploration by some species of pine, but root carbohydrate levels and nutrient concentrations will not be greatly affected, leaving rates of root herbivory and decomposition unaltered.

King, S.P., M.R. Badger, and R.T. Furbank. 1998. CO₂ refixation characteristics of developing canola seeds and silique wall. *Australian Journal of Plant Physiology* 25(3):377-386.

The potential for developing canola (Brassica napus L.) seeds and the interior silique (pod) wall to refix respired CO₂ has been investigated. From ribulose-1,5-bisphosphate carboxylase-oxygenase (Rubisco) and phosphoenolpyruvate carboxylase (PEPC) activities, seeds were estimated to have a greater CO₂ fixation capacity than silique wall endocarp during oil filling. The major component of seed fixation capacity was embryo Rubisco, which had a total activity of 6.3 nmol min⁻¹ embryo⁻¹ (3.7 μmol min⁻¹ mg chlorophyll⁻¹) at 28 days after anthesis (DAA) with smaller contributions from seed coat and embryo PEPC. Rubisco activities were probably maximal in vivo because of high silique cavity CO₂ concentrations (0.8 to 2.5%). Seed chlorophyll content rapidly increased over 10-fold from 20 to 30 DAA and, with 20% of incident light transmitted through the silique wall, embryos demonstrated appreciable photosynthetic electron transport rates and most energy produced appeared to be used for Rubisco-catalysed CO₂ fixation. Endocarp refixation capacity was less than seeds because chlorophyll content was not enriched and PEPC activities were relatively small. These data indicate that developing seeds and also endocarp refix respired CO₂ and that embryo chlorophyll plays a critical role in this refixation.

Kinney, K.K., and R.L. Lindroth. 1997. Responses of three deciduous tree species to atmospheric CO₂ and soil NO₃- availability. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 27(1):1-10.

This research evaluated the direct and interactive effects of atmospheric CO₂ and soil NO₃- availability on growth and biomass partitioning of quaking aspen (*Populus tremuloides* Michx.), red oak (*Quercus rubra* L.), and sugar maple (*Acer saccharum* Marsh.). In the split split plot experimental design, NO₃- availability (low and high) and tree species were nested in two levels of atmospheric CO₂ (ambient, 355 μ mol/L; elevated, 650 μ mol/L). Seedlings were grown for 57 days in environmental control rooms. Increased CO₂ and NO₃- availability positively and (mostly) independently influenced total growth and relative growth rates. Moderate to weak interactions between CO₂ and NO₃- for several growth parameters (e.g., leaf production, shoot length, root collar diameter) in some species indicated an enhanced response to CO₂ enrichment under conditions of high NO₃- availability. Interactive effects were most pronounced in aspen. Seedling growth and allocation responses to CO₂ and NO₃- were frequently species specific and associated with successional status. For example, proportional increases in growth in response to elevated CO₂ were greatest for sugar maple and least for quaking aspen, whereas the converse was true with respect to response to high NO₃- availability. This research indicates that the impact of enriched CO₂ atmospheres on forest communities will be influenced by both nutrient availability and unique species characteristics.

Kinney, K.K., R.L. Lindroth, S.M. Jung, and E.V. Nordheim. 1997. Effects of CO₂ and NO₃- availability on deciduous trees: Phytochemistry and insect performance. *Ecology* 78(1):215-230.

Increasing concentrations of atmospheric CO₂ will interact with other environmental factors to influence the physiology and ecology of trees. This research evaluated how plant phytochemical responses to enriched atmospheric CO₂ are affected by the availability of soil nitrate (NO₃-) and how these chemical changes, in turn, alter the performance of a tree-feeding folivore. Seedlings of three deciduous tree species-quaking aspen (*Populus tremuloides*), red oak (*Quercus rubra*), and sugar maple (*Acer saccharum*)-were grown in ambient (355 μ mol/L) or elevated (650 μ mol/L) CO₂ in combination with low (1.25 mmol/L) or high (7.5 mmol/L) soil NO₃- availability. After 60 d, foliage was analysed for changes in nutrients and allelochemicals likely to be influenced by the availability of CO₂ and NO₃-. Penultimate gypsy moth larvae (*Lymantria dispar*) were reared on foliage (aspen and maple) to determine how performance would be affected by host chemical changes. Using the framework of carbon-nutrient balance (CNB) theory, we tested three hypotheses regarding the impact of CO₂ and NO₃-availability on plant chemistry and insect performance: (1) nitrogen-based compounds will decrease, and carbon-based compounds will increase in response to elevated CO₂ and/or low NO₃-; (2) aspen will exhibit the greatest change in C:N ratios, and maple the least; and (3) phytochemical changes will influence gypsy moth performance, with larvae fed aspen being affected more than those fed maple. Concentrations of nitrogen and soluble protein decreased, whereas concentrations of starch, condensed tannins, and ellagitannins increased, in response to elevated CO₂ and/or low NO₃-. Responses of simple carbohydrates and phenolic glycosides were variable, however, suggesting that foliar accumulations of "dynamic metabolites" do not follow the predictions of CNB theory as well as do those of stable end products. With respect to Hypothesis 2, we found that absolute (net) changes in foliar C:N ratios were greatest for aspen and least for oak,

whereas relative (proportional) changes were greatest for maple and least for aspen. Thus, Hypothesis 2 was only partially supported by the data. Considering Hypothesis 3, we found that elevated CO₂ treatments had little effect on gypsy moth development time, growth rate, or larval mass. Larvae reared on aspen foliage grown under elevated CO₂ exhibited increased consumption but decreased conversion efficiencies. Gypsy moth responses to NO₃- were strongly host specific: the highest consumption and food digestibility occurred in larvae on high-NO₃- aspen, whereas the fastest growth rates occurred in larvae on high-NO₃- maple. In short, our results again only partially supported the predicted pattern. They indicate, however, that the magnitude of insect response elicited by resource-mediated shifts in host chemistry will depend on how levels of compounds with specific importance to insect fitness (e.g., phenolic glycosides in aspen) are affected. Overall, we observed relatively few true interactions (i.e., nonadditive) between carbon and nitrogen availability vis a vis foliar chemistry and insect performance. Tree species, however, frequently interacted with CO₂ and/or NO₃-availability to affect both sets of parameters. These results suggest that the effects of elevated atmospheric CO₂ on terrestrial plant communities will not be homogeneous, but will depend on species composition and soil nutrient availability.

Kinsman, E.A., C. Lewis, M.S. Davies, J.E. Young, D. Francis, I.D. Thomas, K.H. Chorlton, and H.J. Ougham. 1996. Effects of temperature and elevated CO₂ on cell division in shoot meristems: Differential responses of two natural populations of *Dactylis glomerata* L. *Plant, Cell and Environment* 19(6):775-780.

The aim was to establish whether temperature and/or elevated [CO₂] (similar to 700 μ mol mol⁻¹) affects the cell doubling time (cdt) in the different zones of the shoot apex of two natural populations of *Dactylis glomerata* originating in Portugal (38 degrees 53' N) and in Sweden (63 degrees 09' N). In the Portuguese population at ambient [CO₂], only the pith rib meristem (PRM) exhibited a significant shortening of cdt from 10 to 30 degrees C. Elevated [CO₂] resulted in a significant shortening of cdt, particularly in the PRM where cdt was reduced 4- and 6- fold at 10 and 20 degrees C, respectively, but only 2-fold at 30 degrees C. In the Swedish population at ambient [CO₂], there were no consistent temperature-dependent alterations to cdt and this population was less responsive to elevated [CO₂] than the Portuguese population. Nevertheless, elevated [CO₂] resulted in a significant shortening of the cdt for some of the zones; the maximum reduction occurred in the PRM at 30 degrees C. We concluded that in the shoot apex of the Portuguese population, and most notably in the PRM, 10 and 20 degrees C were non-optimal temperatures for cell division, whilst the Swedish population was relatively buffered against temperature change. Elevated [CO₂] resulted in substantially greater reductions in cdt in the shoot meristem of the Portuguese population than in that of the Swedish population.

Kinsman, E.A., C. Lewis, M.S. Davies, J.E. Young, D. Francis, B. Vilhar, and H.J. Ougham. 1997. Elevated CO₂ stimulates cells to divide in grass meristems: a differential effect in two natural populations of *Dactylis glomerata*. *Plant, Cell and Environment* 20(10):1309-1316.

In this study, we tested the hypothesis that elevated [CO₂] shortens the cell cycle in meristems of *Dactylis glomerata*, more in a Portuguese population (38 degrees 53'N) than in a Swedish population (63 degrees

09'N). In the shoot meristem, the cell cycle shortened to about the same extent (approximate to 26%) in both populations exposed to the elevated [CO₂] treatment. In the root meristem, the cell cycle shortened by 17% in the Portuguese and by 8% in the Swedish population. However, the proportion of rapidly cycling cells increased in the Portuguese much more than in the Swedish population in both meristems. In the root meristem, there was a 1.86-fold increase in the Portuguese compared with a 1.31-fold increase in the Swedish. In the shoot meristem, the increases were 1.5-3-fold for the Portuguese and 1.2-fold for the Swedish. The data are consistent in showing that a major response to the elevated [CO₂] treatment was an increase in the proportion of cells that were cycling and that this was more marked for the Portuguese population. A more general response to the elevated [CO₂] treatment was a shortening of the cell cycle regardless of population.

Kirdmanee, C., Y. Kitaya, and T. Kozai. 1995. Effects of CO₂ enrichment and supporting material in-vitro on photoautotrophic growth of eucalyptus plantlets in-vitro and ex-vitro. *In Vitro Cellular & Developmental Biology-Plant* 31(3):144-149.

Eucalyptus camaldulensis shoots were cultured photoautotrophically in vitro for 6 wk with four different types of supporting materials (agar matrix, Gelrite matrix, plastic net, or vermiculite) under CO₂-nonenriched or CO₂-enriched conditions. Plantlets from each treatment in vitro were then grown ex vitro in a greenhouse for 4 wk. The growth and net photosynthetic rate of plantlets in, vitro, as well as subsequent growth, survival percentage, transpiration rate, and net photosynthetic rate of plantlets ex vitro were evaluated. CO₂ enrichment significantly increased growth (total dry weight and number of primary roots) and net photosynthetic rate of plantlets in vitro, as well as the growth and survival percentage of plantlets ex vitro regardless of the type of supporting materials. The growth in vitro was greatest in the vermiculite, followed by the plastic net, Gelrite matrix, and agar matrix (in descending order) under either the CO₂-nonenriched or CO₂-enriched conditions. The growth and survival percentage of plantlets ex vitro were highest in the vermiculite under the CO₂-enriched condition. The extensive root system produced in vitro was necessary for growth and survival of plantlets ex vitro.

Kirkham, M.B., H. He, T.P. Bolger, D.J. Lawlor, and E.T. Kanemasu. 1991. Leaf photosynthesis and water-use of big bluestem under elevated carbon-dioxide. *Crop Science* 31(6):1589-1594.

With the atmospheric concentration of CO₂ increasing, it is important to know how this will affect crop growth. The objective of the study was to determine the effect of elevated CO₂ on big bluestem (*Andropogon gerardii* Vitman) growing in a tallgrass prairie on a Tully silty clay loam (fine, mixed, mesic Pachic Argiustoll) kept at a high water level (field capacity) or a low water level (half field capacity). Sixteen cylindrical plastic chambers were placed on the prairie to maintain the two levels of CO₂ (mean $\pm$ SD: 337 $\pm$ 32 μ mol mol⁻¹ and 81 $\pm$ 81 μ mol mol⁻¹) over a full growing season. Soil-water content was measured weekly with a neutron probe. Photosynthesis, transpiration, stomatal resistance, and intercellular CO₂ concentration were determined with a portable leaf Photosynthetic system. Canopy temperature was monitored with an infrared thermometer. Elevated (doubled) CO₂ reduced transpiration rate of big bluestem by 25 and 35% under the high- and low-water treatments, respectively. Under both watering regimes, stomatal

resistance was greater by almost-equal-to 1.6 s cm⁻¹ with doubled CO₂ than with ambient CO₂. Plants grown with doubled CO₂ at high- and low-water levels had warmer canopy temperatures (average 1.15 and 0.70-degrees-C warmer, respectively) than plants grown at ambient CO₂. Carbon-dioxide concentration did not affect the rate of photosynthesis, even though intercellular CO₂ concentration was increased under high CO₂. Elevated CO₂ did not increase the height of plants grown at the high water level, but it did increase the height at the low water level by an average of 9 cm.

Kirschbaum, M.U.F. 1994. The sensitivity of C-3 photosynthesis to increasing CO₂ concentration - a theoretical-analysis of its dependence on temperature and background CO₂ concentration. *Plant, Cell and Environment* 17(6):747-754.

The atmospheric CO₂ concentration has increased from the pre-industrial concentration of about 280 μ mol mol⁻¹ to its present concentration of over 350 μ mol mol⁻¹, and continues to increase. As the rate of photosynthesis in C-3 plants is strongly dependent on CO₂ concentration, this should have a marked effect on photosynthesis, and hence on plant growth and productivity. The magnitude of photosynthetic responses can be calculated based on the well-developed theory of photosynthetic response to intercellular CO₂ concentration. A simple biochemically based model of photosynthesis was coupled to a model of stomatal conductance to calculate photosynthetic responses to ambient CO₂ concentration. In the combined model, photosynthesis was much more responsive to CO₂ at high than at low temperatures. At 350 μ mol mol⁻¹, photosynthesis at 35 degrees C reached 51% of the rate that would have been possible with non-limiting CO₂, whereas at 5 degrees C, 77% of the CO₂ non-limited rate was attained. Relative CO₂ sensitivity also became smaller at elevated CO₂, as CO₂ concentration increased towards saturation. As photosynthesis was far from being saturated at the current ambient CO₂ concentration, considerable further gains in photosynthesis were predicted through continuing increases in CO₂ concentration. The strong interaction with temperature also leads to photosynthesis in different global regions experiencing very different sensitivities to increasing CO₂ concentrations.

Kirschbaum, M.U.F. 1999. Modelling forest growth and carbon storage in response to increasing CO₂ and temperature. *Tellus Series B-Chemical and Physical Meteorology* 51(5):871-888.

The response of plant growth to increasing climate change remains one of the unresolved issues in understanding the future of the terrestrial biosphere. It was investigated here by using the comprehensive forest growth model CenW 1.0.5 which integrates routines for the fluxes of carbon and water, interception of radiation and the cycling of nutrients. It was run with water and/or nutrient limitations on a background of naturally observed climate at Canberra, Australia. It was parameterised for *Pinus radiata*, the commercially most important plantation species in Australia. The simulations showed that under water-limited conditions, forest growth was highly sensitive to doubling CO₂, with growth increases of over 50% on average and even greater increases in dry years. In contrast, when water supply was adequate, but nutrients were limiting, growth increases were smaller, with an initial increase of about 15% during the first year after CO₂ was doubled. This growth increase diminished further over subsequent years so that after 20 years, there

was virtually no remaining effect. This diminishing response was due to developing nutrient limitations caused by extra carbon input which immobilised nutrients in the soil. When both water and nutrients were adequate, growth was increased by about 15-20% with no decrease over time. Increasing ambient temperature had a positive effect on growth under nutrient limited conditions by stimulating nitrogen mineralisation rates, but had very little effect when nutrients were non-limiting. Responses were qualitatively similar when conditions were changed gradually. In response to increasing CO₂ by 2 $\mu\text{mol mol}^{-1} \text{yr}^{-1}$ over 50 years, growth was increased by only 1% under nutrient- limited condition but by 16% under water-limited conditions. When temperature and CO₂ were both changed to emulate conditions between 1950 and 2030, growth was enhanced between 5-15% over the 80-year period due to the effect of CO₂ on photosynthesis and water economy especially under water-limited conditions, and due to the effect of increasing temperature in mineralising greater amounts of nutrients. These results show that there is not one universally applicable biological growth response to increasing temperature and CO₂, but that they interact in complex ways with a number of other growth limiting factors. Any response factor of plants to CO₂ can only be quantified if the important interacting factors can be independently characterised for different situations.

Kirschbaum, M.U.F. 2000. Will changes in soil organic carbon act as a positive or negative feedback on global warming? *Biogeochemistry* 48(1):21-51.

The world's soils contain about 1500 Gt of organic carbon to a depth of 1m and a further 900 Gt from 1-2m. A change of total soil organic carbon by just 10% would thus be equivalent to all the anthropogenic CO₂ emitted over 30 years. Warming is likely to increase both the rate of decomposition and net primary production (NPP), with a fraction of NPP forming new organic carbon. Evidence from various sources can be used to assess whether NPP or the rate of decomposition has the greater temperature sensitivity, and, hence, whether warming is likely to lead to an increase or decrease in soil organic carbon. Evidence is reviewed from laboratory-based incubations, field measurements of organic carbon storage, carbon isotope ratios and soil respiration with either naturally varying temperatures or after experimentally increasing soil temperatures. Estimates of terrestrial carbon stored at the Last Glacial Maximum are also reviewed. The review concludes that the temperature dependence of organic matter decomposition can be best described as: $d(T) = \exp[3.36 (T - 40)/(T + 31.79)]$ where $d(T)$ is the normalised decomposition rate at temperature T (in degrees C). In this equation, decomposition rate is normalised to '1' at 40 degrees C. The review concludes by simulating the likely changes in soil organic carbon with warming. In summary, it appears likely that warming will have the effect of reducing soil organic carbon by stimulating decomposition rates more than NPP. However, increasing CO₂ is likely to simultaneously have the effect of increasing soil organic carbon through increases in NPP. Any changes are also likely to be very slow. The net effect of changes in soil organic carbon on atmospheric CO₂ loading over the next decades to centuries is, therefore, likely to be small.

Kirschbaum, M.U.F., D.A. King, H.N. Comins, R.E. McMurtrie, B.E. Medlyn, S. Pongracic, D. Murty, H. Keith, R.J. Raison, P.K. Khanna, and D.W. Sheriff. 1994. Modeling forest response to increasing CO₂ concentration under nutrient-limited conditions. *Plant, Cell and Environment* 17(10):1081-1099.

The growth rates of woody plants depend on both the rate of photosynthetic carbon gain and the availability of essential nutrients. Instantaneous carbon gain is known to increase in response to increasing atmospheric CO₂ concentration, but it is uncertain whether this will translate into increased growth in the longer term under nutrient-limited conditions. An analytical model to address this question was developed by Comins and McMurtrie (1993, *Ecological Applications* 3, 666- 681). Their model was further tested and analysed. Manipulation of various assumptions in the model revealed its key assumptions and allowed a more confident prediction of expected growth responses to CO₂ enrichment under nutrient-limited conditions. The analysis indicated that conclusions about the CO₂ sensitivity of production were strongly influenced by assumptions about the relationship between foliar and heartwood nitrogen concentrations. With heartwood nitrogen concentration proportional to foliar nitrogen concentration, the model predicted a strong response of plant productivity to increasing CO₂ concentration, whereas with heartwood nitrogen concentration set constant, the model predicted only a very slight growth response to changing CO₂ concentration. On the other hand, predictions were only slightly affected by: (1) assumptions about the extent of nitrogen retranslocation out of senescing roots and foliage or wood during heartwood formation; (2) the effects of nitrogen status on specific Leaf area or (3) leaf longevity; (4) carbon allocation between different plant parts; or (5) changes in the N:C ratio of organic matter sequestered in the passive pool of soil organic matter. Modification of the effect of foliar nitrogen concentration on the light utilization coefficient had only a small effect on the CO₂ sensitivity for pines. However, this conclusion was strongly dependent on the chosen relationship between single- leaf photosynthesis and leaf nitrogen concentration. Overall, the analysis suggested that trees growing under nitrogen- limited conditions can respond to increasing atmospheric CO₂ concentration with considerable increases in growth.

Kirschbaum, M.U.F., B.E. Medlyn, D.A. King, S. Pongracic, D. Murty, H. Keith, P.K. Khanna, P. Snowdon, and R.J. Raison. 1998. Modelling forest-growth response to increasing CO₂ concentration in relation to various factors affecting nutrient supply. *Global Change Biology* 4(1):23-41.

It is well recognized that photosynthesis of C₃ plants is highly responsive to CO₂ concentration. However, in natural ecosystems, plants are subject to a range of feedback effects that can interact with increased photosynthetic carbon gain in different ways so that it is not clear to what extent increased photosynthesis will translate into increased growth. To assess the probable growth response of nutrient-limited forests to increasing CO₂ concentration, we use a previously developed modelling framework and apply it under conditions where the supply of nutrients is affected by a range of different factors. Our analysis indicates that forest growth is likely to be highly stimulated by increasing CO₂ concentration in forests with high fertility, in forests with nitrogen fixing plants, in those subject to fire or where nitrogen in wood is effectively removed from the biologically active cycle either through physical removal of stems in harvesting or through continued stem growth over long time periods. Forest growth is likely to be stimulated by CO₂ concentration in both phosphorus- and sulphur-

limited forests provided nutrients in heartwood of trees are removed from the active nutrient cycle. Without this removal from the cycling system, however, sulphur-limited forests should show little response to increasing CO₂. In phosphorus-limited forests without phosphorus removal, the response to increasing CO₂ depends further on the equilibration state of the large pool of unavailable secondary phosphorus. Considered over periods of centuries during which the secondary pool has equilibrated, growth of phosphorus-limited forests is likely to be only weakly stimulated by increasing CO₂ concentration. However, over shorter periods, increasing CO₂ concentration should lead to a substantial increase in productivity. In general, it can be concluded that systems that are more open with respect to nutrient gains and losses are likely to be more responsive to increasing CO₂ concentration than systems where the amount of available nutrients is less variable. In more open systems, operation at a lower internal nutrient concentration as a result of increasing atmospheric CO₂ concentration can lead to reduced nutrient losses per unit carbon gain. Our analysis shows that the effect of increasing CO₂ on forest growth can differ substantially between forests due to interactions with a range of factors that affect nutrient supply. The response of a particular forest to increasing CO₂ concentration can only be predicted if the main factors controlling nutrient supply and growth in that forest are understood and incorporated into an assessment.

Kitao, M., T.T. Lei, and T. Koike. 1997. Comparison of photosynthetic responses to manganese toxicity of deciduous broad-leaved trees in northern Japan. *Environmental Pollution* 97(1-2):113-118.

The effects of manganese (Mn) toxicity on photosynthesis of four tree species in northern Japan representing different successional traits were examined. The four species are: *Betula ermanii* (Be) and *Alnus hirsuta* (Ah) representing two early successional species, *Ulmus davidiana* var. *japonica* (Ud) as the mid-successional species, and *Acer mono* (Am) as the late successional species. Seedlings were grown hydroponically in a solution containing nutrients and Mn of four concentrations (1, 10, 50, 100 mg litre⁻¹) for 50 days. Gas exchange measurements indicate that in all species, Mn accumulation in leaves resulted in the decline of light-saturated net photosynthetic rate at ambient CO₂ pressure (Pn(amb)) and at saturating (5%) CO₂ pressure (Pn(sat)), and of carboxylation efficiency but has little effect on the maximum efficiency of photochemistry. Sensitivity to elevated levels of Mn differed among species where the decline of Pn(amb) was much more modest in the two early successional species of Be and Ah than the mid- and late successional species of Ud and Am. The same trends were observed in both Pn(sat) and carboxylation efficiency. Based on these results, we suggest that early successional species (*Betula ermanii* and *Alnus hirsuta*) have greater tolerance for excess Mn in leaves than mid- and late successional species. Kitaya, Y., G.H. Niu, T. Kozai, and M. Ohashi. 1998. Photosynthetic photon flux, photoperiod, and CO₂ concentration affect growth and morphology of lettuce plug transplants. *Hortscience* 33(6):988-991.

Lettuce (*Lactuca sativa* L. cv. Summer-green) plug transplants were grown for 3 weeks under 16 combinations of four levels (100, 150, 200,

and 300 $\mu\text{mol.m}^{-2}.\text{s}^{-1}$) of photosynthetic photon flux (PPF), two photoperiods (16 and 24 h), and two levels of CO₂ (400 and 800 $\mu\text{mol.mol}^{-1}$) in growth chambers maintained at an air temperature of 20 $\pm$ 2 °C. As PPF increased, dry mass (DM), percent DM, and leaf number increased, while ratio of shoot to root dry mass (S/R), ratio of leaf length to leaf width (LL/LW), specific leaf area, and hypocotyl length decreased. At the same PPF, DM was increased by 25% to 100% and 10% to 100% with extended photoperiod and elevated CO₂ concentration, respectively. Dry mass, percent DM, and leaf number increased linearly with daily light integral (DLI, the product of PPF and photoperiod), while S/R, specific leaf area, LL/LW and hypocotyl length decreased as DLI increased under each CO₂ concentration. Hypocotyl length was influenced by PPF and photoperiod, but not by CO₂ concentration. Leaf morphology, which can be reflected by LL/LW, was substantially influenced by PPF at 100 to 200 $\mu\text{mol.m}^{-2}.\text{s}^{-1}$, but not at 200 to 300 $\mu\text{mol.m}^{-2}.\text{s}^{-1}$. At the same DLI, the longer photoperiod promoted growth under the low CO₂ concentration, but not under the high CO₂ concentration. Longer photoperiod and/or higher CO₂ concentration compensated for a low PPF.

Kleemola, J., J. Peltonen, and P. Peltonensainio. 1994. Apical development and growth of barley under different CO₂ and nitrogen regimes. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 173(2):79-92.

Increases in atmospheric carbon dioxide (CO₂) concentration have stimulated interest in the response of agricultural crops to elevated levels of CO₂. Several studies have addressed the response of C3 cereals to CO₂, but the interactive effect of nutrient supply and CO₂ on apical development and spikelet set and survival has not been investigated thoroughly. Hence, an experiment was conducted in the greenhouse to evaluate the effect of high (700 $\mu\text{mol CO}_2\text{mol}^{-1}$ air) and low (400 $\mu\text{mol mol}^{-1}$) levels of atmospheric CO₂ on apical development, spikelet set and abortion, and pre- and post-anthesis growth in spring barley (*Hordeum vulgare* L.) grown under high N (0.3 g N pot⁻¹ before sowing +0.11 g N pot⁻¹ week⁻¹) and low N (0.3 g N pot⁻¹) regimes. The plants were grown in 5 L pots. Development of spike was hastened due to CO₂ enrichment, and the C+ plants pollinated few days earlier than the C- plants. Carbon dioxide enrichment had no effect on date of ripening. Development of spike slowed following application of extra N, and plants pollinated 10 days later and matured 2 weeks later when compared with plants under low N. Carbon dioxide enrichment did not affect the number of spikelets at anthesis. Excess N decreased spikelet abortion and the increased maximum number of spikelets under both [CO₂]. Barley plants did not tiller when grown in low [CO₂] and low N. Increased endogenous IAA concentration in those plants, recorded three days before tillers appeared in other treatments, may have contributed to this. Carbon dioxide enrichment increased the C concentration of plants, but decreased the N concentration under high N regime. Both the C and N concentration of plants were increased under high N regime. Carbon dioxide enrichment increased the total dry matter of mature plants by 9% under high N regime and by 21% under low N regime. Under high [CO₂] increased kernel number on tiller spikes, and increased kernel weight both on main stem and on tiller spikes resulted in a 23% increase in kernel yield under low N regime and 76% increase in kernel yield under high N regime. The rate of N application influenced growth and yield components to a greater extent than CO₂ enrichment. At maturity, plant dry matter, kernel weight, the number of kernels per spike, and the number of spikes per plant were higher under high N regime than under low N regime. Long days (16 h), low light intensity (280 $\mu\text{mol m}^{-2}.\text{s}^{-1}$), and at constant temperature of 20-degrees-C high [CO₂] increased kernel weight and the number of kernels on tiller spikes under high and low N application rate, but did not increase the number of kernels on main stem spike, or the number of tillers or tiller spikes per plant.

Klieber, A., B. Ratanachinakorn, and D.H. Simons. 1996. Effects of low oxygen and high carbon dioxide on tomato cultivar 'Bermuda' fruit physiology and composition. *Scientia Horticulturae* 65(4):251-261.

Breaker stage tomatoes (*Lycopersicon esculentum* Mill., cultivar 'Bermuda') were treated in air, 0.5% or 1.0% oxygen (O₂) in nitrogen (N₂) or 80% carbon dioxide (CO₂) in air for 1, 3, 5 or 7 days at 22 degrees C. A 1 day low O₂ treatment delayed ripening after treatment by 1-2 days compared to a ripening period of 4 days for the control; elevated CO₂ for 1 day had no effect on ripening after treatment. Low O₂ increased production of ethanol and acetaldehyde compared to the control and high CO₂. Fruit treated for 3 or more days in low O₂ or high CO₂ showed skin injury and blotchy ripening. Disease incidence increased with treatment time, but could be controlled in 1 day treatments by reducing relative humidity to about 70%. Firmness, total soluble solids, titratable acidity and pH of pericarp and gel of 1 day treated fruit were not different from the control.

Klironomos, J.N., M.C. Rillig, and M.F. Allen. 1996. Below-ground microbial and microfaunal responses to *Artemisia tridentata* grown under elevated atmospheric CO₂. *Functional Ecology* 10(4):527-534.

1. Soil microbes are fed primarily by root-derived substrates, fulfil functions such as mineralization, immobilization, decomposition, pathogenicity and improvement of plant nutrition, and form the basis of the below-ground food web. Hitherto, belowground processes have generally been monitored using a 'black-box' approach, thereby ignoring effects of global change at a finer level of resolution. We describe shifts in the activity between microbial functional groups associated with roots of *Artemisia tridentata*, and the influence of this change on higher trophic levels. 2. We tested the hypothesis that elevated atmospheric CO₂ causes the soil community to change qualitatively. We measured the responses of several soil microbe and soil microfaunal parameters to a double-ambient CO₂ concentration and nutrient additions. The soil community, as measured by those parameters, showed great changes in response to the treatments. There was a very strong interaction between elevated CO₂ and the nutrient addition. 3. Under low nutrient conditions, total microbial biomass did not change under elevated atmospheric CO₂, but doubled under conditions of elevated CO₂ and added nutrients. As we increased the resolution of our analysis, however, results shifted. Under low nutrient conditions, mycorrhizal fungi responded positively to elevated CO₂, whereas with added soil nutrients they responded negatively to the same elevated CO₂ concentration. Bacteria and non-mycorrhizal fungi did not respond under the former conditions but more than doubled in biomass under conditions of elevated CO₂ and added nutrients. Soil fauna was also affected by the treatments. Overall, elevated CO₂ shifted carbon flow in the plant-soil system to a more mutualistic-closed, mycorrhizal-dominated system, whereas the combination of elevated CO₂ and nutrient addition shifted carbon flow to a more opportunistic-open, saprobe/pathogen-dominated one. 4. This indicates that elevated atmospheric CO₂ may lead to far less predictable feedback patterns than previously thought and that qualitative shifts in the soil community may be far more important than mere changes in total C sink strength.

Klironomos, J.N., M.C. Rillig, M.F. Allen, D.R. Zak, M. Kubiske, and K.S. Pregitzer. 1997. Soil fungal-arthropod responses to *Populus tremuloides* grown under enriched atmospheric CO₂ under field conditions. *Global Change Biology* 3(6):473-478.

We investigated the influence of elevated CO₂ and soil N availability on the growth of arbuscular mycorrhizal and non- mycorrhizal fungi, and on the number of mycophagous soil microarthropods associated with the roots of *Populus tremuloides*. CO₂ concentration did not significantly affect percentage infection of *Populus* roots by mycorrhizal or non-mycorrhizal fungi. However, the extra-radical hyphal network was altered both qualitatively and quantitatively, and there was a strong interaction between CO₂ and soil N availability. Under N-poor soil conditions, elevated CO₂ stimulated hyphal length by arbuscular mycorrhizal fungi, but depressed growth by non-mycorrhizal fungi. There was no CO₂ effect at high N availability. High N availability stimulated growth by opportunistic saprobic/pathogenic fungi. Soil mites were not affected by any treatment, but collembolan numbers were positively correlated with the increase in non-mycorrhizal fungi. Results indicate a strong interaction between CO₂ concentration and soil N availability on mycorrhizal functioning and on fungal-based soil food webs.

Klironomos, J.N., M.C. Rillig, M.F. Allen, D.R. Zak, K.S. Pregitzer, and M.E. Kubiske. 1997. Increased levels of airborne fungal spores in response to *Populus tremuloides* grown under elevated atmospheric CO₂. *Canadian Journal of Botany-Revue Canadienne De Botanique* 75(10):1670-1673.

Soil fungi are important components of terrestrial ecosystems. They function as decomposers, pathogens, parasites, and mutualistic symbionts. Their main mode of dispersal is to liberate spores into the atmosphere. In this study we tested the hypothesis that a higher atmospheric CO₂ concentration will induce greater sporulation in common soil fungi, leading to higher concentrations of fungal propagules in the atmosphere. In our field experiment, the concentration of airborne fungal propagules, mostly spores, increased fourfold under twice-ambient CO₂ concentrations. Analysis of decomposing leaf litter (likely the main source of airborne fungal propagules) indicated that the fungi produced fivefold more spores under elevated CO₂. Our results provide evidence that elevations in atmospheric CO₂ concentration can directly affect microbial function, which may have important implications for litter decay, fungal dispersal, and human respiratory health.

Klironomos, J.N., M. Ursic, M. Rillig, and M.F. Allen. 1998. Interspecific differences in the response of arbuscular mycorrhizal fungi to *Artemisia tridentata* grown under elevated atmospheric CO₂. *New Phytologist* 138(4):599-605.

Arbuscular mycorrhizal (AM) fungi form mutualistic symbioses with the root systems of most plant species. These mutualisms regulate nutrient exchange in the plant-soil interface and might influence the way in

which plants respond to increasing atmospheric CO₂. In other experiments, mycorrhizal responses to elevated CO₂ have been variable, so in this study we test the hypothesis that different genera of AM fungi differ in their response, and in turn alter the plant's response, to elevated CO₂. Four species from three genera of AM fungi were tested. *Artemisia tridentata* Nutt. seedlings were inoculated with either *Glomus intraradices* Schenck & Smith, *Glomus etunicatum* Becker & Gerdemann, *Acaulospora* sp. or *Scutellospora calospora* (Nicol. & Gerd.) Walker & Sanders and grown at either ambient CO₂ (350 ppm) or elevated CO₂ (700 ppm). Several significant inter-specific responses were detected. Elevated CO₂ caused percent arbuscular and hyphal colonization to increase for the two *Glomus* species, but not for *Acaulospora* sp. or *S. calospora*. Vesicular colonization was not affected by elevated CO₂ for any fungal species. In the extra-radical phase, the two *Glomus* species produced a significantly higher number of spores in response to elevated CO₂, whereas *Acaulospora* sp. and *S. calospora* developed significantly higher hyphal lengths. These data show that AM fungal taxa differ in their growth allocation strategies and in their responses to elevated CO₂, and that mycorrhizal diversity should not be overlooked in global change research.

Kloppenburg, W.D., B.G. Wolthers, F. Stellaard, H. Elzinga, T. Tepper, P.E. deJong, and R.M. Huisman. 1997. Determination of urea kinetics by isotope dilution with [C-13]urea and gas chromatography isotope ratio mass spectrometry (GC-IRMS) analysis. *Clinical Science* 93(1):73-80.

1. Stable urea isotopes can be used to study urea kinetics in humans, The use of stable urea isotopes for studying urea kinetic parameters in humans on a large scale is hampered by the high costs of the labelled material. We devised a urea dilution for measurement of the distribution volume, production rate and clearance of urea in healthy subjects and renal failure patients using the inexpensive single labelled [C-13]urea isotope with subsequent analysis by headspace chromatography-isotope ratio MS (GC-IRMS) of the [C-13]urea enrichment. 2. The method involves measurement of the molar percentage excess of [C-13]urea in plasma samples taken over a 4 h period after an intravenous bolus injection of [C-13]urea. During the sample processing procedure, the plasma samples together with calibration samples containing a known molar percentage excess of [C-13]urea are acidified with phosphoric acid to remove endogenous CO₂, and are subsequently incubated with urease to convert the urea present in the plasma samples into CO₂. The C-13 enrichment of the generated CO₂ is analysed by means of GC-IRMS. This method allows measurement of the molar percentage excess of [C-13]urea to an accuracy of 0.02%. 3. Reproducibility studies showed that the sample processing procedure [within-run coefficient of variation (CV) <2.8% and between-run CV <8.8%] and the GC-IRMS analysis (within-day CV <1.3% and between-day CV <1.3%) could be repeated with good reproducibility. 4. In clinical urea kinetic studies in a healthy subject and in a renal failure patient without residual renal function, reproducible values of the distribution volume, production rate and clearance of urea were determined using minimal amounts of [C-13]urea (25-50 mg). 5. because only low [C-13]urea enrichments are needed in this urea dilution method using GC-IRMS analysis, the costs of urea kinetic studies are reduced considerably, especially in patients with renal failure.

Knapp, A.K., M. Cocke, E.P. Hamerlynck, and C.E. Owensby. 1994.

Effect of elevated CO₂ on stomatal density and distribution in a C-4 grass and a C-3 forb under field conditions. *Annals of Botany* 74(6):595-599.

Two common tallgrass prairie species, *Andropogon gerardii*, the dominant C-4 grass in this North American grassland, and *Salvia pitcheri*, a C-3 forb, were exposed to ambient and elevated (twice ambient) CO₂ within open-top chambers throughout the 1993 growing season. After full canopy development, stomatal density on abaxial and adaxial surfaces, guard cell length and specific leaf mass (SLM; mg cm⁻²) were determined for plants in the chambers as well as in adjacent unchambered plots. Record high rainfall amounts during the 1993 growing season minimized water stress in these plants (leaf xylem pressure potential was usually > -1.5 MPa in *A. gerardii*) and also minimized differences in water status among treatments. In *A. gerardii*, stomatal density was significantly higher (190 +/- 7 mm⁻²; mean +/- s.e.) in plants grown outside of the chambers compared to plants that developed inside the ambient CO₂ chambers (161 +/- 5 mm⁻²). Thus, there was a significant 'chamber effect' on stomatal density. At elevated levels of CO₂, stomatal density was even lower (P < 0.05; 121 +/- 5 mm⁻²). Most stomata were on abaxial leaf surfaces in this grass, but the ratio of adaxial to abaxial stomatal density was greater at elevated levels of CO₂. In *S. pitcheri*, stomatal density was also significantly lower when plants were grown in the open-top chambers (235 +/- 10 mm⁻² outside vs. 140 +/- 6 mm⁻² in the ambient CO₂ chamber). However, stomatal density was greater at elevated CO₂ (218 +/- 12 mm⁻²) compared to plants from the ambient CO₂ chamber. The ratio of stomata on adaxial vs. abaxial surfaces did not vary significantly in this herb. Guard cell lengths were not significantly affected by growth in the chambers or by elevated CO₂ for either species. Growth within the chambers resulted in lower SLM in *S. pitcheri*, but CO₂ concentration had no effect. In *A. gerardii*, SLM was lower at elevated CO₂. These results indicate that stomatal and leaf responses to elevated CO₂ are species specific, and reinforce the need to assess chamber effects along with treatment effects (CO₂) when using open-top chambers.

Knapp, A.K., S.L. Conard, and J.M. Blair. 1998. Determinants of soil CO₂ flux from a sub-humid grassland: Effect of fire and fire history. *Ecological Applications* 8(3):760-770.

Soil CO₂ flux (J(CO₂)) was measured at midday over a 2-yr period in undisturbed tallgrass prairie (Konza Prairie, Kansas, USA) to quantify seasonal and annual budgets, to evaluate temperature and moisture as determinants of soil CO₂ flux, and to assess the effect of a common land management tool, spring fire, and fire history on soil respiration. We hypothesized that: (1) maximum rates and annual estimates of soil J(CO₂) would be greater in more productive burned sites than in unburned sites, (2) soil J(CO₂) would be greater in newly burned sites with a history of fire exclusion than in annually burned sites (consistent with differences in aboveground production), and (3) soil temperature and water availability would be primary abiotic determinants of soil J(CO₂) in tallgrass prairie. A preliminary assessment of the effects of large herbivores on soil J(CO₂) was included to evaluate the hypothesis that removal of aboveground biomass would reduce soil J(CO₂). Results indicated that spring fire increased maximum monthly soil J(CO₂) by 20-55% relative to unburned tallgrass prairie, with greatest monthly differences measured in April (fourfold higher in burned sites). In burned sites that differed in fire history, maximum monthly J(CO₂) in annually burned prairie was 33% greater than in burned sites with a history of fire exclusion. Soil J(CO₂) in these latter sites was still significantly higher than in unburned sites. Soil J(CO₂) in sites grazed by bison was reduced by as much as 30% relative to adjacent ungrazed areas. Reduced root biomass and activity in grazed areas, unburned sites,

and sites with a history of fire exclusion suggest that plants play a major role in determining soil J(CO₂) in this grassland. Soil temperature at 5 cm was related strongly to midday J(CO₂) in both annually burned sites ($r(2) = 0.58$) and unburned sites ($r(2) = 0.71$). In contrast, differences in soil moisture among sites, enhanced by comparing irrigated grassland to control areas, increased maximum monthly J(CO₂) by only 8%. Thus, soil temperature was the primary abiotic determinant of soil J(CO₂) during this study. Maximum monthly estimates of soil J(CO₂) in tallgrass prairie ranged from 10.3 $\mu\text{mol CO}_2 \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ in unburned sites to 15.1 $\mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ in annually burned irrigated sites, whereas annual estimates varied from 4.7 to 7.8 kg CO₂/m². Over the 2-yr period, spring fire increased estimated annual soil J(CO₂) by 38-51% relative to unburned sites, while irrigation increased annual soil J(CO₂) by 13%. These estimates for tallgrass prairie are much higher than those reported for most temperate ecosystems but are similar to estimates for tropical forests. Characteristics of undisturbed tallgrass prairie that may lead to high levels of soil J(CO₂) include: high above- and belowground productivity; a relatively high proportion of C stored belowground; levels of soil microbial biomass and activity that are among the highest in native ecosystems in the United States; and the lack of a single dominant factor such as temperature, moisture, or nutrient availability, that consistently limits biotic processes during the growing season. The sensitivity of soil J(CO₂) in tallgrass prairie to different land use practices (fire and grazing) suggests that it is critical to include these factors in the development of grassland C budgets, as well as in regional models that estimate biogeochemical responses to land use change.

Knapp, A.K., J.T. Fahnestock, and C.E. Owensby. 1994. Elevated atmospheric CO₂ alters stomatal responses to variable sunlight in a C-4 grass. *Plant, Cell and Environment* 17(2):189-195.

Native tallgrass prairie in NE Kansas was exposed to elevated (twice ambient) or ambient atmospheric CO₂ levels in open-top chambers. Within chambers or in adjacent unchambered plots, the dominant C-4 grass, *Andropogon gerardii*, was subjected to fluctuations in sunlight similar to that produced by clouds or within canopy shading (full sun > 1500 $\mu\text{mol m}^{-2} \text{s}^{-1}$ versus 350 $\mu\text{mol m}^{-2} \text{s}^{-1}$ shade) and responses in gas exchange were measured. These field experiments demonstrated that stomatal conductance in *A. gerardii* achieved new steady state levels more rapidly after abrupt changes in sunlight at elevated CO₂ when compared to plants at ambient CO₂. This was due primarily to the 50% reduction in stomatal conductance at elevated CO₂, but was also a result of more rapid stomatal responses. Time constants describing stomatal responses were significantly reduced (29-33%) at elevated CO₂. As a result, water loss was decreased by as much as 57% (6.5% due to more rapid stomatal responses). Concurrent increases in leaf xylem pressure potential during periods of sunlight variability provided additional evidence that more rapid stomatal responses at elevated CO₂ enhanced plant water status. CO₂-induced alterations in the kinetics of stomatal responses to variable sunlight will likely enhance direct effects of elevated CO₂ on plant water relations in all ecosystems.

Knapp, A.K., E.P. Hamerlynck, J.M. Ham, and C.E. Owensby.

1996. Responses in stomatal conductance to elevated CO₂ in 12 grassland species that differ in growth form. *Vegetatio* 125(1):31-41.

Responses in stomatal conductance ($g(\text{st})$) and leaf xylem pressure potential ($\text{psi}(\text{leaf})$) to elevated CO₂ (2x ambient) were compared among 12 tallgrass prairie species that differed in growth form and growth rate. Open-top chambers (OTCs, 4.5 m diameter, 4.0 m in height) were used to expose plants to ambient and elevated CO₂ concentrations from April through November in undisturbed tallgrass prairie in NE Kansas (USA). In June and August, $\text{psi}(\text{leaf})$ was usually higher in all species at elevated CO₂ and was lowest in adjacent field plots (without OTCs). During June, when water availability was high, elevated CO₂ resulted in decreased $g(\text{st})$ in 10 of the 12 species measured. Greatest decreases in $g(\text{st})$ (ca. 50%) occurred in growth forms with the highest potential growth rates (C-3 and C-4 grasses, and C-3 ruderals). In contrast, no significant decrease in $g(\text{st})$ was measured in the two C-3 shrubs. During a dry period in September, reductions in $g(\text{st})$ at elevated CO₂ were measured in only two species (a C-3 ruderal and a C-4 grass) whereas increased $g(\text{st})$ at elevated CO₂ was measured in the shrubs and a C-3 forb. These increases in $g(\text{st})$ were attributed to enhanced $\text{psi}(\text{leaf})$ in the elevated CO₂ plants resulting from increased soil water availability and/or greater root biomass. During a wet period in September, only reductions in $g(\text{st})$ were measured in response to elevated CO₂. Thus, there was significant interspecific variability in stomatal responses to CO₂ that may be related to growth form or growth rate and plant water relations. The effect of growth in the OTCs, relative to field plants, was usually positive for $g(\text{st})$ and was greatest (> 30%) when water availability was low, but only 6-12% when $\text{psi}(\text{leaf})$ was high. The results of this study confirm the importance of considering interactions between indirect effects of high CO₂ of plant water relations and direct effects of elevated CO₂ on $g(\text{st})$, particularly in ecosystems such as grasslands where water availability often limits productivity. A product of this interaction is that the potential exists for either positive or negative responses in $g(\text{st})$ to be measured at elevated levels of CO₂.

Knapp, A.K., E.P. Hamerlynck, and C.E. Owensby. 1993. Photosynthetic and water relations responses to elevated CO₂ in the C-4 grass *andropogon-gerardii*. *International Journal of Plant Science* 154(4):459-466.

Undisturbed tallgrass prairie, dominated by the C-4 grass *Andropogon gerardii*, was exposed to ambient and elevated (double ambient) levels of atmospheric CO₂ in large open-top chambers throughout the 1991 and 1992 growing seasons. Responses in leaf xylem pressure potential (psi), net photosynthesis (A), and stomatal conductance (g) were measured in both years for *A. gerardii* grown within chambers and from adjacent field plots. In 1992, maximum photosynthetic capacity ($A(\text{max})$), apparent quantum requirement ($Q(r)$), the photosynthetic light compensation point (LCP), and dark respiration ($R(d)$) were also measured. Midday psi was significantly higher in plants grown at elevated CO₂ in both years, and seasonally averaged psi was 0.48-0.70 MPa lower in 1991 (a dry year) than 1992 (a wet year). In 1991, A and g were significantly higher (regardless of measurement CO₂ level) in plants grown at elevated vs. ambient CO₂. These increases were measured in well-watered plants insuring that these plants differed only in CO₂ growth conditions and previous exposure to low psi . Increased A at elevated CO₂ occurred (as much as 7.1 $\mu\text{mol m}^{-2} \text{s}^{-1}$) over a broad range of temperatures (17-35 C), but the temperature optimum for A was similar at both 350 and 700 $\mu\text{mol L}^{-1}$ CO₂. In 1992, no differences in A , $A(\text{max})$, $Q(r)$, LCP, or $R(d)$ were detected when ambient and elevated CO₂ plants were compared. In plants collected

from field plots, R(d), LCP, and leaf N were significantly higher than in plants within the chambers indicating that a chamber effect exists for these parameters. In both years, g was significantly reduced (21%-51%) when measured at 700 vs. 350 $\mu\text{L L}^{-1}$ CO₂. Peak aboveground biomass was increased at elevated CO₂ in 1991 but not in 1992. These data indicate that for C-4 grasses, effects of elevated CO₂ may only be detectable in years with significant water stress, a common occurrence in the central North American tallgrass prairies.

Knapp, P.A., and P.T. Soule. 1998. Recent *Juniperus occidentalis* (western juniper) expansion on a protected site in central Oregon. *Global Change Biology* 4(3):347-357.

The expansion of *Juniperus occidentalis* (western juniper) has been extensive in the last century, and increases in density and cover have been linked with the indirect effects of domestic livestock grazing (i.e. cessation of periodic fires, increases of nurse-plant sites), and more favourable climatic conditions. In this study, we document changes in vegetation (including *J. occidentalis*) in central Oregon over a 23-year period and relate these changes to their probable causes. In June 1995 we returned to the Horse Ridge Research Natural Area (HRRNA), a site that has a history of minimal anthropogenic impacts, to replicate a 1972 vegetation survey. Using the canopy-intercept method, line intercept method, and aerial photography analysis to measure herbaceous cover, shrub cover and tree cover, respectively, we found significant changes had occurred in the 23-year period between studies. Relative changes of tree, shrub, and perennial herbaceous cover were 59%, 7%, and -38%, respectively. Relative increases in *J. occidentalis* density, as measured by the number of clumps and the number of stems, were 37% and 53%, respectively. Mean maximum height of *J. occidentalis* had increased by 10%. We examined the role of potentially confounding influences (e.g. fire, grazing, pathogens, climatic variability) and found that none of the traditional mechanisms implicated in *J. occidentalis* expansion adequately explained the observed changes. We suggest that the role of biological inertia of both anthropogenic and natural means may have had a profound effect on the *J. occidentalis* ecology of HRRNA.

Knapp, T., and R. Mookerjee. 1996. Population growth and global CO₂ emissions - A secular perspective. *Energy Policy* 24(1):31-37.

Considerable scientific effort has been applied to the question of whether worldwide fossil fuel combustion and the resultant emission of CO₂ (as well as emissions of other greenhouse gases) will cause a discernible enhancement of the greenhouse effect in the next century. A more precise understanding of the contribution of human activity to potential global warming (vis-ri-vis natural climatic variability) is of critical policy interest. Surprisingly little research has been devoted to establishing the underlying statistical relationship between human activities and CO₂ emissions. In this paper, we explore the nature of the relationship between global population growth and CO₂ emissions by employing the test of causality developed by Granger on annual data for 1880-1989, as well as more comprehensive error correction and cointegration models. The results suggest a lack of a long-term equilibrium relationship, but imply a short-term dynamic relationship from CO₂ to population growth.

Kobayashi, K. 1994. Mapping results of crop growth simulation in a vector-space. *Agricultural and Forest Meteorology* 68(1-2):43-61.

Crop growth models can be used to address the mode-of-action of the global change impacts on crop yield as well as to predict the extent of the yield change. Presented in this paper are the framework to analyze the simulated yield change caused by the variations of many influencing factors and some methods to visualize the yield change. In the framework, the simulated yield change is mapped into an n-dimensional vector space, where n is the number of the simulated cases, e.g. years or locations. Yield changes owing to the individual impacts as well as the impact of simultaneous changes in all the factors are represented by vectors in the n-dimensional space. Contributions of the individual impacts to the simulated yield change and the interrelations between the impacts can be represented by the magnitude and orientation of the vectors. To visualize the vectors, however, the dimension n must be three or less. This is not the case, in general, and hence some methods are needed to reduce the dimension. By combining the influencing factors into three or less groups, the vectors for each group can be visualized in a subspace of dimension three or less. Impacts within each group may be further visualized in the same way. Taking an average is another way to reduce the dimension of the vector space. With it, the n-dimensional space is partitioned into a one-dimensional space for the mean and an (n - 1)-dimensional space for the deviation of the yield change. These methods were applied to an example of the simulated yield changes in soybean and maize owing to climate change (precipitation increase and temperature rise) and elevated CO₂ (increases in the radiation use efficiency and the water use efficiency). The analyses revealed the differences between soybean and maize with respect to their responses to the simulated impacts of the climate change and the elevated CO₂. These inter-specific differences were related to the differential changes in growth processes. The difference between the two impacts, i.e. the climate change and the CO₂ increase, was also addressed. Utilities of the above approach were discussed and compared with the sensitivity analysis. Limitation of this approach was also discussed.

Kohlmaier, G.H., C. Hager, G. Wurth, M.K.B. Ludeke, P. Ramage, F.W. Badeck, J. Kindermann, and T. Lang. 1995. Effects of the age class distributions of the temperate and boreal forests on the global CO₂ source-sink function. *Tellus Series B-Chemical and Physical Meteorology* 47(1-2):212-231.

The role of the temperate and boreal forests as a global CO₂ source or sink is examined, both for the present time and for the next hundred years. The results of the Forest Resource Assessment for 1990 of the Economic Commission for Europe and the Food and Agricultural Organisation of the United Nations (1992) serve as the main database in this study. Out of the estimated total area of approximately 20 . 10(6) km(2) of forests and wooded lands in the temperate and boreal zone only approximately fifty percent is documented within the category of exploitable forests, which are examined in detail here. In this study, a general formalism of the time evolution of an ensemble of forests within an ecological province is developed using the formalism of the Leslie matrix. This matrix can be formulated if the age class dependent mortalities which arise from the disturbances are known. A distinction is made between the natural disturbances by fire, wind throw and insect

infestations and disturbances introduced through harvesting of timber. Through the use of Richards growth function each age class of a given biome is related to the corresponding biomass and annual increment. The data reported on the mean net annual increment and on the mean biomass serve to calibrate the model. The difference of the reported net annual increment and annual fellings of approximately 550 . 10(6) m(3) roundwood correspond to a sink of 210-330 Mt of carbon per year excluding any changes in the soil balance. it could be shown that the present distribution of forest age classes for the United States, Canada, Europe, or the former Soviet Union does not correspond to a quasi-stationary state, in which biomass is accumulated only due to a stimulated growth under enhanced atmospheric CO₂ levels. The present CO₂ sink function will not persist in the next century, if harvesting rates increase with 0.5% annually or even less. The future state will also be influenced by the effect of the greenhouse climate, the impact of which may range from a stimulating effect on growth. which is calculated by the Frankfurt biosphere model, up to a transitional negative effect through a shift in vegetation zones.

Koike, T. 1995. Effects of CO₂ in interaction with temperature and soil fertility on the foliar phenology of alder, birch, and maple seedlings. *Canadian Journal of Botany-Revue Canadienne De Botanique* 73(2):149-157.

The foliar phenology of potted 1-year-old seedlings of alder (*Alnus hirsuta* Turcz.), maple (*Acer mono Maxim.*), and birch (*Betula platyphylla* Sukatch. var. *japonica* Hara) was observed from May to September in eight growth environments: factorial combinations of temperatures (light:dark, 30:20 degrees C and 26:16 degrees C), CO₂ level (70 and 36 Pa), and nutrient regime (high versus low levels of fertilization). Seedlings grown at high fertility always had more leaves, and under high CO₂, shed leaves slightly later than seedlings grown at low fertility. Except for maple, production of newly formed shoots and leaves was accelerated by high CO₂. In maple, high CO₂ only increased the number of flushes of the leader shoot. Alder and birch accelerated sylleptic shoot and leaf production at high CO₂ in fertile conditions. The production of new leaves by alder grown at high CO₂ and low fertility was almost the same as that grown under normal CO₂ at high fertility. At high CO₂, the timing of winter bud formation of monopodial alder and maple was delayed, while that of sympodial birch was almost the same as at ambient CO₂.

Koike, T., T.T. Lei, T.C. Maximov, R. Tabuchi, K. Takahashi, and B.I. Ivanov. 1996. Comparison of the photosynthetic capacity of Siberian and Japanese birch seedlings grown in elevated CO₂ and temperature. *Tree Physiology* 16(3):381-385.

The effects of increased CO₂ and temperature on the photosynthetic capacity of Siberian white birch and Japanese white birch (*Betula platyphylla* Sukatch. and *B. platyphylla* Sukatch. var. *japonica* Hara) were measured. Birch seedlings were raised with a CO₂ partial pressure of 36 +/- 0.3 Pa (i.e., ambient) or 70 +/- 0.6 Pa at day/night temperatures of either 30/16 degrees C or 26/12 degrees C. Siberian birch leaves were smaller and thicker than Japanese birch leaves. Water use efficiency and nitrogen use efficiency of Siberian birch grown in the CO₂-enriched air were higher than those of Japanese birch. Both species showed a

physiological adjustment to the growth CO₂ partial pressure. Carboxylation efficiency and quantum yield of both species grown in CO₂-enriched air were lower than those of seedlings grown in ambient CO₂. The adaptation of Siberian and Japanese birch to elevated CO₂ and temperature are discussed in relation to predicted climate change.

Kojima, S. 1994. Effects of global climatic warming on the boreal forest. *Journal of Plant Research* 107(1085):91-97.

On the basis of the predictions of the global climatic warming induced by anthropogenic activities, as provided by climatologists, current state of knowledge regarding possible ecological consequences of the warming on the boreal biome was discussed. A 600 to 700 km northward advance of the biome along with the warming was predicted. Such a shift could take place for half a century or so, which would be an unprecedentedly fast rate of progression. This might cause a serious disorder in species composition of the biome, particularly in the boundary regions. As to the carbon sink or source issues, considerable uncertainties and knowledge gaps existed. Elevated temperature and CO₂ levels would stimulate photosynthesis to result in an increase of CO₂ uptake, while the temperature increase would promote decomposition of organic matter especially that stored in the soils to release CO₂ to the atmosphere. Behaviors of northern peat bogs, where ca. 700 Gt of organic matter was thought to be accumulated, would seriously affect the balance. However, overall ecosystematic carbon balance was yet to be fully studied. It was realized that multifunctional approaches needed to be developed so as to integrate pieces of various information into a holistic picture. Need for international collaboration research efforts was also addressed.

Kontak, D.J., and R. Kerrich. 1997. An isotopic (C, O, Sr) study of vein gold deposits in the Meguma terrane, Nova Scotia: Implication for source reservoirs. *Economic Geology and the Bulletin of the Society of Economic Geologists* 92(2):161-180.

Vein quartz, carbonate, and tourmaline from 19 Meguma gold deposits in the Meguma terrane of Nova Scotia have been analyzed for stable (delta(18)O, delta(13)C) and radiogenic (Sr-87/Sr-86) isotopes in order to assess the nature and origin of the vein-forming fluids. As with other mesothermal gold provinces, the Meguma gold deposits are well suited to such a study because carbonate is the next most abundant phase after quartz in these mesothermal lode gold deposits. All vein types have been sampled for quartz and carbonate and, in addition, all compositional and textural varieties of carbonate have been sampled. Vein quartz is of uniform isotopic composition with most delta(18)O values between 10.2 to 17.6 per mil (avg ca. 14 parts per thousand), except for one deposit (West Gore Sb-Au) where values go to 19.4 per mil. There is no systematic variation for quartz within a deposit or position within the Meguma Group stratigraphy. Vein carbonate delta(18)O values range from 11.8 to 27.5 per mil, with most in the 13 to 16 per mil range. The relatively O-18-enriched carbonates reflect exchange with low-temperature fluids based on analyses of quartz-carbonate pairs that indicate disequilibrium fractionation (Delta(quartz-carbonate) less than or equal to 0); this is best illustrated by the strong negative correlation between delta(18)O(carbonate) and Delta(quartz-carbonate). The

$\delta(18)\text{O}(\text{water})$ is estimated at 10 ± 3 per mil for a temperature of vein formation of 350 degrees to 400 degrees C and using the appropriate mineral-water fractionation equations. Whereas $\delta(\text{water})(18)$ values partly overlap the field for magmatic fluids, the values are wholly consistent with a metamorphic fluid, and it is considered unlikely that a primary magmatic fluid signature has been substantially modified due to wall-rock influences given that mesothermal gold systems are sites of high fluid/rock ratios. Vein carbonate has $\delta(13)\text{C}$ values of -13.1 to -25.9 per mil, but a slight negative correlation between $\delta(13)\text{C}(\text{carbonate})$ and $\Delta(\text{quartz-carbonate})$ suggests that the primary values lie in the range -20 to -25 per mil. Thus, the $\delta(13)\text{C}$ values indicate a reduced, biogenic source for the carbon. Oxidation of the reduced carbon, as indicated by CO_2 in fluid inclusions, may have occurred via hydrolysis of graphite or dissolution of carbonate minerals, both of which occur in the wall-rock lithologies of the Meguma Group, the latter of which has the appropriate isotopic composition. The initial Sr-87/Sr-66 of the vein fluid, estimated from the analyses of 52 vein carbonates (17 deposits) and four tourmalines (three deposits), ranges from 0.70118 to 0.72284 and within deposits considerable variation is observed. There is insufficient data to quantify the extent of the low-temperature overprint which has modified the C and O isotope data, although it is likely that some influence is present. Nevertheless, the data cannot be reconciled by a source confined exclusively to the Meguma Group, which suggests, therefore, involvement of another reservoir(s). The isotopic heterogeneity can be explained by variable amounts of contamination of a primary fluid with radiogenic Sr derived from Meguma Group lithologies by interaction along the fluid path or at the site of vein formation concomitant with wall-rock alteration; as discussed above, a dominantly magmatic source is not considered feasible. This fluid source is suggested to be within the structural basement to the Meguma Group, and the Liscomb gneisses are the favored source based on the combined results of the Sr isotope data presented herein and previously published Pb isotope data. Collectively, the data indicate that a primary fluid of metamorphic origin has had its isotopic signature variably modified due to interaction with different reservoirs. The most affected isotopic systems are C and S (based on earlier work on $\delta(35)\text{S}$ values) which are abundant as graphite carbonate and sulfides in the Meguma wall rock, respectively. The range in Sr-87/Sr-86 values of the fluid also reflects contamination, but this was quite variable. The uniform $\delta(18)\text{O}(\text{water})$ value for the fluid indicates that this was the least affected isotopic system, except for the later exchange of carbonate at low temperatures.

Koricheva, J., S. Larsson, E. Haukioja, and M. Keinänen. 1998. Regulation of woody plant secondary metabolism by resource availability: hypothesis testing by means of meta-analysis. *Oikos* 83(2):212-226.

Our aim in this study was to determine how well phenotypic variation in foliar concentrations of carbon-based secondary compounds (CBSCs) in woody plants can be predicted on the basis of two resource-based hypotheses, i.e. the carbon-nutrient balance (CNB) and growth-differentiation balance (GDB) hypotheses. We conducted a meta-analysis of literature data with respect to responses of CBSCs, carbohydrates and nitrogen to six types of environmental manipulations (fertilization with nitrogen or phosphorus, shading, CO_2 enrichment, drought stress, ozone exposure): Plant responses to nitrogen fertilization, shading and CO_2 enrichment in terms of pooled CBSCs and carbohydrates were consistent with predictions made with the two hypotheses. However, among biosynthetically distinct groups of CBSCs

only concentrations of phenylpropanoid-derived compounds changed as predicted; hydrolyzable tannins and terpenoids, in particular, were less responsive. Phosphorus fertilization did not affect concentrations of CBSC or primary metabolites. Plant responses to drought and ozone exposure presumably were driven by plant demands for particular types of compounds (osmolites in the case of drought and antioxidants in the case of ozone exposure) rather than by changes in resource availability. Based on the relative importance of the treatment effects, we propose a hierarchical model of carbon allocation to CBSCs. The model implies that CBSC production is determined by both resource availability and specific demand-side responses. However, these two mechanisms work at different hierarchical levels. The domain of the CNB and GDB hypotheses is at the high hierarchical levels, predicting the total amount of carbon that can be allocated to CBSCs. Predicting altered concentrations of individual CBSCs, i.e. low hierarchy levels, probably demands biosynthetically detailed models which also take into account the history of plant interactions with biotic and abiotic factors.

Korner, C. 1995. Towards a better experimental basis for upscaling plant- responses to elevated CO_2 and climate warming. *Plant, Cell and Environment* 18(10):1101-1110.

Few of the most common assumptions used in models of responses of plants and ecosystems to elevated CO_2 and climate warming have been tested under realistic life conditions. It is shown that some unexpected discrepancies between predictions and experimental findings exist, suggesting that a better empirical basis is required for predictions. The following ten suggestions may improve our potential to scale up from experimental scales to the real world, (1) Experiments should be timed to account for non-linearity in system responsiveness, asynchrony of responses and developmental differences, (2) By altering mineral nutrient supply, a wide range of CO_2 responses can be 'produced', thus requiring realistic soil conditions, (3) Distinctions should be made between 'doubling CO_2 supply' and biologically effective degrees of CO_2 enrichment. (4) Because of the non-linearity of plant responses to CO_2 , studies of at least three instead of two CO_2 concentrations are necessary to describe future trends adequately, (5) Edge effects, in particular unscreened side light, may lead to allometric anomalies, strongly constraining up-scaling to stand-scale CO_2 responses, (6) Variables such as growth, yield, net primary production and C turnover are often confused with carbon pools, carbon sequestration or net ecosystem production, (7) Mono- and interspecific interactions between individuals may lead to completely unpredictable CO_2 responses, (8) Experiments with seedlings benefit from the absence of prehistory effects but are likely to be irrelevant for the responses of larger trees which, on the other hand, may be constrained by carryover effects. Tree ring research indicates immediate sensitivity of large trees to environmental changes, supporting their usefulness in short-term CO_2 -enrichment experiments, (9) In predicting temperature responses, acclimation deserves more attention, (10) The significance of developmental responses is largely under-represented in experimental research, although these responses may overrule many of the other effects of atmospheric change. Results of more realistic experiments which account for these problems will provide a better basis for modelling the future of the biosphere.

Korner, C. 1998. Tropical forests in a CO₂-rich world. *Climatic Change* 39(2-3):297-315.

Tropical forests resemble, besides their enormous genetic diversity, the single largest biomass carbon pool in the world. Only a 'small' annual increase of this pool could trap the current surplus of atmospheric CO₂. The fact that this is not happening already today (after the world has seen a 27% increase in atmospheric CO₂ in only 150 years) sets the boundaries of the likely trends to be expected in the future. In contrast to the possibly small overall responses of the tropical forest carbon pool, individual plant responses to CO₂ enrichment will be significant. Since species and their genotypes will not respond in identical ways, selective processes will be induced which will lead to new community structures and alterations of numerous plant-plant, plant-animal and plant-microbe interactions. Examples are provided for such subtle CO₂ effects, measured both in the greenhouse and in the field. From what is known currently it is concluded that in closed humid tropical forests leaf area index is unlikely to increase, mineral nutrient and water demand may (at least temporarily) become reduced, and leaf tissue quality plus associated consumer behavior will be altered. The big unknown is the behavior of tropical soils and their microflora and fauna. There is a realistic possibility that carbon turnover will be increased in tropical forests in a CO₂-enriched world, which would have substantial implications for nutrient cycling.

Korner, C., and J.A. Arnone. 1992. Responses to elevated carbon-dioxide in artificial tropical ecosystems. *Science* 257(5077):1672-1675.

Carbon, nutrient, and water balance as well as key plant and soil processes were simultaneously monitored for humid tropical plant communities treated with CO₂-enriched atmospheres. Despite vigorous growth, no significant differences in stand biomass (of both the understory and overstory), leaf area index, nitrogen or water consumption, or leaf stomatal behavior were detected between ambient and elevated CO₂ treatments. Major responses under elevated CO₂ included massive starch accumulation in the tops of canopies, increased fine-root production, and a doubling of CO₂ evolution from the soil. Stimulated rhizosphere activity was accompanied by increased loss of soil carbon and increased mineral nutrient leaching. This study points at the inadequacy of scaling-up from physiological baselines to ecosystems without accounting for interactions among components, and it emphasizes the urgent need for whole-system experimental approaches in global-change research.

Korner, C., and M. Diemer. 1994. Evidence that plants from high-altitudes retain their greater photosynthetic efficiency under elevated CO₂. *Functional Ecology* 8(1):58-68.

1. Herbaceous plant species native to low and high altitudes in the Alps evolved under CO₂ partial pressures (P-a) that differ as much as pre-industrial P-a differs from present day P-a at low altitude (e.g. 21% for a 2000-m difference in altitude). 2. In a previous study we showed that the efficiency of CO₂ uptake (ECU) in typical high-altitude species is generally greater than in low-altitude species. Here we investigate whether this difference prevails under longer-term exposure to altered P-a. 3. Alpine and lowland species (mainly *Ranunculus glacialis*/R. acris and *Geum reptans*/G. rivale) were grown under various CO₂ regimes in full daylight growth chambers at their respective natural growth temperature and photoperiod. When they were grown at twice the present CO₂ level only moderate downward adjustment of photosynthesis was observed in both groups of species. The adjustments were not enough to compensate for the effect of increased CO₂ supply. These trends prevailed under reciprocally exchanged alpine/lowland partial pressure of CO₂ at the same total atmospheric pressure. 4. Irrespective of altitudinal origin, greatest downward adjustment of photosynthesis was found in species with the most pronounced accumulation of non-structural carbohydrate and dilution of leaf nitrogen when grown under elevated CO₂ (e.g. in G. rivale). 5. These results suggest that, at least initially, the alpine plant species studied may attain relatively greater carbon gains in a CO₂-enriched atmosphere than comparable lowland plant species.

Korner, C., M. Diemer, B. Schappi, P. Niklaus, and J. Arnone. 1997. The responses of alpine grassland to four seasons of CO₂ enrichment: a synthesis. *Acta Oecologica-International Journal of Ecology* 18(3):165-175.

Alpine grassland at 2470 m altitude in the Swiss Central Alps was exposed to elevated CO₂ by using open top chambers (16 ambient, 16 elevated CO₂). Some plots received mineral fertilizer at a rate of N-deposition commonly measured in low altitude parts of Europe. Here we present a summary of results and data from the final harvest. Above-ground biomass measured after the completion of growth in the fourth season of treatment was not affected by CO₂ enrichment as was found by previous biometric estimates, but mean below-ground biomass was slightly stimulated (+12%, n.s.). In contrast, net CO₂ uptake per unit land area was strongly stimulated by CO₂ enrichment at the beginning of the experiment, and during the early part of each season. However, the CO₂ stimulation decreased during the later part of each growing season. By year four, also mid-season differences in CO₂ uptake per unit land area had disappeared. Neither microbial biomass, soil respiration in the laboratory, nor in situ land-area-based CO₂ evolution during the 10 week growing season increased under elevated CO₂. The total biomass N-pool and free soil nitrate and ammonium (capture by ion exchange resin bags) remained unaffected, whereas leaf nitrogen concentration was reduced and nonstructural carbohydrate concentration increased under elevated CO₂ in forbs. These differences in tissue composition largely disappeared during senescence and litter formation. Despite low CO₂ responsiveness at ecosystem level, species responses differed in terms of nitrogen, carbohydrates, tillering and flowering, suggesting the possibility for long-term changes in community structure. Addition of NPK equivalent to 40 kg N ha⁻¹ a⁻¹ had massive effects on all plant traits studied, but did not enable stimulated growth under CO₂ enrichment. However, when fertilizer and CO₂ enrichment were provided jointly, soil microbes were stimulated indicating a co-limitation by carbon and nutrients (most likely nitrogen). Since responses to elevated CO₂ were absent in both warm and cold growing seasons, we conclude that this late successional plant community is carbon saturated at current atmospheric CO₂ concentrations for reasons not directly

related to nutrient supply and climate. Perhaps, contrary to our expectation, evolutionary adjustments of this "old" ecosystem to the life conditions at high altitudes caused carbon to become a surplus resource today.

Korner, C., and F. Miglietta. 1994. Long-term effects of naturally elevated CO₂ on mediterranean grassland and forest trees. *Oecologia* 99(3-4):343-351.

We investigated the carbon supply status in species-rich mediterranean plant communities growing in a bowl-shaped 1-ha "CO₂ spring" area near Sienna, Italy. A geothermic "lime-kiln" has provided these communities, for as long as historical records are available, with pure CO₂ that mixes with ambient air at canopy level to daytime means of 500-1000 ppm CO₂. Immediately outside the spring area similar plant communities are growing on similar substrate, and in the same climate, but under ca. 355 ppm CO₂. We found no evidence that plants in the CO₂ spring area grow faster, flower earlier or become larger. However, we found very large differences in tissue quality among the 40 species studied inside and outside the spring area. Depending on weather conditions, the mean concentration of total non-structural carbohydrates (TNC, sugars and starch) in leaves of herbaceous plants was 38-47% higher in the spring area. Fast growing ruderals growing on garden soil inside and outside the spring area show the same response. Among trees, leaves of the deciduous *Quercus pubescens* contain twice as much TNC inside as outside the vent area, whereas evergreen *Q. ilex* leaves show no significant difference. TNC levels in branch wood paralleled leaf values. TNC in shade leaves was also higher. Elevated CO₂ had no effect on the sugar fraction, therefore differences in TNC are due to starch accumulation. Leaf nitrogen concentration decreases under elevated CO₂. These observations suggest that the commonly reported TNC accumulation and N depletion in leaves growing under elevated CO₂ are not restricted to the artificial conditions of short-term CO₂ enrichment experiments but persist over very long periods. Such an alteration of tissue composition can be expected to occur in other plant communities also if atmospheric CO₂ levels continue to rise. Effects on food webs and nutrient cycling are likely.

Korner, C., S. Pelaezriedl, and A.J.E. Vanbel. 1995. CO₂ responsiveness of plants - a possible link to phloem loading. *Plant, Cell and Environment* 18(5):595-600.

Of the many responses of plants to elevated CO₂, accumulation of total non-structural carbohydrates (TNC in % dry weight) in leaves is one of the most consistent. Insufficient sink activity or transport capacity may explain this obvious disparity between CO₂ assimilation and carbohydrate dissipation and structural investment. If transport capacity contributes to the problem, phloem loading may be the crucial step. It has been hypothesized that symplastic phloem loading is less efficient than apoplastic: phloem loading, and hence plant species using the symplastic pathway and growing under high light and good water supply should accumulate more TNC at any given CO₂ level, but particularly under elevated CO₂. We tested this hypothesis by carrying out CO₂ enrichment experiments with 28 plant species known to belong to groups of contrasting phloem loading type. Under current ambient CO₂ symplastic loaders were found to accumulate 36% TNC compared with only 19% in apoplastic loaders ($P = 0.0016$), CO₂ enrichment to 600 μ

mol mol⁻¹ increased TNC in both groups by the same absolute amount, bringing the mean TNC level to 41% in symplastic loaders (compared to 25% in apoplastic loaders), which may be close to TNC saturation (coupled with chloroplast malfunction). Eight tree species, ranked as symplastic loaders by their minor vein companion cell configuration, showed TNC responses more similar to those of apoplastic herbaceous loaders. Similar results are obtained when TNC is expressed on a unit leaf area basis, since mean specific leaf areas of groups were not significantly different. We conclude that phloem loading has a surprisingly strong effect on leaf tissue composition, and thus may translate into alterations of food webs and ecosystem functioning, particularly under high CO₂.

Korner, C., and M. Wurth. 1996. A simple method for testing leaf responses of tall tropical forest trees to elevated CO₂. *Oecologia* 107(4):421-425.

The effects of atmospheric CO₂ enrichment on mature trees in their natural environment are largely unknown. Here we present a new, and inexpensive technique which can be used in situ to address some key physiological questions related to the CO₂ problem. Small, light-weight cups mounted on the lower side of rigid leaves at the top of tall tropical forest trees were supplied with CO₂-enriched air derived from a low-technology air mixing device utilizing forest floor CO₂ evolution. We present the scientific rationale for such field experiments, technical details, an assessment of potential cup artifacts and first results illustrating effects of elevated CO₂ on stomata and carbohydrate accumulation in the canopies of mature trees.

Korthals, R.L., S.L. Knight, R.R. Crawford, and L.L. Christianson. 1995. Development and testing of a simple carbon-dioxide enrichment controller for growth chambers. *Transactions of the ASAE* 38(1):207-211.

Proportional and proportional plus integral (PI) computer algorithms were implemented with a low cost pulse width modulated injection system to control CO₂ in a 7.8 m³ growth chamber. Experimental studies with plants in the growth chamber showed that average CO₂ concentrations over 12 h were within 3 and 1 μ mol mol⁻¹ of set point for the proportional and PI controllers, respectively. The positive offset in CO₂ concentration found for the proportional control was attributed to sampled measurements and pulse width modulated CO₂ injection, and discussion was presented on how true errors differ from measured error estimates for pulse width modulated injection with long sampling periods relative to injection periods.

Kostkarick, R., and W.J. Manning. 1993. Radish (*Raphanus sativus* L.) - a model for studying plant-responses to air-pollutants and other environmental stresses. *Environmental Pollution* 82(2):107-138.

The use of *Raphanus sativus* L. as a model crop for studies on plant response to environmental stresses is reviewed with emphasis on the effects of different atmospheric pollutants (O₃, SO₂, NO₂, acidic precipitation) and their combinations. Responses to temperature, light

supply, water stress, and atmospheric CO₂ are also studied and discussed. In addition, the references reviewed are evaluated in terms of their experimental protocols on growth conditions and recommendations for optimal ranges of environmental and cultural variables, i.e. light, temperature, nutrient supply are given. Its distinct pattern of biomass partitioning, the small dimensions along with short and easy culture make radish an excellent experimental plant. The fleshy below-ground storage organ, formed by the hypocotyl and upper radicle, acts as the major sink during vegetative development. Abundant assimilate supply due to elevated levels of CO₂ along with high irradiation frequently promote hypocotyl growth more than shoot growth, whereas under conditions of stress shoot growth is maintained at the expense of the hypocotyl. This makes the hypocotyl:shoot ratio of radish a very sensitive and suitable indicator for various environmental stresses. Potential weaknesses and short-comings of radish in its role as a model crop, particularly the high variability of injury and growth responses, are discussed along with possible solutions. Future research needs are derived from the summarized results presented and from some disparities among findings within the literature reviewed.

Kothavala, Z. 1999. The duration and severity of drought over eastern Australia simulated by a coupled ocean-atmosphere GCM with a transient increase in CO₂. *Environmental Modelling & Software* 14(4):243-252.

The combined effects of precipitation and temperature simulated by a coupled ocean-atmosphere General Circulation Model that showed an El Nino-like pattern with a transient increase in CO₂, was examined for its effects on drought over eastern Australia. The Palmer Drought Severity Index (PDSI) was applied to determine the duration and severity of drought over a 30-year period due to decreased precipitation over the region. Application of the PDSI, using monthly mean temperature and total monthly precipitation to the final 30 years of the transient CO₂ simulation revealed more prolonged and more intense periods of drought under enhanced greenhouse conditions when compared to a similar time span of the present-day simulation. Kottke, I. 1997. Fungal adhesion pad formation and penetration of root cuticle in early stage mycorrhizas of *Picea abies* and *Laccaria amethystea*. *Protoplasma* 196(1-2):55-64.

Primary events during the establishment of the fungus-root symbiosis in ectomycorrhizas are still little understood. No attention has been paid so far to the adhesion of hyphae to the root cuticle and penetration of this barrier, although the importance of the cuticle has been shown for pathogen-plant interactions. Early developmental stages of in vitro mycorrhization of *Laccaria amethystea* on *Picea abies* after short periods of incubation in growth chambers under elevated CO₂ concentrations were studied by light and transmission electron microscopy. No structural changes in mycorrhization related to elevated CO₂ were found, but fine roots and mycorrhizas developed faster. Adhesion pad formation was observed at hyphal tips in contact with the root cuticle. The adhesion pad was connected to the outer cell wall layer of the hypha and reacted positively to the Swift reaction for cysteine rich proteins.

Although the reaction cannot be considered as totally specific, findings are discussed in respect to hydrophobins, which have recently been found to be expressed during early steps in ectomycorrhizal development. The root cuticle was dissolved and penetrated by fungal tips of the fingerlike branching mycelium attached to the root surface. The findings are compared with well documented pathogenic fungus-plant interactions at the cuticle. The possibility of restriction of hyphal attack to that part of the cuticle covering cell junctions is discussed.

Explants excised from strawberry (*Fragaria x ananassa* Duch.) plantlets were cultured in vitro for 21 days on half-strength MS (Murashige & Skoog 1962) basal liquid medium with 20 g l⁻¹ sucrose and without sugar in the vessels capped with gas permeable microporous polypropylene film. The experiments were conducted under CO₂ nonenriched (350-450-μmol mol⁻¹ in the culture room) and CO₂ enriched (2,000-μmol mol⁻¹ during the photoperiod in the culture room) conditions with a PPF (photosynthetic photon flux) of 200-μmol m⁻² s⁻¹. The CO₂ concentration in the vessels decreased to approximately 200-μmol mol⁻¹ during the photoperiod on day 21 under CO₂ nonenriched conditions. The fresh and dry weight, net photosynthetic rate (NPR) per plantlet, NPR per g leaf fresh weight, NPR per g leaf dry weight, the number of unfolded leaves, and ion uptake of PO₄(3-), NO₃-, Ca²⁺, Mg²⁺ and K⁺ on day 21 were the greatest under photoautotrophic (no sugar in the medium) and CO₂ enriched conditions. The residual percent of PO₄(3-) was 3% on day 21 under photoautotrophic and CO₂ enriched conditions.

Kozai, T., C. Kubota, and B.R. Jeong. 1997. Environmental control for the large-scale production of plants through in vitro techniques. *Plant Cell Tissue and Organ Culture* 51(1):49-56.

Leafy or chlorophyllous explants of a number of plant species currently micropropagated have been found to have high photosynthetic ability. Their growth and development have been promoted on sugar-free medium rather than on sugar-containing medium, provided that the environmental factors, such as CO₂ concentration, light intensity and relative humidity, are controlled for promoting photosynthesis and transpiration of explants/shoots/plantlets in vitro. Thus, environmental control is essential for promoting photosynthetic growth and development of in vitro plantlets. Several types of sugar-free (photoautotrophic) culture systems for large-scale micropropagation of plants have been developed. Advantages of sugar-free over conventional (heterotrophic or photomixotrophic) micropropagation systems are as follows: growth and development of plantlets in vitro are faster and more uniform, plantlets in vitro have less physiological and morphological disorders, biological contamination in vitro is less, plantlets have a higher percentage of survival during acclimatization ex vitro, and larger culture vessels could be used because of less biological contamination. Hence, production costs could be reduced and plant quality could be improved significantly with photoautotrophic micropropagation. Methods for the measurement and control of in vitro environments and the beneficial effects of environmental control on photosynthetic growth, development, and morphogenesis in large-scale production of

micropropagated plantlets are presented.

Kozai, T., S. Kushihashi, C. Kubota, and K. Fujiwara. 1992. Effect of the difference between photoperiod and dark period temperatures, and photosynthetic photon flux-density on the shoot length and growth of potato plantlets invitro. *Journal of the Japanese Society for Horticultural Science* 61(1):93-98.

Potato plantlets (*Solanum tuberosum* L. cv. Benimaru) under CO₂ enriched and photoautotrophic culture conditions were subjected to three different photo-/dark period temperature combinations (25-degrees/15-degrees-C, 20/20-degrees-C and 15-degrees/25- degrees-C) and two levels of photosynthetic photon flux densities (74 and 147-mu-mol.m-2.sec-1). The shoot length of the plantlets under the same photosynthetic photon flux density (PPF) was reduced with decreasing the difference between photoperiod and dark period temperatures (it is named DIF, photoperiod temperature minus dark period temperature). No marked differences in the fresh and dry weights per plantlet were observed among the three DIF treatments in each PPF treatment. The higher PPF led to a decrease in the shoot length, an increase in the fresh weight, dry weight and leaf area per plantlet in each DIF treatment. It is suggested that shoot length of plantlets in vitro under CO₂ enriched and photoautotrophic culture conditions can be controlled without reducing the weight increments and leaf area per plantlet by regulating the difference between photoperiod and dark period temperatures.

Kozai, T., K. Watanabe, and B.R. Jeong. 1995. Stem elongation and growth of *solanum-tuberosum* L in-vitro in response to photosynthetic photon flux, photoperiod and difference in photoperiod and dark period temperatures. *Scientia Horticulturae* 64(1-2):1-9.

Stem elongation and growth of potato plantlets under three DIF (difference in photoperiod and dark period temperatures) levels, -9, 0 and +9, combined with two PPF (photosynthetic photon flux) levels, 70 (low) and 140 (high) mu mol m(-2) s(-1) provided by white cool fluorescent lamps, under 16 h day(-1) (long) or 8 h day(-1) (short) photoperiods, were studied. Four nodal cuttings were cultured for 21 days on 0.6 X 10(-4) m(3) MS (Murashige and Skoog, 1962, *Physiol. Plant.*, 15: 473-497) agar (8 kg m(-3)) medium with no added sugar in 3.7 X 10(-3) m(3) polycarbonate boxes. Each box had two 10 mm holes covered with microporous filter to facilitate air exchange (3.6 air exchanges per hour). The average daily temperature in the culture room was set the same at 23 degrees C for all treatments, and CO₂ concentration and relative humidity were maintained at 400-500 mu mol mol(-1) and 50-70%, respectively. Stem length was significantly suppressed under 0 or -9 DIF, high PPF and long photoperiod. Stem diameter, leaf area and number of leaves were significantly enhanced by long photoperiod and high PPF, but affected little by DIF level. Specific leaf area was little affected by photoperiod, but decreased under high PPF and under low DIF. Long photoperiod and high PPF led to an increase in the fresh and dry weights maintaining similar percentage dry matter and to enhanced root growth. Under the same amount of integrated PPF, fresh and dry weights of leaf, stem, root and whole plantlet were significantly higher under the long photoperiod and low PPF conditions than under the short photoperiod and high PPF conditions. Because of suppressed root growth under short photoperiod, shoot to root dry weight ratio increased under short photoperiod, but was not affected by DIF. It is suggested that under photoautotrophic

conditions a combination of high PPF level, long photoperiod, and zero or negative DIF produces potato plantlets in vitro of short and thick stem with similar number and increased area of leaves, which are desirable for transfer to ex vitro conditions.

Kramer, G.F., E.H. Lee, R.A. Rowland, and C.L. Mulchi. 1991. Effects of elevated CO₂ concentration on the polyamine levels of field-grown soybean at 3 O₃ regimes. *Environmental Pollution* 73(2):137-152.

Effects of increased ozone (O₃) and carbon dioxide (CO₂) on polyamine levels were determined in soybean (*Glycine max* L. Merr. cv. Clark) grown in open-top field chambers. The chamber treatments consisted of three O₃ regimes equal to charcoal filtered (CF), non-filtered (NF), and non-filtered plus 40 nl litre-1 O₃ and CO₂ treatments equal to 350, 400 and 500-mu-l litre-1 for a total of nine treatments. Leaf samples were taken at three different times during the growing season. Examination of growth and physiological characteristics, such as photosynthesis, stomatal resistance, and shoot weight, revealed that increasing CO₂ ameliorated the deleterious effects of increased O₃. Results from the initial harvest, at the pre-flowering growth stage (23 days of treatment), showed that increasing O₃ at ambient CO₂ caused increases in putrescine (Put) and spermidine (Spd) of up to six-fold. These effects were lessened with increased CO₂. Elevated CO₂ increased polyamines in plants treated with CF air, but had no effect in the presence of ambient or enhanced O₃ levels. Leaves harvested during peak flowering (37 days of treatment) showed O₃-induced increases in Put and Spd at ambient CO₂ concentrations. However, increased CO₂ levels inhibited this response by blocking the O₃-induced polyamine increase. Leaves harvested during the pod fill stage (57 days of treatment) showed no significant O₃ or CO₂ effects on polyamine levels. Our results demonstrate that current ambient O₃ levels induce the accumulation of Put and Spd early in the growing season and that further increases in O₃ could result in even greater polyamine increases. These results are consistent with a possible antiozonant function for polyamines. The ability of increased CO₂ to protect soybeans from O₃ damage, however, does not appear to involve polyamine accumulation.

Kramer, K., A. Friend, and I. Leinonen. 1996. Modelling comparison to evaluate the importance of phenology and spring frost damage for the effects of climate change on growth of mixed temperate-zone deciduous forests. *Climate Research* 7(1):31-41.

The importance of 3 phenological types of deciduous tree, and the effects of the occurrence of frost damage on growth of mixed-species forests, were evaluated using the models FORGRO and HYBRID. The climate change scenarios used were a doubling of the CO₂ concentration (700 mu mol mol(-1)) and an increase in temperature ranging from 0 to 7 degrees C. Both FORGRO and HYBRID are mechanistic models treating eco-physiological processes in detail. FORGRO highlights potential growth in managed forests where all individuals of one species are of the same age and size, whereas HYBRID highlights growth in natural forests, including regeneration and mortality of individual trees that differ in age and size. Furthermore, the importance of inaccurate prediction of phenological events and frost hardness for growth in mixed-species stands was evaluated by comparing dynamic models to

regression models. The dynamic models predict the timing of phenological events annually and the progression of frost hardness during dormancy, whereas the regression models represent empirical relationships between the change in the average date of phenological events with a rise in mean winter temperature and the level of frost hardness at the moment of leaf unfolding. The results of the climate change scenarios indicate for both FORGRO and HYBRID that: (1) the differences in net primary production (NPP) of the 3 phenological types considered are enhanced when grown in a mixed-species stand compared to a monospecies stand; and (2) the effects of frost damage on growth are more prominent in mixed-species stands than in monospecies stands. Regarding the accuracy of the dynamic approach compared to the regression approach for predicting the timing of leaf unfolding and spring frost damage, the dynamic approach for leaf unfolding results in a similar response of NPP to the regression approach, both for the monospecies and the mixed-species situation. The dynamic approach, however, yields larger differences in the NPP between the phenological types because the model predicts a greater advancement of leaf unfolding than does the regression approach. Comparing the regression approach to the dynamic approach with regard to frost hardness, the regression approach shows a greater frequency of frost damage; because, according to the dynamic approach the minimum level of frost hardness is attained after the date of leaf unfolding, thus reducing this frequency.

Kramer, K., and G.M.J. Mohren. 1996. Sensitivity of FORGRO to climatic change scenarios: A case study on *Betula pubescens*, *Fagus sylvatica* and *Quercus robur* in the Netherlands. *Climatic Change* 34(2):231-237.

The impacts of the climate change predictions of four general circulation models (GFDL, GISS, OSU and UKMO) on net primary production (NPP) of *Betula pubescens*, *Fagus sylvatica* and *Quercus robur* in The Netherlands were analysed using the process-based model FORGRO. FORGRO is a model suitable to simulate growth of managed monospecies stands. For the GCMs mentioned, both transient and equilibrium 2 x CO₂ scenarios of temperature and precipitation change were evaluated and compared with responses under current climate. It was found that the NPP increases in the transient scenarios, but remains the same or declines in the 2 x CO₂ scenarios. This is because respiration increases more with rising temperature than photosynthesis. During the transient scenarios this effect gradually increases, while in the 2 x CO₂ scenario this effect is operating over the entire simulation period. If water limitation is taken into account, then the NPP of the reference scenario is reduced. In both the transient and 2 x CO₂ scenarios this water limitation is annulated, resulting in a stronger response of NPP compared to the situation without water limitation. This enhancement of the response is most pronounced in the transient scenario due to the gradual effect of temperature on respiration. Similar results were obtained with a version of FORGRO in which the photosynthesis module of HYBRID (PGEN) is incorporated, although the response in FORGRO- PGEN is usually higher than that of FORGRO. This is because the response of photosynthesis to CO₂ rises with increasing temperature as defined in the PGEN-model, but not according to FORGRO.

1221

Krapfenbauer, A., and K. Wriessnig. 1995. Anthropogenic environmental-pollution - the share of agriculture. *Bodenkultur* 46(3):269-283.

The increase of environmental pollution is in direct relation to the consumption of fossil coal, gas and oil and the progressive growth of the world population. Since 1950 these issues increased considerably and they will continue to increase in the future. At the moment the population increases by 1.9 %, the consumption of energy between 2 and 3 % and the environmental pollution up to 3.5 % annually. With the progressive growth of the world population and the increase in prosperity in the developed countries the demand for food increased also progressively and therewith the productivity index of the units of arable land, by growing consumption of fertilizers and the installation of irrigation systems. At the same time the pollution of air, water and soil caused by agriculture also grew progressively. But up to date there is still a shortcoming of reliable statistical facts and figures. A higher productivity index of the units of arable land in the different ecoclimatic zones of the earth leads to higher production and consumption by an inevitably higher turnover of plant nutrients and diverse gaseous substances, for example carbon mono- and dioxide, diverse compounds of nitrogen etc. At the same time an excess of the "critical loads" for soil, air and water must be expected. The main items of the emissions produced by an intensified agriculture are, besides carbon mono- and dioxide, methane, nitric and nitrous oxide, ammonia and diverse hydrocarbons. A higher productivity index is consequently related to a higher consumption. This also leads to an intensified turnover of carbon dioxide. There is consequently a progressive input of carbon dioxide resulting from the emissions of burning fossil fuel in the recently produced and consumed biomass. This inevitably leads to a higher level of carbon dioxide in the air. A main source of emissions of methane and ammonia is animal breeding. In Austria at this time from each of the 3,508.000 hectares of land used by agriculture annual emissions of 63 kg methane and 11 kg ammonia are resulting theoretically. The use of organic and inorganic fertilizers, the growing cultivation of legumes and the emissions of nitrogen compounds resulting from burning processes elevate likewise the pool and the annual turnover of nitrogen compounds by production and consumption of biomass. Inevitably related to it is a growing amount of the annual input of nitrogen compounds to the air, the soil and the water. A rough approximation says that at present agriculture contributes to the global anthropogenic pollution of the environment (air, soil and water) 85 % of the ammonia, 81 % of the nitrous oxide, 35 % of nitric mono- and dioxide, 70 % of the methane, 52 % of the carbon monoxide and 21 % of the carbon dioxide. Not considered in the figure for carbon dioxide is the inevitable increase of the level of CO₂ in the air by the elevated turnover of biomass. The world population growth in the future leads to an increasing contribution of agriculture to the anthropogenic environmental pollution. For the developed countries this is an obligatory challenge to avoid surplus production. On a global scale there must be a sensible reduction of animal breeding to reduce the high emissions of methane and ammonia from this sector of agriculture. It must also be considered, that by feeding animals with vegetable food stuff, which also could be used for direct nutrition of man, the efficiency of it is lowered by a factor of 1:10. In spite of a growing crisis to maintain the alimentation of the growing world population in many countries the nutrition of man must rapidly be centered on vegetable food stuff rich in protein. At the same time an essential reduction of the environmental pollution resulting from animal breeding could be realized. Beside of it and other reducing issues a continuous growth of the world population, the energy consumption and environmental pollution will make it necessary to observe the development and reactions in the environment by monitoring and phenological observations. The results must be used to counteract finally by looking for adaptation strategies. Considering the realities it must be realized that by all means to mobilize for counteracting the environmental pollution directly, a certain climate change will be inevitable. The consequences will also be an outstanding challenge for the agriculture.

1222

Krapp, A., B. Hofmann, C. Schafer, and M. Stitt. 1993. Regulation of the expression of *rbcS* and other photosynthetic genes by carbohydrates - a mechanism for the sink regulation of photosynthesis. *Plant Journal* 3(6):817-828.

These experiments were carried out to investigate whether accumulation of carbohydrate leads to decreased expression of genes involved in photosynthesis. Addition of glucose to autotrophic cell suspension cultures of *Chenopodium* led to a large and reversible decrease of the steady state transcript levels of *rbcS*, *cab* and *atp-delta* within 5 h, but did not decrease 18S rRNA or transcript for two glycolytic enzymes. Run-on transcription in isolated nuclei showed that transcription rate had been decreased. [S-35]Methionine feeding showed that de novo synthesis of Rubisco was inhibited. Decreased *rbcS* transcript was also found after feeding glucose to detached leaves, and in transgenic plants expressing invertase in the apoplast to inhibit phloem transport, and in leaves on intact tobacco and potato plants which were cold-girdled to decrease export. The decrease of *rbcS* transcript level occurred within 12 h of cold-girdling. Comparison of carbohydrate content and *rbcS* transcript level indicated that carbohydrate content per se is not the direct signal for regulation of gene expression. Feeding of transported analogues indicates that metabolism rather than transport of the sugars is required. Over-expression of *rbcS* was found in low CO₂, again indicating metabolic control of expression. It is proposed that photosynthetic gene expression is inhibited by metabolic factors related to high carbohydrate content, and that this represents a basic mechanism for the 'sink regulation' of photosynthesis.

Krapp, A., and M. Stitt. 1995. An evaluation of direct and indirect mechanisms for the sink-regulation of photosynthesis in spinach - changes in gas-exchange, carbohydrates, metabolites, enzyme-activities and steady-state transcript levels after cold-girdling source leaves. *Planta* 195(3):313-323.

Mature source leaves of spinach (*Spinacia oleracea* L.) plants growing hydroponically in a 9 h light (350 $\mu\text{mol photons}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$)/15 h dark cycle at 20 degrees C in a climate chamber were fitted with a cold girdle around the petiole, 2 h into the light period. Samples were taken 1, 3 and 7 h later, and at the end of the photoperiod for the following 4 d. Control samples were taken from ungirdled leaves. In the first 7 h after fitting the cold girdle there was (compared to the control leaves) a two to fivefold accumulation of sucrose, glucose, fructose and starch, a 40-50% increase of hexose-phosphates and ribulose-1,5-bisphosphate, a decrease of glycerate-3-phosphate, a small decrease in sucrose-phosphate synthase activation, an increase of fructose-2,6-bisphosphate, increased activation of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), but no significant change in photosynthetic rate or stomatal conductance. Steady-state transcript levels for *rbcS* (small subunit of Rubisco) and *atp-D* (D-subunit of the thylakoid ATP synthase) decreased 30%, *cab* (chlorophyll-a-binding protein) decreased by 15% and *agp-S* (S-isoenzyme of ADP-glucose pyrophosphorylase) and *nra* (nitrate reductase) rose twofold. On the following days, levels of carbohydrates continued to rise and the changes of metabolites were maintained. Transcripts for *rbcS*, *cab* and *atpD* declined to 20, 70 and 25% of the control values. From day 3 onward the maximum activity of Rubisco declined. This was accompanied by a further increase of Rubisco activation to over 90% and, from day 4 onwards, an inhibition of photosynthesis which was associated with high internal CO₂ concentration (*c(i)*), high ribulose-1,5-bisphosphate, and low glycerate-3-phosphate. When the cold-girdle was removed on day 5 there was a gradual recovery of photosynthesis and decline of *c(i)* over the next 2 d.

Hexose-phosphates levels and transcripts for *rbcS*, *cab* and *atp-D* completely recovered within 2 d, even though the levels of carbohydrates had not fully recovered. Activity of Rubisco only reverted partly after 2 d, and Rubisco activation state and the ribulose-1,5-bisphosphate/glycerate-3-phosphate ratio were still higher than in control leaves. Transcripts for *nra* and *agp-S* were also still higher than in control leaves. It is concluded (i) that a reversible modulation of gene expression in response to the export rate plays a central role in the mid-term feedback "sink" regulation of photosynthesis, and (ii) that feedback regulation of CO₂ fixation by changes of P-i are of little importance in spinach under these conditions. Further (iii) the rapid and reciprocal changes in *nra* and *agpS* transcripts, compared to *rbcS*, provide evidence that gene expression could also contribute to the modulation of nitrate assimilation and carbohydrate storage in conditions of decreased sink demand.

Kriebitzsch, W.U., M. Liesebach, and F. Scholz. 1999. The influence of elevated CO₂ on growth parameters of various provenances of European beech (*Fagus sylvatica* L.) at different irradiance. *Forstwissenschaftliches Centralblatt* 118(1):51-65.

In a greenhouse experiment one year old seedlings of seven provenances of beech (*Fagus sylvatica* L.) were grown under controlled conditions at two CO₂ levels (350 ppm and 650 ppm) and different light intensities (2%, 17% and 100% relative irradiance). The response of the plants to the various treatments was investigated by means of the leaf development during the growing season. At the end of the vegetation period leaf area and leaf dry weight per single leaf and per plant were measured. At the beginning of the growing period the provenances differed significantly in height and at the end of the vegetation period also in the mean leaf number, leaf area and leaf dry weight per plant. The area per single leaf is - in contrast to leaf dry weight and the specific leaf area - similar among all seven provenances. The light has an effect on all measured leaf parameters. In full light the leaf development started very early. Leaf number, leaf area, and leaf dry weight per single leaf and per plant decrease and specific leaf area increases under low light conditions. In the treatment "elevated CO₂ environment and full irradiance" leaf number, leaf area and leaf dry weight per single leaf and per plant increased too. At reduced irradiance a higher CO₂ content does not influence the measured leaf parameters. The results show already at this early stage that the climatic factors influencing plant growth and elevated CO₂ interact strongly. For an overall view of the plants' reaction to growth conditions, investigations of the gas exchange of the leaves

and anatomical and morphological studies will be added.

Krishnan, P., and G. Ramakrishnayya. 1999. Survival of rice during complete submergence: effect of potassium bicarbonate application. *Australian Journal of Plant Physiology* 26(8):793-800.

The effect of potassium bicarbonate application to floodwater on the survival and growth of submergence-tolerant (FR13A) and -intolerant (IR42) rice cultivars during complete submergence was investigated. Potassium bicarbonate, applied at different rates to enhance floodwater carbon dioxide concentrations, increased the floodwater oxygen concentration. The treatment that had CuSO₄, added alone to reduce algal growth showed the lowest O₂ concentration at the time of submergence and after 10 d of submergence. Potassium bicarbonate at higher rates tended to maintain the floodwater pH near neutrality while copper sulfate affected pH increase during a 10-day period of complete submergence. Potassium bicarbonate addition led to 100% survival of tolerant FR13A. Potassium bicarbonate, even at 0.01 mol m⁻³ enhanced the survival of intolerant IR42 to 69% and at 0.1, 0.5 and 1.0 mol m⁻³, the survival was above 85%. Dry weights of submerged plants showed increases in both rice cultivars in floodwater treated with potassium bicarbonate. The dry weight and leaf chlorophyll concentration of both cultivars increased with increasing rates of potassium bicarbonate. Algal chlorophyll concentration of floodwater treated with potassium bicarbonate was comparable to that of the control without copper sulfate. The findings suggest a possibility of environmental manipulation of floodwater by potassium bicarbonate

application to enhance the survival and growth of rice cultivars during complete submergence.

Kronfuss, G., A. Polle, M. Tausz, W.M. Havranek, and G. Wieser. 1998. Effects of ozone and mild drought stress on gas exchange, antioxidants and chloroplast pigments in current-year needles of young Norway spruce [*Picea abies* (L.) Karst.]. *Trees-Structure and Function* 12(8):482-489.

To investigate the effects of ozone exposure and soil drought, singly and in combination, on gas-exchange, antioxidant contents and pigments in current-year needles of Norway spruce [*Picea abies* (L.) Karst.] 4-year-old seedlings were fumigated in growth chambers with either charcoal-filtered air or with 100 nl l⁻¹ ozone for 106 days. After 3 weeks a 20% reduction in gas exchange was observed in ozone-treated seedlings. However, no further decrease occurred in spite of continued ozone exposure. Whole needle ascorbate and apoplastic ascorbate increased until the end of the experiment and contents were 62% and 82%, respectively, higher than in ozone-free controls. This increase in ascorbate might have protected net photosynthesis from further decline. Ozone pre-treated plants and ozone-free controls were subjected to soil drought for 38 days which caused stomatal narrowing. Thereby ozone uptake was reduced when compared to well watered seedlings. At the end of the experiment drought alone, and even more in combination with ozone, had also caused an increase in ascorbate. Glutathione increased only in drought-stressed seedlings. The redox states of the ascorbate and the glutathione pools were not affected by any treatment. Superoxide dismutase activity declined under both stresses but was most reduced by ozone alone. While chlorophyll and neoxanthin contents remained unchanged, carotenenes were significantly decreased upon drought. The combination of O₃ and drought induced increased lutein contents, an increased pool size of the xanthophyll cycle as well as an increased epoxidation status of the xanthophyll cycle. These results suggest that spruce needles seem to be able to acclimate to ozone stress but also to drought stress by increasing their ascorbate pools and protecting pigments.

Krug, H., and H.P. Liebig. 1995. Models for planning and control of transplant production in climate controlled greenhouses .2. Production control. *Gartenbauwissenschaft* 60(1):22-28.

A model has been developed to control transplant growth. It is based on growth curves, derived under varied greenhouse climates (global irradiances, artificial light, air and soil heating, CO₂-concentration), and corresponding growth rates, which were related to the intensities of the climatic factors by a regression function. The best fit for the growth rates was obtained by splitting the raising period in an exponential phase, described by a constant Relative Growth Rate, and a linear phase, described by the Mean Growth Rate. As the frequency distribution shows, 81% of the 186 sets from October to March hit the 4 +/- 0.2 g data of the growth function in +/- 2 days. Simulations for the most extremes out of 36 years weather conditions for 5 dates from October to February show the deviations from the estimated curves based on long term normals, the potentials of climate control by decreasing or increasing set points of air temperature, CO₂ concentration, and artificial light as well as the effects of the starting point for control. Aspects of application and completion as well as the necessity of timing

by CO₂ enrichment and artificial lighting are discussed.

Kruger, E.L., J.C. Volin, and R.L. Lindroth. 1998. Influences of atmospheric CO₂ enrichment on the responses of sugar maple and trembling aspen to defoliation. *New Phytologist* 140(1):85-94.

Impacts of defoliation on the growth and physiology of sugar maple (*Acer saccharum* Marsh.) and trembling aspen (*Populus tremuloides* Michx.) were examined in ambient and CO₂-enriched atmospheres. Saplings were grown for 70 d in controlled environments, wherein CO₂ mole fractions averaged either 356 $\mu\text{mol mol}^{-1}$ or 645 $\mu\text{mol mol}^{-1}$, under a PPf of 500 $\mu\text{mol m}^{-2} \text{s}^{-1}$. On day 49 of the study, 50 % of the leaf area was removed from a subset of each species in both CO₂ environments. Relative growth rate (RGR) and its physiological and morphological determinants were monitored before and after defoliation. For non-defoliated saplings of both species, a slight stimulation of RGR (c. 5 %) in elevated CO₂ led to a modest increase (9-11 %) in final sapling weight. In the case of maple, the minimal growth response corresponded with minor CO₂ effects on specific leaf area (SLA) and leaf weight ratio (LWR), and an apparent CO₂-induced down-regulation of photosynthetic metabolism. For aspen, the CO₂ stimulation of photosynthesis was largely offset by a decrease in SLA. Responses to defoliation differed markedly between species and CO₂ environments. Defoliation decreased maple RGR in ambient CO₂, whereas the opposite occurred in elevated CO₂. The latter led to complete recovery of plant weight (compensation), and was attributed to a defoliation-induced increase in carbon allocation to new leaves, along with a reversal of photosynthetic CO₂ acclimation in that foliage. In both environments, aspen RGR increased after defoliation, facilitating almost full compensation. Defoliation increased light penetration into the aspen canopy, and it was estimated that the resultant stimulation of photosynthesis in lower leaves would have more than offset the concomitant decrease in LWR. CO₂ enrichment might substantially enhance the ability of certain tree species to recover from herbivory. Moreover, responses to elevated CO₂ might be largest in the presence of stresses, such as herbivory, that decrease plant source:sink ratios.

Kruijt, B., C. Barton, A. Rey, and P.G. Jarvis. 1999. The sensitivity of stand-scale photosynthesis and transpiration to changes in atmospheric CO₂ concentration and climate. *Hydrology and Earth System Sciences* 3(1):55-69.

The 3-dimensional forest model MAESTRO was used to simulate daily and annual photosynthesis and transpiration fluxes of forest stands and the sensitivity of these fluxes to potential changes in atmospheric CO₂ concentration ([CO₂]), temperature, water stress and phenology. The effects of possible feed-backs from increased leaf area and limitations to leaf nutrition were simulated by imposing changes in leaf area and nitrogen content. Two different tree species were considered: *Picea sitchensis* (Bong.) Carr., a conifer with long needle longevity and large leaf area, and *Betula pendula* Roth., a broad-leaved deciduous species with an open canopy and small leaf area. Canopy photosynthetic production in trees was predicted to increase with atmospheric [CO₂] and length of the growing season and to decrease with increased water stress. Associated increases in leaf area increased production further only in the *B. pendula* canopy, where the original leaf area was relatively small. Assumed limitations in N uptake affected *B. pendula* more than *P. sitchensis*. The effect of increased temperature was shown to depend

on leaf area and nitrogen content. The different sensitivities of the two species were related to their very different canopy structure. Increased [CO₂] reduced transpiration, but larger leaf area, early leaf growth, and higher temperature all led to increased water use. These effects were limited by feedbacks from soil water stress. The simulations suggest that, with the projected climate change, there is some increase in stand annual 'water use efficiency', but that actual water losses to the atmosphere may not always decrease.

Krupa, S.V. 1997. Global climate change: Processes and products - An overview. *Environmental Monitoring and Assessment* 46(1-2):73-88.

Our knowledge of global climate change has many uncertainties. Whether global air temperature will increase, by how much, and when, are subject to debate, but there is little doubt that tropospheric concentrations of several trace gases are increasing. While possible increases in the average air temperature is a product of these changes, the increases in the trace gases alone will have an effect on agriculture. Increases in the ambient concentrations of carbon dioxide are expected to have a positive net effect on crop production. In contrast, any increases in the penetration of surface-level ultraviolet-B (280-320 nm) radiation, and known increases in surface ozone concentrations, are considered to have adverse effects on certain crops. Our present knowledge of the joint effects on crops of elevated levels of carbon dioxide, ultraviolet-B radiation and ozone, and possible alterations in air temperature and precipitation patterns, is virtually zero. Therefore, any predictions of the effects of global climate change on agriculture are subject to significant uncertainties. In contrast, coupling of climate change (only temperature and precipitation) models to crop production has led to a number of future scenarios. In spite of their present limitations, results from these efforts can be useful in planning for future agriculture.

Krupa, S.V., and R.N. Kickert. 1993. The greenhouse-effect - the impacts of carbon-dioxide (CO₂), ultraviolet-b (uv-b) radiation and ozone (O₃) on vegetation (crops). *Vegetatio* 104:223-238.

Man's influence on the 'greenhouse effect,' the heating of the atmosphere due to increasing concentrations of tropospheric trace gases, is of much international concern. Among the climatic variables, elevated levels of carbon dioxide (CO₂), ultraviolet-B (UV-B) radiation and ozone (O₃) are known to have a direct effect on vegetation. Our current knowledge of these effects is mainly based on studies involving single stress mode. Thus, the joint effects of CO₂, UV-B and O₃ on vegetation are poorly understood. Nevertheless, based on the literature analysis of plant response to individual stress factors, it can be concluded that sorghum, pea, bean, potato, oat, lettuce, cucumber, rice and tomato are among the crop species potentially sensitive to the joint effects of the aforementioned three variables. Similar information for tree species is essentially lacking. At least with some climatic variables such as O₃, present modeling efforts of cause-effect relationships have proven to be controversial. While at a regional geographic scale ambient CO₂ concentrations appear to be relatively homogeneous, ambient concentrations of O₃ exhibit significant temporal and spatial variability. Because of the protective action of O₃ against UV-B, similar but inverse

temporal and spatial variability is expected in the surface levels of UV-B. Thus, future experimental designs should consider these exposure dynamics and modeling cause-effect relationships should be directed to stochastic processes.

Krupa, S.V., and A.H. Legge. 1995. Air-quality and its possible impacts on the terrestrial ecosystems of the north-american great-plains - an overview. *Environmental Pollution* 88(1):1-11.

Over the past several decades, numerous studies have been conducted on the impacts of air pollutants (air quality) on terrestrial ecosystems (crops and forests). Although ambient air is always composed of pollutant mixtures, in determining the relative air quality and its ecosystem impacts at a given geographic location and time, a predominant number of studies have shown that at the present time surface level O₃ is the most important phytotoxic air pollutant. Within the North American Great Plains, the precursors; for surface-level O₃ are mainly anthropogenic NO_x and VOCs (volatile organic compounds). Texas and Alberta are the top regions of such emissions in the United States and Canada, respectively. This appears to be due mainly to the prevalence of natural gas and/or oil industry in the two regions and the consequent urbanization. Nevertheless, the total emissions of NO_x and VOCs within the North American Great Plains represent only about 25- 36% of the corresponding total emissions within the contiguous United States and the whole of Canada. Within the Great Plains many major crop and tree species are known to be sensitive to O₃. This sensitivity assessment, however, is based mainly on our knowledge from univariate (O₃ only) exposure-plant response studies. In the context of global climate change, in almost all similar univariate studies, elevated CO₂, concentrations have produced increases in plant biomass (both crop and tree species). The question remains as to whether this stimulation will offset any adverse effects of elevated surface O₃ concentrations. Future research must address this important issue both for the Great Plains and for all other geographic locations, taking into consideration spatial and temporal variabilities in the ambient concentrations of the two trace gases.

Kubiske, M.E., and K.S. Pregitzer. 1996. Effects of elevated CO₂ and light availability on the photosynthetic light response of trees of contrasting shade tolerance. *Tree Physiology* 16(3):351-358.

Photosynthetic light response curves (A/PPFD), leaf N concentration and content, and relative leaf absorbance (alpha(r)) were measured in 1-year-old seedlings of shade-intolerant *Betula papyrifera* Marsh., moderately shade-tolerant *Quercus rubra* L. and shade-tolerant *Acer rubrum* L. Seedlings were grown in full sun or 26% of full sun (shade) and in ambient (350 ppm) or elevated (714 ppm) CO₂ for 80 days. In the shade treatments, 80% of the daily PPFD on cloud-free days was provided by two 30-min sun patches at midday. In *Q. rubra* and *A. rubrum*, leaf N concentration and α , were significantly higher in seedlings in the shade treatments than in the sun treatments, and leaf N concentration was lower in seedlings in the ambient CO₂ treatments than in the elevated CO₂ treatments. Changes in α , and leaf N content suggest that reappportionment of leaf N into light harvesting machinery in response to shade and elevated CO₂ tended to increase with increasing shade tolerance of the plant. Shifts induced by elevated CO₂ in the A/PPFD relationship in sun plants were largest in *B. papyrifera* and least in *A. rubrum*: the reverse was true for shade plants. Elevated CO₂ resulted in

increased light-saturated A in every species x light treatment combination, except in shaded *B. papyrifera*. The light compensation point (T) decreased in response to shade in all species, and in response to elevated CO₂ in *A. rubrum* and *Q. rubra*. *Acer rubrum* had the greatest increases in apparent quantum yield (ϕ) in response to shade and elevated CO₂. To illustrate the effects of shifts in A, r and ϕ on daily C gain, daily integrated C balance was calculated for individual sun and shade leaves. Ignoring possible stomatal effects, estimated daily (24 h) leaf C balance was 218 to 442% higher in the elevated CO₂ treatments than in the ambient CO₂ treatments in both sun and shade seedlings of *Q. rubra* and *A. rubrum*. These results suggest that the ability of species to acclimate photosynthetically to elevated CO₂ may, in part, be related to their ability to adapt to low irradiance. Such a relationship has implications for altered C balance and nitrogen use efficiency of understory seedlings.

Kubiske, M.E., and K.S. Pregitzer. 1997. Ecophysiological responses to simulated canopy gaps of two tree species of contrasting shade tolerance in elevated CO₂. *Functional Ecology* 11(1):24-32.

1. One-year-old seedlings of shade tolerant *Acer rubrum* and intolerant *Betula papyrifera* were grown in ambient and twice ambient (elevated) CO₂, and in full sun and 80% shade for 90 days. The shaded seedlings received 30-min sun patches twice during the course of the day. Gas exchange and tissue-wafer relations were measured at midday in the sun plants and following 20 min of exposure to full sun in the shade plants to determine the effect of elevated CO₂ on constraints to sun-patch utilization in these species. 2. Elevated CO₂ had the largest stimulation of photosynthesis in *B. papyrifera* sun plants and *A. rubrum* shade plants. 3. Higher photosynthesis per unit leaf area in sun plants than in shade plants of *B. papyrifera* was largely owing to differences in leaf morphology. *Acer rubrum* exhibited sun/shade differences in photosynthesis per unit leaf mass consistent with biochemical acclimation to shade. 4. *Betula papyrifera* exhibited CO₂ responses that would facilitate tolerance to leaf water deficits in large sun patches, including osmotic adjustment and higher transpiration and stomatal conductance at a given leaf-water potential, whereas *A. rubrum* exhibited large increases in photosynthetic nitrogen-use efficiency. 5. Results suggest that species of contrasting successional ranks respond differently to elevated CO₂, in ways that are consistent with the habitats in which they typically occur.

Kubiske, M.E., K.S. Pregitzer, C.J. Mikan, D.R. Zak, J.L. Maziasz, and J.A. Teeri. 1997. *Populus tremuloides* photosynthesis and crown architecture in response to elevated CO₂ and soil N availability. *Oecologia* 110(3):328-336.

We tested the hypothesis that elevated CO₂ would stimulate proportionally higher photosynthesis in the lower crown of *Populus* trees due to less N retranslocation, compared to tree crowns in ambient CO₂. Such a response could increase belowground C allocation, particularly in trees with an indeterminate growth pattern such as *Populus tremuloides*. Rooted cuttings of *P. tremuloides* were grown in ambient and twice ambient (elevated) CO₂ and in low and high soil N

availability (89 $\pm$ 7 and 333 $\pm$ 16 ng N g⁻¹ day⁻¹) net mineralization, respectively) for 95 days using open-top chambers and open-bottom root boxes. Elevated CO₂ resulted in significantly higher maximum leaf photosynthesis (A(max)) at both soil N levels. A(max) was higher at high N than at low N soil in elevated, but not ambient CO₂. Photosynthetic N use efficiency was higher at elevated than ambient CO₂ in both soil types. Elevated CO₂ resulted in proportionally higher whole leaf A in the lower three-quarters to one-half of the crown for both soil types. At elevated CO₂ and high N availability, lower crown leaves had significantly lower ratios of carboxylation capacity to electron transport capacity (V-cmax/J(max)) than at ambient CO₂ and/or low N availability. From the top to the bottom of the tree crowns, V-cmax/J(max) increased in ambient CO₂, but it decreased in elevated CO₂ indicating a greater relative investment of N into light harvesting for the lower crown. Only the mid-crown leaves at both N levels exhibited photosynthetic down regulation to elevated CO₂. Stem biomass segments (consisting of three nodes and internodes) were compared to the total A(leaf) for each segment. This analysis indicated that increased A(leaf) at elevated CO₂ did not result in a proportional increase in local stem segment mass, suggesting that C allocation to sinks other than the local stem segment increased disproportionately. Since C allocated to roots in young *Populus* trees is primarily assimilated by leaves in the lower crown, the results of this study suggest a mechanism by which C allocation to roots in young trees may increase in elevated CO₂.

Kubiske, M.E., K.S. Pregitzer, D.R. Zak, and C.J. Mikan. 1998. Growth and C allocation of *Populus tremuloides* genotypes in response to atmospheric CO₂ and soil N availability. *New Phytologist* 140(2):251-260.

We grew cuttings of two early (mid Oct.) and two late (early Nov.) leaf-fall *Populus tremuloides* Michx. genotypes (referred to as genotype pairs) for c. 150 d in open-top chambers to understand how twice-ambient (elevated) CO₂ and soil N availability would affect growth and C allocation. For the study, we selected genotypes differing in leaf area duration to find out if late-season photosynthesis influenced C allocation to roots. Both elevated CO₂ and high soil N availability significantly increased estimated whole-tree photosynthesis, but they did so in different ways. Elevated CO₂ stimulated leaf-level photosynthesis rates, whereas high soil N availability resulted in greater total plant leaf area. The early leaf-fall genotype pair had significantly higher photosynthesis rates per unit leaf area than the late leaf-fall genotype pair and elevated CO₂ enhanced this difference. The early leaf-fall genotype pair had less leaf area than the late leaf-fall genotype pair, and their rate of leaf area development decreased earlier in the season. Across both genotype pairs, high soil N availability significantly increased fine root length production and mortality by increasing both the amount of root length present, and by decreasing the life span of individual roots. Elevated CO₂ resulted in significantly increased fine root production and mortality in high N but not low N soil and did not affect fine root life span. The early leaf-fall genotype pair had significantly greater fine root length production than the late leaf-fall genotype pair across all CO₂ and N treatments. These differences in belowground C allocations are consistent with the hypothesis that belowground C and N cycling is strongly influenced by soil N availability and will increase under elevated atmospheric CO₂. In addition, this study reinforces the need for better understanding of the variation in tree responses to elevated CO₂, within and among species.

Kubo, Y., O. Hirata, A. Inaba, and R. Nakamura. 1996. Respiration and ethylene production in fruits and vegetables held in carbon dioxide-enriched atmospheres - Effects of temperature and carbon dioxide concentration. *Journal of the Japanese Society for Horticultural Science* 65(2):403-408.

The rates of respiration and ethylene production in various fruits and vegetables held in 0.60% CO₂ at 25 degrees C or 60% CO₂ at 5-25 degrees C were determined by an automated microcomputer system. In peaches, apples, tomatoes, and broccoli, dose-dependent decreases of O₂ uptake and C₂H₄ production were observed during treatment with various concentrations of CO₂ at 25 degrees C. Oxygen uptake in bananas was inhibited at 10% CO₂ and higher, whereas C₂H₄ production increased as the ambient CO₂ concentration was elevated. CO₂ concentration had little or no effect on O₂ uptake in satsuma mandarin. Oxygen uptake in lettuce at 20% CO₂ and below was similar to that under air, whereas induction of C₂H₄ production and an enhanced O₂ uptake were observed in lettuce held in 40% CO₂ and higher. Inhibition of O₂ uptake and C₂H₄ production in peaches by 60% CO₂ declined as the temperature was lowered to the range of 5-25 degrees C. In broccoli held in 60% CO₂, the inhibition of O₂ uptake was temperature-dependent, but C₂H₄ production was suppressed to trace level at all temperatures. The induction of C₂H₄ production and enhancement of O₂ uptake in lettuce by 60% CO₂ occurred distinctly at 25 degrees C, slightly at 15 degrees C, but not at 10 degrees C and 5 degrees C.

Kubo, Y., K. Sakota, A. Inaba, and R. Nakamura. 1996. Effects of high carbon dioxide exposure on ethylene biosynthesis in peach and tomato fruits. *Journal of the Japanese Society for Horticultural Science* 65(2):409-415.

Ethylene production, oxygen uptake, the activities of 1-aminocyclopropane-1-carboxylic acid (ACC) synthase and ACC oxidase in vivo and the contents of ACC and 1-(malonylamino)cyclopropane-1-carboxylic acid (MACC) were determined in peach and tomato fruits held in carbon dioxide-enriched atmosphere. Ethylene production in peaches decreased to a trace level with 60% carbon dioxide and in tomatoes to 50% of the initial level. The ethylene production rates in both fruits reverted to the initial level when the fruits were transferred back to air. Oxygen uptake in both fruits was markedly inhibited during carbon dioxide exposure. In vivo activities of ACC oxidase and ACC synthase in both fruits were also inhibited during carbon dioxide exposure. ACC content in peaches held in carbon dioxide-enriched atmosphere decreased but it increased in tomatoes. The level of MACC in peaches was constant during carbon dioxide treatment, whereas that in tomatoes slightly increased. These results indicate that inhibition in ethylene production by carbon dioxide may be mediated mainly by reduced conversion of ACC to ethylene in tomatoes, whereas in peaches, the inhibition is attributed to both reduced conversion of S-adenosylmethionine to ACC and ACC to ethylene.

Kubo, Y., H. Tsuji, A. Inaba, and R. Nakamura. 1993. Effects of elevated CO₂ concentrations on the ripening of banana fruit by exogenous C₂H₄. *Journal of the Japanese Society for Horticultural Science* 62(2):451-455.

Green bananas were treated with 0 to 60% CO₂ and 1 to 100 PPM C₂H₄ to study their interaction on the ripening process. 1. The CO₂ treatment did not block completely the initiation of ripening of banana by exogenous C₂H₄. When the concentration of applied C₂H₄ was kept constant and the CO₂ concentration high, the appearance of the yellow pigment in the peel was delayed. 2. The combination of various concentrations of CO₂ and C₂H₄ on the respiratory climacterics in green banana, monitored with an automated microcomputer system, revealed that the onset of the climacteric rise of bananas under any CO₂ concentration combined with 1 PPM C₂H₄ commenced simultaneously with fruits which were kept under air and 1 PPM C₂H₄. However, the progress of the climacteric rise was slower and the peaks were lower at high CO₂ concentration than they were at low CO₂ concentrations. With 60% CO₂ and 100 PPM C₂H₄, the fruit color remained green until the end of the gas treatment, in spite of the slow respiratory rise and ripening of the flesh. Our results suggest that the elevated CO₂ concentration has no effect on the initiation-time of banana ripening induced by exogenous C₂H₄ but lowers the progress rate of ripening.

Kuehny, J.S., M.M. Peet, P.V. Nelson, and D.H. Willits. 1991. Nutrient dilution by starch in CO₂-enriched chrysanthemum. *Journal of Experimental Botany* 42(239):711-716.

Increasing growth irradiance and CO₂ generally decreases foliar nutrient concentration on a dry weight basis and increases foliar starch concentration. However, the extent to which starch concentrations 'dilute' foliar nutrient concentrations when the latter are expressed on a dry weight basis is not known. To determine the importance of differential starch accumulation in calculating nutrient concentrations on a dry weight basis, leaf nutrient and starch concentrations were measured in Chrysanthemum x morifolium 'Fiesta' (Ramat.) cuttings grown at three irradiance levels and two CO₂ levels for eight weeks in both winter and spring. On a dry weight basis, foliar concentrations of most nutrients were lower in both seasons as a result of the elevated CO₂ and irradiance levels, and total dry weights were higher. Per cent starch was greater at the high CO₂ level in both seasons but was only greater at higher irradiances in the winter experiment. When starch was subtracted from the leaf dry weights, the differences between CO₂ and irradiance treatments disappeared with respect to N, P, K, Ca, Mg, S, and B but not for Fe, Mn, Zn, and Cu.

Kuhn, M., C. Niewohner, M. Isenbeck-Schroter, and H.D. Schulz. 1998. Determination of major and minor constituents in anoxic thermal brines of deep sandstone aquifers in Northern Germany. *Water Research* 32(2):265-274.

The common process of low energy geothermal exploitation is the doublet of production- and reinjection borehole. The quality of water reinjected into a elastic reservoir is essential for the reliability of an injection well. In order to estimate precipitation reactions it is necessary to obtain extensive reliable analysis data of the water for the use of thermodynamic modelling. For thermal anoxic brines, the analysis of major and especially minor ion content is difficult because of matrix effects and possible iron precipitation. A selection of analysing methods were applied to two anoxic thermal brines of deep sandstone aquifers of Northern Germany. Detection limits and measured data of the major constituents are presented of Na⁺, K⁺, NH₄⁺, Ca²⁺, Mg²⁺, Ba²⁺, Sr²⁺, Fe- total, Mn²⁺, SiO₄⁴⁻, B(OH)(3), Zn²⁺, Pb²⁺, Cd²⁺, F⁻, Cl⁻, Br⁻, I⁻, SO₄²⁻, SO₃²⁻, S²⁻, PO₄³⁻, NO₃⁻, NO₂⁻ and DOC. The measurements were done with ICP-OES, ionselective electrodes, photometry, polarography, titration methods, ion chromatography and TOC-analyzer. Except for SO₄(2-) and Cl⁻, the anion analysis was done on-site, since the high iron content in the anoxic water requires acidification in order to prevent iron hydroxide precipitation. The minor constituents Zn²⁺, Pb²⁺, Cu²⁺, Cd²⁺, Cr³⁺, Sc³⁺, Co²⁺, Y³⁺, La³⁺, Ce³⁺, Al³⁺, were enriched by trace matrix separation using the cation exchange resin Chelex((R))100. The element concentrations in the acidic eluates of the Chelex((R))100 columns were measured using ICP- MS. The pH dependency of the exchange equilibrium at pH values of 4, 5 and 6 (buffered and unbuffered) as well as the relation to the salt content between 35 and 250 g(-1) total dissolved solids of Na-K-Ca-Mg-Cl-SO₄ were evaluated by sensitivity analysis. Kull, O., A. Sober, M.D. Coleman, R.E. Dickson, J.G. Isebrands, Z. Gagnon, and D.F. Karnosky. 1996. Photosynthetic responses of aspen clones to simultaneous exposures of ozone and CO₂. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 26(4):639-648.

Current projections indicate steady increases in both tropospheric ozone and carbon dioxide well into the next century with concurrent increases in plant stress. Because information about effects of these interacting stresses on forest trees is limited, we have conducted ozone and carbon dioxide experiments using ozone-tolerant and ozone-sensitive trembling aspen (*Populus tremuloides* Michx.) clones (clones 216 and 259, respectively). Aspen plants were grown either in pots (square-wave study) or in the ground (episodic study) in open-top chambers. Plants in the square-wave study were exposed for a single growing season to charcoal-filtered air (CF) or to CF plus elevated carbon dioxide (CO₂), ozone (O-3), or O-3 plus CO₂ (O-3 + CO₂). Plants in the episodic study were exposed for three growing seasons to CF, twice simulated ambient (2x) O-3 (2x O-3), or 2x O-3 plus CO₂ (2x O-3 + CO₂). Photosynthetic measurements were made either in the open-top chambers at treatment CO₂ concentrations or in controlled-environment cuvettes with various CO₂ concentrations, producing assimilation versus intercellular CO₂ concentration (A/C-i) curves. Ozone decreased photosynthetic rate and stomatal conductance and accelerated leaf senescence. Elevated CO₂ increased photosynthetic rate and decreased stomatal conductance when measured at treatment CO₂ concentrations, and exacerbated the negative effect of O-3 on photosynthesis. For example, for clone 259, photosynthesis decreased 9% for the O-3 treatment compared with the CF treatment, but decreased 24% for the O-3 + CO₂ treatment compared with the CO₂ treatment. Similar decreases for clone 216 of 2% and 6% for O-3 and O-3 + CO₂, respectively, were not significant. A/C-i curves showed that O-3 decreased carboxylation efficiency and maximum photosynthetic rate and that photosynthetic inhibition in response to O-3 was greater with

elevated CO₂. The simultaneous declines in all factors of photosynthetic gas exchange measurements suggest that the equilibrium between stomatal conductance, carboxylation, and light harvesting systems was not disrupted by O-3 and O-3 x CO₂ interactions. Carbon dioxide did not ameliorate the detrimental effects of O-3 on the leaf photosynthetic apparatus. In fact, the O-3-tolerant clone appeared more sensitive to O-3 with elevated CO₂.

Kunz, R.P., R.E. Schulze, and R.J. Scholes. 1995. An approach to modelling spatial changes of plant carbon:nitrogen ratios in southern Africa in relation to anticipated global climate change. *Journal of Biogeography* 22(2-3):401-408.

The carbon to nitrogen (C:N) ratio is the main factor determining the forage quality of a plant, with a low C:N ratio indicating relatively good plant digestibility and a high C:N ratio inferring relatively poor forage quality. Global atmospheric composition and climate change effects on plant carbon to nitrogen ratios are thus likely to be important when predicting possible second-order impacts of the enhanced greenhouse effect on rangeland forage quality and the resultant feeding habits of foraging animals and herbivorous insects. Equations relating the assimilation of total carbon and nitrogen rates to monthly air temperature, the ambient CO₂ level and soil fertility were used together with detailed spatial climatic and soil databases to simulate regional patterns of C:N ratios over southern Africa. Carbon to nitrogen ratios were estimated for both the present climate and for a possible future climate scenario defined by a general 2 degrees C mean daily temperature increase over southern Africa (but with latitudinal, seasonal and diurnal adjustments made), an increase in atmospheric CO₂ concentration from 360 to 560 ppmv, but with no changes in precipitation patterns. When C:N differences between future and present climates are examined, results indicate both relative increases and decreases over southern Africa in a regional context, ranging from - 8 to + 8%. Areas where the C:N ratios decreased indicate that for the future climate scenario which was assumed the relative increase in assimilated nitrogen would be greater than that for carbon. Similarly, areas where the C:N ratios increased indicate that the relative increase in assimilated carbon would be greater than that for nitrogen. In this study, regions sensitive to climate change effects on C:N ratios in southern Africa have therefore been identified and with that, those areas where the consumption of plant matter may be expected to increase or decrease as a result of anticipated global climate change.

Kurets, V.K., S.N. Drozdov, and E.G. Popov. 1999. Intraspecific diversity in the response of net photosynthesis in cucumber plants to elevated concentrations of atmospheric carbon dioxide. *Russian Journal of Plant Physiology* 46(2):159-162.

Relationships between net photosynthesis of intact cucumber plants (*Cucumis sativus* L., cvs. Alma-Atinskii 1, Teplichnyi rannii 65, and Syurpriz 66) and irradiance, air and soil temperatures, and ambient CO₂ concentration were simulated by the multiway factorial method. Analysis of the models demonstrated marked cultivar-specific differences in plant responses to environmental conditions, in terms of both the potential highest values and conditions for their expression. This allowed us to conclude that the models of relationships between CO₂ exchange in intact plants and environmental conditions can be used for the

assessment of biological diversity at the intraspecific level.

Kurooka, H., S. Fukunaga, E. Yuda, S. Nakagawa, and S. Horiuchi. 1990. Effect of carbon-dioxide enrichment on vine growth and berry quality of kyoho grapes. *Journal of the Japanese Society for Horticultural Science* 59(3):463-470.

Although ambient temperature is kept adequate, grape cultivation under covered facilities during winter months in Japan gives rise to low yields of poor quality berries because of low light intensities. This investigation was conducted in leaf chamber, using *Vitis labruscana* Bailey cv. Kyoho, to determine the influence of leaf age, light intensity, and CO₂ concentrations on photosynthesis. The effects of CO₂ enrichment on vine growth and fruit quality were also investigated in growth chambers. 1. The rate of photosynthesis per unit leaf area (Pn) between May 28 and September 19 rapidly increased with leaf growth, reaching a maximum of 18.9 mg CO₂/dm²/hr, 37 days after the unfolding of a leaf. Pn then gradually decreased with leaf age. In young leaves, higher CO₂ concentrations and stronger light intensities resulted in a significant increase in Pn. Older leaves exhibited a similar enhancement of Pn upon exposure to high light intensity. Pn was saturated at 828 ppm CO₂. 2. Administration of 1,000 to 1,100 ppm CO₂ to vines for an 8 hr/day at a late stage of berry development until harvest had no effect on berry size but resulted in an increase in sugar and anthocyanin contents but a decrease in organic acid content. Dry weight of newly developed roots doubled as a result of CO₂ enrichment. 3. Application of CO₂ under a long-day photoperiod at an early stage of berry development to a week before veraison markedly promoted shoot elongation. Furthermore, CO₂ enrichment gave a 36% increase in both berry and cluster weights and also a higher sugar-acid ratio at harvest.

Kurschner, W.M., I. Stulen, F. Wagner, and P.J.C. Kuiper. 1998. Comparison of palaeobotanical observations with experimental data on the leaf anatomy of durmast oak [*Quercus petraea* (Fagaceae)] in response to environmental change. *Annals of Botany* 81(5):657-664.

To test whether stomatal density measurements on oak leaf remains are reliable tools for assessing palaeoatmospheric carbon dioxide concentration [CO₂], under changing Late Miocene palaeoenvironmental conditions, young seedlings of oak (*Quercus petraea*, Liebl.) were grown at elevated vs. ambient atmospheric [CO₂] and at high humidity combined with an increased air temperature. The leaf anatomy of the young oaks was compared with that of fossil leaves of the same species. In the experiments, stomatal density and stomatal index were significantly decreased at elevated [CO₂] in comparison to ambient [CO₂]. Elevated [CO₂] induced leaf cell expansion and reduced the intercellular air space by 35%. Leaf cell size or length were also stimulated at high air humidity and temperature. Regardless of a temperate or subtropical palaeoclimate, leaf cell size in fossil oak was not enhanced, since neither epidermal cell density nor length of the stomatal apparatus changed. The absence of these effects may be attributed to the phenological response of trees to climatic changes that

balanced temporal changes in environmental variables to maintain leaf growth under optimal and stable conditions. *Quercus petraea*, which evolved under recurring depletions in the palaeoatmospheric [CO₂], may possess sufficient phenotypic plasticity to alter stomatal frequency in hypostomatous leaves allowing high maximum stomatal conductance and high assimilation rates during these phases of low [CO₂]. (C) 1998 Annals of Botany Company.

Kurschner, W.M., F. Wagner, E.H. Visscher, and H. Visscher. 1997. Predicting the response of leaf stomatal frequency to a future CO₂-enriched atmosphere: constraints from historical observations. *Geologische Rundschau* 86(2):512-517.

The majority of the water flux from the earth's land surface to the atmosphere passes through the tiny pores (stomata) in the leaves of land plants. The maximum conductance to diffusion of the leaves, determined by the number and geometry of stomata, has a profound effect on the terrestrial water and energy balance. Among tree species, there is ever increasing evidence that anthropogenic increase in atmospheric CO₂ concentrations results in a decrease in stomatal frequency. The rate of historical CO₂ responsiveness of individual tree species can be used to calibrate empirical models of non-linear (sigmoid) stomatal frequency response to CO₂ increase. Modelled response curves for European tree birches (*Betula pendula*, *Betula pubescens*) and Durmast oak (*Quercus petraea*) predict different response limits to CO₂ increase (similar to 350 and similar to 400 ppmv, respectively), indicating that non-linear stomatal frequency responses may vary from one tree species to another. Information on a wider selection of species is needed, but the models suggest that the maximum effect of anthropogenic CO₂ increase on stomatal frequency has already been reached. Further research is required to establish the effect of rapidly declining response rates on future stomatal conductance of the ecologically contrasting trees of boreal, temperate, subtropical and tropical forests.

Kurz, C., U. Schmieden, P. Strobel, and A. Wild. 1998. The combined effect of CO₂, ozone, and drought on the radical scavenging system of young oak trees (*Quercus petraea*) - A phytotron study. *Chemosphere* 36(4-5):783-788.

In order to study the combined effects of CO₂, ozone, and drought, we simulated in a controlled environment the climatic conditions of a German oak stand with high ozone (daytime: 80 ppb, control: 20 ppb) during one vegetative period under a regime of low and high CO₂ concentration (370 vs 720 ppm) and drought (4 weeks < -800 hPa). To investigate the effects of CO₂, ozone and drought on the radical scavenging system, we monitored the level of glutathione, ascorbate, and α -tocopherol. However, it is important that, under the regime of elevated CO₂, the antioxidative behaviour of glutathione and ascorbate appears to be masked by their function as storage molecules for sulfur or carbon. Kutik, J., L. Natr, H.H. DemmersDerks, and D.W. Lawlor. 1995. Chloroplast ultrastructure of sugar beet (*Beta vulgaris* L.) cultivated in normal and elevated CO₂ concentrations with two contrasted nitrogen supplies. *Journal of Experimental Botany* 46(293):1797-1802.

Sugar beet (*Beta vulgaris* L., cultivar Celt) plants were grown under simulated field conditions in pots and supplied with adequate or deficient nitrogen (HN and LN, respectively) combined with two CO₂ concentrations, ambient (c. 350 μ mol mol⁻¹) CO₂-AC), or elevated CO₂ (c. 600 μ mol mol⁻¹) CO₂-HC). Chloroplast structure in mesophyll palisade cells of mature leaves (leaf number 19 in HN and 9 in LN), sampled at midday on 16 August 1993 was studied by transmission electron microscopy and quantified stereologically. The ultrastructure of palisade parenchyma chloroplasts was affected by the elevated CO₂ concentration and strikingly affected by nitrogen supply. Chloroplast diameter (cross-sectional length) was slightly, but not significantly, greater in HC than AC treatments within an N treatment, but was smaller in LN than HN; chloroplast cross-sectional area also increased with HC in both N treatments, but only significantly so in LN. Elevated CO₂ reduced the proportion of total thylakoids (significant at 5% and 0.1% in HN and LN, respectively) due to decreased granal thylakoids, but the proportion of inter-granal (stromal) thylakoid membranes was not affected compared to chloroplasts from plants grown with ambient CO₂. Chloroplast stroma increased as a proportion of chloroplast volume with elevated compared to ambient CO₂ with HN but not LN. Starch inclusions were not significantly different with elevated compared to ambient CO₂ at HN, but the proportion of starch increased considerably at elevated compared to ambient CO₂ at LN, indicating an over-production of assimilates. Plastoglobuli in chloroplasts increased with deficient N, but decreased with elevated CO₂. Larger chloroplasts with a greater proportion of stroma, but a smaller proportion of granal thylakoids, suggest increased CO₂ assimilating capacity and decreased light harvesting/PSII capacity with elevated CO₂.

Kwa, S.H., Y.C. Wee, and P.P. Kumar. 1995. Ammonium and nitrate uptake and nitrate reductase activity of photoautotrophic callus cultures of the fern *Platynerium coronarium* (Koenig) DESV. *In Vitro Cellular & Developmental Biology-Plant* 31(4):211-214.

The uptake of nitrate and ammonium by callus of *Platynerium coronarium* from the culture medium was examined. Nitrate reductase activity of photoautotrophic callus cultures under CO₂ enrichment was significantly lower compared to the cultures without CO₂ enrichment, but higher than that of heterotrophic callus cultured on medium with 2% (wt/vol) sucrose. When sucrose concentration of the heterotrophic culture was lowered to 0.2%, nitrate reductase activity increased. The level of nitrate reductase activity increased by about 25% in the heterotrophic callus with an increase in 2,4-D from 2 μ M to 10 μ M, despite a decline in fresh weight gain. However, photoautotrophic cultures with 1% CO₂ enrichment showed 20% decline in nitrate reductase activity and 45% decline in fresh weight gain with a similar increase in 2,4-D level. The rate of uptake of nitrate from the culture medium was unrelated to the level of nitrate reductase activity in the callus. For photoautotrophic callus under CO₂ enrichment, the presence of 1% (vol/vol) CO₂ generally resulted in the highest rate of nitrate uptake. The rate of uptake of ammonium was higher for callus cultured on 2 μ M 2,4-D compared to that on 10 μ M 2,4-D.

Kwa, S.H., Y.C. Wee, and P.P. Kumar. 1997. Ribulose-1,5-bisphosphate carboxylase and phosphoenolpyruvate carboxylase activities of photoautotrophic callus of *Platycerium coronarium* (Koenig ex OF Muell.) Desv. under CO₂ enrichment. *Plant Cell Tissue and Organ Culture* 50(2):75-82.

The *in vitro* activities of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) and phosphoenolpyruvate carboxylase (PEPC) were measured in cell-free extracts of *Platycerium coronarium* callus cultured for up to 42 days under photoautotrophic conditions with CO₂ enrichment. With an increase in CO₂ in the culture environment to 10% (v/v) at low light, the apparent photoautotrophic fixation of CO₂ by Rubisco declined, whereas the non-photoautotrophic CO₂ fixation by PEPC activity was enhanced. Hence, photosynthesis appears to play a lesser role in providing carbon skeletons and energy with prolonged culture in a CO₂-enriched environment. Instead, the anaplerotic supply of C-skeletons by PEPC may be important under such a situation. Short-term (HCO₃⁻)-C-14 fixation experiments indicated that photoautotrophic callus cultured for 3 weeks with 10% CO₂ enrichment assimilated less (CO₂)-C-14 than the control (0.03% CO₂). Analyses of C-14-metabolites indicated that about 50% of the total soluble (CO₂)-C-14 fixed was in the organic acid fraction and 35% in the amino acid fraction. Despite the changes in the *in vitro* Rubisco/PEPC activity-ratio, no significant change in the C-14 distribution pattern was apparent in response to increasing sucrose or CO₂ concentrations. The suppression of Rubisco activity and total chlorophyll content in high sucrose or elevated CO₂ concentrations suggests an inhibition of the capacity for photoautotrophic callus growth under these conditions.

Kwa, S.H., Y.C. Wee, T.M. Lim, and P.P. Kumar. 1995. Establishment and physiological analyses of photoautotrophic callus-cultures of the fern *Platycerium coronarium* (Koenig) Desv under CO₂ enrichment. *Journal of Experimental Botany* 46(291):1535-1542.

Gametophyte-derived callus cultures of *Platycerium coronarium* could be maintained under photoautotrophic conditions on Murashige and Skoog medium supplemented with 2 µM 2,4-dichlorophenoxyacetic acid (2,4-D) and with CO₂ enrichment. Progressive reduction of sucrose from the medium resulted in a reduction in growth, but an increase in total chlorophyll content. When subculturing was delayed beyond 2 weeks, callus cells differentiated into gametophytes on the medium with less than or equal to 0.2% sucrose and no CO₂ enrichment. Enriching the photoautotrophic cultures on 2 µM 2,4-D with 1% CO₂ resulted in about 1.7-fold increase in fresh weight within 42 d. Total chlorophyll content was generally higher with 1% CO₂ enrichment than with 10%. F-v/F-m ratio was higher for callus on low levels of sucrose (less than or equal to 0.5%) than that on sucrose greater than or equal to 1.0%. An increase in autofluorescence of chloroplasts, but not the size, was observed with decreasing sucrose levels in the medium. Autofluorescence decreased with increase in CO₂ from 0.03%. Our data are in agreement with the view that long-term exposure to high levels of CO₂ can cause a decrease in photosynthetic capacity.

Kytoviita, M.M., J. Pelloux, V. Fontaine, B. Botton, and P. Dizengremel. 1999. Elevated CO₂ does not ameliorate effects of ozone

on carbon allocation in *Pinus halepensis* and *Betula pendula* in symbiosis with *Paxillus involutus*. *Physiologia Plantarum* 106(4):370-377.

The effect of 700 µmol CO₂ mol⁻¹, 200 mmol ozone mol⁻¹ and a combination of the two on carbon allocation was examined in *Pinus halepensis* co-cultured with *Betula pendula* in symbiosis with the ectomycorrhizal fungus *Paxillus involutus*. The results show that under low nutrient and ozone levels, elevated CO₂ has no effect on the growth of *B. pendula* or *P. halepensis* seedlings nor on net carbon partitioning between plant parts. Elevated CO₂ did not enhance the growth of the fungus in symbiosis with the birch. On the other hand, ozone had a strong negative effect on the growth of the birch, which corresponded with the significantly reduced growth rates of the fungus. Exposure to elevated CO₂ did not ameliorate the negative effects of ozone on birch; in contrast, it acted as an additional stress factor. Neither ozone nor CO₂ had significant effects on biomass accumulation in the pine seedlings. Ozone stimulated the spread of mycorrhizal infection from the birch seedlings to neighbouring pines and had no statistically significant effects on phosphoenolpyruvate carboxylase (PEPC) or ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) activity in the pine needles or on PEPC activity in pine roots.

Laforge, F., C. Lussier, Y. Desjardins, and A. Gosselin. 1991. Effect of light-intensity and CO₂ enrichment during *in vitro* rooting on subsequent growth of plantlets of strawberry, raspberry and asparagus in acclimatization. *Scientia Horticulturae* 47(3-4):259-269.

Growth of plantlets of asparagus (*Asparagus officinalis* L.), raspberry (*Rubus idaeus* L.) and strawberry (*Fragaria X ananassa* Duch.), treated during the *in vitro* rooting stage under three photosynthetic photon flux densities (PPFD) (80, 125 and 250 µmol s⁻¹ m⁻²) (17.5, 26.9 and 53.8 W m⁻² (PAR), respectively) and three CO₂ enrichment levels (CDE) (330, 1650 and 3000 µmol mol⁻¹), was monitored during the acclimatization stage. For the three species, generic differences were observed in the plant response to treatments. A significant residual growth enhancement was caused by CDE. High PPFD *in vitro* increased the dry weight of strawberry and fresh weight of asparagus in acclimatization. Raspberry leaf dry weight was increased by 262% in acclimatization after *in vitro* treatment with high CDE. This enhanced the performance of micropropagated plantlets in acclimatization and reduced by 2 weeks the acclimatization period with raspberry. Our results suggest that *in vitro* leaves may be a source of nutritional reserves for leaves initiated *ex vitro*, but do not exclude a morphogenetic effect of CO₂ during the *in vitro* rooting stage.

Laik, A., and G.E. Edwards. 1997. CO₂ and temperature-dependent induction in C-4 photosynthesis: an approach to the hierarchy of rate-limiting processes. *Australian Journal of Plant Physiology* 24(4):505-516.

Rate-limiting processes for C-4 photosynthesis were examined in *Sorghum bicolor*, an NADP-ME type species, and *Amaranthus cruentus*, an NAD-ME type C-4 species, by studying the kinetics of transient changes in photosynthetic rates following rapid changes in CO₂ or temperature. Primary responses (faster than 15 s) to increasing CO₂ or

temperature are considered direct effects on the turnover rate of the C-4 cycle, whereas medium transient changes (2-3 min) are considered due to build-up of C-4 cycle intermediates, and the slowest transient changes (20-30 min) are thought to be related to end product synthesis. Reciprocal plot of carboxylation rates versus cell wall (dissolved) CO₂ concentration (C-w) gives an apparent K-m (CO₂) of 8 μ M and a V-m of 200 μ mol m⁻² s⁻¹ for PEP carboxylase, which is about 4 times higher than the maximum rate of photosynthesis. Under strictly limiting CO₂, the rate of PEP carboxylation in C-4 photosynthesis is independent of temperature (20-35 degrees C), suggesting a physical rather than a biochemical limitation. It is suggested that the rates of C-3 and C-4 cycles are coordinated through the pool sizes of the C-4 cycle, which are in equilibrium with the pool of 3-phosphoglyceric acid. At low CO₂, the C-4 pools decrease and are slowly regenerated at elevated CO₂, restricting the CO₂ response of C-4 photosynthesis.

Laitat, E., and H. Boussard. 1995. Comparative response on gas exchange of *Picea* spp exposed to increased atmospheric CO₂ in open top chambers at two test sites. *Journal of Biogeography* 22(2-3):241-248.

We took comparative measurements of gas exchange response curves of two species of spruce (*Picea abies* (L.) Karst and *Picea sitchensis* (Bong.) Carr.) exposed to high levels of atmospheric carbon dioxide (CO₂) in two test stations: Vielsalm (Belgium) and Glendevon (United Kingdom). The photosynthetic response of these two species to variations in concentrations of intercellular CO₂ and to variations in light intensity were measured in situ using an integrated transportable differential CO₂ and water vapour exchange measuring system. The response curves were adjusted by the Mitscherlich function. The statistical analysis of our measurements and adjustments reveal similarities in the reaction of *Picea abies* and *Picea sitchensis* to a doubling of the present level of atmospheric CO₂. Regarding the photosynthesis response curves to intercellular CO₂ variation, we noted a decrease in the maximum photosynthesis rate and the carboxylation rate accompanied by an increased compensation point. Regarding the photosynthesis response curves to the light variation, we found that dark respiration and photochemical efficiency remained unchanged, and the maximum photosynthesis rate was slightly higher in an atmosphere enriched in CO₂. These experimental contexts would seem to indicate that the current and forecast levels of CO₂ are not ecological factors limiting primary productivity, and that the increase in atmospheric CO₂ interacts with other environmental factors.

Lake, J.C., and L. Hughes. 1999. Nectar production and floral characteristics of *Tropaeolum majus* L. grown in ambient and elevated carbon dioxide. *Annals of Botany* 84(4):535-541.

Tropaeolum majus (nasturtiums) were grown from seed in growth cabinets, under 380 and 750 ppmv CO₂. Elevated CO₂ significantly increased nectar secretion rate, both in flowers milked of nectar daily and in once sampled, 3-d-old flowers. Elevated CO₂ did not affect time to flowering, total number of flowers produced, pollen to ovule ratio, or the total or individual concentrations of nectar amino acids. The dry weight and longevity of individual flowers was also unchanged. Nectar sugar content was unchanged by elevated CO₂ in a subset of flowers

used to assess the 3-d-old nectar volume. This subset did not show the same increase in nectar volume under elevated CO₂ as the full set, resulting in the concentration of sugars remaining unchanged. Overall, the quantity rather than the quality of the nectar changed under elevated CO₂ while flower characteristics remained constant, implying that the identity of pollinators may remain the same while foraging behaviour (e.g. number of visits per plant, distance travelled) may change in the future. (C) 1999 Annals of Botany Company.

Lal, M., K.K. Singh, L.S. Rathore, G. Srinivasan, and S.A. Saseendran. 1998. Vulnerability of rice and wheat yields in NW India to future changes in climate. *Agricultural and Forest Meteorology* 89(2):101-114.

Agricultural sector is one of the sensitive areas which would be influenced by the projected global warming and associated climate change. In spite of the uncertainties about the precise magnitude of climate change on regional scales, an assessment of the possible impacts of changes in key climatic elements on our agricultural resources is important for formulating response strategies. In this study, vulnerability of wheat and rice crops in northwest India to the projected climate change is examined. CERES wheat and rice models adopted for the study were validated for their ability to reproduce yields at the selected NW Indian stations. The sensitivity experiments with these models showed higher yields for both wheat and rice (28% and 15% respectively for a doubling of CO₂) under elevated CO₂ levels. A 3 degrees C (2 degrees C) rise in air temperature nearly cancels out the positive effect of elevated CO₂ on the wheat (rice) yields. While the wheat crops are found to be sensitive to increase in maximum temperature, the rice crops are vulnerable to increase in minimum temperature. The combined effect of enhanced CO₂ and imposed thermal stress on the wheat (rice) crop is 21% (4%) increase in yield for the irrigation schedule presently practised in the region. While the adverse impacts of likely water shortage on wheat crops would be minimised to a certain extent under elevated CO₂ levels, they would largely be maintained for the rice crops resulting in about 20% net decline in rice yields. In general, acute water shortage conditions combined with the thermal stress should adversely affect both the wheat and more severely the rice productivity in NW India even under the positive effects of elevated CO₂ in the future. Lal, M., K.K. Singh, G. Srinivasan, L.S. Rathore, D. Naidu, and C.N. Tripathi. 1999. Growth and yield responses of soybean in Madhya Pradesh, India to climate variability and change. *Agricultural and Forest Meteorology* 93(1):53-70.

This study is aimed at assessing the impact of thermal and moisture stresses associated with observed intraseasonal and interannual variability in key climatic elements on the nature and extent of losses in growth and yield of soybean crop in central India through the use of CROPGRO model. The crops are found to be more sensitive to higher cumulative heat units during cropping season. The yields respond substantially to temporal variations in rainfall (associated with observed swings in the continuity of monsoon). Prolonged dry spells at critical life stages of the soybean crop are found to adversely affect crop development and growth and hence the yields at selected sites. We have also examined the plausible effects of future climate change on soybean

yields in the selected region based on simulations carried out for doubled atmospheric CO₂ level and with modified weather variables using the available seasonal projections for the future. Our findings on the response of elevated CO₂ concentrations in the atmosphere suggest higher yields (50% increase) for soybean crop for a doubling of CO₂. However, a 3 degrees C rise in surface air temperature almost cancels out the positive effects of elevated CO₂ on the yield. Soybean crops at selected site are more vulnerable to increases in maximum temperature than in minimum temperature. The combined effect of doubled CO₂ and anticipated thermal stress (likely by middle of the next century) on soybean crop is about 36% increase in yield at the selected sites. A decline in daily rainfall amount by 10% restricts this yield gain to about 32%. Deficient rainfall with uneven distribution during the monsoon season could be a critical factor for the soybean productivity even under the positive effects of elevated CO₂ in the future. Lal, M., P.H. Whetton, A.B. Pittock, and B. Chakraborty. 1998. Simulation of present-day climate over the Indian subcontinent by general circulation models. *Terrestrial Atmospheric and Oceanic Sciences* 9(1):69-96.

There continues to be some improvement in the ability of general circulation models to simulate the present-day climate on large scales although further improvements in the model resolution and parameterization of physical processes are still needed for the realistic simulation of regional climates. Quantitative assessment of the magnitude of climate change on a regional scale and its implications are essential for understanding, planning and management of resources at national/regional levels. In developing countries like India, where the economy is largely regulated by variability in summer monsoon rainfall, the consideration of measures for reducing the impacts of global change should begin as soon as possible, particularly with regard to floods and droughts, cyclone disaster preparedness, hydrological planning in semi-arid regions and coastal zone management issues. With this in view, we examine here the skill of a range of global climate models in simulating the regional climatology of the Indian subcontinent. This is a necessary first step in preparing climate change scenarios for the region. The simulation of the current broad scale patterns of mean sea level pressure, temperature and precipitation over the northern hemisphere and over the Indian subcontinent in particular are assessed for a broad range of global climate modelling experiments. The experiments included both slab ocean and coupled ocean experiments. Five experiments are identified as having a fairly realistic simulation and may be considered acceptable for use in regional climate change assessments. All of these are of relatively high resolution and use a Q-flux correction (in the slab ocean experiments) or a flux correction (in the coupled ocean experiments). A further four experiments, with somewhat poorer regional climate simulations, are acceptable but only to a moderate degree of confidence. However, some six experiments have such marked deficiencies in their simulation of present-day regional climatology that we consider them unacceptable for regional climate change assessment.

Lal, R. 1997. Residue management, conservation tillage and soil restoration for mitigating greenhouse effect by CO₂-enrichment. *Soil & Tillage Research* 43(1-2):81-107.

This manuscript reviews the potential impact of residue management, conservation tillage and soil restoration on carbon sequestration in world soils. The greenhouse effect is among four principal ecological issues of global concern that include: (i) adequacy of land resources to meet needs of present and future generations; (ii) role of world soils and agricultural practices in the 'greenhouse' effect; (iii) potential of crop residue management, restoration of degraded soils, and conservation tillage in carbon sequestration in soil; and (iv) minimizing risks of soil degradation by enhancing soil resilience and soil quality. Annual increase in CO₂ concentration in the atmosphere is 3.2 x 10¹⁵ g, and there exists a potential to mitigate this effect through C sequestration in soils. Just as world soils are an important active pool of organic carbon and play a major role in the global carbon cycle, crop residue is a major renewable resource which also has an important impact on the global carbon cycle. I have estimated the annual production of crop residue to be about 3.4 billion Mg in the world. If 15% of C contained in the residue can be converted to passive soil organic carbon (SOC) fraction, it may lead to C sequestration at the rate of 0.2 x 10¹⁵ g/yr. Similarly restoring presently degraded soils, estimated at about 2.0 billion ha, and increasing SOC content by 0.01%/yr may lead C sequestration at the rate of 3.0 Pg C/yr. Conservation tillage is an important tool for crop residue management, restoration of degraded soil, and for enhancing C sequestration in soil. Conservation tillage, any tillage system that maintains at least 30% of the soil surface covered by residue, was practised in 1995 on about 40 x 10⁶ ha or 35.5% of planted area in USA. It is projected that by the year 2020, conservation tillage may be adopted on 75% of cropland in USA (140 x 10⁶ ha), 50% in other developed countries (225 x 10⁶ ha), and 25% in developing countries (172 x 10⁶ ha). The projected conversion of conventional to conservation tillage may lead to a global C sequestration by 2020 at a low estimate of 1.5 x 10¹⁵ g, and at a high estimate of 4.9 x 10¹⁵ g of C. These potentials of C sequestration can be realized through adoption of regional, national and global soil policy that stipulate appropriate use of world soil resources. Lambers, H. 1993. Rising co₂, secondary plant-metabolism, plant-herbivore interactions and litter decomposition - theoretical considerations. *Vegetatio* 104:263-271.

A brief account is given of the ecological significance of quantitatively important secondary plant compounds, mainly those of a phenolic nature, in herbivory and decomposition. Phenolic compounds accumulate to a greater extent in slow-growing species than in fast-growing ones, particularly when soil conditions (nutrients, water) restrict growth. Two hypotheses to explain the increased concentration of phenolics when soil conditions are unfavorable are presented. The first hypothesis (the 'carbon supply model of secondary plant metabolism') considers the increased levels of non-structural carbohydrates as the major trigger. The second hypothesis (the 'amino acid diversion model of secondary plant metabolism') states that increased accumulation of phenolics stems from a decreased use of a common precursor (phenylalanine or tyrosine) for protein synthesis. Current experimental evidence, though still fairly limited, supports the second hypothesis, but further testing is required before the first model can be rejected. So far, there is very little evidence for a direct effect of atmospheric CO₂ on the concentration of secondary compounds in higher plants. However, there are likely to be indirect effects, due to a stronger limitation by the nitrogen supply in plants whose growth has been promoted by atmospheric CO₂. It is concluded that it is very likely that phenolic compounds accumulate to a greater extent in plants exposed to elevated

CO₂, due to a greater limitation of nutrients, rather than as a direct effect of elevated CO₂.

Lambers, H., I. Stulen, and A. vanderWerf. 1996. Carbon use in root respiration as affected by elevated atmospheric CO₂. *Plant and Soil* 187(2):251-263.

The use of fossil fuel is predicted to cause an increase of the atmospheric CO₂ concentration, which will affect the global pattern of temperature and precipitation. It is therefore essential to incorporate effects of temperature and water supply on the carbon requirement for root respiration of plants to predict effects of elevated [CO₂] on the carbon budget of natural and managed systems. There is insufficient information to support the contention that an increase in the concentration of CO₂ in the atmosphere will enhance the CO₂ concentration in the soil to an extent that is likely to affect root respiration. Moreover, there is no convincing evidence for a direct effect of elevated atmospheric [CO₂] on the rate of root respiration per unit root mass or the fraction of carbon required for root respiration. However, there are likely to be indirect effects of elevated [CO₂] on the carbon requirement of plants in natural systems. Firstly, it is very likely that the carbon requirement of root respiration relative to that fixed in photosynthesis will increase when elevated [CO₂] induces a decrease in nutrient status of the plants. Although earlier papers have emphasized that elevated [CO₂] favours investment of biomass in roots relative to that in leaves, these are in fact indirect effects. The increase in root weight ratio is due to the more rapid depletion of nutrients in the root environment as a consequence of enhanced growth. This will decrease the specific rate of root respiration, but increase the carbon requirement as a fraction of the carbon fixed in photosynthesis. It is likely that these effects will be minor in systems where the nutrient supply is very high, e.g. in many managed arable systems, and increase with decreasing soil fertility, i.e. in many natural systems. Secondly, a decrease in rainfall in some parts of the world may cause a shortage in water supply which favours the carbon partitioning to roots. Water stress is likely to reduce rates of root respiration per unit root mass, but enhance the fraction of total assimilates required for root respiration, due to greater allocation of biomass to roots. Increased temperatures are unlikely to affect the specific rate of root respiration in all species. Broadly generalized, the effect of temperature on biomass allocation is that the relative investment of biomass in roots is lowest at a certain optimum temperature and increases at both higher and lower temperatures. The root respiration of some species acclimates to growth temperature, so that the effect of global temperature rise is entirely accounted for by the effect of temperature on biomass allocation. The specific rate of root respiration of other species will increase with global warming. In response to global warming the carbon requirement of roots is likely to decrease in temperate regions, when temperatures are suboptimal for the roots' capacity to acquire water. Here global warming will induce a smaller biomass allocation to the roots. Conversely, the carbon requirements are more likely to increase in mediterranean environments, where temperatures are often supraoptimal and a rise in temperature will induce greater allocation of biomass to the roots.

Lambers, H., R. VandenBoogaard, E.J. Veneklaas, and R. Villar.

1995. Effects of global environmental change on carbon partitioning in vegetative plants of *Triticum aestivum* and closely related *Aegilops* species. *Global Change Biology* 1(6):397-406.

The use of fossil fuel is predicted to cause an increase of the atmospheric CO₂ concentration, which will affect the global pattern of temperature and precipitation. It is therefore essential to incorporate effects of temperature and water supply on carbon partitioning of plants to predict effects of elevated [CO₂] on growth and yield of *Triticum aestivum*. Although earlier papers have emphasized that elevated [CO₂] favours investment of biomass in roots relative to that in leaves, it has now become clear that these are indirect effects, due to the more rapid depletion of nutrients in the root environment as a consequence of enhanced growth. Broadly generalized, the effect of temperature on biomass allocation in the vegetative stage is that the relative investment of biomass in roots is lowest at a certain optimum temperature and increases at both higher and lower temperatures. This is found not only when the temperature of the entire plant is varied, but also when only root temperature is changed whilst shoot temperature is kept constant. Effects of temperature on the allocation pattern can be explained largely by the effect of root temperature on the roots' capacity to transport water. Effects of a shortage in water supply on carbon partitioning are unambiguous: roots receive relatively more carbon. The pattern of biomass allocation in the vegetative stage and variation in water-use efficiency are prime factors determining a plant's potential for early growth and yield in different environments. In a comparison of a range of *T. aestivum* cultivars, a high water-use efficiency at the plant level correlates positively with a large investment in both leaf and root biomass, a low stomatal conductance and a large investment in photosynthetic capacity. We also present evidence that a lower investment of biomass in roots is not only associated with lower respiratory costs for root growth, but also with lower specific costs for ion uptake. We suggest the combination of a number of traits in future wheat cultivars, i.e. a high investment of biomass in leaves, which have a low stomatal conductance and a high photosynthetic capacity, and a low investment of biomass in roots, which have low respiratory costs. Such cultivars are considered highly appropriate in a future world, especially in the dryer regions. Although variation for the desired traits already exists among wheat cultivars, it is much larger among wild *Aegilops* species, which can readily be crossed with *T. aestivum*. Such wild relatives may be exploited to develop new wheat cultivars well-adapted to changed climatic conditions.

Lamhamedi, M.S., and P.Y. Bernier. 1994. Ecophysiology and field performance of black spruce (*Picea mariana*) - a review. *Annales Des Sciences Forestieres* 51(6):529-551.

This paper presents a literature review of black spruce (*Picea mariana* [Mill] BSP) ecophysiology concerning the response of net photosynthesis and stomata to changes in environmental factors. Current knowledge on root growth, mineral nutrition and response to high temperature, CO₂ enrichment and climate change, frosts, water stress and flooding are also covered. The review ends with an overview of stand establishment and field performance of planted seedlings. The authors highlight the need for research on the long-term effects of multiple stresses, such as climate change and air pollution on the black spruce ecosystem.

Landolt, W., and I. Pfenninger. 1997. The effect of elevated CO₂ and soil type on non-structural carbohydrates in beech leaves and Norway spruce needles growing in model ecosystems. *Acta Oecologica-International Journal of Ecology* 18(3):351-359.

Young beech and Norway spruce trees from two Swiss provenances were both planted in an acidic and calcareous soil in 16 open-top chambers. Half of the plants were exposed to elevated CO₂ (ambient, ambient + 200 μ l l⁻¹ (-1), 24 hrs/day, 365 days/year) and enhanced nitrogen deposition (2.5, 25 kg ha⁻¹ yr⁻¹) throughout a single growing season. Leaf and needle samples from all 64 trees were collected (2 provenances x 2 soil types x 4 treatments x 4 replications) at the end of July and September. These were analysed for starch, soluble carbohydrates and total non-structural carbohydrates (TNC). Increased starch and TNC levels were found in plants under elevated CO₂ and those growing on the acidic soil. These effects were not consistent in both species or on both sampling dates. Soluble carbohydrates were only affected significantly by soil type. So far no interactions have been found between CO₂, N or soil type on any date and in any fraction. It is concluded that soil type should be considered when discussing the effects of elevated CO₂ on starch, soluble carbohydrate or TNC contents in beech and spruce trees.

Landsberg, J., and M.S. Smith. 1992. A functional scheme for predicting the outbreak potential of herbivorous insects under global atmospheric change. *Australian Journal of Botany* 40(4-5):565-577.

There are many possible ways in which changes in the global atmosphere could influence the outbreak potential of herbivorous insects; we clarify these by developing a scheme for analysing insect populations in terms of functional attributes that are both important in population regulation and responsive to global change. This analysis shows that elevated CO₂ is not likely to have a major influence on probability of insect outbreak, except possibly in systems in which nitrogen-based defensive compounds are produced by plants in response to herbivory. Systems that will have high potential to outbreak, if climatic conditions become more favourable for plant growth and responses are not constrained by other resources, include those in which both herbivorous insects and host plants have highly flexible growth patterns and activity cues. Global changes that increase environmental stress on host plants are most likely to favour sap-feeding insects. Critical enemy (predator or parasitoid) control of the dormant phase of herbivorous insects may be very important in preventing or allowing outbreaks, but is often poorly understood.

Lange, D.L., and A.A. Kader. 1997. Changes in alternative pathway and mitochondrial respiration in avocado in response to elevated carbon dioxide levels. *Journal of the American Society for Horticultural Science* 122(2):245-252.

Partially ripened avocado [*Persea americana* (Mill.) cv, Hass] fruit harvested in either June or Aug, 1994 were kept at 10 degrees C in air (21% O₂), 20% CO₂ (17% O₂, balance N₂), or 40% CO₂ (13% O₂, balance N₂) for 7 to 12 days and then were transferred to air at 10 degrees C for 2 to 3 days. Mitochondrial respiration was stimulated in

response to elevated CO₂, treatments at 10 degrees C. A shift to alternative pathway (Alt) respiration occurred on day 4 in experiments using avocados from both harvest dates, with a return to initial levels in only the 20% CO₂-treated fruit (June-harvested fruit after return to air). Elevated CO₂ at 20 degrees C decreased the in vitro O₂ consumption of isolated mitochondria compared to mitochondria kept in air. The Alt pathway contributed less to the total O₂ uptake of CO₂-treated mitochondria compared to mitochondria kept in air. The respiratory control ratios of the CO₂-treated fruit and mitochondria were higher and lower, respectively, than the air controls. Induction of 33 to 37 kD proteins (corresponding to the size of the alternative oxidase proteins) occurred in avocados after 4 days in 40% CO₂. These results indicate that elevated CO₂ has various effects depending on concentration, duration and temperature of exposure, and mitochondrial function of avocado fruit, such as increased and altered respiratory oxidation and up-regulation of alternative oxidase proteins.

Lange, D.L., and A.A. Kader. 1997. Effects of elevated carbon dioxide on key mitochondrial respiratory enzymes in 'Hass' avocado fruit and fruit disks. *Journal of the American Society for Horticultural Science* 122(2):238-244.

Prelimacteric avocado [*Persea americana* (Mill.) cv, Hass] fruit or fruit disks as well as fruit harvested in either June (midseason) or August (late season) and partially ripened were kept in air (21% O₂ + 78% N₂), 20% CO₂ + 17% O₂ (63% N₂), or 40% CO₂ + 13% O₂ (47% N₂) at either 10 or 20 degrees C. Ethylene production by preclimacteric fruit completely inhibited during CO₂ exposure, whereas there was only partial inhibition of ethylene production when partially ripened fruit were exposed. Compared to the fruit stored in air, O₂ uptake of fruit stored in 20% CO₂ was decreased by 20%, whereas the fruit stored in 40% CO₂ showed 25% more O₂ uptake than air-stored fruit. Fruit subjected to a storage regime of 40% CO₂ at 10 degrees C followed by 2 d in air had the best visual quality. In general, climacteric fruit treated with 20% CO₂ at 10 degrees C showed increased pyruvate dehydrogenase (PDH) activity and decreased cytochrome oxidase (CytOx) activity. Fruit stored in 40% CO₂ had reduced CytOx activity compared to air-stored fruit, and PDH activity was variable depending on the harvest season of the fruit. Our results show that the effect of elevated CO₂ on a given enzyme depends on concentration of CO₂, duration of exposure, physiological state of the fruit, and type of tissue exposed.

Lange, D.L., and A.A. Kader. 1997. Elevated carbon dioxide exposure alters intracellular pH and energy charge in avocado fruit tissue. *Journal of the American Society for Horticultural Science* 122(2):253-257.

Changes in cytosolic and vacuolar pH, ATP, ADP, and the ATP : ADP ratio were measured in whole fruit or mesocarp disks of avocado [*Persea americana* (Mill.) cv, Hass] during brief exposures to elevated CO₂. Intact climacteric fruit exposed to air (21% O₂), 20% CO₂ (17% O₂, balance N₂), or 40% CO₂ (13% O₂, balance N₂) had cytosolic pH values of 7.0, 6.6, and 6.4, respectively, while mesocarp disks had cytosolic pH values of 6.9, 6.7, and 6.4, respectively. The beta-ATP levels of intact climacteric fruit exposed to 20% CO₂ or 40% CO₂ for 2 h were reduced by 25% or 43%, respectively, relative to air-exposed fruit. HPLC analysis of nucleotide phosphates from preclimacteric

avocados revealed that ATP levels and the ATP : ADP ratio increased in 40% compared to the air-stored fruit. However, 1 day after transfer to air, the effects of elevated CO₂ had dissipated. These modifications in cellular state could alter the activity of respiratory enzymes in fruit exposed to elevated CO₂ atmospheres.

Lange, O.L., T.G.A. Green, H. Reichenberger, and A. Meyer. 1996. Photosynthetic depression at high thallus water contents in lichens: Concurrent use of gas exchange and fluorescence techniques with a cyanobacterial and a green algal Peltigera species. *Botanica Acta* 109(1):43-50.

Lichens, being poikilohydric, have varying thallus water contents (WC) and show a complex interaction between net photosynthesis (NP) and WC. NP can be depressed at low WC (desiccation effects) and, in some species, also at high WC. In the latter case the depression is normally ascribed to increased CO₂ diffusion resistances through water blockage. Recently, an earlier explanation, that the depression at high WC is due to recycling of CO₂ from increased dark respiration processes (DR), has been given renewed prominence. The two explanations were distinguished by the concurrent use of gas exchange and chlorophyll fluorescence techniques to investigate NP:WC relationships in the lichens Peltigero leucophlebia (green algal) and P. neckeri (cyanobacterial). Both species had a distinct optimal WC for NP with depressed values at low and high WC. The maximal quantum yield for both CO₂ fixation (initial slope of light response curves of NP) and photosystem II (fluorescence signals of dark-adapted thalli) was depressed only at low WC and remained high at optimal and greater WC. In contrast, the relative electron transport rate (ETR, derived from fluorescence signals of thalli in the light) tracked NP and was depressed at low and high WC. The depression of both NP and ETR at high WC (not that at low WC) could be prevented by using elevated external CO₂ concentrations. A single, linear relationship was found between all values of gross photosynthesis (NP + DR) and ETR regardless of external CO₂ concentration or WC. Our results show that, for these lichens, the depression in NP at high WC is a real fall in photosynthetic rate of the photobionts and is not due to recycling of CO₂. The removal of the depression in NP and ETR at high WC by using elevated external CO₂ levels allows us to conclude that an additional CO₂ diffusion resistance is present.

Lange, O.L., S.C. Hahn, G. Muller, A. Meyer, and J.D. Tenhunen. 1996. Upland tundra in the foothills of the Brooks Range, Alaska: Influence of light, water content and temperature on CO₂ exchange of characteristic lichen species. *Flora* 191(1):67-83.

In a previous publication we described diel courses of CO₂ exchange and microclimate conditions for characteristic Lichens in their natural habitat within upland tundra communities of northern Alaska. The influence of individual environmental factors on net photosynthesis (NP) of Cetraria cucullata, Dactylina arctica, Masonhalea richardsonii, Peltigera aphthosa, Peltigera malacea, Stereocaulon alpinum, and Thamnolia vermicularis was analyzed in the present study. CO₂ exchange measurements were conducted in the laboratory, and clear response characteristics with respect to light, water content (WC), temperature, and external CO₂ concentration were established under controlled conditions. In addition, dependencies of NP on these factors were extracted from field data. These measurements show a high scatter

in data points, however, they represent the range of actual performance of the lichens under natural conditions. In general both, field and laboratory data sets, agree well with respect to absolute rates of photosynthetic capacity as well as response characteristics. The combined information from both sources enable us to identify and describe those physiological features which are relevant for photosynthetic production of the lichens at this tundra site. There were large differences in maximal rates of NP attained under natural ambient CO₂ which were expressed more strongly under conditions of CO₂ saturation. Photosynthetic capacity of the cyanobacterial P. malacea is ten times higher than that of the green algal M. richardsonii. In the field, actual photosynthesis often seemed to be depressed due to photoinhibition. Photosynthetic carbon gain occurred even with thallus temperatures of -10 degrees C, while the temperature optimum of NP was between 11 and 22 degrees C. Most of the species responded to supra-optimal degrees of WC with a pronounced depression in NP. Elevated ambient CO₂ concentration prevented this decrease in NP, indicating that it was caused by increased resistance of the thallus to CO₂ diffusion. Depression of NP at high thallus WC regularly occurred under natural conditions, impairing primary production. Response characteristic of the lichens to experimental increase in ambient CO₂ is highly dependent on thallus hydration. At optimal WC some species are already saturated by natural ambient CO₂ at least at lower light intensities. Possible future increase in natural ambient CO₂ concentration will impact lichen NP in particular when the thalli are highly water saturated.

Laporte, M.M., J.A. Galagan, J.A. Shapiro, M.R. Boersig, C.K. Shewmaker, and T.D. Sharkey. 1997. Sucrose-phosphate synthase activity and yield analysis of tomato plants transformed with maize sucrose-phosphate synthase. *Planta* 203(2):253-259.

Sucrose synthesis is a major element of the interactions between photosynthesis and plant growth and development. Tomato (*Lycopersicon esculentum* Mill. cv. UC82B) plants transformed with maize sucrose-phosphate synthase (SPS; EC 2.3.1.14) expressed from either a ribulose-1,5-bisphosphate carboxylase- oxygenase (Rubisco) small subunit promoter (SSU) or the cauliflower mosaic virus 35S promoter (35S) were used to study effects of increased sucrose synthesis rates on plant growth. The plants were grown in growth chambers, field plots, and open-top chambers. The 35S plants had a 2 to 3-fold increase in young-leaf SPS activity, a 10 to 20-fold increase in young-root SPS activity and no increase in young-fruit SPS activity. The leaf SPS activity in one of the 35S lines fell to control levels by two months of age. The SSU plants had a 4 to 5-fold increase in leaf SPS activity and no significant increase in root or young-fruit SPS activity. One 35S line, which maintained high leaf SPS activity throughout development, yielded 70-80% more than controls at both normal and elevated CO₂ in open-top chambers in the field and 20-30% more than controls in two additional field trials. The other 35S line and the two SSU lines either yielded less or did not differ from controls under several growth conditions. Since only one of four transformed lines showed an increase in yield, we can not yet conclude that increased leaf SPS activity leads to increased yield. However, increased leaf SPS activity appears to result in increased fruit sugar content since all three lines with increased leaf SPS usually also had increased fruit sugars.

Larigauderie, A., J.F. Reynolds, and B.R. Strain. 1994. Root response to CO₂ enrichment and nitrogen supply in loblolly-pine. *Plant and Soil* 165(1):21-32.

This paper examines how elevated CO₂ and nitrogen (N) supply affect plant characteristics of loblolly pine (*Pinus taeda* L.) with an emphasis on root morphology. Seedlings were grown in greenhouses from seeds during one growing season at two atmospheric CO₂ concentrations (375 and 710 μ mol L⁻¹) and two N levels (High and Low). Root morphological characteristics were determined using a scanner and an image analysis program on a Macintosh computer. In the high N treatment, elevated CO₂ increased total plant dry weight by 80% and did not modify root to shoot (R/S) dry weight ratio, and leaf and plant N concentration at the end of the growing season. In the low N treatment, elevated CO₂ increased total dry weight by 60%. Plant and leaf N concentration declined and R/S ratio tended to increase. Nitrogen uptake rate on both a root length and a root dry weight basis was greater at elevated CO₂ in the high N treatment and lower in the low N treatment. We argue that N stress resulting from short exposures to nutrients might help explain the lower N concentrations observed at high CO₂ in other experiments; Nitrogen and CO₂ levels modified root morphology. High N increased the number of secondary lateral roots per length of first order lateral root and high CO₂ increased the length of secondary lateral roots per length of first order lateral root. Number and length of first order lateral roots were not modified by either treatment. Specific root length of main axis, and to a lower degree, of first order laterals, declined at high CO₂, especially at high N. Basal stem diameter and first order root diameters increased at high CO₂, especially at high N. Elevated CO₂ increased the proportion of upper lateral roots within the root system.

Larsen, M., and C.B. Watkins. 1995. Firmness and concentrations of acetaldehyde, ethyl-acetate and ethanol in strawberries stored in controlled and modified atmospheres. *Postharvest Biology and Technology* 5(1-2):39-50.

'Pajaro' strawberries (*Fragaria x ananassa* Duch.) were stored at 0 degrees C in a range of controlled atmosphere (CA) conditions with CO₂ concentrations up to 24%, O₂ concentrations down to 1%, or a combination of 10% CO₂ and 2% O₂. Elevated CO₂ concentrations resulted in firmer fruit, while low O₂ did not affect texture. Off-flavours developed after 3 days of storage at 20% CO₂, but decreased when fruit was subsequently held for 24 h at 20 degrees C. However, off-flavours were persistent after CA storage for 7 days or more. Off-flavours were related to increases in ethyl acetate and ethanol concentrations but not to acetaldehyde. Beneficial atmospheres of close to 10% CO₂ and 2% O₂ resulted in a firmer texture and delayed ripening with no off-flavour development. However, fruit quality was poor when similar atmospheres were developed in modified atmosphere (MA)-producing polythene bags. Rapid imposition of CA resulted in better quality fruit than when MAs around the fruit were developed gradually.

Larson, D.L. 1994. Potential effects of anthropogenic greenhouse gases on avian habitats and populations in the northern great-plains. *American Midland Naturalist* 131(2):330-346.

Biotic response to the buildup of greenhouse gases in Earth's atmosphere

is considerably more complex than an adjustment to changing temperature and precipitation. The fertilization effect CO₂ has on some plants, the impact UVB radiation has on health and productivity of organisms, and the resulting changes in competitive balance and trophic structure must also be considered. The intent of this paper is to review direct and indirect effects of anthropogenic greenhouse gases on wildlife, and to explore possible effects on populations of birds and their habitats in the northern Great Plains. Many of the potential effects of increasing greenhouse gases, such as declining plant nutritional value, changes in timing of insect emergence, and fewer and saltier wetlands, foreshadow a decline in avian populations on the Great Plains. However, other possible effects such as increased drought resistance and water use efficiency of vegetation, longer growing seasons, and greater overall plant biomass promise at least some mitigation. Effects of multiple simultaneous perturbations such as can be expected under doubled CO₂ scenarios will require substantial basic research to clarify.

Lasceve, G., H. Gautier, J. Jappe, and A. Vavasseur. 1993. Modulation of the blue-light response of stomata of *Commelina communis* by CO₂. *Physiologia Plantarum* 88(3):453-459.

Effects of CO₂ on stomatal movements of *Commelina communis* L. were studied with plants, epidermal strips and guard cell protoplasts. With plants, the stomatal response induced by a blue light pulse was studied for different ambient CO₂ concentration ranging from CO₂-deprived air to 100 Pa in darkness or under red light. It was observed that the blue light response could be obtained not only under a red light background but also in darkness and CO₂-free air, the two responses being quite similar. With epidermal strips, the effect of CO₂ on ferricyanide reductase activity at the guard cell plasmalemma was studied by transmission electron microscopy. In the presence of ferric ions, reduced ferricyanide gives an electron dense precipitate of Prussian Blue. In darkness and air, no precipitate was observed. In darkness and CO₂-free air as well as under light and normal air, a precipitate was found along the plasmalemma of the guard cells, indicating a ferricyanide reductase activity. With guard cell protoplasts suspended in a medium either in equilibrium with air or in a CO₂-free medium the H⁺ extrusion induced by a blue light pulse added to a red light background was measured. A low CO₂ content was obtained by adding photosynthetic algae to the suspension of guard cell protoplasts. In a CO₂-free medium the rate of H⁺ extrusion was enhanced. The results are discussed on the basis of a possible competition for reducing power between CO₂ fixation and a putative blue light dependent redox chain located on the plasma membrane.

Lashof, D.A., B.J. DeAngelo, S.R. Saleska, and J. Harte. 1997. Terrestrial ecosystem feedbacks to global climate change. *Annual Review of Energy and the Environment* 22:75-118.

Anthropogenic greenhouse gases are expected to induce changes in global climate that can alter ecosystems in ways that, in turn, may further affect climate. Such climate-ecosystem interactions can generate either positive or negative feedbacks to the climate system, thereby

either enhancing or diminishing the magnitude of global climate change. Important terrestrial feedback mechanisms include CO₂ fertilization (negative feedbacks), carbon storage in vegetation and soils (positive and negative feedbacks), vegetation albedo (positive feedbacks), and peatland methane emissions (positive and negative feedbacks). While the processes involved are complex, not readily quantifiable, and demonstrate both positive and negative feedback potential, we conclude that the combined effect of the feedback mechanisms reviewed here will likely amplify climate change relative to current projections that have not yet adequately incorporated these mechanisms.

Lau, O.L. 1998. Effect of growing season, harvest maturity, waxing, low O₂ and elevated CO₂ on flesh browning disorders in 'Braeburn' apples. *Postharvest Biology and Technology* 14(2):131-141.

British Columbia-grown 'Braeburn' apples (*Malus x domestica* Borkh.) stored for 6 months in air at 0 degrees C were, on average, 70 N in flesh firmness and had 0.48% titratable acidity. Fruit held in 1.2 or 1.5% O₂ + 1.0 or 1.2% CO₂ controlled atmosphere (CA) storage were 8 N firmer, 20% higher in titratable acidity, and had significantly less core browning and superficial scald than fruit held in air for the same period. However, CA-stored fruit were highly susceptible to Braeburn browning disorder (BBD) and internal cavities (IC) after cool growing seasons [1993, 1995, and 1996; < 1300 degree-days > 10 degrees C (DD10) accumulated between May 1 and harvest]. Susceptibility of fruit to BBD and IC was greatest in late-harvested fruit (starch index > 2.5 on a 0-9 scale) stored in 3.0% CO₂ and 1.5% O₂. Storage at 1.7, 2.0, 3.0 and 4.0 degrees C did not decrease BBD or IC incidence and tended to increase core browning (1996) and flesh softening (1994 and 1996) compared with fruit kept at 0 degrees C. Coating fruit with Shellac wax, but not Carnauba wax, increased BBD in air-stored fruit. Following a cool growing season it is recommended that 'Braeburn' apples be harvested at starch index values between 2.5 and 3.0 and stored in air storage at 0 degrees C to avoid the risks of scald, BBD and IC. The fruit may be stored in <1.0% CO₂ (preferably close to 0.1%) and > 1.5% O₂ after warm seasons (>1300 DD10). (C) 1998 Elsevier Science B.V. All rights reserved.

Lauber, W., and C. Korner. 1997. In situ stomatal responses to long-term CO₂ enrichment in calcareous grassland plants. *Acta Oecologica-International Journal of Ecology* 18(3):221-229.

A calcareous grassland community growing under full season CO₂ enrichment at low altitude in the Swiss Jura mountains was investigated for diurnal and seasonal variations of leaf diffusive conductance. A new CO₂ enrichment method (Screen aided CO₂ control, SACC) permitted in situ leaf porometry under natural climatic conditions without disturbance of plants. At 600 ppm CO₂, leaf conductance in the dominant species, *Bromus erectus* (a species so far not showing a growth response to elevated CO₂) was reduced to half the values measured in controls. In contrast, leaf conductance in *Carex flacca*, a species of low cover (the only species so far exhibiting a dramatic growth stimulation by CO₂ fertilization) remained almost unaffected by elevated CO₂. *Sanguisorba minor*, *Plantago media*, and *Cirsium acaule* showed

intermediate responses. *Trifolium montanum*, studied only on a single day, showed a reduction like *Bromus*. Differences between treatments were largest under humid conditions and disappeared during dry periods. In none of the species studied did stomatal density or stomatal index differ between treatments. A parallel investigation of whole ecosystem evapotranspiration indicated only small (< 10%) and non significant CO₂ responses, suggesting that both aerodynamic effects at the canopy level and a great interspecific variation of leaf level responses overshadow the clear CO₂ response of *Bromus* stomata. The different stomatal responses to CO₂ enrichment are likely to alter species specific water consumption, and may thus affect community structure in the long run.

Laurila, H.A. 1995. Modelling the effects of elevated CO₂ and temperature on Swedish and German spring wheat varieties with CERES-wheat and AFRC-wheat crop models. *Journal of Biogeography* 22(4-5):591-595.

A study validating the CERES-wheat and the AFRC-wheat crop models was performed on Swedish (cv. Polkka) and German (cv. Nandu) spring wheat (*Triticum aestivum* L.) varieties under northern long day conditions. Validation consisted of the calibration of the phenological submodels in both crop models for Finnish conditions. Calibration results were used in simulating the effects of elevated CO₂ and temperature on the yields and biomass production and the phenological development of the Swedish and the German varieties. The Swedish variety is currently commonly-cultivated in Finland. Based on the validation work, the CERES-wheat and the AFRC-wheat models will be used in the climate change Geographical Information System (GIS) for Finnish national scale crop potential estimations: different climate change scenarios for cereals will simulate the future Finnish growing conditions currently prevailing in Denmark and northern Germany.

Lavelle, P., D. Bignell, M. Lepage, V. Wolters, P. Roger, P. Ineson, O.W. Heal, and S. Dhillon. 1997. Soil function in a changing world: the role of invertebrate ecosystem engineers. *European Journal of Soil Biology* 33(4):159-193.

In this review the interactions between plant, animal and microbial components of the soil biota are represented by a model which allocates a pivotal functional role to the large, abundant invertebrates which ingest or manipulate both organic and mineral material, forming long-lasting microstructures. These invertebrates are designated soil ecosystem engineers and it is argued using data on numerical and biomass densities, geographical distribution and known functional roles, that earthworms and termites are the most important engineers in terrestrial ecosystems. Evidence is presented that they may exert influence on the diversity and activity of biota in subordinate trophic levels, for example litter transformers, micropredators and microfloras mediating fundamental nutrient transformations. Links between the activity and diversity of engineers and the physical properties of soils, including structural heterogeneity, stability, distribution of organic matter and infiltration and retention of water are also described. In considering the probable effects of global change on engineers, it is hypothesized that living plants affect both the abundance and diversity of engineers, through the quantity and quality of litter and other effects. Changes in their communities will therefore affect engineers. Expected changes in

temperature will expand the latitudinal distribution of termites and favour humivorous termites and endogeic earthworm species that feed in the soil. In some regions, however, these changes will not occur since local fauna may not include representatives of these groups. Although elevated CO₂ may impact engineers through effects on plant growth (notably an increase in C/N ratio), land use intensification, particularly physical disturbance of forests, is of more immediate concern as changes in the functional group balance within engineers communities can be demonstrated. In addition, exotic species of earthworms may colonize disturbed land, with adverse effects on soil structure. Disturbance affects termites by reducing diversity (especially of soil-feeding forms) and some species may reach crop pest status, owing to changes in the availability of organic matter.

Lavigne, C., A. Mignot, and J. Stocklin. 1999. Genetic variation in the response of pollen germination to nutrient availability and elevated atmospheric CO₂ concentrations in *Epilobium angustifolium*. *International Journal of Plant Science* 160(1):109-115.

It is expected that global climatic changes could lead to shifts in the genotypic composition of species that exhibit genetic variation in the response of fitness-related traits to an increase of atmospheric CO₂. In plants that reproduce sexually, fitness can be described both by a female and a male component. Whereas the existence of genetic variation in the response to elevated CO₂ of traits related to female fitness has been the focus of recent studies, studies on the response of the male component of fitness are still missing. Here, we report on the effects of elevated atmospheric CO₂ and nutrient availability on the pollen quality of five full-sib families of *Epilobium angustifolium*. We did not detect an effect of the treatments on the in vitro pollen tube growth. However, we observed significant variation among families for pollen germination probabilities and a significant family x CO₂ x nutrient interaction on this trait. This indicates that, in combination with nutrients increased CO₂ could exert a selection pressure resulting in changes in the genetic structure of populations and in their mean response to CO₂. It seems important that this evolution is included in models simulating the consequences of climate change on plant communities.

Lavigne, M.B. 1996. Comparing stem respiration and growth of jack pine provenances from northern and southern locations. *Tree Physiology* 16(10):847-852.

Stem respiration rates of 31-year-old jack pine (*Pinus banksiana* Lamb.) trees from northern and southern provenances growing in a common garden were compared. At 15 degrees C, the seasonal course of stem respiration rate of northern provenances was not statistically different from that of southern provenances. A relationship existed between maintenance respiration rate and stem growth rate. Because relationships between sapwood relative growth rate and annual growth and maintenance respiration rates were similar for northern and southern provenances, no clinal differences in stem respiration rates were

observed.

Lavola, A., and R. Julkunentiitto. 1994. The effect of elevated carbon-dioxide and fertilization on primary and secondary metabolites in birch, *Betula-pendula* (roth). *Oecologia* 99(3-4):315-321.

Seedlings of European white birch (*Betula pendula* Roth) were grown in growth chambers for one growth season under four carbon dioxide regimes (350, 700, 1050 and 1400 ppm) and at three fertilization levels (0, 100 and 500 kg ha⁻¹ monthly). The soluble carbohydrates and secondary phenolics in the leaves and stems were analysed. It was found that fertilizer addition reduced the amounts of glucose and fructose while sucrose remained almost unaffected. The sugar content of leaves increased at 700 ppm and 1050 ppm of CO₂ and decreased at the highest CO₂ concentration (1400 ppm). The amounts of proanthocyanidins and flavonoids in leaves decreased with fertilization addition and increased with CO₂ enrichment. The production of simple phenolic glucosides varied according to the fertilization and CO₂ treatments. The triterpenoid content of stems seemed to increase with fertilization and CO₂ addition. Our results indicate that the production of phytochemicals in the birch seedlings is very sensitive to both fertilization and CO₂ addition, which is in agreement with earlier studies, and thus provide some support for the hypothesis of carbon allocation to plant defence when there is an excess of carbon and nutrient. The considerable variation in the production of secondary components may indicate that the synthesis of these defensive metabolites can be regulated by a plant to certain extent, depending on the ability of the plant to acclimate to changes in the physical environment.

Lawler, I.R., W.J. Foley, I.E. Woodrow, and S.J. Cork. 1997. The effects of elevated CO₂ atmospheres on the nutritional quality of Eucalyptus foliage and its interaction with soil nutrient and light availability. *Oecologia* 109(1):59-68.

Seedlings of *Eucalyptus tereticornis* (Smith) were grown under two levels of availability each of CO₂ (352 and 793 µmol mol⁻¹), soil nutrients (1/24 and 1/4 Hoagland's solution) and light (full and 30% sunlight). Low soil nutrient availability or high light increased the C:N ratio of leaves, leading to lower leaf nitrogen concentrations, higher leaf specific weights and higher levels of both total phenolics and condensed tannins. These results were consistent with other studies of the effect of environmental resource availability on foliage composition. Similar results were observed when the C:N ratio of leaves was increased under elevated CO₂. The changes in leaf chemistry induced by the treatments affected the performance of 4th-instar larvae of *Chrysophtharta flaveola* (Chapuis) fed on the leaves. Increased C:N ratios of leaves reduced digestive efficiencies and pupal body sizes and increased mortality. Below a threshold nitrogen concentration of approximately 1% dry mass, severe reductions in the performance of larvae were recorded. Such changes may have significant consequences for herbivores of *Eucalyptus*, particularly in view of projected increases in atmospheric CO₂.

Lawlor, D.W., and R.A.C. Mitchell. 1991. The effects of increasing CO₂ on crop photosynthesis and productivity - a review of field studies. *Plant, Cell and Environment* 14(8):807-818.

Only a small proportion of elevated CO₂ studies on crops have taken place in the field. They generally confirm results obtained in controlled environments: CO₂ increases photosynthesis, dry matter production and yield, substantially in C₃ species, but less in C₄, it decreases stomatal conductance and transpiration in C₃ and C₄ species and greatly improves water-use efficiency in all plants. The increased productivity of crops with CO₂ enrichment is also related to the greater leaf area produced. Stimulation of yield is due more to an increase in the number of yield-forming structures than in their size. There is little evidence of a consistent effect of CO₂ on partitioning of dry matter between organs or on their chemical composition, except for tubers. Work has concentrated on a few crops (largely soybean) and more is needed on crops for which there are few data (e.g. rice). Field studies on the effects of elevated CO₂ in combination with temperature, water and nutrition are essential; they should be related to the development and improvement of mechanistic crop models, and designed to test their predictions.

Lawlor, D.W., R.A.C. Mitchell, J. Franklin, V.J. Mitchell, S.P. Driscoll, and E. Delgado. 1993. Facility for studying the effects of elevated carbon-dioxide concentration and increased temperature on crops. *Plant, Cell and Environment* 16(5):603-608.

The requirements for the experimental study of the effects of global climate change conditions on plants are outlined. A semi-controlled plant growth facility is described which allows the study of elevated CO₂ and temperature, and their interaction on the growth of plants under radiation and temperature conditions similar to the field. During an experiment on winter wheat (cv. Mercia), which ran from December 1990 through to August 1991, the facility maintained mean daytime CO₂ concentrations of 363 and 692 cm³ m⁻³ for targets of 350 and 700 cm³ m⁻³ respectively. Temperatures were set to follow outside ambient or outside ambient +4-degrees-C, and hourly means were within 0.5-degrees-C of the target for 92% of the time for target temperatures greater than 6-degrees-C. Total photosynthetically active radiation incident on the crop (solar radiation supplemented by artificial light with natural photoperiod) was 2% greater than the total measured outside over the same period.

The ecotron - a controlled environmental facility for the investigation of population and ecosystem processes. *Philosophical Transactions of the Royal Society of London*

Series B-Biological Sciences 341(1296):181-194.

This paper reports on aspects of the design and philosophy of the Ecotron, an integrated series of 16 controlled environmental chambers at the NERC Centre for Population Biology. The Ecotron serves as an experimental means for analysing population and community dynamics and ecosystem processes under controlled physical conditions. Within the chambers, terrestrial experimental communities are assembled into foodwebs of desired complexity from a pool of species selected for their preadaptations to the physical conditions of the Ecotron. These species include decomposers (earthworms, snails, microarthropods and microbes), primary producers (16 species of plants), primary consumers (four species of herbivorous arthropods), and secondary consumers (four species of parasitoids). The design of the Ecotron is unique in several aspects with respect to its blend of biology and technology. It supports small, dynamic communities of up to 30 plant and metazoan species, thereby making it among the more biologically complex controlled environmental systems currently in use. Its architecture permits replication and variation of spatial scale in experimental design. Its artificial climate simulates natural environmental conditions within chambers allowing experimental control over light, water, temperature, humidity, and in the near future CO₂ and uv-B radiation. Sensors monitor both macro- and micro-environmental conditions of a number of physical factors within the chambers. Preliminary experiments show the Ecotron to be an excellent facility for long-term population and community-level experiments. We discuss the results of one of these early experiments and briefly consider ongoing and future experiments.

Leadley, P.W., and B.G. Drake. 1993. Open top chambers for exposing plant canopies to elevated CO₂ concentration and for measuring net gas-exchange. *Vegetatio* 104:3-15.

Open top chamber design and function are reviewed. All of the chambers described maintain CO₂ concentrations measured at a central location within +/- 30 ppm of a desired target when averaged over the growing season, but the spatial and temporal range within any chamber may be closer to 100 ppm. Compared with unchambered companion plots, open top chambers modify the microenvironment in the following ways: temperatures are increased up to 3-degrees-C depending on the chamber design and location of the measurement; light intensity is typically diminished by as much as 20%; wind velocity is lower and constant; and relative humidity is higher. The chamber environment may significantly alter plant growth when compared with unchambered controls, but the chamber effect on growth has not been clearly attributed to a single or even a few environmental factors. A method for modifying an open top chamber for tracking gas exchange between natural vegetation and the ambient air is described. This modification consists of the addition of a top with exit chimney to reduce dilution of chamber CO₂ by external ambient air, is quickly made and permits estimation of the effects of elevated CO₂ and water vapor exchange. The relatively simple design and construction of open top chambers make them the most likely method to be used in the near future for long-term elevated CO₂ exposure of small trees, crops and grassland ecosystems. Improvements in the basic geometry to improve control of temperature, reduce the variation of CO₂ concentrations, and increase the turbulence and wind speed in the canopy boundary layer are desirable objectives. Similarly, modifications for measuring water vapor and carbon dioxide gas exchange will extend the usefulness of open top chambers to include non-destructive monitoring of the responses of ecosystems to rising atmospheric CO₂.

Leadley, P.W., P. Niklaus, R. Stocker, and C. Korner. 1997. Screen-aided CO₂ control (SACC): a middle ground between FACE and open-top chambers. *Acta Oecologica-International Journal of Ecology* 18(3):207-219.

We have developed a novel CO₂ exposure system for natural vegetation that is a middle ground between Free Air CO₂ Enrichment (FACE) and traditional open-top chambers (OTC). Screen-Aided CO₂ Control (SACC) technology uses much less CO₂ per experiment and per replicate than FACE and is superior to OTCs in terms of its effects on microclimate. A SACC unit consists of a thin metal frame, a clear plastic "screen", and a pipe at the base of the screen through which CO₂ enriched jets of air are directed into the unit. There is a gap between the ground and the bottom of the pipe and the screen is relatively short in comparison to the maximum height of the vegetation. Our SACC units are hexagonal and enclose a ground area of 1.27 m². SACC works in the following way: 1) the screen breaks the wind and creates turbulent mixing within the unit, 2) the mixing of the outside air with the CO₂ enriched jets of air, generates relatively uniform CO₂ concentrations within the screened-in vegetation, and 3) a fully automated system monitors CO₂ concentrations and adjusts CO₂ injection rates for each unit every ca. 10 minutes to maintain preset CO₂ concentrations. Twenty-four hour means of CO₂ concentrations in the middle of a unit are typically maintained within 1 μl(-1) of their set points. Spatial variation and short-term fluctuations in CO₂ concentration are similar to those in OTCs and FACE. CO₂ consumption at our site is 5 kg CO₂ day(-1) replicate(-1) for a total of ca. 30 tons per year for 20 elevated CO₂ SACC units. Compared to OTCs, SACC units have reduced temperature peaks at full sunlight, minimal effects on solar radiation, reduced rainfall interception by chamber walls, and freer access of small animals to experimental plots. We believe that SACC is the best method for exposing short stature vegetation to elevated CO₂ when financial constraints do not allow for a properly replicated FACE experiment.

Leadley, P.W., P.A. Niklaus, R. Stocker, and C. Korner. 1999. A field study of the effects of elevated CO₂ on plant biomass and community structure in a calcareous grassland. *Oecologia* 118(1):39-49.

The effects of elevated CO₂ on plant biomass and community structure have been studied for four seasons in a calcareous grassland in northwest Switzerland. This highly diverse, semi-natural plant community is dominated by the perennial grass *Bromus erectus* and is mown twice a year to maintain species composition. Plots of 1.3 m² were exposed to ambient or elevated CO₂ concentrations (n = 8) using a novel CO₂ exposure technique, screen-aided CO₂ control (SACC) starting in March 1994. In the 1st year of treatment, the annual harvested biomass (sum of aboveground biomass from mowings in June and October) was not significantly affected by elevated CO₂. However, biomass increased significantly at elevated CO₂ in the 2nd (+20%, P = 0.05), 3rd (+21%, P = 0.02) and 4th years (+29%, P = 0.02). There were no detectable differences in root biomass in the top 8 cm of soil between CO₂ treatments on eight out of nine sampling dates. There were significant differences in CO₂ responsiveness between functional groups (legumes, non-leguminous forbs, graminoids) in the 2nd (P = 0.07) and 3rd (P < 0.001) years of the study. The order of CO₂ responsiveness among functional groups changed substantially from the 2nd to the 3rd year; for example, non-leguminous forbs had the smallest relative response in the

2nd year and the largest in the 3rd year. By the 3rd year of CO₂ exposure, large species-specific differences in CO₂ response had developed. For five important species or genera the order of responsiveness was *Lotus corniculatus* (+271%), *Carex flacca* (+249%), *Bromus erectus* (+33%), *Sanguisorba minor* (no significant CO₂ effect), and six *Trifolium* species (a negative response that was not significant). The positive CO₂ responses in *Bromus* and *Carex* were most closely related to increases in tiller number. Species richness was not affected by CO₂ treatment, but species evenness increased under elevated CO₂ (modified Hill ratio; P = 0.03) in June of the 3rd year, resulting in a marginally significant increase in species diversity (Simpson's index; P = 0.09). This and other experiments with calcareous grassland plants show that elevated atmospheric CO₂ concentrations can substantially alter the structure of calcareous grassland communities and may increase plant community biomass.

Leadley, P.W., and J.F. Reynolds. 1992. Long-term response of an arctic sedge to climate change - a simulation study. *Ecological Applications* 2(4):323-340.

It appears that polar regions of the Earth will bear the brunt of global temperature increases. Because of the ecological importance of the sedge *Eriophorum vaginatum* in the arctic and the large amount of data available on its growth and physiology, we chose this species as a test case to model the potential long-term response of arctic plants to global climate change. Our simulation model utilizes a mechanistic framework and includes the effects of light, temperature, season length, nitrogen availability, and CO₂ concentration on *E. vaginatum* growth dynamics. The model was parameterized based on a series of published studies of the growth responses of *E. vaginatum* to nutrients and validated using (1) field studies on the growth responses of *E. vaginatum* to temperature and shading, and (2) the effects of elevated CO₂ and temperature on *E. vaginatum* photosynthesis. The effect of a 50-yr period of climate change on peak biomass (overwintering biomass plus seasonal production) in *E. vaginatum* was explored. We use climate change here to refer to linear increases over a 50-yr period in temperature (from 8-degrees to 13-degrees-C), season length (from 100 to 120 d), and atmospheric CO₂ (from 340 to 680 μL/L). Similarly, a wide range of nitrogen availabilities (from 9 to 18 g.m⁻².yr⁻¹) was also examined because of its importance in productivity. The model predicts that a simultaneous increase in the direct effects of temperature, season length, and CO₂, with no change in nitrogen availability, will result in a slight decrease in peak biomass. A simulated long-term doubling of nitrogen availability results in an almost-equal-to 70% increase in peak biomass, whereas with concurrent changes in climate and nitrogen availability, the model predicts a slight decline in peak biomass compared to increases in nitrogen alone. In essence, the model predicts that climate change will have substantial effects on *E. vaginatum* only indirectly through changes in nitrogen availability. Simulated peak biomass responds linearly up to a doubling of current nitrogen availabilities. Therefore, at low-to-moderate increases in nitrogen availability, the predicted response of *E. vaginatum* to climate change is linearly (and almost exclusively) dependent on our ability to predict the effects of climate change on nitrogen cycling. At nitrogen availabilities > 2 x current availabilities, the relationship flattens out very rapidly because the plant becomes limited by carbon uptake. Thus, if nitrogen availabilities more than double in the future, *E. vaginatum* may shift from being a nutrient-limited to a carbon-limited system and, consequently, increased season length and elevated CO₂ concentrations may play an important role in controlling *E. vaginatum* productivity.

Leadley, P.W., and J. Stocklin. 1996. Effects of elevated CO₂ on model calcareous grasslands: Community, species, and genotype level responses. *Global Change Biology* 2(4):389-397.

We investigated the responses of model calcareous grassland communities to three CO₂ concentrations: 330, 500, and 660 $\mu\text{mol L}^{-1}$. The communities were composed of six species, *Bromus erectus* Hudson, *Festuca ovina* L., *Prunella vulgaris* L., *Prunella grandiflora* (L.) Scholler, *Hieracium pilosella* L., and *Trifolium repens* L., that are native to the calcareous grasslands of Europe. Genotypic variation in CO₂ response was studied in *Bromus erectus* and *Festuca ovina*. Plants were harvested after c. 126 days of growth. We found that: 1 At the community level, there were marginally significant (0.1 greater than or equal to $P > 0.05$) increases in leaf and litter dry weight with increasing CO₂ concentration. 2 There were significant differences between species in CO₂ response, including both negative and positive responses. *Prunella vulgaris* had a significant negative response; *Hieracium pilosella* and *Festuca ovina* had significant positive responses; *Prunella grandiflora* had a marginally significant positive response; and *Bromus erectus* and *Trifolium repens* did not have significant responses. 3 There was significant variation among genotypes in the response to elevated CO₂ in *Bromus erectus*, but not in *Festuca ovina*. Based on the observed species- and genotype-level variation in CO₂ response of calcareous grassland plants in this and other studies, we speculate that increasing atmospheric CO₂ concentrations will alter community structure in calcareous grasslands.

Leavitt, S.W., E.A. Paul, A. Galadima, F.S. Nakayama, S.R. Danzer, H. Johnson, and B.A. Kimball. 1996. Carbon isotopes and carbon turnover in cotton and wheat FACE experiments. *Plant and Soil* 187(2):147-155.

The Maricopa cotton and wheat FACE (free-air CO₂ enrichment) experiments offer propitious opportunity to quantify carbon turnover. The commercial CO₂ ($\delta^{13}\text{C}$ approximate to -37 parts per thousand) used to elevate CO₂ concentration in field plots provided a strongly C-12-depleted tracer. Soil CO₂ and $\delta^{13}\text{C}$ of soil organic carbon (SOC) in CO₂-enriched and Control plots were measured between the final cotton FACE project (October 1991) and the end of the second wheat experiment (June 1994). The initial C-13-depletion in SOC of cotton FACE plots (measured by the difference in $\delta^{13}\text{C}$ between FACE and Control plots) persisted at the same level (1.9 parts per thousand) 1.5 years after the experiment ended. A similar depletion was observed in soil CO₂ evolved in the same plots, indicating ongoing decomposition of the new SOC. The SOC $\delta^{13}\text{C}$ of wheat plots before and after two growing seasons showed increasing C-13-depletion in FACE relative to Control. Isotopic mass balance was consistent with 5-6% new carbon input from the two wheat crops. This is lower than the 12-13% calculated for FACE cotton and perhaps a consequence of the larger root system of cotton or the 3-year duration of the cotton experiments versus 2 years for the wheat.

Leavitt, S.W., E.A. Paul, B.A. Kimball, G.R. Hendrey, J.R. Mauney, R. Rauschkolb, H. Rogers, K.F. Lewin, J. Nagy, P.J. Pinter, and H.B. Johnson. 1994. Carbon-isotope dynamics of free-air CO₂-enriched cotton and soils. *Agricultural and Forest Meteorology* 70(1-4):87-101.

A role for soils as global carbon sink or source under increasing atmospheric CO₂ concentrations has been speculative. Free-air carbon dioxide enrichment (FACE) experiments with cotton, conducted from 1989 to 1991 at the Maricopa Agricultural Center in Arizona, maintained circular plots at 550 $\mu\text{mol mol}^{-1}$ CO₂ with tank CO₂ while adjacent ambient control plots averaged about 370 $\mu\text{mol mol}^{-1}$ CO₂. This provided an exceptional test for entry of carbon into soils because the petrochemically derived tank CO₂ used to enrich the air above the FACE plots was depleted in both radiocarbon (C-14 content was 0% modern carbon (pmC)) and C-13 ($\delta^{13}\text{C}$ almost-equal-to -36 parts per thousand) relative to background air, thus serving as a potent isotopic tracer. Flask air samples, and plant and soil samples were collected in conjunction with the 1991 experiment. Most of the isotopic analyses on the plants were performed on the holo-cellulose component. Soil organic carbon was obtained by first removing carbonate with HCl, floating off plant fragments with a NaCl solution, and picking out remaining plant fragments under magnification. The $\delta^{13}\text{C}$ of the air above the FACE plots was approximately -15 to -19 parts per thousand, i.e. much more C-13 depleted than the background air of approximately -7.5 parts per thousand. The $\delta^{13}\text{C}$ values of plants and soils in the FACE plots were 10-12 parts per thousand and 2 parts per thousand C-13-depleted, respectively, compared with their control counterparts. The C-14 content of the FACE cotton plants was approximately 40 pmC lower than that of the control cotton, but the C-14 results from soils were conflicting and therefore not as revealing as the $\delta^{13}\text{C}$ of soils. Soil stable-carbon isotope patterns were consistent, and mass balance calculations indicate that about 10% of the present organic carbon content in the FACE soil derived from the 3 year FACE experiment. At a minimum, this is an important quantitative measure of carbon turnover, but the presence of C-13-depleted carbon, even in the recalcitrant 6 N HCl resistant soil organic fraction (average age 2200 years before present (BP)), suggests that at least some portion of this 10% is an actual increase in carbon accumulation. Similar isotopic studies on FACE experiments in different ecosystems could permit more definitive assessment of carbon turnover rates and perhaps provide insight into the extent to which soil organic matter can accommodate the 'missing' carbon in the global carbon cycle.

LeCain, D.R., and J.A. Morgan. 1998. Growth, gas exchange, leaf nitrogen and carbohydrate concentrations in NAD-ME and NADP-ME C-4 grasses grown in elevated CO₂. *Physiologia Plantarum* 102(2):297-306.

Plants with the C-4 photosynthetic pathway have predominantly one of three decarboxylation enzymes in their bundle sheath cells. Within the grass family (Poaceae) bundle sheath leakiness to CO₂ is purported to be lowest in the nicotinamide adenine dinucleotide phosphate-malic enzyme (NADP-ME, EC 1.1.1.40) group, highest in the NAD-ME (EC 1.1.1.39) group and intermediate in the phosphoenolpyruvate carboxykinase (PCK, EC 4.1.1.32) group. We investigated the hypothesis that growth and photosynthesis of NAD-ME C-4 grasses would respond more to elevated CO₂ treatment than NADP-ME grasses. Plants were grown in 8-l pots in growth chambers with ample water and fertilizer for 39 days at a continuous CO₂ concentration of either 350 or 700 $\mu\text{mol l}^{-1}$. NAD-ME species included *Bouteloua gracilis* Lag. ex Steud (Blue grama), *Buchloe dactyloides* (Nutt.) Engelm. (Buffalo grass) and *Panicum virgatum* L. (Switchgrass) and the NADP-ME species were *Andropogon gerardii* Vittman (Big bluestem), *Schizachyrium scoparium* (Michx.) Nash (Little bluestem), and *Sorghastrum nutans* (L.) Nash

(Indian grass). Contrary to our hypothesis, growth of the NADP-ME grasses was generally greater under elevated CO₂ (significant for *A. gerardii* and *S. mutans*), while none of the NAD-ME grasses had a significant growth response. Increased leaf total non-structural carbohydrate (TNC) was associated with greater growth responses of NADP-ME grasses. Decreased leaf nitrogen in NADP-ME species grown at elevated CO₂ was found to be an artifact of TNC dilution. Assimilation (A) vs intercellular CO₂ (C_i) curves revealed that leaf photosynthesis was not saturated at 350 $\mu\text{mol l}^{-1}$ CO₂ in any of these C-4 grasses. Assimilation of elevated CO₂-grown *A. gerardii* was higher than in plants grown in ambient CO₂. In contrast, *B. gracilis* grown in elevated CO₂ displayed lower A, a trait more commonly reported in C-3 plants. Photosynthetic acclimation in *B. gracilis* was not related to leaf TNC or nitrogen concentrations, but A:C_i curves suggest a reduction in activity of both phosphoenolpyruvate (PEP) carboxylase (EC 4.1.1.31) and ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco, EC 4.1.1.39). Some adaptation of stomatal functioning was also seen in *B. gracilis* and *A. gerardii* leaves grown in elevated CO₂. Our study shows that C-4 grasses have the capacity for increased growth and photosynthesis under elevated CO₂ even when water and nutrients are non-limiting. While it was the NADP-ME species which had significant responses in the present study, we have previously reported significant growth increases in elevated CO₂ for *B. gracilis*.

Ledergerber, S., P.W. Leadley, J. Stocklin, and B. Baur. 1998. Feeding behaviour of juvenile snails (*Helix pomatia*) to four plant species grown at elevated atmospheric CO₂. *Acta Oecologica-International Journal of Ecology* 19(1):89-95.

The feeding behaviour of juveniles of the land snail *Helix pomatia* was examined in model plant communities consisting of *Trifolium repens*, *Hieracium pilosella*, *Bromus erectus* and *Prunella vulgaris* that are common species in extensively managed calcareous grasslands in the Swiss Jura mountains. The plant communities were grown either at ambient (350 ppm) or elevated (600 ppm) CO₂ concentrations. Leaves of *T. repens* and *P. vulgaris* grown in elevated atmospheric CO₂ had a lower specific leaf area, and leaves of *T. repens* had lower percentage N on a dry weight basis than leaves grown under ambient CO₂ concentration. Snails fed on all four plant species, but showed a overwhelming preference for *T. repens* (percentages of total biomass consumed were 91.9 % at 350 ppm and 97.6 % at 600 ppm). The species-specific feeding intensity of juvenile *H. pomatia* did not differ between the two treatments. The total dry weight of *T. repens* consumed by the snails was marginally greater ($P = 0.06$) at elevated CO₂, but there were no significant differences in leaf N or leaf area eaten. These findings are similar to numerous other studies showing that invertebrates increase their consumption of plant material to balance reductions in plant N concentrations at elevated CO₂ treatments. *Helix pomatia* that fed on plants grown at elevated CO₂ atmosphere showed a larger increase in relative wet weight than those that fed on plants from ambient CO₂ conditions. However, the weight gain of *H. pomatia* was

poorly correlated with amount of plant tissue consumed, so we suggest that the effect of CO₂ on weight gain in *H. pomatia* was due to a change in the quality of *T. repens* leaves. (C) Elsevier, Paris.

Ledergerber, S., G.H. Thommen, and B. Baur. 1997. Grazing damage to plants and gastropod and grasshopper densities in a CO₂-enrichment experiment on calcareous grassland. *Acta Oecologica-International Journal of Ecology* 18(3):255-261.

Plant-herbivore interactions may change as atmospheric CO₂ concentrations continue to rise. We examined the effects of elevated atmospheric CO₂ and CO₂-exposure chambers on the grazing damage to plants, and on the abundances of potential herbivores (terrestrial gastropods and grasshoppers) in a calcareous grassland in the Jura mountains of Switzerland (village of Nenzlingen). Individuals of most plant species examined showed slight grazing damage. However, plots with CO₂ enrichment and plots with ambient atmosphere did not differ in the extent of grazing damage. Similarly, plots with CO₂ enrichment and plots with ambient atmosphere did not differ in either gastropod or grasshopper density. Experimental plots with and without chambers did not differ in the number of gastropods. However, the densities of gastropods and grasshoppers and extent of grazing damage to plants were generally lower in the experimental area than in the grassland outside the experimental field.

Lee, E.H., R.C. Pausch, R.A. Rowland, C.L. Mulchi, and B.F.T. Rudorff. 1997. Responses of field-grown soybean (cv. Essex) to elevated SO₂ under two atmospheric CO₂ concentrations. *Environmental and Experimental Botany* 37(2-3):85-93.

The objective of this research was to determine the effects of elevated concentrations of carbon dioxide (CO₂) and sulfur dioxide (SO₂) on field-grown soybean. Soybeans (*Glycine max* L. Merr. cv. 'Essex') were grown a full-season in open-top field chambers exposed to either ambient (350 $\mu\text{mol l}^{-1}$) or elevated CO₂ (500 $\mu\text{mol l}^{-1}$) levels under two levels of SO₂ (0.00 and 0.12 $\mu\text{mol l}^{-1}$). Enriched CO₂, with or without SO₂ treatments, significantly increased net photosynthesis rates, leaf area index (LAI; in R4 growth stage) and leaf dry weight, but did not significantly affect stomatal resistance, transpiration rates, leaf area, plant height, total biomass or grain yield. Elevated SO₂ treatments significantly decreased photosynthesis and LAI during pod fill stages, but did not significantly affect stomatal resistance, transpiration, total biomass, plant height or grain yield. Sulfur dioxide inhibited growth and development (i.e., LAI) during canopy coverage before any effects on photosynthesis were detected. The interactive effects of CO₂ and SO₂ treatments on the gas exchange parameters were significant during pod fill, where high SO₂ reduced photosynthesis at ambient CO₂ but not under elevated CO₂. Leaf area index values were likewise reduced by SO₂ exposure under ambient CO₂ during late flowering and pod fill stages. Thus, enriched CO₂ under high SO₂ exposure partially compensated for the negative impact of SO₂ stress on PS and LAI during the pod fill stages. (C) 1997 Elsevier Science B.V.

Lee, H.S.J., and P.G. Jarvis. 1995. Trees differ from crops and from each other in their responses to increases in CO₂ concentration. *Journal of Biogeography* 22(2-3):323-330.

Length of exposure, degree of maturity and type of tissue all affect the results obtained in response to elevated CO₂ treatment of trees. Seedlings are most responsive and, in many cases, the first few weeks or months of exposure may set the pattern for future growth. Measurements of leaf photosynthesis and respiration are not good predictors for incorporation of carbon into tissue. Seasonal changes in non-structural carbohydrates, emissions of isoprenes from leaves and exudation from roots can 'waste' photosynthate. However, these are difficult or impossible to quantify. Currently, the only generalization that can be made is that growth will be accelerated but the magnitude of this depends on tissue type, nutrition and environmental conditions. The implications of this for a future elevated atmospheric CO₂ world are complex. Interactions and competition between species should be incorporated into long-term studies. These studies must, themselves, be incorporated into appropriate models which take into account regional soils and climates for use in prediction of the effects of global climate change on trees and forests.

Lee, H.Y., W.S. Chow, and Y.N. Hong. 1999. Photoinactivation of photosystem II in leaves of *Capsicum annuum*. *Physiologia Plantarum* 105(2):377-384.

Leaf discs of *Capsicum annuum* L. were illuminated in air enriched with 1% CO₂ in the absence or presence of lincomycin, an inhibitor of chloroplast-encoded protein synthesis. The loss of functional photosystem (PS) II complexes with increase in cumulative light dose (photon exposure), assessed by the O₂ yield per single-turnover flash, was greater in leaves of plants grown in low light than those in high light; it was also exacerbated in the presence of lincomycin. A single exponential decay can describe the relationship between the loss of functional PSII and increase in cumulative photon exposure. From this relationship we obtained both the maximum quantum yield of photoinactivation of PSII at limiting photon exposures and the coefficient *k*, interpreted as the probability of photoinactivation of PSII per unit photon exposure. Parallel measurements of chlorophyll fluorescence after light treatment showed that 1/F_o--1/F_m was linearly correlated with the functionality of PSII, where F_o and F_m are the chlorophyll fluorescence yields corresponding to open and closed PSII reaction centers, respectively. Using 1/F_o--1/F_m as a convenient indicator of PSII functionality, it was found that PSII is present in excess; only after the loss of about 40% functional PSII complexes did PSII begin to limit photosynthetic capacity in capsicum leaves.

Lee, J.J., D.L. Phillips, and R.F. Dodson. 1996. Sensitivity of the US corn belt to climate change and elevated CO₂. Soil erosion and organic carbon. *Agricultural Systems* 52(4):503-521.

Climate models indicate that increasing atmospheric concentrations of carbon dioxide and other greenhouse gases could alter climate globally. The EPIC (Erosion/Productivity Impact Calculator) model was used to

examine the sensitivity of soil erosion (wind, water) and soil organic carbon (SOC) (15 cm and 1 m depth) across the US corn belt to changes in temperature (+2 degrees C), precipitation (+/-10%, +/-20%), wind speed (+/-10%, +/-20%), and atmospheric CO₂ concentration (350, 625 ppmv). One-hundred-year simulations were run for each of 100 sites under 36 climate/CO₂ regimes. The 100-year regionally aggregated mean water erosion rates increased linearly with precipitation, whereas the wind erosion rates decreased and total erosion rates increased by 15-18%. Total erosion increased with increased temperature. Increasing CO₂ from 350 to 625 ppmv (with temperature increased by 2 degrees C and mean wind speed held constant) had no effect on water erosion, despite increases in annual total and peak runoff; this was attributed to increased vegetation cover. Wind erosion decreased by 4-11% under increased CO₂. Wind erosion was very sensitive to mean wind speed, increasing four-fold and decreasing 10-fold for a 20% increase or decrease in mean wind speed, respectively. This was attributed to a threshold effect. SOC to 1 m decreased 4.8 Mg-C ha⁻¹ from an initial value of 18.1 Mg-C ha⁻¹ during the 100-year baseline simulation. About 50% of this loss (2.3 Mg-C ha⁻¹) was due to transport off-site by soil erosion. SOC in the top 15 cm decreased 0.8 Mg-C ha⁻¹ from an initial value of 4.9 Mg-C ha⁻¹. Increased temperature and precipitation accelerated these losses of SOC, whereas increased CO₂ slowed the losses. Copyright (C) 1996 Published by Elsevier Science Ltd

Lee, X.H., J.D. Fuentes, R.M. Staebler, and H.H. Neumann. 1999. Long-term observation of the atmospheric exchange of CO₂ with a temperate deciduous forest in southern Ontario, Canada. *Journal of Geophysical Research-Atmospheres* 104(D13):15975-15984.

This paper reports the results of the analysis of eddy covariance CO₂ data obtained at a successional forest of maple and aspen at Camp Borden in southern Ontario, Canada, between July 1995 and December 1997. Main findings are (1) The Michaelis-Menton model explains >50-65% of the observed variance of the daytime net ecosystem carbon exchange (NEE) during the growing season; leaf wetness appears to be an important variable contributing to the remaining variance. (2) The whole-ecosystem respiration rate as a function of the 5-cm soil temperature shows a seasonal "hysteresis" (higher rate in the later part of the year), suggesting a nonnegligible contribution by deep soil/roots and the influence of litter age. (3) There is evidence of photosynthetic activities immediately after the spring snowmelt/soil warming, but the daily NEE did not switch sign till about 40 days later; our best estimates of the annual net carbon uptake by the ecosystem net ecosystem production (NEP) are -1.0, -1.2, and -2.8 t C ha⁻¹ yr⁻¹ for the periods July 19, 1995, to July 18, 1996, January 1 to December 31, 1996, and January 1 to December 31, 1997, respectively, with an uncertainty of +/- 0.4 t C ha⁻¹ yr⁻¹. (4) The higher NEP value in 1997 than in 1996 was caused by lower growing season soil temperature, cooler spring and fall transitional periods, and higher photon flux in 1997; possible enhancement in canopy photosynthetic capacity may also have played a role. In addition, three main sources of uncertainties, data gap, fetch, and mass flow, are discussed, it is suggested that collective use of the methods available for assessing the whole-ecosystem respiration (friction velocity threshold, mass flow theory, and dark respiration from the forest light response) may increase the confidence level of NEP estimates.

Leech, R.M., and J.L. Marrison. 1996. Immunofluorescent

quantitation of chloroplast proteins. *Plant Journal* 10(6):1169-1175.

Using scanning light microscopy software to detect and measure immunofluorescence in leaf sections Rubisco concentration in situ in chloroplasts has been accurately determined throughout development. The fluorescence measurements were calibrated by comparison with values for Rubisco accumulation obtained from rocket immunoelectrophoresis profiles of soluble protein from isolated cells and from chloroplasts using a purified sample of Rubisco as the standard. It has been shown that in situ immunofluorescence can be used for cytoquantitation of proteins within individual chloroplasts to a sensitivity of 1fg and also for the comparison of the protein levels in adjacent chloroplasts and cells. Several important applications of this new technique are discussed.

Leemans, R. 1992. Modeling ecological and agricultural impacts of global change on a global scale. *Journal of Scientific & Industrial Research* 51(8-9):709-724.

The changing composition of the atmosphere could lead to significant changes in regional and continental climate. The methodology to develop consistent climate-change scenarios and to link them to different impact-models is discussed. Results of both static and dynamic models are presented and the advantages and disadvantages of the different approaches are addressed. Examples are drawn from different impact studies on large-scale vegetation patterns, forest dynamics and agricultural systems. General conclusions of these studies are that vegetation and agricultural zones will shift on global, continental and regional scales, but that large uncertainties still exist in the timing, actual response and rate of change of the current zones. Despite these uncertainties, the direction of these models indicates future developments and could be used for policy purposes.

Leemans, R., A. vanAmstel, C. Battjes, E. Kreileman, and S. Toet. 1996. The land cover and carbon cycle consequences of large-scale utilizations of biomass as an energy source. *Global Environmental Change-Human and Policy Dimensions* 6(4):335-357.

The use of modern biomass for energy generation has been considered in many studies as a possible measure for reducing or stabilizing global carbon dioxide (CO₂) emissions. In this paper we assess the impacts of large-scale global utilization of biomass on regional and grid scale land cover, greenhouse gas emissions, and carbon cycle. We have implemented in the global environmental change model IMAGE the LESS biomass intensive scenario, which was developed for the Second Assessment Report of IPCC. This scenario illustrates the potential for reducing energy related emission by different sets of fuel mixes and a higher energy efficiency. Our analysis especially covers different consequences involved with such modern biomass scenarios. We emphasize influences of CO₂ concentrations and climate change on biomass crop yield, land use, competition between food and biomass crops, and the different interregional trade patterns for modern biomass based energy. Our simulations show that the original LESS scenario is rather optimistic on the land requirements for large-scale biomass plantations. Our simulations show that 797 Mha is required while the original LESS scenario is based on 550 Mha. Such expansion of agricultural land will influence deforestation patterns and have

significant consequences for environmental issues, such as biodiversity. Altering modern biomass requirements and the locations where they are grown in the scenario shows that the outcome is sensitive for regional emissions and feedbacks in the C cycle and that competition between food and modern biomass can be significant. We conclude that the cultivation of large quantities of modern biomass is feasible, but that its effectiveness to reduce emissions of greenhouse gases has to be evaluated in combination with many other environmental land use and socio-economic factors. Leishman, M.R., L. Hughes, K. French, D. Armstrong, and M. Westoby. 1992. Seed and seedling biology in relation to modeling vegetation dynamics under global climate change. *Australian Journal of Botany* 40(4-5):599-613.

The distribution of many plant species will change with global climate change, depending on their ability to disperse into, and establish in, new communities. Past migrations of species under climate change have been an order of magnitude slower than the rate of predicted climate change for the next century. The limited evidence available suggests that chance long distance dispersal events will be critically important in determining migration rates. We examine the JABOWA-derived gap replacement models and vital attributes/FATE models and ask: what do we need to know about dispersal and establishment to make improved projections of vegetation dynamics under climate change using these models? The minimal modifications of these models required to incorporate directional migration of species are described. To predict establishment success of species, we suggest that a more fundamental understanding is needed of how establishment ability under different conditions relates to seed and seedling attributes and how this may be affected by elevated CO₂. Finally, we examine whether plant functional types based on vegetative attributes (used to model the response of adult plants) are correlated with functional types based on seed and seedling attributes. Available evidence suggests that the two sets of attributes are not strongly correlated; consequently, models of vegetation dynamics will need to incorporate seed biology explicitly.

Lenssen, G.M., J. Lamers, M. Stroetenga, and J. Rozema. 1993. Interactive effects of atmospheric CO₂ enrichment, salinity and flooding on growth of C-3 (*Elymus athericus*) and C-4 (*Spartina anglica*) salt-marsh species. *Vegetatio* 104:379-388.

The growth response of Dutch salt marsh species (C3 and C4) to atmospheric CO₂ enrichment was investigated. Tillers of the C3 species *Elymus athericus* were grown in combinations of 380 and 720 μ mol l⁻¹ CO₂ and low (0) and high (300 mM NaCl) soil salinity. CO₂ enrichment increased dry matter production and leaf area development while both parameters were reduced at high salinity. The relative growth response to CO₂ enrichment was higher under saline conditions. Growth increase at elevated CO₂ was higher after 34 than 71 days. A lower response to CO₂ enrichment after 71 days was associated with a decreased specific leaf area (SLA). In two other experiments the effect of CO₂ (380 and 720 μ mol l⁻¹) on growth of the C4 species *Spartina anglica* was studied. In the first experiment total plant dry weight was reduced by 20% at elevated CO₂. SLA also decreased at high CO₂. The effect of elevated CO₂ was also studied in combination with soil salinity (50 and 400 mM NaCl) and flooding. Again plant weight was reduced (10%) at elevated

CO₂, except under the combined treatment high salinity/non- flooded. But these effects were not significant. High salinity reduced total plant weight while flooding had no effect. Causes of the salinity-dependent effect of CO₂ enrichment on growth and consequences of elevated CO₂ for competition between C3 and C4 species are discussed.

Lenssen, G.M., W.E. Vanduin, P. Jak, and J. Rozema. 1995. The response of aster-tripolium and puccinellia-maritima to atmospheric carbon-dioxide enrichment and their interactions with flooding and salinity. *Aquatic Botany* 50(2):181-192.

The effects of 380 and 720 $\mu\text{mol mol}^{-1}$ atmospheric CO₂ on growth, dry matter allocation, net leaf photosynthesis and stomatal conductance of the C3 salt marsh species Aster tripolium L. and Puccinellia maritima (Hudson) Parl. were studied. Plants were grown in pots under combinations of low (50-250 mM NaCl) or high (450-550 mM NaCl) salinity and non- flooded or flooded salt marsh soil. High salinity reduced growth of both species, while flooding increased biomass production of A. tripolium. Root weight of A. tripolium and total plant weight of P. maritima was increased by atmospheric CO₂ enrichment when the soil was flooded. Under non-flooded conditions, the effect of elevated CO₂ on growth was small (P. maritima) or absent (A. tripolium). The relative increase in total plant weight of both species by elevated CO₂ was higher under saline conditions. Dry matter allocation between root, stem and leaf, as reflected in leaf weight ratio and shoot to root ratio, was not changed by elevated CO₂, while specific leaf area was slightly decreased by CO₂ enrichment. Elevated CO₂ stimulated net leaf photosynthesis of both species, while stomatal conductance decreased. These effects were not changed by salinity or flooding treatment.

Leonardos, E.D., M.J. Tsujita, and B. Grodzinski. 1994. Net carbon-dioxide exchange-rates and predicted growth-patterns in alstroemeria-jacqueline at varying irradiances, carbon-dioxide concentrations, and air temperatures. *Journal of the American Society for Horticultural Science* 119(6):1265-1275.

The influence of irradiance, CO₂ concentration, and air temperature on leaf and whole-plant net C exchange rate (NCER) of Alstroemeria 'Jacqueline' was studied. At ambient CO₂, leaf net photosynthesis was maximum at irradiances above 600 $\mu\text{mol m}^{-2}\text{s}^{-1}$ photosynthetically active radiation (PAR), while whole-plant NCER required 1200 $\mu\text{mol m}^{-2}\text{s}^{-1}$ PAR to be saturated. Leaf and whole-plant NCERs were doubled under CO₂ enrichment of 1500 to 2000 $\mu\text{l CO}_2/\text{liter}$. Leaf and whole-plant NCERs declined as temperature increased from 20 to 35°C. Whereas the optimum temperature range for leaf net photosynthesis was 17 to 23°C, whole-plant NCER, even at high

light and high CO₂, declined above 12°C. Dark respiration of leaves and whole plants increased with a Q₁₀ of approximate to 2 at 15 to 35°C. In an analysis of day effects, irradiance, CO₂ concentration, and temperature contributed 58%, 23%, and 14%, respectively, to the total variation in NCER explained by a second-order polynomial model ($R^2=0.85$). Interactions among the factors accounted for 4% of the variation in day C assimilation. The potential whole- plant growth rates during varying greenhouse day and night temperature regimes were predicted for short- and long-day scenarios. The data are discussed with the view of designing experiments to test the importance of C gain in supporting flowering and high yield during routine harvest of Alstroemeria plants under commercial greenhouse conditions.

LeThiec, D., and M. Dixon. 1996. Acclimation of photosynthesis in Norway spruce and red oak grown in open-top chambers and subjected to natural drought and to elevated CO₂. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 26(1):87-94.

Eight-year-old Norway spruce (Picea abies (L.) Karst.) and 6- year-old red oak (Quercus rubra L.) trees planted directly into the soil were enclosed in open-top chambers and exposed to either 350 or 700 $\mu\text{mol mol}^{-1}$ of CO₂ for three growing seasons. During the third year a natural drought was allowed to develop, reducing the predawn leaf water potential to between - 0.80 and -1.15 MPa. Intensive gas-exchange measurements were performed before, during, and after the drought. CO₂ response curves revealed mesophyll limitation to photosynthesis in drought-stressed trees grown in elevated levels of CO₂. The water-use efficiency was greater for trees grown at elevated CO₂, but less so during drought in red oak and the same between treatments for drought-stressed spruce. Diurnal measurements showed that enhancement of assimilation rates of trees grown at 700 $\mu\text{mol mol}^{-1}$ depended upon the time of day that measurements were made. There was an acclimation to increased CO₂ in both species that could not be explained by leaf area differences, available soil for roots, nutrient limitation, or starch accumulation.

Lethiec, D., M. Dixon, P. Loosveldt, and J.P. Garrec. 1995. Seasonal and annual variations of phosphorus, calcium, potassium and manganese contents in different cross-sections of picea-abies (L) karst needles and quercus-rubra L leaves exposed to elevated co₂. *Trees-Structure and Function* 10(2):55-62.

Norway spruce and red oak trees were planted directly into the soil and enclosed in open-top chambers. For 2 years the trees were exposed to both ambient and elevated CO₂ concentrations (700 $\mu\text{mol mol}^{-1}$) and during this time variations in nutrient concentrations were studied. CO₂-treated plants had decreases in global leaf concentrations of nitrogen, potassium, calcium and manganese for both species. When different areas of the foliage were analysed however, the response showed much variability between the respective sites and between species. Furthermore the nutrient concentrations changed differently as the plant material aged and this change showed inter-treatment differences. These results show how it may be important to analyse plant material of different ages and at different cell sites when studying nutrient levels.

Leung, L.R., and S.J. Ghan. 1999. Pacific northwest climate sensitivity simulated by a regional climate model driven by a GCM. Part II: 2XCO₂ simulations. *Journal of Climate* 12(7):2031-2053.

Global climate change due to increasing concentrations of greenhouse gases has stimulated numerous studies and discussions about its possible impacts on water resources. Climate scenarios generated by climate models at spatial resolutions ranging from about 50 km to 400 km may not provide enough spatial specificity for use in impact assessment. In Parts I and II of this paper, the spatial specificity issue is addressed by examining what information on mesoscale and small-scale spatial features can be gained by using a regional climate model with a subgrid parameterization of orographic precipitation and land surface cover, driven by a general circulation model. Numerical experiments have been performed to simulate the present-day climatology and the climate conditions corresponding to a doubling of atmospheric CO₂ concentration. This paper describes and contrasts the large-scale and mesoscale features of the greenhouse warming climate signals simulated by the general circulation model and regional climate model over the Pacific Northwest. Results indicate that changes in the large-scale circulation exhibit strong seasonal variability. There is an average warming of about 2 degrees C, and precipitation generally increases over the Pacific Northwest and decreases over California. The precipitation signal over the Pacific Northwest is only statistically significant during spring, when both the change in the large-scale circulation and increase in water vapor enhance the moisture convergence toward the north Pacific coast. The combined effects of surface temperature and precipitation changes are such that snow cover is reduced by up to 50% on average, causing large changes in the seasonal runoff. This paper also describes the high spatial resolution (1.5 km) climate signals simulated by the regional climate model. Reductions in snow cover of 50%-90% are found in areas near the snow line of the control simulation. Analyses of the variations of the climate signals with surface elevation ranging from sea level to 4000 m over two mountain ranges in the Pacific Northwest show that because of changes in the altitude of the freezing level, strong elevation dependency is found in the surface temperature, rainfall, snowfall, snow cover, and runoff signals.

Leverenz, J.W. 1995. Shade shoot structure of conifers and the photosynthetic response to light at 2 co₂ partial pressures. *Functional Ecology* 9(3):413-421.

1. The response of net photosynthesis to irradiance was measured for shade-adapted shoots of different conifer species. Shoots were illuminated unidirectionally or in a light integrating sphere to study the effects of shoot structure. 2. Shoot structure was quantified as R(max) the ratio of the shoot-silhouette area to the leaf-silhouette area. 3. The initial slopes and the convexities (rate of bending) of the light response curves were strongly affected by R(max) during unilateral illumination. There was also a strong positive effect of R(max) on the maximum efficiency of net photosynthesis and a strong negative effect of R(max) on the light compensation point. 4. Increasing atmospheric CO₂ partial pressure (C-a) from 35 to 70 Pa did not affect the convexity of the light response curves nor rates of dark respiration. 5. Increasing C-a affected the initial slope, the light compensation point, the maximum rate of photosynthesis and the efficiency of net photosynthesis. 6. Except for the maximum rate of net photosynthesis, the responses to C-a were controlled by shoot structure. 7. Studies of the effect of atmospheric CO₂ on photosynthesis and growth in conifers need to consider variations in shoot structure.

Levis, S., J.A. Foley, and D. Pollard. 1999. Potential high-latitude vegetation feedbacks on CO₂-induced climate change. *Geophysical Research Letters* 26(6):747-750.

We use a fully coupled climate-vegetation model to examine the potential effects of changes in vegetation cover on simulations of CO₂-induced climate change. We find that vegetation feedbacks, acting mainly through changes in surface albedo, enhance greenhouse warming in the northern high latitudes during spring and summer months. In spring and summer, land surfaces north of 45 degrees N are warmed by 3.3 and 1.7 degrees C by a doubling of CO₂ alone; vegetation feedbacks produce an additional warming of between 1.1-1.6 and 0.4-0.5 degrees C, respectively. In winter, however, vegetation feedbacks appear to oppose the 5.6 degrees C radiative warming, particularly over Eurasia. These results demonstrate that vegetation feedbacks are potentially significant and must be included in assessments of anthropogenic climate change.

Lewin, K.F., G.R. Hendrey, J. Nagy, and R.L. Lamorte. 1994. Design and application of a free-air carbon-dioxide enrichment facility. *Agricultural and Forest Meteorology* 70(1-4):15-29.

Growth chambers and other enclosures used in plant physiology and growth studies tend to introduce chamber effects that alter the microclimate around the plants compared with the natural environment. A free-air (chamberless) carbon dioxide enrichment (FACE) system has been developed by Brookhaven National Laboratory (BNL) to provide controlled fumigation conditions while minimizing the potential to impose a discernible chamber effect. This system is capable of exposing large numbers of field-grown plants to elevated levels of atmospheric carbon dioxide (CO₂) from seedling emergence until physiologic maturity. A FACE User Facility was established at the Maricopa Agricultural Center, University of Arizona, for continuous enrichment of CO₂ at a set point of 550 μmol mol⁻¹ during daylight hours throughout the cotton crop growing seasons of 1989-1991. The facility consisted of four circular BNL FACE arrays and associated equipment placed in a commercial cotton plantation. FACE array diameters of 23, 25, and 27 m were tested. The FACE facility included the ability to operate the experimental plots under two watering regimes using an automated, sub-surface irrigation system. CO₂ was stored in a 48 000 kg receiver and vaporized with a heat exchanger that used water at ambient temperature as the energy source. The 1 min average CO₂ concentration was held to within +/- 20% of the set point more than 98% of the time that the arrays were operating during all three seasons. In 1991, the long term average CO₂ concentration measured at 63 points throughout the volume of a 20 m diameter experimental plot (ground to canopy top) centered within a 25 m diameter FACE array was 568 μmol mol⁻¹. All of the FACE arrays operated for more than 99% of the planned experimental period in 1991. These 3 years of operation have demonstrated that the BNL FACE technology can be used as a basis for a large scale facility devoted to studying the fate of carbon in the terrestrial environment.

Lewis, C.E., G. Peratoner, A.J. Cairns, D.R. Causton, and C.H. Foyer. 1999. Acclimation of the summer annual species, *Lolium temulentum*, to CO₂ enrichment. *Planta* 210(1):104-114.

Lolium temulentum L. Ba 3081 was grown hydroponically in air (350 $\mu\text{mol mol}^{-1}$ CO_2) and elevated CO_2 (700 $\mu\text{mol mol}^{-1}$ CO_2) at two irradiances (150 and 500 $\mu\text{mol m}^{-2} \text{s}^{-1}$) for 35 days at which point the plants were harvested. Elevated CO_2 did not modify relative growth rate or biomass at either irradiance. Foliar carbon-to-nitrogen ratios were decreased at elevated CO_2 and plants had a greater number of shorter tillers, particularly at the lower growth irradiance. Both light-limited and light-saturated rates of photosynthesis were stimulated. The amount of ribulose-1,5-bisphosphate carboxylase-oxygenase (Rubisco) protein was increased at elevated CO_2 , but maximum extractable Rubisco activities were not significantly increased. A pronounced decrease in the Rubisco activation state was found with CO_2 enrichment, particularly at the higher growth irradiance. Elevated- CO_2 -induced changes in leaf carbohydrate composition were small in comparison to those caused by changes in irradiance. No CO_2 -dependent effects on fructan biosynthesis were observed. Leaf respiration rates were increased by 68% in plants grown with CO_2 enrichment and low light. We conclude that high CO_2 will only result in increased biomass if total light input favourably increases the photosynthesis-to-respiration ratio. At low irradiances, biomass is more limited by increased rates of respiration than by CO_2 -induced enhancement of photosynthesis.

Lewis, J.D., K.L. Griffin, R.B. Thomas, and B.R. Strain. 1994. Phosphorus supply affects the photosynthetic capacity of loblolly-pine grown in elevated carbon-dioxide. *Tree Physiology* 14(11):1229-1244.

Effects of phosphorus supply and mycorrhizal status on the response of photosynthetic capacity to elevated CO_2 were investigated in loblolly pine (*Pinus taeda* L.) seedlings. Seedlings were grown in greenhouses maintained at either 35.5 or 71.0 Pa CO_2 in a full factorial experiment with or without mycorrhizal inoculum (*Pisolithus tinctorius* (Pers.) Coker & Couch) and with an adequate or a limiting supply of phosphorus. Assimilation versus internal CO_2 partial pressure (C_i) curves were used to estimate maximum Rubisco activity ($V_{c,\text{max}}$), electron transport mediated ribulose 1,5-bisphosphate regeneration capacity (J_{max}), phosphate regeneration capacity (PiRC) and daytime respiration rates (R_d). Nonmycorrhizal seedlings grown with limiting phosphorus had significantly reduced $V_{c,\text{max}}$ and PiRC compared to seedlings in other treatments. Elevated CO_2 increased photosynthetic capacity in nonmycorrhizal seedlings in the low phosphorus treatment by increasing PiRC , whereas it induced phosphorus limitation in mycorrhizal seedlings in the low phosphorus treatment and did not affect the photosynthetic capacity of seedlings in the high phosphorus treatment. Despite the variety of effects on photosynthetic capacity, seedlings in the elevated CO_2 treatments had higher net assimilation rates than seedlings in the ambient CO_2 treatments. We conclude that phosphorus supply affects photosynthetic capacity during long-term exposure to elevated CO_2 through effects on Rubisco activity and ribulose 1,5-bisphosphate regeneration rates.

Lewis, J.D., D. Olszyk, and D.T. Tingey. 1999. Seasonal patterns of photosynthetic light response in Douglas-fir seedlings subjected to elevated atmospheric CO_2 and temperature. *Tree Physiology* 19(4-5):243-252.

Increases in atmospheric CO_2 concentration and temperature are predicted to increase the light response of photosynthesis by increasing

light-saturated photosynthetic rates and apparent quantum yields. We examined the interactive effects of elevated atmospheric CO_2 concentration and temperature on the light response of photosynthesis in Douglas-fir (*Pseudotsuga menziesii* (Mirb.) France) seedlings. Seedlings were grown in sunlit chambers controlled to track either ambient (similar to 400 ppm) CO_2 or ambient + 200 ppm CO_2 , at ambient temperature or ambient +4 degrees C. Photosynthetic light response curves were measured over an 18-month period beginning 32 months after treatments were initiated. Light-response curves were measured at the growth CO_2 concentration, and were used to calculate the light-saturated rate of photosynthesis, light compensation point, quantum yield and respiration rate. Elevated CO_2 increased apparent quantum yields during two of five measurement periods, but did not significantly affect light-saturated net photosynthetic rates, light compensation points or respiration rates. Elevated temperature increased all parameters. There were no significant interactions between CO_2 concentration and temperature. We conclude that down-regulation of photosynthesis occurred in the elevated CO_2 treatments such that carbon uptake at a given irradiance was similar across CO_2 treatments. In contrast, increasing temperature may substantially increase carbon uptake rates in Douglas-fir, assuming other environmental factors do not limit photosynthesis; however, it is not clear whether the increased carbon uptake will increase growth rates or be offset by increased carbon efflux through respiration.

Lewis, J.D., and B.R. Strain. 1996. The role of mycorrhizas in the response of *Pinus taeda* seedlings to elevated CO_2 . *New Phytologist* 133(3):431-443.

The effects of mycorrhizal status, phosphorus supply and CO_2 partial pressure on production and allocation of biomass in seedlings from two populations of *Pinus taeda* L. were examined. Seedlings from a North Carolina and a Florida population were grown in sterile soil in a full-factorial experiment with one of two phosphorus treatments (low P, high P) and at one of two CO_2 partial pressures (35.5, 71.0 Pa). One half of the seedlings were inoculated with *Pisolithus tinctorius* (Pers.) Coker & Couch hyphae and spores. Seedlings were harvested 60, 90 and 120 d after emergence. Elevated CO_2 significantly increased total seedling dry mass in all treatments at all three harvests. Phosphorus limitation reduced seedling growth, and mycorrhizas increased seedling growth in seedlings limited by phosphorus supply. Generally, however, there were no interactions between CO_2 , phosphorus supply and mycorrhizal status on dry mass of seedlings. Mycorrhizas probably did not affect the response of dry mass to elevated CO_2 because phosphorus limitation did not reduce response of dry mass to elevated CO_2 . Phosphorus-limited seedlings responded to elevated CO_2 as a result of increased phosphorus uptake, resulting from increased total root dry mass, and increased phosphorus use efficiency. Although mycorrhizal colonization did not affect the response of biomass to elevated CO_2 , it significantly reduced the response of needle area. As a result, specific leaf area (leaf area per unit plant biomass) was lower in mycorrhizal seedlings grown in elevated CO_2 than in mycorrhizal seedlings grown in ambient CO_2 . Because there were no effects on relative growth rate or seedling dry mass, reductions in specific leaf area suggest that elevated CO_2 reduced the relative cost of the symbiosis.

Lewis, J.D., R.B. Thomas, and B.R. Strain. 1994. Effect of elevated CO₂ on mycorrhizal colonization of loblolly- pine (Pinus taeda L.) seedlings. *Plant and Soil* 165(1):81-88.

Interactive effects of elevated atmospheric CO₂ and phosphorus supply on mycorrhizal colonization rates were investigated using loblolly pine (Pinus taeda L.) seedlings from Florida and coastal North Carolina. Seedlings from both populations were grown in greenhouses maintained at either 35.5 Pa or 71.0 Pa CO₂. In both CO₂ treatments, seedlings were grown in a full factorial experiment with or without mycorrhizal inoculum and with an adequate or a limiting supply of phosphorus. Seedlings were harvested 60, 90 and 120 days after emergence and at each harvest root subsamples were examined to determine the percent of fine roots that were mycorrhizal. Additionally, root carbohydrate and nutrient levels were measured at each harvest. Root starch, sugar and total non-structural carbohydrate (TNC) concentrations were increased by growth in elevated CO₂ and decreased by mycorrhizal colonization. Phosphorus stress decreased root starch concentrations, increased root sugar concentrations and did not significantly affect TNC concentrations. However, despite significant effects on root carbohydrate levels, there were generally no significant treatment effects on mycorrhizal colonization. Additionally, at all harvests, root starch and sugar concentrations were not correlated with percent of fine roots that were mycorrhizal. These results suggest that although elevated CO₂ may significantly increase root carbohydrate levels, the increases may not affect the percent of fine roots that are mycorrhizal.

Lewis, J.D., D.T. Tissue, and B.R. Strain. 1996. Seasonal response of photosynthesis to elevated CO₂ in loblolly pine (Pinus taeda L.) over two growing seasons. *Global Change Biology* 2(2):103-114.

Trees growing in natural systems undergo seasonal changes in environmental factors that generate seasonal differences in net photosynthetic rates. To examine how seasonal changes in the environment affect the response of net photosynthetic rates to elevated CO₂, we grew Pinus taeda L. seedlings for three growing seasons in open-top chambers continuously maintained at either ambient or ambient + 30 Pa CO₂. Seedlings were grown in the ground, under natural conditions of light, temperature and nutrient and water availability. Photosynthetic capacity was measured bimonthly using net photosynthetic rate vs. intercellular CO₂ partial pressure (A-C-i) curves. Maximum Rubisco activity (V_c(max)) and ribulose 1,5-bisphosphate regeneration capacity mediated by electron transport (J(max)) and phosphate regeneration (PiRC) were calculated from A-C-i curves using a biochemically based model. Rubisco activity, activation state and content, and leaf carbohydrate, chlorophyll and nitrogen concentrations were measured concurrently with photosynthesis measurements. This paper presents results from the second and third years of treatment. Mean leaf nitrogen concentrations ranged from 13.7 to 23.8 mg g⁻¹, indicating that seedlings were not nitrogen deficient. Relative to ambient CO₂ seedlings, elevated CO₂ increased light-saturated net photosynthetic rates 60-110% during the summer, but < 30% during the winter. A relatively strong correlation between leaf temperature and the relative response of net photosynthetic rates to elevated CO₂ suggests a strong effect of leaf temperature. During the third growing season, elevated CO₂ reduced Rubisco activity 30% relative to ambient CO₂ seedlings, nearly completely balancing Rubisco and RuBP- regeneration regulation of photosynthesis. However, reductions in Rubisco activity

did not eliminate the seasonal pattern in the relative response of net photosynthetic rates to elevated CO₂. These results indicate that seasonal differences in the relative response of net photosynthetic rates to elevated CO₂ are likely to occur in natural systems.

Leymarie, J., G. Lasceve, and A. Vavasseur. 1998. Interaction of stomatal responses to ABA and CO₂ in Arabidopsis thaliana. *Australian Journal of Plant Physiology* 25(7):785-791.

Stomatal responses to ABA and CO₂ were investigated in Arabidopsis thaliana (L.) Heynh. wild-type and ABA insensitive mutants (abi1-1, abi2-1, abi1-1 abi2-1) at the whole plant and at the isolated epidermis levels. In wild-type plants, feeding roots with ABA (1-50 μ M) triggered a rapid drop in leaf conductance which levelled off during the following photoperiods, and strongly inhibited the increase in conductance induced by light. The rapid response was strongly inhibited in abi1-1, abi2-1 and abi1-1 abi2-1 double mutants, but a residual long-term decrease in leaf conductance was still observed. In wild-type plants, exogenous ABA strongly enhanced the response to CO₂ removal. Conversely, in the absence of CO₂ the effect of ABA was drastically reduced in epidermal strip experiments. These results reveal a strong interaction between sensing of ABA and CO₂ in stomata of A. thaliana. Despite an initially wide stomatal aperture in abi-1, abi-2 and double mutant plants, their stomatal responses to light and CO₂ removal were half those of wild-type plants. Moreover these responses were totally independent of the presence of ABA, suggesting that ABI1 and ABI2 are either directly involved in the interaction between the two signalling pathways or, alternatively located upstream of this point of interaction.

Leymarie, J., G. Lasceve, and A. Vavasseur. 1999. Elevated CO₂ enhances stomatal responses to osmotic stress and abscisic acid in Arabidopsis thaliana. *Plant, Cell and Environment* 22(3):301-308.

Carbon dioxide and abscisic acid (ABA) are two major signals triggering stomatal closure. Their putative interaction in stomatal regulation was investigated in well-watered air-grown or double CO₂-grown Arabidopsis thaliana plants, using gas exchange and epidermal strip experiments. With plants grown in normal air, a doubling of the CO₂ concentration resulted in a rapid and transient drop in leaf conductance followed by recovery to the pre-treatment level after about two photoperiods. Despite the fact that plants placed in air or in double CO₂ for 2 d exhibited similar levels of leaf conductance, their stomatal responses to an osmotic stress (0.16-0.24 MPa) were different. The decrease in leaf conductance in response to the osmotic stress was strongly enhanced at elevated CO₂. Similarly, the drop in leaf conductance triggered by 1 μ M ABA applied at the root level was stronger at double CO₂. Identical experiments were performed with plants fully grown at double CO₂. Levels of leaf conductance and carbon assimilation rate measured at double CO₂ were similar for air-grown and elevated CO₂-grown plants. An enhanced response to ABA was still observed at high CO₂ in pre- conditioned plants. It is concluded that: (i) in the absence of stress, elevated CO₂ slightly affects leaf conductance in A. thaliana; (ii) there is a strong interaction in stomatal responses to

CO₂ and ABA which is not modified by growth at elevated CO₂.

Li, A., G.M. Berntson, D.L. Godbold, and F.A. Bazzaz. 1998. The dynamics of root production and loss in *Betula papyrifera* seedlings in response to elevated CO₂ and an aluminium pulse. *Zeitschrift Fur Pflanzenernahrung Und Bodenkunde* 161(1):17-21.

Seedlings of *Betula papyrifera* were grown in sand/nutrient solution cultures in rhizotrone growth containers under elevated (700 ppm) or ambient (375 ppm) atmospheric CO₂ concentrations for approximately 10 weeks. Thirty seven days after the begin of the experiment the plants were exposed to a 10 day pulse of 400 or 1200 μM Al. Elevated atmospheric CO₂ increased both root production and loss. Exposure to Al reduced root production and slightly reduced root loss. The reduced root production due to Al was amplified after the pulse had receded, resulting in a significantly lower net and gross root production at the end of the experiment. There were no clear CO₂ x Al interactions.

Li, A.G., A. Trent, G.W. Wall, B.A. Kimball, Y.S. Hou, P.J. Pinter, R.L. Garcia, D.V. Hunsaker, and R.L. Lamorte. 1997. Free-air CO₂ enrichment effects on rate and duration of apical development of spring wheat. *Crop Science* 37(3):789-796.

Rates and durations of individual phases of wheat (*Triticum aestivum* L.) apical development are among the most important factors that determine yield components. Because atmospheric CO₂ has been increasing steadily, it is important to evaluate the effects of elevated CO₂ on wheat development. This study was conducted to determine rates and durations of leaf, spikelet, and floret primordium initiation in a Free-Air Carbon Dioxide Enrichment (FACE) system. Spring wheat (cv. Yecora Roja) was planted at the University of Arizona Maricopa Agricultural Center. The two CO₂ concentrations were 550 (elevated) and 370 (ambient) $\mu\text{mol mol}^{-1}$ CO₂. Individual plant samples were collected every 3 to 4 d. We dissected the main stem (MS), coleoptile tiller (T0), primary tillers (T1, T2, and T3) and secondary tillers (T00, T01, T02, T10, T11, and T12) and counted primordia. Apex primordium data were fitted to a four-piece linear-spline segmented regression model with the SAS proc NLIN. No influence of elevated CO₂ (550 $\mu\text{mol mol}^{-1}$) on leaf primordium initiation of MS was detected. Nevertheless, CO₂ enrichment significantly increased rates of spikelet primordium initiation of MS, T1, T2, T10, and T11, and diminished the durations of spikelet development phase of MS, T1, T2, T3, T10, and T11. Within the floret phase, CO₂ enrichment significantly increased rates of floret primordium initiation of MS, T0, T1, T2, and T3, and diminished the time to the completion of floret primordium initiation of MS, T0, T1, T3, and T11. The information from this study will be utilized to predict wheat apical development and grain production in the elevated atmospheric CO₂ environments of the future.

Li, A.G., G.W. Wall, A. Trent, and Y.S. Hou. 1999. Free-air CO₂ enrichment effects on apex dimensional growth of spring wheat. *Crop Science* 39(4):1083-1088.

Although primordium initiation in wheat (*Triticum aestivum* L.) has been extensively researched, a complete description of the growth dynamics of the apex at elevated CO₂ concentrations is lacking. This study determined the rates of main stem and tiller apical elongation and widening in plants grown under two levels of CO₂ concentration. Spring wheat was grown at the University of Arizona's Maricopa Agricultural Center at elevated (550 $\mu\text{mol mol}^{-1}$) or ambient (370 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. Individual plant samples were collected at different developmental stages and dissected. After dissection, the lengths and widths of the spires of the main stem (MS), coleoptile tiller (T0), primary tillers (T1, T2, and T3), and secondary tillers (T00, T01, T02, T10, T11, and T12) were measured with a stage micrometer. Apex dimensions were fitted to an exponential model. Elevated CO₂ increased the apex lengths of T2 at the double ridge stage, and of T3 and T10 at the double ridge and the terminal spikelet stages, and the apex widths of T2 at double ridge stage, and of T2, T3, T10, and T11 at the flag leaf appearance stage. Combining these results with a parallel study, the longer apices did not have more spikelet primordia, but wider apices had more floret primordia. Elevated CO₂ changed apex elongation or widening patterns within a plant by enhancing elongation or widening rates of the MS, and later formed tillers. Earlier-formed tillers were less responsive to elevated CO₂ levels. This information will be used in modeling wheat apical development and grain production in the elevated atmospheric CO₂ environments of the future.

Li, C.S., S. Frolking, and R. Harriss. 1994. Modeling carbon biogeochemistry in agricultural soils. *Global Biogeochemical Cycles* 8(3):237-254.

An existing model of C and N dynamics in soils was supplemented with a plant growth submodel and cropping practice routines (fertilization, irrigation, tillage, crop rotation, and manure amendments) to study the biogeochemistry of soil carbon in arable lands. The new model was validated against field results for short-term (1-9 years) decomposition experiments, the seasonal pattern of soil CO₂ respiration, and long-term (100 years) soil carbon storage dynamics. A series of sensitivity runs investigated the impact of varying agricultural practices on soil organic carbon (SOC) sequestration. The tests were simulated for corn (maize) plots over a range of soil and climate conditions typical of the United States. The largest carbon sequestration occurred with manure additions; the results were very sensitive to soil texture (more clay led to greater sequestration). Increased N fertilization generally enhanced carbon sequestration, but the results were sensitive to soil texture, initial soil carbon content, and annual precipitation. Reduced tillage also generally (but not always) increased SOC content, though the results were very sensitive to soil texture, initial SOC content, and annual precipitation. A series of long-term simulations investigated the SOC equilibrium for various agricultural practices, soil and climate conditions, and crop rotations. Equilibrium SOC content increased with decreasing temperatures, increasing clay content, enhanced N fertilization, manure amendments, and crops with higher residue yield. Time to equilibrium appears to be one hundred to several hundred years. In all cases, equilibration time was longer for increasing SOC content than for decreasing SOC content. Efforts to enhance carbon sequestration in agricultural soils would do well to focus on those specific areas and agricultural practices with the greatest potential for increasing soil carbon content.

Li, J.H., P. Dijkstra, C.R. Hinkle, R.M. Wheeler, and B.G. Drake. 1999. Photosynthetic acclimation to elevated atmospheric CO₂ concentration in the Florida scrub-oak species *Quercus geminata* and *Quercus myrtifolia* growing in their native environment. *Tree Physiology* 19(4-5):229-234.

Long-term effects of elevated CO₂ concentration (ambient plus 350 $\mu\text{mol mol}^{-1}$) on leaf photosynthetic acclimation of two species of a scrub-oak community, *Quercus myrtifolia* Willd. and *Quercus geminata* Small, were studied. Plants of both species were grown in open-top chambers in their natural habitat at Kennedy Space Center, Florida, USA. Compared to ambient CO₂, elevated CO₂ stimulated photosynthetic rates by 73 and 51% for *Q. geminata* and *Q. myrtifolia*, respectively. Maximum rate of carboxylation (V_{cmax}) was significantly reduced by elevated CO₂ in *Q. myrtifolia* (28%) but not in *Q. geminata*. Maximum rate of potential electron transport (J_{max}) was not significantly reduced by elevated CO₂ in either species. In response to elevated CO₂, specific leaf area decreased in *Q. myrtifolia* (22%), but not in *Q. geminata*. Elevated CO₂ caused a significant accumulation of sugars (54%) and starch (264%) in *Q. myrtifolia* leaves, but not in *Q. geminata* leaves. Total Rubisco activity in *Q. myrtifolia* leaves was reduced 40% by elevated CO₂, whereas no significant reduction occurred in *Q. geminata* leaves. Although both species share a common habitat, they exhibited marked differences in photosynthetic acclimation to elevated CO₂ concentration.

Li, J.H., J. Gale, A. Novoplansky, S. Barak, and M. Volokita. 1999. Response of tomato plants to saline water as affected by carbon dioxide supplementation. II. Physiological responses. *Journal of Horticultural Science & Biotechnology* 74(2):238-242.

Photosynthesis of tomato plants (*Lycopersicon esculentum* (L.) Mill. cv. F144) was studied under conditions of CO₂ supplementation and salinity. The purpose of the study was to elucidate the mechanisms underlying the effects of salinity on the acclimation of tomato plants to CO₂ supplementation. Plants were grown under either low (355 $\mu\text{mol mol}^{-1}$) or elevated (1200 $\pm$ 50 $\mu\text{mol mol}^{-1}$) CO₂ and were irrigated with low concentrations of mixed salts. The highest salinity level (E.C. 7 dS m^{-1}) was that used to produce quality tomatoes in the Negev highlands, in Israel. During early development (three weeks after planting), the net photosynthetic rate of the leaves was much higher under elevated CO₂, and other than a slight decrease in quantum yield efficiency as measured by fluorescence ($\Delta F/F_{\text{m}}$), no signs of acclimation to high levels of CO₂ were apparent. Clear acclimation to high CO₂ concentration was evident ten weeks after planting when the net photosynthetic rate, photosynthetic capacity, and carboxylation efficiency of leaves of non-salinized plants were strongly suppressed under elevated CO₂. This was accompanied by reductions in carboxylation efficiency, Rubisco activity and PSII quantum yield, and an increased accumulation of leaf soluble sugars. The reduction in photosynthetic capacity in the high CO₂ plants was less in plants grown at the highest salinity level. This was correlated with an increase in the PSII quantum yield parameters ($F_{\text{v}}/F_{\text{m}}$ and $\Delta F/F_{\text{m}}$) but not with Rubisco activity which was affected by the Cat treatments only. These results explain the effects of high CO₂ on yields in tomatoes grown at high levels of salt (Li et al., 1999).

Li, J.H., M. Sagi, J. Gale, M. Volokita, and A. Novoplansky. 1999. Response of tomato plants to saline water as affected by carbon dioxide supplementation. I. Growth, yield and fruit quality. *Journal of Horticultural Science & Biotechnology* 74(2):232-237.

Tomato plants (*Lycopersicon esculentum* (L.) Mill. cv. F144) were irrigated with low concentrations of mixed salts; the highest level (E.C. 7 dS m^{-1}) simulated conditions used to produce quality tomatoes in the Negev highlands. CO₂ enrichment (to 1200 $\mu\text{mol mol}^{-1}$, given during the daytime) increased plant growth at the early stage of development. However, later growth enhancement was maintained only when combined with salt stress. In the absence of CO₂ supplementation, overall growth decreased with salt (7 dS m^{-1}) to 58% and fresh biomass yields to 53% of the controls. However, under elevated CO₂ concentrations total plant dry biomass was not reduced by salt stress. CO₂ enrichment of plants grown with 7 dS m^{-1} salt increased total fresh fruit yields by 48% and maintained fruit quality in terms of total soluble salts, glucose and acidity. Fruit ripening was about 10 d earlier under CO₂ enrichment, regardless of salinity treatment. It is suggested that a combined utilization of brackish water and CO₂ supplementation may enable the production of high-quality fruits without incurring all the inevitable loss in yields associated with salt treatment.

Li, Q.L., and D.T. Canvin. 1997. Oxygen photoreduction and its effect on CO₂ accumulation and assimilation in air-grown cells of *Synechococcus* UTEX 625. *Canadian Journal of Botany-Revue Canadienne De Botanique* 75(2):274-283.

Mass spectrometric measurements of O-16(2), O-18(2), and (CO₂)-C-13 were used to measure the rates of gross O-2 evolution, O-2 uptake, and CO₂ assimilation in relation to light intensity, temperature, pH, and O-2 concentration by air-grown cells of the cyanobacterium *Synechococcus* UTEX 625. CO₂ fixation and O-2 photoreduction increased with increased light intensity and, although CO₂ fixation was saturated at 250 $\mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$, O-2 photoreduction was not saturated until about 550 $\mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$. At high light intensity addition of inorganic carbon to the cells stimulated O-2 photoreduction 2-fold when CO₂ fixation was allowed and 5-fold when CO₂ fixation was inhibited with iodoacetamide. The ability of O-2 to act as an acceptor of photosynthetically generated reducing power was dependent upon the O-2 concentration, and the substrate concentration required for half maximum rate ($K_{1/2}(\text{O-2})$) was 53.2 $\pm$ 4.2 μM (mean $\pm$ SD, $n = 3$). The Q_{10} for oxygen photoreduction was about 2. A certain amount (10%) of O-2 appeared to be required for maximum photosynthesis, as photosynthesis was inhibited under anaerobic conditions, especially at high light intensity. The point of inhibition is unknown but it seemed unlikely to be on CO₂ transport or the concentration of intracellular dissolved inorganic carbon (C-i), as the rate of initial CO₂ transport was enhanced and the intracellular C-i pool increased in size under anaerobic conditions.

Liakatas, A., D. Roussopoulos, and W.J. Whittington. 1998. Controlled-temperature effects on cotton yield and fibre properties. *Journal of Agricultural Science* 130:463-471.

Temperature effects on cotton yield and fibre properties of three cotton cultivars were determined. Plants were grown in pots maintained in growth rooms at varying day and night temperatures representing seasonally constant or varying (C) or daily varying (V) regimes. Yield and fibre characters responded to variation of daily mean and amplitude of temperature. Mean temperature reduction improved yield components, but fibre length, uniformity, strength and micronaire were increased by high, particularly high day, temperatures. A large daily temperature amplitude produced an intermediate number of flowers and the lowest retention percentage. Fruiting and yield were increased by reduction in temperature down to the threshold mean temperature of 22 degrees C. However, V-regimes with a low minimum temperature acted as a further drop (below 22 degrees C) of temperature and adversely affected these characters. An adverse effect of low minimum temperature combined with a moderate day temperature was observed also on lint percentage and fibre properties. Varietal differences were more pronounced for highly heritable characters such as fibre properties, for which significant interactions between varieties and temperature also occurred. Differences in reproductive development were not sufficient to be of much practical importance.

Liang, N.S., and K. Maruyama. 1995. Interactive effects of CO₂ enrichment and drought stress on gas exchange and water-use efficiency in *Alnus firma*. *Environmental and Experimental Botany* 35(3):353-361.

Independent and interactive effects of atmospheric CO₂ enrichment and drought stress on leaf conductance, photosynthetic performance, transpiration and water-use efficiency in 2-year-old *Alnus firma*, a common pioneer tree species, were assessed. Measurements were conducted in a controlled environment laboratory at three CO₂ concentrations [350 (ambient), 600 and 900 (enrichment) $\mu\text{mol mol}^{-1}$] and combined with five water regimes [leaf water potential of higher than -0.3 (well-watered), -0.5 and -0.8 (moderate drought), -1.0 and lower than -1.2 (serious drought stress) MPa]. Under well-watered conditions, rates of net photosynthesis significantly ($P < 0.01$) increased with increasing CO₂ concentrations; leaf conductance significantly decreased. With drought stress established, leaf conductance, photosynthesis and transpiration decreased. However, leaf water-use efficiency increased with drought stress, with potential transpiration affected sooner than potential photosynthesis. The combined effects of CO₂ enrichment and drought stress on water-use efficiency were significant in that the result of net photosynthesis was stimulated while transpiration in CO₂ enriched plants resembled that of unenriched plants under conditions of drought stress. The results presented here suggest that if a doubling of atmospheric CO₂ concentration occurs by the mid-21st Century, then the photosynthetic rate of *A. firma* in drought-affected regions may be expected to increase. A reduction in total water use, however, is not indicated.

Liang, N., K. Maruyama, and Y. Huang. 1995. Interactions of elevated CO₂ and drought stress in gas-exchange and water-use efficiency in 3 temperate deciduous tree species. *Photosynthetica* 31(4):529-539.

The effect of CO₂ increase on gas exchange and water-use efficiency (WUE) in three temperate deciduous species (*Fagus crenata*, *Ginkgo biloba* and *Alnus firma*) under gradually-developing drought-stress was assessed. Seedlings were grown within transparent open-top cabinets and maintained for 4 months at mean CO₂ concentrations of either 350 (ambient; C-350) or 700 $\mu\text{mol mol}^{-1}$ (elevated; C-700) and combined with five water regimes [leaf water potential, $\Psi(\text{w})$, higher than -0.3 (well-watered), -0.5 and -0.8 (moderate drought), -1.0 and fewer than -1.2 MPa (serious drought-stress)]. Increase in CO₂ concentration induced a 60 % average increase in net photosynthetic rate (P-N) under well-watered conditions. The effect of C-700 became more pronounced with drought stress established, with an 80 % average increase in P-N at $\Psi(\text{w})$, as low as -0.8 MPa; leaf conductance to water vapour transfer ($g(\text{s})$) and transpiration rate (E), however, were significantly decreased. Consequently, WUE increased under drought, through drought stress affected potential E sooner than potential P-N. The interaction of CO₂ x drought stress on WUE was significant in that P-N was stimulated while E in C-700 enriched plants resembled that of C-350 plants under drought. Hence if a doubling of atmospheric CO₂ concentration occurs by the mid 21(st) century, then greater P-N in *F. crenata*, *G. biloba* and *A. firma* may be expected and the drought susceptibility of these species will be substantially enhanced.

Liang, N., K. Maruyama, and Y. Huang. 1996. Effects of CO₂ concentration on the photosynthetic and carboxylation efficiencies of *Fagus crenata* and *Quercus crispula*. *Photosynthetica* 32(3):355-365.

To determine the effects of limited and elevated CO₂ concentrations on leaf photosynthesis which may suggest the effects of global CO₂ level increase and global warming on forest structure, the photosynthetic and carboxylation efficiencies were investigated in two representative co-occurring tree species in the cool-temperate natural forests in central Japan, *Fagus crenata* and *Quercus crispula*. Measurements were performed for four-year-old seedlings in CO₂-air mixtures of 175, 350, 700 and 900 $\mu\text{mol mol}^{-1}$, respectively, with photosynthetic irradiance (I) decreasing gradually from 1200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ to darkness, and at 25 $\pm$ 0.2 degrees C leaf temperature and 1.8 $\pm$ 0.2 kPa leaf to air vapour pressure deficit. The CO₂ concentrations strongly stimulated net photosynthetic rate, P-N ($p < 0.001$), and the photosynthetic efficiency, α , for both *F. crenata* and *Q. crispula*. Carboxylation efficiency of *Q. crispula* was dependent on I, with a significantly higher efficiency of CO₂ utilization at an I of 1200 than of 500 $\mu\text{mol m}^{-2} \text{s}^{-1}$. A decrease in I from 1200 to 500 $\mu\text{mol m}^{-2} \text{s}^{-1}$, however, did not prevent a curvilinear increase in P-N at increased CO₂ concentrations. In contrast, *F. crenata* seedlings showed less difference in PN between low-I and high-I environments. Nonetheless, *F. crenata* showed a greater CO₂ response, with α increased by 25 % from 350 to 700 $\mu\text{mol}(\text{CO}_2) \text{mol}^{-1}$. α of *Q. crispula*, however, increased by less than 20 % as CO₂ concentration increased from 350 to 700 $\mu\text{mol mol}^{-1}$. The higher P-N at high CO₂ concentration under low I was attributed to the CO₂ concentration

accompanied by a significant decrease in compensation irradiance. These results suggest that the continuous increase in global CO₂ concentrations will directly result in an increase in photosynthetic efficiencies of both *F. crenata* and *Q. crispula*. The competitive relationship between the two species will change if a doubling of atmospheric CO₂ concentration occurs by the mid of the 21(st) century, with *F. crenata* benefiting more from CO₂ fertilization than *Q. crispula*.

Lim, L.Y., Y.C. Hew, S.C. Wong, and C.S. Hew. 1992. Effects of light-intensity, sugar and co-2 concentrations on growth and mineral uptake of dendrobium plantlets. *Journal of Horticultural Science* 67(5):601-611.

The effects of light intensity, sugar and CO₂ concentrations on nitrate and ammonium uptake, growth and photosynthetic activity of dendrobium plantlets grown on agar medium were studied. There was a preferential uptake of ammonium over nitrate. Uptake of nitrate was relatively low and increased with increase in light intensity or when the culture medium was supplemented with sugar. Ammonium uptake was also affected by light. However, the rates of ammonium and nitrate uptake were sluggish. The fresh weight of plantlets increased with the presence of sugar in the media but the relative growth rate decreased. CO₂ enrichment did not increase ion uptake or growth. The nutrition of plantlets in culture was mainly heterotrophic, as indicated by the changes in titratable acidity, delta-C-13 values and (CO₂)-C-14 fixation.

Lin, E.D., Y.F. Liu, and Y. Li. 1997. Agricultural C cycle and greenhouse gas emission in China. *Nutrient Cycling in Agroecosystems* 49(1-3):295-299.

This paper assesses the production, consumption and store of organic carbon in the agricultural system, including all products from agriculture, of China. An estimation showed that about 90% of carbon uptake by agricultural systems would be emitted or returned to the atmosphere by several types from 1990 to 2000, others remain in durable agricultural products and soil. Even though the fixation rate is getting lower, generally speaking Chinese agriculture is a "sink" but not a "source" in respect to the atmospheric CO₂ and CH₄ concentrations in both the current period and that after few decades. China's Soil stores 12% of the whole soil carbon in the World. Considering the different global warming potentials (GWP), an approach to the country budgets of CO₂ and CH₄ has been presented based on the measurements in rice paddies and in the Tibet and Inner Mongolia grasslands.

Lin, G.H., J. Adams, B. Farnsworth, Y.D. Wei, B.D.V. Marino, and J.A. Berry. 1999. Ecosystem carbon exchange in two terrestrial ecosystem mesocosms under changing atmospheric CO₂ concentrations. *Oecologia* 119(1):97-108.

The ecosystem-level carbon uptake and respiration were measured under different CO₂ concentrations in the tropical rainforest and the coastal

desert of Biosphere 2, a large enclosed facility. When the mesocosms were sealed and subjected to step- wise changes in atmospheric CO₂ between daily means of 450 and 900 $\mu\text{mol mol}^{-1}$, net ecosystem exchange (NEE) of CO₂ was derived using the diurnal changes in atmospheric CO₂ concentrations. The step-wise CO₂ treatment was effectively replicated as indicated by the high repeatability of NEE measurements under similar CO₂ concentrations over a 12-week period. In the rainforest mesocosm, daily NEE was increased significantly by the high CO₂ treatments because of much higher enhancement of canopy CO₂ assimilation relative to the increase in the nighttime ecosystem respiration under high CO₂. Furthermore, the response of daytime NEE to increasing atmospheric CO₂, in this mesocosm was not linear, with a saturation concentration of 750 $\mu\text{mol mol}^{-1}$. In the desert mesocosm, a combination of a reduction in ecosystem respiration and a small increase in canopy CO₂ assimilation in the high CO₂ treatments also enhanced daily NEE. Although soil respiration was not affected by the short-term change in atmospheric CO₂ in either mesocosm, plant dark respiration was increased significantly by the high CO₂ treatments in the rainforest mesocosm while the opposite was found in the desert mesocosm. The high CO₂ treatments increased the ecosystem light compensation points in both mesocosms. High CO₂ significantly increased ecosystem radiation use efficiency in the rainforest mesocosm, but had a much smaller effect in the desert mesocosm. The desert mesocosm showed much lower absolute response in NEE to atmospheric CO₂ than the rainforest mesocosm, probably because of the presence of C-4 plants. This study illustrates the importance of large-scale experimental research in the study of complex global change issues.

Lin, G.H., J.R. Ehleringer, P.T. Rygielwicz, M.G. Johnson, and D.T. Tingey. 1999. Elevated CO₂ and temperature impacts on different components of soil CO₂ efflux in Douglas-fir terracosms. *Global Change Biology* 5(2):157-168.

Although numerous studies indicate that increasing atmospheric CO₂ or temperature data are available on the responses of three major components of soil respiration [i.e. rhizosphere respiration (root and root exudates), litter decomposition, and oxidation of soil organic matter] to different CO₂ and temperature conditions. In this study, we applied a dual stable isotope approach to investigate the impact of elevated CO₂ and elevated temperature on these components of soil CO₂ efflux in Douglas-fir terracosms. We measured both soil CO₂ efflux rates and the C-13 and O-18 isotopic compositions of soil CO₂ efflux in 12 sun-lit and environmentally controlled terracosms with 4- year-old Douglas fir seedlings and reconstructed forest soils under two CO₂ concentrations (ambient and 200 ppmv above ambient) and two air temperature regimes (ambient and 4 degrees C above ambient). The stable isotope data were used to estimate the relative contributions of different components to the overall soil CO₂ efflux. In most cases, litter decomposition was the dominant component of soil CO₂ efflux in this system, followed by rhizosphere respiration and soil organic matter oxidation. Both elevated atmospheric CO₂ concentration and elevated temperature stimulated rhizosphere respiration and litter decomposition. The oxidation of soil organic matter was stimulated only by increasing temperature. Release of newly fixed carbon as root respiration was the most responsive to elevated CO₂, while soil organic matter decomposition was most responsive to increasing temperature. Although some assumptions associated with this new method need to be further validated, application of this dual-isotope approach can provide new insights into the responses of soil carbon dynamics in forest ecosystems to future climate changes.

Lin, G.H., B.D.V. Marino, Y.D. Wei, J. Adams, F. Tubiello, and J.A. Berry. 1998. An experimental and modeling study of responses in ecosystems carbon exchanges to increasing CO₂ concentrations using a tropical rainforest mesocosm. *Australian Journal of Plant Physiology* 25(5):547-556.

The ecosystem carbon exchanges in the enclosed rainforest of Biosphere 2, an enclosed apparatus comprised of large synthetic ecosystems, were measured and modeled during the winter of 1995-1996 under different atmospheric CO₂ concentrations. On eight separate days, this mesocosm was exposed to various levels of CO₂ ranging from about 380 to 820 $\mu\text{mol mol}^{-1}$ daily mean and then sealed 24 hours for continuous measurements of ecosystem CO₂ fluxes. Our results indicated that net ecosystem carbon exchange in the mesocosm was enhanced by increasing CO₂ over the short periods studied (2-7 weeks), but, as expected from physiological studies, the response is not linear. The main effect of short-term CO₂ change was the enhancement of canopy CO₂ assimilation, while soil respiration was not affected by the atmospheric CO₂ concentration. The whole ecosystem radiation use efficiency was significantly higher under higher CO₂. The results of direct measurements were predicted well by a simple canopy model (the 'big-leaf' model) that incorporates current physiological understanding of the biochemistry of leaf photosynthesis. Validation of this model with a range of CO₂ and light levels indicates that it can be used with confidence to predict the responses of natural ecosystems to global climate change. Response of ecosystem processes to elevated CO₂ with relaxation time longer than a few weeks could not be resolved in this study, but longer-term closure experiments are planned to examine these processes.

Lin, W.H., K.Z. Bai, and T.Y. Kuang. 1999. Effects of elevated CO₂ and high temperature on single leaf and canopy photosynthesis of rice. *Acta Botanica Sinica* 41(6):624-628.

The increase of atmospheric CO₂ concentration is indisputable. In such condition, photosynthetic response of leaf is relatively well studied, while the comparison of that between single leaf and whole canopy is less emphasized. The stimulation of elevated CO₂ on canopy photosynthesis may be different from that on single leaf level. In this study, leaf and canopy photosynthesis of rice (*Oryza sativa* L.) were studied throughout the growing season. High CO₂ and temperature had a synergistic stimulation on single leaf photosynthetic rate until grain filling. Photosynthesis of leaf was stimulated by high CO₂, although the stimulation was decreased by higher temperature at grain filling stage. On the other hand, the stimulation of elevated CO₂ on canopy photosynthesis leveled off with time. Stimulation at canopy level disappeared by grain filling stage in both temperature treatments. Green leaf area index was not significantly affected by CO₂ at maturity, but greater in plants grown at higher temperature. Leaf nitrogen content decreased with the increase of CO₂ concentration although it was not statistically significant at maturity. Canopy respiration rate increased at flowering stage indicating higher carbon loss: Shading effect caused by leaf development reached maximum at flowering stage. The CO₂ stimulation on photosynthesis was greater in single leaf than in canopy. Since enhanced CO₂ significantly increased biomass of rice stems and panicles, increase in canopy respiration caused diminishment of CO₂

stimulation in canopy net photosynthesis. Leaf nitrogen in the canopy level decreased with CO₂ concentration and may eventually hasten CO₂ stimulation on canopy photosynthesis. Early senescence of canopy leaves in high CO₂ is also a possible cause.

Lin, W.H., L.H. Ziska, O.S. Namuco, and K. Bai. 1997. The interaction of high temperature and elevated CO₂ on photosynthetic acclimation of single leaves of rice in situ. *Physiologia Plantarum* 99(1):178-184.

Rice (*Oryza sativa* L. cv. IR72) was grown at three different CO₂ concentrations (ambient, ambient + 200 $\mu\text{mol mol}^{-1}$, ambient + 300 $\mu\text{mol mol}^{-1}$) at two different growth temperatures (ambient, ambient + 4 degrees C) from sowing to maturity to determine long-term photosynthetic acclimation to elevated CO₂ with and without increasing temperature. Single leaves of rice showed a cooperative enhancement of photosynthetic rate with elevated CO₂ and temperature during tillering, relative to the elevated CO₂ condition alone. However, after flowering, the degree of photosynthetic stimulation by elevated CO₂ was reduced for the ambient + 4 degrees C treatment. This increasing insensitivity to CO₂ appeared to be accompanied by a reduction in ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) activity and/or concentration as evidenced by the reduction in the assimilation (A) to internal CO₂ (C-1) response curve. The reproductive response (e.g. percent filled grains, panicle weight) was reduced at the higher growth temperature and presumably reflects a greater increase in floral sterility. Results indicate that while CO₂ and temperature could act synergistically at the biochemical level, the direct effect of temperature on floral development with a subsequent reduction in carbon utilization may change sink strength so as to limit photosynthetic stimulation by elevated CO₂, concentration.

Lincoln, D.E. 1993. The influence of plant carbon-dioxide and nutrient supply on susceptibility to insect herbivores. *Vegetatio* 104:273-280.

The carbon/nutrient ratio of plants has been hypothesized to be a significant regulator of plant susceptibility to leaf-eating insects. As rising atmospheric carbon dioxide stimulates photosynthesis, host plant carbon supply is increased and the accompanying higher levels of carbohydrates, especially starch, apparently 'dilute' the protein content of the leaf. When host plant nitrogen supply is limited, plant responses include increased carbohydrate accumulation, reduced leaf protein content, but also increased carbon-based defensive chemicals. No

change, however, has been observed in the concentration of leaf defensive allelochemicals with elevated carbon dioxide during host plant growth. Insect responses to carbon-fertilized leaves include increased consumption with little change in growth, or alternatively, little change in consumption with decreased growth, as well as enhanced leaf digestibility, reduced nitrogen use efficiency, and reduced fecundity. The effects of plant carbon and nutrient supply on herbivores appear to result, at least in part, from independent processes affecting secondary metabolism.

Lincoln, D.E., E.D. Fajer, and R.H. Johnson. 1993. Plant insect herbivore interactions in elevated CO₂ environments. *Trends in Ecology and Evolution* 8(2):64-68.

The increasing concentration of CO₂ in the atmosphere is expected to lead to global changes in the physical environment of terrestrial organisms. We are beginning to understand how these changes are transmitted into pervasive effects on the interactions between plants and their leaf-feeding insect herbivores. An elevated CO₂ atmosphere often stimulates plant carbon assimilation and growth and alters carbon allocation patterns. This, in turn, determines the quality of plants as resources for herbivorous insects. These 'quality' factors include: the concentrations of water, nitrogen and allelochemicals in host-plant leaves, and the toughness and starch and fiber content of leaf tissue. Because these parameters change in plants grown in enriched CO₂ environments, the doubled CO₂ levels anticipated for the next century will alter the dynamics of plant-insect herbivore interactions because herbivore consumption, growth and fitness are affected by the typically lower quality of plants grown under these conditions.

Lindhout, P., and G. Pet. 1990. Effects of CO₂ enrichment on young plant-growth of 96 genotypes of tomato (*Lycopersicon esculentum*). *Euphytica* 51(2):191-196.

The early growth of 96 genotypes of tomato was studied at 320 ppm CO₂ and at 750 ppm CO₂ in separate climate rooms. Plants were harvested at 40 and 55 days after sowing. Fresh and dry weights were determined. Large differences between genotypes were found for average plant fresh and dry weights and for relative growth rates. The average overall growth enhancement by CO₂ enrichment was 2.3. Two genotypes showed significant genotype x CO₂ interaction. The consequences of these results for tomato breeding are discussed.

Lindner, M., H. Bugmann, P. Lasch, M. Flechsig, and W. Cramer. 1997. Regional impacts of climatic change on forests in the state of Brandenburg, Germany. *Agricultural and Forest Meteorology* 84(1-2):123-135.

The changes of climate projected for the next century will most likely alter both the environment and the growth of forests. In a regional case study, the two forest gap models FORSKA and FORCLIM were applied to simulate vegetation composition using spatially differentiated site

data on a 10 x 10-km grid across the state of Brandenburg, Northeast Germany. Three climate scenarios were used to investigate the possible consequences of a changing climate on the environmental constraints of forest growth in the state. To test the: plausibility of the forest composition simulated by the two models, their results were compared with a map of potential natural vegetation as well as with each other. The simulation results show that both models respond realistically to the spatial variability of the environment and thus are suitable for regional applications. However, there are a number of quantitative differences between the simulation results of the models. FORSKA's strength is in simulating the ecological effects of the spatial variability of soil water holding capacity and nitrogen availability, whereas FORCLIM realistically portrays the climate-induced distribution limits of trees, e.g. beech (*Fagus sylvatica* L.). The study suggests that climatic change could have considerable consequences for future competitive relationships between species. According to the two models, the main driving force of vegetation change would be the increased occurrence of drought, which already today determines some distribution limits of tree species in Brandenburg. Under the strongest change of climate investigated in the present study, none of the species currently present on the landscape could grow any more in certain areas of Brandenburg. Conclusions are drawn concerning the importance of regional model applications for testing model performance under a wide variety of environmental conditions as well as for forest planning. Regional analyses of the impacts of climate change on forests may help to develop forest management strategies to cope with the risk of changing environmental conditions.

Lindner, M., R. Sievanen, and H. Pretzsch. 1997. Improving the simulation of stand structure in a forest gap model. *Forest Ecology and Management* 95(2):183-195.

There is currently great interest in improving the applicability of forest gap models to changing environmental conditions, in order to facilitate the assessment of possible impacts of climatic change on forest ecosystems. Moreover, for the development of mitigation strategies, it is necessary to include forest management options in the models. Both the simulation of transient effects of climatic change and of forest management regimes require a realistic representation of stand structure in gap models, since tree species respond to variations in stand density in characteristic ways, depending on their ecological strategies. In this study, we compared the effect of five different height growth functions that are sensitive to stand density on simulated stand structure of the FORSKA forest gap model. We used long term observation data from a beech thinning trial at Fabrikschleichach, Bavaria, to test the alternative functions. First, we compared simulation results of the original FORSKA model with measured stand development from 1870 to 1990. Whereas simulated stand level variables (e.g. biomass, mean diameter and height) showed good correspondence with observations, individual tree dimensions and simulated stand structure were quite unrealistic. After calibrating parameters of the height growth functions with data from a lightly thinned plot at Fabrikschleichach, we ran the model with data from a heavily thinned plot for validation. All five functions considerably improved the simulation of height/diameter relationships and stand structure. However, there were distinct differences between functions. The best correspondence with measurements was shown by a function which uses the relative radiation intensity in the centre of a tree crown as an indicator of the competition status of the tree. This function is rather simple and needs only two growth parameters, which can be derived for different functional types of species, according to their shade tolerance. With the new, flexible height growth function it should be possible to extend the applicability of gap models to more realistic simulation experiments including forest management and

natural disturbances. To our knowledge, this was the first attempt to employ long term forest observation data for the calibration and validation of a forest gap model. The results suggest that such data could be very useful in model testing and improvement. (C) 1997 Elsevier Science B.V.

Lindqvist, K., and R. Lignell. 1997. Intracellular partitioning of (CO₂)-C-14 in phytoplankton during a growth season in the northern Baltic. *Marine Ecology-Progress Series* 152(1-3):41-50.

During the phytoplankton succession in the northern Baltic in 1988, the distribution of (CO₂)-C-14 assimilated by algae into the main molecular groups [proteins, polysaccharides, lipids and low molar mass compounds (LMC)] after in situ Light (6 h) and Light to dark (20 h from ca 11:00 to 07:00 h) incubations at 2 m depth (just below maximum (CO₂)-C-14 fixation) was studied. By early May, the high winter levels of mineral nutrients were depleted from the water column, and in middle May the spring bloom predominated by large dinoflagellates (diatoms subdominant) peaked. The proportion of C-14 lipids was usually ca 15% of total (CO₂)-C-14 fixation, but it showed a distinct peak of 40% in middle May. The C-14-Lipid peak probably reflected nutrient stress of the algae, since nutrient (N+P) enrichment decreased this peak by 15 percentage points in 100 l enclosures. During the decline of the spring bloom, the proportion of C-14 proteins increased despite low ambient mineral N concentrations. In summer, the phytoplankton community (mainly small flagellates) consistently exhibited remarkable channelling of (CO₂)-C-14 into proteins (50 to 60%), which conformed to the low particulate organic C:N ratios of ca 7 (mol/mol). Summer upwellings, which introduced nutrients into the mixed layer, seemed to be accompanied by the highest proportions of C-14 proteins. The proportion of C-14 polysaccharides was usually ca 20%. After 6 h incubations, this proportion was significantly (on average 10 percentage points) higher than after 20 h, while the inverse was true with C-14 proteins, which reflected continuous nocturnal synthesis of proteins (enzymes) at the expense of polysaccharide storage products. In conclusion, the high proportions of algal C-14 proteins in summer suggest that phytoplankton is usually not physiologically N limited in our study area and provides N-sufficient food for herbivores, hence enabling high efficiency of algal C transfer to higher trophic levels.

Lindroth, R.L., G.E. Arteel, and K.K. Kinney. 1995. Responses of 3 saturniid species to paper birch grown under enriched CO₂ atmospheres. *Functional Ecology* 9(2):306-311.

1. Interactions between trees and tree-feeding insects are likely to shift under conditions of enriched atmospheric CO₂ owing to changes in foliar chemical composition. This study addressed the effects of CO₂-mediated changes in leaf chemistry on performance of three silkmoth (Saturniidae) species: cecropia (*Hyalophora cecropia*), luna (*Actias luna*) and polyphemus (*Antheraea polyphemus polyphemus*). 2. Growth under elevated CO₂ atmospheres decreased nitrogen concentrations (23%) but tripled starch and doubled condensed tannin concentrations, resulting in a marked increase in foliar carbon:nitrogen ratio. 3. Survival of first stadium larvae was marginally reduced when reared on high CO₂ leaves. 4. Development rates were prolonged, growth rates tended to decline,

consumption increased and food processing efficiencies decreased for fourth stadium larvae reared on high CO₂ leaves. The magnitude of responses varied among species. 5. Overall performance of these saturniid species, at least when feeding on birch, is predicted to decline under atmospheric CO₂ conditions anticipated for the next century.

Lindroth, R.L., S.M. Jung, and A.M. Feuer. 1993. Detoxication activity in the gypsy-moth - effects of host CO₂ and NO₃-availability. *Journal of Chemical Ecology* 19(2):357-367.

We investigated the effects of host species and resource (carbon dioxide, nitrate) availability on activity of detoxication enzymes in the gypsy moth, *Lymantria dispar*. Larvae were fed foliage from quaking aspen or sugar maple grown under ambient or elevated atmospheric CO₂, with low or high soil NO₃-availability. Enzyme solutions were prepared from larval midguts and assayed for activity of cytochrome P-450 monooxygenase, esterase, glutathione transferase, and carbonyl reductase enzymes. Activity of each enzyme system was influenced by larval host species, CO₂ or NO₃-availability, or an interaction of factors. Activity of all but glutathione transferases was highest in larvae reared on aspen. Elevated atmospheric CO₂ promoted all but transferase activity in larvae reared on aspen, but had little if any impact on enzyme activities of larvae reared on maple. High NO₃-availability enhanced activity of most enzyme systems in gypsy moths fed high CO₂ foliage, but the effect was less consistent for insects fed ambient CO₂ foliage. This research shows that gypsy moths respond biochemically not only to interspecific differences in host chemistry, but also to resource-mediated, intraspecific changes in host chemistry. Such responses are likely to be important for the dynamics of plant-insect interactions as they occur now and as they will be altered by global atmospheric changes in the future.

Lindroth, R.L., and K.K. Kinney. 1998. Consequences of enriched atmospheric CO₂ and defoliation for foliar chemistry and gypsy moth performance. *Journal of Chemical Ecology* 24(10):1677-1695.

Elevated concentrations of atmospheric CO₂ are likely to interact with other factors affecting plant physiology to alter plant chemical profiles and plant-herbivore interactions. We evaluated the independent and interactive effects of enriched CO₂ and artificial defoliation on foliar chemistry of quaking aspen (*Populus tremuloides*) and sugar maple (*Acer saccharum*), and the consequences of such changes for short-term performance of the gypsy moth (*Lymantria dispar*). We grew aspen and maple seedlings in ambient (similar to 360 ppm) and enriched (650 ppm) CO₂ environments at the University of Wisconsin Biotron. Seven weeks after budbreak, trees in half of the rooms were subjected to 50% defoliation. Afterwards, foliage was collected for chemical analyses, and feeding trials were conducted with fourth-stadium gypsy moths. Enriched CO₂ altered foliar levels of water, nitrogen, carbohydrates, and phenolics, and responses generally differed between the two tree species. Defoliation induced chemical changes only in aspen. We found no significant interactions between CO₂ and defoliation for levels of carbon-based defenses (phenolic glycosides and tannins). CO₂ treatment altered the performance of larvae fed aspen, but not maple, whereas defoliation had little effect on performance of insects. In general, results from this experimental system do not support the hypothesis that induction of carbon-based chemical defenses, and

attendant effects on insects, will be stronger in a CO₂-enriched world.

Lindroth, R.L., K.K. Kinney, and C.L. Platz. 1993. Responses of deciduous trees to elevated atmospheric CO₂ - productivity, phytochemistry, and insect performance. *Ecology* 74(3):763-777.

Although rising levels of atmospheric carbon dioxide are expected to directly affect forest ecosystems, little is known of how specific ecological interactions will be modified. This research evaluated the effects of enriched CO₂ on the productivity and phytochemistry of forest trees and performance of associated insects. Our experimental system consisted of three tree species (quaking aspen [*Populus tremuloides*], red oak [*Quercus rubra*], sugar maple [*Acer saccharum*]) that span a range from fast to slow growing, and two species of leaf-feeding insects (gypsy moth [*Lymantria dispar*] and forest tent caterpillar [*Malacosoma disstria*]). Carbon-nutrient balance theory provided a framework for tests of three hypotheses; in response to enriched CO₂: (1) relative increases in tree growth rates will be greatest for aspen and least for maple, (2) relative decreases in protein and increases in carbon-based compounds will be greatest for aspen and least for maple, and (3) relative reductions in performance will be greatest for insects fed aspen and least for insects fed maple. We grew 1-yr-old seedlings for 60 d under ambient (385 ± 5 μL/L) or elevated (642 ± 2 μL/L) CO₂ regimes at the University of Wisconsin Biotron. After 50 d, we conducted feeding trials with penultimate-instar gypsy moth and forest tent caterpillars. After 60 d, a second set of trees was harvested and partitioned into root, stem, and leaf tissues. We subsequently analyzed leaf material for a variety of compounds known to affect performance of insect herbivores. In terms of actual dry-matter production, aspen responded the most to enriched CO₂ atmospheres whereas maple responded the least. Proportional growth increases (relative to ambient plants), however, were highest for oak and least for maple. Effects of elevated CO₂ on biomass allocation patterns differed among the three species; root-to-shoot ratios increased in aspen, decreased in oak, and did not change in maple. Enriched CO₂ altered concentrations of primary and secondary metabolites in leaves, but the magnitude and direction of effects were species-specific. Aspen showed the largest change in storage carbon compounds (starch), whereas maple experienced the largest change in defensive carbon compounds (condensed and hydrolyzable tannins). Consumption rates of insects fed high-CO₂ aspen increased dramatically, but growth rates declined. The two species of insects differed in response to oak and maple grown under enriched CO₂. Gypsy moths grew better on high-CO₂ Oak, whereas forest tent caterpillars were unaffected; tent caterpillars tended to grow less on high-CO₂ maple, whereas gypsy moths were unaffected. Changes in insect performance parameters were related to changes in foliar chemistry. Responses of plants and insects agreed with some, but not all, of the predictions of carbon-nutrient balance theory. This study illustrates that tree productivity and chemistry, and the performance of associated insects, will change under CO₂ atmospheres predicted for the next century. Changes in higher level ecological processes, such as community structure and nutrient cycling, are also implicated.

Lindroth, R.L., S. Roth, E.L. Kruger, J.C. Volin, and P.A. Koss. 1997. CO₂-mediated changes in aspen chemistry: Effects on gypsy moth performance and susceptibility to virus. *Global Change Biology* 3(3):279-289.

We investigated the effects of long-term CO₂ enrichment on foliar chemistry of quaking aspen (*Populus tremuloides*) and the consequences of chemical changes for performance of the gypsy moth (*Lymantria dispar*) and susceptibility of the gypsy moth to a nucleopolyhedrovirus (NPV). Foliage was collected from outdoor open-top chambers and fed to insects in a quarantine rearing facility. Under enriched CO₂, levels of leaf nitrogen declined marginally, levels of starch and phenolic glycosides did not change, and levels of condensed tannins increased. Long-term bioassays revealed reduced growth (especially females), prolonged development and increased consumption in larvae fed high-CO₂ foliage but no significant differences in final pupal weights or female fecundity. Short-term bioassays showed weaker, and sex-specific, effects of CO₂ treatment on larval performance. Correlation analyses revealed strong, negative associations between insect performance and phenolic glycoside concentrations, independent of CO₂ treatment. Larval susceptibility to NPV did not differ between CO₂ treatments, suggesting that effects of this natural enemy on gypsy moths are buffered from CO₂-induced changes in foliar chemistry. Our results emphasize that the impact of enriched CO₂ on plant-insect interactions will be determined not only by how concentrations of plant compounds are altered, but also by the relevance of particular compounds for insect fitness. This work also underscores the need for studies of genetic variation in plant responses to enriched CO₂ and long-term population-level responses of insects to CO₂-induced changes in host quality.

Linker, R., I. Seginer, and P.O. Gutman. 1998. Optimal CO₂ control in a greenhouse modeled with neural networks. *Computers and Electronics in Agriculture* 19(3):289-310.

CO₂ enrichment in warm climates requires a delicate balance between the need to ventilate and the desire to enrich. Model-based optimization can achieve this balance, but requires reliable models of the greenhouse environment and of the crop response. This study assumes that the crop response is known, and focuses on the greenhouse model. Neural network greenhouse models were trained using data collected over two summer months in a small greenhouse. The models were reduced to minimum size, by predicting separately the temperature and CO₂ concentration, and by eliminating any unessential input. The resulting models not only fit the data well, they also seem qualitatively correct, and produce reasonable optimization results. Using these models, the effect of evaporative cooling on extending the enrichment duration is demonstrated. (C) 1998 Elsevier Science B.V. All rights reserved.

Lippert, M., K.H. Haberle, K. Steiner, H.D. Payer, and K.E. Rehfuess. 1996. Interactive effects of elevated CO₂ and O₃ on photosynthesis and biomass production of clonal 5-year-old Norway spruce [*Picea abies* (L.) Karst] under different nitrogen nutrition and irrigation treatments. *Trees-Structure and Function* 10(6):382-392.

To study the: single and combined effects of elevated carbon dioxide (CO₂), ozone (O₃), nitrogen nutrition, and water supply on photosynthetic gas exchange and biomass accumulation of Norway

spruce, a four-factorial experiment was conducted in closed environmental chambers. Each factor was applied at two levels: (i) ambient and elevated (ambient + 200 $\mu\text{mol l}^{-1}$) CO_2 , (ii) 20 and 80 nl l^{-1} O-3, (iii) low and high nitrogen fertilization, and (iv) a well watered and a drought treatment. Neither elevated O-3 nor CO_2 significantly changed stomatal conductances of spruce needles. Adverse effects of elevated O-3 on photosynthetic parameters such as net assimilation rate and carboxylation efficiency occurred only when the plants were well watered and in a good nutritional status. After 6 weeks enhanced atmospheric CO_2 resulted in increased net assimilation rates provided that nutrition was well balanced and plants were well watered. Acclimation processes became apparent and are interpreted as a consequence of sink regulation. While O-3 effects were apparent only in biomass of 1-year-old plant material, elevated CO_2 resulted in higher biomass of the buds expanding during the exposure and increased root biomass significantly. Above- and below-ground biomass were strongly influenced by the water and nutrition treatments.

Lippert, M., K. Steiner, T. Pfirrmann, and H.D. Payer. 1997. Assessing the impact of elevated O-3 and CO_2 on gas exchange characteristics of differently K supplied clonal Norway spruce trees during exposure and the following season. *Trees-Structure and Function* 11(5):306-315.

Well-supplied and K-deficient 4-year-old clonal Norway spruce trees were exposed to combinations of two levels of ozone (20 and 80 nl l^{-1}) O-3 and carbon dioxide (350 and 750 $\mu\text{mol l}^{-1}$) CO_2 to study the effects of possible future climate factors on gas exchange characteristics. The fumigation was performed in environmental chambers for a complete growing season. After the exposure, plants were cultivated outdoors to investigate possible recovery and delayed effects. During the exposure 1-year-old needles responded to the 80 nl l^{-1} O-3 treatment by a sharp but transient decrease of both apparent carboxylation efficiency (CE) and maximum photosynthetic capacity ($A(2500)$). Elevated CO_2 also reduced CE and $A(2500)$. The effect became stronger in the course of the exposure and was accompanied by decreases of N and P as well as chlorophyll contents. In case of K deficiency, the acclimation response of current-year needles was even more pronounced reflecting lower sink capacities for carbon metabolites. The joint application of elevated O-3 and CO_2 resulted in the lowest values of gas exchange parameters and chlorophyll contents. At the beginning of the growing season after the exposure and under outdoor conditions, all these treatment effects disappeared in the needles which had developed during the fumigation. In the course of the development of the new flush, however, the well-supplied 1-year-old needles which had been treated with 80 nl l^{-1} O-3 and 350 $\mu\text{mol l}^{-1}$ CO_2 in the year before, exhibited a sharp decline of CE and $A(2500)$. Simultaneously, chlorotic mottle and bands developed. These delayed symptoms are discussed in the context of the previously published "memory" effect for O-3 (Sandermann et al. 1989). Additionally, evidence is presented that shoot development is altered in plants which had been exposed to elevated O-3.

Liu, S.Y., and R.O. Teskey. 1995. Responses of foliar gas-exchange to long-term elevated CO_2 concentrations in mature loblolly-pine trees. *Tree*

Physiology 15(6):351-359.

Branches of field-grown mature loblolly pine (*Pinus taeda* L.) trees were exposed for 2 years (1992 and 1993) to ambient or elevated CO_2 concentrations (ambient + 165 $\mu\text{mol mol}^{-1}$) or ambient + 330 $\mu\text{mol mol}^{-1}$ CO_2). Exposure to elevated CO_2 concentrations enhanced rates of net photosynthesis (P-n) by 53-111% compared to P-n of foliage exposed to ambient CO_2 . At the same CO_2 measurement concentration, the ratio of intercellular to atmospheric CO_2 concentration (C-i/C-a) and stomatal conductance to water vapor did not differ among foliage grown in an ambient or enriched CO_2 concentration. Analysis of the relationship between P-n and C-i indicated no significant change in carboxylation efficiency of ribulose-1,5- bisphosphate carboxylase/oxygenase during growth in elevated CO_2 concentrations. Based on estimates derived from P-n/C-i curves, there were no apparent treatment differences in dark respiration, CO_2 compensation point or P-n at the mean C-i. In 1992, foliage in the three CO_2 treatments yielded similar estimates of CO_2 -saturated P-n (P-max), whereas in 1993, estimates of P-max were higher for branches grown in elevated CO_2 than in ambient CO_2 . We conclude that field-grown loblolly pine trees do not exhibit downward acclimation of leaf-level photosynthesis in their long-term response to elevated CO_2 concentrations.

Liu, Y.T., T.M. Karnauchow, K.F. Jarrell, D.L. Balkwill, G.R. Drake, D. Ringelberg, R. Clarno, and D.R. Boone. 1997. Description of two new thermophilic *Desulfotomaculum* spp., *Desulfotomaculum putei* sp. nov, from a deep terrestrial subsurface, and *Desulfotomaculum luciae* sp. nov, from a hot spring. *International Journal of Systematic Bacteriology* 47(3):615-621.

Six strains of thermophilic, endospore-forming, sulfate-reducing bacteria were enriched and isolated from 2.7 km below the earth's surface in the Taylorsville Triassic Basin in Virginia. The cells of these strains were motile rods that were 1 to 1.1 μm in diameter and 2 to 5 μm long. The cells grew by oxidizing H₂, formate, methanol (weakly), lactate (incompletely, to acetate and CO_2), or pyruvate (incompletely) while reducing sulfate to sulfide; acetate did not serve as a catabolic substrate. Thiosulfate or sulfite could replace sulfate as an electron acceptor. The results of a phylogenetic analysis of the 16S rRNA gene indicated that these strains belong to the genus *Desulfotomaculum*, but are distinct from previously described *Desulfotomaculum* species. Thus, we propose a new species, *Desulfotomaculum putei*, for them, with strain TH-11 (= SMCC W459) as the type strain. The results of our phylogenetic analysis also indicated that strain SLTT, which was isolated from a hot spring and has been described previously (T. M. Karnauchow, S. F. Koval, and K. F. Jarrell, *Syst. Appl. Microbiol.*, 15:296-310, 1992), is also a member of the genus *Desulfotomaculum* and is distinct from other species in this genus. We therefore propose the new species *Desulfotomaculum luciae* for this organism; strain SLT (= SMCC W644) is the type strain of *D. luciae*.

Livingston, N.J., D. Whitehead, F.M. Kelliher, Y.P. Wang, J.C. Grace, A.S. Walcroft, J.N. Byers, T.M. McSeveny, and P. Millard. 1998. Nitrogen allocation and carbon isotope fractionation in relation to intercepted radiation and position in a young *Pinus radiata* D. Don tree.

The three dimensional distribution of intercepted radiation, intercellular CO₂ concentration (C-i) and late summer needle nitrogen (N) concentration were determined at the tips of all 54 branches in a 6.2-m-tall *Pinus radiata* D, Don tree growing in a New Zealand plantation. Measurements included above- and below-canopy irradiance, leaf stable carbon isotopic composition ($\delta^{13}\text{C}$) and tree canopy architecture. The radiation absorption component of the model, MAESTRO, was tested on site and then used to determine the branch tip distribution of intercepted radiation. We hypothesized that in branch tip needles: (i) the allocation of nitrogen and other nutrients would be closely associated with the distribution of intercepted radiation, reflecting carbon gain optimization theory, and (ii) C-i would predominantly reflect changes in photosynthetic rate (A) rather than stomatal conductance (g(s)), indicating that the increase in A for a given increase in N concentration was larger than the corresponding increase in g(s). Needle nitrogen concentration was poorly related to intercepted radiation, regardless of the period over which the latter was calculated. At a given height, there was a large azimuthal variation in intercepted radiation but N concentration was remarkably uniform around the tree canopy. There was, however, a linear and positive correspondence between N concentration and $\delta^{13}\text{C}$ and needle height above ground ($r(2) = 0.73$ and 0.68 , respectively). The very strong linear correspondence between N concentration and C-i ($r(2) = 0.71$) was interpreted, using gas exchange measurements, as supporting our second hypothesis. Recognizing the strong apical control in *P. radiata* and possible effects of leaf nitrogen storage in an evergreen species, we propose that the tree leader must have constituted a very strong carbon sink throughout the growing season, and that the proximity of branch tip needles to the leader affected their photosynthetic capacity and nutrient concentration, independent of intercepted radiation. This implies an integrated internal determination of resource allocation within the tree and challenges the current convention that resources are optimally distributed according to the profile of intercepted radiation.

Lloyd, J. 1999. The CO₂ dependence of photosynthesis, plant growth responses to elevated CO₂ concentrations and their interaction with soil nutrient status. II. Temperate and boreal forest productivity and the combined effects of increasing CO₂ concentrations and increased nitrogen deposition at a global scale. *Functional Ecology* 13(4):439-459.

1. Appropriate rates of carbon acquisition by temperate and boreal forests are re-evaluated. Based on continental-scale forestry data it is suggested that the productivity of temperate and boreal forests has been overestimated previously. 2. Using these values, a model of the integrated response of ecosystems to carbon dioxide concentration and soil nitrogen availability is presented. The model does not assume constant C/N ratios in plant or soil and considers effects of increases in atmospheric CO₂ concentrations and nitrogen deposition separately or together. 3. For temperate-zone forests a co-occurrence of a CO₂ increase and nitrogen deposition doubles the increase in net primary productivity and carbon sequestration that would be the case for nitrogen deposition occurring on its own. Considered separately, the effect of the atmospheric CO₂ increase is less than even moderate rates of anthropogenic N deposition for temperate or boreal forests. By contrast, for tropical forests, the atmospheric CO₂ increase is sufficient to induce large rates of carbon accumulation in plants and soil. 4. Application of the model at the global scale suggests large localized sinks for CO₂ in either tropical rain forests or in forested or grassland areas of Europe and North America where appreciable N deposition occurs. Overall, the

model suggests a terrestrial sink owing to CO₂ fertilization and N deposition of about 0.2 Pmol C per year. About half of this is in the mid-latitudes of the northern hemisphere and about half in the tropics.

Lloyd, J. 1999. Current perspectives on the terrestrial carbon cycle. *Tellus Series B-Chemical and Physical Meteorology* 51(2):336-342.

Over the last 5 or so years, there have been significant advances in the understanding of the current role of the terrestrial biosphere in the global carbon cycle, especially in terms of how pools and fluxes are affected by variations in climate (including interannual variability as well as longer-term climate change), increases in atmospheric CO₂ concentrations and changed rates of atmospheric nitrogen deposition. At the same time, significant advances have been made in terms of both direct measurement of ecosystem productivity and in an understanding of the key underlying mechanisms modulating carbon fluxes from terrestrial systems. A brief synopsis of these advances is the subject of this paper.

Loaiza, J., and M. Cantwell. 1997. Postharvest physiology and quality of cilantro (*Coriandrum sativum* L). *Hortscience* 32(1):104-107.

Respiration rates of freshly harvested cilantro were moderately high (CO₂ at 15 to 20 $\mu\text{L} \cdot \text{g}^{-1} \cdot \text{h}^{-1}$) and ethylene production rates were low ($<0.2 \text{ nL} \cdot \text{g}^{-1} \cdot \text{h}^{-1}$) at 5 degrees C and were typical of green leafy tissues. Cilantro stored in darkness at a range of temperatures in air or controlled atmospheres was evaluated periodically for visual quality, decay, aroma, off-odor, color, and chlorophyll content. Cilantro stored in air at 0 degrees C had good visual quality for 18 to 22 days, while at 5 and 7.5 degrees C good quality was maintained for about 14 and 7 days, respectively. An atmosphere of air plus 5% or 9% CO₂ extended the shelf-life of cilantro stored at 7.5 degrees C to about 14 days. Quality of cilantro stored in 3% O₂ plus CO₂ was similar to that stored in air plus CO₂. Atmospheres enriched with 9% to 10% CO₂ caused dark lesions after 18 days; 20% CO₂ caused severe injury after 7 days. Although visual quality could be maintained for up to 22 days, typical cilantro aroma decreased notably after 14 days, regardless of storage conditions.

Loats, K.V., and J. Rebeck. 1999. Interactive effects of ozone and elevated carbon dioxide on the growth and physiology of black cherry, green ash, and yellow- poplar seedlings. *Environmental Pollution* 106(2):237-248.

Potted seedlings of black cherry (*Prunus serotina* Ehrh.) (BC), green ash (*Fraxinus pennsylvanica* Marsh.) (GA), and yellow- poplar (*Liriodendron tulipifera* L.) (YP) were exposed to one of the four treatments: (1) charcoal-filtered air (CF) at ambient CO₂ (control); (2) twice ambient O₃ (2XO(3)); (3) twice ambient CO₂ (650 µl l⁻¹) plus CF air (2xCO(2)); or (4) twice ambient CO₂ (650 µl l⁻¹) plus twice ambient O₃ (2XCO(2)+2XO(3)). The treatments were duplicated in eight continuously stirred tank reactors for 10 weeks. Gas exchange was measured during the last 3 weeks of treatment and all seedlings were destructively harvested after 10 weeks. Significant interactive effects of O₃ and CO₂ on the gas exchange of all three species were limited. The effects of elevated CO₂ and O₃, singly and combined, on light-saturated net photosynthesis (A(max)) and stomatal conductance (g(s)) were inconsistent across species. In all three species, elevated O₃ had no effect on g(s). Elevated CO₂ significantly increased A(max) in GA and YP foliage, and decreased g(s) in YP foliage. Maximum carbon exchange rates and quantum efficiencies derived from light-response curves increased, while compensation irradiance and dark respiration decreased in all three species when exposed to 2xCO(2). Elevated O₃ affected few of these parameters but any change that was observed was opposite to that from exposure to 2xCO(2)-air. Interactive effects of CO₂ and O₃ on light-response parameters were limited. Carboxylation efficiencies, derived from CO₂-response curves (A/C-i curves) decreased only in YP foliage exposed to 2xCO(2)-air. In general, growth was significantly stimulated by 2xCO(2) in all three species; though there were few significant growth responses following exposure to 2xO(3) or the combination of 2xCO(2) plus 2xO(3). Results indicate that responses to interacting stressors such as O₃ and CO₂ are species specific. (C) 1999 Published by Elsevier Science Ltd. All rights reserved.

Lockwood, J.G. 1999. Is potential evapotranspiration and its relationship with actual evapotranspiration sensitive to elevated atmospheric CO₂ levels? *Climatic Change* 41(2):193-212.

The possibility is examined that potential evapotranspiration values may be sensitive to changes in atmospheric carbon dioxide content. Enhanced levels of atmospheric CO₂ increase water use efficiency of vegetation by improving growth rates and suppressing transpiration per unit leaf area. Highly cultivated crops without water or nutrient constraints are able to show the greatest growth improvements. In many natural or semi-natural ecosystems, under enhanced atmospheric CO₂ concentrations, limits on the availability of soil nutrients severely constrains the possibility of improvements in growth and significant increases in leaf area index that could compensate for a decrease in transpiration per unit leaf area. Thus, in many natural or semi-natural ecosystems, which often form water gathering grounds in river basins, enhanced levels of CO₂ will suppress transpiration and perhaps increase the proportion of precipitation that forms runoff or ground water. In low vegetation covers, such as grassland, the rates of transpiration and also evaporation from canopies that are wet after rainfall (interception loss) are very similar. In these canopies, evapotranspiration is unlikely to be significantly increased by small increases in leaf area index. It is suggested that the suppression of potential evapotranspiration by enhanced CO₂ levels will be small, but that actual transpiration from

tall, slow growing vegetation covers may be significantly suppressed. Thus for some vegetation covers the relationship between actual and potential evapotranspiration may be sensitive to CO₂ levels. If this is so, it could be of importance to many water balance calculations. The suppression of evapotranspiration by enhanced CO₂ levels will be most noticeable in dry climates where interception loss is insignificant and largely masked in very wet climates where a large proportion of evapotranspiration consists of interception loss.

Loehle, C. 1995. Anomalous responses of plants to CO₂ enrichment. *Oikos* 73(2):181-187.

A number of unexplained responses of plants to CO₂ enrichment have been observed. These anomalies can be explained on the basis of growth analysis of whole plants. Some plants may fail to respond to enrichment because they are long-lived and have conservative growth responses or come from impoverished habitats. Apparent (but not real) acclimation to CO₂ enrichment might be observed if only part of the growth curve over the life of a perennial is studied. The apparent increased efficiency of nitrogen use may merely be an increase in storage of nonstructural carbohydrate. A model analysis of these effects is presented. Discrepancies among species in relative responses of different plant parts are argued to be largely a function of where the plant typically stores nonstructural carbohydrates, which itself is a function of plant growth stage. Thus, a closer consideration of plant growth strategies and growth partitioning is needed to properly interpret results of CO₂ enrichment studies.

Loiseau, P., and J.F. Soussana. 1999. Elevated [CO₂], temperature increase and N supply effects on the accumulation of below-ground carbon in a temperate grassland ecosystem. *Plant and Soil* 212(2):123-134.

The effects of elevated [CO₂] (700 µl l⁻¹) [CO₂] and temperature increase (+3 degrees C) on carbon accumulation in a grassland soil were studied at two N-fertiliser supplies (160 and 530 kgN ha⁻¹ year⁻¹) in a long-term experiment (2.5 years) on well established ryegrass swards (*Lolium perenne* L.) supplied with the same amounts of irrigation water. For all experimental treatments, the C:N ratio of the top soil organic matter fractions increased with their particle size. Elevated CO₂ concentration increased the C:N ratios of the below-ground phytomass and of the macro-organic matter. A supplemental fertiliser N or a 3 degrees C increase in elevated [CO₂] reduced it. At the last sampling date, elevated [CO₂] did not affect the C:N ratio of the soil organic matter fractions, but increased significantly the accumulation of roots and of macro- organic matter above 200 µm (MOM). An increased N-fertiliser supply stimulated the accumulation of the non harvested plant phytomass and of the OM between 2 and 50 µm, without positive effect on the macro-organic matter > 200 µm. Elevated [CO₂] increased C accumulation in the OM fractions above 50 µm by +2.1 tC ha⁻¹, on average, whereas increasing the fertiliser N supply led to an average supplemental accumulation of +0.8 tC ha⁻¹. There was no significant effect of a 3 degrees C temperature increase under elevated [CO₂] on C accumulation in the OM fractions above 50 µm.

Loiseau, P., and J.F. Soussana. 1999. Elevated [CO₂], temperature increase and N supply effects on the turnover of below-ground carbon in a temperate grassland ecosystem. *Plant and Soil* 210(2):233-247.

The effects of elevated [CO₂] (700 μ l l⁻¹ CO₂) and temperature increase (+3 degrees C) on carbon turnover in grassland soils were studied during 2.5 years at two N fertiliser supplies (160 and 530 kg N ha⁻¹ y⁻¹) in an experiment with well-established ryegrass swards (*Lolium perenne*) supplied with the same amounts of irrigation water. During the growing season, swards from the control climate (350 μ l l⁻¹ [CO₂] at outdoor air temperature) were pulse labelled by the addition of (CO₂)-C-13. The elevated [CO₂] treatments were continuously labelled by the addition of fossil-fuel derived CO₂ (C-13 of -40 to -50 parts per thousand). Prior to the start of the experimental treatments, the carbon accumulated in the plant parts and in the soil macro-organic matter ('old' C) was at -32 parts per thousand. During the experiment, the carbon fixed in the plant material ('new' C) was at -14 and -54 parts per thousand in the ambient and elevated [CO₂] treatments, respectively. During the experiment, the C-13 isotopic mass balance method was used to calculate, for the top soil (0-15 cm), the carbon turnover in the stubble and roots and in the soil macro-organic matter above 200 μ m (MOM). Elevated [CO₂] stimulated the turnover of organic carbon in the roots and stubble and in the MOM at N+, but not at N-. At the high N supply, the mean replacement time of 'old' C by 'new' C declined in elevated, compared to ambient [CO₂], from 18 to 7 months for the roots and stubble and from 25 to 17 months for the MOM. This resulted from increased rates of 'new' C accumulation and of 'old' C decay. By contrast, at the low N supply, despite an increase in the rate of accumulation of 'new' C, the soil C pools did not turnover faster in elevated [CO₂], as the rate of 'old' C decomposition was reduced. A 3 degrees C temperature increase in elevated [CO₂] decreased the input of fresh C to the roots and stubble and enhanced significantly the exponential rate for the 'old' C decomposition in the roots and stubble. An increased fertiliser N supply reduced the carbon turnover in the roots and stubble and in the MOM, in ambient but not in elevated [CO₂]. The respective roles for carbon turnover in the coarse soil OM fractions, of the C:N ratio of the litter, of the inorganic N availability and of a possible priming effect between C- substrates are discussed.

Long, S.P., N.R. Baker, and C.A. Raines. 1993. Analyzing the responses of photosynthetic CO₂ assimilation to long-term elevation of atmospheric CO₂ concentration. *Vegetatio* 104:33-45.

Understanding how photosynthetic capacity acclimates when plants are grown in an atmosphere of rising CO₂ concentrations will be vital to the development of mechanistic models of the response of plant productivity to global environmental change. A limitation to the study of acclimation is the small amount of material that may be destructively harvested from long-term studies of the effects of elevation of CO₂ concentration. Technological developments in the measurement of gas exchange, fluorescence and absorption spectroscopy, coupled with theoretical developments in the interpretation of measured values now allow detailed analyses of limitations to photosynthesis *in vivo*. The use of leaf chambers with Ulbricht integrating spheres allows separation of

change in the maximum efficiency of energy transduction in the assimilation of CO₂ from changes in tissue absorbance. Analysis of the response of CO₂ assimilation to intercellular CO₂ concentration allows quantitative determination of the limitation imposed by stomata, carboxylation efficiency, and the rate of regeneration of ribulose 1:5 biphosphate. Chlorophyll fluorescence provides a rapid method for detecting photoinhibition in heterogeneously illuminated leaves within canopies in the field. Modulated fluorescence and absorption spectroscopy allow parallel measurements of the efficiency of light utilisation in electron transport through photosystems I and II *in situ*.

Long, S.P., and B.G. Drake. 1991. Effect of the long-term elevation of CO₂ concentration in the field on the quantum yield of photosynthesis of the C3 sedge, *Scirpus olneyi*. *Plant Physiology* 96(1):221-226.

CO₂ concentration was elevated throughout 3 years around stands of the C3 sedge *Scirpus olneyi* on a tidal marsh of the Chesapeake Bay. The hypothesis that tissues developed in an elevated CO₂ atmosphere will show an acclimatory decrease in photosynthetic capacity under light-limiting conditions was examined. The absorbed light quantum yield of CO₂ uptake (ϕ_i -abs) and the efficiency of photosystem II photochemistry were determined for plants which had developed in open top chambers with CO₂ concentrations in air of 680 micromoles per mole, and of 351 micromoles per mole as controls. An Ulbricht sphere cuvette incorporated into an open gas exchange system was used to determine ϕ_i -abs and a portable chlorophyll fluorimeter was used to estimate the photochemical efficiency of photosystem II. When measured in an atmosphere with 10 millimoles per mole O₂ to suppress photorespiration, shoots showed a ϕ_i -abs of 0.093 $\pm$ 0.003, with no statistically significant difference between shoots grown in elevated or control CO₂ concentrations. Efficiency of photosystem II photochemistry was also unchanged by development in an elevated CO₂ atmosphere. Shoots grown and measured in 680 micromoles per mole of CO₂ in air showed a ϕ_i -abs of 0.078 $\pm$ 0.004 compared with 0.065 $\pm$ 0.003 for leaves grown and measured in 351 micromoles per mole CO₂ in air; a highly significant increase. In accordance with the change in ϕ_i -abs, the light compensation point of photosynthesis decreased from 51 $\pm$ 3 to 31 $\pm$ 3 micromoles per square meter per second for stems grown and measured in 351 and 680 micromoles per mole of CO₂ in air, respectively. The results suggest that even after 3 years of growth in elevated CO₂, there is no evidence of acclimation in capacity for photosynthesis under light-limited conditions which would counteract the stimulation of photosynthetic CO₂ uptake otherwise expected through decreased photorespiration.

Long, S.P., and P.R. Hutchin. 1991. Primary production in grasslands and coniferous forests with climate change - an overview. *Ecological Applications* 1(2):139-156.

In energy terms primary production is the driving step of the global carbon cycle. To predict the interaction of ecosystems with the "greenhouse" effect, it is necessary to understand how primary production, consumption, and decomposition will respond to climate change. Most estimates of primary production have been made by extrapolation from measured standing crops. For grasslands we show this approach to be seriously in error. Even where detailed studies of

turnover and belowground production have been undertaken, errors are invariably high, severely limiting the value of models based on correlation of climate with measured production. Detailed information is available on the responses of individual plant processes to individual climatic variables at the leaf, plant, and stand level, giving potential for a more mechanistic approach in modelling. This approach is limited by lack of information on multivariate interactions and on some key physiological processes, and by uncertainties in scaling up to populations and communities. Despite this, some important insights to possible community responses, particularly those of C3 and C4 types, may be gained from knowledge of responses at the plant level and below. This review outlines the expected character of climate change in grasslands and coniferous forests. Knowledge of the responses of different physiological processes underlying production to individual aspects of climate change is considered, and its implications for higher levels of organization are discussed. Although feasible, mechanistic models of production compound the errors associated with individual process responses with uncertainties surrounding interaction and scaling up, and result in very large errors in any prediction of response to climate change. We conclude that there is insufficient information to predict accurately the response of primary production to climate change. The key processes for which information is inadequate and the parameters that have meaning at different scales need to be identified. Of particular promise is the approach of predicting production from light interception and conversion efficiency.

Lootens, P., and J. Heursel. 1998. Irradiance, temperature, and carbon dioxide enrichment affect photosynthesis in *Phalaenopsis* hybrids. *Hortscience* 33(7):1183-1185.

The short-term effects of photosynthetic photon flux (PPF), day/night temperatures and CO2 concentration on CO2 exchange were determined for two *Phalaenopsis* hybrids. At 20 degrees C, the saturating PPF for photosynthesis was 180 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. At this PPF and ambient CO2 level (380 $\mu\text{L}\cdot\text{L}^{-1}$), a day/night temperature of 20/15 degrees C resulted in the largest daily CO2 uptake. Higher night temperatures probably increased the respiration rate and lowered daily CO2 uptake in comparison with 20/15 degrees C. An increase in the CO2 concentration from 380 to 950 $\mu\text{L}\cdot\text{L}^{-1}$ increased daily CO2 uptake by 82%.

Lord, D., S. Morissette, and J. Allaire. 1993. Influence of light-intensity, nocturnal air-temperature and carbon-dioxide levels on greenhouse black spruce seedlings (*Picea mariana*). *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 23(1):101-110.

Growth of containerized black spruce seedlings grown in greenhouses was studied in relation to factors known to influence plant growth. Artificial light intensity (3.80 and 72.04 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) and night air temperature (5, 10, 12.5, 15, and 20-degrees-C) were considered in a first experiment and artificial light intensity (4.24 and 59.57 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) and CO2 air concentration (ambient and 1000 $\mu\text{L}\cdot\text{L}^{-1}$) in a second one. Higher light intensity and CO2 enrichment increased dry

biomass of seedlings as well as growth in height and stem diameter. Both factors similarly enhanced the last two parameters since height/diameter ratios showed little variation among treatments. Reducing night air temperature down to 10-degrees-C did not significantly influence height growth nor biomass increase when high intensity light was provided. Lower light intensity raised the threshold to 12.5-degrees-C. Shoot height, diameter, and dry biomass as well as the number of branches and buds per millimeter were strongly reduced by a 5-degrees-C night air temperature. High intensity light enhanced growth of containerized black spruce seedlings more than CO2 enrichment or a 5-degrees-C night air temperature. When used simultaneously, these growth enhancing factors had a synergistic effect during most of the treatment period; thereafter, the effect became partially additive. The relative growth rate peaked at the onset of exponential shoot growth and decreased after this point. However, the enhancing factors were still efficient since absolute growth differences between seedlings grown under the most-favorable conditions and controls kept increasing. The faster growing pace imposed by these growth enhancing conditions during the treatment period was maintained over the entire first growing season.

Loretan, P.A., C.K. Bonsi, D.G. Mortley, R.M. Wheeler, C.L. Mackowiak, W.A. Hill, C.E. Morris, A.A. Trotman, and P.P. David. 1994. Effects of several environmental-factors on sweet-potato growth. *Life Sciences and Space Research XXV (3) 14(11):277-280.*

Effects of relative humidity, light intensity and photoperiod on growth of 'Ga Jet' and 'TI-155' sweetpotato cultivars, using the nutrient film technique (NFT), have been reported. In this study, the effect of ambient temperature regimes (constant 28 degrees C and diurnal 28:22 degrees C day:night) and different CO2 levels (ambient, 400, 1 000, and 10 000 $\mu\text{L}\cdot\text{L}^{-1}$ - 400, 1 000 and 10 000 ppm) on growth of one or both of these cultivars in NFT are reported. For a 24-h photoperiod, no storage roots were produced for either cultivar in NFT when sweetpotato plants were grown at a constant temperature of 28 degrees C. For the same photoperiod, when a 28:22 degrees C diurnal temperature variation was used, there were still no storage roots for 'TI-155' but the cv. 'Ga Jet' produced 537 g/plant of storage roots. For both a 12-h and 24-h photoperiod, 'Ga Jet' storage root fresh and dry weight tended to be higher with a 28:22 degrees C diurnal temperature variation than with a constant 28 degrees C temperature regime. Preliminary results with both 'Ga Jet' and 'TI-155' cultivars indicate a distinctive diurnal stomatal response for sweetpotato grown in NFT under an ambient CO2 level. The stomatal conductance values observed for 'Ga Jet' at elevated CO2 levels indicated that the difference between the light- and dark-period conductance rates persisted at 400, 1 000, and 10 000 $\mu\text{L}\cdot\text{L}^{-1}$.

Louche-Tessandier, D., G. Samson, C. Hernandez-Sebastia, P. Chagvardieff, and Y. Desjardins. 1999. Importance of light and CO2 on the effects of endomycorrhizal colonization on growth and photosynthesis of potato plantlets (*Solanum tuberosum*) in an in vitro tripartite system. *New Phytologist* 142(3):539-550.

A factorial analysis was conducted to investigate the effects of different levels of photosynthetic photon flux (PPF) and CO2 concentration on the interactions between the vesicular-arbuscular endomycorrhizal fungus *Glomus intraradices* and potato plantlets (*Solanum tuberosum*) cultured in an in vitro tripartite system. We observed that CO2 enrichment from 350 to 10000 ppm stimulated root colonization by the fungus, and that

this stimulation was more pronounced under high PPF (300 $\mu\text{mol m}^{-2} \text{s}^{-1}$) than low PPF (60 $\mu\text{mol m}^{-2} \text{s}^{-1}$). Consistent with these observations, the effects of G. intraradices on dry matter production in potato plantlets were strongly dependent on the CO₂ and PPF levels during cultivation. There was no significant effect of the mycorrhizal fungus on dry matter production at 350 ppm of CO₂. However, under the high CO₂ concentration, mycorrhiza had opposite effects on dry matter production depending on the PPF: a decrease (-21%) and a stimulation (+25%) of dry matter production after 2 wk of growth under low and high PPF, respectively, were observed in presence of G. intraradices relative to plantlets grown in its absence. Furthermore, in mycorrhizal plantlets grown under high levels of both PPF and CO₂ the chlorophyll and carotenoid contents as well as the quantum yields of photosynthetic electron transport and the photochemical quenching qP of the chlorophyll-a fluorescence measured near the PPF during growth were all higher than in non-infected plantlets. Our results therefore indicate that mycorrhizal G. intraradices can alleviate the down regulation of photosynthesis related to sink limitation, and its effect on dry matter production is strongly dependent on the levels of CO₂ and PPF during growth which determine the balance between the photosynthetic carbon uptake by the plantlets and the carbon cost by the fungus.

Lovelock, C.E., D. Kylo, M. Popp, H. Isopp, A. Virgo, and K. Winter. 1997. Symbiotic vesicular-arbuscular mycorrhizae influence maximum rates of photosynthesis in tropical tree seedlings grown under elevated CO₂. *Australian Journal of Plant Physiology* 24(2):185-194.

To investigate the importance of phosphorus and carbohydrate concentrations in influencing photosynthetic capacity of tropical forest tree seedlings under elevated CO₂, we grew seedlings of *Beilschmiedia pendula* (Sw.) Hemsl. (Lauraceae) under elevated CO₂ concentrations either with or without vesicular-arbuscular (VA) mycorrhizae. VA-mycorrhizae increased phosphorus concentrations in all plant organs (leaves, stems and roots). Maximum rates of photosynthesis (A(max)) measured under saturating levels of CO₂ and light were correlated with leaf phosphorus concentrations. VA-mycorrhizae also increased leaf carbohydrate concentrations, particularly under elevated CO₂, but levels were low and within the range observed in naturally occurring forest species. Root carbohydrate concentrations were reduced in VA-mycorrhizal plants relative to non-mycorrhizal plants. These results indicate an important role for VA-mycorrhizae in controlling photosynthetic rates and sink strength in tropical trees, and thus in determining their response to future increases in atmospheric CO₂ concentrations.

1388

Lovelock, C.E., D. Kylo, and K. Winter. 1996. Growth responses to vesicular-arbuscular mycorrhizae and elevated CO₂ in seedlings of a

tropical tree, *Beilschmiedia pendula*. *Functional Ecology* 10(5):662-667.

1. Vesicular-arbuscular (VA) mycorrhizae increased relative growth rates (RGR) of the shade-tolerant tropical tree species *Beilschmiedia pendula* at both ambient and doubled CO₂ concentrations. 2. RGR was correlated with the net assimilation rate (NAR) of plants. Within this general correlation, in plants with similar RGR, NAR was decreased in VA-mycorrhizal plants compared with non-mycorrhizal plants. As RGR is the product of NAR and the leaf area ratio (LAR, the ratio of leaf area to plant mass), increases in RGR in VA-mycorrhizal plants were the results of increased LAR. Thus, VA-mycorrhizae increased growth rates of *B. pendula* by altering the morphology of the seedlings. 3. Under elevated CO₂ the amount of fungus within roots increased in VA-mycorrhizal plants compared with those grown under ambient CO₂ and this was associated with a greater post-inoculation depression in leaf growth. Post-inoculation depressions in leaf growth and the lower NAR (in plants with similar RGR) of VA-mycorrhizal plants indicate there is increased carbon transfer to soils under elevated CO₂.

Lovelock, C.E., J. Posada, and K. Winter. 1999. Effects of elevated CO₂ and defoliation on compensatory growth and photosynthesis of seedlings in a tropical tree, *Copaifera aromatica*. *Biotropica* 31(2):279-287.

After defoliation by herbivores, some plants exhibit enhanced rates of photosynthesis and growth that enable them to compensate for lost tissue, thus maintaining their fitness relative to competing, undefoliated plants. Our aim was to determine whether compensatory photosynthesis and growth would be altered by increasing concentrations of atmospheric CO₂. Defoliation of developing leaflets on seedlings of a tropical tree, *Copaifera aromatica*, caused increases in photosynthesis under ambient CO₂, but not under elevated CO₂. An enhancement in the development of buds in the leaf axils followed defoliation at ambient levels of CO₂. In contrast, under elevated CO₂, enhanced development of buds occurred in undefoliated plants with no further enhancement in bud development due to exposure to elevated CO₂. Growth of leaf area after defoliation was increased, particularly under elevated CO₂. Despite this increase, defoliated plants grown under elevated CO₂ were further from compensating for tissue lost during defoliation after 5-1/2 weeks than those grown under ambient CO₂ concentrations.

Lovelock, C.E., A. Virgo, M. Popp, and K. Winter. 1999. Effects of elevated CO₂ concentrations on photosynthesis, growth and reproduction of branches of the tropical canopy tree species, *Luehea seemannii* Tr. & Planch. *Plant, Cell and Environment* 22(1):49-59.

Mature trees have already experienced substantial increases in CO₂ concentrations during their lifetimes, and will experience continuing increases in the future. Small open-top chambers were used to enclose branchlets that were at a height of between 20 and 25 m in the canopy of the tree species *Luehea seemannii* Tr. & Planch. in a tropical forest in Panama. Elevated concentrations of CO₂ increased the rate of photosynthetic carbon fixation and decreased stomatal conductance of leaves, but did not influence the growth of leaf area per chamber, the production of flower buds and fruit nor the concentration of

nonstructural carbohydrates within leaves. The production of flower buds was highly correlated with the leaf area produced in the second flush of leaves, indicating that the branchlets of mature trees of *Luehea seemannii* are autonomous to a considerable extent. Elevated levels of CO₂ did increase the concentration of nonstructural carbohydrates in woody stem tissue. Elevated CO₂ concentration also they increased the ratio of leaf area to total biomass of branchlets, and tended to reduce individual fruit weight. These data suggest that the biomass allocation patterns of mature trees may change under future elevated levels of CO₂. Although there were no effects on growth during the experiment, the possibility of increased growth in the season following CO₂ enrichment due to increased carbohydrate concentrations in woody tissue cannot be excluded.

Lovelock, C.E., K. Winter, R. Mersits, and M. Popp. 1998. Responses of communities of tropical tree species to elevated CO₂ in a forest clearing. *Oecologia* 116(1-2):207-218.

Communities of ten species of tropical forest tree seedlings from three successional classes were grown at ambient and elevated CO₂ in large open-top chambers on the edge of a forest in Panama. Communities grew from 20 cm to approximately 2 m in height in 6 months. No enhancements in plant biomass accumulation occurred under elevated CO₂ either in the whole communities or in growth of individual species. Reductions in leaf area index under elevated CO₂ were observed, as were decreases in leaf nitrogen concentrations and increases in the C:N ratio of leaf tissue. Species tended to respond individually to elevated CO₂, but some generalizations of how successional groupings responded could be made. Early and mid-successional species generally showed greater responses to elevated CO₂ than late-successional species, particularly with respect to increases in photosynthetic rates and leaf starch concentrations, and reductions in leaf area ratio. Late-successional species showed greater increases in C:N ratios in response to elevated CO₂ than did other species. Our results indicate that there may not be an increase in the growth of regenerating tropical forest under elevated CO₂, but that there could be changes in soil nutrient availability because of reductions in leaf tissue quality, particularly in late-successional species.

Luan, J.S., Y.Q. Luo, and J.F. Reynolds. 1999. Responses of a loblolly pine ecosystem to CO₂ enrichment: a modeling analysis. *Tree Physiology* 19(4-5):279-287.

The development of the Free-Air CO₂ Enrichment (FACE) facilities represents a substantial advance in experimental technology for studying ecosystem responses to elevated CO₂. A challenge arising from the application of this technology is the utilization of short-term FACE results for predicting long-term ecosystem responses. This modeling study was designed to explore interactions of various processes on ecosystem productivity at elevated CO₂ on the decadal scale. We used a forest model (FORDYN) to analyze CO₂ responses-particularly soil nitrogen dynamics, carbon production and storage-of a loblolly pine ecosystem in the Duke University Forest. When a 14-year-old stand was exposed to elevated CO₂, simulated increases in annual net primary productivity (NPP) were 13, 10 and 7.5% in Years 1, 2 and 10,

respectively, compared with values at ambient CO₂. Carbon storage increased by 4% in trees and 9.2% in soil in Year 10 in response to elevated CO₂. When the ecosystem was exposed to elevated CO₂ from the beginning of forest regrowth, annual NPP and carbon storage in trees and soil were increased by 32, 18 and 20%, respectively, compared with values at ambient CO₂. In addition, simulation of a 20% increase in mineralization rate led to a slight increase in biomass growth and carbon storage, but the simulated 20% increase in fine root turnover rate considerably increased annual NPP and carbon storage in soil. The modeling results indicated that (1) stimulation of NPP and carbon storage by elevated CO₂, is transient and (2) effects of elevated CO₂ on ecosystem processes-canopy development, soil nitrogen mineralization and root turnover-have great impacts on ecosystem C dynamics. A detailed understanding of these processes will improve our ability to predict long-term ecosystem responses to CO₂ enrichment.

Lucas, W.J., A. Olesinski, R.J. Hull, J.S. Haudenschild, C.M. Deom, R.N. Beachy, and S. Wolf. 1993. Influence of the tobacco mosaic-virus 30-kDa movement protein on carbon metabolism and photosynthate partitioning in transgenic tobacco plants. *Planta* 190(1):88-96.

Transgenic tobacco (*Nicotiana tabacum* L.) plants expressing the 30-kDa movement protein of tobacco mosaic virus (TMV-MP) were employed to investigate the influence of a localized change in mesophyll-bundle sheath plasmodesmal size exclusion limit on photosynthetic performance and on carbon metabolism and allocation. Under conditions of saturating irradiance, tobacco plants expressing the TMV-MP were found to have higher photosynthetic CO₂-response curves compared with vector control plants. However, this difference was significant only in the presence of elevated CO₂ levels. Photosynthetic measurements made in the greenhouse, under endogenous growth conditions, revealed that there was little difference between TMV-MP-expressing and control tobacco plants. However, analysis of carbon metabolites within source leaves where a TMV-MP-induced increase in plasmodesmal size exclusion limit had recently taken place established that the levels of sucrose, glucose, fructose and starch were considerably elevated above those present in equivalent control leaves. Although expression of the TMV-MP did not alter total plant biomass, it reduced carbon allocation to the lower region of the stem and roots. This difference in biomass distribution was clearly evident in the lower root-to-shoot ratios for the TMV-MP transgenic plants. Microinjection (dye-coupling) studies established that the TMV-MP-associated reduction in photosynthate delivery (allocation) to the roots was not due to a direct effect on root cortical plasmodesmata. Rather, this change appeared to result from an alteration in phloem transport from young source leaves in which the TMV-MP had yet to exert its influence over plasmodesmal size exclusion limits. These results are discussed in terms of the rate-limiting steps involved in sucrose movement into the phloem.

Ludeke, M.K.B., S. Donges, R.D. Otto, J. Kindermann, F.W. Badeck, P. Ramge, U. Jakel, and G.H. Kohlmaier. 1995. Responses in npp and carbon stores of the northern biomes to a CO₂-induced climatic-change, as evaluated by the Frankfurt biosphere model (fbm). *Tellus Series B-Chemical and Physical Meteorology* 47(1-2):191-205.

To assess the role of the boreal and temperate forests and the tundra ecosystems in a future CO₂-induced climate change, the Frankfurt biosphere model(FBM) was applied to the 3xCO₂ climate as calculated by the GCM of the MPI für Meteorologie in Hamburg. The FBM predicts on a 1 degrees x 1 degrees spatial grid the seasonal and perannual course of leaf biomass and feeder roots, woody biomass, soil carbon and soil water in response to the seasonal course of light, precipitation and temperature. The phenology is controlled by the flux balance of carbon gains and losses, thus being dependent on the driving climate and the state of vegetation. Two equilibrium runs based on the 3xCO₂ climate were performed: (1) Considering the pure climate effect (with no direct CO₂ fertilization) we obtained a 22% decrease of the net primary production (NPP) due to enhanced autotrophic respiration and increased water limitation. Together with the effect on the soils this results in a 170 Gt carbon source. (2) Considering a CO₂-induced enhancement of the maximum photosynthesis the pure climate effect is more than compensated and we predict a NPP increase of 9% and a total carbon sink of 50 Ct C. This effect may even be an underestimate if one takes into consideration a shift in the optimum temperature for photosynthesis under enhanced levels of atmospheric CO₂ as proposed by Long and Drake.

Ludewig, F., U. Sonnewald, F. Kauder, D. Heineke, M. Geiger, M. Stütt, B.T. Müller-Röber, B. Gillissen, C. Kuhn, and W.B. Frommer. 1998. The role of transient starch in acclimation to elevated atmospheric CO₂. *Febs Letters* 429(2):147-151.

Although increased concentrations of CO₂ stimulate photosynthesis, this stimulation is often lost during prolonged exposure to elevated carbon dioxide, leading to an attenuation of the potential gain in yield. Under these conditions, a wide variety of species accumulates non-structural carbohydrates in leaves. It has been proposed that starch accumulation directly inhibits photosynthesis, that the rate of sucrose and starch synthesis limits photosynthesis, or that accumulation of sugars triggers changes in gene expression resulting in lower activities of Rubisco and inhibition of photosynthesis. To distinguish these explanations, transgenic plants unable to accumulate transient starch due to leaf mesophyll-specific antisense expression of AGP B were grown at ambient and elevated carbon dioxide. There was a positive correlation between the capacity for starch synthesis and the rate of photosynthesis at elevated CO₂ concentrations, showing that the capability to synthesize leaf starch is essential for photosynthesis in elevated carbon dioxide. The results show that in elevated carbon dioxide, photosynthesis is restricted by the rate of end product synthesis. Accumulation of starch is not responsible for inhibition of photosynthesis. Although transgenic plants contained increased levels of hexoses, transcripts of photosynthetic genes were not downregulated and Rubisco activity was not decreased arguing against a role of sugar sensing in acclimation to high CO₂. Lukewille, A., and R.F. Wright. 1997. Experimentally increased soil temperature causes release of nitrogen at a boreal forest catchment in southern Norway. *Global Change Biology* 3(1):13-21.

Boreal forest ecosystems are sensitive to global warming, caused by increasing emissions of CO₂ and other greenhouse gases. Assessment of

the biological response to future climate change is based mainly on large-scale models. Whole-ecosystem experiments provide one of the few available tools by which ecosystem response can be measured and with which global models can be evaluated. Boreal ecosystem response to global change may be manifest by alterations in nitrogen (N) dynamics, as N is often the growth limiting nutrient. The CLIMEX (Climate Change Experiment) project entails catchment-scale manipulations of CO₂ (to 560 ppmv) and temperature (by + 3 to + 5 degrees C) to whole forest ecosystems in southern Norway. Soil temperature is increased at 400-m(2) EGIL catchment by means of electric cables placed on the soil surface. Soil warming at EGIL catchment caused an increase in nitrate and ammonium concentrations in runoff in the first year of treatment. We hypothesize that higher temperature increased N release by mineralization. Whether these responses are only transient will be shown by additional years' treatment.

Lund, C.P., W.J. Riley, L.L. Pierce, and C.B. Field. 1999. The effects of chamber pressurization on soil-surface CO₂ flux and the implications for NEE measurements under elevated CO₂. *Global Change Biology* 5(3):269-281.

Soil and ecosystem trace gas fluxes are commonly measured using the dynamic chamber technique. Although the chamber pressure anomalies associated with this method are known to be a source of error, their effects have not been fully characterized. In this study, we use results from soil gas-exchange experiments and a soil CO₂ transport model to characterize the effects of chamber pressure on soil CO₂ efflux in an annual California grassland. For greater than ambient chamber pressures, experimental data show that soil-surface CO₂ flux decreases as a nonlinear function of increasing chamber pressure; this decrease is larger for drier soils. In dry soil, a gauge pressure of 0.5 Pa reduced the measured soil CO₂ efflux by roughly 70% relative to the control measurement at ambient pressure. Results from the soil CO₂ transport model show that pressurizing the flux chamber above ambient pressure effectively flushes CO₂ from the soil by generating a downward flow of air through the soil air-filled pore space. This advective flow of air reduces the CO₂ concentration gradient across the soil-atmosphere interface, resulting in a smaller diffusive flux into the chamber head space. Simulations also show that the reduction in diffusive flux is a function of chamber pressure, soil moisture, soil texture, the depth distribution of soil CO₂ generation, and chamber diameter. These results highlight the need for caution in the interpretation of dynamic chamber trace gas flux measurements. A portion of the frequently observed increase in net ecosystem carbon uptake under elevated CO₂ may be an artifact resulting from the impact of chamber pressurization on soil CO₂ efflux.

Luo, Y., J.L. Chen, J.F. Reynolds, C.B. Field, and H.A. Mooney. 1997. Disproportional increases in photosynthesis and plant biomass in a Californian grassland exposed to elevated CO₂: a simulation analysis. *Functional Ecology* 11(6):696-704.

1. Elevated CO₂ concentrations often lead to increased photosynthetic carbon uptake in plants, but this does not necessarily result in a proportional increase in plant biomass. We examined this paradox for grasslands in northern California that have been exposed to elevated

CO₂ since 1992. We evaluated the effects of physiological adjustments on plant growth and carbon balance of the dominant species, *Avena barbata*, using a plant growth model. 2. Without physiological adjustments, an observed 70% increase in leaf photosynthesis in elevated CO₂ was predicted to increase plant biomass by 97% whereas experimental measurements suggested 5 and 13% decreases in 1992 and 1993, respectively, and a 40% increase in 1994. 3. Simulations with an increase in carbon allocation to roots by 29%, or leaf death rate by 80%, or non-structural carbohydrate storage by 60%, or leaf mass per unit area by 25% each predicted an approximately 40% increase in plant biomass in 1994 under elevated CO₂. It follows that greater suppression of the biomass responses to elevated CO₂, in 1992 and 1993 resulted from variable combinations of these physiological adjustments. 4. This modelling study concludes that (a) an increase in carbon loss or (b) a decrease in carbon-use efficiency or (c) an increase in carbon allocation to root growth will result in an increase in biomass growth that is less than that in leaf photosynthesis under elevated CO₂. Alternatively, if carbon loss is reduced (e.g., depressed respiration) and/or carbon allocation to leaf growth is increased, biomass growth may be stimulated more than leaf photosynthesis by atmospheric CO₂ concentration. Moreover, this modelling exercise suggests that physiological adjustments may have substantial effects on ecosystem carbon processes by varying ecosystem carbon influx, litterfall and Litter quality.

Luo, Y., C.B. Field, and H.A. Mooney. 1994. Predicting responses of photosynthesis and root fraction to elevated [CO₂](a) - interactions among carbon, nitrogen, and growth. *Plant, Cell and Environment* 17(11):1195-1204.

At elevated atmospheric CO₂ concentrations ([CO₂](a)), photosynthetic capacity (A(max)) and root fraction (eta(R), the ratio of root to plant dry mass) increased in some studies and decreased in others. Here, we have explored possible causes of this, focusing on the relative magnitudes of the effects of elevated [CO₂](a) on specific leaf (n(m)) and plant (n(p)) nitrogen concentrations, leaf mass per unit area (h), and plant nitrogen productivity (alpha). In our survey of 39 studies with 35 species, we found that elevated [CO₂](a) led to decreased n(m) and n(p) in all the studies and to increased h and alpha in most of the studies. The magnitudes of these changes varied with species and with experimental conditions. Based on a model that integrated [CO₂](a)-induced changes in leaf nitrogen into a biochemically based model of leaf photosynthesis, we predicted that, to a first approximation, photosynthesis will be upregulated (A(max) will increase) when growth at increased [CO₂](a) leads to increases in h that are larger than decreases in n(m). Photosynthesis will be downregulated (A(max) will decrease) when increases in h are smaller than decreases in n(m). The model suggests that photosynthetic capacity increases at elevated [CO₂](a) only when additional leaf mesophyll more than compensates the effects of nitrogen dilution. We considered two kinds of regulatory paradigms that could lead to varying responses of eta(R) to elevated [CO₂](a), and compared the predictions of each with the data. A simple static model based on the functional balance concept predicts that eta(R) should increase when neither n(p) nor h is very responsive to elevated [CO₂](a). The quantitative and qualitative agreement of the predictions with data from the literature, however, is poor. A model that predicts eta(R) from the relative sensitivities of photosynthesis and relative growth rate to elevated [CO₂](a) corresponds much more closely to the observations. In general, root fraction increases if the response of photosynthesis to [CO₂](a) is greater than that of relative growth rate.

Luo, Y., C.B. Field, and H.A. Mooney. 1997. Adapting GePSi (generic plant simulator) for modeling studies in the Jasper Ridge CO₂ project. *Ecological Modelling* 94(1):81-88.

In order to conduct modeling studies on the effects of elevated atmospheric carbon dioxide concentration ([CO₂]) on plant and ecosystem processes at the Jasper Ridge grassland in northern California, the generic plant simulator (GePSi) (Chen: J.-L. and Reynolds, J.F., 1997. *Ecol. Model.*, 94: 53-66), is modified to simulate grass dynamics. This modification was attempted by the authors of this paper, who had no prior experience with the model. Prior to this project, GePSi, which is implemented in the object-oriented programming (OOP) language, C++, had only been used to model trees and woody shrubs. This exercise addressed several of the concepts presented in this volume concerning the purported benefits of genericness, modularity, and OOP in plant modeling. The objective of this paper is to briefly summarize the extent to which these benefits were realized and some of the problems encountered. Our evaluation is presented in terms of: (1) design considerations, including the importance of how the modules in GePSi were defined; and (2) the implementation phase, which critiques the use of OOP for facilitating the transfer of the model. This study suggests that generic, modular models such as GePSi will facilitate the interactions of model developers and users and reduce duplication of effort in model development. Luo, Y.H., and B.R. Strain. 1992. Leaf water status in velvetleaf under long-term interactions of water-stress, atmospheric humidity, and carbon-dioxide. *Journal of Plant Physiology* 139(5):600-604.

Well watered and water-stressed *Abutilon theophrasti*, were grown with relative humidity of 45% or 85% at 30-degrees-C and CO₂ concentrations of 350 or 650-mu-mol mol⁻¹. Elevated leaf water potentials of the water-stressed plants grown in both high and low humidities were caused by CO₂ enrichment. Elevated water content (kg m⁻² leaf area) caused by CO₂ enrichment, higher water content at a given water potential, and notably lower rate in desiccation from detached leaves all occurred only in the plants grown in low humidity. These results may be related to enhanced dehydration resistance of the plants that experienced long-term low humidity.

Luo, Y.Q., R.B. Jackson, C.B. Field, and H.A. Mooney. 1996. Elevated CO₂ increases belowground respiration in California grasslands. *Oecologia* 108(1):130-137.

This study was designed to identify potential effects of elevated CO₂ on belowground respiration (the sum of root and heterotrophic respiration) in field and microcosm ecosystems and on the annual carbon budget. We made three sets of respiration measurements in two CO₂ treatments, i.e., (1) monthly in the sandstone grassland and in microcosms from November 1993 to June 1994; (2) at the annual peak of live biomass (March and April) in the serpentine and sandstone grasslands in 1993 and 1994; and (3) at peak biomass in the microcosms with monocultures of seven species in 1993. To help understand ecosystem carbon cycling,

we also made supplementary measurements of belowground respiration monthly in sandstone and serpentine grasslands located within 500 m of the CO₂ experiment site. The seasonal average respiration rate in the sandstone grassland was 2.12 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in elevated CO₂, which was 32% higher than the 1.49 $\mu\text{mol m}^{-2} \text{s}^{-1}$ measured in ambient CO₂ ($P = 0.007$). Studies of seven individual species in the microcosms indicated that respiration was positively correlated with plant biomass and increased, on average, by 70% with CO₂. Monthly measurements revealed a strong seasonality in belowground respiration, being low (0–0.5 $\mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$) in the two grasslands adjacent to the CO₂ site) in the summer dry season and high (2–4 $\mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$) in the sandstone grassland and 2–7 $\mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$) in the microcosms) during the growing season from the onset of fall rains in November to early spring in April and May. Estimated annual carbon effluxes from the soil were 323 and 440 $\text{g C m}^{-2} \text{year}^{-1}$ for the sandstone grasslands in ambient and elevated CO₂. That CO₂-stimulated increase in annual soil carbon efflux is more than twice as big as the increase in aboveground net primary productivity (NPPa) and approximately 60% of NPPa in this grassland in the current CO₂ environment. The results of this study suggest that below-ground respiration can dissipate most of the increase in photosynthesis stimulated by elevated CO₂.

Luo, Y.Q., and H.A. Mooney. 1995. Long-term CO₂ stimulation of carbon influx into global terrestrial ecosystems: Issues and approaches. *Journal of Biogeography* 22(4-5):797-803.

Estimating the additional amount of global photosynthetic carbon influx into terrestrial ecosystems (P-G) becomes possible with a leaf-level factor (L) developed by Luo & Mooney only when an increase in atmospheric CO₂ concentration (C-a) is small. Applying the L factor to study long-term stimulation of P-G with a large increase in C-a needs understanding of adjustments in leaf properties, canopy structure and ecosystem nitrogen availability, which could, potentially, feedback to photosynthetic carbon influx. Leaf photosynthetic properties vary greatly with elevated CO₂ among species. Aggregation over a group of species, however, shows a small change, suggesting that globally averaged changes in leaf properties may be trivial. Canopy adjustment in elevated CO₂ is largely unknown whereas indirect measurements suggest faster development of foliar canopy in elevated than ambient CO₂. Biogeochemical feedback of nitrogen on global carbon influx is involved with two general issues: CO₂ effects on ecosystem nitrogen availability and interactive effects of nitrogen and CO₂ on photosynthesis. Although nitrogen itself strongly influences photosynthesis, regulation of CO₂ effects on photosynthesis by nitrogen is still inconclusive. Ecosystem nitrogen availability is determined by a balance of several nitrogen fluxes, including plant uptake, mineralization, deposition, fixation, denitrification, volatilization and leaching. Elevated CO₂ stimulates more plant biomass growth, demanding more nitrogen uptake. Mineralization increased in two studies, decreased in one and was unchanged in one. CO₂ stimulation of nitrogen fixation increases nitrogen availability in ecosystems, potentially to match increased photosynthetic potential in the long term. Effects of volatilization, denitrification and leaching are yet to be assessed. Overall, intact ecosystem studies of canopy structure and nitrogen dynamics in elevated CO₂ are particularly needed for our quantifying long-term stimulation of global photosynthetic carbon influx.

Luo, Y.Q., and P.S. Nobel. 1993. Growth-characteristics of newly initiated cladodes of *Opuntia ficus-indica* as affected by shading, drought and elevated CO₂. *Physiologia Plantarum* 87(4):467-474.

Biomass accumulation and area expansion of newly initiated cladodes of *Opuntia ficus-indica* were studied to help understand the high productivity of this Crassulacean acid metabolism species. In a glasshouse, both dry weight and area increased more and more rapidly for about 30 days and then increased linearly with time up to 63 days. The relative growth rate averaged 0.12 day⁻¹, comparable to values for productive C₃ and C₄ plants. New cladodes initiated on basal cladodes with 2-fold higher initial dry weight grew twice as fast. Drought reduced biomass accumulation and area expansion of new cladodes by 62 and 52%, respectively. A 70% reduction in irradiation decreased biomass accumulation of new cladodes by 17% and their thickness by 11%. In a growth chamber containing 720 $\mu\text{mol CO}_2 (\text{mol air})^{-1}$, biomass of newly initiated cladodes was 7% higher, area was 8% less, specific mass was 16% higher and less carbohydrate was translocated from basal cladodes than for 360 $\mu\text{mol CO}_2 \text{mol}^{-1}$. The large capacity for storage of carbohydrate and water in basal cladodes of *O. ficus-indica* apparently buffered environmental stresses, thereby reducing their effects on growth of daughter cladodes.

Luo, Y.Q., J. Reynolds, Y.P. Wang, and D. Wolfe. 1999. A search for predictive understanding of plant responses to elevated [CO₂]. *Global Change Biology* 5(2):143-156.

This paper reviews two decades of effort by the scientific community in a search for predictive understanding of plant responses to elevated [CO₂]. To evaluate the progress of research in leaf photosynthesis, plant respiration, root nutrient uptake, and carbon partitioning, we divided scientific activities into four phases: (I) initial assessments derived from our existing knowledge base to provide frameworks for experimental studies; (II) experimental tests of the initial assessments; (III) in cases where assessments were invalidated, synthesis of experimental results to stimulate alternative hypotheses and further experimentation; and (IV) formation of new knowledge. This paper suggests that photosynthetic research may have gone through all four phases, considering that (a) variable responses of photosynthesis to [CO₂] are generally explainable, (b) extrapolation of leaf-level studies to the global scale has been examined, and (c) molecular studies are under way. Investigation of plant respiratory responses to [CO₂] has reached the third phase: experimental results have been accumulated, and mechanistic approaches are being developed to examine alternative hypotheses in search for new concepts and/or new quantitative frameworks to understand respiratory responses to elevated [CO₂]. The study of nutrient uptake kinetics is still in the second phase: experimental evidence has contradicted some of the initial assessments, and more experimental studies need to be designed before generalizations can be made. It is quite unfortunate that we have not made much progress in understanding mechanisms of carbon partitioning during the past two decades. This is due in part to the fact that some of the holistic theories, such as functional balance and optimality, have not evolved into testable hypotheses to guide experimental studies. This paper urges modelers to play an increasing role in plant-CO₂ research by disassembling these existing theories into hypotheses and urges experimentalists to design experiments to examine these holistic concepts.

Luo, Y.Q., D.A. Sims, and K.L. Griffin. 1998. Nonlinearity of photosynthetic responses to growth in rising atmospheric CO₂: an experimental and modelling study. *Global Change Biology* 4(2):173-183.

Nonlinear responses of photosynthesis to the CO₂ concentration at which plants were grown (C-g) have been often reported in the literature. This study was designed to develop mechanistic understanding of the nonlinear responses with both experimental and modelling approaches. Soybean (*Glycine max*) was grown in five levels of C-g (280, 350, 525, 700, 1000 ppm) with either a high or low rate of nitrogen fertilization. When the rate of nitrogen fertilization was high, the photosynthetic rate measured at C-g was highest in plants from the 700 ppm CO₂ treatment. When the rate of nitrogen fertilization was low, little variation was observed in the photosynthetic rates of plants from the different treatments measured at their respective C-g. Measurements of CO₂-induced changes in mass-based leaf nitrogen concentration (n(m)) an index of changes in biochemical processes and leaf mass per unit area (h, an index of morphological properties) were used in a model and indicate that the nonlinearity of photosynthetic responses to C-g is largely determined by relative changes in photosynthetic sensitivity, biochemical downregulation, and morphological upregulation. In order to further understand the nonlinear responses, we compiled data from the literature on CO₂-induced changes in n(m) and h. These compiled data indicate that h generally increases and n(m) usually decreases with increasing C-g, but that the trajectories and magnitudes of the changes in h and n(m) vary with species and growth environments. Integration of these variables (n(m) and h) into a biochemically based model of photosynthesis enabled us to predict diverse responses of photosynthesis to C-g. Thus a general mechanism is suggested for the highly variable, nonlinear responses of photosynthesis to C-g reported in the literature.

Luo, Y.Q., D.A. Sims, R.B. Thomas, D.T. Tissue, and J.T. Ball. 1996. Sensitivity of leaf photosynthesis to CO₂ concentration is an invariant function for C-3 plants: A test with experimental data and global applications. *Global Biogeochemical Cycles* 10(2):209-222.

Rising atmospheric CO₂ concentration (C-a) may alter two components (sensitivity and acclimation) of global photosynthetic carbon influx into terrestrial ecosystems (P-G). Most existing global models focus on long-term acclimation. We have developed a leaf-level function (L) to quantify short-term increment of P-G associated with sensitivity. The L function is the normalized response of leaf photosynthesis to a small change in C-a and has been suggested to be an invariant function for C-3 plants grown in diverse environments. This paper tests the hypothesis that L is an invariant function. We calculated values of L from 9 sets of experimental data which incorporated photosynthetic responses of 12 plant species to measurement conditions of light and temperature and to growth in different light, temperature, nitrogen, phosphorus, water stress, and CO₂ concentration. Absolute rates of leaf photosynthesis differed by more than tenfold due to species differences and environmental variation. However, L values derived from these data sets converged into a narrow range defined by two equations of the L function, confirming that L was insensitive to differences in photosynthetic capacity among species and between plants acclimated to different growth environments. Using the L function, we predict that a yearly increase of 1.5 parts per million (ppm) in C-a will induce an increase in P-G by 0.18 to 0.34 Gt

(1 Gt = 10¹⁵ g) C yr⁻¹ in 1993, provided that (1) P-G = 120 Gt C yr⁻¹, (2) 85% of P-g is generated by C-3 plant assimilation, and (3) the 1.5-ppm increase in C-a will not induce significant photosynthetic acclimation.

Lurie, S. 1993. Modified atmosphere storage of peaches and nectarines to reduce storage disorders. *Journal of Food Quality* 16(1):57-65.

Low density polyethylene or polyolefin films were used to seal pack various varieties of peaches and nectarines. Low density polyethylene film of 40 micron thickness was beneficial in extending storage life of these fruits and decreasing internal flesh breakdown and reddening, while polyolefin film was ineffective. Six fruits per pack generated a higher CO₂ and lower O₂ modified atmosphere than two or four fruits per pack and gave better quality fruit after storage. The improvement of fruit quality was correlated with elevated CO₂ levels rather than with decreased O₂ levels.

Luscher, A., G.R. Hendrey, and J. Nosberger. 1998. Long-term responsiveness to free air CO₂ enrichment of functional types, species and genotypes of plants from fertile permanent grassland. *Oecologia* 113(1):37-45.

To test inter- and intraspecific variability in the responsiveness to elevated CO₂, 9-14 different genotypes of each of 12 perennial species from fertile permanent grassland were grown in *Lolium perenne* swards under ambient (35 Pa) and elevated (60 Pa) atmospheric partial pressure of CO₂ (pCO₂) for 3 years in a free air carbon dioxide enrichment (FACE) experiment. The plant species were grouped according to their functional types: grasses (*L. perenne*, *L. multiflorum*, *Arrhenatherum elatius*, *Dactylis glomerata*, *Festuca pratensis*, *Holcus lanatus*, *Trisetum flavescens*), non-legume dicots (*Rumex obtusifolius*, *R. acetosa*, *Ranunculus frisianus*), and legumes (*Trifolium repens*, *T. pratense*). Yield (above a cutting height of 4.5 cm) was measured three times per year. The results were as follow. (1) There were highly significant differences in the responsiveness to elevated pCO₂ between the three functional types; legumes showed the strongest and grasses the weakest yield increase at elevated pCO₂. (2) There were differences in the temporal development of responsiveness to elevated pCO₂ among the functional types. The responsiveness of the legumes declined from the first to the second year, while the responsiveness of the non-legume dicots increased over the 3 years. During the growing season, the grasses and the non-legume dicots showed the strongest response to elevated pCO₂ during reproductive growth in the spring. (3) There were no significant genotypic differences in responsiveness to elevated pCO₂. Our results suggest that, due to interspecific differences in the responsiveness to elevated pCO₂, the species proportion within fertile temperate grassland may change if the increase in pCO₂ continues. Due to the temporal differences in the responsiveness to elevated pCO₂ among species, complex effects of elevated pCO₂ on competitive interactions in mixed swards must be expected. The existence of genotypic variability in the responsiveness to elevated pCO₂, on which selection could act, was not found under our experimental conditions.

Luscher, A., and J. Nosberger. 1997. Interspecific and intraspecific variability in the response of grasses and legumes to free air CO₂ enrichment. *Acta Oecologica-International Journal of Ecology* 18(3):269-275.

Nine to fourteen genotypes of seven grass and two legume species from permanent grassland were grown at two levels of atmospheric CO₂ concentration in gaps of established *Lolium perenne* swards in a Free Air Carbon dioxide Enrichment (FACE) experiment. Cumulative biomass of individual plants was determined for two growing seasons. In the first year, elevated CO₂ increased biomass production in all species. The CO₂-induced increase in the biomass of *Trifolium repens* and *L. pratense* (159%) was much greater than the increase in the grass species (27%). In the second year the response to elevated CO₂ was weaker in grasses (2%, ns) and legumes (73%). However, interspecific differences in the response to CO₂ remained significant. Interspecific differences in the response to elevated CO₂ occurred between the two functional groups of grasses and legumes, while within these groups no significant interspecific differences were found. In contrast to the interspecific variability in the response to CO₂, no significant intraspecific variability in the response to CO₂ was detected. Our results suggest that significant interspecific differences in the response to CO₂ occur. Intraspecific differences in the response to elevated CO₂ were, however, not detected. Thus, it seems unlikely that evolutionary adaptation of the species' response to elevated CO₂ will level out the interspecific differences in the response to CO₂.

Lussenhop, J., A. Treonis, P.S. Curtis, J.A. Teeri, and C.S. Vogel. 1998. Response of soil biota to elevated atmospheric CO₂ in poplar model systems. *Oecologia* 113(2):247-251.

We tested the hypotheses that increased belowground allocation of carbon by hybrid poplar saplings grown under elevated atmospheric CO₂ would increase mass or turnover of soil biota in bulk but not in rhizosphere soil. Hybrid poplar saplings (*Populus x euramericana* cv. Eugenei) were grown for 5 months in open-bottom root boxes at the University of Michigan Biological Station in northern, lower Michigan. The experimental design was a randomized-block design with factorial combinations of high or low soil N and ambient (34 Pa) or elevated (69 Pa) CO₂ in five blocks. Rhizosphere microbial biomass carbon was 1.7 times greater in high- than in low-N soil, and did not respond to elevated CO₂. The density of protozoa did not respond to soil N but increased marginally ($P < 0.06$) under elevated CO₂. Only in high-N soil did arbuscular mycorrhizal fungi and microarthropods respond to CO₂. In high-N soil, arbuscular mycorrhizal root mass was twice as great, and extramatrical hyphae were 11% longer in elevated than in ambient CO₂ treatments. Microarthropod density and activity were determined in situ using minirhizotrons. Microarthropod density did not change in response to elevated CO₂, but in high-N soil, microarthropods were more strongly associated with fine roots under elevated than ambient treatments. Overall, in contrast to the hypotheses, the strongest response to elevated atmospheric CO₂ was in the rhizosphere where (1) unchanged microbial biomass and greater numbers of protozoa ($P < 0.06$) suggested faster bacterial turnover, (2) arbuscular mycorrhizal root length increased, and (3) the number of microarthropods observed on fine roots rose.

Lutze, J.L., and R.M. Gifford. 1995. Carbon storage and productivity of a carbon dioxide enriched nitrogen limited grass sward after one year's growth. *Journal of Biogeography* 22(2-3):227-233.

Determining the response of nitrogen restricted ecosystems to carbon dioxide enrichment is important in evaluating the role of the terrestrial biosphere in the unidentified sink in global carbon cycle models. Swards of the C3 grass *Danthonia richardsonii* (Cashmere) were established in large pots filled with a soil of low C and N content. The swards were continuously supplied with N at rates of 2, 6 and 18 g m⁻² yr⁻¹, and exposed to atmospheric CO₂ concentrations of either 357 or 712 μ mol L⁻¹. After 1 year's growth the high CO₂ treatments gained 19, 53 and 43% more C than at low CO₂ concentrations for the low, medium and high N treatments, respectively. This extra C gain was found in all plant and soil pools at the medium N level. At the low N level no extra C was found in the roots. At the high N level no extra carbon was found in the soil. Leaf area index was not affected by growth at high CO₂. The extra C was gained with the same total N investment in green leaf in the two lowest N treatments, and with 30% less N in green leaf at the highest N level. Growth at the high CO₂ concentration resulted in all C pools having a higher C:N ratio. Total water use was decreased and water use efficiency increased by growth at the high CO₂ concentration. It was noted that if these results were transferable to the field, and if the higher C:N ratios do not reduce longer term productivity by reducing N-mineralization rates, grasslands could form a substantial part of the unidentified C sink. The potential feedback of decreased N availability in the longer term is being investigated in the final 3 years of the experiment.

Lutze, J.L., and R.M. Gifford. 1998. Acquisition and allocation of carbon and nitrogen by *Danthonia richardsonii* in response to restricted nitrogen supply and CO₂ enrichment. *Plant, Cell and Environment* 21(11):1133-1141.

Dry weight (DW) and nitrogen (N) accumulation and allocation were measured in isolated plants of *Danthonia richardsonii* (Wallaby Grass) for 37 d following seed imbibition. Plants were grown at approximate to 365 or 735 μ mol L⁻¹ CO₂ with N supply of 0.05, 0.2 or 0.5 mg N plant⁻¹ d⁻¹. Elevated CO₂ increased DW accumulation by 28% (low-N) to 103% (high-N), following an initial stimulation of relative growth rate. Net assimilation rate and leaf nitrogen productivity were increased by elevated CO₂, while N concentration was reduced. N uptake per unit root surface area was unaffected by CO₂ enrichment. The ratio of leaf area to root surface area was decreased by CO₂ enrichment. Allometric analysis revealed a decrease in the shoot-N to root-N ratio at elevated CO₂, while the shoot-DW to root-DW ratio was unchanged. Allometric analysis showed leaf area was reduced, while root surface area was unchanged by elevated CO₂, indicating a down-regulation of total plant capacity for carbon gain rather than a stimulation of mineral nutrient acquisition capacity. Overall, growth in elevated CO₂ resulted in changes in plant morphology and nitrogen use, other than those associated simply with changing plant size and non-structural carbohydrate content.

Lutze, J.L., and R.M. Gifford. 1998. Carbon accumulation, distribution and water use of *Danthonia richardsonii* swards in response to CO₂ and nitrogen supply over four years of growth. *Global Change*

Microcosms of *Danthonia richardsonii* (Cashmore) accumulated more carbon when grown under CO₂ enrichment (719 $\mu\text{mol L}^{-1}$ cf. 359 $\mu\text{mol L}^{-1}$) over a four-year period, even when nitrogen availability severely restricted productivity (enhancement ratios for total microcosm C accumulation of 1.21, 1.14 and 1.29 for mineral N supplies of 2.2, 6.7 and 19.8 g N $\text{m}^{-2} \text{y}^{-1}$, respectively). The effect of CO₂ enrichment on total system carbon content did not diminish with time. Increased carbon accumulation occurred despite the development over time of a lower leaf area index and less carbon in the green leaf fraction at high CO₂. The extra carbon accumulated at high CO₂ in the soil, senesced leaf and leaf litter fractions at all N levels, and in root at high-N, while at low- and mid-N less carbon accumulated in the root fraction at high CO₂. The rate of leaf turnover was increased under CO₂ enrichment, as indicated by increases in the carbon mass ratio of senesced to green leaf lamina. Microcosm evapotranspiration rates were lower at high CO₂ when water was in abundant supply, resulting in higher average soil water contents. The higher soil water contents at high CO₂ have important implications for microcosm function, and may have contributed significantly to the increased carbon accumulation at high CO₂. These results indicate that CO₂ enrichment can increase carbon accumulation by a simple soil-plant system, and that any increase in whole system carbon accumulation may not be evident from snapshot measurements of live plant carbon.

Lutze, J.L., J.S. Roden, C.J. Holly, J. Wolfe, J.J.G. Egerton, and M.C. Ball. 1998. Elevated atmospheric [CO₂] promotes frost damage in evergreen tree seedlings. *Plant, Cell and Environment* 21(6):631-635.

Growth under elevated [CO₂] promoted spring frost damage in field grown seedlings of snow gum (*Eucalyptus pauciflora* Sieb. ex Spreng.), one of the most frost tolerant of eucalypts. Freezing began in the leaf midvein, consistent with it being a major site of frost damage under field conditions. The average ice nucleation temperature was higher in leaves grown under elevated [CO₂] (- 5.7 degrees C versus - 4.3 degrees C), consistent with the greater incidence of frost damage in these leaves (34% versus 68% of leaves damaged). These results have major implications for agriculture, forestry and vegetation dynamics, as an increase in frost susceptibility may reduce potential gains in productivity from CO₂ fertilization and may affect predictions of vegetation change based on increasing temperature.

Luxmoore, R.J., P.J. Hanson, J.J. Beauchamp, and J.D. Joslin. 1998. Passive nighttime warming facility for forest ecosystem research. *Tree Physiology* 18(8-9):615-623.

A nighttime warming experiment is proposed. Over the last four decades a significant rise in nighttime minimum temperature has been determined from analysis of meteorological records from a global distribution of locations. The experiment involves nighttime deployment of infrared (IR) reflecting curtains around four sides of a forest canopy and across the top of the forest to mimic the top-down warming effect of cloud cover. The curtains are deployed with cable and pulley systems mounted on a tower and scaffolding structure built around the selected forest site. The trunk space is not enclosed except as an optional manipulation. The curtains reflect long-wave radiation emitted from the forest and ground back into the forest warming the trees, litter, and soil.

Excellent infrared reflection can be obtained with commercially available fabrics that have aluminum foil bonded to one side. A canopy warming of 3 to 5 degrees C is expected on cloudless nights, and on cloudy nights, a warming of 1 to 3 degrees C is anticipated relative to a control plot. The curtains are withdrawn by computer control during the day and also at night during periods with precipitation or excessive wind. Examples of hypothesized ecosystem responses to nighttime warming include: (1) increase in tree maintenance respiration (decreasing carbon reserves and ultimately tree growth), (2) increase in the length of the growing season (increasing growth), (3) increase in soil respiration, (4) increase in litter decomposition, (5) increase in mineralization of N and other nutrients from soil organic matter, (6) increase in nutrient uptake (increasing growth), and (7) increase in N immobilization in litter. Hypothesis 1 has the opposite consequence for tree growth to Hypotheses 2 and 6, and thus opposite consequences for the feedback regulation that vegetation has on net greenhouse gas releases to the atmosphere. If Hypothesis 1 is dominant, warming could lead to more warming from the additional CO₂ emissions. Site-specific meteorological, ecophysiological, and phenological measurements are obtained in the warming treatment and in a carefully selected control plot to investigate site-specific hypotheses. Measurements made on both plots for a baseline period and during the period of curtain deployment provide data to test the hypotheses statistically by the "before-after-control-impact" method applicable to unreplicated experiments. The enclosure has a modular design that can be adapted and combined with other forest-scale manipulation experiments such as free air CO₂ enrichment and throughfall displacement.

Luxmoore, R.J., S.D. Wullschlegel, and P.J. Hanson. 1993. Forest responses to CO₂ enrichment and climate warming. *Water, Air, and Soil Pollution* 70(1-4):309-323.

Two of the major uncertainties in forecasting future terrestrial sources and sinks of CO₂ are the CO₂-enhanced growth response of forests and soil warming effects on net CO₂ efflux from forests. Carbon dioxide enrichment of tree seedlings over time periods less than 1 yr has generally resulted in enhanced rates of photosynthesis, decreased respiration, and increased growth, with minor increases in leaf area and small changes in C allocation. Exposure of woody species to elevated CO₂ over several years has shown that high rates of photosynthesis may be sustained, but net C accumulation may not necessarily increase if CO₂ release from soil respiration increases. The impact of the 25% rise in atmospheric CO₂ with industrialization has been examined in tree ring chronologies from a range of species and locations. In contrast to the seedling tree results, there is no convincing evidence for CO₂-enhanced stem growth of mature trees during the last several decades. However, if mature trees show a preferential root growth response to CO₂ enrichment, the gain in root mass for an oak-hickory forest in eastern Tennessee is estimated to be only 9% over the last 40 years. Root data bases are inadequate for detecting such an effect. A very small shift in ecosystem nutrients from soil to vegetation could support CO₂-enhanced growth. Climate warming and the accompanying increase in mean soil temperature could have a greater effect than CO₂ enrichment on terrestrial sources and sinks of CO₂. Soil respiration and N mineralization have been shown to increase with soil temperature. If plant growth increases with increased N availability, and more C is fixed in growth than is released by soil respiration, then a negative feedback on climate warming will occur. If warming results in a net increase in CO₂ efflux from forests, then a positive feedback will follow. A 2 to 4-degrees-C increase in soil temperature could increase CO₂ efflux from soil by 15 to 32% in eastern deciduous forests. Quantifying C budget

responses of forests to future global change scenarios will be speculative until mature tree responses to CO₂ enrichment and the effects of temperature on terrestrial sources and sinks of CO₂ can be determined.

MacDonald, N.W., D.L. Randlett, and D.R. Zak. 1999. Soil warming and carbon loss from a lake states spodosol. *Soil Science Society of America Journal* 63(1):211-218.

Elevated soil temperatures may increase C loss from soils by accelerating microbial respiration and dissolved organic C leaching. We evaluated the effect of elevated soil temperatures on C losses from a forest Spodosol by incubating soil cores from surface (Oa + A + E) and subsurface (Bhs) horizons at two seasonal temperature regimes. One regime simulated the normal course of soil temperatures in northern lower Michigan, and the other simulated soil temperatures representing an amount of warming that might occur under some global warming theory calculations. We measured the amounts of CO₂-C respired and dissolved organic C leached from the soil cores during a 33-wk period. Microbial respiration rates, after adjustment for variation in initial rates, were significantly increased by soil warming and were greater in surface than in subsurface horizons. Warming significantly increased cumulative C respired, with greater losses from surface soils (greater than or equal to 50 mg C g⁻¹ C) as compared with subsurface soils (less than or equal to 25 mg C g⁻¹ C). Mean quantities of dissolved organic C leached, ranging from 2.3 to 3.2 mg C g⁻¹ C, did not differ significantly by soil horizon or temperature regime. Increased microbial respiration in surface soil horizons was the process most responsive to soil warming in the Spodosol samples we examined. Whether this is a short-term effect that would disappear once pools of labile C are exhausted, or represents a long-term response to soil warming, remains uncertain.

Mackay, R.M., and M.A.K. Khalil. 1995. Doubled co₂ experiments with the global-change-research-center 2-dimensional statistical dynamical climate model. *Journal of Geophysical Research-Atmospheres* 100(D10):21127-21135.

The zonally averaged response of the Global Change Research Center two-dimensional (2-D) statistical dynamical climate model (GCRC 2-D SDCM) to a doubling of atmospheric carbon dioxide (350 parts per million by volume (ppmv) to 700 ppmv) is reported. The model solves the two-dimensional primitive equations in finite difference form (mass continuity, Newton's second law, and the first law of thermodynamics) for the prognostic variables: zonal mean density, zonal mean zonal velocity, zonal mean meridional velocity, and zonal mean temperature on a grid that has 18 nodes in latitude and 9 vertical nodes (plus the surface). The equation of state, $p = \rho RT$, and an assumed hydrostatic atmosphere, $\Delta p = -\rho g \Delta z$, are used to diagnostically calculate the zonal mean pressure and vertical velocity for each grid node, and the moisture balance equation is used to estimate the precipitation rate. The model includes seasonal variations in solar intensity, including the effects of eccentricity, and has observed land and ocean fractions set for each zone. Seasonally varying values of cloud amounts, relative

humidity profiles, ozone, and sea ice are all prescribed in the model. Equator to pole ocean heat transport is simulated in the model by turbulent diffusion. The change in global mean annual surface air temperature due to a doubling of atmospheric CO₂ in the 2-D model is 1.61 K, which is close to that simulated by the one-dimensional (1-D) radiative convective model (RCM) which is at the heart of the 2-D model radiation code (1.67 K for the moist adiabatic lapse rate assumption in 1-D RCM). We find that the change in temperature structure of the model atmosphere has many of the characteristics common to General Circulation Models, including amplified warming at the poles and the upper tropical troposphere, and stratospheric cooling. Because of the potential importance of atmospheric circulation feedbacks on climate change, we have also investigated the response of the zonal wind field to a doubling of CO₂ and have found distinct patterns of change that are related to the change in temperature structure. In addition, we find that both the global mean kinetic energy and simulated Hadley circulation increase when CO₂ is doubled. The increase in mean kinetic energy is a result of the increase in upper level meridional temperature gradients simulated by the model. It is stressed that changes in atmospheric dynamics associated with increased carbon dioxide may also be very important to the final steady state distribution of such greenhouse gases as ozone and water vapor. Hence further research in this regard is warranted.

Mackowiak, C.L., and R.M. Wheeler. 1996. Growth and stomatal behavior of hydroponically cultured potato (*Solanum tuberosum* L) at elevated and super-elevated CO₂. *Journal of Plant Physiology* 149(1-2):205-210.

Potato cultivars Denali and Norland were grown in a controlled environment under low irradiance and CO₂ partial pressures of 50, 100, 500, and 1000 Pa. The highest CO₂ partial pressures, 500 and 1000 Pa, reduced tuber yield when compared to 100 Pa CO₂. Upper canopy stomatal conductance was greatest at the higher CO₂ partial pressures (500 and 1000 Pa) for both cultivars, and conductance of Denali was consistently higher than Norland. Stomatal conductance tended to decline sooner with plant age at 50 and 100 Pa CO₂ than at 500 and 1000 Pa. Water uptake was also greatest at the higher CO₂ partial pressures, which resulted in lowest water-use efficiencies at 500 and 1000 Pa. These observations suggest that stomatal function under very high CO₂ partial pressures (500-1000 Pa) does not follow known patterns observed at moderate partial pressures (50-100 Pa). Although there is little concern about CO₂ partial pressures reaching extreme levels in the natural environment, this information should be useful for controlled environments or space life support systems (e.g. space vehicles or habitats), where CO₂ partial pressures of 500-1000 Pa are common.

Madsen, T.V. 1993. Growth and photosynthetic acclimation by *ranunculus-aquaticus* L in response to inorganic carbon availability. *New Phytologist* 125(4):707-715.

Relative growth rates of *Ranunculus aquatilis* L. were measured in the laboratory at dissolved inorganic carbon (DIC) concentrations between 0.2 and 5.2 mM at air-equilibrium CO₂ (16 μ M) and also at 0.55 mM DIC with elevated CO₂ (350 μ M). For plants grown at air-equilibrium CO₂, growth was limited by inorganic carbon below 1.6 mM DIC and

the apparent half saturation constant was 0.5 mM. The growth rate at elevated CO₂ was 50% higher than the carbon saturated rates obtained at high DIC concentrations and air-equilibrium CO₂, where HCO₃⁻ is dominant. This difference is suggested to be caused by differences in uptake mechanisms for CO₂ and HCO₃⁻. Uptake of CO₂ is a diffusive process, whereas HCO₃⁻ use is an active process which involves uptake/transport systems in the cell membranes. The plants acclimated to the DIC regime for growth by reductions in carboxylation efficiency and bicarbonate affinity, but enhanced photosynthetic capacity at elevated DIC. Within the range of concentrations used, the acclimation to CO₂ and HCO₃⁻ was quantitatively similar, except for the HCO₃⁻ uptake capacity which increased at high DIC and air-equilibrium CO₂ but declined at elevated CO₂. Dark respiration was unaffected by inorganic carbon per se, but increased with growth rate. Maintenance respiration was constant among treatments. It is concluded that inorganic carbon, apart from being the primary substrate for photosynthesis, has secondary growth regulatory effects which affect the photosynthetic apparatus of the plants.

Madsen, T.V., S.C. Maberly, and G. Bowes. 1996. Photosynthetic acclimation of submersed angiosperms to CO₂ and HCO₃⁻. *Aquatic Botany* 53(1-2):15-30.

Photosynthetic acclimation after growth under a factorial combination of three concentrations of CO₂ (1, 16 and 910 μ M) and two concentrations of HCO₃⁻ (0.2 and 1.5 mM) was measured for *Callitriche cophocarpa* Sendt., *Elodea canadensis* L.C. Rich. and *Ranunculus peltatus* Schrank. *Callitriche cophocarpa* was restricted to CO₂ as a carbon source while the other two species also used HCO₃⁻. None of the species showed C-4-like photosynthesis as evidenced by low activities of phosphoenolpyruvate carboxylase. Carbon exchange characteristics and biochemical capacities were down-regulated in response to increasing inorganic carbon during growth. In all three species, P-max initial slope of net photosynthesis versus [CO₂], rubisco activity, protein content and chlorophyll content decreased, and CO₂ compensation concentration increased with increased inorganic carbon. In addition, for the two HCO₃⁻ users, the rate of HCO₃⁻-dependent photosynthesis at zero [CO₂] and 1.5 mM HCO₃⁻ decreased with inorganic carbon. The response to increased [GO₂] was greater than that to increased [HCO₃⁻]. Morphological acclimation to inorganic carbon was evident in all species. The root/shoot ratio increased with increasing [CO₂] but was unaffected by [HCO₃⁻]. The specific leaf area declined with carbon availability in *Callitriche* and *Ranunculus*, whereas no change was observed in *Elodea*. There was a significant positive correlation between various carbon exchange characteristics and between these and the chlorophyll content and rubisco activity, suggesting that carbon exchange, light capture and carbon fixation are regulated in parallel in response to carbon availability. The general down-regulation response shown by these aquatic plants to elevated inorganic carbon resembles the response of some terrestrial C-3 species to elevated CO₂.

Madsen, T.V., K. Sandjensen, and S. Beer. 1993. Comparison of photosynthetic performance and carboxylation capacity in a range of aquatic macrophytes of different growth forms. *Aquatic Botany* 44(4):373-384.

Photosynthesis, carbon extraction capacity and ribulose-1,5-bisphosphate carboxylase/oxygenase (RUBISCO) activity were determined for 35 species of submerged aquatic macrophytes differing with respect to taxonomy, growth form and habitat. Photosynthetic rates per unit of chlorophyll and dry weight at ambient CO₂ concentrations (about 15 μ M) as well as carbon extraction capacity increased among plant groups in the order: isoetids, amphibious species, elodeids with no apparent HCO₃⁻ use, elodeids with HCO₃⁻ use, marine angiosperms and marine macroalgae. Photosynthetic rates at elevated CO₂ concentrations (300-350 μ M) showed the same pattern but smaller differences among the groups. Only for some of the marine macroalgae did photosynthesis at ambient CO₂ approach photosynthesis at elevated CO₂. Species with high carbon extraction capacity, presumably based on active HCO₃⁻ use, usually had low RUBISCO activity, low chlorophyll content and low surface to volume ratio. The opposite pattern was found among species with low carbon extraction capacity. The low chlorophyll content and high chlorophyll specific photosynthesis of species with high carbon transport capability (i.e. particularly the marine algae), suggest that running costs associated with inorganic carbon assimilation are reduced when a CO₂ concentrating system operates.

Maevskaya, S.N., T.F. Andreeva, S.Y. Voevodskaya, and N.N. Cherkanova. 1990. Effect of elevated CO₂ concentration on photosynthesis and nitrogen-metabolism of mustard plants. *Soviet Plant Physiology* 37(5):687-692.

We investigated the effect of prolonged (8- to 10-day) influence of elevated atmospheric CO₂ content (0.14%) on the photosynthetic rate and nitrogen metabolism in mustard plants (*Brassica juncea* L.). The photosynthetic rate and intensity of nitrogen metabolism in leaves of mustard plants in the vegetative phase of growth are higher under conditions of elevated atmospheric CO₂ concentration than in leaves of plants that developed under conditions of normal CO₂ content in the atmosphere. Intensification of nitrogen metabolism occurred mainly due to increase of NR activity. Activity of GS and GO increased to a lesser extent. Significant changes were detected in the rates of synthesis of separate amino acids. Thus, formation of alanine and aspartic acid increased by 84 and 40%, respectively, but the rates of glycine and serine synthesis declined. The excess of amino acids (alanine and aspartic acid) is evacuated from the metabolic pool into vacuoles, with the result that a normal metabolic pool of amino acids is preserved. A state of homeostasis is preserved, protein and chlorophyll synthesis is not disturbed, and growth and biomass accumulation intensify in plants under conditions of elevated CO₂ concentration.

Magan, N., and E.S. Baxter. 1996. Effect of increased CO₂ concentration and temperature on the phyllosphere mycoflora of winter wheat flag leaves during ripening. *Annals of Applied Biology* 129(2):189-195.

The impact of elevated carbon dioxide (CO₂, 600/700 μ mol mol⁻¹) and temperature (+ 4 degrees C) on phyllosphere fungi colonising flag leaves of mini crops of winter wheat cv. Mercia between anthesis and

harvest was determined in a computer- controlled environment facility in 1993 and 1994. In both years the total fungal populations (cm²/leaf) were found to have increased due to exposure to either elevated CO₂ and elevated CO₂ + temperature treatments. This was mainly due to significant increases in populations of *Cladosporium* spp. (*C. cladosporioides* and *C. herbarum*) on the flag leaves during ripening. Other phyllosphere component species such as white and pink yeasts were not markedly affected by treatments. The range of fungal species found in such controlled environment chambers was narrower than that commonly found on flag leaves of field grown crops. Common and important colonisers of leaves and ripening ears such as *Aureobasidium pullulans*, *Epicoccum nigrum* and *Fusarium* spp. were seldom isolated.

Maillard, P., E. Deleens, F. Castell, and F.A. Daudet. 1999. Source-sink relationships for carbon and nitrogen during early growth of *Juglans regia* L. seedlings: analysis at two elevated CO₂ concentrations. *Annals of Forest Science* 56(1):59-69.

Assimilation and allocation of carbon (C) and nitrogen (N) were studied in seedlings (*Juglans regia* L.) grown for 55 days under controlled conditions (22 degrees C, 12 h, 90 % relative humidity [RH]) using two CO₂ concentrations (550 and 800 μ mol L⁻¹ CO₂). C and N decrease in seeds was unaltered by CO₂. At the end of seed contribution (day 35), C and N accumulation in seedlings was favoured under 800 μ mol L⁻¹ CO₂, resulting in an increase of about +50 % for C and +35 % for N. Growth enhancement was larger in roots than in shoot, resulting in a higher root:shoot ratio (R:S = 0.62) with respect to 550 μ mol L⁻¹ CO₂ (R:S = 0.40) at day 55. These results were due, in order, to: 1) a shoot respiration temporarily depressed by CO₂, 2) a reduction by 46 % of the root + soil respiration, 3) a stimulation by 14 % of the C assimilation and 1) an increased uptake and assimilation of N coming from the rooting medium. An increased use of N originated from the seed was observed in leaves and lateral roots, suggesting optimisation of distribution of stored N pools by seedlings. These changes finally gave rise to an increased C:N ratio for taproot (+27 %), roots (+20 %), stem (+28 %), and leaves (+12 %), suggesting a N dilution in the tissues. ((C) Inra/Elsevier, Paris.).

Majeau, N., and J.R. Coleman. 1996. Effect of CO₂ concentration on carbonic anhydrase and ribulose-1,5-bisphosphate carboxylase/oxygenase expression in pea. *Plant Physiology* 112(2):569-574.

The effect of external CO₂ concentration on the expression of carbonic anhydrase (CA) and ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) was examined in pea (*Pisum sativum* cv Little Marvel) leaves. Enzyme activities and their transcript levels were reduced in plants grown at 1000 μ mol L⁻¹ CO₂ compared with plants grown in ambient air. Growth at 160 μ mol L⁻¹ CO₂ also appeared to reduce steady-state transcript levels for *rbcs*, the gene encoding the small subunit of Rubisco, and for *ca*, the gene encoding CA; however, *rbcs* transcripts were reduced to a greater extent at this concentration. Rubisco activity was slightly lower in plants grown at 160 μ mol L⁻¹ CO₂, and CA activity was significantly higher than that observed in air-grown plants. Transfer of plants from 1000 μ mol L⁻¹ to air levels of CO₂ resulted in a rapid increase in both *ca* and *rbcs* transcript abundance in fully expanded leaves, followed by an increase in enzyme activity. Plants transferred

from air to high-CO₂ concentrations appeared to modulate transcript abundance and enzyme activity less quickly. Foliar carbohydrate levels were also examined in plants grown continuously at high and ambient CO₂, and following changes in growth conditions that rapidly altered *ca* and *rbcs* transcript abundance and enzyme activities.

Makino, A. 1994. Biochemistry of C₃-photosynthesis in high CO₂. *Journal of Plant Research* 107(1085):79-84.

The short-term responses of C₃ photosynthesis to high CO₂ are described first. Regulation of photosynthesis in the short term is determined by interaction among the capacities of light harvesting, electron transport, ribulose-1,5-bisphosphate carboxylase (Rubisco) and orthophosphate (Pi) regeneration during starch and sucrose synthesis. Photosynthesis under high CO₂ conditions is limited by either electron transport or Pi regeneration capacities, and Rubisco is deactivated to maintain a balance between each step in the photosynthetic pathway. Subsequently, the long-term effects on photosynthesis are discussed. Long-term CO₂ enhancement leads to carbohydrate accumulation. Accumulation of carbohydrates is not associated with a Pi-regeneration limitation on photosynthesis, and this limitation is apparently removed during long-term exposure to high CO₂. Enhanced CO₂ does not affect Rubisco content and electron transport capacity for a given leaf-nitrogen content. In addition, the deactivated Rubisco immediately after exposure to high CO₂ does not recover during the subsequent prolonged exposure. Such evidence may indicate that plants do not necessarily have an ideal acclimation response to high CO₂ at the biochemical level.

Makino, A., M. Harada, T. Sato, H. Nakano, and T. Mae. 1997. Growth and N allocation in rice plants under CO₂ enrichment. *Plant Physiology* 115(1):199-203.

The effects of CO₂ enrichment on growth and N allocation of rice (*Oryza sativa* L.) were examined. The plants were grown hydroponically in growth chambers with a 14-h photoperiod (1000 μ mol quanta m⁻² s⁻¹) and a day/night temperature of 25/20 degrees C. From the 28th to 70th d after germination, the plants were exposed to two CO₂ partial pressures, namely 36 and 100 Pa. The CO₂ enrichment increased the final biomass, but this was caused by a stimulation of the growth rate during the first week of the exposure to elevated CO₂ partial pressures. The disappearance of the initial stimulation of the growth rate was associated with a decreased leaf area ratio. Furthermore, CO₂ enrichment decreased the investment of N in the leaf blades, whereas the N allocation into the leaf sheaths and roots increased. Thus, the decrease in leaf N content by CO₂ enrichment was not due to dilution of N caused by a relative increase in the plant biomass but was due to the change in N allocation at the whole-plant level. We conclude that the growth responses of rice to CO₂ enrichment are mainly controlled by leaf area expansion and N allocation into leaf blades at the whole-plant level.

Makino, A., and T. Mae. 1999. Photosynthesis and plant growth at elevated levels of CO₂. *Plant and Cell Physiology* 40(10):999-1006.

In this review, we discuss the effects of elevated CO₂ levels on photosynthesis in relation to the whole plant growth in terrestrial higher C-3 plants. Short-term CO₂ enrichment stimulates the rate of photosynthesis. Plant mass is also enhanced by CO₂ enrichment. However, the effects of long-term CO₂ enrichment on photosynthesis are variable. Generally, the prolonged exposure to CO₂ enrichment reduces the initial stimulation of photosynthesis in many species, and frequently suppresses photosynthesis. These responses are attributed to secondary responses related to either excess carbohydrate accumulation or decreased N content rather than direct responses to CO₂. Accumulation of carbohydrates in leaves may lead to the repression of photosynthetic gene expression and excess starch seems to hinder CO₂ diffusion. Therefore, the species which have the sink organs for carbohydrate accumulation do not show the suppression of photosynthesis. The suppression of photosynthesis by CO₂ enrichment is always associated with decreases in leaf N and Rubisco contents. These decreases are not due to dilution of N caused by a relative increase in the plant mass but are the result of a decrease in N allocation to leaves at the level of the whole plant, and the decrease in Rubisco content is not selective. Leaf senescence and plant development are also accelerated by CO₂ enrichment. However, they are independent of each other in some species. Thus, various responses to CO₂ observed at the level of a single leaf result from manifold responses at the level of the whole plant grown under conditions of CO₂ enrichment.

Makino, A., T. Shimada, S. Takumi, K. Kaneko, M. Matsuoka, K. Shimamoto, H. Nakano, M. MiyaoTokutomi, T. Mae, and N. Yamamoto. 1997. Does decrease in ribulose-1,5-bisphosphate carboxylase by antisense RbcS lead to a higher N-use efficiency of photosynthesis under conditions of saturating CO₂ and light in rice plants? *Plant Physiology* 114(2):483-491.

Rice (*Oryza sativa* L.) plants with decreased ribulose-1,5-bisphosphate carboxylase (Rubisco) were obtained by transformation with the rice rbcS antisense gene under the control of the rice rbcS promoter. The primary transformants were screened for the Rubisco to leaf N ratio, and the transformant with 65% wild-type Rubisco was selected as a plant set with optimal Rubisco content at saturating CO₂ partial pressures for photosynthesis under conditions of high irradiance and 25 degrees C. This optimal Rubisco content was estimated from the amounts and kinetic constants of Rubisco and the gas-exchange data. The R-1 selfed progeny of the selected transformant were grown hydroponically with different N concentrations. Rubisco content in the R-1 population was distributed into two groups: 56 plants had about 65% wild-type Rubisco,

whereas 23 plants were very similar to the wild type. Although the plants with decreased Rubisco showed 20% lower rates of light-saturated photosynthesis in normal air (36 Pa CO₂), they had 5 to 15% higher rates of photosynthesis in elevated partial pressures of CO₂ (100-115 Pa CO₂) than the wild-type plants for a given leaf N content. We conclude that the rice plants with 65% wild-type Rubisco show a higher N-use efficiency of photosynthesis under conditions of saturating CO₂ and high irradiance.

Makino, Y., K. Iwasaki, and T. Hirata. 1996. A theoretical model for oxygen consumption in fresh produce under an atmosphere with carbon dioxide. *Journal of Agricultural Engineering Research* 65(3):193-203.

A practical model for fresh produce, which includes the effect of the depression of respiration caused by CO₂, is proposed on the basis of the modified Langmuir adsorption theory. The O₂ consumption rates for several kinds of fresh produce under atmospheric conditions with enhanced CO₂ were measured and the data was analysed using the proposed model. The rate parameters of the model for estimating respiration of fresh produce were determined, and the model was found to be adaptable for describing the O₂ consumption in terms of the depression by CO₂. Mathematical analysis of a modified atmosphere packaging (MAP) system for shredded cabbage and broccoli was carried out using the proposed rate equation and the basic mass balance. The simulated results agreed well with the experimental data. The proposed O₂ consumption model is considered to be useful for the design of MAP systems under the atmospheric condition with CO₂ gas. Malanson, G.P. 1993. Comment on modeling ecological response to climatic-change. *Climatic Change* 23(2):95-109.

Researchers have developed many computer simulation models to project ecological responses to climatic change. Three general types of models are examined: transfer functions, stand models, and physiological models. Criteria for evaluation are, first, ability to represent observed and theoretical responses to climatic change i.e., geographical migration, individualistic responses, and disequilibrium or inertia, and second, ability to provide useful information on biological diversity and impacts on society. Because of their roots in ecological interactions at the species level, stand models best meet these criteria at present, but physiological models have greater potential, given unlimited computing power.

Malhi, Y., D.D. Baldocchi, and P.G. Jarvis. 1999. The carbon balance of tropical, temperate and boreal forests. *Plant, Cell and Environment* 22(6):715-740.

Forest biomes are major reserves for terrestrial carbon, and major components of global primary productivity. The carbon balance of forests is determined by a number of component processes of carbon acquisition and carbon loss, and a small shift in the magnitude of these processes would have a large impact on the global carbon cycle. In this paper, we discuss the climatic influences on the carbon dynamics of boreal, temperate and tropical forests by presenting a new synthesis of micrometeorological, ecophysiological and forestry data, concentrating on three case-study sites. Historical changes in the carbon balance of each biome are also reviewed, and the evidence for a carbon sink in each forest biome and its likely behaviour under future global change are discussed. We conclude that there have been significant advances in determining the carbon balance of forests, but there are still critical uncertainties remaining, particularly in the behaviour of soil carbon stocks.

Malmstrom, C.M., and C.B. Field. 1997. Virus-induced differences in the response of oat plants to elevated carbon dioxide. *Plant, Cell and Environment* 20(2):178-188.

Disease is an integral element of agricultural and natural systems, but the roles pathogens play in determining ecosystem response to elevated CO₂ have rarely been examined. To investigate whether disease can alter the response of plants to CO₂, we examined the effects of doubled CO₂ (approximate to 700 $\mu\text{mol mol}^{-1}$) on *Avena sativa* infected with barley yellow dwarf virus (BYDV), a common pathogen of cereals and grasses. Oats infected with BYDV showed a significantly greater biomass response to CO₂ enrichment than did healthy plants. Root mass of diseased plants increased by 37-60% with CO₂ enrichment, but was largely unaffected in healthy plants. CO₂ enrichment increased midday leaf-level photosynthesis and instantaneous water use efficiency by 34 and 93% in healthy plants and by 48 and 174% in infected plants. Foliar carbohydrates increased with both CO₂ enrichment and BYDV infection, but the two factors affected individual peaks dissimilarly. CO₂ enrichment may alter the epidemiology of BYDV by increasing the persistence of infected plants.

Malmstrom, C.M., M.V. Thompson, G.P. Juday, S.O. Los, J.T. Randerson, and C.B. Field. 1997. Interannual variation in global-scale net primary production: Testing model estimates. *Global Biogeochemical Cycles* 11(3):367-392.

Testing estimates of year-to-year variation in global net primary production (NPP) poses some challenges. Large-scale, multiyear records of production are not readily available for natural systems but are for agricultural systems. We use records of agricultural yields at selected sites to test NPP estimates produced by CASA, a global-scale production model driven by both meteorological data and the satellite-derived normalized difference vegetation index (NDVI). We also test estimates produced by the Miami model, which has underlain several analyses of biosphere response to interannual changes in climate. In addition, we test estimates against tree ring data for one boreal site for which data from both coniferous and deciduous species were available. The agricultural

tests demonstrate that CASA can reasonably estimate interannual variation in production. The Miami model estimates variation more poorly. However, differences in NDVI-processing algorithms substantially affect CASA's estimates of interannual variation. Of the four versions tested, the FASIR NDVI most closely reproduced yield data and showed the least correlation with changes in equatorial crossing time of the National Oceanic and Atmospheric Administration satellites. One issue raised is the source of the positive trends evident in CASA's NDVI-based estimates of global NPP. The existence of these trends is consistent with potential stimulation of terrestrial production by factors such as CO₂ enrichment, N fertilization, or temperature warming, but the magnitude of the global trends seen is significantly greater than suggested by constraints imposed by atmospheric fluxes.

Manderscheid, R., J. Bender, H.J. Jager, and H.J. Weigel. 1995. Effects of season long CO₂ enrichment on cereals .2. Nutrient concentrations and grain quality. *Agriculture Ecosystems & Environment* 54(3):175-185.

Two cultivars each of spring wheat (*Triticum aestivum* L., cv. Star and cv. Turbo) and spring barley (*Hordeum vulgare* L., cv. Alexis and cv. Arena) were exposed season-long to ambient (384 p.p.m.) and above ambient CO₂ concentrations (551, 718 p.p.m.) in open-top chambers. Plant samples were taken at the booting stage and at maturity. Concentrations (grams per gram dry weight) of macro (Ca, K, Mg, N, P, S) and micronutrients (Fe, Mn, Zn) were measured in stems, leaves, ears and grains, and the amino acid composition of the grain protein was determined. For most nutrients studied the sequence and size of the response of the four cereal plants to the CO₂ enrichment was cv. Arena < cv. Alexis < cv. Turbo < cv. Star. The CO₂ enrichment usually produced a decrease in nutrient concentrations, which was already detectable at the booting stage and was further enhanced until plant maturity. Nutrient concentrations of straw were more affected than those of grains. The decrease in concentration was greatest for N followed by Mg, Ca and K, and the maximum decrease as compared with ambient CO₂ amounted to 43%, 35%, 33% and 21% for straw, and 30%, 13%, 28% and - 6% for grains. Concentrations of micronutrients were also found to be partially decreased by about 10-30%. At 718 p.p.m. CO₂, grain protein concentrations were 96% (cv. Arena), 85% (cv. Alexis), 72% (cv. Turbo) and 70% (cv. Star) of the ambient CO₂ value, however, the index of essential amino acids was increased. Overall, the CO₂ enrichment did not decrease the nutrient harvest index of all nutrients except of sulphur. Nutrient use efficiency increased by high CO₂ levels for cv. Star and cv. Turbo and decreased for cv. Arena.

Manderscheid, R., J. Bender, U. Schenk, and H.J. Weigel. 1997. Response of biomass and nitrogen yield of white clover to radiation and atmospheric CO₂ concentration. *Environmental and Experimental Botany* 38(2):131-143.

The objectives of the present study were to test (i) whether the effect of season-long CO₂ enrichment on plant dry matter production of white clover (*Trifolium repens* cv. Karina) depends on the temperature or can solely be explained by changes in radiation use efficiency, and (ii)

whether the atmospheric CO₂ concentration affects the relationship between tissue %N and plant biomass. Plants were grown in pots with adequate nutrient and water supply and were exposed to ambient and above ambient CO₂ concentrations (approximately + 80 ppm, + 160 ppm, + 280 ppm) in open-top chambers for two seasons. Nitrogen fertilizer was given only before the experiment started to promote N-2 fixation. Plants were clipped to a height of 5 cm, when the canopy had reached a height of about 20 cm and when the CO₂ effect had not been diminished due to self-shading of the leaves. Photon exposure (400-700 nm) measured above the canopy was linearly related to the above ground biomass, the leaf area index and the nitrogen yield ($r^2 > 0.94$). The slopes of the curves depended on the CO₂ concentration. Since most of the radiation (>90%) was absorbed by the foliage, the slopes were used to calculate the CO₂ effect on the radiation use efficiency of biomass production, which is shown to increase curvilinearly between 380 and 660 ppm CO₂ from 2.7 g MJ⁻¹ to 3.9 g MJ⁻¹. CO₂ enrichment increased above ground biomass by increasing the leaf number, the individual leaf weight and the leaf area; specific leaf weight was not affected. The relative CO₂ response varied between harvests; there was a slight but not significant positive relationship with mean daytime temperature. At the beginning of the season, plant nitrogen concentration in the above ground biomass was decreased by CO₂ enrichment. However, at later growth stages, when the plants depended solely on N-2 fixation, nitrogen concentration was found to be increased when the nitrogen concentration value was adjusted for the decrease due to the higher biomass of the plants exposed to elevated CO₂. Manderscheid, R., and H.J. Weigel. 1995. Do increasing atmospheric CO₂ concentrations contribute to yield increases of German crops. *Journal of Agronomy and Crop Science-Zeitschrift für Acker und Pflanzenbau* 175(2):73-82.

The global atmospheric CO₂-concentration is increasing and there has been an increase in Germany of about 30 ppm from 340 ppm to 370 ppm CO₂ during the last two decades. The hectare yield of many crops has also increased during this time period. The objective of the present study was to estimate whether the past and future change in the atmospheric composition significantly contributes to the increase in hectare yield. Different crop species (beans, *Phaseolus vulgaris*, cv Pfalzer Juni; spring barley, *Hordeum vulgare* L., cvs. Alexis and Arena; spring wheat, *Triticum aestivum* L., cvs. Star and Turbo; maize, *Zea mays* L., cvs. Bonny and Boss) were grown at ambient (372 ppm) and at slightly elevated CO₂-concentrations (459 ppm and 539 ppm) in open-top chambers and the effect of the different CO₂-concentrations on the growth and yield of the plants was measured. The past and future CO₂-effect was estimated from the slope of a linear CO₂-yield curve (percentage increase in yield per ppm CO₂, 100 % at 370 ppm) fitted to the data and those from previous studies on wheat and maize. The percentage increase in yield per ppm CO₂ is insignificant for beans, of borderline significance for silage maize (0.06 % per ppm), and 0.35 % per ppm and 0.26 % per ppm for barley and wheat, respectively. The CO₂-elevation primarily decreases the tiller dieback of the cereals. Considering the increase in CO₂ of 30 ppm and in the hectare yield of 25 % (barley) and 28 % (wheat) from 1970 to 1990, the contribution of CO₂ to the increase in the agricultural production is estimated to be one fourth up to one half of the increase in hectare yield of spring cereals. Given a recent yearly increase of 2 ppm the future CO₂-related increase in hectare yield is estimated to be about 0.5-0.7 % per year.

Manderscheid, R., and H.J. Weigel. 1997. Photosynthetic and growth responses of old and modern spring wheat cultivars to atmospheric CO₂ enrichment. *Agriculture Ecosystems & Environment* 64(1):65-73.

Cultivars of spring wheat (*Triticum aestivum* L.) introduced between 1890 and 1988 were cultivated in pots under optimal growth conditions and exposed during the whole growing season to normal (379 p.p.m.) and elevated CO₂ concentrations (689 p.p.m.) in open-top chambers. CO₂ effects were measured at anthesis on flag leaf composition (chlorophyll and protein) and photosynthetic parameters, and at maturity on plant growth and yield. CO₂ enrichment did not affect light saturated rate of photosynthesis measured at 400 p.p.m. CO₂ or protein, total chlorophyll and dry weight content per unit leaf area. However, single flag leaf area and fresh weight per leaf area were increased by CO₂. This increase was possibly responsible for a significant decrease in the chlorophyll a/b ratio. Under normal atmospheric CO₂ concentration, the total above-ground biomass, stem weight and height, and ear number were negatively correlated with the year of cultivar release. Despite no evidence of CO₂ acclimation, i.e. changes in flag leaf composition, CO₂ enrichment resulted in a greater growth stimulation of the older than the modern cultivars. This was due to a greater CO₂ effect on those growth components that were altered during plant breeding of wheat in the past, i.e. stem weight and height, and ear number. The average CO₂-related increase in biomass and grain yield amounted to ca 46% and 28% for the three old (1890-1943) and three modern cultivars (1965- 1988), respectively. Differences in yield response to CO₂ enrichment between old and modern cultivars could be mainly explained by changes in ear number. (C) 1997 Elsevier Science B.V.

Manninen, P., J. Pakarinen, and H. Kallio. 1997. Large-scale supercritical carbon dioxide extraction and supercritical carbon dioxide countercurrent extraction of cloudberry seed oil. *Journal of Agricultural and Food Chemistry* 45(7):2533-2538.

Dried press residue of cloudberry [*Rubus chamaemorus* (Rosaceae)] was extracted with carbon dioxide at pressures of 90-300 bar and at a temperature of 40 or 60 degrees C using a pilot-scale or a production-scale plant. The yield of the extract at the highest pressure was approximately 15% less than that obtained with Soxhlet extraction using diethyl ether as solvent. The extracts were either solids or viscous oils depending on the amount of neutral lipids, which increased with increasing pressure. No significant differences in the composition of the major constituent fatty acids in any of the extracts were found. The color of the extracts was clearly dependent on the amount of carotenes, which consisted mainly of beta-carotene. The content of carotenes in the extracts did not increase at pressures higher than 150 bar. The amount of tocopherols in the extracts obtained at highest pressure was found to be approximately 3 times less than that at lower pressures. Countercurrent CO₂ extraction of the cloudberry oil extracted at 300 bar and 40 degrees C resulted in enrichment of tocopherols in the extracts and a decrease in the amount of carotenes. The concentrations of tocopherols and carotenes in all of the CO₂ extracts, the countercurrent extracts, and the raffinates were found to be clearly higher than those in the edible part of fresh cloudberry reported by other authors.

Mansfield, J.L., P.S. Curtis, D.R. Zak, and K.S. Pregitzer. 1999. Genotypic variation for condensed tannin production in trembling aspen (*Populus tremuloides*, Salicaceae) under elevated CO₂ and in high- and low-fertility soil. *American Journal of Botany* 86(8):1154-1159.

The carbon/nutrient balance hypothesis suggests that leaf carbon to nitrogen ratios influence the synthesis of secondary compounds such as condensed tannins. We studied the effects of rising atmospheric carbon dioxide on carbon to nitrogen ratios and tannin production. Six genotypes of *Populus tremuloides* were grown under elevated and ambient CO₂ partial pressure and high- and low-fertility soil in field open-top chambers in northern lower Michigan, USA. During the second year of exposure, leaves were harvested three times (June, August, and September) and analyzed for condensed tannin concentration. The carbon/nutrient balance hypothesis was supported overall, with significantly greater leaf tannin concentration at high CO₂ and low soil fertility compared to ambient CO₂ and high soil fertility. However, some genotypes increased tannin concentration at elevated compared to ambient CO₂, while others showed no CO₂ response. Performance of lepidopteran leaf miner (*Phyllonorycter tremuloidiella*) larvae feeding on these plants varied across genotypes, CO₂, and fertility treatments. These results suggest that with rising atmospheric CO₂, plant secondary compound production may vary within species. This could have consequences for plant-herbivore and plant-microbe interactions and for the evolutionary response of this species to global climate change.

Mansfield, T.A. 1998. Stomata and plant water relations: does air pollution create problems? *Environmental Pollution* 101(1):1-11.

Small changes in the gaseous composition of the atmosphere have many different impacts on terrestrial plants. Some of the most important involve changes in stomatal control of leaf conductance. Evolution has provided highly complex mechanisms by which stomata respond to a wide range of environmental factors to balance the conflicting priorities of carbon gain for photosynthesis and water conservation. These mechanisms involve direct responses of the guard cells to aspects of the aerial environment, and hormonal communication within the plant enabling conductance to be adjusted according to soil moisture status. Various aspects of these delicately balanced mechanisms can be disturbed by air pollutants. Impairment of the regulation of plant water use by SO₂ and O₃ has been known for some years, but there are still many obstacles to our understanding of the variations in response between species, or even between genotypes of the same species. A surprising outcome of some recent studies is the suggestion that CO₂ pollution may disrupt the control of water relations in some species because their stomata do not close sufficiently in CO₂-enriched air. It has often been taken for granted that the elevation of atmospheric CO₂ would lead to economies in water use by plant canopies, but the underlying assumptions are now being seriously questioned. Marek, L.F., and M.H. Spalding. 1991. Changes in photorespiratory enzyme-activity in response to limiting CO₂ in *Chlamydomonas reinhardtii*. *Plant Physiology* 97(1):420-425.

The activity of two photorespiratory enzymes, phosphoglycolate phosphatase (PGPase) and glycolate dehydrogenase (glycolate DH), changes when CO₂-enriched wild-type (WT) *Chlamydomonas reinhardtii* cells are transferred to air levels of CO₂. Adaptation to air levels of CO₂ by *Chlamydomonas* involves induction of a CO₂-concentrating mechanism (CCM) which increases the internal inorganic carbon concentration and suppresses oxygenase activity of ribulose-1,5-bisphosphate carboxylase/oxygenase. PGPase in cell extracts shows a transient increase in activity that reaches a maximum 3 to 5 hours after transfer and then declines to the original level within 48 hours. The decline in PGPase activity begins at about the time that physiological evidence indicates the CCM is approaching maximal activity. Glycolate DH activity in 24 hour air-adapted WT cells is double that seen in CO₂-enriched cells. Unlike WT, the high-CO₂-requiring mutant, *cia-5*, does not respond to limiting CO₂ conditions: it does not induce any known aspects of the CCM and it does not show changes in PGPase or glycolate DH activities. Other known mutants of the CCM show patterns of PGPase and glycolate DH activity after transfer to limiting CO₂ which are different from WT and *cia-5* but which are consistent with changes in activity being initiated by the same factor that induces the CCM, although secondary regulation must also be involved.

Marek, M.V., and J. Kalina. 1996. Comparison of two experimental approaches used in the investigations of the long-term effects of elevated CO₂ concentration. *Photosynthetica* 32(1):129-133.

Two experimental devices used in the investigations of the long-term effects of elevated CO₂ were compared from the point of view of occurrence of downregulation of photosynthesis. The comparison was made on the basis of net photosynthetic rate/internal CO₂ concentration (P-N/C-i) response and effective quantum yield of photosystem 2 (PS2), respectively. In branch bags, the needles of Norway spruce showed no down regulation of photosynthetic capacity. However, in open top chambers decreases in maximal P-N (32%), carboxylation efficiency (28%) and potential photochemical efficiency of PS2 (8%), and the quantum yield (up to 50%) were detected.

Marek, M.V., J. Kalina, and M. Matouskova. 1995. Response of photosynthetic carbon assimilation of Norway spruce exposed to long-term elevation of CO₂ concentration. *Photosynthetica* 31(2):209-220.

Young (12 years old) Norway spruce (*Picea abies* [L.] Karst.) trees were exposed to ambient CO₂ or ambient + 350 $\mu\text{mol}(\text{CO}_2) \text{mol}^{-1}$ continuously over 2 growing seasons in open-top chambers, under field conditions of a mountain stand. Comprehensive analysis of CO₂ assimilation was performed after 4 and 22 weeks of the second growing season to evaluate the influence of elevated atmospheric CO₂. A combination of gas exchange and a mathematical model of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBPCO) activity was used. After 4 weeks of exposure no statistically significant stimulation of the radiant energy and CO₂ saturated rate of CO₂ uptake (P-Nsat) by the elevated CO₂ concentration was found. Yet after 24 weeks a statistically significant depression of P-Nsat (38%) and carboxylation efficiency (32%) was observed. Depression of photosynthetic activity by elevated CO₂ resulted from a decrease in the RuBPCO carboxylation rate. The electron transport rate was also modified similarly to the rate of RuBP formation. An accompanying decrease in nitrogen content of the needles (by 12%) together with an increase in total saccharides (by 34%) was observed.

after 24 weeks of exposure to enhanced CO₂.

During an open-top chamber experiment performed in a mountain stand of young (12-year-old) Norway spruce (*Picea abies* [L.] Karst.), the trees were exposed to one of two CO₂ concentrations (ambient CO₂, AC, or AC + 350 $\mu\text{mol mol}^{-1}$) = elevated CO₂, EC) continuously over three growing seasons. To evaluate the EC influence, measurements of the relations between the rate of net CO₂ uptake (P-N) and incidental photosynthetically active photon flux density (PPFD), as well as the content of photosynthetic pigments and chlorophyll (Chl) a fluorescence were taken in the third growing season. The short-term response to EC was evident mainly on ribulose-1,5-bisphosphate carboxylase/oxygenase kinetics without any significant change to the utilization of radiant energy. The long-term effect of EC was responsible for a decrease in P-N, Content of Chl a + b, F-v/F-m ratio, quantum yield of fluorescence, and photochemical quenching. Changes of stoichiometry between the electron transport, Calvin cycle and the end-product synthesis were confirmed for responses to the longterm import of EC and led to a definition of the photosynthetic acclimation to EC in Norway spruce.

Margolis, H.A., and M.G. Ryan. 1997. A physiological basis for biosphere-atmosphere interactions in the boreal forest: an overview. *Tree Physiology* 17(8-9):491-499.

Interdisciplinary field experiments for global change research are large, intensive efforts that study the controls on fluxes of carbon, water, trace gases, and energy between terrestrial ecosystems and the atmosphere at a range of spatial scales. Forest ecophysiology can make significant contributions to such efforts by measuring, interpreting, and modeling these fluxes for the individual components of forest ecosystems and then integrating the results into holistic ecosystem process models. The Boreal Ecosystem-Atmosphere Study (BOREAS) was undertaken because of the importance of the boreal forest biome to various global change issues. The study was conducted from 1993 to 1996 at sites in Saskatchewan and Manitoba, Canada. Results have shown that physiological processes of plants in the boreal forest can have large-scale consequences. For example, the composition of tree species strongly influences flux rates, with deciduous species having much higher carbon and water fluxes than coniferous species. Additionally, physiological limitations to transpiration in boreal conifers, even when soil water is abundant, reduces latent heat flux and increases sensible heat flux over large regions. This physiological control of transpiration can increase the depth of the atmospheric boundary layer on warm spring days to a level similar to that found in desert biomes. This special issue features 10 articles that address various aspects of the physiological basis of biosphere-atmosphere interactions in the boreal forest. The articles emphasize the environmental controls on water flux, carbon flux, and ecosystem productivity.

Marilley, L., U.A. Hartwig, and M. Aragno. 1999. Influence of an elevated atmospheric CO₂ content on soil and rhizosphere bacterial communities beneath *Lolium perenne* and *Trifolium repens* under field conditions. *Microbial Ecology* 38(1):39-49.

The increase in atmospheric CO₂ content alters C-3 plant photosynthetic rate, leading to changes in rhizodeposition and other root activities. This may influence the activity, the biomass, and the structure of soil and rhizosphere microbial communities and therefore the nutrient cycling rates and the plant growth. The present paper focuses on bacterial numbers and on community structure. The rhizospheres of two grassland plants, *Lolium perenne* (ryegrass) and *Trifolium repens* (white clover), were divided into three fractions: the bulk soil, the rhizospheric soil, and the rhizoplaneendrhizosphere. The elevated atmospheric CO₂ content increased the most probable numbers of heterotrophic bacteria in the rhizosphere of *L. perenne*. However, this effect lasted only at the beginning of the vegetation period for *T. repens*. Community structure was assessed after isolation of DNA, PCR amplification, and construction of cloned 16S rDNA libraries. Amplified ribosomal DNA restriction analysis (ARDRA) and colony hybridization with an oligonucleotide probe designed to detect *Pseudomonas* spp. showed under elevated atmospheric CO₂ content an increased dominance of pseudomonads in the rhizosphere of *L. perenne* and a decreased dominance in the rhizosphere of *T. repens*. This work provides evidence for a CO₂-induced alteration in the structure of the rhizosphere bacterial populations, suggesting a possible alteration of the plant-growth-promoting- rhizobacterial (PGPR) effect.

Marino, B.D.V., T.R. Mahato, J.W. Druitt, L. Leight, G.H. Lin, R.M. Russell, and F.N. Tubiello. 1999. The agricultural biome of Biosphere 2: Structure, composition and function. *Ecological Engineering* 13(1-4):199-234.

The agricultural mesocosm of Biosphere 2, known as the Intensive Agricultural Biome (IAB), provided food for the inhabitants of the facility during two periods of material closure between 1991 and 1994 (Mission I, September 26, 1991 to September 26, 1993, eight-person crew; Mission II, March 6, 1994 to September 17, 1994, seven-person crew). The design and operation of the mesocosm and preliminary results for food production of the IAB are described for both periods. The overall rate of crop production for the 0.22 ha area (soil depth of 1 m; soil and atmospheric volumes of approximately 2000 m³ and 38000 m³, respectively) sustained both crews. Overall production rates in Biosphere 2 exceeded those characteristic of fertile agricultural land in the most efficient agrarian communities, despite comparatively lower light levels, lack of insect pollinators and unusually dense insect pests. Crop yields were markedly higher for Mission II than for Mission I due, in part, to experience and improvements based on the first closure. The health of the Biospherians is briefly discussed in the context of a low-

calorie (1800-2200 kcal day⁻¹) per person for Mission I and 2200-2400 kcal day⁻¹ for Mission II), nutrient-dense diet characteristic of the Biosphere 2 food paradigm. High productivity and biodiversity were due to many factors including high resolution climate control, hyper-intensive agricultural practices, selection and planting of food crops adapted to humid, tropical and sub-tropical conditions, nutrient recycling, intensive pest management, and the superambient levels of atmospheric CO₂ (concentrations up to 4500 ppmv were reported during the 1991 to 1994 occupations). Radiation use efficiency (RUE) for wheat for both periods and a post-Mission II planting were comparable to RUEs observed in other experimental elevated CO₂ settings such as Controlled Ecological Life Support-Systems (CELSS) and Free Air CO₂ Enrichment studies (FACE) even though yields were comparatively lower due to low light levels. Integrated management of pests, soil conditions and agricultural practices were key factors in the sustainability of the IAB resulting in minimization of plant loss due to insect herbivory, nematode infestation and reduction in the quality of IAB soils. The use of soils rather than hydroponic systems for the IAB had significant consequences for CO₂, N₂O and O₂ concentrations in the Biosphere 2 atmosphere and rendered primary regeneration technologies ineffective over the periods of closure. The initial high organic carbon content of the IAB soils prescribed by the designers proved to be the largest single source of CO₂ and the largest sink for O₂. The choice of a soil-based compared to a hydroponic-based agricultural system contributed to the accumulation of N₂O to levels as high as 300 times current ambient levels (approximately 310 ppbv). The IAB of Biosphere 2 has the potential; with system improvement, to be a high-yielding, self-sustaining agricultural mesocosm suited for a variety of research endeavors. Mark, U., and M. Tevini. 1997. Effects of solar ultraviolet-B radiation, temperature and CO₂ on growth and physiology of sunflower and maize seedlings. *Plant Ecology* 128(1-2):224-234.

The effects of solar UV-B radiation, in combination with elevated temperature (4 degrees C) and CO₂ (680 µmol L⁻¹) concentration, on sunflower and maize seedlings were studied from May to August in 1991 at the research station Quinta de Sao Pedro in Portugal (38.7 degrees N). The ambient solar radiation of Portugal was reduced to levels of Central European latitudes by using the ozone filter technique. This radiation served as control, while the ambient solar radiation of Portugal was to simulate intense UV-B treatment (+30%). All plants were grown up to 18 days in 4 climate controlled growth chambers simulating a daily course of temperature with T-max=28 degrees C or 32 degrees C, resp., and ambient CO₂ concentrations (340 µmol L⁻¹); in one chamber the CO₂ concentration was twice as high (680 µmol L⁻¹). Under intense UV-B and at 28 degrees C (T-max) all growth parameters (height, leaf area, fresh and dry weight, stem elongation rate, relative growth rate) of sunflower and maize seedlings were reduced down to 35% as compared to controls. An increase in growing temperature by 4 degrees C, alone or in combination with doubled CO₂, compensated or even overcompensated the UV-B effect so that the treated plants were comparable to controls. Chlorophyll content, on a leaf area basis, increased under intense UV-B radiation. This increase was compensated by lower leaf areas, resulting in comparable chlorophyll contents. Similar to growth, also the net photosynthetic rates of sunflower and maize seedlings were reduced down to 29% by intense UV-B calculated on a chlorophyll basis. This reduction was compensated by an increased temperature. Doubling of CO₂ concentration had effects only on sunflower seedlings in which the photosynthetic rates were higher than in the controls. Dark respiration rates of the seedlings were not

influenced by any experimental condition. Transpiration and water use efficiency (wue) were not influenced by intense UV-B. Higher temperatures led to higher transpiration rates and lower water use efficiencies, resp. Doubling of CO₂ reduced the transpiration rate drastically while for wue maximum values were recorded.

Markkola, A.M., A. Ohtonen, U. Ahonen-Jonnarth, and R. Ohtonen. 1996. Scots pine responses to CO₂ enrichment. 1. Ectomycorrhizal fungi and soil fauna. *Environmental Pollution* 94(3):309-316.

Ectomycorrhizal Scots pine seedlings were grown in unfertilized forest soil at ambient and double (ca 700 ppm) atmospheric concentrations of CO₂. The biomass of seedlings and fungal biomass both in the roots and in the soil and the numbers of certain groups of soil animals were measured under summer conditions and after an artificial winter acclimation period. No biomass parameter showed any significant change due to CO₂ elevation. Increases were found during the winter acclimation period in total and fine root biomasses, fungal biomass in the soil and total fungal biomass both in the roots and in the soil, while the ratio of needle biomass:fungal biomass and the shoot:root ratio decreased. The N concentration in previous-year needles was lower in the double CO₂ environment than with ambient CO₂. Enchytraeids almost disappeared in the double CO₂ environment during winter acclimation, while the numbers of nematodes increased at the same time in both treatments. (C) 1997 Elsevier Science Ltd.

1457

Marks, S., and D.E. Lincoln. 1996. Antiherbivore defense mutualism under elevated carbon dioxide levels: A fungal endophyte and grass. *Environmental Entomology* 25(3):618-623.

Previous studies have shown that insects commonly consume more when fed leaf tissue grown under CO₂ enrichment, but with few negative effects on growth. However, lepidopteran larvae fed tissue infected with *Balsania* fungal endophytes (which produce toxic alkaloids) typically eat less but also suffer negative effects on growth and survival. This study was carried out to understand how these 2 factors may interact to affect larval consumption and growth in fall armyworm, *Spodoptera frugiperda* (J. E. Smith) (Lepidoptera: Noctuidae). Infected and uninfected ramets of a single genotype of tall fescue, *Festuca arundinacea* Schreb., were grown under CO₂ concentrations of 400 and 700 µmol CO₂/liter of air. Relative consumption of leaf tissue by larvae was 32% greater in the high CO₂ treatment compared with leaves grown under low CO₂ concentrations, but was not influenced by infection. As expected, larvae had significantly decreased relative growth rates when fed infected tissue, with their growth rates somewhat increased under high CO₂ levels. Increased CO₂ level and infection both led to significantly reduced efficiency of conversion of ingested food. These 2

factors also interacted so that the lowest efficiency of conversion of ingested food was seen when both infection and an enriched atmospheric CO₂ environment were present. As global atmospheric CO₂ levels continue to increase, it appears that fungal endophytes will continue to be important in turfgrasses as protection against insect herbivores and may lead to increased fitness for infected plant genotypes.

Maroco, J.P., G.E. Edwards, and M.S.B. Ku. 1999. Photosynthetic acclimation of maize to growth under elevated levels of carbon dioxide. *Planta* 210(1):115-125.

The effects of elevated CO₂ concentrations on the photochemistry, biochemistry and physiology of C-4 photosynthesis were studied in maize (*Zea mays* L.). Plants were grown at ambient (350 μ mol L⁻¹) or ca. 3 times ambient (1100 μ mol L⁻¹) CO₂ levels under high light conditions in a greenhouse for 30 d. Relative to plants grown at ambient CO₂ levels, plants grown under elevated CO₂ accumulated ca. 20% more biomass and 23% more leaf area. When measured at the CO₂ concentration of growth, mature leaves of high-CO₂-grown plants had higher light-saturated rates of photosynthesis (ca. 15%), lower stomatal conductance (71%), higher water-use efficiency (225%) and higher dark respiration rates (100%). High-CO₂-grown plants had lower carboxylation efficiencies (23%), measured under limiting CO₂, and lower leaf protein contents (22%). Activities of a number of C-3 and C-4 cycle enzymes decreased on a leaf-area basis in the high-CO₂-grown plants by 5-30%, with NADP-malate dehydrogenase exhibiting the greatest decrease. In contrast, activities of fructose 1,6-bisphosphatase and ADP-glucose pyrophosphorylase increased significantly under elevated CO₂ condition (8% and 36%, respectively). These data show that the C-4 plant maize may benefit from elevated CO₂ through acclimation in the capacities of certain photosynthetic enzymes. The increased capacity to synthesize sucrose and starch, and to utilize these endproducts of photosynthesis to produce extra energy by respiration, may contribute to the enhanced growth of maize under elevated CO₂.

Marshall, J.D., and R.A. Monserud. 1996. Homeostatic gas-exchange parameters inferred from C-13/C-12 in tree rings of conifers. *Oecologia* 105(1):13-21.

The CO₂ concentration of the atmosphere has increased by almost 30% in the past two centuries, with most of the increase (> 5 Pa) during the past 60 years. Controlled environment studies of crop plants dependent on the C-3 photosynthetic pathway indicate that an increase of this magnitude would enhance net photosynthesis, reduce stomatal conductance, and increase the difference in CO₂ concentration across the stomata, i.e., CO₂ concentration outside the leaf to that within (c(a)-c(i)). Here we report evidence, based on stable isotope composition of tree rings from three species of field-grown, native conifer trees; that the trees have indeed responded. However, rather than increasing c(a)-c(i), intercellular CO₂ concentrations have shifted upward to match the rise in atmospheric concentrations, holding c(a)-c(i) constant. No differences were detected among Douglas-fir (*Pseudotsuga menziesii*), ponderosa pine (*Pinus ponderosa*), or western white pine (*Pinus monticola*). The values of c(a)-c(i) were inferred from stable carbon isotope ratio ($\delta^{13}\text{C}$) of tree ring holocellulose adjusted for the 0.6- 2.6 parts per

thousand difference between holocellulose and whole sapwood. The cellulose extraction removed contaminants deposited in the tree ring after it formed and the adjustment corrected for the enrichment of cellulose relative to whole tissue. The whole sapwood values were then adjusted for published estimates of past atmospheric $\delta^{13}\text{C}$ and CO₂ concentrations. To avoid confounding tree age with CO₂, cellulose deposited by saplings in the inner rings of trees when the mature trees were saplings, between 1910-1929 and 1941-1970: thus saplings were compared to saplings. In a separate analysis, the juvenile effect, which describes the tendency for $\delta^{13}\text{C}$ to increase in the first decades of a tree's life, was quantified independent of source CO₂ effects. This study provides evidence that conifers have undergone adjustments in the intercellular CO₂ concentration that have maintained c(a)-c(i) constant. Based on these results and others, we suggest that c(a)-c(i) which has also been referred to as the intrinsic water-use efficiency, should be considered a homeostatic gas-exchange set point for these conifer species.

Martin, C.A., J.C. Stutz, B.A. Kimball, S.B. Idso, and D.H. Akey. 1995. Growth and topological changes of citrus-limon (L) burm f eureka in response to high-temperatures and elevated atmospheric carbon-dioxide. *Journal of the American Society for Horticultural Science* 120(6):1025-1031.

Growth and topological indices of 'Eureka' lemon were measured after 6 months in well-watered and well-fertilized conditions and factorial combinations of moderate (29/21C day/night) or high (42/32C day/night) temperatures and ambient (350 to 380 μ mol . mol⁻¹) or elevated (constant 680 μ mol . mol⁻¹) CO₂. In high temperatures, plants were smaller and had higher levels of leaf chlorophyll alpha than in moderate temperatures. Moreover, plants in high temperatures and elevated CO₂ had about 15% higher levels of leaf chlorophyll alpha than those in high temperatures and ambient CO₂. In high temperatures, plant growth in elevated CO₂ was about 87% more than in ambient CO₂. Thus, high CO₂ reduced the negative effect of high temperature on shoot growth. In moderate temperatures, plant growth in elevated CO₂ was only about 21% more than in ambient CO₂. Irrespective of temperature treatments, shoot branch architecture in elevated CO₂ was more hierarchical than those in ambient CO₂. Specific shoot extension, a topological measure of branch frequency, was not affected by elevated CO₂ in moderate temperatures, but was increased by elevated CO₂ enrichment in high temperatures-an indication of decreased branch frequency and increased apical dominance. In moderate temperatures, plants in elevated CO₂ had fibrous root branch patterns that were less hierarchical than at ambient CO₂. The lengths of exterior and interior fibrous roots between branch points and the length of second-degree adventitious lateral branches were increased >50% by high temperatures compared with moderate temperatures. Root length between branch points was not affected by CO₂ levels.

Martin, P. 1992. Exe: a climatically sensitive model to study climate change and co2 enhancement effects on forests. *Australian Journal of Botany* 40(4-5):717-735.

Vegetation plays a significant role in determining the local and regional hydrology of ice-free continental surfaces and the dynamics of the atmosphere above it. Vegetation also influences the global climate directly by affecting atmospheric chemistry. In particular, it partially controls the carbon cycle. In turn, vegetation is influenced by climate and changes in the ambient concentration of CO₂. This may have important consequences for agriculture and natural resource exploitation. A formal recognition of atmosphere/biosphere interrelationships is crucial but insufficient. Systematic investigations of the interactions between climate, plant physiology and ecology are badly needed. In this spirit, this paper presents the results of numerical simulations performed with the Energy, water and momentum exchange, and Ecological dynamics (EXE) model at a local scale over periods of 400-800 (simulation) years. EXE constitutes a first attempt to couple a physiologically based water budget and an explicit treatment of ecological dynamics. In principle, EXE could be forced by the output of an atmospheric general circulation model (GCM). Within this context, the paper demonstrates through the examples it analyses that both potential stomatal response to CO₂ and the possible range of changes in atmospheric relative humidity are likely major factors in determining the ecosystem response to greenhouse warming. Consequently, they should be considered in future studies of this kind. The paper also provides explanations regarding the movement of ecotones, defined as the transition zones between different vegetation assemblages. Taking the North American forest/prairie boundary as a case study, the analysis of the results shows how, in a greenhouse warmed world, St Paul, MN, might look like North Platte, NE. Finally, building on the previous example by using two different models, this study illustrates that results can be strongly model dependent and encourages extreme caution in their interpretation.

Martin, P.H., and A.B. Guenther. 1995. Insights into the dynamics of forest succession and non-methane hydrocarbon trace gas emissions. *Journal of Biogeography* 22(2-3):493-499.

Natural biogenic non-methane hydrocarbon (NMHC) emissions significantly influence the concentrations of free hydroxyl and peroxy radicals, carbon monoxide and tropospheric ozone. Present concerns with air pollution and the global carbon balance call for a better understanding of the respective roles of climate dynamics and vegetation succession in determining NMHC emissions. This constitutes the focus of the present paper. The approach consists in coupling the Energy, Water and Momentum Exchange and Ecological Dynamics model, a climatically sensitive, physically based gap phase forest dynamics model, and NMHC trace gas emission algorithms to assess possible changes in NMHC emissions from forests under stationary and changing climatic conditions. In summary, it is possible to follow the temporal evolution of foliar emissions over centuries using a vegetation dynamics model coupled with an NMHC emissions module. Significant changes in isoprene and terpene emissions can take place as vegetation succession occurs under stationary climatic conditions and as climatic perturbations of the type and magnitude foreseen for global change alter the local microclimate. As illustrated by two examples, emissions may decrease or increase depending on the local climate and vegetation. The respective actions of changes in species absolute and relative abundance and changes in temperature interact very non-linearly making changes in emissions difficult to predict. None the less, coupled models of the kind described here may provide useful insights into the direction of such changes.

Martinez, I., M.I. Orus, and E. Marco. 1997. Carboxysome structure and function in a mutant of *Synechococcus* that requires high levels of CO₂ for growth. *Plant Physiology and Biochemistry* 35(2):137-146.

The high CO₂-requiring mutant N1 of *Synechococcus* sp. PCC 7942 possesses aberrant carboxysomes and is unable to utilize the internal inorganic carbon pool for photosynthesis. Normal carboxysomal carbonic anhydrase (EC 4.2.1.1) and ribulose 1,5 biphosphate carboxylase/oxygenase (EC 4.1.1.39) activities were obtained under saturated substrate concentrations, but limiting concentrations of inorganic carbon resulted in a lower Rubisco activity compared to the wild type. The polypeptidic pattern of carboxysome-enriched fractions showed no differences between wild type and mutant N1, suggesting that the putative gene product inactivated in the mutant does not constitute a polypeptide of the carboxysome shell, but could play an important role in the process of carboxysome assembly. Data obtained are discussed in relation to the proposed quantitative model of the inorganic carbon concentrating mechanism of cyanobacteria.

Martins, A., A. Casimiro, and M.S. Pais. 1997. Influence of mycorrhization on physiological parameters of micropropagated *Castanea sativa* Mill. plants. *Mycorrhiza* 7(3):161-165.

Mycorrhizal micropropagated *Castanea sativa* plants were studied in terms of growth and physiological parameters following in vitro mycorrhization with *Pisolithus tinctorius*. Mycorrhization enhanced growth of micropropagated chestnut plants, increased their protein content and photosynthetic rates, decreased the respiratory rates and CO₂ compensation point, RuBisCO activity was not significantly different in mycorrhizal and control plants, although there was an increase in the amount of RuBisCO in the former. Mycorrhization increased plant biomass and improved plants physiological status, thus enhancing the acclimatization process.

Martos, J.M.G. 1993. Effect of CO₂ in storage atmosphere on mill olive fruit physiology. *Grasas Y Aceites* 44(2):81-84.

Olive fruits (*Olea europaea*) used for oil production were stored at 5-degrees-C and four different atmospheres (%CO₂/%O₂/%N₂: 0/21/78; 5/20/75; 10/19/71 and 20/17/63). At 5-degrees-C the enrichment of the storage atmosphere with greater-than-or-equal-to 5% CO₂ concentrations produced a proportional increase of the physiological disorder occurring in stored fruits. This occurrence had a strong relationship with the appearance of fruit decay. Simple refrigeration at 5-degrees-C was sufficient to maintain the same degree of ripening of olive fruits for 60 days. However, a longer period of storage at 5-degrees-C originated a remarkable incidence of chilling injuries in the fruits.

Masle, J. 1992. Will plant performance on soils prone to drought or with

high mechanical impedance to root penetration be improved under elevated atmospheric CO₂ concentration? *Australian Journal of Botany* 40(4-5):491-500.

Plants growing on dry soils or on soils with high mechanical resistance to root penetration grow more slowly and exhibit lower stomatal conductance than those growing on moist and loose soils. In most situations in nature where edaphic stresses develop rather slowly (compared to stresses imposed in most pot experiments conducted under controlled conditions), photosynthesis is mainly reduced via stomatal effects rather than via changes in mesophyll capacity for photosynthesis. Elevated CO₂ will induce an increase in the internal partial pressure of CO₂, despite stomatal conductance being lowered even further. Photosynthesis will therefore be improved, and leaf turgor will be increased. It is widely thought that growth on dry or hard soils is not carbon limited because levels of soluble carbohydrates in the leaves and root cells are increased. It is shown in this paper that growth on soil with high mechanical resistance does respond to elevated CO₂. However, this response is smaller than expected from the increase of carbon assimilation rate because: (a) carbon partitioning is altered so that supplementary carbohydrates are preferentially allocated to the roots; (b) leaf growth sensitivity to internal availability of sugars is lower than in plants growing on loose soils. These alterations of 'sink activity' and carbon partitioning are mediated by unknown signalling factor(s) induced in the roots. It is not known whether the root factors acting in droughted plants are of the same nature. In both droughted and impeded plants the interacting effects of these factors and of ambient CO₂ levels are likely to result in improved transpiration efficiency. More experiments are needed in this area, however, especially to ascertain the relative contribution of changes in growth patterns versus changes in the patterns of water use. In conclusion, the importance of identifying the nature of the sink limitations induced by root signals is emphasised. It is a fundamental area of research to be developed not only for assessing growth responses to rising CO₂ under edaphic stress, but likely also for reconciling conflicting responses of field- grown and pot-grown plants.

Masle, J., G.S. Hudson, and M.R. Badger. 1993. Effects of ambient CO₂ concentration on growth and nitrogen use in tobacco (*Nicotiana tabacum*) plants transformed with an antisense gene to the small-subunit of ribulose-1,5- biphosphate carboxylase oxygenase. *Plant Physiology* 103(4):1075-1088.

Growth of the R1 progeny of a tobacco plant (*Nicotiana tabacum*) transformed with an antisense gene to the small subunit of ribulose-1,5-carboxylase/oxygenase (Rubisco) was analyzed under 330 and 930 mbar of CO₂, at an irradiance of 1000 $\mu\text{mol quanta m}^{-2} \text{ s}^{-1}$. Rubisco activity was reduced to 30 to 50% and 13 to 18% of that in the wild type when one and two copies of the antisense gene, respectively, were present in the genome, whereas null plants and wild-type plants had similar phenotypes. At 330 mbar of CO₂ all antisense plants were smaller than the wild type. There was no indication that Rubisco is present in excess in the wild type with respect to growth under high light. Raising ambient CO₂ pressure to 930 mbar caused plants with one copy of the DNA transferred from plasmid to plant genome to achieve the same size as the wild type at 330 mbar, but plants with two copies remained smaller. Differences in final size were due mostly to early differences in relative rate of leaf area expansion ($\text{m}^2 \text{ m}^{-2} \text{ d}^{-1}$) or of biomass accumulation ($\text{g g}^{-1} \text{ d}^{-1}$): within less than 2 weeks after germination relative growth rates reached a steady-state value similar for all plants. Plants with greater carboxylation rates were characterized by a higher ratio of leaf carbon to leaf area, and at later stages, they were

characterized also by a relatively greater allocation of structural and nonstructural carbon to roots versus leaves. However, these changes per se did not appear to be causing the long-term insensitivity of relative growth rates to variations in carboxylation rate. Nor was this insensitivity due to feedback inhibition of photosynthesis in leaves grown at high partial pressure of CO₂ in the air ($p(a)$) or with high Rubisco activity, even when the amount of starch approached 40% of leaf dry weight. We propose that other intrinsic rate-limiting processes that are independent of carbohydrate supply were involved. Under plentiful nitrogen supply, reduction in the amount of nitrogen invested in Rubisco was more than compensated for by an increase in leaf nitrate. Nitrogen content of organic matter, excluding Rubisco, was unaffected by the antisense gene. In contrast, it was systematically lower at elevated $p(a)$ than at normal $p(a)$. Combined with the positive effects of $p(a)$ on growth, this resulted in the single-dose antisense plants growing as fast at 930 mbar of CO₂ as the wild-type plants at 330 mbar of CO₂ but at a lower organic nitrogen cost.

Matamala, R., and B.G. Drake. 1999. The influence of atmospheric CO₂ enrichment on plant-soil nitrogen interactions in a wetland plant community on the Chesapeake Bay. *Plant and Soil* 210(1):93-101.

We investigated plant and soil nitrogen pools and soil processes in monospecific stands of the C-3 sedge *Scirpus olneyi* and the C-4 grass *Spartina patens* grown in the field in open top chambers in a brackish marsh on the Chesapeake Bay. Stands of *S. olneyi* responded to eight years of elevated CO₂, by increased rates of net ecosystem gas exchange and a large stimulation of net ecosystem production. We conducted our study in the summer of 1994 and 1995 when soil cores were collected and aboveground biomass was estimated. Nitrogen concentration in elevated CO₂ treatments was reduced 15% in stems of *S. olneyi* and 8% in the upper 10 cm of the soil profile. While total plant nitrogen per unit of land area remained the same between treatments, total soil nitrogen showed a non- significant tendency to decrease in the upper 10 cm of the soil profile in elevated CO₂ both years of study. A significant decrease in soil bulk density largely contributed to the observed decrease in soil nitrogen. Exchangeable nitrogen and potential denitrification rates were also reduced in elevated CO₂, but net nitrogen mineralization was unchanged by elevated CO₂ treatment in *S. olneyi* both years. Plants and soils in a pure stand of the C-4 grass, *S. patens*, showed none of these effects of elevated CO₂ treatment. Our data provides evidence of changes in nitrogen dynamics of an ecosystem exposed to elevated CO₂ for eight years; however due to the variability in these data, we cannot say if or how these changes are likely to impact the effect of rising CO₂ on primary production or carbon accumulation in this ecosystem in the future.

Mathooko, F.M. 1996. Regulation of ethylene biosynthesis in higher plants by carbon dioxide. *Postharvest Biology and Technology* 7(1-2):1-26.

Elevated CO₂ levels used with or without reduced O₂ levels regulate many biochemical and physiological processes in higher plants, among them ethylene biosynthesis. The mode of action of elevated CO₂ in the

regulation of ethylene biosynthesis is still a subject of much debate. Various hypotheses have been put forward to explain its model(s) of action and most of them have pointed out that CO₂ regulates ethylene biosynthesis, at least in part, by counteracting ethylene action. This is thought to be mainly through the regulation of 1-aminocyclopropane-1-carboxylate (ACC) synthase, presumably the rate-limiting enzyme in the ethylene biosynthetic pathway, and in some instances ACC oxidase. The present review brings together recent developments on the biochemical, physiological and molecular bases for the regulation by CO₂ of ethylene biosynthesis in higher plants. The mode of activation of ACC oxidase by CO₂ is also discussed.

Mathooko, F.M. 1996. Regulation of respiratory metabolism in fruits and vegetables by carbon dioxide. *Postharvest Biology and Technology* 9(3):247-264.

The respiratory rate of fruits and vegetables can be used as an indicator for designing storage conditions to maximize the longevity of these commodities. One postharvest technique that has been used to prolong the storage life of some of these commodities is the use of a controlled atmosphere. The modulation of respiratory metabolism of such commodities held in controlled atmospheres containing reduced oxygen and/or elevated carbon dioxide levels has been thought of as the primary reason for the beneficial effects on the commodities. However, the mechanism by which elevated carbon dioxide influences the regulation of respiratory metabolism is still obscure and several hypotheses have been proposed for its mode(s) of action. The regulation may be directed towards the glycolytic pathway, the fermentative metabolism, the tricarboxylic acid cycle or the electron transport system, presumably through its influence on the synthesis, degradation, inactivation and/or activation of the respective enzymes. It may also be through the antagonistic effects of carbon dioxide on ethylene action as well as its influence on secondary metabolism through an alteration in cell pH. This article discusses the recent developments on the biochemical and physiological fronts as well as the possible mode(s) of action of elevated carbon dioxide in the regulation of respiratory metabolism in fruits and vegetables.

Mathooko, F.M., Y. Kubo, A. Inaba, and R. Nakamura. 1995. Characterization of the regulation of ethylene biosynthesis in tomato fruit by carbon-dioxide and diazocyclopentadiene. *Postharvest Biology and Technology* 5(3):221-233.

The regulation of ethylene biosynthesis by CO₂ and diazocyclopentadiene (DACP), both inhibitors of ethylene action, was investigated in tomato (*Lycopersicon esculentum* Mill. cv. 'Momotaro') fruit held at 25 degrees C. When the tomato fruit at the pink stage of ripeness were treated with 20% CO₂ (+ 20% O₂ + 60% N₂) or DACP, ethylene production by the fruit was rapidly decreased. The inhibition of ethylene production resulted primarily, if not solely, from the suppression of the activities of both 1-aminocyclopropane-1-carboxylic acid (ACC) synthase and ACC oxidase. The inhibition of ACC synthase activity subsequently led to low levels of ACC. CO₂ treatment further

inhibited ACC conjugation into 1- (malonylamino)cyclopropane-1-carboxylic acid (MACC). By contrast, DACP-treated fruit maintained slightly higher levels of MACC relative to the control fruit. When the fruit were transferred from the CO₂-enriched atmosphere to air, ethylene production, ACC and MACC contents and the activities of ACC synthase and ACC oxidase increased gradually to the control level after 24 h, while these values, except for MACC content, remained low in DACP-treated fruit throughout the experimental period. These results indicate that CO₂ and DACP regulate ethylene production in tomato fruit by inhibiting ACC synthase and ACC oxidase activities and further support the hypothesis that the autocatalytic signal associated with ethylene action during fruit ripening stimulates the activities of both enzymes.

Mathooko, F.M., Y. Kubo, A. Inaba, and R. Nakamura. 1995. Induction of ethylene biosynthesis and polyamine accumulation in cucumber fruit in response to carbon-dioxide stress. *Postharvest Biology and Technology* 5(1-2):51-65.

Carbon dioxide stress-induced ethylene biosynthesis, respiration and polyamine accumulation in cucumber fruit (*Cucumis sativus* L. cv. Sharp-1) held at 25 degrees C was investigated. Control fruit produced little ethylene and the respiration rate decreased with increase in incubation time while polyamine levels decreased. Elevated CO₂ induced ethylene production, respiration and polyamine accumulation. Putrescine and spermidine levels increased in response to CO₂ treatment, whereas spermine levels were not significantly affected. No cadaverine was detected in all treatments. The increase in ethylene production paralleled increases in 1-aminocyclopropane-1-carboxylic acid (ACC) and the activities of both ACC synthase and in vitro ACC oxidase. Infiltration of the fruit with aminooxyacetic acid, a potent inhibitor of the conversion of S-adenosylmethionine (AdoMet) to ACC completely blocked CO₂ stress-induced ethylene production. Similarly, cycloheximide, an inhibitor of nucleocytoplasmic protein synthesis effectively blocked CO₂ stress induction of polyamine accumulation, ethylene production, ACC formation and the development of ACC synthase. Withdrawal of CO₂ gas caused cessation of increases in ethylene production, respiration, ACC, putrescine and the activities of ACC synthase and ACC oxidase, but caused increase in spermidine and spermine levels. These data indicate that CO₂ induces de novo synthesis of ACC synthase thereby causing accumulation of ACC and increase in ethylene production and suggest that the conversion of AdoMet to ACC is the rate-limiting step in CO₂ stress-induced ethylene biosynthesis. The induction, however, requires continuous presence of the stimulus. The results also suggest that protein synthesis might be required for the CO₂ stress induction of polyamine biosynthesis. The results further suggest that in cucumber fruit under CO₂ stress, at least, the ethylene and polyamine biosynthetic pathways are not competitive.

Mathooko, F.M., M.W. Mwaniki, A. Nakatsuka, S. Shiomi, Y. Kubo, A. Inaba, and R. Nakamura. 1999. Expression characteristics of CS-ACS1, CS-ACS2 and CS-ACS3, three members of the 1-aminocyclopropane-1-carboxylate synthase gene family in cucumber (*Cucumis sativus* L.) fruit under carbon dioxide stress. *Plant and Cell Physiology* 40(2):164-172.

Fire investigated the expression pattern of three 1-aminocyclopropane-1-carboxylate (ACC) synthase genes, CS-ACS1, CS-ACS2 and CS-ACS3 in cucumber (*Cucumis sativus* L.) fruit under CO₂ stress. CO₂ stress-induced ethylene production paralleled the accumulation of only CS-ACS1 transcripts which disappeared upon withdrawal of CO₂. Cycloheximide inhibited the CO₂ stress-induced ethylene production but superinduced the accumulation of CS-ACS1 transcript. At higher concentrations, cycloheximide also induced the accumulation of CS-ACS2 and CS-ACS3 transcripts. In the presence of CO₂ and cycloheximide, the accumulation of CS-ACS2 transcript occurred within 1h, disappeared after 3h and increased greatly upon withdrawal of CO₂. Inhibitors of protein kinase and types 1 and 2A protein phosphatases which inhibited and stimulated, respectively, CO₂ stress-induced ethylene production had little effect on the expression of these genes. The results presented here identify CS-ACS1 as the main ACC synthase gene responsible for the increased ethylene biosynthesis in cucumber fruit under CO₂ stress and suggest that this gene is a primary response gene and its expression is under negative control since it is expressed by treatment with cycloheximide. The results further suggest that the regulation of CO₂ stress-induced ethylene biosynthesis by reversible protein phosphorylation does not result from enhanced ACC synthase transcription.

Mathooko, F.M., T. Sotokawa, Y. Kubo, A. Inaba, and R. Nakamura. 1993. Retention of freshness in fig fruit by CO₂-enriched atmosphere treatment or modified atmosphere packaging under ambient-temperature. *Journal of the Japanese Society for Horticultural Science* 62(3):661-667.

At 20-degrees-C, freshness retention of figs (*Ficus carica* L. cv. Masui Dauphine) by CO₂-enriched atmosphere treatment or modified atmosphere packaging were studied in an attempt to reduce deterioration during transportation. CO₂-enriched atmosphere treatment inhibited ethylene production, delayed the incidence of mold growth and promoted ethanol production. Majority of the figs exposed to 60% or 80% CO₂ for 2 days were still marketable 1 day after transfer to air at 20-degrees-C. Based on mold growth, figs stored in air and in unperforated polyethylene bags deteriorated slightly faster than those stored in perforated bags. A gas mixture of 80% CO₂ + 20% O₂ or 100% CO₂ introduced into the polyethylene bags before sealing were more effective in the control of mold growth compared to air or 100% N₂ and equally effective in reducing ethylene accumulation as 100% N₂. The results suggest that postharvest deterioration of figs can be reduced by either CO₂-enriched atmosphere treatment or through modified atmosphere packaging.

Matsueda, H., and H.Y. Inoue. 1999. Aircraft measurements of trace gases between Japan and Singapore in October of 1993, 1996, and 1997. *Geophysical Research Letters* 26(16):2413-2416.

Carbon dioxide (CO₂) methane (CH₄), and carbon monoxide (CO) mixing ratios were measured in discrete air samples from aircraft between Japan and Singapore in October. The mixing ratios of all trace gases at 9-12 km were enhanced over the South China Sea in 1997 compared with those in 1993 and 1996. Vertical distributions of all trace

gases over Singapore in 1997 also showed largely elevated mixing ratios at all altitudes. These distributions indicate a wide outflow of trace gases from intense biomass burning in the southeast Asia regions in the very strong El Nino year. The enhanced trace gases showed a strong linear correlation between CH₄ and CO, and between CO and CO₂, with the regression slopes of 0.051 Delta CH(4)ppb/Delta COppb and 0.089 (Delta COppb/Delta CO(2)ppb). The emission ratios are characteristic of fires with relatively lower combustion efficiency from the tropical rain forest and peat lands in Kalimantan and Sumatra of Indonesia.

Matsui, T., O.S. Namuco, L.H. Ziska, and T. Horie. 1997. Effects of high temperature and CO₂ concentration on spikelet sterility in indica rice. *Field Crops Research* 51(3):213-219.

The effects of increasing temperature and CO₂ concentration on floral sterility were examined for rice (cv. IR 72) using open-top chambers located at the International Rice Research Institute in Los Banos, Philippines. The field-based open-top chamber system was used to simulate four different environments: ambient temperature and CO₂ concentration (control); ambient temperature, ambient +300 mu l l(-1) CO₂; ambient +4 degrees C temperature, ambient CO₂ concentration; ambient +4 degrees C temperature, ambient +300 mu l l(-1) CO₂. High temperature during flowering resulted in increased pollen sterility with the degree of sterility exacerbated if rice was exposed to both high temperature and increased CO₂ concentration. The critical air temperature for spikelet sterility (as determined from the number of germinated pollen grains on the stigma) was reduced by ca 1 degrees C at elevated concentrations of carbon dioxide. We speculate that this downward shift in critical temperature may be due to the observed increase in air temperature within the canopy at high CO₂ concentrations. This increase in air temperature, in turn, may be related to stomatal closure and reduced transpirational cooling in an elevated CO₂ environment. Data from this experiment indicate that increasing CO₂ concentration could limit rice yield if average air temperature increased simultaneously.

Matthies, D., and P. Egli. 1999. Response of a root hemiparasite to elevated CO₂ depends on host type and soil nutrients. *Oecologia* 120(1):156-161.

Although elevated CO₂ may affect various forms of ecological interactions, the effect of elevated CO₂ on interactions between parasitic plants and their hosts has received little attention. We examined the effect of elevated CO₂ (590 mu l l(-1)) at two nutrient (NPK) levels on the interactions of the facultative root hemiparasite *Rhinanthus alectorolophus* with two of its hosts, the grass *Lolium perenne* and the legume *Medicago sativa*. To study possible effects on parasite mediation of competition between hosts, the parasite was grown with each host separately and with both hosts simultaneously. In addition, all combinations of hosts were grown without the parasite. Both the parasite and the host plants responded to elevated CO₂ with increased growth, but only at high nutrient levels. The CO₂ response of the hemiparasite was stronger than that of the hosts, but depended on the host species available. With *L. perenne* and *M. sativa* simultaneously available as hosts, the biomass of the parasite grown at elevated CO₂ was 5.7 times that of parasites grown at ambient CO₂. Nitrogen concentration in the parasites was not influenced by the treatments and was not related to

parasite biomass. The presence of the parasite strongly reduced both the biomass of the hosts and total productivity of the system. This effect was much stronger at low than at high nutrient levels, but was not influenced by CO₂ level. Elevated CO₂ did not influence the competitive balance between the two different hosts grown in mixture. The results of this study support the hypothesis that hemiparasites may influence community structure and suggest that these effects are robust to changes in CO₂ concentration.

Matysiak, B., and J. Nowak. 1994. Carbon-dioxide and light effects on photosynthesis, transpiration and ex-vitro growth of homalomena emerald gem plantlets. *Scientia Horticulturae* 57(4):353-358.

Micropropagated plantlets of Homalomena cultivar 'Emerald Gem' were grown ex vitro at two CO₂ concentrations (350 and 1200 $\mu\text{mol mol}^{-1}$) and two light levels (50 and 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photosynthetic photon flux density (PPFD)). Plants grown at 1200 $\mu\text{mol mol}^{-1}$ CO₂ and at 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD accumulated dry weight of shoots and roots three and two times higher, respectively, and had a leaf area 2.4 times higher than that of plants grown at 350 $\mu\text{mol mol}^{-1}$ CO₂ and 50 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD. These plants also had the highest rate of photosynthesis. Carbon dioxide enrichment was more effective than supplementary light to increase plant growth. The CO₂ assimilation rate, photorespiration, transpiration and stomatal conductance to water vapour were strongly promoted by light at 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$, irrespective of CO₂ concentration. CO₂ enrichment enhanced the CO₂ assimilation rate and quantum efficiency but decreased the rate of transpiration at 50 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD and stomatal conductance to water vapour at 50 and 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD.

Matysiak, B., and J. Nowak. 1998. Acclimatization and the growth of Ficus benjamina microcuttings as affected by carbon dioxide concentration. *Journal of Horticultural Science & Biotechnology* 73(2):185-188.

The influence of CO₂ concentrations (350 and 1200 $\mu\text{mol mol}^{-1}$) on the growth of Ficus benjamina microcuttings cv. Golden King and cv. Natasja, was investigated with reference to light levels (50 and 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD, Photosynthetic Photon Flux Density) and the nutrient solution concentrations (0.7, 1.4, 2.1 and 2.8 mS cm^{-1} EC, electrical conductivity). Plants grown in peat + perlite at 1,200 $\mu\text{mol mol}^{-1}$ CO₂ concentration and simultaneously at high PPFD level (150 $\mu\text{mol m}^{-2} \text{s}^{-1}$) had the highest shoot and root fresh weights and the highest leaf area. Elevation of CO₂ concentration at low level of PPFD did not affect the growth of F. benjamina. Survival of F. benjamina microcuttings cultivated in rockwool was low (65-90%) and the growth rate was slow, irrespective of nutrient solution concentration. CO₂ enrichment increased survival and accelerated the growth of these microcuttings. The best growth of F. benjamina microcuttings cultivated in rockwool was at 1,200 $\mu\text{mol mol}^{-1}$ CO₂ and the highest level of electrical conductivity (EC) 2.8 mS cm^{-1} .

Mauney, J.R., B.A. Kimball, P.J. Pinter, R.L. Lamorte, K.F. Lewin,

J. Nagy, and G.R. Hendrey. 1994. Growth and yield of cotton in response to a free-air carbon-dioxide enrichment (FACE) environment. *Agricultural and Forest Meteorology* 70(1-4):49-67.

To quantify the growth and yield responses to CO₂ enrichment in an open field setting, free-air CO₂ enrichment (FACE) technology was used to expose a cotton (*Gossypium hirsutum* L.) crop to 550 $\mu\text{mol mol}^{-1}$ CO₂ throughout the growing seasons of 1989, 1990 and 1991 in fields near Maricopa, Arizona. In 1990 and 1991 a water stress treatment was also imposed. Response data for all years were consistent, and the data for 1991 were the least compromised by unusual weather or equipment failures. In that season the biomass was increased 37% by the 48% increase in CO₂ concentration. Harvestable yield was increased 43%. The increase in biomass and yield was attributed to increased early leaf area, more profuse flowering and a longer period of fruit retention. The FACE treatment increased water-use efficiency (WUE) to the same amount in the well-irrigated plots as in the water-stressed plots. The increase in WUE was due to the increase in biomass production rather than a reduction of consumptive use.

Mavrogianopoulos, G.N., J. Spanakis, and P. Tsikalas. 1999. Effect of carbon dioxide enrichment and salinity on photosynthesis and yield in melon. *Scientia Horticulturae* 79(1-2):51-63.

Melon (*Cucumis melo* L. Cv Parnon) grown in rockwool culture in the greenhouse was CO₂ enriched, for 5 h every morning, at 400, 800 and 1200 $\mu\text{mol mol}^{-1}$ and trickle-irrigated with nutrient solutions amended with 0, 25 and 50 mM NaCl. High CO₂ level increased fruit yield, the increase being greater in unsalinated plants than in salinated. With total shoot fresh weight, the increase was greater in salinated plants. CO₂ enrichment also increased leaf growth and the chlorophyll content of the measured leaves. Addition of NaCl in the nutrient solution caused significant reduction in total yield, the reduction being greater at higher concentrations of CO₂. At 25 mM NaCl, the decrease in yield resulted mainly from the smaller fruit size, but at 50 mM yield reduction was due both to smaller fruit size and to fewer fruits per plant. Addition of NaCl caused significant reduction in total shoot fresh weight in all cases, the reduction being greater at the lower level of CO₂. Salinity also, significantly reduced leaf surface irrespective of CO₂ level. Chlorophyll content was reduced by NaCl mainly at the level of 50 mM NaCl. A stronger correlation was found between salinity and shoot fresh weight, plant height and leaf surface area, than salinity and yield and other characteristics. Measurements of gas exchange showed that, for the above mentioned CO₂ and NaCl concentrations, net assimilation was affected by CO₂ to a greater degree than by salinity. Stomatal conductance was most affected by salinity at a concentration of 50 mM NaCl. (C) 1999 Elsevier Science B.V. All rights reserved.

Mayeux, H.S., H.B. Johnson, H.W. Polley, M.J. Dumesnil, and G.A. Spanel. 1993. A controlled environment chamber for growing plants across a subambient CO₂ gradient. *Functional Ecology* 7(1):125-133.

1. An elongated, controlled environment chamber is described in which a continuous, reproducible gradient of subambient CO₂ Concentration ([CO₂]) is maintained during daylight hours to assess plant responses to past increases in atmospheric [CO₂]. 2. The [CO₂] of air moved unidirectionally through the 37-6-m long chamber by a blower is progressively depleted by photosynthesis of plants growing in the

chamber. 3. Plant top- growth is contained in a transparent film tunnel which rests upon an enclosed soil volume that is 45 cm wide and 76 cm deep. 4. The desired minimum concentration to which CO₂ is depleted at the end of the chamber, usually 150 or 200 $\mu\text{mol l}^{-1}$, is maintained by varying the blower speed with a micrologger program dependent upon real-time sensing Of [CO₂] and light intensity. 5. Dewpoint and dry bulb temperatures are also controlled by a micrologger- and computer-monitored air- conditioning system.

Mayeux, H.S., H.B. Johnson, H.W. Polley, and S.R. Malone. 1997. Yield of wheat across a subambient carbon dioxide gradient. *Global Change Biology* 3(3):269-278.

Yields and yield components of two cultivars of day-neutral spring wheat (*Triticum aestivum* L.) were assessed along a gradient of daytime carbon dioxide (CO₂) concentrations from about 200 to near 350 $\mu\text{mol CO}_2$ (mol air^{-1}) in a 38 m-long controlled environment chamber. The range in CO₂ concentration studied approximates that of Earth's atmosphere since the last ice age. This 75% rise in CO₂ concentration increased grain yields more than 200% under well-watered conditions and by 80- 150% when wheat was grown without additions of water during the last half of the 100-day growing season. The 27% increase in CO₂ from the pre-industrial level of 150 years ago (275 $\mu\text{mol mol}^{-1}$) to near the current concentration (350 $\mu\text{mol mol}^{-1}$) increased grain yields of 'Yaqui 54' and 'Seri M82' spring wheats by 55% and 53%, respectively, under well-watered conditions. Yield increased because of greater numbers of grains per spike, rather than heavier grains or numbers of spikes per plant. Water use increased little with CO₂ concentration, resulting in improved water use efficiency as CO₂ rose. Data suggest that rising CO₂ concentration contributed to the substantial increase in average wheat yields in the U.S. during recent decades.

Mayr, C., M. Miller, and H. Insam. 1999. Elevated CO₂ alters community-level physiological profiles and enzyme activities in alpine grassland. *Journal of Microbiological Methods* 36(1-2):35-43.

Plots of an alpine grassland in the Swiss Alps were treated with elevated (680 $\mu\text{mol l}^{-1}$) and ambient CO₂ (355 $\mu\text{mol l}^{-1}$) in open top chambers (OTC). Several plots were also treated with NPK-fertilizer. Community level physiological profiles (CLPPs) of the soil bacteria were examined by Biolog GN microplates and enzyme activities were determined through the release of methylumbelliferyl (MUF) and methylcoumarin (MC) from MUF- or MC-labelled substrates. A canonical discriminant analysis (CDA) followed by multivariate analysis of variance showed a significant effect of elevated CO₂ on the CLPPs both under fertilized and unfertilized conditions. Further, the installation of the OTCs caused significant shifts in the CLPPs (chamber effect). Of the four enzyme activities tested, the beta-D-cellobiohydrolase (CELase) and N-acetyl-beta-D- glucosaminidase (NAGase) activity were enhanced under elevated CO₂. L-Leucin-7-aminopeptidase (APEase) activity decreased, when the plots received fertilizer. beta-D-Glucosidase (GLUase) remained unaffected. The results suggest effects of elevated CO₂ on specific microbial activities even under low mineral nutrient conditions and when bulk parameters like microbial biomass or respiration, which have been investigated on the same site, remain unaffected. The observed medium-term changes point at possible long-term consequences for the ecosystem that may not be specified yet. (C) 1999 Elsevier Science B.V. All rights reserved.

Maytin, C.E., M.F. Acevedo, R. Jaimez, R. Andressen, M.A. Harwell, A. Robock, and A. Azocar. 1995. Potential effects of global climatic-change on the phenology and yield of maize in venezuela. *Climatic Change* 29(2):189-211.

Simulated impacts of global and regional climate change, induced by an enhanced greenhouse effect and by Amazonian deforestation, on the phenology and yield of two grain corn cultivars in Venezuela (CENIAP PB-8 and OBREGON) are reported. Three sires were selected: Turen, Barinas and Yaritagua, representing two important agricultural regions in the country. The CERES-Maize model, a mechanistic process-based model, in the Decision Support System for Agrotechnology Transfer (DSSAT) was used for the crop simulations. These simulations assume non-limiting nutrients, no pest damage and no damage from excess water; therefore, the results indicate only the difference between baseline and perturbed climatic conditions, when other conditions remain the same. Four greenhouse-induced global climate change scenarios, covering different sensitivity levels, and one deforestation-induced regional climate change scenario were used. The greenhouse scenarios assume increased air temperature, increased rainfall and decreased incoming solar radiation, as derived from atmospheric GCMs for doubled CO₂ conditions. The deforestation scenarios assume increased air temperature, increased incoming solar radiation and decreased rainfall, as predicted by coupled atmosphere- biosphere models for extensive deforestation of a portion of the Amazon basin. Two baseline climate years for each site were selected, one year with average precipitation and another with lower than average rainfall. Scenarios associated with the greenhouse effect cause a decrease in yield of both cultivars at all three sites, while the deforestation scenarios produce small changes. Sensitivity tests revealed the reasons for these responses. Increasing temperatures, especially daily maximum temperatures, reduce yield by reducing the duration of the phenological phases of both cultivars, as expected from CERES- Maize. The reduction of the duration of the kernel filling phase has the largest effect on yield. Increases of precipitation associated with greenhouse warming have no effects on yield, because these sites already have adequate precipitation; however, the crop model used here does not simulate potential negative effects of excess water, which could have important consequences in terms of soil erosion and nutrient leaching. Increases in solar radiation increased yields, according to the non-saturating light response of the photosynthesis rate: of a C-4 plant like corn, compensating for reduced yields from increased temperatures in deforestation scenarios. In the greenhouse scenarios, reduced insolation (due to increased cloud cover) and increased temperatures combine to reduce yields; a combination of temperature increase with a reduction in solar radiation produces fewer and lighter kernels.

Mbata, G.N., and C. Reichmuth. 1996. The comparative effectiveness of different modified atmospheres for the disinfestation of Bambarra groundnuts, *Vigna subterranea* (L) Verde, infested by *Callosobruchus subinnotatus* (Pic) (Coleoptera:Bruchidae). *Journal of Stored Products Research* 32(1):45-51.

Four atmospheres containing high levels of carbon dioxide (CO₂) and different quantities of oxygen (0, 2.0, 3.7, 5.1%) were investigated for their toxicity to *Callosobruchus subinnotatus* (Pie), The quantity of oxygen contained in atmospheres influenced the disinfestation levels in

bambarra groundnuts infested by *C. subinnotatus*. The different developmental stages had varying susceptibilities to the atmospheres. Atmospheres containing low concentrations of oxygen (2.0, 3.7%) enhanced the mortality of adults. The anoxic atmosphere of 100% CO₂ was more toxic to eggs, larvae, and pupae than the other atmospheres. There was a progressive decrease in toxicity as the quantity of oxygen in the inert atmospheres increased. Copyright (C) 1996 Elsevier Science Ltd

McConnaughay, K.D.M., S.L. Bassow, G.M. Berntson, and F.A. Bazzaz. 1996. Leaf senescence and decline of end-of-season gas exchange in five temperate deciduous tree species grown in elevated CO₂ concentrations. *Global Change Biology* 2(1):25-33.

We measured rates of leaf senescence and leaf level gas exchange during autumnal senescence for seedlings of five temperate forest tree species under current and elevated atmospheric CO₂ concentrations and low- and high-nutrient regimes. Relative indices of whole canopy carbon gain, water loss and water use efficiency through the senescent period were calculated based on a simple integrative model combining gas exchange per unit leaf area and standing canopy area per unit time. Seedlings grown under elevated [CO₂] generally had smaller canopies than their current [CO₂]-grown counterparts throughout most of the senescent period. This was a result of smaller pre-senescent canopies or accelerated rates of leaf drop. Leaf-level photosynthetic rates were higher under elevated [CO₂] for grey birch canopies and for low-nutrient red maple and high-nutrient ash canopies, but declined rapidly to values below those of their current [CO₂] counterparts by midway through the senescent period. CO₂ enrichment reduced photosynthetic rates for the remaining species throughout some or all of the senescent period. As a result of smaller canopy sizes and reduced photosynthetic rates, elevated [CO₂]-grown seedlings had lower indices of whole canopy end-of-season carbon gain with few exceptions. Leaf level transpiration rates were highly variable during autumnal senescence, and neither [CO₂] nor nutrient regime had consistent effects on water loss per unit leaf area or integrated whole canopy water loss throughout the senescent period. Indices of whole canopy, end-of-season estimates of water use efficiency, however, were consistently lower under CO₂ enrichment, with few exceptions. These results suggest that whole canopy end-of-season gas exchange may be altered significantly in an elevated [CO₂] world, resulting in reduced carbon gain and water use efficiency for many temperate forest tree seedlings. Seedling growth and survivorship, and ultimately temperate forest regeneration, could be reduced in CO₂-enriched forests of the future.

McConnaughay, K.D.M., G.M. Berntson, and F.A. Bazzaz. 1993. Limitations to CO₂-induced growth enhancement in pot studies. *Oecologia* 94(4):550-557.

Recently, it has been suggested that small pots may reduce or eliminate plant responses to enriched CO₂ atmospheres due to root restriction. While smaller pot volumes provide less physical space available for root growth, they also provide less nutrients. Reduced nutrient availability alone may reduce growth enhancement under elevated CO₂. To investigate the relative importance of limited physical rooting space separate from and in conjunction with soil nutrients, we grew plants at ambient and double-ambient CO₂ levels in growth containers of varied volume, shape, nutrient concentration, and total nutrient content. Two species (*Abutilon theophrasti*, a C₃ dicot with a deep tap root and *Setaria faberii*, a C₄ monocot with a shallow diffuse root system) were

selected for their contrasting physiology and root architecture. Shoot demography was determined weekly and biomass was determined after eight and ten weeks of growth. Increasing total nutrients, either by increasing nutrient concentration or by increasing pot size, increased plant growth. Further, increasing pot size while maintaining equal total nutrients per pot resulted in increased total biomass for both species. CO₂-induced growth and reproductive yield enhancements were greatest in pots with high nutrient concentrations, regardless of total nutrient content or pot size, and were also mediated by the shape of the pot. CO₂-induced growth and reproductive yield enhancements were unaffected by pot size (growth) or were greater in small pots (reproductive yield), regardless of total nutrient content, contrary to predictions based on earlier studies. These results suggest that several aspects of growth conditions within pots may influence the CO₂ responses of plants; pot size, pot shape, the concentration and total amount of nutrient additions to pots may lead to over- or underestimates of the CO₂ responses of real-world plants.

McConnaughay, K.D.M., and J.S. Coleman. 1999. Biomass allocation in plants: Ontogeny or optimality? A test along three resource gradients. *Ecology* 80(8):2581-2593.

We examined biomass allocation patterns throughout the entire vegetative growth phase for three species of annual plants along three separate gradients of resource availability to determine whether observed patterns of allocational plasticity are consistent with optimal partitioning theory. Individuals of the annual plant species *Abutilon theophrasti*, *Chenopodium album*, and *Polygonum pensylvanicum* were grown from locally field-gathered seed in controlled greenhouse conditions across gradients of light, nutrients, and water. Frequent harvests were used to determine the growth and allocation (root vs. shoot, and leaf area vs. biomass) responses of these plants over a 57-d period. Growth analysis revealed that each species displayed significant plasticity in growth rates and substantial amounts of ontogenetic drift in root: shoot biomass ratios and ratios of leaf area to biomass across each of the three resource gradients. Ontogenetically controlled comparisons of root : shoot and leaf area ratios across light and nutrient gradients were generally consistent with predictions based on optimal partitioning theory; allocation to roots decreased and leaf area increased under low light and high nutrient conditions. These trends were confirmed, though were less dramatic, in allometric plots of biomass allocation throughout ontogeny. These species did not alter biomass allocation (beyond ontogenetic drift) in response to the broadly varying water regimes. Furthermore, many of the observed differences in biomass allocation were limited to a given time during growth and development. We conclude that, for these rapidly growing annual species, plasticity in biomass allocation patterns is only partially consistent with optimal partitioning theory, and that these plastic responses are ontogenetically constrained. Further, while these species did adjust biomass allocation patterns in response to light and nutrient availability, they did not adjust biomass allocation in response to water availability, despite dramatic plasticity in growth rates along all three resource gradients. Our results support a developmentally explicit model of plasticity in biomass allocation in response to limiting resources.

McConnaughay, K.D.M., A.B. Nicotra, and F.A. Bazzaz. 1996. Rooting volume, nutrient availability, and CO₂-induced growth enhancements in temperate forest tree seedlings. *Ecological Applications* 6(2):619-627.

We examined growth and allocation responses to CO₂ enrichment for three species of co-occurring temperate forest tree seedlings grown in pots of varying rooting volumes and nutrient supply. Under both current and projected future CO₂ atmospheres, tree seedling growth was substantially greater with greater total nutrient supply (either due to increased nutrient addition rate or increased rooting volume) for all species. Increasing rooting volume alone, holding total nutrient supply constant, increased growth for gray and yellow birch and decreased growth for red maple. Root/shoot ratios were less and specific leaf masses were greater for plants grown in smaller pots, suggesting that the smaller pots did restrict root growth with consequences for whole-plant carbon allocation. After 12 wk of growth at light levels simulating those found in small gaps in temperate forests, each species exhibited growth, allocational and/or architectural differences due to increased CO₂. Of 11 traits measured, 9 were significantly altered by CO₂ regime. Gray birch responded in architectural and allocational parameters only; total carbon accumulation after 12 wk of growth was not affected by CO₂ regime. Red maple and especially yellow birch grew larger in elevated CO₂, and were less responsive in architectural and allocational parameters than gray birch. Increasing N concentration did not increase CO₂-induced growth enhancements, except for increased leaf production in gray birch. In fact, CO₂-induced increases in branch production were greatest at low nutrient concentration. Pot size had no effect on CO₂-induced growth responses, except that CO₂-induced enhancement in branch production was greater in smaller pots. With few exceptions, conditions within pots did not influence responses to elevated CO₂, despite the many growth and architectural responses manifested by these tree seedlings in response to CO₂, nutrient regime, and pot size.

McDonald, E.P., J. Agrell, and R.L. Lindroth. 1999. CO₂ and light effects on deciduous trees: growth, foliar chemistry, and insect performance. *Oecologia* 119(3):389-399.

This study examined the effects of CO₂ and light availability on sapling growth and foliar chemistry, and consequences for insect performance. Quaking aspen (*Populus tremuloides* Michx.), paper birch (*Betula papyrifera* Marsh.), and sugar maple (*Acer saccharum* Marsh.) were grown in controlled environment greenhouses under ambient or elevated CO₂ (38.7 and 69.6 Pa), and low or high light availability (375 and 855 $\mu\text{mol m}^{-2} \text{s}^{-1}$). Because CO₂ and light are both required for carbon assimilation, the levels of these two resources are expected to have strong interactive effects on tree growth and secondary metabolism. Results from this study support that prediction, indicating that the relative effect of rising atmospheric CO₂ concentrations on the growth and secondary metabolism of deciduous trees may be dependent on light environment. Trees in ambient CO₂-low light environments had substantial levels of phytochemicals despite low growth rates; the concept of basal secondary metabolism is proposed to explain allocation to secondary metabolites under growth-limiting conditions. Differences between CO₂ and light effects on the responses of growth and secondary metabolite levels suggest that relative allocation is not dependent solely on the amount of carbon assimilated. The relative growth rates and indices of feeding efficiency for gypsy moth (*Lymantria dispar* L.) larvae fed foliage from the experimental treatments showed no significant interactive effects of light and CO₂, although some main effects and many host species interactions were significant. Gypsy moth

performance was negatively correlated with CO₂- and light-induced increases in the phenolic glycoside content of aspen foliage. Insects were not strongly affected, however, by treatment differences in the nutritional and secondary chemical components of birch and maple.

McElwain, J.C. 1998. Do fossil plants signal palaeoatmospheric CO₂ concentration in the geological past? *Philosophical Transactions of the Royal Society of London Series B-Biological Sciences* 353(1365):83-95.

Fossil, subfossil, and herbarium leaves have been shown to provide a morphological signal of the atmospheric carbon dioxide (CO₂) environment in which they developed by means of their stomatal density and index. An inverse relationship between stomatal density/index and atmospheric CO₂ concentration has been documented for all the studies to date concerning fossil and subfossil material. Furthermore, this relationship has been demonstrated experimentally by growing plants under elevated and reduced CO₂ concentrations. To date, the mechanism that controls the stomatal density response to atmospheric CO₂ concentration remains unknown. However, stomatal parameters of fossil plants have been successfully used as a proxy indicator of palaeo-CO₂ levels. This paper presents new estimates of palaeoatmospheric CO₂ concentrations for the Middle Eocene (Lutetian), based on the stomatal ratios of fossil Lauraceae species from Bournemouth in England. Estimates of atmospheric CO₂ concentrations derived from stomatal data from plants of the Early Devonian, Late Carboniferous, Early Permian and Middle Jurassic ages are reviewed in the light of new data. Semi-quantitative palaeo-CO₂ estimates based on the stomatal ratio (a ratio of the stomatal index of a fossil plant to that of a selected nearest living equivalent) have in the past relied on the use of a Carboniferous standard. The application of a new standard based on the present-day CO₂ level is reported here for comparison. The resultant ranges of palaeo-CO₂ estimates made from standardized fossil stomatal ratio data are in good agreement with both carbon isotopic data from terrestrial and marine sources and long-term carbon cycle modelling estimates for all the time periods studied. These data indicate elevated atmospheric CO₂ concentrations during the Early Devonian, Middle Jurassic and Middle Eocene, and reduced concentrations during the Late Carboniferous and Early Permian. Such data are important in demonstrating the long-term responses of plants to changing CO₂ concentrations and in contributing to the database needed for general circulation model climatic analogues.

McElwain, J.C., and W.G. Chaloner. 1995. Stomatal density and index of fossil plants track atmospheric carbon-dioxide in the paleozoic. *Annals of Botany* 76(4):389-395.

It has been demonstrated that the leaves of a range of forest tree species have responded to the rising concentration of atmospheric CO₂ over the last 200 years by a decrease in both stomatal density and stomatal index. This response has also been demonstrated experimentally by growing plants under elevated CO₂ concentrations. Investigation of Quaternary fossil leaves has shown a corresponding stomatal response to changing CO₂ concentrations through a glacial-interglacial cycle, as revealed by ice core data. Tertiary leaves show a similar pattern of stomatal density change, using palynological evidence of palaeo-temperature as a proxy

measure of CO₂ concentration. The present work extends this approach into the Palaeozoic fossil plant record. The stomatal density and index of Early Devonian, Carboniferous and Early Permian plants has been investigated, to test for any relationship that they may show with the changes in atmospheric CO₂ concentration, derived from physical evidence, over that period. Observed changes in the stomatal data give support to the suggestion from physical evidence, that atmospheric CO₂ concentrations fell from an Early Devonian high of 10-12 times its present value, to one comparable to that of the present day by the end of the Carboniferous. These results suggest that stomatal density of fossil leaves has potential value for assessing changes in atmospheric CO₂ concentration through geological time. (C) 1995 Annals of Botany Company

McElwain, J.C., and W.G. Chaloner. 1996. The fossil cuticle as a skeletal record of environmental change. *Palaios* 11(4):376-388.

The plant cuticle with its stomatal pores represents an important interface between the plant and its surrounding environment. The potential of cuticular features such as cuticle thickness, stomatal density, stomatal index and stomatal ratio to signal the environment in which they grew and developed have been reviewed. In particular new stomatal data from three Yorkshire Middle Jurassic species, *Brachyphyllum crucis* Kendall, *Brachyphyllum mamillare* Lindley and Hutton and *Ginkgo huttonii* (Sternberg) Heer, have been compared with those of two selected nearest living equivalent (NLE) species *Athrotaxis cupressoides* and *Ginkgo biloba*, in an attempt to deduce the atmospheric carbon dioxide concentration from that time. It appears that the development of a thick cuticle can represent an adaptation to more than one kind of environmental constraint and evidently is a feature of certain taxonomic groups. It was concluded therefore that cuticle thickness, taken on its own was not a suitable palaeo-ecological indicator. In contrast however stomatal parameters of fossil plants seem to have great potential as palaeo-atmospheric indicators of carbon dioxide and in this sense as "skeletal evidence of palaeo-ecological change." The stomatal density and index results of the Jurassic species were significantly lower ($P < 0.0001$) than those of their selected NLE species, therefore indicating elevated atmospheric CO₂ concentrations for the Middle Jurassic. In addition the stomatal ratios of the Jurassic species were in agreement with those of previous Devonian and Carboniferous stomatal ratio results. These results are consistent with the evidence from carbon cycle modelling and carbon isotopic data which infer elevated atmospheric CO₂ concentrations during the Middle Jurassic of 4 to 5 times and 6 to 10 times the present atmospheric level respectively.

McGuire, A.D., L.A. Joyce, D.W. Kicklighter, J.M. Melillo, G. Esser, and C.J. Vorosmarty. 1993. Productivity response of climax temperate forests to elevated- temperature and carbon-dioxide - a north-american comparison between 2 global-models. *Climatic Change* 24(4):287-310.

We assess the appropriateness of using regression- and process- based approaches for predicting biogeochemical responses of ecosystems to global change. We applied a regression-based model, the Osnabruck Model (OBM), and a process-based model, the Terrestrial Ecosystem Model (TEM), to the historical range of temperate forests in North America in a factorial experiment with three levels of temperature (+0-degrees-C, +2-degrees-C, and +5-degrees-C) and two levels Of CO₂

(350 ppmv and 700 ppmv) at a spatial resolution of 0.5-degrees latitude by 0.5-degrees longitude. For contemporary climate (+0-degrees-C, 3 50 ppmv), OBM and TEM estimate the total net primary productivity (NPP) for temperate forests in North America to be 2.250 and 2.602 x 10(15) g C . yr-1, respectively. Although the continental predictions for contemporary climate are similar, the responses of NPP to altered changes qualitatively differ; at +0-degrees-C and 700 PPMV CO₂, OBM and TEM predict median increases in NPP of 12.5% and 2.5%, respectively. The response of NPP to elevated temperature agrees most between the models in northern areas of moist temperate forest, but disagrees in southern areas and in regions of dry temperate forest. In all regions, the response to CO₂ is qualitatively different between the models. These differences occur, in part, because TEM includes known feedbacks between temperature and ecosystem processes that affect N availability, photosynthesis, respiration, and soil moisture. Also, it may not be appropriate to extrapolate regression-based models for climatic conditions that are not now experienced by ecosystems. The results of this study suggest that the process-based approach is able to progress beyond the limitations of the regression-based approach for predicting biogeochemical responses to global change.

McGuire, A.D., J.M. Melillo, and L.A. Joyce. 1995. The role of nitrogen in the response of forest net primary production to elevated atmospheric carbon-dioxide. *Annual Review of Ecology and Systematics* 26:473-503.

We review experimental studies to evaluate how the nitrogen cycle influences the response of forest net primary production (NPP) to elevated CO₂. The studies in our survey report that at the tissue level, elevated CO₂ reduces leaf nitrogen concentration an average 21%, but that it has a smaller effect on nitrogen concentrations in stems and fine roots. In contrast, higher soil nitrogen availability generally increases leaf nitrogen concentration. Among studies that manipulate both soil nitrogen availability and atmospheric CO₂, photosynthetic response depends on a linear relationship with the response of leaf nitrogen concentration and the amount of change in atmospheric CO₂ concentration. Although elevated CO₂ often results in reduced tissue respiration rate per unit biomass, the link to changes in tissue nitrogen concentration is not well studied.

McGuire, A.D., J.M. Melillo, D.W. Kicklighter, and L.A. Joyce. 1995. Equilibrium responses of soil carbon to climate change: Empirical and process-based estimates. *Journal of Biogeography* 22(4-5):785-796.

We use a new version of the Terrestrial Ecosystem Model (TEM), which has been parameterized to control for reactive soil organic carbon (SOC) across climatic gradients, to evaluate the sensitivity of SOC to a 1 degrees C warming in both empirical and process-based analyses. In the empirical analyses we use the steady state SOC estimates of TEM to derive SOC-response equations that depend on temperature and volumetric soil moisture, and extrapolate them across the terrestrial biosphere at 0.5 degrees spatial resolution. For contemporary climate and atmospheric CO₂, mean annual temperature explains 34.8% of the variance in the natural logarithm of TEM-estimated SOC. Because the

inclusion of mean annual volumetric soil moisture in the regression explains an additional 19.6%, a soil moisture term in an equation of SOC response should improve estimates. For a 1 degrees C warming, the globally derived empirical model estimates a terrestrial SOC loss of 22.6 10(15) g (Pg), with 77.9% of the loss in extra-tropical ecosystems. To explore whether loss estimates of SOC are affected by the spatial scale at which the response equations are derived, we derive equations for each of the eighteen ecosystems considered in this study. The sensitivity of terrestrial SOC estimated by summing the losses predicted by each of the ecosystem empirical models is greater (27.9 Pg per degrees C) than that estimated by the global empirical model; the 12.2 Pg loss (43.7%) in tropical ecosystems suggests that they may be more sensitive to warming. The global process-based loss of SOC estimated by TEM in response to a 1 degrees C warming (26.3 Pg) is similar to the sum of the ecosystem empirical losses, but the 13.6 Pg loss (51.7%) in extra-tropical ecosystems suggests that they may be slightly less sensitive to warming. For the modelling of SOC responses, these results suggest that soil moisture is useful to incorporate in empirical models of SOC response and that globally derived empirical models may conceal regional sensitivity of SOC to warming. The analyses in this study suggest that the maximum loss of SOC to the atmosphere per degrees C warming is less than 2% of the terrestrial soil carbon inventory. Because the NPP response to elevated CO₂ has the potential to compensate for this loss, the scenario of warming enhancing soil carbon loss to further enhance warming is unlikely in the absence of land use or changes in vegetation distribution.

McGuire, A.D., J.M. Melillo, D.W. Kicklighter, Y.D. Pan, X.M. Xiao, J. Helfrich, B. Moore, C.J. Vorosmarty, and A.L. Schloss. 1997. Equilibrium responses of global net primary production and carbon storage to doubled atmospheric carbon dioxide: Sensitivity to changes in vegetation nitrogen concentration. *Global Biogeochemical Cycles* 11(2):173-189.

We ran the terrestrial ecosystem model (TEM) for the globe at 0.5 degrees resolution for atmospheric CO₂ concentrations of 340 and 680 parts per million by volume (ppmv) to evaluate global and regional responses of net primary production (NPP) and carbon storage to elevated CO₂ for their sensitivity to changes in vegetation nitrogen concentration. At 340 ppmv, TEM estimated global NPP of 49.0 10(15) g (Pg) C yr⁻¹ and global total carbon storage of 1701.8 Pg C; the estimate of total carbon storage does not include the carbon content of inert soil organic matter. For the reference simulation in which doubled atmospheric CO₂ was accompanied with no change in vegetation nitrogen concentration, global NPP increased 4.1 Pg C yr⁻¹ (8.3%), and global total carbon storage increased 114.2 Pg C. To examine sensitivity in the global responses of NPP and carbon storage to decreases in the nitrogen concentration of vegetation, we compared doubled CO₂ responses of the reference TEM to simulations in which the vegetation nitrogen concentration was reduced without influencing decomposition dynamics ("lower N" simulations) and to simulations in which reductions in vegetation nitrogen concentration influence decomposition dynamics ("lower N+D" simulations). We conducted three lower N simulations and three lower N+D simulations in which we reduced the nitrogen concentration of vegetation by 7.5, 15.0, and 22.5%. In the lower N simulations, the response of global NPP to doubled atmospheric CO₂ increased approximately 2 Pg C yr⁻¹ for each incremental 7.5% reduction in vegetation nitrogen concentration, and vegetation carbon increased approximately an additional 40 Pg C, and soil carbon increased an additional 30 Pg C, for a total carbon storage increase of approximately 70 Pg C. In the lower N+D simulations, the responses of NPP and vegetation carbon storage were

relatively insensitive to differences in the reduction of nitrogen concentration, but soil carbon storage showed a large change. The insensitivity of NPP in the N+D simulations occurred because potential enhancements in NPP associated with reduced vegetation nitrogen concentration were approximately offset by lower nitrogen availability associated with the decomposition dynamics of reduced litter nitrogen concentration. For each 7.5% reduction in vegetation nitrogen concentration, soil carbon increased approximately an additional 60 Pg C, while vegetation carbon storage increased by only approximately 5 Pg C. As the reduction in vegetation nitrogen concentration gets greater in the lower N+D simulations, more of the additional carbon storage tends to become concentrated in the north temperate- boreal region in comparison to the tropics. Other studies with TEM show that elevated CO₂ more than offsets the effects of climate change to cause increased carbon storage. The results of this study indicate that carbon storage would be enhanced by the influence of changes in plant nitrogen concentration on carbon assimilation and decomposition rates. Thus changes in vegetation nitrogen concentration may have important implications for the ability of the terrestrial biosphere to mitigate increases in the atmospheric concentration of CO₂ and climate changes associated with the increases.

McHale, P.J., M.J. Mitchell, and F.P. Bowles. 1998. Soil warming in a northern hardwood forest: trace gas fluxes and leaf litter decomposition. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 28(9):1365-1372.

The response of trace gas fluxes (CO₂ CH₄ and N₂) and litter decomposition to increased soil temperature was evaluated in a northern hardwood forest. Four experimental plots (10 x 10 m) had heating cables installed within the forest floor. Temperatures at 5 cm were increased 2.5, 5.0, or 7.5 degrees C in individual heated plots during the field season in 1993 and 1994. The fourth plot was a cabled, nonheated reference. Trace gas fluxes were monitored using closed chambers. Soil moisture was monitored using tensiometers and time domain reflectometry. Changes in leaf litter decomposition were quantified using litter bags for American beech (*Fagus grandifolia* Ehrh.) and sugar maple (*Acer saccharum* Marsh.) litter. Fluxes of CO₂ increased exponentially with increased soil temperatures within treatments and were higher in heated plots than in the reference plot. Temperature coefficients (Q₁₀) and mass remaining of American beech leaf litter decreased with the level of heating, suggesting a nonlinear microbial response to elevated temperatures. Soil water content exhibited the most influence on CH₄ and N₂O flux in the second season. The experimental manipulations showed the importance of evaluating the influence of soil temperature coupled with effects of N and moisture availability.

McIntyre, M., and B. McNeil. 1998. Morphogenetic and biochemical effects of dissolved carbon dioxide on filamentous fungi in submerged cultivation. *Applied Microbiology and Biotechnology* 50(3):291-298.

The inhibitory effects of elevated CO₂ in submerged fermentation processes involving bacteria and yeasts have been extensively examined. However, until recently, there have been few similar studies involving filamentous fungi, despite the economic importance of this group of organisms. Many of the investigations that have been carried out have

involved inappropriate simulation methods and, as a result, may have overestimated the morphogenetic and biochemical effects of elevated CO₂ on filamentous fungi. Recent studies, involving continuous culture of *Aspergillus niger* and the use of computerised image analysis systems, have allowed a more detailed and accurate description of elevated CO₂ inhibition and quantification of the subtler morphogenetic effects. A critical evaluation of the various experimental methods that have been used to simulate, at laboratory scale, what is assumed to occur in large-scale bioreactors is necessary. The review of simulation methods employed has much broader relevance to many other microbial and cell culture systems, emphasising the need to think about the appropriateness and relevance of experimental design.

McKane, R.B., E.B. Rastetter, J.M. Melillo, G.R. Shaver, C.S. Hopkins, D.N. Fernandes, D.L. Skole, and W.H. Chomentowski. 1995. Effects of global change on carbon storage in tropical forests of south-america. *Global Biogeochemical Cycles* 9(3):329-350.

We used a process-based model of ecosystem biogeochemistry (MEL-GEM) to evaluate the effects of global change on carbon (C) storage in mature tropical forest ecosystems in the Amazon Basin of Brazil. We first derived a single parameterization of the model that was consistent with all the C stock and turnover data from three intensively studied sites within the Amazon Basin that differed in temperature, rainfall, and cloudiness. The range in temperature, soil moisture, and photosynthetically active radiation (PAR) among these sites is about as large as the anticipated changes in these variables in the tropics under CO₂-induced climate change. We then tested the parameterized model by predicting C stocks along a 2400-km transect in the Amazon Basin. Comparison of predicted and measured vegetation and soil C stocks along this transect suggests that the model provides a reasonable approximation of how climatic and hydrologic factors regulate present-day C stocks within the Amazon Basin. Finally, we used the model to predict and analyze changes in ecosystem C stocks under projected changes in atmospheric CO₂ and climate. The central hypothesis of this exercise is that changes in ecosystem C storage in response to climate and CO₂ will interact strongly with changes in other element cycles, particularly the nitrogen (N) and phosphorus (P) cycles. We conclude that C storage will increase in Amazonian forests as a result of (1) redistribution of nutrients from soil (with low C:nutrient ratios) to vegetation (with high C:nutrient ratios), (2) increases in the C:nutrient ratio of vegetation and soil, and (3) increased sequestration of external nutrient inputs by the ecosystem. Our analyses suggest that C:nutrient interactions will constrain increases in C storage to a maximum of 63 Mg/ha during the next 200 years, or about 16% above present-day stocks. However, it is impossible to predict how much smaller the actual increase in C storage will be until more is known about the controls on soil P availability. On the basis of these analyses, we identify several topics for further research in the moist tropics that must be addressed to resolve these uncertainties.

McKane, R.B., E.B. Rastetter, G.R. Shaver, K.J. Nadelhoffer, A.E. Giblin, J.A. Laundre, and F.S. Chapin. 1997. Climatic effects on tundra carbon storage inferred from experimental data and a model. *Ecology* 78(4):1170-1187.

We used a process-based model of ecosystem carbon (C) and nitrogen (N) dynamics, MEL-GEM (Marine Biological Laboratory General Ecosystem Model), to integrate and analyze the results of several experiments that examined the response of arctic tussock tundra to manipulations of CO₂, temperature, light, and soil nutrients. The experiments manipulated these variables over 3- to 9-yr periods and were intended to simulate anticipated changes in the arctic environment. Our objective was to use the model to extend the analysis of the experimental data so that unmeasured changes in ecosystem C storage and the underlying mechanisms controlling those changes could be estimated and compared. Using an inverse calibration method, we derived a single parameter set for the model that closely simulated the measured responses of tussock tundra to all of the experimental treatments. This parameterization allowed us to infer confidence limits for ecosystem components and processes that were not directly measured in the experiments. Thus, we used the model to estimate changes in ecosystem C storage by inferring key soil processes within the constraints imposed by measured components of the ecosystem C budget. Because tussock tundra is strongly N limited, we hypothesized that changes in ecosystem C storage in response to the experimental treatments would be constrained by several key aspects of C-N interactions: (1) changes in the amount of N in the ecosystem, (2) changes in the C:N ratios of vegetation and soil, and (3) redistribution of N between soil (with a low C:N ratio) and vegetation (with a high C:N ratio). The model results reveal widely differing patterns of change in C-N interactions and constraints on change in ecosystem C storage among treatments. For example, after 9 yr the elevated CO₂ (2 x ambient) treatment and the N fertilized (10 g N.m⁻² yr⁻¹) treatment increased ecosystem C stocks by 1.4 and 2.9%, respectively. Whereas the increase in the CO₂ treatment was due solely to an increase in the C:N ratios of vegetation and soil, the increase in the fertilized treatment was due to increased ecosystem N content and a shift of N from soil to vegetation. In contrast, the greenhouse (3.5 degrees C above ambient) and shade (one-half ambient light) treatments decreased ecosystem C stocks by 1.9 and 2.7%, respectively. The primary reason for the net C losses in these treatments was an increase in respiration relative to photosynthesis, with a consequent decrease in the ecosystem C:N ratio. However, when we simulated the elevated temperatures in the greenhouse treatment without the confounding effects of decreased light intensity (an artifact of the greenhouse structures), there was a long-term increase in ecosystem C stocks because of increased photosynthetic response to the temperature-induced shift of N from soil to vegetation. If our simulated changes in ecosystem C storage are extrapolated for the approximate to 43 Pg C contained in arctic tundras globally, the maximum net gain or loss (approximate to 0.3% per yr) from tundra would be equivalent to 0.13 Pg C/yr. Although fluxes of this magnitude would have a relatively minor impact on current changes in atmospheric CO₂, the long-term impact on tundra C stores could be significant. The synthesis and insights provided by the model should make it possible to extrapolate into the future with a better understanding of the processes governing long-term changes in tundra C storage.

McKee, I.F., J.F. Bullimore, and S.P. Long. 1997. Will elevated CO₂ concentrations protect the yield of wheat from O₃-3 damage? *Plant, Cell and Environment* 20(1):77-84.

This study investigated the interacting effects of carbon dioxide and ozone concentrations on the growth and yield of spring wheat (*Triticum aestivum* L, cv, Wembley). Plants were exposed from time of sowing to harvest to reciprocal combinations of two carbon dioxide and two ozone treatments: [CO₂] at 350 or 700 µmol mol⁻¹, and [O₃] at <5 or 60

nmol mol⁻¹), Records of leaf emergence, leaf duration and tillering were taken throughout leaf development, At harvest, biomass, yield and partitioning were analysed. Our data showed that elevated [CO₂] fully protected against the detrimental effect of elevated [O₃] on biomass, but not yield.

McKee, I.F., M. Eiblmeier, and A. Polle. 1997. Enhanced ozone-tolerance in wheat grown at an elevated CO₂ concentration: ozone exclusion and detoxification. *New Phytologist* 137(2):275-284.

Elevated [CO₂] has been shown to protect photosynthesis and growth of wheat against moderately elevated [O₃]. To investigate the role of ozone exclusion and detoxification in this protection, spring wheat (*Triticum aestivum* L. cv. Wembley) was grown from seed, in controlled-environment chambers, under reciprocal combinations of [CO₂] at 350 or 700 μ mol mol⁻¹ and [O₃] peaking at < 5 or 60 nmol mol⁻¹, respectively. Cumulative ozone dose to the mesophyll and antioxidant status were determined throughout flag leaf development. Catalase activity correlated with rates of photorespiration and declined in response to elevated [CO₂] and/or [O₃]. Superoxide dismutase activity was not significantly affected by either condition. Neither ascorbate nor glutathione content was enhanced by elevated [CO₂]. In wheat, at moderately elevated [O₃], our results show that stomatal exclusion plays a major role in the protective effect of elevated [CO₂] against O₃ damage.

McKee, I.F., P.K. Farage, and S.P. Long. 1995. The interactive effects of elevated CO₂ and O₃ concentration on photosynthesis in spring wheat. *Photosynthesis Research* 45(2):111-119.

This study investigated the interacting effects of carbon dioxide and ozone on photosynthetic physiology in the flag leaves of spring wheat (*Triticum aestivum* L. cv. Wembley), at three stages of development. Plants were exposed throughout their development to reciprocal combinations of two carbon dioxide and two ozone treatments: [CO₂] at 350 or 700 μ mol mol⁻¹, [O₃] at < 5 or 60 nmol mol⁻¹. Gas exchange analysis, coupled spectrophotometric assay for RuBisCO activity, and SDS-PAGE, were used to examine the relative importance of pollutant effects on i) stomatal conductance, ii) quantum yield, and iii) RuBisCO activity, activation, and concentration. Independently, both elevated [CO₂] and elevated [O₃] caused a loss of RuBisCO protein and V_{cmax}. In combination, elevated [CO₂] partially protected against the deleterious effects of ozone. It did this partly by reducing stomatal conductance, and thereby reducing the effective ozone dose. Elevated [O₃] caused stomatal closure largely via its effect on photoassimilation.

McKee, I.F., and F.I. Woodward. 1994. CO₂ enrichment responses of wheat - interactions with temperature, nitrate and phosphate. *New Phytologist* 127(3):447-453.

Rising levels of atmospheric CO₂, climate change, and fertilizer pollution provide the ecological imperative for investigating the interaction between plant responses to atmospheric CO₂ concentration, temperature and nutrient supply. In this study spring wheat (*Triticum aestivum* L. cv. Wembley) was grown at 40, 50, 60 and 70 Pa atmospheric CO₂ pressure and three experiments were conducted to investigate interactions between growth responses to the CO₂ treatment and: (i) temperature (24/16 degrees C vs. 18/10 degrees C - day/night), (ii) nutrient solution nitrate concentration (2.5, 5, 10 and 15 mM Ca(NO₃)₂·4H₂O), and (iii) phosphate concentration (0.025 and 0.5 mM KH₂PO₄). Dry mass and root/shoot ratio increased with CO₂ level at the higher temperature. These responses were reversed at the lower temperature. The increase in yield with CO₂ enhancement was limited by low rates of nutrient supply in both absolute and relative terms. In the elevated CO₂ treatments, the shoot nitrogen concentration was reduced, as was the proportional allocation to the uppermost leaves. These results are discussed with respect to possible physiological mechanisms and potential for improved crop performance in a future, elevated CO₂ world.

McKee, I.F., and F.I. Woodward. 1994. The effect of growth at elevated CO₂ concentrations on photosynthesis in wheat. *Plant, Cell and Environment* 17(7):853-859.

Rising levels of atmospheric CO₂ will have profound, direct effects on plant carbon metabolism. In this study we used gas exchange measurements, models describing the instantaneous response of leaf net CO₂ assimilation rate (A) to intercellular CO₂ partial pressure (C_i), in vitro enzyme activity assay, and carbohydrate assay in order to investigate the photosynthetic responses of wheat (*Triticum aestivum* L., cv. Wembley) to growth under elevated partial pressures of atmospheric CO₂ (C_a). At flag leaf ligule emergence, the modelled, in vivo, maximum carboxylation velocity for RuBisCO was significantly lower in plants grown at elevated C_a than in plants grown at ambient C_a (70 Pa compared with 40 Pa). By 12 d after ligule emergence, no significant difference in this parameter was detectable. At ligule emergence, plants grown at elevated C_a exhibited reduced in vitro initial activities and activation states of RuBisCO. At their respective growth C_i values, the photosynthesis of 40-Pa-grown plants was sensitive to p(O₂) and to p(CO₂), whereas that of 70-Pa-grown plants was insensitive. Both sucrose and starch accumulated more rapidly in the leaves of plants grown at 70 Pa. At flag leaf ligule emergence, modelled non-photorespiratory respiration in the light (R_d) was significantly higher in 70-Pa-grown plants than in 40-Pa-grown plants. By 12 d after ligule emergence no significant differences in R_d were detectable.

McKeehen, J.D., D.J. Smart, C.L. Mackowiak, R.M. Wheeler, and S.S. Nielsen. UNKNOWN YEAR. Effect of CO₂ levels on nutrient content of lettuce and radish. *Natural and Artificial Ecosystems* :85-92.

Atmospheric carbon-dioxide enrichment is known to affect the yield of lettuce and radish grown in controlled environments, but little is known about CO₂ enrichment effects on the chemical composition of lettuce and radish. These crops are useful model systems for a Controlled Ecological Life-Support System (CELSS), largely because of their relatively short production cycles. Lettuce (*Lactuca sativa* L.) cultivar 'Waldmann's Green' and radish (*Raphanus sativus* L.) cultivar 'Giant White Globe' were grown both in the field and in controlled environments, where hydroponic nutrient solution, light, and temperature were regulated, and where CO₂ levels were controlled at 400, 1000, 5000, or 10,000 ppm. Plants were harvested at maturity, dried, and analyzed for proximate composition (protein, fat, ash, and carbohydrate), total nitrogen (N), nitrate N, free sugars, starch, total dietary fiber, and minerals. Total N, protein N, nonprotein N (NPN), and nitrate N generally increased for radish roots and lettuce leaves when grown under growth chamber conditions compared to field conditions. The nitrate-N level of lettuce leaves, as a percentage of total NPN, decreased with increasing levels of CO₂ enrichment. The ash content of radish roots and of radish and lettuce leaves decreased with increasing levels of CO₂ enrichment. The levels of certain minerals differed between field- and chamber-grown materials, including changes in the calcium (Ca) and phosphorus (P) contents of radish roots and lettuce leaves, resulting in reduced Ca/P ratio for chamber- grown materials. The free-sugar contents were similar between the field and chamber-grown lettuce leaves, but total dietary fiber content was much higher in the field-grown plant material. The starch content of growth-chamber lettuce increased with CO₂ level.

McLaughlin, S., and K. Percy. 1999. Forest health in North America: Some perspectives on actual and potential roles of climate and air pollution. *Water, Air, and Soil Pollution* 116(1-2):151-197.

The perceived health of forest ecosystems over large temporal and spatial scales can be strongly influenced by the frames of reference chosen to evaluate both forest condition and the functional integrity of sustaining forest processes. North American forests are diverse in range, species composition, past disturbance history, and current management practices. Therefore the implications of changes in environmental stress from atmospheric pollution and/or global climate change on health of these forests will vary widely across the landscape. Forest health surveys that focus on the average forest condition may do a credible job of representing the near-term trends in economic value while failing to detect fundamental changes in the processes by which these values are sustained over the longer term. Indications of increased levels of environmental stress on forest growth and nutrient cycles are currently apparent in several forest types in North America. Measurements of forest ecophysiological responses to air pollutants in integrated case studies with four forest types (southern pine, western pine, high elevation red spruce, and northeastern hardwoods) indicate that ambient levels of ozone and/or acidic deposition can alter basic processes of water, carbon, and nutrient allocation by forest trees. These changes then provide a mechanistic basis for pollutant stress to enhance a wider range of natural stresses that also affect and are affected by these resources. Future climatic changes may ameliorate (+ CO₂) or exacerbate (+ temperature, + UV-B) these effects. Current projections of forest responses to global climate change do not consider important physiological changes induced by air pollutants that may amplify climatic stresses. These include reduced rooting mass, depth, and

function, increased respiration, and reduced water use efficiency. Monitoring and understanding the relative roles of natural and anthropogenic stress in influencing future forest health will require programs that are structured to evaluate responses at appropriate frequencies across gradients in both forest resources and the stresses that influence them. Such programs must also be accompanied by supplemental process-oriented and pattern-oriented investigations that more thoroughly test cause and effect relationships among stresses and responses of both forests and the biogeochemical cycles that sustain them.

McMaster, G.S., D.R. LeCain, J.A. Morgan, L. Aiguo, and D.L. Hendrix. 1999. Elevated CO₂ increases wheat CER, leaf and tiller development, and shoot and root growth. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 183(2):119-128.

Whole-plant responses to elevated CO₂ throughout the life cycle are needed to understand future impacts of elevated atmospheric CO₂. In this study, *Triticum aestivum* L. leaf carbon exchange rates (CER) and carbohydrates, growth, and development were examined at the tillering, booting, and grain-filling stages in growth chambers with CO₂ concentrations of 350 (ambient) or 700 (high) $\mu\text{mol mol}^{-1}$. Single-leaf CER values measured on plants grown at high CO₂ were 50% greater than those measured on plants grown at ambient CO₂ for all growth stages, with no photosynthetic acclimation observed at high CO₂. Leaves grown in high CO₂ had more starch and simple sugars at tillering and booting, and more starch at grain-filling, than those grown in ambient CO₂. CER and carbohydrate levels were positively correlated with leaf appearance rates and tillering (especially third-, fourth- and fifth-order tillers). Elevated CO₂ slightly delayed tiller appearance, but accelerated tiller development after appearance. Although high CO₂ increased leaf appearance rates, final leaf number/culm was not effected because growth stages were reached slightly sooner. Greater plant biomass was related to greater tillering. Doubling CO₂ significantly increased both shoot and root dry weight, but decreased the shoot to root ratio. High CO₂ plants had more spikes plant⁻¹ and spikelets spike⁻¹, but a similar number of fertile spikelets spike⁻¹. Elevated CO₂ resulted in greater shoot, root and spike production and quicker canopy development by increasing leaf and tiller appearance rates and phenology.

McMaster, H.J. 1999. The potential impact of global warming on hail losses to winter cereal crops in New South Wales. *Climatic Change* 43(2):455-476.

This study was undertaken to determine the impact of potential global warming on the magnitude of hail losses to winter cereal crops within two areas situated on the western slopes of New South Wales, Australia. A model relating historical crop hail losses to climatic variables was developed for each area. These models included seasonal measures of vertical instability, low-level moisture and the height of the freezing level. In both areas, windshear was not found to be an important factor influencing seasonal crop hail losses. The two crop hail loss models were then used in conjunction with upper-air climatic data from three single

mixed-layer global climate models (GCMs). Each GCM was run for 1 x CO₂ conditions and for 2 x CO₂ conditions. The enhanced greenhouse effect on climatic variables was taken to be the difference between their values for these two runs. Changes to climatic variables were then translated directly into changes in the percentage value of the winter cereal crop lost due to hail. In both areas, the three GCMs agreed concerning the direction of change in each of the variables used in the crop hail loss model. GCM simulations of the greenhouse effect resulted in a decline in winter cereal crop hail losses, with the exception of one GCM simulation at one location where losses increased slightly. None of the changes due to the enhanced greenhouse effect, however, were significant owing to a large observed seasonal variability of crop hail losses. Also, the simulated seasonal variability of crop hail losses did not change significantly due to the enhanced greenhouse effect. These results depended on two important assumptions. Firstly, it was assumed that the dominant relationships between climatic variables and crop hail losses in the past would remain the same in a future climate. Secondly, it was assumed that the single mixed-layer GCMs used in the study were correctly predicting climate change under enhanced greenhouse conditions.

McMurtrie, R.E., and H.N. Comins. 1996. The temporal response of forest ecosystems to doubled atmospheric CO₂ concentration. *Global Change Biology* 2(1):49-57.

Vegetation responses to high [CO₂] include both direct photosynthetic effects and indirect effects associated with various plant and soil feedbacks. Synthesis of these direct and indirect effects requires ecosystem process models describing the cycling of carbon and essential mineral nutrients through plants and soils. Here we use the ecosystem model G'DAY to investigate responses to an instantaneous doubling of [CO₂]. The analysis indicates that the magnitude and even direction of the growth response to high [CO₂] can vary widely on different timescales, because responses on different timescales are determined by different ecosystem-level feedbacks and hence by different sets of key model parameters. Of particular importance are parameters describing the flexibility of plant and soil nitrogen to carbon (N:C) ratios; large responses occur if N:C ratios decline significantly at high [CO₂], with little or no response if N:C ratios are inflexible. According to G'DAY, the CO₂-response changes over time because responses on longer timescales are dictated by the N:C ratios of less rapidly cycled organic matter.

McMurtrie, R.E., H.N. Comins, M.U.F. Kirschbaum, and Y.P. Wang. 1992. Modifying existing forest growth-models to take account of effects of elevated CO₂. *Australian Journal of Botany* 40(4-5):657-677.

Most published process models of the growth of forest stands are concerned predominantly with either tree physiology or nutrient cycling, concentrating respectively on photosynthetic carbon gain and allocation, or on decomposition and nutrient uptake processes. Mechanistic formulations of direct CO₂ effects on photosynthesis have been incorporated in some physiology-based models, whereas modifications incorporating direct CO₂ effects in nutrient-driven models have usually been more empirical. Physiology-based models predict considerable CO₂-fertiliser effects, while nutrient driven models tend to be less

sensitive to elevated ambient CO₂ concentration (C(a)). This paper describes how effects of elevated C(a) can be incorporated in these various types of forest growth models. The magnitude of the simulated response to elevated C(a) varies markedly depending on a particular model's spatial and temporal resolution and on which processes are incorporated. Two physiology-based models of forest canopy processes (MAESTRO and BIOMASS) and a plant-soil model (G'DAY) are considered here. MAESTRO and BIOMASS incorporate mechanistic descriptions of the biochemical basis of photosynthesis by C3 plants, while G'DAY contains a simplified formulation but includes soil processes. All three models are used to simulate the response to an instantaneous doubling of C(a). Simulations of MAESTRO and BIOMASS show that on a clear day total canopy photosynthesis is temperature-dependent with increases of approximately 10, 45 and 70% at 10, 25 and 40-degrees-C respectively. A simulation for a stand of *Pinus radiata* growing with abundant water and nutrients and mean annual day-time temperature of 14.8-degrees-C shows an increase of 25% in annual canopy photosynthesis. On nutrient-limited sites plant responses to elevated C(a) are constrained by feedbacks associated with rates of decomposition and nutrient cycling. According to the G'DAY model, which incorporates these feedbacks, an instantaneous doubling of C(a) leads to a 27% initial productivity increase lasting less than a decade and a more modest increase of 8% sustained in the long term.

McMurtrie, R.E., and Y.P. Wang. 1993. Mathematical-models of the photosynthetic response of tree stands to rising co₂ concentrations and temperatures. *Plant, Cell and Environment* 16(1):1-13.

Two published models of canopy photosynthesis, MAESTRO and BIOMASS, are simulated to examine the response of tree stands to increasing ambient concentrations of carbon dioxide (C(a)) and temperatures. The models employ the same equations to described leaf gas exchange, but differ considerably in the level of detail employed to represent canopy structure and radiation environment. Daily rates of canopy photosynthesis simulated by the two models agree to within 10% across a range of CO₂ concentrations and temperatures. A doubling of C(a) leads to modest increases of simulated daily canopy photosynthesis at low temperatures (10% increase at 10-degrees- C), but larger increases at higher temperatures (60% increase at 30-degrees-C). The temperature and CO₂ dependencies of canopy photosynthesis are interpreted in terms of simulated contributions by quantum-saturated and non-saturated foliage. Simulations are presented for periods ranging from a diurnal cycle to several years. Annual canopy photosynthesis simulated by BIOMASS for trees experiencing no water stress is linearly related to simulated annual absorbed photosynthetically active radiation, with light utilization coefficients for carbon of epsilon = 1.66 and 2.07 g MJ⁻¹ derived for C(a) of 350 and 700 mumol mol⁻¹, respectively.

Medlyn, B.E. 1996. Interactive effects of atmospheric carbon dioxide and leaf nitrogen concentration on canopy light use efficiency: A modeling analysis. *Tree Physiology* 16(1-2):201-209.

Potential increases in plant productivity in response to increasing atmospheric CO₂ concentration are likely to be constrained by nutrient

limitations. However, the interactive effects of nitrogen nutrition and CO₂ concentration on growth are difficult to define because both factors affect several aspects of growth, including photosynthesis, respiration, and leaf area. By expressing growth as a product of light intercepted and light use efficiency (epsilon), it is possible to decouple the effects of nutrient availability and CO₂ concentration on photosynthetic rates from their effects on other aspects of plant growth. I used measured responses of leaf photosynthesis to leaf nitrogen (N) content and CO₂ concentration to parameterize a model of canopy radiation absorption and photosynthesis, and then used the model to estimate the response of E to elevated CO₂ concentration for *Pinus radiata* D. Don, *Nothofagus fusca* (Hook. f.) Orst. and *Eucalyptus grandis* W. Hill ex Maiden. Down-regulation of photosynthesis at elevated CO₂ was represented as a reduction in either leaf N content or leaf Rubisco activity. The response of epsilon to elevated CO₂, which differed among the three species, was analyzed in terms of the underlying relationships between leaf photosynthesis and leaf N content. The response was independent of leaf N content when photosynthesis was down-regulated to the same extent at low and high leaf N content. Interactive effects of N availability and CO₂ on growth are thus likely to be the result of either differences in down-regulation of photosynthesis at low and high N availability or interactive effects of CO₂ and N availability on other aspects of plant growth.

Medlyn, B.E. 1996. The optimal allocation of nitrogen within the C-3 photosynthetic system at elevated CO₂. *Australian Journal of Plant Physiology* 23(5):593-603.

The distribution of nitrogen among compounds involved in photosynthesis varies in response to changes in environmental conditions such as photon flux density. However, the extent to which the nitrogen distribution within leaves adjusts in response to increased atmospheric CO₂ is unclear. A model was used to determine the nitrogen distribution which maximises photosynthesis under realistic light regimes at both current and elevated levels of CO₂, and a comparison was made with observed leaf nitrogen distributions reported in the literature. The model accurately predicted the distribution of nitrogen within the photosynthetic system for leaves grown at current levels of CO₂, except at very high leaf nitrogen contents. The model predicted that, under a doubling of CO₂ concentration from its current level, the ratio of electron transport capacity to Rubisco activity (J(max):V-cmax) should increase by 40%. In contrast, measurements of J(max):V-cmax taken from the literature show a slight but non-significant increase in response to an increase in CO₂. The discrepancy between predicted and observed J(max):V-cmax suggests that leaf nitrogen distribution does not acclimate optimally to elevated CO₂. Alternatively, the discrepancy may be due to effects of CO₂ which the model fails to take into account, such as a possible decrease in the conductance to CO₂ transfer between the intercellular spaces and the sites of carboxylation at elevated CO₂.

Medlyn, B.E., and P.G. Jarvis. 1999. Design and use of a database of

model parameters from elevated [CO₂] experiments. *Ecological Modelling* 124(1):69-83.

This paper describes a new approach for linking experiments and models: a searchable database of model parameter values obtained directly from experiments. The experiments were carried out as part of a major European project studying the long-term effects of elevated [CO₂] on European forest species. To ensure that the information obtained from these experiments was fully utilised in the modelling component of the project, a database was used to store and synthesise experimental data. Key features of the database include: (1) Data is stored as model parameters rather than raw experimental data, which aids transfer of information from experiments to models. (2) Extensive meta-data is stored, which is crucial for correct interpretation of parameter values. (3) The database has a relational structure, which facilitates data retrieval. In this paper, we document the structure of the database. The structure is flexible and generic and could easily be adapted to suit other fields of research. We illustrate the use of the database with examples from the project. (C) 1999 Elsevier Science B.V. All rights reserved.

Megonigal, J.P., and W.H. Schlesinger. 1997. Enhanced CH₄ emissions from a wetland soil exposed to elevated CO₂. *Biogeochemistry* 37(1):77-88.

Methane emissions from wetland soils are generally a positive function of plant size and primary productivity, and may be expected to increase due to enhanced rates of plant growth in a future atmosphere of elevated CO₂. We performed two experiments with *Orontium aquaticum*, a common emergent aquatic macrophyte in temperate and sub-tropical wetlands, to determine if enhanced rates of photosynthesis in elevated CO₂ atmospheres would increase CH₄ emissions from wetland soils. *O. aquaticum* was grown from seed in soil cores under ambient and elevated (ca. 2-times ambient) concentrations of CO₂ in an initial glasshouse study lasting 3 months and then a growth chamber study lasting 6 months. Photosynthetic rates were 54 to 71% higher under elevated CO₂ than ambient CO₂, but plant biomass was not significantly different at the end of the experiment. In each case, CH₄ emissions were higher under elevated than ambient CO₂ levels after 2 to 4 months of treatment, suggesting a close coupling between photosynthesis and methanogenesis in our plant-soil system. Methane emissions in the growth chamber study increased by 136%. We observed a significant decrease in transpiration rates under elevated CO₂ in the growth chamber study, and speculate that elevated CO₂ may also stimulate CH₄ emissions by increasing the extent and duration of flooding in some wetland ecosystems. Elevated CO₂ may dramatically increase CH₄ emissions from wetlands, a source that currently accounts for 40% of global emissions.

Meier, M., and J. Fuhrer. 1997. Effect of elevated CO₂ on orchard grass and red clover grown in mixture at two levels of nitrogen or water

supply. *Environmental and Experimental Botany* 38(3):251-262.

A mixture of orchard grass (*Dactylis glomerata* L.) and red clover (*Trifolium pratense* L.) was grown in microcosms at either ambient (40 Pa) or elevated CO₂ (78 Pa) and supplied with two levels of nitrogen (N) or two levels of irrigation. The aim was to study how reduced N or water supply affect the CO₂ response of shoot and root growth, in relationship to changes in the plant C/N ratio. Plant growth was monitored non-destructively, and shoot dry mass was determined after 41 days (first growth period) and after 67 days (second growth period). Stubble and root dry mass, and C/N ratios in roots and shoots were measured only after regrowth. Elevated CO₂ continuously stimulated growth of the mixture, and increased the shoot biomass in the absence of N or water limitations without changing the shoot/root dry weight ratio, nor the C/N ratio. The CO₂-effect on orchard grass tended to be stronger than the effect on red clover, and was more pronounced during the first as compared to the second growth period. At low N, yield of red clover showed the stronger CO₂ response, whereas with reduced water supply the relative CO₂-stimulation of shoot biomass in orchard grass was more pronounced. Both low-N and reduced water supply decreased shoot, root, and stubble biomass, decreased the shoot/root ratio, and increased the C/N ratio. Elevated CO₂ reduced negative effects of limited N or water supply on shoot growth, but the positive CO₂ effect at low N declined with time. The interaction between CO₂ and N was most pronounced for stubble mass, whereas the interaction between CO₂ and reduced water supply was only significant for root mass. It is concluded that changes in shoot/root ratio are mainly caused by low N and reduced water supply via changes in the N-status of the plant, and that elevated CO₂ has little effect on the shoot/root ratio, but tends to reduce negative effects of limiting N and water on growth. Meier, M., M. Saurer, C. Haldemann, and J. Fuhrer. 1997. Effect of elevated CO₂ on the carbon balance of a grass-clover mixture. *Acta Oecologica-International Journal of Ecology* 18(3):313-317.

Experiments were carried out to investigate the effect of elevated CO₂ (780 $\mu\text{mol mol}^{-1}$) on the C-balance and carbon release from the roots of a mixture of *Dactylis glomerata* and *Trifolium pratense*. The plants were grown for 67 days in a growth chamber with controlled watering and fertilisation, with an intermediate harvest after 41 days. Elevated CO₂ increased total net uptake of carbon (C) by about 30% by the end of regrowth. Total net C-uptake and the amount of C recovered in the second harvest were balanced at both CO₂ concentrations, and the root: shoot ratio was not affected by elevated CO₂. C-13-allocation to roots, and C-13 released into the root environment were measured following pulse-labelling with (CO₂)- C-13 at the end of regrowth. Relative to the amount of C-13 taken up by the shoot, C-13 allocation to roots was 1.6%, and C-13 released from roots was only 0.4%. No significant difference in these proportions was observed at elevated CO₂, but in absolute terms, plants grown at elevated CO₂ released more C-13 from the roots.

Meinander, O., S. Somersalo, T. Holopainen, and R.J. Strasser. 1996. Scots pines after exposure to elevated ozone and carbon dioxide probed by reflectance spectra and chlorophylla fluorescence transients. *Journal of Plant Physiology* 148(1-2):229-236.

Natural Scots pines have been exposed to filtered air, ambient air and air with elevated O₃ or/and CO₂ in open top chambers. The trees showed no differences in their optical responses prior to the fumigations. After the fumigation period of three months the plants were in good health. The position of the maximum derivative of the green light reflectance in carbon dioxide fumigated pines was shifted from the control pines inflection point, by approximately 4 nm towards shorter wavelengths. The position of the red edge derivative maximum showed no significant changes. By fluorescence techniques (as OJIP - fast fluorescence transients) nearly no change was found in the quantum yield for electron transport ($\phi(o)$ or excitation energy trapping $\phi(Po)$). However, the estimated activities as absorption, trapping or electron transport per cross-section increased considerably for all samples with elevated O₃ or CO₂. This increased activity seems to be due to an increased antenna size in O₃ treated samples. At elevated CO₂ the antenna size is decreased whereas the density of reaction centers per cross-section increased. This means that two different stress-adaptation mechanisms can lead to a similar macroscopic phenomenon like e.g. an increased metabolic activity.

Melack, J.M., J. Dozier, C.R. Goldman, D. Greenland, A.M. Milner, and R.J. Naiman. 1997. Effects of climate change on inland waters of the Pacific Coastal Mountains and Western Great Basin of North America. *Hydrological Processes* 11(8):971-992.

The region designated as the Pacific Coastal Mountains and Western Great Basin extends from southern Alaska (64 degrees N) to southern California (34 degrees N) and ranges in altitude from sea level to 6200 m. Orographic effects combine with moisture-laden frontal systems originating in the Pacific Ocean to produce areas of very high precipitation on western slopes and dry basins of internal drainage on eastern hanks of the mountains. In the southern half of the region most of the runoff occurs during winter or spring, while in the northern part most occurs in summer, especially in glaciated basins. Analyses of long-term climatic and hydrological records, combined with palaeoclimatic reconstructions and simulations of future climates, are used as the basis for likely scenarios of climatic variations. The predicted hydrological response in northern California to a climate with doubled CO₂ and higher temperatures is a decrease in the amount of precipitation falling as snow, and substantially increased runoff during winter and less in late spring and summer. One consequence of the predicted earlier runoff is higher salinity in summer and autumn in San Francisco Bay. In saline lakes, the incidence of meromixis and the associated reduction in nutrient supply and algal abundance is expected to vary significantly as runoff fluctuates. In subalpine lakes, global warming will probably will lead to increased productivity. Lacustrine productivity can also be altered by changes in wind regimes, drought- enhanced forest fires and maximal or minimal snowpacks associated with atmospheric anomalies such as El Nino-Southern Oscillation (ENSO) events. Reduced stream temperature from increased contributions of glacial meltwater and decreased channel stability from changed runoff patterns and altered sediment loads has the potential to reduce the diversity of zoobenthic communities in predominately glacier-fed rivers. Climatic warming is likely to result in reduced growth and survival of sockeye salmon in freshwater, which would, in turn, increase marine mortality. Further research activities should include expanded studies at high elevations and of glacier mass balances and glacial runoff, applications of remote sensing to monitor changes, further refinement of regional climatic models to improve forecasts of future conditions and continued analyses of long-term physical, chemical and biological data to help understand responses to future climates. Melillo, J.M., J. Borchers, J. Chaney, H. Fisher, S. Fox, A. Haxeltine, A. Janetos, D.W. Kicklighter, T.G.F. Kittel, A.D. McGuire, R. McKeown, R. Neilson, R. Nemani, D.S. Ojima, T. Painter, Y. Pan, W.J. Parton, L. Pierce, L. Pitelka, C. Prentice, B. Rizzo, N.A. Rosenbloom, S. Running, D.S. Schimel, S. Sitch, T. Smith, and I. Woodward. 1995. Vegetation ecosystem modeling and analysis project - comparing biogeography and biogeochemistry models in a continental-scale study of terrestrial ecosystem responses to climate-change and CO₂ doubling. *Global Biogeochemical Cycles* 9(4):407-437.

We compare the simulations of three biogeography models (BIOME2, Dynamic Global Phytogeography Model (DOLY), and Mapped Atmosphere-Plant Soil System (MAPSS)) and three biogeochemistry models (BIOME-BGC (BioGeochemistry Cycles), CENTURY, and Terrestrial Ecosystem Model (TEM)) for the conterminous United States under contemporary conditions of atmospheric CO₂ and climate. We also compare the simulations of these models under doubled CO₂ and a range of climate scenarios. For contemporary conditions, the biogeography models successfully simulate the geographic distribution of major vegetation types and have similar estimates of area for forests (42 to 46% of the conterminous United States), grasslands (17 to 27%), savannas (15 to 25%), and shrublands (14 to 18%). The biogeochemistry models estimate similar continental-scale net primary production (NPP; 3125 to 3772 x 10¹² gC yr⁻¹) and total carbon storage (108 to 118 x 10¹⁵ gC) for contemporary conditions. Among the scenarios of doubled CO₂ and associated equilibrium climates produced by the three general circulation models (Oregon State University (OSU), Geophysical Fluid Dynamics Laboratory (GFDL), and United Kingdom Meteorological Office (UKMO)), all three biogeography models show both gains and losses of total forest area depending on the scenario (between 38 and 53% of conterminous United States area). The only consistent gains in forest area with all three models (BIOME2, DOLY, and MAPSS) were under the GFDL scenario due to large increases in precipitation. MAPSS lost forest area under UKMO, DOLY under OSU, and BIOME2 under both UKMO and OSU. The variability in forest area estimates occurs because the hydrologic cycles of the biogeography models have different sensitivities to increases in temperature and CO₂. However, in general, the biogeography models produced broadly similar results when incorporating both climate change and elevated CO₂ concentrations. For these scenarios, the NPP estimated by the biogeochemistry models increases between 2% (BIOME-BGC with UKMO climate) and 35% (TEM with UKMO climate). Changes in total carbon storage range from losses of 33% (BIOME-BGC with UKMO climate) to gains of 16% (TEM with OSU climate). The CENTURY responses of NPP and carbon storage are positive and intermediate to the responses of BIOME-BGC and TEM. The variability in carbon cycle responses occurs because the hydrologic and nitrogen cycles of the biogeochemistry models have different sensitivities to increases in temperature and CO₂. When the biogeochemistry models are run with the vegetation distributions of the biogeography models, NPP ranges from no response (BIOME-BGC with all three biogeography model vegetations for UKMO climate) to increases of 40% (TEM with MAPSS vegetation for OSU climate). The total carbon storage response ranges from a decrease of 39% (BIOME-BGC with MAPSS vegetation for UKMO climate) to an increase of 32% (TEM with MAPSS vegetation for OSU and GFDL climates). The UKMO responses of BIOME-BGC with MAPSS vegetation are primarily caused by decreases in forested area and temperature-induced water stress. The OSU and GFDL responses of TEM with MAPSS vegetations are primarily caused by forest expansion and temperature-enhanced nitrogen cycling.

Melillo, J.M., R.A. Houghton, D.W. Kicklighter, and A.D. McGuire. 1996. Tropical deforestation and the global carbon budget. *Annual Review of Energy and the Environment* 21:293-310.

The CO₂ concentration of the atmosphere has increased by almost 30% since 1800. This increase is due largely to two factors: the combustion of fossil fuel and deforestation to create croplands and pastures. Deforestation results in a net flux of carbon to the atmosphere because forests contain 20-50 times more carbon per unit area than agricultural lands. In recent decades, the tropics have been the primary region of deforestation. The annual rate of CO₂ released due to tropical deforestation during the early 1990s has been estimated at between 1.2 and 2.3 gigatons C. The range represents uncertainties about both the rates of deforestation and the amounts of carbon stored in different types of tropical forests at the time of cutting. An evaluation of the role of tropical regions in the global carbon budget must include both the carbon flux to the atmosphere due to deforestation and carbon accumulation, if any, in intact forests. In the early 1990s, the release of CO₂ from tropical deforestation appears to have been mostly offset by CO₂ uptake occurring elsewhere in the tropics, according to an analysis of recent trends in the atmospheric concentrations of O-2 and N-2. Interannual variations in climate and/or CO₂ fertilization may have been responsible for the CO₂ uptake in intact forests. These mechanisms are consistent with site-specific measurements of net carbon fluxes between tropical forests and the atmosphere, and with regional and global simulations using process-based biogeochemistry models.

Melillo, J.M., A.D. McGuire, D.W. Kicklighter, B. Moore, C.J. Vorosmarty, and A.L. Schloss. 1993. Global climate-change and terrestrial net primary production. *Nature* 363(6426):234-240.

A process-based model was used to estimate global patterns of net primary production and soil nitrogen cycling for contemporary climate conditions and current atmospheric CO₂ concentration. Over half of the global annual net primary production was estimated to occur in the tropics, with most of the production attributable to tropical evergreen forest. The effects of CO₂ doubling and associated climate changes were also explored. The responses in tropical and dry temperate ecosystems were dominated by CO₂, but those in northern and moist temperate ecosystems reflected the effects of temperature on nitrogen availability.

Melkonian, J., S.J. Riha, and D.S. Wilks. 1998. Simulation of elevated CO₂ effects on daily net canopy carbon assimilation and crop yield. *Agricultural Systems* 58(1):87-106.

Three formulations for estimating the impact of elevated CO₂ on daily net canopy carbon assimilation (A) are compared. The formulations are all physiologically based but vary in the detail with which A is represented. When implemented in two crop models, all formulations

predict increased yield under elevated CO₂, with the formulation incorporating the most detailed representation of A predicting the smallest yield increase. In the crop model with more complex representations of growth and yield, and where increased photoassimilates under elevated CO₂ are allowed to affect processes such as leaf area development, yield predictions under elevated CO₂ can be substantially greater than the predicted increase in A for each formulation. These results indicate that the representation of A and assumptions regarding adaptation to elevated CO₂ of A, crop growth and carbon partitioning will have large impacts on simulation model predictions of crop yields at elevated CO₂. Menard, C., and B. Dansereau. 1992. Influence of photosynthetic photon flux-density and planting scheme on growth and development of cultivar royalty roses. *Scientia Horticulturae* 50(3):197-207.

The influence of photosynthetic photon flux density (PPFD) and planting scheme on growth, development, yield and quality of RosaXhybrida cultivar 'Royalty' was investigated. Three planting schemes (two, three, and four parallel rows) and three light treatments (ambient light and ambient light Plus supplemental lighting with either 50 or 100-mu-mol s⁻¹ m⁻² PPFD (high pressure sodium lamps) were studied. Generally, supplementary PPFD enhanced the vegetative and reproductive growth of the plants compared to plants grown in ambient light conditions. Marketable yield per plant was increased significantly by 79% (P<0.05) for the crop period from 1 January to 24 March 1988 when a PPFD of 50-mu-mol s⁻¹ m⁻² was added to ambient light conditions. Carbon dioxide enrichment increased yield by 113% when a PPFD of 50-mu-mol s⁻¹ m⁻² was added to ambient light during the crop period of 1 January to 24 March, 1989. The number of flowers per plant in the superior classes (commercial classification: 'Select' and 'No. 1') was enhanced for this period compared with the same period the previous year when no supplemental carbon dioxide was provided. Generally the planting scheme of two parallel rows gave the best overall results.

Miao, S.L. 1995. Acorn mass and seedling growth in quercus-rubra in response to elevated co₂. *Journal of Vegetation Science* 6(5):697-700.

In order to explore whether seed size affects plant response to elevated CO₂ plants grown from red oak (Quercus rubra L.) acorns were studied for differences in their first year response to CO₂ concentrations of 350 and 700 ul/l. Overall, at final harvest, total biomass of plants grown in elevated CO₂ were 47 % larger than that of plants grown in ambient CO₂. There were significant interactions between CO₂ treatments and initial acorn mass for total biomass, as well as for root, leaf, and stem biomass. Although total biomass increased with increasing initial acorn mass for both high and ambient CO₂ plants, high CO₂ plants exhibited a greater increase than ambient CO₂ plants, as indicated by a steeper slope in high CO₂ plants. However, CO₂ levels did not affect biomass partitioning traits, such as root/shoot ratio, leaf, stem, and root weight ratios, and leaf area ratio. These results suggest that variation in seed size or initial plant size can cause intraspecific variation in response to elevated CO₂.

Miao, S.L., P.M. Wayne, and F.A. Bazzaz. 1992. Elevated co-2

differentially alters the responses of cooccurring birch and maple seedlings to a moisture gradient. *Oecologia* 90(2):300-304.

To determine the effects of elevated CO₂ and soil moisture status on growth and niche characteristics of birch and maple seedlings, gray birch (Betula populifolia) and red maple (Acer rubrum) were experimentally raised along a soil moisture gradient ranging from extreme drought to flooded conditions at both ambient and elevated atmospheric CO₂ levels. The magnitude of growth enhancement due to CO₂ was largely contingent on soil moisture conditions, but differently so for maple than for birch seedlings. Red maple showed greatest CO₂ enhancements under moderately moist soil conditions, whereas gray birch showed greatest enhancements under moderately dry soil conditions. Additionally, CO₂ had a relatively greater ameliorating effect in flooded conditions for red maple than for gray birch, whereas the reverse pattern was true for these species under extreme drought conditions. For both species, elevated CO₂ resulted in a reduction in niche breadths on the moisture gradient; 5% for gray birch and 23% for red maple. Species niche overlap (proportional overall) was also lower at elevated CO₂ (0.98 to: 0.88:11%). This study highlights the utility of of experiments crossing CO₂ levels with gradients of other resources as effective tools for elucidating the potential consequences of elevated CO₂ on species distributions and potential interactions in natural communities.

Micallef, B.J., K.A. Haskins, P.J. Vanderveer, K.S. Roh, C.K. Shewmaker, and T.D. Sharkey. 1995. Altered photosynthesis, flowering, and fruiting in transgenic tomato plants that have an increased capacity for sucrose synthesis. *Planta* 196(2):327-334.

Photosynthesis, leaf assimilate partitioning, flowering, and fruiting were examined in two lines of Lycopersicon esculentum Mill. transformed with a gene coding for sucrose-phosphate synthase (SPS) (EC 2.3.1.14) from Zea mays L. expressed from a tobacco ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) small subunit promoter. Plants were grown at either 35 or 65 Pa CO₂ and high light (1000 mu mol photons . m⁻². s⁻¹). Limiting and maximum SPS activities were significantly greater (up to 12 times) in the leaves of SPS-transformed lines for all treatments. Partitioning of carbon into sucrose increased 50% for the SPS transformants. Intact leaves of the control lines exhibited CO₂-insensitivity of photosynthesis at high CO₂ levels, whereas the SPS transformants did not exhibit CO₂-insensitivity. The O-2-sensitivity of photosynthesis was also greater for the SPS-transformed lines compared to the untransformed control when measured at 65 Pa CO₂. These data indicate that the SPS transformants had a reduced limitation on photosynthesis imposed by end-product synthesis. Growth at 65 Pa CO₂ resulted in reduced photosynthetic capacity for control lines but not for SPS-transformed lines. When grown at 65 Pa CO₂, SPS transformed lines had a 20% greater photosynthetic rate than controls when measured at 65 Pa CO₂ and a 35% greater rate when measured at 105 Pa CO₂. Photosynthetic rates were not different between lines when grown at 35 Pa CO₂. The time to 50% blossoming was reduced and the total number of inflorescences was significantly greater for the SPS transformants when grown at either 35 or 65 Pa CO₂. At 35 Pa CO₂, the total fruit number of the SPS transformants was up to 1.5 times that of the controls, the fruit matured earlier, and there was up to a 32% increase in total fruit dry weight. Fruit yield was not significantly different between the lines when grown at 65 Pa CO₂. Therefore, there was not a strict relationship between yield and leaf photosynthesis rate. Flowering and fruit development of the SPS-transformed lines grown at 35 Pa CO₂ showed similar trends to the controls grown at 65 Pa CO₂. Incidences of bios som-end rot were also reduced in the SPS-transformed lines. These data indicate that altering starch/sucrose partitioning by increasing the

capacity for sucrose synthesis can affect acclimation to elevated CO₂ partial pressure and flowering and fruiting in tomato.

Micallef, B.J., P.J. Vanderveer, and T.D. Sharkey. 1996. Responses to elevated CO₂ of *Flaveria linearis* plants having a reduced activity of cytosolic fructose-1,6-bisphosphatase. *Plant, Cell and Environment* 19(1):10-16.

Wide variation exists in the growth responses of C-3 plants to elevated CO₂ levels. To investigate the role of photosynthetic feedback in this phenomenon, photosynthetic parameters and growth were measured for lines of *Flaveria linearis* with low, intermediate or high cytosolic fructose-1,6-bisphosphatase (cytFBPase) activity when grown at either 35 or 65 Pa CO₂. The effects of pot size on the responses of these lines to elevated CO₂ were also examined. Photosynthesis and growth of plants with low cytFBPase activity were less responsive to elevated CO₂, and these plants had a reduced maximum potential for photosynthesis and growth. Plants with intermediate cytFBPase activity also showed a lower relative growth enhancement when grown at 65 Pa CO₂. There was a significant pot size effect on photosynthesis and growth for line 85-1 (high cytFBPase). This effect was greatest for Line 85-1 when grown at 35 Pa CO₂, since these plants showed the greatest downward acclimation of photosynthesis when grown in small pots. There was a minimal pot size effect for line 84-9 (low cytFBPase), and this could be partly attributed to the reduced CO₂ sensitivity of this line. It is proposed that the capacity for sucrose synthesis in C-3 plants is partly responsible for their wide variation in CO₂ responsiveness.

Michaels, P.J. 1993. Benign greenhouse. *Research & Exploration* 9(2):222-233.

Several lines of evidence are emerging that suggest that the "popular vision" of global warming-major agricultural damage, disastrous sea-level rise, and ecological disequilibrium-is flawed. The popular vision is driven primarily by the prospect of enhanced daytime warming, particularly in summer. What has been observed is a warming that is beneath the projections that support the popular vision, and a warming that has occurred virtually all during the night in the Northern Hemisphere. In the Southern Hemisphere there is also evidence of disproportionate night warming. Several sources of data indicate that this night warming has been caused by an increase in cloudiness that could be a consequence of the greenhouse enhancement itself. The results of the night warming-longer growing seasons, little change in moisture stress, and a possible increase in ice volume-are opposite to the popular vision of climatic change.

Midgley, G.F., W.D. Stock, and J.M. Juritz. 1995. Effects of elevated CO₂ on Cape Fynbos species adapted to soils of different nutrient status: Nutrient- and CO₂-responsiveness. *Journal of Biogeography* 22(2-3):185-191.

The combined effects of elevated atmospheric CO₂ and nutrient supply rate on plant biomass accumulation were determined for four

Leucadendron species (Proteaceae) of the mediterranean climate Fynbos Biome, South Africa. Juvenile individuals were grown for 6 months in experiments comprising 2X2 factorial combinations of substrate nutrient supply rate and atmospheric CO₂ concentration in open-top chambers in a greenhouse. The four selected *Leucadendron* species included one pair of species common on extremely nutrient-poor acid sands (typical of the Fynbos Biome), and another pair associated with more nutrient rich substrates (rare in the Fynbos Biome). Plant biomass accumulation data were analysed to explore the determinants of plant CO₂ responsiveness, particularly the role of plant sink strength characteristics. Results lead us to speculate that the nitrogen:phosphorus supply ratio may have limited plant CO₂ responsiveness in three of the four species under conditions of higher nutrient supply rate. Intrinsic plant growth characteristics, possibly related to the relative ability of the species to generate sinks, may ultimately have limited the capacity of all species to respond to elevated CO₂.

Midgley, G.F., S.J.E. Wand, and N.W. Pammenter. 1999. Nutrient and genotypic effects on CO₂-responsiveness: Photosynthetic regulation in *Leucadendron* species of a nutrient-poor environment. *Journal of Experimental Botany* 50(333):533-542.

Four South African *Leucadendron* congeners with divergent soil N and P preferences were grown as juveniles at contrasting nutrient concentrations at ambient (350 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ levels. Photosynthetic parameters were related to leaf nutrient and carbohydrate status to reveal controls of carbon uptake rate. In all species, elevated CO₂ depressed both the maximum Rubisco catalytic activity (V-c, V-max, by 19-44%) and maximum electron transport rate (J(max) by 13-39%), indicating significant photosynthetic acclimation of both measures. Even so, all species had increased maximum light-saturated rate of net CO₂ uptake (A(max)) at the elevated growth CO₂ level, due to higher intercellular CO₂ concentration (c(i)). Leaf nitrogen concentration was central to photosynthetic performance, correlating with A(max), V-c, V-max and J(max). V-c, V-max and J(max) were linearly cc-correlated, revealing a relatively invariable J(max):V-c, V-max ratio, probably due to N resource optimization between light harvesting (RuBP regeneration) and carboxylation. Leaf total non-structural carbohydrate concentration (primarily starch) increased in high CO₂, and was correlated with the reduction in V-c, V-max and J(max). Apparent feedback control of V-c, V-max and J(max) was thus surprisingly consistent across all species, and may regulate carbon exchange in response to end-product fluctuation. If so, elevated CO₂ may have emulated an excess end-product condition, triggering both V-c, V-max and J(max) down-regulation. In *Leucadendron*, a general physiological mechanism seems to control excess carbohydrate formation, and photosynthetic responsiveness to elevated CO₂, independently of genotype and nutrient concentration. This mechanism may underlie photosynthetic acclimation to source:sink imbalances resulting from such diverse conditions as elevated CO₂, low sink strength, low carbohydrate export, and nutrient limitation.

1998. Isotope discrimination and photosynthesis of vegetation growing in the Bossoleto CO₂ spring. *Chemosphere* 36(4-5):771-776.

The Bossoleto CO₂ spring emits CO₂ which has a stable carbon isotopic ratio ($\delta^{13}\text{C} = -8$ parts per thousand). We determined $\delta^{13}\text{C}$ on leaves of several individual species growing in Bossoleto and in a nearby control site at ambient CO₂. $\delta^{13}\text{C}$ was 6‰ more negative in leaves of species collected from the grassland community of Bossoleto, indicating increased discrimination (Δ) against the heavy carbon isotope. No such changes were found in ruderal species growing in the same spring, suggesting that photosynthetic capacity was much less affected. Δ was substantially increased under elevated CO₂ in leaves of *Quercus pubescens* but not in *Quercus ilex*, which also did not show any increase in non-structural carbohydrates. Gas-exchange measurements made on *Plantago lanceolata*, supported the view that photosynthetic capacity is decreased in plants grown under elevated CO₂ and on poor soils. Miglietta, F., A. Giuntoli, and M. Bindi. 1996. The effect of free air carbon dioxide enrichment (FACE) and soil nitrogen availability on the photosynthetic capacity of wheat. *Photosynthesis Research* 47(3):281-290.

A. simple system for free air carbon dioxide enrichment (FACE) was recently developed and it is here briefly described. Such a MiniFACE system allowed the elevation of CO₂ concentration of small field plots avoiding the occurrence of large spatial and temporal fluctuations. A CO₂ enrichment field experiment was conducted in Italy in the season 1993-1994 with wheat (cv. Super-dwarf Mercia). A randomized experimental design was used with the treatment combination CO₂ x soil N, replicated twice. Gas exchange measurements showed that photosynthetic capacity was significantly decreased in plants exposed to elevated CO₂ and grown under nitrogen deficiency. Photosynthetic acclimation was, in this case, due to the occurrence of reduced rates of rubP saturated and rubP regeneration limited photosynthesis. Gas exchange measurements did not instead reveal any significant effect of elevated CO₂ on the photosynthetic capacity of leaves of plants well fertilized with nitrogen, in spite of a transitory negative effect on rubP regeneration limited photosynthesis that was detected to occur in the central part of a day with high irradiance. It is concluded that the levels of nitrogen fertilization will play a substantial role in modulating CO₂ fertilization effects on growth and yields of wheat crops under the scenario of future climate change.

Miglietta, F., M. Lanini, M. Bindi, and V. Magliulo. 1997. Free air CO₂ enrichment of potato (*Solanum tuberosum*, L.): design and performance of the CO₂-fumigation system. *Global Change Biology* 3(5):417-427.

Free Air CO₂ Enrichment (FACE) systems are used to fumigate unconfined field plots with CO₂. As these installations can treat a sufficiently large area without interfering with natural climatic conditions, they are considered important tools for global change research worldwide. However, there is general consensus that elevated capital costs of existing FACE systems as well as high running costs may prevent their application at the required level of scale. A new and small FACE system that was designed to reduce both capital costs and

CO₂ use, is described in this paper. Due to its intermediate size (8 m diameter) between the smaller Mini-FACE systems that were developed in Italy and the larger systems designed by the Brookhaven National Laboratory in the USA, it was named Mid-FACE. The Mid-FACE was at first developed as a prototype and then used to enrich field grown potato crops in a CO₂ concentration gradient experimental design. Technical details of a Mid-FACE prototype and of the operational set-up are presented in this paper together with performance data in terms of temporal and spatial control of CO₂ concentrations within the experimental area.

Miglietta, F., V. Magliulo, M. Bindi, L. Cerio, F.P. Vaccari, V. Loduca, and A. Peressotti. 1998. Free air CO₂ enrichment of potato (*Solanum tuberosum* L.): development, growth and yield. *Global Change Biology* 4(2):163-172.

A FACE (Free Air CO₂ Enrichment) experiment was carried out on Potato (*Solanum tuberosum* L., cv. Primura) in 1995 in Italy. Three FACE rings were used to fumigate circular field plots of 8 m diameter while two rings were used as controls at ambient CO₂ concentrations. Four CO₂ exposure levels were used in the rings (ambient, 460, 560 and 660 $\mu\text{mol mol}^{-1}$). Phenology and crop development, canopy surface temperature, above-and below- ground biomass were monitored during the growing season. Crop phenology was affected by elevated CO₂, as the date of flowering was progressively anticipated in the 660, 560, 460 $\mu\text{mol mol}^{-1}$ treatments. Crop development was not affected significantly as plant height, leaf area and the number of leaves per plant were the same in the four treatments. Elevated atmospheric CO₂ levels had, instead, a significant effect on the accumulation of total nonstructural carbohydrates (TNC = soluble sugars + starch) in the leaves during a sunny day. Specific leaf area was decreased under elevated CO₂ with a response that paralleled that of TNC concentrations. This reflected the occurrence of a progressive increase of photosynthetic rates and carbon assimilation in plants exposed to increasingly higher levels of atmospheric CO₂. Tuber growth and final tuber yield were also stimulated by rising CO₂ levels. When calculated by regression of tuber yield vs. the imposed levels of CO₂ concentration, yield stimulation was as large as 10% every 100 $\mu\text{mol mol}^{-1}$ increase, which translated into over 40% enhancement in yield under 660 $\mu\text{mol mol}^{-1}$. This was related to a higher number of tubers rather than greater mean tuber mass or size. Leaf senescence was accelerated under elevated CO₂ and a linear relationship was found between atmospheric CO₂ levels and leaf reflectance measured at 0.55 μm wavelength. We conclude that significant CO₂ stimulation of yield has to be expected for potato under future climate scenarios, and that crop phenology will be affected as well.

Miglietta, F., and A. Raschi. 1993. Studying the effect of elevated co₂ in the open in a naturally enriched environment in central Italy. *Vegetatio* 104:391-400.

A gas vents area was recently localized in Central Italy. The gas emitted from the vents is composed by 92% of carbon dioxide and this produces an anomaly in the composition of the atmosphere over an area of about 2 ha. Atmospheric carbon dioxide concentration was measured by means of an infrared gas analyzer and diffusion tubes in several points and for some days within the area. Measurements revealed that the site can be

at least divided into three sub-areas having increasing CO₂ concentration in the air. A preliminary analysis of natural vegetation in the area was conducted by counting stomatal and epidermal cells number and measuring guard cell size on leaves of several oak trees growing both near and far away from the vents. This analysis suggested that elevated CO₂ may have reduced the size of guard cells leaving stomatal density and stomatal index unaltered.

Miglietta, F., A. Raschi, I. Bettarini, R. Resti, and F. Selvi. 1993. Natural CO₂ springs in Italy - a resource for examining long-term response of vegetation to rising atmospheric CO₂ concentrations. *Plant, Cell and Environment* 16(7):873-878.

It is estimated that more than 100 geothermal CO₂ springs exist in central-western Italy. Eight springs were selected in which the atmospheric CO₂ concentrations were consistently observed to be above the current atmospheric average of 354 µmol mol⁻¹. CO₂ concentration measurements at some of the springs are reported. The springs are described, and their major topographic and vegetational features are reported. Preliminary observations made on natural vegetation growing around the gas vents are then illustrated. An azonal pattern of vegetation distribution occurs around every CO₂ spring regardless of soil type and phytoclimatic areas. This is composed of pioneer populations of a Northern Eurasian species (*Agrostis canina* L.) which is often associated with *Scirpus lacustris* L. The potential of these sites for studying the long-term response of vegetation to rising atmospheric CO₂ concentrations is discussed.

Miglietta, F., A. Raschi, R. Resti, and M. Badiani. 1993. Growth and ontomorphogenesis of soybean (*Glycine max* Merrill) in an open, naturally CO₂-enriched environment. *Plant, Cell and Environment* 16(8):909-918.

Springs emitting carbon dioxide are frequent in Central Italy and provide a way of testing the response of plants to CO₂ enrichment under natural conditions. Results of a CO₂ enrichment experiment on soybean at a CO₂ spring (Solfatara) are presented. The experimental site is characterized by significant anomalies in atmospheric CO₂ concentration produced by a large number of vents emitting almost pure CO₂ (93%) plus small amounts of hydrogen sulphide, methane, nitrogen and oxygen. Within the gas vent area, plants were grown at three sub-areas whose mean CO₂ concentrations during daytime were 350, 652 and 2370 µmol mol⁻¹, respectively. Weekly harvests were made to measure biomass growth, leaf area and ontogenetic development. Biomass growth rate and seed yield were enhanced by elevated CO₂. In particular, ontomorphogenetic development was affected by elevated CO₂ with high levels of CO₂ increasing the total number of main stem leaf nodes and the area of the main stem trifoliolate leaves. Biochemical analysis of plant tissue suggested that there was no effect of the small amounts of H₂S on the response to CO₂ enrichment. Non-protein sulphhydryl compounds did not accumulate in leaf tissues and the overall capacity of leaf extracts to oxidize exogenously added NADH was not decreased. The limitations and advantages of experimenting with crop plants at elevated CO₂ in the open and in the proximity of carbon dioxide springs are discussed.

Miglietta, F., M. Tanasescu, and A. Marica. 1995. The expected effects of climate change on wheat development. *Global Change Biology* 1(6):407-415.

Air temperature and the atmospheric concentrations of carbon dioxide are expected to rise. These two factors have a great potential to affect development, growth and yield of crops, including wheat. Rising air temperature may affect wheat development more than rising atmospheric CO₂ as there is not yet evidence that elevated CO₂ concentrations can directly induce changes in wheat development. In winter wheat, temperature has a complex effect on development due to its strong interaction with vernalization and photoperiod. In this paper, potential effects of rising temperature on the development of winter wheat from sowing to heading are considered in the light of this complex controlling mechanism. Data from a large series of field trials made in Romania is analysed at first and, subsequently, the IATA-Wheat Phenology model is used to calculate the impact of air warming on wheat development under different climate change scenarios. Data from the field trials showed very clearly the occurrence of a complex temperature/photoperiod/vernalization interaction for field sown crops and demonstrated that the photoperiodic and vernalization responses have a key role in controlling the duration of the emergence-heading period. Temperature plays, instead, a central role in controlling seed germination and crop emergence as well as leaf initiation and leaf appearance rate. The results of model analysis showed very well that the impact of an even or uneven distribution of warming effects may be very different. In the first case, the model predicted that the duration of the vegetative period was at least partly reduced in some years. In the second case, the model suggested that if warming will be more pronounced in winter than in spring, as predicted for some areas of the world by General Circulation Models, we may expect an increase in the duration of the vegetative phase of growth. On the contrary, in case of a spring warming but unchanged winter temperatures, we may expect a substantial decrease in the duration of the vegetative period.

Mikkelsen, T.N., and H. Ropoulsen. 1994. Exposure of Norway spruce to ozone increases the sensitivity of current year needles to photoinhibition and desiccation. *New Phytologist* 128(1):153-163.

Physiological effects of ozone exposure over three consecutive growing seasons on current year needles of Norway spruce were studied in open-top chambers, during daily fumigation cycles in the summer, and after the termination of ozone fumigation in autumn 1990. The trees were exposed to two levels of ozone: charcoal filtered air and non-filtered air to which 30 nl l⁻¹ of ozone was added in three consecutive years from 1988 to 1990, daily from May to September (8 hours a day). Photosynthesis, stomatal conductance, transpiration and chlorophyll fluorescence were studied on selected days. Significant decreases in net photosynthesis and chlorophyll fluorescence (F_v-F_m) were found during periods with co-occurrence of high ozone concentrations and high light intensities, indicating interactions between effects of ozone and photoinhibition. After termination of fumigation enhanced rates of photosynthesis were seen in the trees which had been exposed to ozone. A significant decrease in F_v-F_m was found for twigs from ozone treated trees when exposed to severe desiccation.

Miller, A., C.H. Tsai, D. Hemphill, M. Endres, S. Rodermel, and M. Spalding. 1997. Elevated CO₂ effects during leaf ontogeny - A new perspective on acclimation. *Plant Physiology* 115(3):1195-1200.

For many plants growth in elevated CO₂ leads to reduced rates of photosynthesis. To examine the role that leaf ontogeny plays in the acclimation response, we monitored photosynthesis and some related parameters at short intervals throughout the ontogenetic development of tobacco (*Nicotiana tabacum* L.) leaves under ambient (350 μ mol L⁻¹) and high (950 μ mol L⁻¹) CO₂ conditions. The pattern of photosynthetic rate over time was similar between the two treatments and consistent with the expected pattern for a typical dicot leaf. However, the photosynthesis pattern in high-CO₂-grown tobacco was shifted temporally to an earlier maximum and subsequent senescent decline. Ribulose-1,5-bisphosphate carboxylase/oxygenase activity appeared to be the main factor regulating photosynthetic rates in both treatments. Therefore, we propose a new model for interpreting the acclimation response. Lowered photosynthetic rates observed during acclimation appear to be the result of a shift in the timing of the normal photosynthetic stages of leaf ontogeny to an earlier onset of the natural decline in photosynthetic rates associated with senescence.

Miller, C., and D.L. Urban. 1999. Forest pattern, fire, and climatic change in the Sierra Nevada. *Ecosystems* 2(1):76-87.

In the Sierra Nevada, distributions of forest tree species are largely controlled by the soil-moisture balance. Changes in temperature or precipitation as a result of increased greenhouse gas concentrations could lead to changes in species distributions. In addition, climatic change could increase the frequency and severity of wildfires. We used a forest gap model developed for Sierra Nevada forests to investigate the potential sensitivity of these forests to climatic change, including a changing fire regime. Fuel moisture influences the fire regime and couples fire to climate. Fires are also affected by fuel loads, which accumulate according to forest structure and composition. These model features were used to investigate the complex interactions between climate, fire, and forest dynamics. Eight hypothetical climate-change scenarios were simulated, including two general circulation model (GCM) predictions of a 2 x CO₂ world. The response of forest structure, species composition, and the fire regime to these changes in the climate were examined at four sites across an elevation gradient. Impacts on woody biomass and species composition as a result of climatic change were site specific and depended on the environmental constraints of a site and the environmental tolerances of the tree species simulated. Climatic change altered the fire regime both directly and indirectly. Fire frequency responded directly to climate's influence on fuel moisture, whereas fire extent was affected by changes that occurred in either woody biomass or species composition. The influence of species composition on fuel-bed bulk density was particularly important. Future fires in the Sierra Nevada could be both more frequent and of greater spatial extent if GCM predictions prove true.

Miller, J.B., D. Yakir, J.W.C. White, and P.P. Tans. 1999. Measurement of O-18/O-16 in the soil-atmosphere CO₂ flux. *Global Biogeochemical Cycles* 13(3):761-774.

Measurements of O-18 in atmospheric CO₂ can be used to trace gross photosynthetic and respiratory CO₂ fluxes between the atmosphere and the terrestrial biosphere. However, this requires knowledge of the O-18 signatures attributable to the fluxes from soil and leaves. Newly developed methods were employed to measure the O-18 of soil-respired CO₂ and depth profiles of near-surface soil CO₂ in order to evaluate the factors influencing isotopic soil-atmosphere CO₂ exchange. The O-18 soil-respired CO₂ varied predominantly as a function of the O-18 of soil water which, in turn, changed with soil drying and with seasonal variations in source water. The O-18 of soil-respired CO₂ corresponds to full isotopic equilibrium with soil water at a depth ranging between 5 and 15 cm. The O-18 of respired CO₂, in reality, results from a weighted average of partial equilibria over a range of depths. Soil water isotopic enrichment of up to 10 parts per thousand in the top 5 cm did not appear to strongly influence the isotopic composition of the respired CO₂. We demonstrate that during measurements "invasion" of atmospheric CO₂ (the diffusion of ambient CO₂ into the soil, followed by partial equilibration and retrodiffusion) must be considered to accurately calculate the O-18 of the soil-respired CO₂. The impact of invasion in natural settings is also considered. We also have determined the effective kinetic fractionation of CO₂ diffusion out of the soil to be 7.2 $\pm$ 0.3 parts per thousand. High-resolution (1 cm) depth profiles of O-18 of near-surface (top 10 cm) soil CO₂ were carried out by gas chromatography-isotope ratio mass spectrometry (IRMS). This novel technique allowed us to observe the competitive diffusion-equilibration process near the soil surface and to test simulations by a diffusion and equilibration model of the soil CO₂ O-18 content.

Miller, J.E., A.S. Heagle, and W.A. Pursley. 1998. Influence of ozone stress on soybean response to carbon dioxide enrichment: II. Biomass and development. *Crop Science* 38(1):122-128.

Previous research has shown that elevated CO₂ concentrations can increase plant growth, whereas the air pollutant O-3 is phytotoxic. Because elevated concentrations of these gases will co-occur, the objective of our experiment was to determine if estimates of plant growth response to future levels of CO₂ and O-3 require experiments to test the gases in combination. Soybean plants [*Glycine max* (L.) Merr. cv. Essex] were exposed in open-top chambers to combinations of O-3 and CO₂ from plant emergence through physiological maturity. Ozone treatments were charcoal-filtered air (CF), nonfiltered air (NF), and NF with O-3 added for 12 h d⁻¹ (NF+) (seasonal mean 12 h d⁻¹ O-3 concentrations of 20, 50, or 79 nL L⁻¹, respectively). Carbon dioxide exposures were for 24 h d⁻¹ giving seasonal mean 12 h d⁻¹ concentrations of 370, 482, 599, or 713 μ mol L⁻¹. Over the season, elevated CO₂ usually stimulated growth and O-3 suppressed growth. Elevated CO₂ usually increased partitioning of biomass to branches, decreased partitioning to pods, increased specific leaf weight, and decreased leaf area ratio. Ozone suppressed leaf and root weight ratios, increased pod weight ratios, and decreased specific leaf weight. Toward the end of the season, both O-3 and CO₂ accelerated reproductive development. Elevated CO₂ moderated suppression of growth by O-3, and the highest CO₂ concentration completely ameliorated O-3 effects on main stem biomass, root biomass, and leaf area. Ozone, however, limited some positive growth responses to CO₂, especially at less than a doubling of CO₂ concentrations. These results indicate that in order to understand the future impacts of atmospheric gases such as elevated CO₂ and O-3 on crop growth, their combined effects should be

determined.

Mishra, R.S., M.Z. Abidin, and D.C. Uprety. 1999. Interactive effects of elevated CO₂ and moisture stress on the photosynthesis, water relation and growth of Brassica species. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 182(4):223-229.

Interactive effects of elevated CO₂ and moisture stress on photosynthesis, growth and water relation of Brassica species were studied using open top chamber technology. Brassica species responded to the elevated CO₂ significantly under moisture stress condition. The adverse effect of moisture stress on the photosynthesis and plant water components were minimized by elevated levels of CO₂. Drought susceptible species of *B. campestris* and *B. nigra* responded better to elevated CO₂ compared to drought tolerant Brassica species such as *B. carinata* and *B. juncea*. The plant water potential significantly improved by elevated CO₂ coupled with higher stomatal resistance and root growth.

Mitchell, C.A., C.H. Chun, W.E. Brandt, and S.S. Nielsen. 1997. Environmental modification of yield and nutrient composition of 'Waldmann's Green' leaf lettuce. *Journal of Food Quality* 20(1):73-80.

Leaf number, dry weight, and nutrient composition of *Lactuca sativa* L. cv. 'Waldmann's Green' leaves were compared following 9 days of treatment in a controlled environment room under various combinations of photosynthetic photon flux (PPF: 350 vs 800 $\mu\text{mol m}^{-2} \text{s}^{-1}$), atmospheric CO₂ level (ambient vs 1500 $\mu\text{mol mol}^{-1}$), and single-strength (1X: 15 mM) vs double-strength (2X: 30 mM) nitrogen (N) as NO₃⁻ alone or as NH₄⁺ + NO₃⁻ (1:5 molar ratio). CO₂ enrichment greatly enhanced leaf number under all PPF and N conditions, but increased leaf dry weight only at high PPF. Conditions favoring high photosynthesis enhanced leaf starch content 3-fold, and protein content increased as much as 64% with 2X NH₄⁺+NO₃⁻. Free sugar content was 6 to 9% of leaf dry weight for all treatment combinations, while fat was 1.5 to 3.5%. Ash content varied from 15 to 20% of leaf dry weight. Modified controlled environments can be used to enhance the nutritional content as well as the yield of crops to be used for life support in space-deployed, self-sustaining human habitats. Leaf lettuce is a useful model crop for demonstrating the potential of nutritional value added by environmental manipulation.

Mitchell, J.F.B. 1990. Greenhouse warming - is the midholocene a good analog. *Journal of Climate* 3(11):1177-1192.

The mid-Holocene period (from approximately 9000 to 6000 years before present) is often suggested as an analogue for enhanced greenhouse warming. The changes in net radiative forcing at the top of atmosphere are very different; increases in greenhouse gases producing a small annual mean warming of little seasonal or latitudinal variation, whereas during the Holocene the annual mean did not change but there were large seasonal and latitudinal variations. Two climate model experiments, one in which CO₂ amounts are doubled and the other in which the value of the earth's orbital parameters are altered to those

appropriate to 9000 years before present (BP), are compared. Any similarity in the simulated response is found to be limited to the northern continents and, even there, the mechanisms producing the changes differ between the two experiments. Assuming that the gross behavior of the model is realistic, the Holocene is not a good analogue for a "greenhouse" warming. Furthermore, as the mechanisms operating in the two experiments are different, a model which produces a realistic simulation for the mid-Holocene and present climate need not necessarily produce a reliable simulation of greenhouse warming. However, a comparison of simulated climates for the mid-Holocene and that reconstructed from paleoclimatic data may help to constrain the existing range of subgrid-scale parametrizations used in climate models.

Mitchell, K.A., P.V. Bolstad, and J.M. Vose. 1999. Interspecific and environmentally induced variation in foliar dark respiration among eighteen southeastern deciduous tree species. *Tree Physiology* 19(13):861-870.

We measured variations in leaf dark respiration rate (R_d) and leaf nitrogen (N) across species, canopy light environment, and elevation for 18 co-occurring deciduous hardwood species in the southern Appalachian mountains of western North Carolina. Our overall objective was to estimate leaf respiration rates under typical conditions and to determine how they varied within and among species. Mean dark respiration rate at 20 degrees C (R_d-mass, $\mu\text{mol CO}_2 (\text{kg leaf dry mass})^{-1} \text{s}^{-1}$) for all 18 species was 7.31 $\mu\text{mol kg}^{-1} \text{s}^{-1}$. Mean R_d-mass of individual species varied from 5.17 $\mu\text{mol kg}^{-1} \text{s}^{-1}$ for *Quercus coccinea* Muenchh. to 8.25 $\mu\text{mol kg}^{-1} \text{s}^{-1}$ for *Liriodendron tulipifera* L. Dark respiration rate varied by leaf canopy position and was higher in leaves collected from high-light environments. When expressed on an area basis, dark respiration rate (R_d-area, $\mu\text{mol CO}_2 (\text{kg leaf dry area})^{-1} \text{s}^{-1}$) showed a strong linear relationship with the predictor variables leaf nitrogen (N-area, g N (m leaf area)⁻²) and leaf structure (LMA, g leaf dry mass (m leaf area)⁻²) ($r^2 = 0.62$). This covariance was largely a result of changes in leaf structure with canopy position; smaller thicker leaves occur at upper canopy positions in high-light environments. Mass-based expression of leaf nitrogen and dark respiration rate showed that nitrogen concentration (N-mass, mg N (g leaf dry mass)⁻¹) was only moderately predictive of variation in R_d-mass for all leaves pooled ($r^2 = 0.11$), within species, or among species. We found distinct elevational trends, with both R_d-mass and N-mass higher in trees originating from high-elevation, cooler growth environments. Consideration of interspecies differences, vertical gradients in canopy light environment, and elevation, may improve our ability to scale leaf respiration to the canopy in forest process models.

Mitchell, R.A.C., C.R. Black, S. Burkart, J.I. Burke, A. Donnelly, L. de Temmerman, A. Fangmeier, B.J. Mulholland, J.C. Theobald, and M. van Oijen. 1999. Photosynthetic responses in spring wheat grown under elevated CO₂ concentrations and stress conditions in the European, multiple-site experiment 'ESPACE-wheat'. *European Journal of Agronomy* 10(3-4):205-214.

Spring wheat cv. Minaret crop stands were grown under ambient and elevated CO₂ concentrations at seven sites in Germany, Ireland, the UK, Belgium and the Netherlands. Six of the sites used open-top chambers and one used a controlled environment mimicking field conditions. The

effect of elevated CO₂ for a range of N application regimes, O-3 concentrations, and growth temperatures on flag leaf photosynthesis was studied. Before anthesis, flag leaf photosynthesis was stimulated about 50% by 650 compared with 350 $\mu\text{mol mol}^{-1}$ CO₂ at all sites, regardless of other treatments. Furthermore, there was no evidence of a decrease in photosynthetic capacity of flag leaves due to growth at elevated CO₂ before anthesis, even for low N treatments. However, photosynthetic capacity, particularly carboxylation capacity, of flag leaves was usually decreased by growth at elevated CO₂ after anthesis, especially in low N treatments. Acclimation of photosynthesis to elevated CO₂ therefore appears to occur only slowly, consistent with a response to changes in sink-source relationships, rather than a direct response. Effect of elevated CO₂ on stomatal conductance was much more variable between sites and treatments, but on average was decreased by similar to 10% at 650 compared with 350 $\mu\text{mol mol}^{-1}$ CO₂. Carboxylation capacity of flag leaves was decreased by growth at elevated O-3 both before and after anthesis, regardless of CO₂ concentration. (C) 1999 Elsevier Science B.V. All rights reserved.

Mitchell, R.A.C., C.L. Gibbard, V.J. Mitchell, and D.W. Lawlor. 1996. Effects of shading in different developmental phases on biomass and grain yield of winter wheat at ambient and elevated CO₂. *Plant, Cell and Environment* 19(5):615-621.

Winter wheat (*Triticum aestivum* cv. Mercia) was grown in a controlled-environment facility under simulated field conditions at ambient (360 $\mu\text{mol mol}^{-1}$) and elevated (690 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. Some of the plants were shaded to mimic cloudy conditions during three periods of about 20 d duration between terminal spikelet and start of grain-fill, giving 16 treatments in all. Elevated CO₂ increased grain yield by about 20%, while shading in any period decreased yield, with the greatest effect in the last period, encompassing anthesis. No interactions between these effects were significant for grain yield, but there were complex interactions for mean grain size. Observed effects of shading and elevated CO₂ on biomass production were well predicted by a simulation model. Observed effects of treatments on yield could be related to effects on biomass using a simple model which assumes that yield is proportional to biomass production, with coefficients of 0.42 (g grain yield g⁻¹ biomass) for the first two periods and 0.74 for the last period. Wheat models should therefore include developmental changes in sensitivity of yield to biomass production, but biomass changes induced by different CO₂ concentrations or light environments can be treated as having equivalent effects on grain yield.

Mitchell, R.A.C., D.W. Lawlor, V.J. Mitchell, C.L. Gibbard, E.M. White, and J.R. Porter. 1995. Effects of elevated CO₂ concentration and increased temperature on winter-wheat - test of arcwheat1 simulation-model. *Plant, Cell and Environment* 18(7):736-748.

Winter wheat (*Triticum aestivum* L., cv. Mercia) was grown in a controlled-environment facility at two CO₂ concentrations (targets 350 and 700 $\mu\text{mol mol}^{-1}$), and two temperature regimes (tracking ambient and ambient + 4 degrees C). Observations of phenology, canopy growth, dry matter production and grain yield were used to test the ARCWHEAT1 simulation model. Dry-matter production and grain yield were increased at elevated CO₂ concentration (27 and 39%, respectively) and reduced at increased temperature (-16 and -35%, respectively). ARCWHEAT1 substantially underestimated canopy

growth for all treatments. However, differences in the facility environment from field conditions over the winter, indicated by the unusually rapid canopy growth observed in this period, meant that empirical model relationships were being used outside the conditions for which they were developed. The ARCWHEAT1 productivity submodel, given observed green area indices as inputs, overestimated the effect of CO₂ on productivity. An alternative, more mechanistic submodel of productivity, based on the SUCROS87 and Farquhar and von Caemmerer models, simulated observed crop biomass very closely. When these productivity simulations were inputted into the ARCWHEAT1 partitioning and grain-fill submodels, grain yield was predicted poorly, mainly as a result of the assumption that the number of grains is proportional to total growth during a short preanthesis phase. While yield was not correlated with growth in this phase, it was correlated with growth in longer preanthesis phases, indicating that ARCWHEAT1 could be improved by taking into account the contribution of earlier growth in determining yield.

Mitchell, R.A.C., V.J. Mitchell, S.P. Driscoll, J. Franklin, and D.W. Lawlor. 1993. Effects of increased CO₂ concentration and temperature on growth and yield of winter-wheat at 2 levels of nitrogen application. *Plant, Cell and Environment* 16(5):521-529.

Winter wheat (*Triticum aestivum* L., cv. Mercia) was grown in chambers under light and temperature conditions similar to the UK field environment for the 1990/1991 growing season at two levels each of atmospheric CO₂ concentration (seasonal means: 361 and 692 $\mu\text{mol mol}^{-1}$), temperature (tracking ambient and ambient +4-degrees-C) and nitrogen application (equivalent to 87 and 489 kg ha⁻¹ total N applied). Total dry matter productivity through the season, the maximum number of shoots and final ear number were stimulated by CO₂ enrichment at both levels of the temperature and N treatments. At high N, there was a CO₂-induced stimulation of grain yield (+15%) similar to that for total crop dry mass (+12%), and there was no significant interaction with temperature. This contrasts with other studies, where positive interactions between the effects of increases in temperature and CO₂ have been found. Temperature had a direct, negative effect on yield at both levels of the N and CO₂ treatments. This could be explained by the temperature-dependent shortening of the phenological stages, and therefore, the time available for accumulating resources for grain formation. At high N, there was also a reduction in grain set at ambient +4-degrees-C temperature, but the overall negative effect of warmer temperature was greater on the number of grains (-37%) than on yield (-18%), due to a compensating increase in average grain mass. At low N, despite increasing total crop dry mass and the number of ears, elevated CO₂ did not increase grain yield and caused a significant decrease under ambient temperature conditions. This can be explained in terms of a stimulation of early vegetative growth by CO₂ enrichment leading to a reduction in the amount of N available later for the formation and filling of grain.

Mitchell, R.J., G.B. Runion, S.A. Prior, H.H. Rogers, J.S. Amthor, and F.P. Henning. 1995. Effects of nitrogen on pinus-palustris foliar respiratory responses to elevated atmospheric CO₂ concentration. *Journal of Experimental Botany* 46(291):1561-1567.

Indirect effects of atmospheric CO₂ concentration [CO₂], on longleaf pine (*Pinus palustris* Mill.) foliage respiration were studied by growing trees in a factorial arrangement of low and high [CO₂] (369 and 729 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) and low and high N (40 and 400 kg ha⁻¹ yr⁻¹). Direct effects of [CO₂] on leaf respiration were tested by measuring respiration rates of foliage from all treatments at two CO₂ levels (360 and 720 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) at the time of measurement. Elevated CO₂ did not directly or indirectly affect leaf respiration when expressed on a leaf area or mass basis, but a significant increase in respiration per unit leaf N was observed in trees grown in elevated [CO₂] (indirect response to elevated [CO₂]). The lack of a [CO₂] effect on respiration, when analysed on an area or mass basis, may have resulted from combined effects of [CO₂] on factors that increase respiration (e.g. greater availability of non-structural carbohydrates stimulating growth and carbon export from leaves) and on factors that decrease respiration (e.g. lower N concentration leading to lower construction costs and maintenance requirements). Thus, [CO₂] affected factors that influence respiration, but in opposing ways.

Mitra, A., P.S. Bhattacharya, S. Dey, S.K. Sawarkar, and B.C. Bhattacharyya. 1998. Photoautotrophic in vitro culture of Chrysanthemum under CO₂ enrichment. *Biotechnology Techniques* 12(4):335-337.

Photoautotrophic culture of Chrysanthemum was established under CO₂ enrichment (2% v/v). The shoot length and number of leaves were almost equal (2.7 cm and 14 respectively) both under photoautotrophic and photomixotrophic cultures, recorded after four weeks of incubation. Similarly, average dry mass of the plantlets were comparable (31 and 28 mg respectively) under both conditions. The number of branches and internode length which influence the number of propagule potential for mass propagation, were also identical. Nevertheless, photoautotrophic cultivation minimized the risk of contamination in cultures, which in turn will reduce the production cost.

Mitra, A., S. Dey, and S.K. Sawarkar. 1998. Photoautotrophic in vitro multiplication of the orchid *Dendrobium* under CO₂ enrichment. *Biologia Plantarum* 41(1):145-148.

An attempt to reduce the production cost on tissue cultured plants, photoautotrophic culture of a high value orchid *Dendrobium* was established under CO₂-enriched conditions. The shoot length and the number of leaves were almost equal in plantlets grown on medium with 2 % sucrose or without sucrose and under normal or enhanced (40 g m⁻³) CO₂ concentration, whereas the fresh and dry masses were higher in cultures grown in sucrose containing media or under CO₂ enrichment. Development of roots was observed only on media without sucrose, but CO₂ enrichment did not have significant effects on in vitro rootings.

Mitsuda, H. 1999. Toward solutions for food crisis in the 21st century - From basic research to development of innovative food technologies. *Proceedings of the Japan Academy Series B-Physical and Biological Sciences* 75(8):246-253.

The population explosion in the 21st century will have a severe impact on the problems associated with food supply and the environment. Even at present, the shortage of food protein resources is an acute problem. Effective countermeasures to cope with the ever worsening shortage of protein resources in the next century are absolutely essential. We have developed methods to produce and isolate single cell proteins in an ample yield. We have also found that among food grains rice has the highest protein content, and have found that the protein in the grain is present in discrete particles, for which we coined the name "protein bodies". Rice protein has a relatively good balance of essential amino acids, and hence a relatively high nutritional value. We were able to increase the nutritional value further by fortifying it with L-lysine by a novel soaking method. New methods of food preservation will be important to cope with the 21st century food problems, because a large amount of food is lost either on the farm or during storage, to microorganisms, rodents and insects. We developed the carbon dioxide exchange method (CEM), in which food is stored under CO₂ in hermetically sealed containers (called Hibernation Rice), CO₂ is reversibly adsorbed to, and desorbed from the amino groups of food proteins. We also developed underwater and underground food storage methods earlier (1967-72), to take advantage of constant low temperatures in these conditions. Based on these studies, large scale storage methods in 200 kg steel drums in CO₂ have been developed on an industrial scale which is operated on a commercial base. Methylbromide destroys the ozone layer, and will be banned completely from use for food presentation or any other purposes. Storage under CO₂ is far superior to methylbromide because CO₂ completely eliminates the rice weevil and other insects, has no toxicity or public health problems, and is economical. CO₂ is a very effective synergist when used with the pasteurization gas, ozone, to sterilize foods against the virulent pathogenic strain of *E.coli*, O-157 and black pepper which are known to be contaminated with bacteria. The use of CO₂ may add to an already high production of CO₂ from other sources, such as combustion of fossil fuels. Effective measures to prevent leakage of CO₂ are needed. We are striving for an innovative idea to pre-vent the escape of CO₂ and the consequential warming of the earth.

Miyachi, S., J. Burger, K. Kotzabasis, J. Thielmann, and H. Senger. 1996. Photosynthetic characteristics of three strains of cyanobacteria grown under low- or high-CO₂ conditions. *Zeitschrift Fur Naturforschung C-A Journal of Biosciences* 51(1-2):40-46.

Quantum requirements of photosynthetic oxygen evolution at 679 nm, fluorescence emission spectra at liquid nitrogen temperature (77 K) and fluorescence induction kinetics in the presence of DCMU, were measured in the cyanobacteria *Anabaena variabilis* M3, *Anabaena variabilis* ATCC 29413 and *Anacystis nidulans* R2, each grown under low- or high-CO₂ conditions. Low- CO₂ grown cells of the cyanobacteria showed a higher quantum requirement of photosynthetic oxygen evolution and a higher ratio of F-710-740 to F-680-700 fluorescence and a lower variable fluorescence in the presence of DCMU than high-CO₂ grown cells. These findings indicate a change in excitation energy distribution in favour of photosystem I. The result might be an enhancement in ATP formation caused by cyclic electron flow which in turn provokes dissolved inorganic carbon (DIG) accumulation in these low-CO₂ grown cells.

Miyashita, Y., Y. Kitaya, C. Kubota, and T. Kozai. 1996.

Photoautotrophic growth of potato plantlets as affected by explant leaf area, fresh weight and stem length. *Scientia Horticulturae* 65(2-3):199-202.

Photoautotrophic growth in vitro of potato (*Solanum tuberosum* L. cv. Benimaru) explants varied with their initial leaf area and stem length. Photoautotrophic growth was much greater in leafy than in leafless explants. Variability in photoautotrophic growth was smallest in the explants with the greatest leaf area. The results indicated that use of explants with a large leaf area is important to maximize photoautotrophic growth and to minimize variation in photoautotrophic growth of explants in vitro.

Mjwara, J.M., C.E.J. Botha, and S.E. Radloff. 1996. Photosynthesis, growth and nutrient changes in non-nodulated *Phaseolus vulgaris* grown under atmospheric and elevated carbon dioxide conditions. *Physiologia Plantarum* 97(4):754-763.

The response of *Phaseolus vulgaris* L. cv. Contender grown under controlled environment at either ambient or elevated (360 and 700 $\mu\text{mol mol}^{-1}$, respectively) CO_2 concentrations ($[\text{CO}_2]$), was monitored from 10 days after germination (DAG) until the onset of senescence. Elevated CO_2 had a pronounced effect on total plant height (TPH), leaf area (LA), leaf dry weight (LD), total plant biomass (TB) accumulation and specific leaf area (SLA). All of these were significantly increased under elevated carbon dioxide with the exception of SLA which was significantly reduced. Other than high initial growth rates in CO_2 -enriched plants, relative growth rates remained relatively unchanged throughout the growth period. While the trends in growth parameters were clearly different between $[\text{CO}_2]$, some physiological processes were largely transient, in particular, net assimilation rate (NAR) and foliar nutrient concentrations of N, Mg and Cu. CO_2 enrichment significantly increased NAR, but from 20 DAG, a steady decline to almost similar levels to those measured in plants grown under ambient CO_2 occurred. A similar trend was observed for leaf N content where the loss of leaf nitrogen in CO_2 -enriched plants after 20 DAG, was significantly greater than that observed for ambient- CO_2 plants. Under enhanced CO_2 , the foliar concentrations of K and Mn were increased significantly whilst P, Ca, Fe and Zn were reduced significantly. Changes in Mg and Cu concentrations were insignificant. In addition, high CO_2 grown plants exhibited a pronounced leaf discoloration or chlorosis, coupled with a significant reduction in leaf longevity.

Mo, G., D. Nie, M.B. Kirkham, H. He, L.K. Ballou, F.W. Caldwell, and E.T. Kanemasu. 1992. Root and shoot weight in a tallgrass prairie under elevated carbon-dioxide. *Environmental and Experimental Botany* 32(3):193-201.

The atmospheric concentration of carbon dioxide (CO_2) is increasing and knowing how this will affect native vegetation is important. The objective of this study was to determine the effect of elevated CO_2 on root growth in a tallgrass prairie kept at a high water level (73 cm of water in a 200 cm soil profile) and a low water level (66 cm of water in 200 cm). Sixteen cylindrical plastic chambers were placed on the prairie to maintain two levels of CO_2 (ambient or twice ambient). At the end of two seasons' exposure to the different treatments, dry weight and length of roots in the 0-40 cm depth were determined. Shoot growth also was measured to determine shoot: root ratios. The CO_2 and water treatments had no significant effect on root dry weight in the 0-40 cm depth. In the

0-10 cm depth, doubled CO_2 reduced dry weight and length of roots of plants grown under the high water level by 47 and 31 %, respectively. Warm-season, C4 grasses had the highest shoot dry weight, which was greatest under the high water, ambient CO_2 treatment. The shoot: root ratio did not change with treatment.

Mohanraju, R., B.S. Rajagopal, and L. Daniels. 1997. Isolation and characterization of a methanogenic bacterium from mangrove sediments. *Journal of Marine Biotechnology* 5(2-3):147-152.

A methanogenic bacterium was enriched with trimethylamine and isolated from mangrove sediments. The isolate was a non-spore-forming regular to slightly irregular coccus (0.4-1 mm in diameter). The isolate required sodium chloride for growth with maximal methanogenesis at 420 mM NaCl at 30 degrees C. The optimal growth temperature was 30-35 degrees C with maximal methane production at 30 degrees C. The maximum growth rate was between pH 6.6 and 7.2 with maximum methane production at pH 6.8. The growth requirement of sulfide was 10-15 mM with maximum methane production at 10 mM at 30 degrees C. Mono-, di-, and trimethylamine or methanol were substrates for the methanogen; sodium acetate and H-2: CO_2 were not. The DNA base content is consistent with the type descriptions of Methanococoides methylutens, a methylotrophic methanogen isolated from submarine sediments. The isolate was found to utilize methylamines that are found in mangroves without having to compete with sulfate-reducing bacteria for H-2.

Monje, O., and B. Bugbee. 1998. Adaptation to high CO_2 concentration in an optimal environment: radiation capture, canopy quantum yield and carbon use efficiency. *Plant, Cell and Environment* 21(3):315-324.

The effect of elevated $[\text{CO}_2]$ on wheat (*Triticum aestivum* L, Veery 10) productivity was examined by analysing radiation capture, canopy quantum yield, canopy carbon use efficiency, harvest index and daily C gain. Canopies were grown at either 330 or 1200 $\mu\text{mol mol}^{-1}$ $[\text{CO}_2]$ in controlled environments, where root and shoot C fluxes were monitored continuously from emergence to harvest. A rapidly circulating hydroponic solution supplied nutrients, water and root zone oxygen. At harvest, dry mass predicted from gas exchange data was 102.8 $\pm$ 4.7% of the observed dry mass in six trials. Neither radiation capture efficiency nor carbon use efficiency were affected by elevated $[\text{CO}_2]$, but yield increased by 13% due to a sustained increase in canopy quantum yield. CO_2 enrichment increased root mass, tiller number and seed mass. Harvest index and chlorophyll concentration were unchanged, but CO_2 enrichment increased average life cycle net photosynthesis (13%, $P < 0.05$) and root respiration (24%, $P < 0.05$). These data indicate that plant communities adapt to CO_2 enrichment through changes in C allocation. Elevated $[\text{CO}_2]$ increases sink strength in optimal environments, resulting in sustained increases in photosynthetic capacity, canopy quantum yield and daily C gain

throughout the life cycle.

Monz, C.A., H.W. Hunt, F.B. Reeves, and E.T. Elliott. 1994. The response of mycorrhizal colonization to elevated CO₂ and climate-change in *Paspalum-smithii* and *Bouteloua-gracilis*. *Plant and Soil* 165(1):75-80.

Large intact soil cores of nearly pure stands of *Paspalum smithii* (western wheatgrass, C-3) and *Bouteloua gracilis* (blue grama, C-4) were extracted from the Central Plains Experimental Range in northeastern Colorado, USA and transferred to controlled environment chambers. Cores were exposed to a variety of water, temperature and CO₂ regimes for a total of four annual growth cycles. Root subsamples were harvested after the completion of the second and fourth growth cycles at a time corresponding to late winter, and were examined microscopically for the presence of mycorrhizae. After two growth cycles in the growth chambers, 54% of the root length was colonized in *P. smithii*, compared to 35% in blue grama. Field control plants had significantly lower colonization. Elevation of CO₂ increased mycorrhizal colonization in *B. gracilis* by 46% but had no effect in *P. smithii*. Temperatures 4 degrees C higher than normal decreased colonization in *P. smithii* by 15%. Increased annual precipitation decreased colonization in both species. Simulated climate change conditions of elevated CO₂, elevated temperature and lowered precipitation decreased colonization in *P. smithii* but had less effect on *B. gracilis*. After four growth cycles in *P. smithii*, trends of treatments remained similar, but overall colonization rate decreased.

Mooney, H.A. 1991. Biological response to climate change - an agenda for research. *Ecological Applications* 1(2):112-117.

Our knowledge of the structure and functioning of terrestrial ecosystems on a global scale is not developed to a sufficient degree to understand - much less predict - the consequences of climate change either on the systems themselves or on subsequent atmospheric interactions. In many regards we have lagged behind the atmospheric scientists, and to a certain degree the oceanographers, in establishing a global understanding of the dynamics of our respective systems. This is due in part to the inherently greater complexity of biotic systems, but also to the lack of appropriate tools to measure regional biotic processes. These tools are now becoming available and with them a better understanding of terrestrial and atmospheric interactions. Even as these capabilities become a reality we must be realistic in recognizing that we have so far to go along the road to understanding that useful predictive capacity may elude us for a long time to come. What we now need to do is act on the recommendations that have been emerging over the past few years and develop a global program to document more precisely the distribution, structure, and quantity of the earth's biotic systems, their principal functional properties, and - most difficult of all - their changing nature. In order to do this we will have to: (1) perfect some of the emerging new tools for assessing these properties, (2) fill some of the gaps in our knowledge about the relevant processes, and (3) establish an international network of long-term observations and large-scale ecosystem manipulations. We have been aware of these needs and shortcomings for some time and we must move from plans to concerted international action.

Mooney, H.A., and G.W. Koch. 1994. The impact of rising CO₂ concentrations on the terrestrial biosphere. *Ambio* 23(1):74-76.

Large advances have been made in linking terrestrial biospheric and atmospheric processes in real time. Further, it is now possible to model the potential response of the Earth's primary productivity to the changing climate and to changes in atmospheric CO₂ concentration. We still have limited information, however, on the total responses of ecosystems to enhanced CO₂ because of the complex web of possible interactions. What is needed are experiments on whole ecosystems under enhanced CO₂ in which all of the potential interactions and feedbacks can be monitored, including plant-microbe, plant-herbivore, and plant-atmosphere interactions. A global network of experiments in the major biomes of the world is being developed within the International Geosphere-Biosphere Programme (IGBP) to resolve questions related to the implications of a changed pattern of biomass distribution in the biosphere.

Moore, B.D., S.H. Cheng, J. Rice, and J.R. Seemann. 1998. Sucrose cycling, Rubisco expression, and prediction of photosynthetic acclimation to elevated atmospheric CO₂. *Plant, Cell and Environment* 21(9):905-915.

Photosynthetic acclimation to elevated CO₂ cannot presently be predicted due to our limited understanding of the molecular mechanisms and metabolic signals that regulate photosynthetic gene expression. We have examined acclimation by comparing changes in the leaf content of RuBP carboxylase/oxygenase (Rubisco) with changes in the transcripts of Rubisco subunit genes and with leaf carbohydrate metabolism. When grown at 1000 mm(3) dm(-3) CO₂, 12 of 16 crop species at peak vegetative growth had a 15-44% decrease in leaf Rubisco protein, but with no specific association with changes in transcript levels measured at midday. Species with only modest reductions in Rubisco content (10-20%) often had a large reduction in Rubisco small subunit gene mRNAs (> 30%), with no reduction in large subunit gene mRNAs. However, species with a very large reduction in Rubisco content generally had only small reductions in transcript mRNAs. Photosynthetic acclimation also was not specifically associated with a change in the level of any particular carbohydrate measured at midday. However, a threshold relationship was found between the reduction in Rubisco content at high CO₂ and absolute levels of soluble acid invertase activity measured in plants grown at ambient or high CO₂. This relationship was valid for 15 of the 16 species examined. There also occurred a similar, albeit less robust, threshold relationship between the leaf hexose/sucrose ratio at high CO₂ and a reduced photosynthetic capacity greater than or equal to 20%. These data indicate that carbohydrate repression of photosynthetic gene expression at elevated CO₂ may involve leaf

sucrose cycling through acid invertase and hexokinase.

Moore, B.D., D.E. Palmquist, and J.R. Seemann. 1997. Influence of plant growth at high CO₂ concentrations on leaf content of ribulose-1,5-bisphosphate carboxylase/oxygenase and intracellular distribution of soluble carbohydrates in tobacco, snapdragon, and parsley. *Plant Physiology* 115(1):241-248.

We have examined the possible role of leaf cytosolic hexoses and the expression of mannitol metabolism as mechanisms that may affect the repression of photosynthetic capacity when plants are grown at 1000 versus 380 $\mu\text{L L}^{-1}$ CO₂. In plants grown at high CO₂, leaf ribulose-1,5-bisphosphate carboxylase/oxygenase content declined by greater than or equal to 20% in tobacco (*Nicotiana sylvestris*) but was not affected in the mannitol-producing species snapdragon (*Antirrhinum majus*) and parsley (*Petroselinum hortense*). In the three species mesophyll glucose and fructose at midday occurred almost entirely in the vacuole (>99%), irrespective of growth CO₂ levels. The estimated cytosolic concentrations of glucose and fructose were less than or equal to 100 μM . In the three species grown at high CO₂, total leaf carbohydrates increased 60 to 100%, but mannitol metabolism did not function as an overflow mechanism for the increased accumulation of carbohydrate. In both snapdragon and parsley grown at ambient or high CO₂, mannitol occurred in the chloroplast and cytosol at estimated midday concentrations of 0.1 M or more each. The compartmentation of leaf hexoses and the metabolism of alternate carbohydrates are further considered in relation to photosynthetic acclimation to high levels of CO₂.

Moore, T.R., N.T. Roulet, and J.M. Waddington. 1998. Uncertainty in predicting the effect of climatic change on the carbon cycling of Canadian peatlands. *Climatic Change* 40(2):229-245.

Northern peatlands play an important role globally in the cycling of C, through the exchange of CO₂ with the atmosphere, the emission of CH₄, the production and export of dissolved organic carbon (DOC) and the storage of C. Under 2 x CO₂ GCM scenarios, most Canadian peatlands will be exposed to increases in mean annual temperature ranging between 2 and 6 degrees C and increases in mean annual precipitation of 0 to 15 %, with the most pronounced changes occurring during the winter. The increase in CO₂ uptake by plants, through warmer temperatures and elevated atmospheric CO₂, is likely to be offset by increased soil respiration rates in response to warmer soils and lowered water tables. CH₄ emissions are likely to decrease in most peatlands because of lowered water tables, except where the peat surface adjusts to fluctuating water tables, and in permafrost, where the collapse of dry plateau and palsas will lead to increased CH₄ emission. There likely will be little change in DOC production, but DOC export to water bodies will decrease as runoff decreases. The storage of C in peatlands is sensitive to all C cycle components and is difficult to predict. The challenge is to develop quantitative models capable of making these predictions for different peatlands. We present some qualitative responses, with levels of uncertainty. There will be, however, as much variation in response to climatic change within a peatland as there will be among peatland

regions.

Moore, T.R., J.A. Trofymow, B. Taylor, C. Prescott, C. Camire, L. Duschene, J. Fyles, L. Kozak, M. Kranabetter, I. Morrison, M. Siltanen, S. Smith, B. Titus, S. Visser, R. Wein, and S. Zoltai. 1999. Litter decomposition rates in Canadian forests. *Global Change Biology* 5(1):75-82.

The effect of litter quality and climate on the rate of decomposition of plant tissues was examined by the measurement of mass remaining after 3 years' exposure of 11 litter types placed at 18 forest sites across Canada. Amongst sites, mass remaining was strongly related to mean annual temperature and precipitation and amongst litter types the ratio of Klason lignin to nitrogen in the initial tissue was the most important litter quality variable. When combined into a multiple regression, mean annual temperature, mean annual precipitation and Klason lignin:nitrogen ratio explained 73% of the variance in mass remaining for all sites and tissues. Using three doubled CO₂ GCM climate change scenarios for four Canadian regions, these relationships were used to predict increases in decomposition rate of 4-7% of contemporary rates (based on mass remaining after 3 years), because of increased temperature and precipitation. This increase may be partially offset by evidence that plants growing under elevated atmospheric CO₂ concentrations produce litter with high lignin:nitrogen ratios which slows the rate of decomposition, but this change will be small compared to the increased rate of decomposition derived from climatic changes.

Moorhead, D.L., and A.E. Linkins. 1997. Elevated CO₂ alters belowground exoenzyme activities in tussock tundra. *Plant and Soil* 189(2):321-329.

A three-year exposure to a CO₂ concentration of 680 $\mu\text{mol mol}^{-1}$ altered the enzymic characteristics of root surfaces, associated ectomycorrhizae, and in soils surrounding roots in a tussock tundra ecosystem of north Alaska, USA. At elevated CO₂, phosphatase activity was higher on *Eriophorum vaginatum* root surfaces, ectomycorrhizal rhizomorphs and mantles associated with *Betula nana* roots, and in Oe and Oi soil horizons associated with plant roots. Also, endocellulase and exocellulase activities at elevated CO₂ were higher in ectomycorrhizal rhizomorphs and lower in Oe and Oi soil horizons associated with roots. These results suggest that arctic plants respond to raised CO₂ by increasing activities associated with nutrient acquisition, e.g. higher phosphatase activities on surfaces of roots and ectomycorrhizae, and greater cellulase activity in ectomycorrhizae. Changes in enzyme activities of surrounding soils are consistent with an increase in carbon exudation from plant roots, which would be expected to inhibit cellulase activities and stimulate phosphatase activities of soil microflora. These data were used to modify existing simulation models describing tussock phosphatase activities and litter decay. Model projections suggest that observed increases in phosphatase activities at 680 $\mu\text{mol mol}^{-1}$ CO₂, could augment total annual phosphorus release within tussocks by more than 40%, at present levels of root and ectomycorrhizae biomass. This includes a nearly three- fold increase in potential phosphatase activity of *E. vaginatum* roots, per unit of surface area. Observed

reductions in cellulase activities could diminish cellulose turnover by 45% in soils within rooting zones, which could substantially increase mineral nitrogen availability in soils due to lowered microbial immobilization.

Moorhead, D.L., R.L. Sinsabaugh, A.E. Linkins, and J.F. Reynolds. 1996. Decomposition processes: Modelling approaches and applications. *The Science of the Total Environment* 183(1-2):137-149.

Decomposition is a fundamental ecosystem process, strongly influencing ecosystem dynamics through the release of organically bound nutrients. Decomposition is also a complex phenomenon that can be modified by changes in the characteristics of the decaying materials or prevailing environmental conditions. For these reasons, the impacts of local, regional or global environmental changes on the quality and turnover of dead organic matter are of considerable interest. However, realistic limits to the complexity, as well as temporal and spatial scales, of experimental studies restrict their usefulness in extrapolating long-term or large-scale results of simultaneous environmental changes. Alternatively, many simulation models have been constructed to gain insight to potential impacts of anthropogenic activities. Because structure and approach determine the strengths and limitations of a model, they must be considered when applying one to a problem or otherwise interpreting model behaviour. There are two basically different types of models: (1) empirical models generally ignore underlying processes when describing system behaviour, while (2) mechanistic models reproduce system behaviour by simulating underlying processes. The former models are usually accurate within the range of conditions for which they are constructed but tend to be unreliable when extended beyond these limits. In contrast, application of a mechanistic model to novel conditions assumes only that the underlying mechanisms behave in a consistent manner. In this paper, we examine models developed at different levels of resolution to simulate various aspects of decomposition and nutrient cycling and how they have been used to assess potential impacts of environmental changes on terrestrial ecosystems.

Morcuende, R., P. Perez, R. MartinezCarrasco, I.M. DelMolino, and L.S. DeLaPuente. 1996. Long- and short-term responses of leaf carbohydrate levels and photosynthesis to decreased sink demand in soybean. *Plant, Cell and Environment* 19(8):976-982.

Axillary buds and the apical portion of shoots of soybean [*Glycine max* (L.) Merr. cultivar Turchina] plants were trimmed to investigate long-term regulation of photosynthesis by sink demand at ambient CO₂ and 22 degrees C. Also, in intact and trimmed shoots, the CO₂ level was increased to 660 $\mu\text{mol mol}^{-1}$ and temperature was lowered to 5 degrees C to examine the superimposed short-term responses of photosynthesis to low sink demand. Under growth conditions, trimming the shoots increased leaf photosynthesis and the levels of sucrose, glucose-6-phosphate (G6P) and 3-phosphoglycerate (PGA), as well as the G6P/fructose-6-phosphate (F6P) and sucrose/starch ratios, while it decreased the level of starch and the triose-phosphate (glyceraldehyde 3-

phosphate and dihydroxyacetone phosphate, TP)/PGA ratio. Photosynthesis enhancement was accompanied by increased chlorophyll contents and ribulose-1,5-bisphosphate carboxylase oxygenase (Rubisco) activity. Sink removal consistently increased photosynthesis measured under a variety of conditions (growth CO₂ or a short-term change to 660 $\mu\text{mol mol}^{-1}$ CO₂; growth temperature or a short-term change to 5 degrees C), except when low temperature was combined with ambient CO₂; the increase in photosynthesis was higher under short-term elevated CO₂ than at ambient CO₂. In contrast with its effect at ambient CO₂, shoot trimming increased the levels of TP and ribulose-1,5-bisphosphate (RuBP) and the TP/PGA ratio under high-CO₂ conditions.

Morgan, J.A., H.W. Hunt, C.A. Monz, and D.R. Lecain. 1994. Consequences of growth at 2 carbon-dioxide concentrations and 2 temperatures for leaf gas-exchange in *Pascopyrum smithii* (C-3) and *Bouteloua gracilis* (C-4). *Plant, Cell and Environment* 17(9):1023-1033.

Continually rising atmospheric CO₂ concentrations and possible climatic change may cause significant changes in plant communities. This study was undertaken to investigate gas exchange in two important grass species of the short-grass steppe, *Pascopyrum smithii* (western wheatgrass), C-3, and *Bouteloua gracilis* (blue grama), C-4, grown at different CO₂ concentrations and temperatures. Intact soil cores containing each species were extracted from grasslands in north-eastern Colorado, USA, placed in growth chambers, and grown at combinations of two CO₂ concentrations (350 and 700 $\mu\text{mol mol}^{-1}$) and two temperature regimes (field average and elevated by 4 degrees C). Leaf gas exchange was measured during the second, third and fourth growth seasons. All plants exhibited higher leaf CO₂ assimilation rates (A) with increasing measurement CO₂ concentration, with greater responses being observed in the cool-season C-3 species *P. smithii*. Changes in the shape of intercellular CO₂ response curves of A for both species indicated photosynthetic acclimation to the different growth environments. The photosynthetic capacity of *P. smithii* leaves tended to be reduced in plants grown at high CO₂ concentrations, although A for plants grown and measured at 700 $\mu\text{mol mol}^{-1}$ CO₂ was 41% greater than that in plants grown and measured at 350 $\mu\text{mol mol}^{-1}$ CO₂. Low leaf N concentration may have contributed to photosynthetic acclimation to CO₂. A severe reduction in photosynthetic capacity was exhibited in *P. smithii* plants grown long-term at elevated temperatures. As a result, the potential response of photosynthesis to CO₂ enrichment was reduced in *P. smithii* plants grown long-term at the higher temperature.

Morgan, J.A., W.G. Knight, L.M. Dudley, and H.W. Hunt. 1994. Enhanced root-system C-sink activity, water relations and aspects of nutrient acquisition in mycotrophic *Bouteloua gracilis* subjected to CO₂ enrichment. *Plant and Soil* 165(1):139-146.

In order to better elucidate fixed-C partitioning, nutrient acquisition and water relations of prairie grasses under elevated [CO₂], we grew the C-4 grass *Bouteloua gracilis* (H.B.K.) lag ex Steud. from seed in soil-packed, column- lysimeters in two growth chambers maintained at current

ambient [CO₂] (350 μ mol L⁻¹) and twice enriched [CO₂] (700 μ mol L⁻¹). Once established, plants were deficit irrigated; growth chamber conditions were maintained at day/night temperatures of 25/16 degrees C, relative humidities of 35%/90% and a 14-hour photoperiod to simulate summer conditions on the shortgrass steppe in eastern Colorado. After 11 weeks of growth, plants grown under CO₂ enrichment had produced 35% and 65% greater total and root biomass, respectively, and had twice the level of vesicular-arbuscular mycorrhizal (VAM) infection (19.8% versus 10.8%) as plants grown under current ambient [CO₂]. The CO₂-enriched plants also exhibited greater leaf water potentials and higher plant water use efficiencies. Plant N uptake was reduced by CO₂ enrichment, while P uptake appeared little influenced by CO₂ regime. Under the conditions of the experiment, CO₂ enrichment increased root biomass and VAM infection via stimulated growth and adjustments in C partitioning below-ground.

Morgan, J.A., D.R. LeCain, J.J. Read, H.W. Hunt, and W.G. Knight. 1998. Photosynthetic pathway and ontogeny affect water relations and the impact of CO₂ on *Bouteloua gracilis* (C-4) and *Pascopyrum smithii* (C-3). *Oecologia* 114(4):483-493.

The eastern Colorado shortgrass steppe is dominated by the C-4 grass, *Bouteloua gracilis*, but contains a mixture of C-3 grasses as well, including *Pascopyrum smithii*. Although the ecology of this region has been extensively studied, there is little information on how increasing atmospheric CO₂ will affect it. This growth chamber study investigated gas exchange, water relations, growth, and biomass and carbohydrate partitioning in *B. gracilis* and *P. gracilis* grown under present ambient and elevated CO₂ concentrations of 350 μ mol L⁻¹ and 700 μ mol L⁻¹, respectively, and two deficit irrigation regimes. The experiment was conducted in soil-packed columns planted to either species over a 2-month period under summer-like conditions and with no fertilizer additions. Our objective was to better understand how these species and the functional groups they represent will respond in future CO₂-enriched environments. Leaf CO₂ assimilation (A(n)), transpiration use efficiency (TUE, or A(n)/transpiration), plant growth, and whole-plant water use efficiency (WUE, or plant biomass production/water evapotranspired) of both species were greater at elevated CO₂, although responses were more pronounced for *P. smithii*. Elevated CO₂ enhanced photosynthesis, TUE, and growth in both species through higher soil water content (SWC) and leaf water potentials (Psi) and stimulation of photosynthesis. Consumptive water use was greater and TUE less for *P. smithii* than *B. gracilis* during early growth when soil water was more available. Declining SWC with time was associated with a steadily increased sequestering of total non-structural carbohydrates (TNCs), storage carbohydrates (primarily fructans for *P. Smithii*) and biomass in belowground organs of *P. smithii*, but not *B. gracilis*. The root:shoot ratio of *P. smithii* also increased at elevated CO₂ while the root:shoot ratio of *B. gracilis* was unresponsive to CO₂. These partitioning responses may be the consequence of different ontogenetic strategies of a cool-season and warm-season grass entering a warm, dry summer period; the cool-season *P. smithii* responds by sequestering TNCs belowground in preparation for summer dormancy, while resource partitioning of the warm-season *B. gracilis* remains unaltered. One consequence of greater partitioning of resources into *P. smithii* belowground organs in the present study was maintenance of higher Psi and A(n) rates. This, along with differences in photosynthetic pathway, may have accounted for the greater responsiveness of *P. smithii* to CO₂ enrichment compared to *B. gracilis*.

Moriguchi, T., and R.J. Romani. 1995. Mitochondrial self-restoration as an index to the capacity of avocado fruit to sustain atmospheric stress at 2 climacteric states. *Journal of the American Society for Horticultural Science* 120(4):643-649.

A strong association is implicit between mitochondrial function and the energy demands of cells responding to stress. Yet, the dynamics of this organelle-cellular dependency have been difficult to resolve. This study examines a new diagnostic parameter namely, mitochondrial maintenance and self-restoration as exhibited by the course of respiratory functions (States 3 and 4 respiratory rates, respiratory control) of mitochondria extracted during and after exposure of intact 'Hass' avocado (*Persea americana*) fruit to different stress atmospheres: anoxia (100% N₂) or high (25% and 75%) CO₂ for varying durations. Comparisons are made with direct exposure of the mitochondria themselves to similar atmospheres. In general, exposure of the fruit to CO₂ rich atmospheres enhanced the capacity of their mitochondria to restore energy-linked functions whereas anoxia caused irreparable damage. The physiological (climacteric) state of the fruit also affected the stress capacity of the mitochondria contained therein, anaerobiosis being more harmful to mitochondria in riper fruit. In contrast to their effects in vivo, in vitro anoxia appeared to sustain mitochondrial energy-linked functions, whereas high CO₂ was clearly harmful. These and other observations are discussed in the context of mitochondrial self-restoration or homeostasis and its relevance to postharvest stress-atmosphere storage for purposes such as pathogen suppression or insect control.

Morin, F., M. Andre, and T. Betsche. 1992. Growth-kinetics, carbohydrate, and leaf phosphate content of clover (*Trifolium subterraneum* L.) after transfer to a high CO₂ atmosphere or to high light and ambient air. *Plant Physiology* 99(1):89-95.

Intact air-grown (photosynthetic photon flux density, 400 microeinsteins per square meter per second) clover plants (*Trifolium subterraneum* L.) were transferred to high CO₂ (4000 microliters CO₂ per liter; photosynthetic photon flux density, 400 microeinsteins per square meter per second) or to high light (340 microliters CO₂ per liter; photosynthetic photon flux density, 800 microeinsteins per square meter per second) to similarly stimulate photosynthetic net CO₂ uptake. The daily increment of net CO₂ uptake declined transiently in high CO₂, but not in high light, below the values in air/standard light. After about 3 days in high CO₂, the daily increment of net CO₂ uptake increased but did not reach the high light values. Nightly CO₂ release increased immediately in high light, whereas there was a 3-day lag phase in high CO₂. During this time, starch accumulated to a high level, and leaf deterioration was observed only in high CO₂. After 12 days, starch was two- to threefold higher in high CO₂ than in high light, whereas sucrose was similar. Leaf carbohydrates were determined during the first and fourth day in high CO₂. Starch increased rapidly throughout the day. Early in the day, sucrose was low and similar in high CO₂ and ambient air (same light). Later, sucrose increased considerably in high CO₂. The findings that (a) much more photosynthetic carbon was partitioned into the leaf starch pool in high CO₂ than in high light, although net CO₂ uptake was similar, and that (b) rapid starch formation occurred in high CO₂ even when leaf sucrose was only slightly elevated suggest that low sink capacity was not the main constraint in high CO₂. It is proposed that carbon partitioning between starch (chloroplast) and sucrose (cytosol) was perturbed by high CO₂ because of the lack of photorespiration. Total phosphate pools were determined in leaves.

Concentrations based on fresh weight of orthophosphate, soluble esterified phosphate, and total phosphate markedly declined during 13 days of exposure of the plants to high CO₂ but changed little in high light/ambient air. During this time, the ratio of orthophosphate to soluble esterified phosphate decreased considerably in high CO₂ and increased slightly in high light/ambient air. It appears that phosphate uptake and growth were similarly stimulated by high light, whereas the coordination was weak in high CO₂.

Morison, J.I.L. 1993. Response of plants to CO₂ under water limited conditions. *Vegetatio* 104:193-209.

The influence of increased atmospheric CO₂ on the interaction between plant growth and water use is proving to be one of the most profound impacts of the anthropogenic 'Greenhouse Effect'. This paper illustrates the interaction between CO₂ and water in plant growth at a range of scales. Most published work has concentrated on water use efficiency, especially at shorter time scales, and has shown large increases of leaf water use efficiency with increased CO₂. However, the magnitude of the effect is variable, and does not consistently agree with predictions from simple leaf gas exchange considerations. The longer the time scales considered, the less the information and the more the uncertainty in the response to CO₂, because of the additional factors that have to be considered, such as changes in leaf area, respiration of non-photosynthetic tissues and soil evaporation. The need for more detailed studies of the interactions between plant evaporation, water supply, water status and growth is stressed, as increased CO₂ can affect all of these either directly, or indirectly through feedbacks with leaf gas exchange, carbon partitioning, leaf growth, canopy development and root growth.

Morison, J.I.L. 1998. Stomatal response to increased CO₂ concentration. *Journal of Experimental Botany* 49:443-452.

The stomatal response to CO₂ is important in understanding stomatal physiology, and important in understanding vegetation-atmosphere exchanges at all scales from the individual plant up to global vegetation. Despite the long history of experiments on stomatal responses to CO₂ there are still considerable uncertainties in both these tasks. The difficulty in understanding differences in stomatal conductance between plants grown for any length of time in different CO₂ atmospheres is stressed because of the many other possible changes in the plants' carbohydrate, nutrient and water relations. The other key issues that are highlighted are: whether stomata acclimate to CO₂ either in parallel with any mesophyll photosynthetic acclimation or independently of changes in the mesophyll; whether stomata on different leaf surfaces respond to CO₂ similarly; and whether reported changes in stomatal frequency are important to leaf gas exchange. The need for direct examination of stomatal sensitivity of plants grown in different CO₂ concentrations is stressed.

Morison, J.I.L., and D.W. Lawlor. 1999. Interactions between increasing CO₂ concentration and temperature on plant growth. *Plant, Cell and Environment* 22(6):659-682.

The global environment is changing with increasing temperature and atmospheric carbon dioxide concentration, [CO₂]. Because these two factors are concomitant, and the global [CO₂] rise will affect all biomes across the full global range of temperatures, it is essential to review the theory and observations on effects of temperature and [CO₂] interactions on plant carbon balance, growth, development, biomass accumulation and yield. Although there are sound theoretical reasons for expecting a larger stimulation of net CO₂ assimilation rates by increased [CO₂] at higher temperatures, this does not necessarily mean that the pattern of biomass and yield responses to increasing [CO₂] and temperature is determined by this response. This paper reviews the interactions between the effects of [CO₂] and temperature on plants. There is little unequivocal evidence for large differences in response to [CO₂] at different temperatures, as studies are confounded by the different responses of species adapted and acclimated to different temperatures, and the interspecific differences in growth form and development pattern. We conclude by stressing the importance of initiation and expansion of meristems and organs and the balance between assimilate supply and sink activity in determining the growth response to increasing [CO₂] and temperature.

Morokuma, M., M. Yajima, and S. Yonemura. 1996. Effects of elevated CO₂ concentration and warming on growth and yield of rice. *Japanese Journal of Crop Science* 65(2):222-228.

Effects of combined treatments of CO₂ (400, 660, 1200 ppm) and air temperature (outdoor tracking, outdoor+2 degrees C) on growth and yield of rice (*Oryza sativa* L. cv. Nipponbare) grown in growth chambers under natural sunlight were investigated. The effects of container size (tank, 3.5 l pot) on growth and yield were also examined. Plants were grown under simulated paddyfield conditions. Growth parameters under the elevated CO₂ and temperature conditions were promoted at the maximum tiller number stage but not at the heading stage, without appreciable difference in such parameters. In the 660HT plot, dry weight increased about 30% at both stages compared with the 400NT plot. In the 1200HT plot, it increased more than that of the 660HT plot at the maximum tiller number stage but at the heading stage, the degree of promotion was decreased substantially. Dry matter distribution to leaf blades was reduced, and the nitrogen ratio in leaf blades were low in plants grown in both 660HT and 1200HT plants. In the 1200HT plot, the yield was remarkably reduced probably due to the high temperature sterility. Potted, limited-root-space plants grew smaller above-ground parts than did tank plants (less limited), without any difference in root production. From these results, the production processes of rice crop are discussed in terms of climate conditions predicted for the future.

Morse, S.R., and F.A. Bazzaz. 1994. Elevated CO₂ and temperature alter recruitment and size hierarchies in C-3 and C-4 annuals. *Ecology* 75(4):966-975.

In order to understand the implications of changes in global CO₂ concentrations and temperature for the growth and fitness of individual plants, performance must be investigated in relation to the performance of other plants within a population. In this study we examined patterns of recruitment, mortality, and size structure of monospecific stands in response to ambient (400 µmol/L) and elevated CO₂ concentrations (700 µmol/L) across three temperature regimes; 18 degrees, 28 degrees, and 38 degrees C. We created experimental populations of two annual plants that differ in their photosynthetic pathway and water use patterns: *Abutilon theophrasti* (C-3) and *Amaranthus retroflexus* (C-4). The effects of CO₂, temperature, and their interactions on population structure were complex and species dependent. For both species increasing temperature resulted in higher germination and faster initial growth rates. These initial temperature responses increased the intensity and role of competition in determining stand size and structure. Postemergence responses to elevated CO₂ differed markedly between the two species. For *Abutilon*, the C-3 species, self-thinning and the mean biomass of the survivors increased under elevated CO₂. For *Amaranthus*, survivorship, but not growth, increased under elevated CO₂ conditions. We attribute differences in response between species not only to photosynthetic pathway, but also to differences in the onset of competition mediated through differences in plant form and in resource uptake and deployment. The patterns of stand development in response to CO₂ and temperature suggest that the effects of changing CO₂ and temperature may be understood within mechanistically based models of resource use. Temperature regulates the rate of resource use and the onset of interference among plants, while CO₂ functions both as a resource and a resource regulator. Although mortality was concentrated later in stand development for *Abutilon* than *Amaranthus*, overall patterns of stand size and structure were similar for both species; mortality and size inequalities increased with increasing temperature and CO₂. Because size is often correlated with fecundity, an increase in size hierarchies in response to elevated CO₂, in conjunction with a decrease in survivorship, may result in a smaller effective population size. Our ability to predict changes in effective population size due to changing size hierarchies alone, however, should also consider developmental shifts in response to elevated CO₂ that may result in, as in this study, a decrease in the minimum size at the onset of flowering.

Morse, S.R., P. Wayne, S.L. Miao, and F.A. Bazzaz. 1993. Elevated CO₂ and drought alter tissue water relations of birch (*Betula populifolia* marsh) seedlings. *Oecologia* 95(4):599-602.

The effect of increasing atmospheric CO₂ concentrations on tissue water relations was examined in *Betula populifolia*, a common pioneer tree species of the northeastern U.S. deciduous forests. Components of tissue water relations were estimated from pressure volume curves of tree seedlings grown in either ambient (350 µmol/L) or elevated CO₂ (700 µmol/L), and both mesic and xeric water regimes. Both CO₂ and water treatment had significant effects on osmotic potential at full hydration, apoplasmic fractions, and tissue elastic moduli. Under xeric conditions and ambient CO₂ concentrations, plants showed a decrease in osmotic potentials of 0.15 MPa and an increase in tissue elastic moduli at full hydration of 1.5 MPa. The decrease in elasticity may enable plants to improve the soil-plant water potential gradient given a small change in water content, while lower osmotic potentials shift the zero turgor loss point to lower water potentials. Under elevated CO₂, plants in xeric conditions had osmotic potentials 0.2 MPa lower than mesic plants and decreased elastic moduli at full hydration. The increase in tissue elasticity at elevated CO₂ enabled the xeric plants to maintain positive turgor pressures at lower water potentials and tissue water contents. Surprisingly, the elevated CO₂ plants under mesic conditions had the

most inelastic tissues. We propose that this inelasticity may enable plants to generate a favorable water potential gradient from the soil to the plant despite the low stomatal conductances observed under elevated CO₂ conditions.

Mortensen, L.M. 1992. Diurnal photosynthesis and transpiration of *Ficus benjamina* L. as affected by length of photoperiod, CO₂ concentration and light level. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 42(2):100-105.

The diurnal net photosynthesis of *Ficus benjamina* L., cultivar Cleo, was studied at different daylengths (12, 18 and 24 h day⁻¹), photosynthetic photon flux densities (40 and 120 µmol m⁻² s⁻¹ PPFD) and CO₂ concentrations (350 and 700 µmol mol⁻¹). Net photosynthesis increased to a maximum after 5-6 and 6-7 h of light at 12 and 18 h day⁻¹ photoperiods, respectively, followed by a decrease towards the end of the photoperiod. At a photoperiod of 18 h day⁻¹ similar diurnal curves were found at 350 and 700 µmol mol⁻¹ CO₂, and at 40 and 120 µmol m⁻² s⁻¹ PPFD. Five days after the photoperiod was changed from 18 to a 24 h day⁻¹ the diurnal rhythm disappeared. Transpiration followed the same diurnal rhythm as that for photosynthesis. The water-use efficiency was enhanced by raising the CO₂ concentration. A decrease in the CO₂ concentration from 700 to 350 µmol mol⁻¹ after six days at high CO₂ first significantly decreased the photosynthesis, but three days later it reached the same level as that at high CO₂.

Mortensen, L.M. 1992. Effects of ozone concentration on growth of tomato at various light, air humidity and carbon-dioxide levels. *Scientia Horticulturae* 49(1-2):17-24.

The effect of ozone (O₃) concentration on the growth of *Lycopersicon esculentum* was studied at different photosynthetic photon flux densities (PPFD), relative air humidities (RH) and carbon dioxide (CO₂) concentrations. Increasing the O₃ concentration from < 10 to 85 nl l⁻¹ for 6 h per day reduced the shoot dry weight 35% at 70% RH and 62% at 90% RH. Increasing the PPFD from 100 to 350 µmol m⁻² s⁻¹ significantly reduced the effect of O₃ in one of two experiments. The most pronounced interaction between RH, PPFD and O₃ was found on plant height. High O₃ levels generally decreased plant height at low PPFD and had no, or a stimulating, effect at high PPFD. Raising the RH from 70 to 90% significantly increased the negative effect of O₃ on height. Increasing the O₃ concentration from < 10 to 65 nl l⁻¹ significantly decreased plant height at low CO₂ concentration (300-340 µmol l⁻¹), but small effects were found at high CO₂ concentration (700-800 µmol l⁻¹).

Mortensen, L.M. 1994. Effects of carbon-dioxide concentration on assimilate partitioning, photosynthesis and transpiration of *Betula pendula* Roth and *Picea abies* (L.) Karst seedlings at 2 temperatures. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 44(3):164-169.

Seedlings of *Betula pendula* Roth. and *Picea abies* (L.) Karst. were grown at 350 and 700 $\mu\text{mol mol}^{-1}$ CO_2 for 35 or 45 days at 15 and 20 degrees C in eight growth chambers. The mean photosynthetic flux was 15-22 $\mu\text{mol m}^{-2} \text{day}^{-1}$. The mean relative growth rate was increased by 7% in *Betula* and by 10% in *Picea* at the highest CO_2 concentration. This corresponded to an increase in the total plant dry weight of 20 and 19%, respectively. The shoot:root and leaf:stem ratios were unaffected by the CO_2 concentration in both species. High CO_2 levels increased the stem diameter and the number of lateral shoots in *Betula*. Increasing the temperature did not affect the assimilate partitioning between leaf stem and root in *Betula*, but the needle:stem ratio decreased in *Picea*. Elevated CO_2 concentration increased the number of lateral shoots in *Betula* more at 15 than at 20 degrees C, however, the total weight of the lateral shoots was not affected. With this exception the effect of CO_2 was generally the same at both temperatures. Measurements of the CO_2 exchange rates indicated that a slight acclimation to high CO_2 had taken place at the end of the experimental period in the two species. Elevated CO_2 slightly decreased the transpiration rate of *Betula*.

Mortensen, L.M. 1994. Effects of day-night temperature-variations on growth, morphogenesis and flowering of *Kalanchoe blossfeldiana* V poelln at different CO_2 concentrations, daylengths and photon flux densities. *Scientia Horticulturae* 59(3-4):233-241.

Growth and flowering of *Kalanchoe blossfeldiana* were studied at two temperature treatments (constant, CT; day lower than night temperature, negative DIF) in combination with two CO_2 concentrations (360 and 900 $\mu\text{mol mol}^{-1}$), two daylengths (DL; 12 and 18 h) and two photosynthetic photon flux densities (PPFD; 85 and 130 $\mu\text{mol m}^{-2} \text{s}^{-1}$). In addition to the two temperature treatments, a 2-h low temperature pulse (DROP) was included in combination with short days and low CO_2 levels. The experiment was conducted in 18 growth chambers with artificial light only. The plant dry weight at saleable stage was the same at the different temperature treatments irrespective of CO_2 concentration, DL or PPFD. The dry weight was similarly (31- 40%) increased by CO_2 enrichment, or increasing DL or PPFD. Total plant height was slightly, but consistently increased by negative DIF relative to CT, irrespective of the level of the other climate factors. The DROP treatment in short DL increased the height relative to both negative DIF and CT. Negative DIF delayed flowering by 2-4 days at 360 $\mu\text{mol mol}^{-1}$ CO_2 , but promoted it by 2-4 days at 900 $\mu\text{mol mol}^{-1}$ CO_2 . Fresh weight of flowers was unaffected by temperature treatments irrespective of DL and PPFD. It was concluded that the best plant quality was obtained at constant temperature throughout day and night irrespective of the level of the other climate factors.

Mortensen, L.M. 1994. Effects of elevated CO_2 concentrations on growth and yield of 8 vegetable species in a cool climate. *Scientia Horticulturae* 58(3):177-185.

The effects of elevated CO_2 concentrations on the yield of *Allium cepa* (onion), *Allium ampeloprasum* (leek), *Apium graveolens* var. dulce (celery), *Apium graveolens* var. rapaceum (celery root), *Brassica pekinensis* (chinese cabbage), *Daucus carota* (carrot), *Lactuca sativa* (lettuce) and *Petroselinum crispum* (parsley) grown in containers, were studied in SiX 9-M2 large field plots surrounded by 1.8-m high plastic foil walls ('field chambers'). Three of the chambers were supplied with pure CO_2 gas through perforated tubes. Increasing the CO_2 concentration from ambient (355 $\mu\text{mol mol}^{-1}$) to 800-900 $\mu\text{mol mol}^{-1}$

increased the yield (fresh weight) by 23% in onion (two cultivars) and by 8% in carrot (three cultivars). The dry weight based yield increase was 18% in lettuce (three cultivars), 19% in carrot and 17% in parsley (one cultivar). The yields of leek (two cultivars), chinese cabbage (three cultivars), celery (one cultivar) and celery root (one cultivar) were not significantly affected by the CO_2 concentration. Generally, no 'chamber effect' was found on the yields of the different species.

Mortensen, L.M. 1994. The influence of carbon-dioxide or ozone concentration on growth and assimilate partitioning in seedlings of 9 conifers. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 44(3):157-163.

Seedlings of nine different conifers were exposed to 355 and 730 $\mu\text{mol mol}^{-1}$ CO_2 , or low ($< 15 \mu\text{mol mol}^{-1}$) and elevated O-3 concentration (70 nmol mol^{-1}) for 81-116 days. The experiments were conducted in growth chambers placed in a greenhouse. Increased CO_2 concentration enhanced the mean relative growth rate (RGR) and total plant dry weight by 4 and 33% in *Larix leptolepis*, by 4 and 38% in *Larix sibirica*, by 7 and 47% in *Picea glauca* and by 3 and 16% in *Picea sitchensis*, respectively. The growth rates and dry weights of *Pinus contorta*, *Pinus mugo* and *Pseudotsuga menziesii* were not significantly affected. Carbon dioxide enrichment enhanced RGR of two provenances of *Picea abies* by 4 and 6%, respectively, while a third provenance was unaffected. In *Pinus sylvestris*, only the RGR of one of three provenances was stimulated by CO_2 enrichment (4%). After two growth seasons CO_2 enrichment enhanced RGR and total plant dry weight by 11 and 35% in *Picea abies* and by 12 and 36% in *Pinus sylvestris*, respectively. Elevated CO_2 decreased the shoot:root ratio in *Larix leptolepis*, and decreased the needle:stem ratio in *Picea glauca*, but increased it in *Pseudotsuga menziesii*. Elevated O-3 significantly decreased the plant dry weight in *Picea sitchensis*, *Pseudotsuga menziesii* and in one of three provenances of *Pinus sylvestris*, while the other species and provenances were unaffected. Increased O-3 concentration increased the shoot:root dry weight ratio in one of three *Picea abies* provenances, in all three *Pinus sylvestris* provenances and in *Pinus contorta*. The needle:stem ratio was enhanced by O-3 in seven of the nine species. The O-3 exposure caused chlorosis of needles in all species except *Pseudotsuga menziesii*.

Mortensen, L.M. 1995. Diurnal carbon-dioxide exchange-rates of greenhouse roses under artificial-light as compared with daylight conditions in summer. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 45(2):148-152.

Carbon dioxide exchange rates (CER) of greenhouse roses (cut flowers) were measured under daylight conditions in a greenhouse in July, and under artificial light only (300 $\mu\text{mol mol}^{-2} \text{s}^{-1}$ PPFD in 18 h day(-1)) at two CO_2 concentrations (350 and 700 $\mu\text{mol mol}^{-1}$). The daily CER varied considerably from day to day owing to the large variation in solar radiation. Light saturation of CER seemed not to be reached even on clear days, and a light dose (PAP = number of photosynthetic active photons) produced by variable light over one week in summer gave the same total CER as a similar PAP produced by a constant PPFD. CER at constant PPFD increased rapidly during the first two hours of the photoperiod, followed by a slight increase during the subsequent hours, before CER slightly decreased towards the end of the photoperiod. Raising the CO_2 concentration significantly increased CER during the entire photoperiod, and by 32% as a mean for the whole photoperiod.

Elevated CO₂ decreased the night respiration of the plants by 30%. As a total of the light and dark period, CO₂ enrichment increased CER by 38%.

Mortensen, L.M. 1995. Effect of carbon-dioxide concentration on biomass production and partitioning in betula-pubescons ehrh seedlings at different ozone and temperature regimes. *Environmental Pollution* 87(3):337-343.

Seedlings of *Betula pubescens* were grown at two CO₂ concentrations, in combination with either two O₃ concentrations or two air temperatures, during 34-35 days at 24 h day⁻¹ photoperiod in growth chambers placed in a greenhouse. Increasing the CO₂ concentration from 350 to 560 $\mu\text{mol mol}^{-1}$ at 17-degrees-C air temperature increased the dry weight of the main leaves, main stem, branches and root. The mean relative growth rate (RGR) was increased 10% by CO₂ enrichment, while increasing the O₃ concentration from 7 to 62 nmol mol^{-1} decreased the RGR by 9%. The relative biomass distribution between the different plant components was not significantly affected by the CO₂ concentration irrespective of the O₃ concentration. No significant interactions between CO₂ and O₃ concentration were found except on leaf size, which was stimulated more by elevated CO₂ concentration at high, compared to low, O₃ levels. In another experiment, elevated CO₂ (700 $\mu\text{mol mol}^{-1}$) significantly increased the dry weight of the different plant components, and more at 20-degrees-C than at 15-degrees-C. Raising the CO₂ concentration increased the RGR by 5 and 10% at 15 and 20-degrees-C, respectively. CO₂ enrichment increased the branch dry weight relatively more than the dry weight of the other plant parts. Increasing the CO₂ concentration or temperature increased the plant height and stem diameter, however, no interactions between CO₂ and temperature were found.

Mortensen, L.M. 1997. Effects of carbon dioxide concentrations on three grass species grown in mixture in two soil types at different ozone concentrations or temperatures. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 47(1):14-19.

A seed mixture of *Phleum pratense* L., *Lolium perenne* L. and *Festuca pratensis* Huds. was grown in sphagnum peat or sandy soil in six growth chambers placed in a greenhouse compartment. Two different experiments were performed. Increasing the CO₂ concentration from 375 to 740 $\mu\text{mol mol}^{-1}$ increased the total dry weight of the grass mixture by about 30%, while an increase in the O-3 concentration from < 10 to 50 nmol mol^{-1} decreased the dry weight by 18% as a mean in both experiments. The relative dry weights of the three species were not significantly affected by elevated CO₂ concentrations at low O-3, while *Lolium* increased its relative dry weight at high O-3 concentrations at low CO₂ on the expenditure of *Phleum* dry weight. CO₂ enrichment counteracted some of this O-3 effect. No significant interaction between CO₂ concentration and temperature (14 and 19 degrees C mean temperature) was found with respect to the dry weights of the three species. The soil type had generally no influence on the effect of CO₂ and O-3. However, plant growth was significantly slower in sandy soil than in peat.

Mortensen, L.M. 1998. Effects of elevated CO₂ concentration on growth of *Betula pubescens* Ehrh. in different climatic conditions. *Scandinavian Journal of Forest Research* 13(2):197-203.

Seedlings of *Betula pubescens* Ehrh. (mountain birch) were grown at ambient and elevated CO₂ concentrations in environment- controlled growth chambers, and in chambers or wind tunnels in the field. In the two preliminary experiments in a controlled environment, CO₂ enrichment increased the dry weights of six birch provenances grown at a daily mean temperature (MT) of 17 degrees C and 15 provenances grown at 12.5 degrees C MT by 27 and 7%, respectively. In more realistic conditions in field chambers (13.9 degrees C MT), the shoot dry weight of plants grown for 65 days was not significantly affected by the elevated CO₂ concentration. In a parallel experiment, CO₂ enrichment increased the shoot dry weight by 36% in both unheated (14.7 degrees C MT) and heated (18.1 degrees C MT) wind tunnels. In a final experiment over two seasons in open- top chambers at 850 m a.s.l., elevated CO₂ concentrations increased the root (42%) but not the shoot dry weight. The results are discussed in relation to variable climatic conditions.

Mortensen, L.M. 1999. Effects of different carbon dioxide and ozone concentrations on shoot growth of *Phleum pratense* L. and *Betula pubescens* Ehrh. as influenced by day length and irradiance. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 49(1):50-56.

Seedlings of *Phleum pratense* L. (timothy) and *Betula pubescens* Ehrh. (mountain birch) were grown for 37 or 42 days at all combinations of two CO₂ concentrations (350 and 700 $\mu\text{mol mol}^{-1}$), two O-3 concentrations (13 and 59 nmol mol^{-1}) in 8 h day⁻¹), two day lengths (17 and 24 h DL) and two levels of supplementary lighting (150 and 210 $\mu\text{mol m}^{-2} \text{s}^{-1}$) photosynthetic photon flux, PPF) in 16 growth chambers placed in a greenhouse. Elevated CO₂ concentration increased the mean shoot dry weight by 47% in timothy and by 39% in birch. No significant interactions were found between CO₂ and O-3, DL or PPF with respect to shoot dry weight in the two species. The number of shoots in timothy was generally enhanced by CO₂ enrichment. The number of branches in birch was strongly enhanced by elevated CO₂ at 17 but not at 24 h DL, and the ratio of the fresh weight of branches to main shoot was significantly increased irrespective of DL. Increasing the O-3 concentration caused visible leaf injuries both in timothy (chlorosis/necrosis) and in birch (yellow stipples/brown spots), while the shoot weight was not significantly affected. The number of O-3-induced injuries in timothy was decreased by increasing the CO₂ concentration or the total irradiance (increasing DL and/or PPF). The number of injuries in birch was slightly decreased by increasing PPF; however, CO₂ enrichment had no effect.

Mortensen, L.M. 1999. Foliar injuries caused by ozone in *Betula pubescens* Ehrh. and *Phleum pratense* L. as influenced by climatic conditions before and during O-3 exposure. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 49(1):44-49.

Seedlings of *Betula pubescens* Ehrh. (mountain birch) and *Phleum pratense* L. (timothy) were grown for 42 days under full light or 50% shade in the field at 12 degrees C, and at comparable photosynthetic active radiation (PAR) levels in a greenhouse at 18 degrees C. Plants from the four pretreatments were exposed to 78 nmol mol⁻¹ (ppb) O₃ (8 h day⁻¹) under two temperatures (15 and 25 degrees C), two relative air humidities (50 and 80% RH) or two CO₂ concentrations (400 and 750 µmol mol⁻¹) during 7 days. The accumulated O₃ dose over 40 nmol mol⁻¹ O₃ (AOT40) was 2.6 µmol mol⁻¹-hours (ppm-h). Decreasing the temperature during exposure significantly increased the amount of injury induced by O₃ in leaves of birch (yellow mottling/bronzing) as well as timothy (chlorosis/necrosis). Increasing the air humidity or decreasing the CO₂ concentration strongly enhanced the injuries caused by O₃ in timothy, but not in birch. In general, both birch and timothy plants grown in the greenhouse and in the field had the same O₃ sensitivity. However, decreasing the PAR level during the pretreatment enhanced leaf injury in birch but not in timothy. At the most sensitive exposure climate, 15 degrees C/80% RH, leaf injury developed at an AOT40 of 0.7-0.9 ppm-h in both species.

Mortensen, L.M., and R. Moe. 1992. Effects of CO₂ enrichment and different day/night temperature combinations on growth and flowering of *Rosa* L. and *Kalanchoe blossfeldiana* V. poelln. *Scientia Horticulturae* 51(1-2):145-153.

The effects of increasing the CO₂ concentration from 350 to 700-µmol⁻¹ on growth and flowering of *Rosa* L. and *Kalanchoe blossfeldiana* at four different day/night temperature combinations (20/20-degrees-C, 23/14-degrees-C and 17/26- degrees-C day/night, and 20/20-degrees-C with 2 h at 14- degrees-C in the morning) were studied in 16 growth chambers. An increase in the CO₂ concentration resulted in enhanced total dry weight, stem: leaf fresh weight ratio, flower fresh weight, length and diameter of the rose shoot, while the number of days until flowering was not affected. With the 17/26-degrees-C treatment, rose shoots were 3-4 cm shorter, and with the 23/14- degrees-C treatment flowering occurred about 2 days earlier than with the other temperature treatments. The results were the same for *Rosa* cultivars 'Frisco' and 'Kiss'. No significant interactions between CO₂ and temperature were found. Plant dry weight and fresh weight of flowers in *Kalanchoe* were generally enhanced by CO₂ enrichment. The effects of CO₂ on dry weight, plant height and flower stem length were greater with the 23/14-degrees-C treatment compared with the effects of the other temperature treatments. A constant temperature (20/20- degrees-C) and the 23/14-degrees-C treatments gave the shortest and tallest plants, respectively.

Mortensen, L.M., and A. Saebo. 1996. The effect of elevated CO₂ concentration on growth of *Phleum pratense* L. in different parts of the growth season. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 46(2):128-134.

Seedlings of *Phleum pratense* L. (timothy) of the same age were grown in five sequential four-week periods during one growth season (May 5-September 23) at low (380 µmol mol⁻¹) and high (650 µmol mol⁻¹) CO₂ concentration. The experiment was performed in 10 x 9 m² field plots surrounded by plastic foil walls ("field chambers") in the relatively cool climate (10- 13 degrees C mean temperature) of the west coast of Norway (59 degrees N latitude). Raising the CO₂ concentration generally decreased the height of the grass (8-23%), especially at the beginning and end of the growth season. The number of shoots was

significantly increased (13-42%) by CO₂ enrichment in all growth periods except the last. Elevated CO₂ did not influence the above-ground biomass (dry weight) in the first (May) and last (September) period, but increased it by 14-51% in the intervening periods (June-August). Positive effects of CO₂ enrichment on plant biomass were correlated with positive effects on the number of shoots. Elevated CO₂ concentrations resulted in 25-64% denser plant biomass (dry weight per unit air volume) in the different growth periods. In general, a positive "chamber effect" on plant height and dry weight was found in spite of the small air temperature differences between the insides and the outsides of the chambers. A greenhouse experiment showed that wind speeds above 3 m s⁻¹ strongly decreased height and dry weight of timothy seedlings. The reduced wind speeds inside the chambers could therefore explain the "chamber effects" found.

Mosier, A.R. 1998. Soil processes and global change. *Biology and Fertility of Soils* 27(3):221-229.

Contributors to the Intergovernmental Panel on Climate Change (IPCC) generally agree that increases in the atmospheric concentration of greenhouse trace gases (i.e., CO₂, CH₄, N₂O, O₃) since preindustrial times, about the year 1750, have led to changes in the earth's climate. During the past 250 years the atmospheric concentrations of CO₂, CH₄, and N₂O have increased by 30, 145, and 15%, respectively. A doubling of preindustrial CO₂ concentrations by the end of the twenty-first century is expected to raise global mean surface temperature by about 2 degrees C and increase the frequency of severe weather events. These increases are attributed mainly to fossil fuel use, land-use change, and agriculture. Soils and climate changes are related by bidirectional interactions. Soil processes directly affect climatic changes through the production and consumption of CO₂, CH₄, and N₂O and, indirectly, through the production and consumption of NH₃, NO_x, and CO. Although CO₂ is primarily produced through fossil fuel combustion, land-use changes, conversion of forest and grasslands to agriculture, have contributed significantly to atmospheric increase of CO₂. Changes in land use and management can also result in the net uptake, sequestration, of atmospheric CO₂. CH₄ and N₂O are produced (30% and 70%, respectively) in the soil, and soil processes will likely regulate future changes in the atmospheric concentration of these gases. The soil-atmosphere exchange of CO₂, CH₄, and N₂O are interrelated, and changes in one cycle can impact changes in the N cycle and resulting soil-atmosphere exchange of N₂O. Conversely, N addition increases C sequestration. On the other hand, soil processes are influenced by climatic change through imposed changes in soil temperature, soil water, and nutrient competition. Increasing concentrations of atmospheric CO₂ alters plant response to environmental parameters and frequently results in increased efficiency in use of N and water. In annual crops increased CO₂ generally leads to increased crop productivity. In natural systems, the long-term impact of increased CO₂ on ecosystem sustainability is not known. These changes may also result in altered CO₂, CH₄, and N₂O exchange with the soil. Because of large temporal and spatial variability in the soil-atmosphere exchange of trace gases, the measurement of the absolute amount and prediction of the changes of these fluxes, as they are impacted by global change on regional and global scales, is still difficult. In recent years, however, much progress has been made in decreasing the uncertainty of field scale flux measurements, and efforts are being directed to large scale field and modeling programs. This paper briefly relates soil process and issues akin to the soil-atmosphere exchange of CO₂, CH₄, and N₂O. The impact of climate change, particularly increasing atmospheric CO₂ concentrations, on soil processes is also briefly discussed.

Mousseau, M. 1993. Effects of elevated CO₂ on growth, photosynthesis and respiration of sweet chestnut (*Castanea-sativa* Mill). *Vegetatio* 104:413-419.

Two year old sweet chestnut seedlings (*Castanea sativa* Mill) were grown in pots at ambient (350 $\mu\text{mol}\cdot\text{mol}^{-1}$) and double (700 $\mu\text{mol}\cdot\text{mol}^{-1}$) atmospheric CO₂ concentration in constantly ventilated greenhouses during entire growing seasons. CO₂ enrichment caused either no significant change or a decrease in shoot growth response, depending on yearly weather condition either reduced or unchanged under elevated CO₂. However, when grown under controlled conditions in a growth chamber, leaf area was enlarged with elevated CO₂. The CO₂ exchanges of whole plants were measured during the growing season. In elevated CO₂, net photosynthetic rate was maximum in May and then decreased, reaching the level of the control at the end of the season. End of night dark respiration of enriched plants was significantly lower than that of control plants; this difference decreased with time and became negligible in the fall. The original CO₂ level acted instantaneously on the respiration rate: a double concentration in CO₂ decreased the respiration of control plants and a reduced concentration enhanced the respiration of enriched plants. The carbon balance of a chestnut seedling may then be modified in elevated CO₂ by increased carbon inputs and decreased carbon outputs.

Mousseau, M., and B. Saugier. 1992. The direct effect of increased CO₂ on gas-exchange and growth of forest tree species. *Journal of Experimental Botany* 43(253):1121-1130.

CO₂ enrichment of the atmosphere is now well documented and its effect on the growth of world forests is being questioned by the scientific community. The direct effects of increased CO₂ on tree species are reviewed: the different experimental approaches are described, as well as the principal results already obtained. Short-term experiments have shown an increased photosynthetic rate, as predicted by leaf models. In longer experiments this increase is reduced after a few weeks or months by mechanisms that remain to be found. Elevated CO₂ seems to decrease the dark respiration rate, but the results are still controversial. Biomass partitioning in elevated CO₂ is clearly related to the mineral supply of the trees: An increase in root investment in elevated CO₂ is related to a poor mineral status. The mineral content of trees grown in elevated CO₂ is generally lowered compared to controls. No general rule has yet been found for the effect of increased CO₂ on leaf area development. The paper emphasizes large areas of ignorance: the reasons for the different responses of different species, which may be related to their developmental strategies, are largely ignored. Much experimental effort is needed to parameterize all the physiological processes which are susceptible to change with an increase in atmospheric CO₂, leading to a change in forest tree growth.

Moya, T.B., L.H. Ziska, O.S. Namuco, and D. Olszyk. 1998. Growth

dynamics and genotypic variation in tropical, field- grown paddy rice (*Oryza sativa* L.) in response to increasing carbon dioxide and temperature. *Global Change Biology* 4(6):645-656.

While previous studies have examined the growth and yield response of rice to continued increases in CO₂ concentration and potential increases in air temperature, little work has focused on the long-term response of tropical paddy rice (i.e. the bulk of world rice production) in situ, or genotypic differences among cultivars in response to increasing CO₂ and/or temperature. At the International Rice Research Institute, rice (cv IR72) was grown from germination until maturity for 4 field seasons, the 1994 and 1995 wet and the 1995 and 1996 dry seasons at three different CO₂ concentrations (ambient, ambient + 200 and ambient + 300 $\mu\text{mol}\cdot\text{mol}^{-1}$ CO₂) and two air temperatures (ambient and ambient + 4 degrees C) using open-top field chambers placed within a paddy site. Overall, enhanced levels of CO₂ alone resulted in significant increases in total biomass at maturity and increased seed yield with the relative degree of enhancement consistent over growing seasons across both temperatures. Enhanced levels of temperature alone resulted in decreases or no change in total biomass and decreased seed yield at maturity across both CO₂ levels. In general, simultaneous increases in air temperature as well as CO₂ concentration offset the stimulation of biomass and grain yield compared to the effect of CO₂ concentration alone. For either the 1995 wet and 1996 dry seasons, additional cultivars (N-22, NPT1 and NPT2) were grown in conjunction with IR72 at the same CO₂ and temperature treatments. Among the cultivars tested, N-22 showed the greatest relative response of both yield and biomass to increasing CO₂, while NPT2 showed no response and IR72 was intermediate. For all cultivars, however, the combination of increasing CO₂ concentration and air temperature resulted in reduced grain yield and declining harvest index compared to increased CO₂ alone. Data from these experiments indicate that (a) rice growth and yield can respond positively under tropical paddy conditions to elevated CO₂, but that simultaneous exposure to elevated temperature may negate the CO₂ response to grain yield; and, (b) sufficient intraspecific variation exists among cultivars for future selection of rice cultivars which may, potentially, convert greater amounts of CO₂ into harvestable yield.

Mtolera, M.S.P., J. Collen, M. Pedersen, and A.K. Semesi. 1995. Destructive hydrogen peroxide production in *Eucheuma denticulatum* (Rhodophyta) during stress caused by elevated pH, high light intensities and competition with other species. *European Journal of Phycology* 30(4):289-297.

Growth of *Eucheuma denticulatum* was studied in the field and in laboratory experiments. Field co-cultivation of E. denticulatum with the green alga *Ulva reticulata* or the seagrass *Thalassia* sp, reduced daily growth rate (DGR) of a Tanzanian and a Philippine strain of E. denticulatum by 10-100% and 10-55%, respectively, depending upon the type of water current: a unidirectional water current produced the best growth. Laboratory co-cultivation of a Tanzanian strain of E. denticulatum with U. reticulata also reduced DGR (to 8% of the control) and nitrate-nitrogen uptake rate (to < 30% of the control) of E. denticulatum and, moreover, it increased epiphytism of a red filamentous alga on E. denticulatum. E. denticulatum monoculture at pH 8.6 +/- 0.5 or at photosynthetic photon flux densities (PPFDs) higher than its growth optimum (350 +/- 50 $\mu\text{mol photons m}^{-2}\text{s}^{-1}$) also

increased epiphytism. The lack of a competitive mechanism for inorganic carbon uptake in *Eucheuma* may have contributed to its reduced growth during co-cultivation. During co-cultivation, elevated pH regimes (PH > 8.5) were created around the *Eucheuma* thalli as a result of photosynthesis, thus decreasing the concentration of CO₂ in the seawater to values around 1 μ M. As *Eucheuma* depends mainly on the CO₂ in the seawater for its growth a higher pH can cause CO₂ limitation by decreasing CO₂ concentration. Hydrogen peroxide (H₂O₂) production from the Tanzanian strain was also determined by luminol-dependent chemiluminescence. H₂O₂ production was found to increase with increased pH and PPFD (probably as a result of oxidative stress). Preincubation of plants with catalase for 5 min before addition of luminol prevented chemiluminescence, confirming H₂O₂ as the substrate of the luminol reaction. We suggest that the inefficiency of E, denticulatum in HCO₃⁻ utilisation contributes to its poor growth during field coexistence with seagrasses or *Ulva* sp. and that carbon deficiency induces H₂O₂ production in E, denticulatum.

Muchow, R.C., and T.R. Sinclair. 1991. Water deficit effects on maize yields modeled under current and greenhouse climates. *Agronomy Journal* 83(6):1052-1059.

The availability of water imposes one of the major limits on rainfed maize (*Zea mays* L.) productivity. This analysis was undertaken in an attempt to quantify the effects of limited water on maize growth and yield by extending a simple, mechanistic model in which temperature regulates crop development and intercepted solar radiation is used to calculate crop biomass accumulation. A soil water budget was incorporated into the model by accounting for inputs from rainfall and irrigation, and water use by soil evaporation and crop transpiration. The response functions of leaf area development and crop gas exchange to the soil water budget were developed from experimental studies. The model was used to interpret a range of field experiments using observed daily values of temperature, solar radiation, and rainfall or irrigation, where water deficits of varying durations developed at different stages of growth. The relative simplicity of the model and its robustness in simulating maize yields under a range of water-availability conditions allows the model to be readily used for studies of crop performance under alternate conditions. One such study, presented here, was a yield assessment for rainfed maize under possible "greenhouse" climates where temperature and atmospheric CO₂ concentration were increased. An increase in temperature combined with decreased rainfall lowered grain yield, although the increase in crop water use efficiency associated with elevated CO₂ concentration, ameliorated the response to the greenhouse climate. Grain yields for the greenhouse climates as compared to current conditions increased, or decreased only slightly, except when the greenhouse climate was assumed to result in severely decreased rainfall.

Mudrik, V.A., A.K. Romanova, B.N. Ivanov, N.S. Novichkova, and V.A. Polyakova. 1997. Effect of increased CO₂ concentration on growth, photosynthesis, and composition of *Pisum sativum* L. plants. *Russian Journal of Plant Physiology* 44(2):141-146.

Pea (*Pisum sativum* L.) plants grown for 3 weeks at 0.03 (control plants)

or 0.5% CO₂ (CO₂-plants) concentration were used to study the effects of increased CO₂ concentration on plant growth, CO₂ exchange, morphological pattern, and the content of carbohydrates and protein in plant leaves. The fresh and dry weights, the ratio of plant dry weight to the total area of its leaves and stipules, and the root/shoot dry weight ratio were 150, 42, and 24%, respectively, higher in the CO₂- plants. Protein content was similar in the leaves of CO₂- exposed and control plants, whereas the content of sugars and starch was significantly higher in the leaves of the CO₂- plants. The rate of CO₂ exchange per plant measured at 0.5% CO₂ in plants grown under this carbon dioxide concentration was 1.8 times higher than in control plants grown and measured at a low CO₂ concentration. Within the range of the studied CO₂ concentrations, the net photosynthesis measured at 0.5% CO₂ in the plants previously grown at this level of CO₂ content in the air was enhanced only due to the rise in CO₂ concentration used by plants as a substrate for carboxylation. However, in the CO₂-plants, the rate of photosynthesis measured at 0.03 and 0.5% CO₂ and calculated per dry weight unit was lower than that in the control plants. The causes of limitations imposed on photosynthesis at a higher CO₂ concentration are discussed. It is proposed that accumulation of sugars induced a nonstomatal limitation of photosynthesis in the CO₂-plants. An increase in the root/shoot ratio indicates some changes in the hormonal status of plants under the influence of a high CO₂ concentration.

Muellerdombois, D. 1992. Potential effects of the increase in carbon-dioxide and climate change on the dynamics of vegetation. *Water, Air, and Soil Pollution* 64(1-2):61-79.

The continued CO₂ loading of the atmosphere appears to be responsible for inducing three new force factors controlling dynamic changes in the world's vegetation. They come from (1) enhanced fertilization with the single most important plant nutrient, (2) the widely expected global temperature increase, and (3) aggravated weather disturbances. Increased CO₂ absorption may enhance plant growth but it may also increase soil-nutrient limitations. It surely will enhance the metabolism of forest trees similarly as global warming will enhance plant metabolism, but both factors may also shorten the lifespan of perennial plants. Increased weather disturbances can be expected to produce new physiological stresses on the standing vegetation, particularly on habitats with poor soils. Since wide-spread forest decline has been reported from both the Atlantic and Pacific region, it seems possible that the roughly synchronic mass mortality of trees during the past two decades is related to the global increase in CO₂. The paper gives an overview of forest decline and dieback as known from past and present research and suggests how the changing atmospheric environment may interact in this widely observed contemporary Phenomenon of vegetation dynamics.

Mulchi, C., B. Rudorff, E. Lee, R. Rowland, and R. Pausch. 1995. Morphological responses among crop species to full-season exposures to enhanced concentrations of atmospheric CO₂ and O₃. *Water, Air, and Soil Pollution* 85(3):1379-1386.

Field studies using open-top chambers were conducted at USDA- BARC involving the growth of soybeans ('89 & '90), wheat ('91 & '92), and corn ('91), under increased concentrations of atmospheric CO₂ and O₃. Treatment responses were compared in all cases to plants grown in charcoal-filtered (CF) air (seasonal 7-h mean = 25 $\pm$ 3 n mol O₃ mol(-1)) having 350 or 500 μ mol CO₂ mol(-1). Elevated seasonal O₃

levels for the soybean, wheat, and corn studies averaged 72.2 $\pm$ 4, 62.7 $\pm$ 2, and 70.2 n mol O-3 mol(-1), respectively. Results presented were obtained for plants grown in silt loam soil under well-watered conditions. Grain yield increases in response to elevated CO₂ in the absence of O-3 stress averaged 9.0, 12.0, and 1.0% for soybean, wheat, and corn, respectively. Reductions in grain yields in response to the elevated O-3 treatments at 350 μ mol CO₂ mol(-1) averaged 20.0, 29.0 and 13.0% for soybean, wheat, and corn, respectively. Reductions in grain yields in response to elevated O-3 at 500 μ mol CO₂ mol(-1) averaged 20.0, 8.0, and 7.0% for soybean, wheat, and corn, respectively. Dry biomass and harvest index in wheat were significantly reduced by O-3 stress at 350 μ mol mol(-1) CO₂ but not at 500 μ mol mol(-1) CO₂. Seed weight 1000(-1) for soybeans and wheat was significantly increased by CO₂ enrichment and decreased by O-3 stress. Seed weight 1000(-1) in corn was increased by O-3 stress suggesting that O-3 affected pollination resulting in fewer kernels per ear.

Mulholland, B.J., J. Craigon, C.R. Black, J.J. Colls, J. Atherton, and G. Landon. 1997. Effects of elevated carbon dioxide and ozone on the growth and yield of spring wheat (*Triticum aestivum* L.). *Journal of Experimental Botany* 48(306):113-122.

Spring wheat cv. Minaret was grown under three carbon dioxide (CO₂) and two ozone (O-3) concentrations from seedling emergence to maturity in open-top chambers. Under elevated CO₂ concentrations, the green leaf area index of the main shoot was increased, largely due to an increase in green leaf area duration. Biomass increased linearly in response to increasing CO₂ (ambient, 550 and 680 ppm). At anthesis, stem and ear dry weights and plant height were increased by up to 174%, 5% and 9 cm, respectively, and biomass at maturity was 23% greater in the 680 ppm treatment as compared to the ambient control. Grain numbers per spikelet and per ear were increased by 0.2 and 5 grains, respectively, and this, coupled with a higher number of ears bearing tillers, increased grain yield by up to 33%. Exposure to a 7 h daily mean O-3 concentration of 60 ppb induced premature leaf senescence during early vegetative growth (leaves 1-7) under ambient CO₂ concentrations. Damage to the main shoot and possible seedling mortality during the first 3 weeks of exposure altered canopy structure and increased the proportion of tillers 1 and 2 which survived to produce ears at maturity was increased; as a result, grain yield was not significantly affected. In contrast to the older leaves, the flag leaf (leaf 8) sustained no visible O-3 damage, and mean grain yield per ear was not affected. Interactions between elevated CO₂ and O-3 influenced the severity of visible leaf damage (leaves 1-7), with elevated CO₂ apparently protecting against O-3-induced premature senescence during early vegetative growth. The data suggest that the flag leaf of Minaret, a major source of assimilate during grain fill, may be relatively insensitive to O-3 exposure. Possible mechanisms involved in damage and/or recovery are discussed.

Mulholland, B.J., J. Craigon, C.R. Black, J.J. Colls, J. Atherton, and G. Landon. 1997. Impact of elevated atmospheric CO₂ and O-3 on gas exchange and chlorophyll content in spring wheat (*Triticum aestivum* L.). *Journal of Experimental Botany* 48(315):1853-1863.

Stands of spring wheat grown in open-top chambers (OTCs) were used to assess the individual and interactive effects of season-long exposure to elevated atmospheric carbon dioxide (CO₂) and ozone (O-3) on the photosynthetic and gas exchange properties of leaves of differing age

and position within the canopy. The observed effects were related to estimated ozone fluxes to individual leaves. Foliar chlorophyll content was unaffected by elevated CO₂, but photosynthesis under saturating irradiances was increased by up to 100% at 680 μ mol mol(-1) CO₂ relative to the ambient CO₂ control; instantaneous water use efficiency was improved by a combination of increased photosynthesis and reduced transpiration. Exposure to a seasonal mean O-3 concentration (7 h d(-1)) of 84 nmol mol(-1) under ambient CO₂ accelerated leaf senescence following full expansion, at which time chlorophyll content was unaffected. Stomatal regulation of pollutant uptake was limited since estimated O-3 fluxes to individual leaves were not reduced by elevated atmospheric CO₂. A common feature of O-3-treated leaves under ambient CO₂ was an initial stimulation of photosynthesis and stomatal conductance for up to 4 d and 10 d, respectively, after full leaf expansion, but thereafter both variables declined rapidly. The O-3-induced decline in chlorophyll content was less rapid under elevated CO₂ and photosynthesis was increased relative to the ambient CO₂ treatment. A/C-i analyses suggested that an increase in the amount of in vivo active RuBisCO may be involved in mitigating O-3-induced damage to leaves. The results obtained suggest that elevated atmospheric CO₂ has an important role in restricting the damaging effects of O-3 on photosynthetic activity during the vegetative growth of spring wheat, and that additional direct effects on reproductive development were responsible for the substantial reductions in grain yield obtained at final harvest, against which elevated CO₂ provided little or no protection.

Mulholland, B.J., J. Craigon, C.R. Black, J.J. Colls, J. Atherton, and G. Landon. 1998. Effects of elevated CO₂ and O-3 on the rate and duration of grain growth and harvest index in spring wheat (*Triticum aestivum* L.). *Global Change Biology* 4(6):627-635.

Wheat (*Triticum aestivum* L.) cv. Minaret was grown in open-top chambers (OTCs) in 1995 and 1996 under three carbon dioxide (CO₂) and two ozone (O-3) levels. Plants were harvested regularly between anthesis and maturity to examine the rate of grain growth (dG/dt; mg d(-1)) and the rate of increase in harvest index (dHI/dt; % d(-1)). The duration of grain filling was not affected by elevated CO₂ or O-3, but was 12 days shorter in 1995, when the daily mean temperature was over 3 degrees C higher than in 1996. Season-long exposure to elevated CO₂ (680 μ mol mol(-1)) significantly increased the rate of grain growth in both years and mean grain weight at maturity (MGW) was up to 11% higher than in the chambered ambient air control (chAA; 383 μ mol mol(-1)). However, the increase in final yield obtained under elevated CO₂ relative to the chAA control in 1996 resulted primarily from a 27% increase in grain number per unit ground area. dG/dt was significantly reduced by elevated O-3 under ambient CO₂ conditions in 1995, but final grain yield was not affected because of a concurrent increase in grain number. Neither dG/dt nor dHI/dt were affected by the higher mean O-3 concentrations applied in 1996 (77 vs. 66 nmol mol(-1)); the differing effects of O-3 on grain growth in 1995 and 1996 observed in both the ambient and elevated CO₂ treatments may reflect the contrasting temperature environments experienced. Grain yield was nevertheless reduced under elevated O-3 in 1996, primarily because of a substantial decrease in grain number. The data obtained show that, although exposure to elevated CO₂ and O-3 individually or in combination may affect both dG/dt and dHI/dt, the presence of elevated CO₂ does not protect against substantial O-3-induced yield losses resulting from its direct deleterious impact on reproductive processes. The implications of these results for food production under future climatic conditions are considered.

Mulholland, B.J., J. Craigon, C.R. Black, J.J. Colls, J. Atherton, and G. Landon. 1998. Growth, light interception and yield responses of spring wheat (*Triticum aestivum* L.) grown under elevated CO₂ and O-3 in open-top chambers. *Global Change Biology* 4(2):121-130.

Spring wheat cv. Minaret was grown to maturity under three carbon dioxide (CO₂) and two ozone (O-3) concentrations in open-top chambers (OTC). Green leaf area index (LAI) was increased by elevated CO₂ under ambient O-3 conditions as a direct result of increases in tillering, rather than individual leaf areas. Yellow LAI was also greater in the 550 and 680 $\mu\text{mol mol}^{-1}$ CO₂ treatments than in the chambered ambient control; individual leaves on the main shoot senesced more rapidly under 550 $\mu\text{mol mol}^{-1}$ CO₂, but senescence was delayed at 680 $\mu\text{mol mol}^{-1}$ CO₂. Fractional light interception (f) during the vegetative period was up to 26% greater under 680 $\mu\text{mol mol}^{-1}$ CO₂ than in the control treatment, but seasonal accumulated intercepted radiation was only increased by 8%. As a result of greater carbon assimilation during canopy development, plants grown under elevated CO₂ were taller at anthesis and stem and ear biomass were 27 and 16% greater than in control plants. At maturity, yield was 30% greater in the 680 $\mu\text{mol mol}^{-1}$ CO₂ treatment, due to a combination of increases in the number of ears per m², grain number per ear and individual grain weight (IGW). Exposure to a seasonal mean (7 h d⁻¹) of 84 nmol mol^{-1} O-3 under ambient CO₂ decreased green LAI and increased yellow LAI, thereby reducing both f and accumulated intercepted radiation by approximately 16%. Individual leaves senesced completely 7-28 days earlier than in control plants. At anthesis, the plants were shorter than controls and exhibited reductions in stem and ear biomass of 15 and 23%. Grain yield at maturity was decreased by 30% due to a combination of reductions in ear number m⁻², the numbers of grains per spikelet and per ear and IGW. The presence of elevated CO₂ reduced the rate of O-3-induced leaf senescence and resulted in the maintenance of a higher green LAI during vegetative growth under ambient CO₂ conditions. Grain yields at maturity were nevertheless lower than those obtained in the corresponding elevated CO₂ treatments in the absence of elevated O-3. Thus, although the presence of elevated CO₂ reduced the damaging impact of ozone on radiation interception and vegetative growth, substantial yield losses were nevertheless induced. These data suggest that spring wheat may be susceptible to O-3-induced injury during anthesis irrespective of the atmospheric CO₂ concentration. Possible deleterious mechanisms operating through effects on pollen viability, seed set and the duration of grain filling are discussed.

Muller, C., W. Reuter, W. Wehrmeyer, H. Dau, and H. Senger. 1993. Adaptation of the photosynthetic apparatus of *Anacystis nidulans* to irradiance and CO₂-concentration. *Botanica Acta* 106(6):480-487.

Homocontinuous cultures of the cyanobacterium *Anacystis nidulans* (syn. *Synechococcus* sp. PCC 6301) were grown at white light intensities of 2 and 20 W/m², and supplied with 0.03 and 3 % CO₂ enriched air. The mutual influence of these growth factors on the development of the photosynthetic apparatus was studied by analyses of the pigment content, by low temperature absorbance and fluorescence spectroscopy, by analyses of oxygen evolution light-saturation curves,

and by SDS PAGE of isolated phycobilisomes. The two growth factors, light and CO₂, distinctly affect the absorption cross section of the photosynthetic apparatus, which is expressed by its pigment pattern, excitation energy distribution and capacity. In response to low CO₂ concentrations, the phycocyanin/allophycocyanin ratios were lower and one linker polypeptide L(R)30, of the phycobilisomes was no longer detectable in SDS PAGE. Apparently, low CO₂ adaptation results in shorter phycobilisome rods. Specifically, upon adaptation to low light intensities, the chlorophyll and the phycocyanin content on a per cell basis increase by about 50 % suggesting a parallel increase in the amount of phycobilisomes and photosystem core-complexes. Low light adaptation and low CO₂ adaptation both cause a shift of the excitation energy distribution in favor of photosystem I. Variations in the content of the "anchor" polypeptides L(CM)60 and L(CM)75 are possibly related to changes in the excitation energy transfer from phycobilisomes to the photosystem II and photosystem I core-complexes.

Muller, J. 1993. Dry-matter production, CO₂ exchange, carbohydrate and nitrogen-content of winter-wheat at elevated CO₂ concentration and drought stress. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 171(4):217-235.

Methods of mathematical modelling and simulation are being used to an increasing degree in estimating the effects of rising atmospheric CO₂ concentration and changing climatic conditions on agricultural ecosystems. In this context, detailed knowledge is required about the possible effects on crop growth and physiological processes. To this aim, the influence of an elevated CO₂ concentration and of drought stress on dry matter production, CO₂ exchange, and on carbohydrate and nitrogen content was studied in two winter wheat varieties from shooting to milk ripeness. Elevated CO₂ concentration leads to a compensation of drought stress and at optimal water supply to an increase of vegetative dry matter and of yield to the fourfold value. This effects were caused by enhanced growth of secondary tillers which were reduced in plants cultivated at atmospheric CO₂ concentration. Analogous effects in the development of ear organs were influenced additionally by competitive interactions between the developing organs. The content and the mass of ethanol soluble carbohydrates in leaves and stems were increased after the CO₂ treatment and exhausted more completely during the grain filling period after drought stress. Plants cultivated from shooting to milk ripeness at elevated CO₂ concentration showed a reduced response of net photosynthesis rate to increasing CO₂ concentration by comparison with untreated plants.

Muller, M., D. Grill, and H. Guttenger. 1994. The effects of interactions between ozone and CO₂ on the chromosomes of Norway spruce root-meristems. *Phyton-Annales Rei Botanicae* 34(2):321-335.

A Norway spruce (*Picea abies* (L.) Karsten) test system was used to study the immediate and after effects of increased ozone or elevated CO₂ or both, on root tip chromosomes. Five-year-old potted spruce trees were exposed in environmental chambers to elevated concentrations of ozone (0.1 cm³m⁻³) for the study of an immediate effect and to elevated concentrations of carbon dioxide (750 cm³m⁻³) and ozone (0.08 cm³m⁻³)

3) as single variables or in combination and then transferred to a field for the observation of an after effect. Elevated ozone caused an increased number of chromosomal abnormalities directly after finishing the fumigation and also 21 months later. Elevated CO₂ more likely induced a decrease rather than an increase in the number of chromosomal aberrations. The most common abnormalities were chromosome stickiness, in the form of connections, clumped metaphases and amorphous chromatin masses. An increased number of chromosomal aberrations especially chromosome stickiness reflects highly toxic effects, usually of an irreversible type leading to cell death.

Munoz, M.T., P. Aguado, N. Ortega, M.I. Escibano, and C. Merodio. 1999. Regulation of ethylene and polyamine synthesis by elevated carbon dioxide in cherimoya fruit stored at ripening and chilling temperatures. *Australian Journal of Plant Physiology* 26(3):201-209.

In this study we focused on the effect of high CO₂ level (20%) on ethylene and polyamine biosynthesis in cherimoya (*Annona cherimola* Mill.) fruits stored at ripening (20 degrees C) and chilling (6 degrees C) temperatures. At ripening temperature, CO₂ inhibited ethylene production, but 1-aminocyclopropane-1- carboxylate (ACC) oxidase activity was similar to that in ripe control fruits. CO₂ treatment led to a decline in putrescine (Put) and a major accumulation of spermidine (Spd) and spermine (Spm) without any effect on arginine decarboxylase (ADC) activity. These results confirm the preferential transformation of Put to Spd and Spm in CO₂-treated fruits. At chilling temperature, the increase in ACC oxidase activity was inhibited and the V-max of ADC increased. A combination of chilling temperature storage and high CO₂ level led to suppression of basal ethylene production while ACC oxidase activity remained unchanged. In addition, fruits held at these conditions had higher polyamine titres than the untreated control. We propose that, in CO₂-treated fruits, the absence of autocatalytic or basal ethylene production, depending on the temperature, may be due to deviation of the S-adenosylmethionine (SAM) pool towards polyamine synthesis, primarily Spd and Spm.

Munoz, M.T., M.I. Escibano, and C. Merodio. 1997. Ethanol metabolism in cherimoya fruit during storage at ambient and under high CO₂ atmospheres. *Journal of Horticultural Science* 72(3):363-370.

Cherimoya fruits (*Annona cherimola*, Mill.) were kept in 20% O₂ + 20% CO₂ for UP to 3 d at 20 degrees C and then transferred to air to study the effect of high CO₂ levels on fermentation enzymes, ethanol and acetaldehyde content and ripening evolution. Ethanol and acetaldehyde content increased during ripening in air mainly associated with the first respiration peak. At the end of the short-term high CO₂ treatment, cherimoya fruit had a lower aerobic respiration rate while concentrations of acetaldehyde and ethanol were greatly increased compared with those of air-control fruit. The activation of fermentation pathway by high CO₂ atmosphere is mainly due to an enhancement in pyruvate decarboxylase (PDC) activity. High CO₂ treatment prevented the ripening process but, after transfer to air a decrease in fermentation metabolism was recorded and fruit was able to ripen, showing a typical decrease in tissue pH.

Murage, E.N., N. Watashiro, and M. Masuda. 1996. Leaf chlorosis and carbon metabolism of eggplant in response to continuous light and carbon dioxide. *Scientia Horticulturae* 67(1-2):27-37.

Leaf chlorosis and carbon metabolism were examined in the youngest fully expanded leaves of eggplants (*Solanum melongena* L. cultivar 'Senryo') grown starting from the third true leaf stage (acropetally) under 12-h and 24-h (continuous) light periods for 6 days, and under continuous illumination with either 0, 6 or 12 h of carbon dioxide (CO₂)-free air per day for 10 days at a photosynthetic photon flux density (PPFD) of 100 $\mu\text{mol m}^{-2} \text{s}^{-1}$. The amount of (CO₂)-C-13 assimilated under continuous light was lower on Day 3 and declined even further on Day 6. On the contrary, starch accumulation and the levels of glucose and fructose were highest under continuous illumination and were at their maximum on the fourth day. However, no difference was observed in the amount of leaf sucrose formed in the 12- and 24-h light treatments. Leaves of plants continuously lit developed leaf chlorosis starting from the fourth day. Growing plants with 12 h of CO₂-free air per day drastically reduced the amounts of starch and sugar accumulated in the leaves, inhibited the development of chlorosis and enhanced the chlorophyll content. With either the 6 or 0 h of CO₂-free air per day, the plants grew better but the leaves accumulated large amounts of starch and sugars and finally developed mild and severe chlorosis, respectively. The results strongly implicated the involvement of carbon metabolism in the predisposition of leaf chlorosis observed under continuous light.

Murakami, A., S.J. Kim, and Y. Fujita. 1997. Changes in photosystem stoichiometry in response to environmental conditions for cell growth observed with the cyanophyte *Synechocystis* PCC 6714. *Plant and Cell Physiology* 38(4):392-397.

Changes in photosystem stoichiometry in response to shift of environments for cell growth other than light regime were studied with the cyanophyte *Synechocystis* PCC 6714 in relation to the change induced by light-quality shift. Following two environment-shifts were examined: the shift of molecular form of inorganic carbon source for photosynthesis from CO₂ to HCO₃⁻ (CO₂ stress) and the increase in salinity of the medium with NaCl (0.5 M) (Na⁺ stress). Both CO₂ and Na⁺ stresses induced the increase in PSI abundance resulting in a higher PSI/PSII stoichiometry. CO₂ stress was found to elevate simultaneously Cyt c oxidase activity (V-max). The feature was the same as that caused by light-quality shift from preferential excitation of PSI to PSII (light stress) though the enhancement by either stress was smaller than that by light stress. Under our experimental conditions, PSI/PSII stoichiometry appeared to increase at a fairly constant rate to the basal level even when the basal level had been differently determined by the light- quality. Enhancing rates for PSI/PSII stoichiometry and for Cyt c oxidase activity were also similar to each other. Since the two stresses affect the thylakoid electron transport similarly to the shift of light-quality, we interpreted our results as follows: three environmental stresses, CO₂, Na⁺, and light stresses, cause changes in electron turnover capacity of PSI and Cyt c oxidase under a similar, probably a common, mechanism for monitoring redox state of thylakoid electron transport system.

Murchie, E.H., and P. Horton. 1997. Acclimation of photosynthesis to irradiance and spectral quality in British plant species: Chlorophyll content, photosynthetic capacity and habitat preference. *Plant, Cell and Environment* 20(4):438-448.

Twenty-two common British angiosperms were examined for their ability to acclimate photosynthetically to sun and shade conditions. Plants were grown under low irradiance, far-red enriched light (50 $\mu\text{mol m}^{-2} \text{s}^{-1}$), selected to mimic as closely as possible natural canopy shade, and moderately high light of insufficient irradiance to induce photoinhibitory or photoprotective responses (300 $\mu\text{mol m}^{-2} \text{s}^{-1}$). Light- and CO_2 -saturated photosynthetic rates of m s^{-1} oxygen evolution (P_{max}) and chlorophyll content were measured. Large variation was found in both parameters, and two 'strategies' for long-term acclimation were identified: firstly a change in chlorophyll per unit leaf area which was found to correlate positively with photosynthetic capacity, and secondly changes in chlorophyll a/b ratio and P_{max} , indicative of alterations at the chloroplast level, which were not associated with a change in chlorophyll content per unit leaf area. Combinations of these two strategies may occur, giving rise to the observed diversity in photosynthetic acclimation. The extent and nature of photosynthetic acclimation were compared with an index of shade association, calculated from the association each species has with woodland. It was found that the greatest flexibility for change at the chloroplast level was found in those species possessing an intermediate shade association, whilst acclimation in 'sun' species proceeded by a change in chlorophyll content; obligate shade species showed little capacity for acclimation at either the chloroplast or leaf level. A framework for explaining the variation between plant species in leaf-level photosynthetic capacity, in relation to the natural light environment, is presented. This is the first time the potential for light acclimation of photosynthesis in different plant species has been satisfactorily linked to habitat distribution.

Murchie, E.H., C. Sarrobert, P. Contard, T. Betsche, C.H. Foyer, and N. Galtier. 1999. Overexpression of sucrose-phosphate synthase in tomato plants grown with CO_2 enrichment leads to decreased foliar carbohydrate accumulation relative to untransformed controls. *Plant Physiology and Biochemistry* 37(4):251-260.

Tomato plants expressing the maize sucrose-phosphate synthase (SPS) cDNA under the control of the promoter of the small subunit of ribulose-1,5-bisphosphate carboxylase oxygenase (rbcS) promoter were grown 5 weeks in air (450 $\mu\text{mol m}^{-2} \text{s}^{-1}$ irradiance, 350 ppm CO_2) and then either maintained in air or exposed to CO_2 enrichment (1 000 ppm CO_2) for 8 d. A linear relationship between the foliar sucrose to starch ratio and maximal extractable SPS activity was found both in air and high CO_2 . Starch accumulation was dramatically increased in all plants subjected to CO_2 enrichment but the CO_2 -dependent increase in foliar starch accumulation was much lower in the leaves of the SPS transformants than in those of the untransformed controls in the same conditions. Maximal extractable ribulose-1,5-bisphosphate carboxylase/oxygenase activity was reduced by growth at high CO_2 to a similar extent in both plant types. The carbon/nitrogen ratios were similar in both plant lines in both growth conditions after 20 d exposure to high CO_2 . A small (5 %) increase in carbon export capacity was observed at high CO_2 in the leaves of transformed plants compared to leaves from untransformed controls. Increased foliar SPS activity did not, however,

prevent acclimation of photosynthesis in plants grown with long-term CO_2 enrichment. (C) Elsevier, Paris.

Murphy, K.P., J.M. Santamaria, W.J. Davies, and P.J. Lumsden. 1998. Ventilation of culture vessels. I. Increased growth in vitro and survival ex vitro of Delphinium. *Journal of Horticultural Science & Biotechnology* 73(6):725-729.

Inclusion of small circular apertures covered with filters in the sides of plastic culture vessels led to a small but significant increase in the multiplication rate of Delphinium cultured in vitro and greater survival following transfer ex vitro. Filters had no effect on the multiplication rate and survival of Hosta. In vessels with apertures there was a large increase in the rate of water loss, but relative humidity was greater than 95% in both intact vessels and in vessels with filters. It is suggested that in vessels with apertures there was an increase in the flow of water vapour from the vessel atmosphere to the external atmosphere, due to a reduced diffusive resistance. The improved performance of Delphinium plants could have resulted from an increase in transpiration and movement of water (and therefore some nutrients) through the plants.

Murray, D.R. 1995. Plant-responses to carbon-dioxide. *American Journal of Botany* 82(5):690-697.

The average atmospheric concentration of CO_2 will probably double before the end of next century. Many of the consequences for plant growth can and should be determined now. In this review the effects of $[\text{CO}_2]$ on a variety of plant processes are summarized: stomatal opening and closing; stomatal density; respiration; root morphogenesis; and flowering. The effects of growth under elevated $[\text{CO}_2]$ on crop yield and seed composition are also discussed. Adverse effects on the composition of C-3 cereal grains are clearly indicated.

Murray, M.B., I.D. Leith, and P.G. Jarvis. 1996. The effect of long term CO_2 enrichment on the growth, biomass partitioning and mineral nutrition of Sitka spruce (*Picea sitchensis* (Bong) Carr). *Trees-Structure and Function* 10(6):393-402.

Sitka spruce [*Picea sitchensis* (Pong.) Carr.] seedlings were grown for 3 years in an outside control plot or in ambient (similar to 355 $\mu\text{mol mol}^{-1}$) or elevated (ambient + 350 $\mu\text{mol mol}^{-1}$) atmospheric CO_2 environments, within open top chambers (OTCs) at the Institute of Terrestrial Ecology, Edinburgh. Sequential harvests were carried out at the end of each growing season and throughout the 1991 growing season, five in all. Plants grown in elevated CO_2 had, (i) 35 and 10% larger root/shoot ratios at the end of the first and third season, respectively, (ii) significantly higher summer leader extension relative growth rates, which declined more rapidly in early autumn than ambient grown plants, (iii) after three growing seasons a significantly increased

mean annual relative growth rate, (iv) consistently lower foliar nutrient concentrations, and (v) after two growing seasons smaller total projected needle areas. Plants grown inside OTCs were taller, heavier and had a smaller root/shoot ratio than those grown outside the chambers. There was no effect of CO₂ concentration on Sitka spruce leaf characteristics, although leaf area ratio, specific leaf area and leaf weight ratio all fell throughout the course of the 3 year experiment.

Murray, M.B., R.I. Smith, I.D. Leith, D. Fowler, H.S.J. Lee, A.D. Friend, and P.G. Jarvis. 1994. Effects of elevated CO₂, nutrition and climatic warming on bud phenology in Sitka spruce (*Picea sitchensis*) and their impact on the risk of frost damage. *Tree Physiology* 14(7-9):691-706.

Effects of elevated CO₂, clone and plant nutrition on bud dormancy of Sitka spruce (*Picea sitchensis* (Bong.) Carr.) were examined. Sitka spruce seedlings were fumigated with ambient or elevated (ambient + 350 $\mu\text{mol mol}^{-1}$) concentrations of CO₂ in open-top chambers for three growing seasons. In 1991 and 1992, elevated CO₂ delayed bud burst in the spring and advanced bud set in the autumn. The effect of the open-top chamber on the thermal requirement for bud burst was greater than the effect of elevated CO₂ (50 and 30 day degrees (D(d)), respectively). In a second study, four clones of Sitka spruce taken from two provenances, at 43 and 54-degrees-N, were fumigated with ambient or elevated CO₂. There was a large natural variation in the timing of bud burst and bud set among the clones. Elevated CO₂ had no effect on bud dormancy of the Skidegate a clone, but it reduced the growing season of the North Bend b clone by 20 days. In a third study, Sitka spruce seedlings growing in ambient or elevated CO₂, were supplied with one of three nutrient regimes, low (0.1 x potential), medium (0.5 x potential) or high (2.0 x potential), using a method and solution based on the Ingestad technique. Elevated CO₂ did not affect bud dormancy in the high-nutrient treatment, but it reduced the growing season of plants in the low-nutrient treatment by 22 days. Increasing plant nutrient supply lengthened the growing season, plants flushed earlier in the spring and set bud later in the autumn. The effects of elevated CO₂ plus a 0, 2 or 4-degrees-C climatic warming on the timing of bud burst and the subsequent risk of frost damage were assessed using a simulation model and meteorological data from three sites, Edinburgh, Braemar and Masset. The model predicted that (i) doubling the CO₂ concentration in the absence of climatic warming, will delay the onset of bud burst at all three sites, (ii) climatic warming in ambient CO₂ will hasten bud burst and (iii) climatic warming in elevated CO₂ will hasten bud burst at Edinburgh and Braemar but to a lesser extent than climatic warming alone. At Masset, a 4-degrees-C warming was required to advance the date of bud burst of seedlings in the elevated CO₂ treatment. At all three sites, elevated CO₂ and climatic warming increased the mean daily temperature on the date of bud burst, thus reducing the risk of subsequent frost damage.

Murthy, R., and P.M. Dougherty. 1997. Effect of carbon dioxide, fertilization and irrigation on loblolly pine branch morphology. *Trees-Structure and Function* 11(8):485-493.

Foliage and wood parameters of branches of 12-year-old loblolly pine (*Pinus taeda* L.) trees were characterized after 21 months of exposure to fertilizer, irrigation and elevated CO₂ treatments. Branches of loblolly pine trees were enclosed in plastic chambers and exposed to ambient,

ambient +175 and ambient +350 $\mu\text{mol mol}^{-1}$ CO₂ concentrations. Measurements of foliage and wood at the fascicle, flush and branch levels were made at the end of the 21 month study period. The +350 CO₂ treatment did not significantly increase fascicle radius or length but did increase the number of fascicles on the first flush. Fertilization significantly increased fascicle radius and length, while irrigation significantly increased number of fascicles and flush length of first flush. The +350 CO₂ treatment also significantly increased flush length of the first flush. Significant interaction of fertilization and irrigation with CO₂ was observed for fascicle length. Significant interactions of fertilization and irrigation were also observed for flush length, number of fascicles and fascicle length. Observed increases in fascicle radius, fascicle length, number of fascicles and flush length may have been responsible for the significantly higher flush leaf area observed for the all three treatments. Also, a combination of fertilization and irrigation increased leaf area by 82% compared to that in the control when averaged across CO₂ treatments. At the branch level +350 CO₂ treatment significantly increased shoot length but not the number of flushes on the branch. In general with the exception of bark density and total number of needle scales, neither fertilization nor irrigation had any significant effect on other branch level parameters. Results from this study indicate that with 'global change' an increase in CO₂ alone may increase leaf area via an increase in flush length and number of fascicles. Combining increases in CO₂ with fertilization and irrigation could greatly enhance leaf area which when coupled to observed increases in net photosynthesis as a result of elevated CO₂ could greatly increase productivity of loblolly pine trees.

Murthy, R., P.M. Dougherty, S.J. Zarnoch, and H.L. Allen. 1996. Effects of carbon dioxide, fertilization, and irrigation on photosynthetic capacity of loblolly pine trees. *Tree Physiology* 16(6):537-546.

Branches of nine-year-old loblolly pine trees grown in a 2 x 2 factorial combination of fertilization and irrigation were exposed for 11 months to ambient, ambient + 175, or ambient + 350 $\mu\text{mol mol}^{-1}$ CO₂. Rates of light-saturated net photosynthesis (A(max)), maximum stomatal conductance to water vapor (g(max)), and foliar nitrogen concentration (% dry mass) were assessed monthly from April 1993 until September 1993 on 1992 foliage (one-year-old) and from July 1993 to March 1994 on 1993 foliage (current-year). Rates of A(max) of foliage in the ambient + 175 CO₂ treatment and ambient + 350 were 32-47 and 83-91% greater, respectively, than that of foliage in the ambient CO₂ treatment. There was a statistically significant interaction between CO₂ treatment and fertilization or irrigation treatment on A(max) on only one measurement date for each age class of foliage. Light-saturated stomatal conductance to water vapor (g(max)) was significantly affected by CO₂ treatment on only four measurement dates. Light-saturated g(max) in winter was only 42% of summer g(max) even though soil water during winter was near field capacity and evaporative demand was low. Fertilization increased foliar N concentration by 30% over the study period when averaged across CO₂ treatments. During the study period, the ambient + 350 CO₂ treatment decreased average foliar N concentration of one-year-old foliage in the control, irrigated, fertilized and irrigated + fertilized plots by 5, 6.4, 9.6 and 11%, respectively, compared with one-year-old foliage in the corresponding ambient CO₂ treatments. The percent increase in A(max) due to CO₂ enrichment was similar in all irrigation and fertilization treatments and the effect persisted throughout the 11-month study period for both one-year-old and current-year foliage.

Murthy, R., S.J. Zarnoch, and P.M. Dougherty. 1997. Seasonal trends of light-saturated net photosynthesis and stomatal conductance of loblolly pine trees grown in contrasting environments of nutrition, water and carbon dioxide. *Plant, Cell and Environment* 20(5):558-568.

Repeated measures analysis was used to evaluate the effect of long-term CO₂ enhancement on seasonal trends of light-saturated rates of net photosynthesis (A(sat)) and stomatal conductance to water vapour (g(sat)) of 9-year-old loblolly pine (*Pinus taeda* L.) trees grown in a 2 x 2 factorial experimental design of nutrition and water. A significant interaction effect of CO₂ and nutrition on mean A(sat) was observed for juvenile foliage. Also, juvenile foliage exposed to + 350 $\mu\text{mol mol}^{-1}$ CO₂ had a higher rate of increase of A(sat) between late summer and early autumn. This would lead to a greater potential for recharging carbohydrate reserves for winter. Mature foliage was affected by CO₂, water and nutrient treatments in two ways. First, A(sat) was significantly increased as a result of elevated CO₂ in January, a period when stomatal conductance was only 47% of the maximum observed rate. Secondly, the rate of increase of A(sat) from winter to early spring was accelerated as a result of both nutrient + water and + 350 $\mu\text{mol mol}^{-1}$ CO₂ treatments. This accelerated response resulted in a greater potential for photosynthate production during the period when growth initiation occurred. Nutrient, water or carbon dioxide treatments did not significantly alter trends in g(sat) for mature or juvenile foliage. A significant nutrition x CO₂ interaction was observed for the mature foliage, suggesting that g(sat) increased with increasing CO₂ and nutrition. These results may have important consequences for the determination of the water use efficiency of loblolly pine. In spite of low g(sat) in the winter to early spring period, there was a substantial gain in A(sat) attributable to elevated CO₂ concentrations.

Muschak, M., L. Willmitzer, and J. Fisahn. 1999. Gas-exchange analysis of chloroplastic fructose-1,6-bisphosphatase antisense potatoes at different air humidities and at elevated CO₂. *Planta* 209(1):104-111.

Gas-exchange measurements were performed to analyze the leaf conductances and assimilation rates of potato (*Solanum tuberosum* L. cv. Desiree) plants expressing an antisense construct against chloroplastic fructose-1,6-bisphosphatase (FBPase, EC 3.1.3.11) in response to increasing photon flux densities, different relative air humidities and elevated CO₂ concentrations. Assimilation rates (A) and transpiration rates (E) were observed during a stepwise increase of photon flux density. These experiments were carried out under atmospheric conditions and in air containing 500 $\mu\text{mol mol}^{-1}$ CO₂. In both gas atmospheres, two levels of relative air humidity (60- 70% and 70-80%) were applied in different sets of measurements. Intercellular CO₂ concentration, leaf conductance, air-to-leaf vapour pressure deficit, and instantaneous water-use efficiency (A/E) were determined. As expected, assimilation rates of the FBPase antisense plants were significantly reduced as compared to the wild type. Saturation of assimilation rates in transgenic plants occurred at a photon flux density of 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$, whereas saturation in wild type plants was observed at 600 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Elevated ambient CO₂ levels did not effect assimilation rates of transgenic plants. At 70- 80% relative humidity and atmospheric CO₂ concentration the FBPase antisense plants had significantly higher leaf conductances than wild-

type plants while no difference. emerged at 60-70%. These differences in leaf conductance vanished at elevated levels of ambient CO₂. Stomatal response to different relative air humidities was not affected by mesophyll photosynthetic activity. It is suggested that the regulation of stomatal opening upon changes in photon flux density is merely mediated by a signal transmitted from mesophyll cells, whereas the intercellular CO₂ concentration plays a minor role in this kind of stomatal response. The results are discussed with respect to stomatal control by environmental parameters and mesophyll photosynthesis.

Musil, C.F., G.F. Midgley, and S.J.E. Wand. 1999. Carry-over of enhanced ultraviolet-B exposure effects to successive generations of a desert annual: interaction with atmospheric CO₂ and nutrient supply. *Global Change Biology* 5(3):311-329.

The performance of fifth generation offspring of a desert annual (*Dimorphotheca sinuata* DC.) were compared in the absence of UV-B, under variable atmospheric CO₂ and nutrient supply after four consecutive generations of concurrent exposure of their progenitors to UV-B at ambient (seasonal range: 2.55-8.85 $\text{kJ m}^{-2} \text{d}^{-1}$) and enhanced (seasonal range: 4.70-11.41 $\text{kJ m}^{-2} \text{d}^{-1}$) levels. Offspring of progenitors grown under elevated UV-B exhibited a diminished photosynthetic rate, a consequence of a reduced leaf density, and diminished foliar levels of carotenoids, polyphenolics and anthocyanins. Conversely nonstructural carbohydrate and chlorophyll b levels were increased. Altered physiology was accompanied by reduced apical dominance and earlier flowering, features generally considered under photomorphogenic control, increased branching and inflorescence production and greater partitioning of biomass to reproductive structures, but diminished seed production. Many of these changes were magnified under nutrient limitation and intensified under atmospheric CO₂ enriched conditions. The latter disagrees with current opinion that elevated CO₂ may reduce detrimental UVB effects, at least over the long-term. Observed correlations between seed production and polyphenolic, especially anthocyanin, levels in offspring, and indications of diminished lignification (thinner leaves, less robust stems and fewer lignified seeds set) all pointed to the involvement of the phenylpropanoid pathway in seed formation and plant structural development and its disruption during long-term UV-B exposure. Comparisons with earlier generations revealed trends with cumulative generations of enhanced UVB exposure of increasing chlorophyll b and nonstructural carbohydrates, decreasing polyphenolics and biomass allocation to vegetative structures, and diminishing seed production despite increasing biomass allocation to reproductive structures. Notwithstanding some physiological compensation (increased chlorophyll b), the accumulation and persistence of these ostensibly inherited changes in physiological and reproductive performance suggest a greater impact of elevated UV-B on vegetation, primary production and regeneration over the long-term than presently envisaged.

Myers, D.A., R.B. Thomas, and E.H. Delucia. 1999. Photosynthetic capacity of loblolly pine (*Pinus taeda* L.) trees during the first year of carbon dioxide enrichment in a forest ecosystem. *Plant, Cell and Environment* 22(5):473-481.

Our objective was to assess the photosynthetic responses of loblolly pine trees (*Pinus taeda* L.) during the first full growth season (1997) at the Brookhaven National Lab/Duke University Free Air CO₂ Enrichment (FACE) experiment. Gas exchange, fluorescence characteristics, and leaf biochemistry of ambient CO₂ (control) needles and ambient + 20 Pa CO₂ (elevated) needles were examined five times during the year. The enhancement of photosynthesis by elevated CO₂ in mature loblolly pine trees varied across the season and was influenced by abiotic and biotic factors. Photosynthetic enhancement by elevated CO₂ was strongly correlated with leaf temperature. The magnitude of photosynthetic enhancement was zero in March but was as great as 52% later in the season. In March, reduced sink demand and lower temperatures resulted in lower net photosynthesis, lower carboxylation rates and higher excess energy dissipation from the elevated CO₂ needles than from control needles. The greatest photosynthetic enhancement by CO₂ enrichment was observed in July during a period of high temperature and low precipitation, and in September during recovery from this period of low precipitation. In July, loblolly pine trees in the control rings exhibited lower net photosynthetic rates, lower maximum rates of photosynthesis at saturating CO₂ and light, lower values of carboxylation and electron transport rates (modelled from A-C_i curves), lower total Rubisco activity, and lower photochemical quenching of fluorescence in comparison to other measurement periods. During this period of low precipitation trees in the elevated CO₂ rings exhibited reduced net photosynthesis and photochemical quenching of fluorescence, but there was little effect on light- and CO₂-saturated rates of photosynthesis, modelled rates of carboxylation or electron transport, or Rubisco activity. These first-year data will be used to compare with similar measurements from subsequent years of the FACE experiment in order to determine whether photosynthetic acclimation to CO₂ occurs in these canopy loblolly pine trees growing in a forest ecosystem.

Myers, R.E., D.E. Deyton, and C.E. Sams. 1996. Applying soybean oil to dormant peach trees alters internal atmosphere, reduces respiration, delays bloom, and thins flower buds. *Journal of the American Society for Horticultural Science* 121(1):96-100.

Dormant 'Georgia Belle' peach [*Prunus persica* (L.) Batsch.] trees were sprayed in early February 1992 with single applications of 0%, 2.5%, 5.0%, 10.0%, or 20.0% (v/v) crude soybean oil. 'Redhaven' trees were sprayed in February 1993 with single applications of 0%, 2.5%, 5.0%, 10.0%, or 15% degummed soybean oil. Additional treatments of two applications of 2.5% or 5.0% oil were included each year. Both crude and degummed soybean oil treatments interfered with escape of respiratory CO₂ from shoots and increased internal CO₂ concentrations in shoots for up to 8 days compared to untreated trees. Respiration rates, relative to controls, were decreased for 8 days following treatment, indicating a feedback inhibition of respiration by the elevated CO₂. Thus, an internal controlled atmosphere condition was created. Ethylene evolution was elevated for 28 days after treatment. Flower bud development was delayed by treating trees with 5% crude or degummed soybean oil. Trees treated with 10% crude or degummed soybean oil bloomed 6 days later than untreated trees. Repeated sprays of one half concentration delayed bloom an additional four days in 1992, but <1 day in 1993 compared to a single spray of the same total concentration. Application of soybean oil caused bud damage and reduced flower bud density (number of flower buds/cm branch length) at anthesis. In a trial comparing petroleum oil and degummed soybean oil, yields of trees treated with 6% or 9% soybean oil were 17% greater than the untreated trees and 29% more than petroleum treated trees. These results suggest that applying soybean oil delays date of peach bloom and may be used as a bloom thinner.

Nadelhoffer, K.J., B.A. Emmett, P. Gundersen, O.J. Kjonaas, C.J. Koopmans, P. Schleppi, A. Tietema, and R.F. Wright. 1999. Nitrogen deposition makes a minor contribution to carbon sequestration in temperate forests. *Nature* 398(6723):145-148.

Humans have altered global nitrogen cycling such that more atmospheric N₂ is being converted ('fixed') into biologically reactive forms by anthropogenic activities than by all natural processes combined(1). In particular, nitrogen oxides emitted during fuel combustion and ammonia volatilized as a result of intensive agriculture have increased atmospheric nitrogen inputs (mostly NO₃ and NH₄) to temperate forests in the Northern Hemisphere(2-4). Because tree growth in northern temperate regions is typically nitrogen-limited(5), increased nitrogen deposition could have the effect of attenuating rising atmospheric CO₂ by stimulating the accumulation of forest biomass. Forest inventories indicate that the carbon contents of northern forests have increased concurrently with nitrogen deposition since the 1950s(6-8). In addition, variations in atmospheric CO₂ indicate a globally significant carbon sink in northern mid-latitude forest regions(9-12). It is unclear, however, whether elevated nitrogen deposition or other factors are the primary cause of carbon sequestration in northern forests. Here we use evidence from N-15-tracer studies in nine forests to show that elevated nitrogen deposition is unlikely to be a major contributor to the putative CO₂ sink in forested northern temperate regions.

Naeem, S., L.J. Thompson, S.P. Lawler, J.H. Lawton, and R.M. Woodfin. 1995. Empirical-evidence that declining species-diversity may alter the performance of terrestrial ecosystems. *Philosophical Transactions of the Royal Society of London Series B-Biological Sciences* 347(1321):249-262.

We examined experimentally the association between species diversity and ecosystem processes in a series of terrestrial mesocosms. We developed and maintained 14 mesocosms whose biota were assembled from a single pool of plant and animal species and whose environmental conditions were identically controlled. Each community contained four trophic levels: primary producers (annual herbs), consumers (herbivorous molluscs and phloem sucking insects), secondary consumers (parasitoids) and decomposers (earthworms, Collembola and microbes). All mesocosms received the same diurnal pattern of light, temperature, relative humidity and water. The initial volume of soil, soil structure, composition, nutrient content and inocula of both soil microbes and nematodes were also identical among replicates. The only experimentally manipulated factor was the number of plant and animal species within each trophic level. High, medium and low diversity communities had nine, 15 or 31 plant and animal species, respectively. We measured five ecosystem processes as response variables in these mesocosms over the course of 206 days: (i) community respiration; (ii) productivity; (iii) decomposition; (iv) nutrient retention; and (v) water retention. The manipulation of diversity produced communities that differed significantly in their ecosystem processes. Our results provide the first evidence (obtained by a direct manipulation of diversity under controlled environmental conditions) that ecosystem processes may be affected by loss of diversity.

Nagy, J., K.F. Lewin, G.R. Hendrey, E. Hassinger, and R. Lamorte.

1994. Face facility CO₂ concentration control and CO₂ use in 1990 and 1991. *Agricultural and Forest Meteorology* 70(1-4):31-48.

CO₂ treatment level control and CO₂ use are reported for free-air carbon dioxide enrichment (FACE) facility operations at the University of Arizona's Maricopa Agricultural Center in 1990 and 1991. These are required for evaluation of the validity of biological experiments conducted in four replicates of paired experimental and control plots in a large cotton field and the cost-effectiveness of the plant fumigation facility. Gas concentration was controlled to 550 $\mu\text{mol mol}^{-1}$ at the center of each experimental plot, just above the canopy. In both years, season-long (April-September) average CO₂ levels during treatment hours (05:00-19:00 h Mountain Standard Time) were 550 $\mu\text{mol mol}^{-1}$ measured at treatment plot centers when the facility was operating. Including downtime, the season average was 548 $\mu\text{mol mol}^{-1}$ in 1991. In 1990, the season averages for the four elevated CO₂ treatments varied from 522 to 544 $\mu\text{mol mol}^{-1}$, owing to extended periods of downtime after lightning damage. Ambient CO₂ concentration during treatment was 370 $\mu\text{mol mol}^{-1}$. Instantaneous measurements of CO₂ concentration were within 10% of the target concentration of 550 $\mu\text{mol mol}^{-1}$ more than 65% of the time when the facility was operating, and 1 min averages were within 10% of the target concentration for 90% of the time. The long-term average of CO₂ concentration measured over the 20 m diameter experimental area of one array at the height of the canopy was in the range 550-580 $\mu\text{mol mol}^{-1}$ during July 1991, with the higher values near the edges. In 1991, CO₂ demand averaged 1250 kg per array per 14 h treatment day, or 4 kg m⁻² of fumigated plant canopy. The FACE facility provided good temporal and spatial control of CO₂ concentration and was a cost-effective method for large-scale field evaluations of the biological effects of CO₂.

Naidu, S.L., and E.H. DeLucia. 1999. First-year growth response of trees in an intact forest exposed to elevated CO₂. *Global Change Biology* 5(5):609-613.

Although elevated atmospheric CO₂ has been shown to increase growth of tree seedlings and saplings, the response of intact forest ecosystems and established trees is unclear. We report results from the first large-scale experimental system designed to study the effects of elevated CO₂ on an intact forest with the full complement of species interactions and environmental stresses. During the first year of exposure to approximate to 1.5 x ambient CO₂, canopy loblolly pine (*Pinus taeda*, L.) trees increased basal area growth rate by 24% but understorey trees of loblolly pine, sweetgum (*Liquidambar styraciflua* L.), and red maple (*Acer rubrum* L.) did not respond. Winged elm (*Ulmus alata* Michx.) had a marginally significant increase in growth rate ($P=0.069$). These data suggest that this ecosystem has the capacity to respond immediately to a step increase in atmospheric CO₂; however, as exposure time increases, nutrient limitations may reduce this initial growth stimulation.

Naidu, S.L., J.H. Sullivan, A.H. Teramura, and E.H. DeLucia. 1993. The effects of ultraviolet-B radiation on photosynthesis of different aged needles in field-grown loblolly-pine. *Tree Physiology* 12(2):151-162.

We examined the effect of supplemental UV-B radiation (290-320 nm) on photosynthetic characteristics of different aged needles of 3-year-old, field-grown loblolly pine (*Pinus taeda* L.). Needles in four age classes were examined: I, most recently fully expanded, year 3; II, first flush,

year 3; III, final flush, year 2; and IV, oldest needles still present, year 2. Enhanced UV-B radiation caused a statistically significant decrease (6%) in the ratio of variable to maximum fluorescence ($F(v)/F(m)$) following dark adaptation only in needles from the youngest age class, suggesting transient damage to photosynthesis. However, no effects of enhanced UV-B radiation on other instantaneous measures of photosynthesis, including maximum photosynthesis, apparent quantum yield and dark respiration, were seen for needles of any age. Foliar nitrogen concentration was unaffected by UV-B treatment. However, the C-13/C-12 carbon isotope ratios ($\delta\text{C-13}$ -a time integrated measure of photosynthetic function) of needles in age classes II and IV were 3% ($P < 0.01$) and 2% ($P < 0.05$) more negative, respectively, in treated plants than in control plants. Exposure to enhanced UV-B radiation caused a 20% decrease in total biomass and a 4% ($P < 0.05$), 25% ($P < 0.01$), and 9% ($P < 0.01$) decrease in needle length of needles in age classes I, II, and IV, respectively. The observed decreases in $\delta\text{C-13}$, and $F(v)/F(m)$ of the needles in the youngest needle age class suggest subtle damage to photosynthesis, although overall growth reductions were probably a result of decreased total leaf surface rather than decreased photosynthetic capacity. Needles of age class IV had lower light- and CO₂-saturated maximum photosynthetic rates (39%), lower dark respiration (34%), lower light saturation points (37%), lower foliar nitrogen concentration (28%), and lower $\delta\text{C-13}$ (14%) values than needles of age class I. Apparent quantum yield and $F(v)/F(m)$ did not change with needle age. The observed changes in photosynthesis and foliage chemical composition with needle age are consistent with previous studies of coniferous trees and may represent adaptations of older needles to shaded conditions within the canopy.

Nakadai, T., H. Koizumi, Y. Usami, M. Satoh, and T. Oikawa. 1993. Examination of the method for measuring soil respiration in cultivated land - effect of carbon-dioxide concentration on soil respiration. *Ecological Research* 8(1):65-71.

An acceleration of soil respiration with decreasing CO₂ concentration was suggested in the field measurements. The result supports that obtained in laboratory experiments in our previous study. The CO₂ concentrations in a chamber of the alkali absorption method (the AA-method) were about 150-250 parts/10(6) lower than that in the atmosphere (about 350 parts/10(6)), while those observed in the open-flow IRGA method (the OF-method) were nearly equal to the soil surface CO₂ levels. The AA-method at such low CO₂ levels in the chamber appears to overestimate the soil respiration. Our results showed that the rates obtained by the AA-method were about twice as large as those by the OF-method in field and laboratory measurements. This finding has important consequences with respect to the validity of the existing data obtained by the AA-method and the estimation of changes in the terrestrial carbon flow with elevated CO₂ concentrations.

Nakamura, T., M. Osaki, T. Koike, Y.T. Hanba, E. Wada, and T. Tadano. 1997. Effect of CO₂ enrichment on carbon and nitrogen interaction in wheat and soybean. *Soil Science and Plant Nutrition* 43(4):789-798.

Effect of CO₂ enrichment on the carbon-nitrogen balance in whole plant and the acclimation of photosynthesis was studied in wheat (spring wheat) and soybean (A62-1 [nodulated] and A62-2 [non-nodulated]) with a combination of two nitrogen application rates (0 g N land area m⁻² and 30 g N land area m⁻²) and two temperature treatments (30/20 degrees C (day/night) and 26/16 degrees C). Results were as

follows. 1. Carbon (dry matter)-nitrogen balance of whole plant throughout growth was remarkably different between wheat and soybean, as follows: 1) in wheat, the relationship between the amount of dry matter (DMt) and amount of nitrogen absorbed (Nt) in whole plant was expressed by an exponential regression, in which the regression coefficient was affected by only the nitrogen application rate, and not by CO₂ and temperature treatments, and 2) in soybean the DMt-Nt relationship was basically expressed by a linear regression, in which the regression coefficient was only slightly affected by the nitrogen treatment (at ON, DMt-Nt balance finally converged to a linear regression). Thus, carbon-nitrogen interaction in wheat was strongly affected by the underground environment (nitrogen nutrition), but not by the above ground environment (CO₂ enrichment and temperature), while that in soybean was less affected by both under and above ground environments. 2. The photosynthetic response curve to CO₂ concentration in wheat and soybean was less affected by the CO₂ enrichment treatment, while that in wheat and soybean (A62-2) was affected by the nitrogen treatment, indicating that nitrogen nutrition is a more important factor for the regulation of photosynthesis regardless of the CO₂ enrichment. 3. Carbon isotope discrimination (δ) in soybean was similar to that in wheat under ambient CO₂, while lower than that in wheat under CO₂ enrichment, suggesting that the carbon metabolism is considerably different between wheat and soybean under the CO₂ enrichment conditions.

Nakano, H., A. Makino, and T. Mae. 1997. The effect of elevated partial pressures of CO₂ on the relationship between photosynthetic capacity and N content in rice leaves. *Plant Physiology* 115(1):191-198.

The effects of growth CO₂ levels on the photosynthetic rates; the amounts of ribulose-1,5-bisphosphate carboxylase (Rubisco), chlorophyll (Chl), and cytochrome f; sucrose phosphate synthase activity; and total N content were examined in young, fully expanded leaves of rice (*Oryza sativa* L.). The plants were grown hydroponically under two CO₂ partial pressures of 36 and 100 Pa at three N concentrations. The light-saturated photosynthesis at 36 Pa CO₂ was lower in the plants grown in 100 Pa CO₂ than those grown in 36 Pa CO₂. Similarly, the amounts of Rubisco, Chl, and total N were decreased in the leaves of the plants grown in 100 Pa CO₂. However, regression analysis showed no differences between the two CO₂ treatments in the relationship between photosynthesis and total N or in the relationship between Rubisco and Chl and total N. Although a relative decrease in Rubisco to cytochrome f for sucrose phosphate synthase was found in the plants grown in 100 Pa CO₂, this was the result of a decrease in total N content by CO₂ enrichment. The activation state of Rubisco was also unaffected by growth CO₂ levels. Thus, decreases in the photosynthetic capacity of the plants grown in 100 Pa CO₂ could be simply accounted for by a decrease in the absolute amount of leaf N.

Nakayama, F.S., G. Huluka, B.A. Kimball, K.F. Lewin, J. Nagy, and G.R. Hendrey. 1994. Soil carbon-dioxide fluxes in natural and CO₂-enriched systems. *Agricultural and Forest Meteorology* 70(1-4):131-140.

Carbon dioxide fluxes between the soil and atmosphere were determined on the 1991 free-air carbon dioxide enrichment (FACE) experiment at the Maricopa Agricultural Center, Maricopa, Arizona. The study was conducted on drip-irrigated cotton in conjunction with other physical and physiological measurements. Fluxes were measured with a 1.6 l closed-chamber static sampling system. The main treatment for the open-air release study had two levels of CO₂-ambient air with CO₂ concentration of approximately 370 $\mu\text{mol mol}^{-1}$ (control) and CO₂-enriched air with CO₂ concentration of approximately 550 $\mu\text{mol mol}^{-1}$ (FACE). The enrichment was made over the daylight hours (05:00-19:00 h). Two quantities of water application, 'wet' (1050 mm) and 'dry' (790 mm), were superimposed on the two CO₂ levels. The observed soil CO₂ fluxes ranged from 2 to 8 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ over the cultivation period. The CO₂ fluxes were significantly higher in the FACE than in the control plots, and also higher for the wet than for the dry irrigation level. In addition, an interaction between CO₂ and water levels was present. The CO₂ enrichment effect on soil CO₂ flux remained for approximately 4 weeks after the enrichment was ended. A detailed study on the procedure for determining flux indicated that some of the random and inconsistent flux values observed in the field could be attributed to a high CO₂ concentration present in the first of the two gas samples taken to estimate flux.

Nakazawa, T., S. Murayama, M. Toi, M. Ishizawa, K. Otonashi, S. Aoki, and S. Yamamoto. 1997. Temporal variations of the CO₂ concentration and its carbon and oxygen isotopic ratios in a temperate forest in the central part of the main island of Japan. *Tellus Series B-Chemical and Physical Meteorology* 49(4):364-381.

Using discrete air sampling, values of $\delta(13)\text{C}$ and $\delta(18)\text{O}$ in atmospheric CO₂, as well as its concentration, were measured in a forest in the central part of the main island of Japan during the period from June 1994 to June 1996 to examine the biospheric contribution to their temporal variations. $\delta(13)\text{C}$ shows a prominent diurnal variation with high values in the daytime and low values in the nighttime, especially during the warm season. $\delta(13)\text{C}$ also vary seasonally, showing a maximum in summer and a minimum in spring. The diurnal and seasonal variations of $\delta(13)\text{C}$ are opposite in phase with those of the CO₂ concentration. The rate of change in $\delta(13)\text{C}$ with respect to the CO₂ concentration is found to be approximately -0.05 parts per thousand/ppmv. This suggests that the diurnal and seasonal variations of the CO₂ concentration are produced primarily by diurnally- and seasonally-dependent photosynthetic-respiratory processes of the biosphere near the observation site, respectively. In the warm season, $\delta(18)\text{O}$ also increases in the daytime and decreased in the nighttime, which is similar to the diurnal variation of $\delta(13)\text{C}$, but opposite to that of the CO₂ concentration. The diurnal $\delta(18)\text{O}$ variation is thought to be caused by the release of isotopically heavy CO₂ during photosynthesis, and light CO₂ during respiration. However, an interpretation of the seasonal $\delta(18)\text{O}$ variation is found to be much more difficult than those of $\delta(13)\text{C}$ and the CO₂ concentration. This is likely due to complicated combinations of different seasonally varying fluxes of biospheric CO₂ into the atmosphere, as well as to various weather-dependent factors governing the $\delta(18)\text{O}$ composition in CO₂.

Napolitano, R., and M.P. Juarez. 1997. Entomopathogenous fungi degrade epicuticular hydrocarbons of *Triatoma infestans*. *Archives of*

Studies were undertaken to analyze the ability of entomopathogenous fungi to degrade insect hydrocarbons. Strains of *Beauveria bassiana* and *Metarhizium anisopliae* pathogenic to the blood-sucking bug *Triatoma infestans* were grown on hydrocarbon and non-hydrocarbon insect lipid extracts and on synthetic hydrocarbon-enriched media as the sole carbon source. Entomopathogenous fungi were shown to utilize hydrocarbons as the only carbon source for their growth. Insect-derived hydrocarbons served more efficiently as metabolic fuel rather than synthetic compounds of similar structure. [^3H]-Pentacosane, [^{11}C]-3,11-dimethylnonacosane, and [^{14}C]-hexadecane were catabolized into different amounts of polar lipids, free fatty acids, and acylglycerols. In experiments using the branched alkane, labeled hydrocarbons of different chain length than the precursor were also synthesized. Evidence of complete catabolism was obtained by a significant release of (CO_2)-C-14 from [^{14}C]-hexadecane. (CO_2)-C-14 production might be used as a simple method to compare hydrocarbon utilization by fungal strains. These data demonstrate that entomopathogenous fungi are able to transform a variety of hydrocarbon structures into different lipid products, part of which may be subsequently utilized for energy production and for the biosynthesis of cellular components. These data are the first evidence of hydrocarbon catabolism and synthesis in entomopathogenous fungi. (C) 1997 Academic Press.

Navarro, C., C. Teisson, F. Cote, and J. Ganry. 1994. Effects of light-intensity and CO_2 concentration on growth of banana plants (*Musa* spp., cultivar petite-naine) in-vitro and subsequent growth following acclimatization. *Scientia Horticulturae* 60(1-2):41-54.

The development of micropropagated banana plants during the in vitro growth phase prior to acclimatization was studied both in tight vessels under two different photosynthetic photon flux densities (PPFD of 30 and 240 $\mu\text{mol m}^{-2} \text{s}^{-1}$) and in continuously flushed vessels under three atmospheric CO_2 concentrations (0.034, 0.24 and 4.0%) at 240 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD. In tight vessels at low PPFD, the CO_2 originating from dark respiration was partially fixed during the light period, indicating photosynthetic activity by the plants in vitro. At high PPFD, CO_2 originating from dark respiration was rapidly fixed in the early hours of the light period and CO_2 concentration became the limiting factor for photosynthetic activity. Plants in vitro grown under high PPFD accumulated 2.3 times the dry matter achieved by plants in low PPFD. However, this developmental advantage acquired in vitro was not maintained ex vitro at the end of the acclimatization phase (on a leaf area basis). In continuously flushed vessels, treatments with 0.24% and 4.0% CO_2 -enriched atmospheres enhanced dry matter accumulation in vitro by 1.6 and 2.3 times, respectively, as compared to a 0.034% CO_2 treatment. Twenty days after transfer ex vitro, the development of plants (on a leaf area basis) from these CO_2 treatments was no longer significantly different. The relative growth rate ex vitro was lower for plants cultured in a CO_2 -enriched atmosphere in vitro than for those cultured at 0.034% CO_2 .

Navas, M.L., E. Garnier, M.P. Austin, and R.M. Gifford. 1999. Effect of competition on the responses of grasses and legumes to elevated atmospheric CO_2 along a nitrogen gradient: differences between isolated plants, monocultures and multi-species mixtures. *New Phytologist* 143(2):323-331.

The responses to CO_2 of perennial grasses (*Danthonia richardsonii* and *Phalaris aquatica*) and legumes (*Lotus pedunculatus* and *Trifolium repens*) were compared under controlled conditions for isolated plants, monoculture stands and mixed-species stands along a N gradient to test whether: plant-plant interactions between species in mixed stands changed with concentration of CO_2 ; responses to CO_2 of species in mixtures could be related to their responses as single stands; responses of mixtures to CO_2 could be related to the responses of individual species to CO_2 and to competition. Plants were grown for 60 d in sand, using nutrient solutions (six nitrate concentrations from 0.25 to 16 mM NO_3), at ambient (c. 357 $\mu\text{mol l}^{-1}$) or elevated CO_2 (c. 712 $\mu\text{mol l}^{-1}$). Species dominance in the mixtures depended more on the range of N than of CO_2 concentration provided: *T. repens* and *L. pedunculatus* dominated at low concentrations of N; *L. pedunculatus* and *P. aquatica* performed better at high concentrations. Responses of species in mixtures to CO_2 were related to their responses in monocultures but not to those of isolated plants. Species biomass proportions in mixtures under ambient CO_2 determined the outcome of mixture responses to CO_2 more than of individual species responses to CO_2 . These results emphasize the influence of plant-plant interactions on community responses to CO_2 , since mixture behaviour under elevated CO_2 could not be scaled-up from responses by isolated plants in this experiment.

Navas, M.L., J.L. Guillermin, J. Fabreguettes, and J. Roy. 1995. The influence of elevated CO_2 on community structure, biomass and carbon balance of mediterranean old-field microcosms. *Global Change Biology* 1(5):325-335.

We studied the effects of a doubling of atmospheric CO_2 concentration on intact monoliths of Mediterranean grassland in growth chambers where climatic field conditions were simulated. During the six month growing season, changes in community structure were monitored by quantifying species richness and cover. The CO_2 exchange of microcosms was measured continuously and the resulting quantity and quality of biomass were evaluated. Species richness and cover did not respond to elevated CO_2 . After one month of treatment, CO_2 exchange measured during the day did not differ between CO_2 levels but the night respiration was two-fold higher under elevated CO_2 . Stimulations of both day and night CO_2 flux by short-term CO_2 enrichment were recorded several times during the growing season. These results suggest that despite some downward adjustment of photosynthesis, net canopy photosynthesis was stimulated by elevated CO_2 , but this stimulation was compensated for by an increased respiration. The 20% stimulation of final phytomass under elevated CO_2 was not significant: it resulted from unchanged live plant matter but a significant, 100% increase in litter accumulation. These results suggest that in low-productivity Mediterranean herbaceous systems, the greatest effect of CO_2 is not on the storage of carbon in biomass but on the turnover of the carbon in the plants.

Navas, M.L., L. Sonie, J. Richarte, and J. Roy. 1997. The influence of elevated CO₂ on species phenology, growth and reproduction in a Mediterranean old-field community. *Global Change Biology* 3(6):523-530.

We studied the effects on the phenology, growth and reproduction of 19 Mediterranean species, of elevating the atmospheric CO₂ concentration ([CO₂]) to twice-ambient. Intact monoliths were taken from an old-field and put, during a six month growing season, into growth chambers in which external climatic conditions were mimicked and [CO₂] was regulated. Fruit set time was significantly changed in six species under elevated [CO₂] and leaf and branch senescence accelerated in most species. Grasses had fewer leaves and legumes were more branched at peak production under elevated [CO₂] than under ambient. Plant seed number was not significantly changed under elevated [CO₂], whereas the reproductive effort of grasses was significantly depressed. Reproductive and vegetative characteristics showed related responses to [CO₂], as species with enhanced biomass had a hastened fruit set time, a higher number of fruits per plant and a higher reproductive biomass under elevated [CO₂] than under ambient conditions, while species with depressed biomass had a delayed fruit set time, a lower number of fruits per plant and a lower reproductive biomass. Our results also show a high interspecific variability in [CO₂] response, but some trends emerged at the family level: the production of vegetative and reproductive modules were depressed in grasses and slightly stimulated in legumes.

Nederhoff, E.M. 1992. Effects of CO₂ on greenhouse grown eggplant (*solanum-melongena* L.). I. Leaf conductance. *Journal of Horticultural Science* 67(6):795-803.

Leaf conductance of eggplant (*Solanum melongena* L., cv. Cosmos) was measured comparatively in two glasshouse compartments, with continuously low or high CO₂ (on average 415 or 685 $\mu\text{mol mol}^{-1}$, respectively). Measurements were carried out on eight days between February and June 1991 in an early planted crop. A regression equation was fitted to the data to account for the effects of PAR, air humidity and CO₂ on leaf conductance. Calculations with this equation demonstrated that leaf conductance was reduced by 10.2% per 100 $\mu\text{mol mol}^{-1}$ increase in CO₂, which is a three to four times stronger response than in other fruit vegetable crops. When, on some occasional days, CO₂ was kept equal in the two compartments, leaf conductance was not different, indicating that stomatal behaviour had not adapted to long lasting CO₂ conditions. The rate of crop transpiration, as estimated with the Penman-Monteith combination equation, was reduced by elevated CO₂ by only a few percent on average and by about 15% in a period of some weeks in spring.

Nederhoff, E.M., and R. Degraaf. 1993. Effects of CO₂ on leaf conductance and canopy transpiration of greenhouse-grown cucumber and tomato. *Journal of Horticultural Science* 68(6):925-937.

The effects of carbon dioxide (CO₂) on stomatal opening and canopy transpiration were investigated in cucumber (*Cucumis sativus* L., cv. Jessica) and tomato (*Lycopersicon esculentum* Mill., cv. Calypso). Stomatal opening (i.e. leaf conductance, g) was measured with a porometer, and canopy transpiration rate (E) with weighing lysimeters on intact plants in large greenhouses. Regression analysis was applied to account for the effects of radiation, air humidity, leaf temperature and CO₂ on g. The effect of CO₂ on E, which is primarily through g and secondarily through adjusted air humidity, was investigated by combining the regression equation for g with the Penman-Monteith equation for E. The relative effect of CO₂, as calculated with the fitted regression equations, was a decrease of about 4% in g for cucumber and of about 3% for tomato, per 100 $\mu\text{mol mol}^{-1}$ increase in CO₂, in the range of about 300 to 1200 $\mu\text{mol mol}^{-1}$ CO₂. The effect of CO₂ on E was smaller than on g and the extent of the effect depended on the conditions, mainly ventilation rate. The ratio K (relative change in calculated E divided by relative change in calculated g) was estimated at less than 0.2, except at low radiation. In reality, K will be even lower, because feedback mechanisms enforce the reduction in g and counteract the reduction in E. So the reduction of the transpiration rate of greenhouse cucumber and tomato caused by moderate CO₂ enrichment is small and mostly negligible, except under low light conditions.

Nederhoff, E.M., A.N.M. Dekoning, and A.A. Rijdsdijk. 1992. Leaf deformation and fruit production of glasshouse grown tomato (*lycopersicon-esculentum* mill) as affected by CO₂ plant-density and pruning. *Journal of Horticultural Science* 67(3):411-420.

During summer, glasshouse grown tomato plants (*Lycopersicon esculentum* Mill.) often demonstrate leaf deformation, reduced leaf area (short leaves) and low Specific Leaf Area (SLA), sometimes accompanied by higher dry matter content of leaves and stems and higher leaf starch content. This so-called "Short Leaves Syndrome" (SLS), which decreases the production capacity, was investigated with emphasis on the effects of CO₂ concentration. As a working hypothesis it was postulated that SLS is indirectly caused by an oversupply of assimilates relative to the sink capacity. An experiment was conducted between 10 May and 31 July 1990 in 12 glasshouse compartments. The sink/source ratio was varied by maintaining two levels of CO₂, multifactorially combined with two plant densities and three pruning treatments. CO₂ enrichment and wider planting enhanced SLS and decreased leaf area and SLA of upper leaves. Leaf pruning and fruit pruning, however, did not give clear effects on vegetative characteristics, although the impact on the sink/source ratio was of the same order of magnitude. As a mechanism for these effects, we suggest that SLS is caused by calcium deficiency in the apex, a condition more severe when much phloem sap (with low calcium content) is available, i.e. when the sink/source ratio is lower. Stronger effects of CO₂ and plant density than of pruning on the incidence of SLS, may be due to local effects of sink/source relationships or to involvement of other processes, like transpiration. In crops with little SLS-symptoms, CO₂ enrichment increased the weight of fruits grown during the treatment period by 31%, whereas in crops with severe SLS, CO₂ enrichment aggravated SLS and had no significant effect on fruit production. CO₂ enrichment in summer is beneficial if SLS is prevented, which can be achieved by maintaining a higher plant density or, in an early crop, an extra shoot on the plants in spring and summer.

Nederhoff, E.M., A.A. Rijdsdijk, and R. Degraaf. 1992. Leaf conductance and rate of crop transpiration of greenhouse grown sweet-

pepper (*capsicum-annuum-L.*) as affected by carbon- dioxide. *Scientia Horticulturae* 52(4):283-301.

The effects of carbon dioxide concentration (CO₂) in the range 300-1100 $\mu\text{mol mol}^{-1}$ on leaf conductance (g) and rate of crop transpiration (E) of sweet pepper (*Capsicum annuum L.*) were investigated in spring 1990. In two greenhouse compartments (154 m²) that were simultaneously exposed to different CO₂ levels, leaf conductance of the upper leaves was measured with a steady state diffusion porometer and crop transpiration rates were measured with three weighing lysimeters per greenhouse compartment. Multiple regression equations, describing the effects of photosynthetic active radiation (PAR), vapour pressure deficit (VPD)-leaf-air, CO₂ and optionally leaf temperature on g, were fitted to the measured data. The fitted regression curves demonstrated that 100 $\mu\text{mol mol}^{-1}$ increase in CO₂ reduced g by about 3%, at any level of CO₂, VPD and PAR, if VPD and PAR would remain constant. Measured rates of crop transpiration were highly correlated to radiation and were in reasonable accordance with the Penman-Monteith combination equation. With this equation it was estimated that a 10% decrease in g would reduce E by 1.5-3% at high levels of g (high radiation) and by 4-7% at low g (dark weather), at least if VPD would remain constant. In a greenhouse-crop system, however, owing to thermal and hydrologic feedbacks, an increase in CO₂ leads to a considerable increase in VPD-leaf-air. This enforces the effect of CO₂ on g and counteracts the effect of CO₂ on E, because the driving force for transpiration is enhanced. Thus, in general the apparent response of g to changes in CO₂ is far greater than the mentioned percentage, whereas the apparent response of E is relatively small.

Neilson, R.P., and R.J. Drapek. 1998. Potentially complex biosphere responses to transient global warming. *Global Change Biology* 4(5):505-521.

Feedback interactions between terrestrial vegetation and climate could alter predictions of the responses of both systems to a doubling of atmospheric CO₂. Most previous analyses of biosphere responses to global warming have used output from equilibrium simulations of current and future climate, as compared to more recently available transient GCM simulations. We compared the vegetation responses to these two different classes of GCM simulation (equilibrium and transient) using an equilibrium vegetation distribution model, MAPSS. Average climatologies were extracted from the transient GCM simulations for current and doubled (2 x) CO₂ concentrations (taken to be 2070-2099) for use by the equilibrium vegetation model. However, the 2 x CO₂ climates extracted from the transient GCM simulations were not in equilibrium, having attained only about 65% of their eventual 2 x CO₂ equilibrium temperature change. Most of the differences in global vegetation response appeared to be related to a very different simulated change in the pole to tropic temperature gradient. Also, the transient scenarios produced much larger increases of precipitation in temperate latitudes, commensurate with a minimum in the latitudinal temperature change. Thus, the (equilibrium) global vegetation response, under the transient scenarios, tends more to a greening than a decline in vegetation density, as often previously simulated. It may be that much of the world could become greener during the early phases of global warming, only to reverse in later, more equilibrated stages. However, whether or not the world's vegetation experiences large drought-induced declines or perhaps large vegetation expansions in early stages could be determined by the degree to which elevated CO₂ will actually benefit natural vegetation, an issue still under debate. There may occur oscillations, perhaps on long timescales, between greener and drier phases, due to different frequency responses of the coupled ocean-atmosphere-biosphere interactions. Such oscillations would likely, of themselves, impart further reverberations to

the coupled Earth System.

Nemry, B., L. Francois, J.C. Gerard, A. Bondeau, and M. Heimann. 1999. Comparing global models of terrestrial net primary productivity (NPP): analysis of the seasonal atmospheric CO₂ signal. *Global Change Biology* 5:65-76.

Eight terrestrial biospheric models (TBMs) calculating the monthly distributions of both net primary productivity (NPP) and soil heterotrophic respiration (R-H) in the Potsdam NPP Model Intercomparison workshop are used to simulate seasonal patterns of atmospheric CO₂ concentration. For each model, we used net ecosystem productivity (NEP=NPP-R-H) as the source function in the TM2 atmospheric transport model from the Max- Planck Institute for Meteorology. Comparing the simulated concentration fields with detrended measurements from 25 monitoring stations spread over the world, we found that the decreasing seasonal amplitude from north to south is rather well reproduced by all the models, though the amplitudes are slightly too low in the north. The agreement between the simulated and observed seasonality is good in the northern hemisphere, but poor in the southern hemisphere, even when the ocean is accounted for. Based on a Fourier analysis of the calculated zonal atmospheric signals, tropical NEP plays a key role in the seasonal cycle of the atmospheric CO₂ in the whole southern hemisphere. The relatively poor match between measured and predicted atmospheric CO₂ in this hemisphere suggests problems with all the models. The simulation of water relations, a dominant regulator of NEP in the tropics, is a leading candidate for the source of these problems.

Newberry, R.M., and J. Wolfenden. 1996. Effects of elevated CO₂ and nutrient supply on the seasonal growth and morphology of *Agrostis capillaris*. *New Phytologist* 132(3):403-411.

Responses to elevated CO₂ have been studied using an upland grass species, *Agrostis capillaris* L. The plants were grown in sand culture with a range of N, P and K concentrations, in 'Solardome' growth chambers with either ambient air or a CO₂ concentration of 250 $\mu\text{mol mol}^{-1}$ above ambient. The interactive effects of high CO₂ and nutrient supply on plant growth and morphology were monitored throughout the growing season. *A. capillaris* exhibited positive growth responses to enhanced CO₂, even at limiting supplies of N and P. Moreover, greater shoot mass at elevated CO₂ was attributed to disproportionate increases in leaf and tiller number, resulting in an increase in the average leaf number per tiller. However, total leaf area remained unaffected, indicating that leaf size was reduced. There was no evidence of any acclimation in the growth response of *A. capillaris* to additional CO₂, even in N and P-stressed plants. On the contrary, a stimulation in leaf production was observed later in the growing season. A consistent interaction was observed between N and P concentrations, whereby the response to one element was greater at higher concentrations of the other. In addition, there were indications of competition among the three elements for uptake at the root. These findings indicate the importance of multifactorial nutrient experiments in developing an understanding of the complex relationships during CO₂ enrichment.

Newbery, R.M., J. Wolfenden, T.A. Mansfield, and A.F. Harrison. 1995. Nitrogen, phosphorus and potassium uptake and demand in *agrostis-capillaris* - the influence of elevated CO_2 and nutrient supply. *New Phytologist* 130(4):565-574.

Responses to elevated CO_2 have been studied using *Agrostis capillaris* L., an upland grass which is abundant on nutrient-poor soils. Plants were grown in sand culture with a wide range of nitrogen, phosphorus and potassium concentrations, and the impact of CO_2 on the demand for nutrients was determined using isotopic root bioassays. Plants grown with the smallest concentrations of N and P showed typical foliar symptoms associated with deficiency of these elements. However, even when supplies of N and P were limiting to growth, additional CO_2 (250 ppm above ambient) influenced neither total N nor total P in above-ground tissues, nor nutrient demands as indicated by the bioassay. The estimates of the demand of the plants for K from the Rb-86 bioassay indicated an appreciable increase when plants were raised in elevated CO_2 . For plants of the same size with the same nutrient supply, those grown in elevated CO_2 consistently displayed an increased internal demand for K. Uptake of K was not, however, enhanced by elevated CO_2 even in non-limiting conditions and it might therefore be limited by a factor other than K supply. The overall conclusion from the experiments is that when *A. capillaris* is grown in elevated CO_2 , uptake of N, P and K fails to increase proportionally with dry mass. This was true even when nutrient supplies were adequate, and it appears that nutrient-use-efficiency might increase to enable the plants to maintain growth in elevated CO_2 .

Newton, P.C.D. 1991. Direct effects of increasing carbon-dioxide on pasture plants and communities. *New Zealand Journal of Agricultural Research* 34(1):1-24.

The atmospheric carbon dioxide (CO_2) level is rising and is expected to double during the next century. This paper reviews information on the responses of pasture species and communities to elevated CO_2 . Data for some further non-arable species are included where relevant. The effect of CO_2 on yield and on morphological and physiological characteristics are considered together with aspects of particular relevance to pasture, for example, herbivory, plant community relationships, and experimental methods for the exposure of pasture to elevated CO_2 . At the plant level, physiological responses to CO_2 include enhanced net photosynthesis and reduced stomatal conductance; morphological changes include greater leaf areas, shoot production, and root:shoot ratios. Little is known about community responses or about plant-herbivore dynamics at elevated CO_2 . Changes in herbage quality, tissue turnover, and botanical composition may be expected but confirmation of these responses will

only be possible when data are available from long-term studies of grazed pasture at elevated CO_2 .

Newton, P.C.D., C.C. Bell, and H. Clark. 1996. Carbon dioxide emissions from mineral springs in Northland and the potential of these sites for studying the effects of elevated carbon dioxide on pastures. *New Zealand Journal of Agricultural Research* 39(1):33-40.

Sites in Northland with mineral springs were examined for their potential as experimental areas to study the effects of elevated carbon dioxide (CO_2) on grassland. A suitable site was defined as having: (1) grassland species; (2) cold springs; (3) high levels of gas flow; and (4) high concentrations of CO_2 . Two sites were selected for detailed study-Hakanoa Springs near Kamo and Waiare Spring near Kaeo. At Hakanoa, the vegetation was scrubby but at least 10 grassland species were present. Two vents released large volumes of CO_2 resulting in concentrations at 10 cm above ground level that ranged from 5000 μ l/litre near the vent to 400 μ l/litre 10 m downwind. At Waiare, the spring was situated in a grazed grass paddock that contained 10 grass species as well as *Trifolium repens* and *Lotus* spp. There was little enrichment of CO_2 above the canopy but high concentrations were measured at mid-canopy height with a maximum value exceeding 2000 μ l/litre. Because of the nature of the enrichment within, but not above the canopy, it appeared that the enrichment was from the soil. This was confirmed by measurements of soil CO_2 efflux that were consistently very high (greater than 9.9 g CO_2 /m² per h in some instances). The springs have existed for decades and the sites offer the potential to study plant material that has been exposed to elevated CO_2 for very long periods.

Newton, P.C.D., H. Clark, C.C. Bell, and E.M. Glasgow. 1996. Interaction of soil moisture and elevated CO_2 on the above-ground growth rate, root length density and gas exchange of turves from temperate pasture. *Journal of Experimental Botany* 47(299):771-779.

Interactions between water availability and elevated atmospheric CO_2 concentrations have the potential to be important factors in determining future forage supply from temperate pastures. Using large turves from an established pasture, the response of these communities at 350 or 700 μ l l⁻¹ CO_2 to a soil moisture deficit and to recovery from the deficit in comparison to turves that were well-watered throughout was measured. Prior to this experiment the turves had been exposed to the CO_2 treatments for 324 d. Net CO_2 exchange continued at elevated CO_2 even when the volumetric soil moisture content was less than 0.10 m³ m⁻³ soil; at the same moisture deficit gas exchange at ambient CO_2 was zero. The additional carbon fixed by the elevated CO_2 turves was primarily allocated below-ground as shown by the maintenance of root length density at the same level as in well-watered turves. When the dry turves were rewetted there was compensatory growth at ambient CO_2 so that the above-ground growth rate exceeded that of turves that had not experienced a moisture deficit. At the start of this experiment, the turves that were growing at 700 μ l l⁻¹ CO_2 had a greater proportion of legume (principally white clover, *Trifolium repens* L.) in the harvested herbage. There was a trend for the legume content at elevated CO_2 to be reduced under a soil moisture deficit. The results indicate different strategies in response to soil moisture deficits depending on the CO_2

concentration, At ambient CO₂, growth stopped, but plants were able to respond strongly on rewatering; while at elevated CO₂ growth continued (particularly belowground), but no additional growth was evident on rewatering. Ecosystem gas exchange measurements taken at the end of the experiment (after 429 d of exposure to CO₂) showed 33% more CO₂ was fixed at elevated CO₂ with only a small (12%) and nonsignificant downward regulation.

Newton, P.C.D., H. Clark, C.C. Bell, E.M. Glasgow, K.R. Tate, D.J. Ross, G.W. Yeates, and S. Saggarr. 1995. Plant growth and soil processes in temperate grassland communities at elevated CO₂. *Journal of Biogeography* 22(2-3):235-240.

Turves of a Mollic Psammaquent soil were used in controlled environment rooms to examine the response of managed temperate pasture communities to 350, 525 or 700 p.p.m. CO₂. Yield of herbage (regrowth over 3-week intervals) increased only slightly with higher CO₂; however, the botanical composition was markedly different. At elevated CO₂ *Paspalum dilatatum* (C4) and *Lolium perenne* (C3) declined as a proportion of harvested yield despite a stimulation of single leaf photosynthesis that was comparable to that found in *Trifolium repens*, a species that increased in abundance. Changes in species composition were largely a consequence of CO₂-induced differences in axillary bud activity. Net primary productivity below-ground was stimulated by CO₂. Soil CO₂-C production was greater in elevated CO₂ treatments, and was consistent with a greater input of herbage and root mass and/or metabolites and of more readily decomposable material. Levels of microbial biomass were unchanged, but enchytraeids were more abundant at elevated CO₂. Tracking of (CO₂)-C-14 into the various C pools also indicated a more rapid turnover of C at elevated CO₂ but no change in pool sizes. No consistent effects on net mineralization of N were observed.

Nguyen, Q.T., T. Kozai, G. Niu, and U.V. Nguyen. 1998. Photosynthetic characteristics of coffee (*Coffea arabusta*) plantlets in vitro in response to different CO₂ concentrations and light intensities. *Plant Cell Tissue and Organ Culture* 55(2):133-139.

The photosynthetic characteristics of coffee (*Coffea arabusta*) plantlets cultured in vitro in response to different CO₂ concentrations inside the culture vessel and photosynthetic photon flux (PPF) were investigated preliminarily. The estimation of net photosynthetic rate (P-n) of coffee plantlets involved three methods: (1) estimating time courses of actual P-n in situ based on measuring CO₂ concentrations inside and outside

the vessel during a 45-day period, (2) estimating P-n in situ at different CO₂ concentrations and PPFs using the above measuring approach for 10-day and 30-day old in vitro plantlets, and (3) estimating P-n of a single leaf at different CO₂ concentrations and PPFs by using a portable photosynthesis measurement system for 45-day old in vitro coffee plantlets. The results showed that coffee plantlets in vitro had relatively high photosynthetic ability and that the P-n increased with the increase in CO₂ concentration inside the vessel. The CO₂ saturation point of in vitro coffee plantlets was high (4500-5000 $\mu\text{mol mol}^{-1}$); on the other hand, the PPF saturation point was not so high as compared to some other species, though it increased with increasing CO₂ concentration inside the vessel.

Nicolas, M.E., R. Munns, A.B. Samarakoon, and R.M. Gifford. 1993. Elevated co₂ improves the growth of wheat under salinity. *Australian Journal of Plant Physiology* 20(3):349-360.

Wheat plants (*Triticum aestivum* cv. Matong and *T. durum* cv. Modoc) were grown at ambient and elevated CO₂ (350 $\mu\text{mol m}^{-3}$ above ambient) in soil with or without 150 mol m^{-3} NaCl for 6 weeks. The increase in dry matter, leaf area and tillering under high CO₂ was relatively greater under saline than non-saline conditions for both cultivars. Tillering was the primary component of growth affected by both salinity and high CO₂. Salinity greatly reduced tillering and high CO₂ partly reversed the effects of salinity. High CO₂ increased dry matter accumulation of the salt-sensitive Modoc to a greater extent (+ 104%) than that of the more salt-tolerant Matong (+ 73 %) in the salt treatment. Transpiration rates were greatly reduced by salinity for both cultivars. Under high CO₂, increased leaf areas compensated for reduced transpiration rates per unit leaf area (i.e. greater stomatal closure), and total transpiration was little affected by CO₂ level within each treatment. The more salt-tolerant Matong showed greater stomatal closure and higher transpiration efficiencies than the salt-sensitive Modoc under salinity. High CO₂ reduced transpiration rate (per unit dry weight) by 40 to 50%, but did not significantly change the rate of sodium accumulation (per unit dry weight), indicating that salt uptake was largely independent of water uptake, and that high CO₂ did not increase growth by reducing the salt load. Our results suggest that high CO₂ increased growth by stimulating the development of tiller buds that would otherwise have been inhibited.

Nicolussi, K., S. Bortenschlager, and C. Korner. 1995. Increase in tree-ring width in sub-alpine *Pinus cembra* from the central alps that may be co₂-related. *Trees-Structure and Function* 9(4):181-189.

It has been suggested many times that elevated atmospheric CO₂ levels should stimulate radial increment of stem growth. However, interpretation of dendrochronologies with respect to a CO₂ signal is a difficult task, since a multitude of environmental and tree factors influence the growth of stems. Here we provide a data set from subalpine stone pine which covers the period from 1750 to 1988, and from which growth rings of the 80- to 90-year age class were analysed. The most common climatological effects are taken into consideration. We found a steady and significant increase of mean ring width for the considered age class from approximately 1 mm per year in the middle of the last century to about 1.4 mm per year at present. Selected periods of equal mean summer temperatures in the last century and in more recent decades still yield a mean stimulation of about 25% for which atmospheric CO₂ enrichment appears to be the most plausible

explanation. The recent dramatic increase of atmospheric N-deposition could confound this interpretation, but chronologies of the last 2 decades during which wet and dry deposition of N-compounds showed the most dramatic increase exhibit no deviation from the long term trend. In contrast to the so far conflicting evidence of tree-ring responses to atmospheric changes the clear signal obtained here may be explained as follows: (1) stone pine produces little late season wood and moisture is never a limiting factor (particularly not in the early season); (2) comparatively good climatic records permitted the selection of thermally comparable periods; (3) trees grew under little spatial competition, (4) cores were collected well below the upper altitudinal range-limit of stone pine, leaving enough physiological leeway under episodic climatic stress, but (5) trees grew at altitudes high enough so that the reduction of the partial pressure of CO₂ could be expected to cause CO₂ to become relatively more limiting than at low elevations.

Nie, D., H. He, M.B. Kirkham, and E.T. Kanemasu. 1992. Photosynthesis of a C3 grass and a C4 grass under elevated CO₂. *Photosynthetica* 26(2):189-198.

The net photosynthetic rate (P(N)), intercellular CO₂ concentration (C(i)), transpiration rate (E), stomatal resistance (r(s)), and water potential (PSI(W)) of a C3 grass (Kentucky bluegrass, *Poa pratensis* L.) and a C4 grass (big bluestem, *Andropogon gerardii* Vitman) growing in the spring in a tallgrass prairie under two levels of CO₂ (ambient and twice ambient) were compared. Elevated CO₂ (HC) increased P(N) of Kentucky bluegrass (C3) by 47.0 % but did not affect P(N) of big bluestem (C4). HC increased C(i) of both grasses by about the same amount (is-approximately-equal-to cm³ m⁻³), but reduced E (and parallelly increased r(s)) of big bluestem more than those of Kentucky bluegrass. HC increased PSI(W) of both grasses by about 30 %. Kentucky bluegrass had a lower PSI(W) than big bluestem, but HC increased PSI(W) of Kentucky bluegrass to values more similar to those of big bluestem under ambient CO₂ (LC). Hence a high PSI(W), resulting from HC, was necessary for a high P(N).

Nie, D., H. He, G. Mo, M.B. Kirkham, and E.T. Kanemasu. 1992. Canopy photosynthesis and evapotranspiration of rangeland plants under doubled carbon-dioxide in closed-top chambers. *Agricultural and Forest Meteorology* 61(3-4):205-217.

It is important to know how the increasing atmospheric concentration of carbon dioxide (CO₂) will affect growth of agricultural plants. The objective of this study was to determine the effect of elevated CO₂ on canopy photosynthetic rate of prairie (rangeland) plants growing under natural field conditions. The dominant plants were warm-season grasses with the C4 type of photosynthesis. Sixteen closed-top, cylindrical, plastic chambers (1.5 m in diameter; 1.8 m tall) were placed on the prairie to maintain two levels of CO₂ (ambient and twice ambient) over a full growing season in 1990. The soil (silty clay loam) was kept at a high water (field capacity) or a low water level (no water added). Carbon dioxide concentration, air temperature, net radiation, canopy photosynthetic rate, and canopy evapotranspiration rate were measured in the 16 chambers on 49 sunny days during the season. The target value for high- CO₂ chambers was 720 cm³ CO₂ m⁻³; the measured mean concentrations varied from 710.8 to 720.1 cm³ CO₂ m⁻³. For chambers with ambient CO₂, the chamber-to-chamber variation was minor, with mean values ranging from 350.8 to 356.0 cm³ CO₂ m⁻³. Daytime air temperatures at 100 cm aboveground in the chambered plots averaged

2.7-degrees-C warmer than outside. Early in the season, net radiation was usually similar among chambers with the different CO₂ and water treatments, but late in the season, differences occurred among chambers, possibly because of the amount of tall grasses that shaded the radiometers. Under the high-water treatment, canopy photosynthesis of plants grown with doubled and ambient CO₂ averaged 41.8 μmol m⁻² s⁻¹ and 44.5 μmol m⁻² s⁻¹, respectively. These results are consistent with previous findings, which showed that the photosynthetic rate of C4 plants on rangeland was not augmented when the CO₂ concentration was increased. Under the low-water treatment, photosynthesis of plants grown with doubled CO₂ was slightly more (36.9 μmol m⁻² s⁻¹) than that of plants grown with ambient CO₂ (31.7 μmol m⁻² s⁻¹). This observation is in agreement with other results, which have shown that high CO₂ alleviates water-stress effects on plants. Elevated CO₂ reduced canopy evapotranspiration rate by 18 and 8%, under the high- and low-water levels, respectively. The results suggested that, as the CO₂ concentration in the atmosphere increases, water lost from rangelands will be reduced.

Nie, D., M.B. Kirkham, L.K. Ballou, D.J. Lawlor, and E.T. Kanemasu. 1992. Changes in prairie vegetation under elevated carbon-dioxide levels and 2 soil-moisture regimes. *Journal of Vegetation Science* 3(5):673-678.

It is important to know how increasing levels of atmospheric CO₂ will affect native vegetation. The objective of this study was to determine the effect of elevated CO₂ concentrations on species composition in a tallgrass prairie kept at a high water level (730 mm of water in a 2000 mm soil profile) and a low water level (660 mm of water in 2000 mm). 16 cylindrical plastic chambers were placed on the prairie to maintain two levels of CO₂ (ambient or twice ambient) during two growing seasons in 1989 and 1990. Frequency of species was determined on 25 July 1989 and on 5 and 10 October 1990. At the beginning of the study, *Poa pratensis* (Kentucky bluegrass), the dominant C3 species, had the highest frequency of 43.3%, but decreased with time. However, at the end of the experiment and under the high soil-water level, there were more *P. pratensis* plants in the elevated CO₂ treatment (frequency: 13.5%) than in the ambient CO₂ treatment (1.0%). Under the low soil water regime, the reverse occurred (frequencies: 3.6 % and 11.0 % for high and low CO₂, respectively). The frequency of major C4 plants, *Andropogon gerardii* (big bluestem), *A. scoparius* (little bluestem) and *Sorghastrum nutans* (Indian grass) was not affected by CO₂. However, water did affect their frequency. Under low water, the frequency of *A. gerardii* decreased between 1989 and 1990. Under both soil moisture levels, the frequencies of *S. nutans* and *A. scoparius* increased. At the end of the study, Indian grass grown with high water had the highest frequency of all species on the prairie (frequency at the end of the study in October, 1990, of 44.4% and 47.4% for the high and low CO₂ levels, respectively). Unlike Indian grass, little bluestem grew better under low water conditions than under high water conditions. These results suggest that, if the climate becomes drier, *A. scoparius* will flourish more than *S. nutans* or *A. gerardii*, and *P. pratensis* may die out. Elevated CO₂ might not increase survival of C3 Plants under dry conditions, if temperatures are too high for them.

Nie, G.Y., D.L. Hendrix, A.N. Webber, B.A. Kimball, and S.P. Long. 1995. Increased accumulation of carbohydrates and decreased photosynthetic gene transcript levels in wheat grown at an elevated CO₂ concentration in the field. *Plant Physiology* 108(3):975-983.

Repression of photosynthetic genes by increased soluble carbohydrate concentrations may explain acclimation of photosynthesis to elevated CO₂ concentration. This hypothesis was examined in a field crop of spring wheat (*Triticum aestivum* L.) grown at both ambient (approximately 360 $\mu\text{mol mol}^{-1}$) and elevated (550 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ concentrations using free-air CO₂ enrichment at Maricopa, Arizona. The correspondence of steady-state levels of mRNA transcripts (coding for the 83-kD photosystem I apoprotein, sedoheptulose-1,7-bisphosphatase, phosphoribulokinase, phosphoglycerokinase, and the large and small subunits of ribulose-1,5-bisphosphate carboxylase/oxygenase) with leaf carbohydrate concentrations (glucose-6-phosphate, glucose, fructose, sucrose, fructans, and starch) was examined at different stages of crop and leaf development and through the diurnal cycle. Overall only a weak correspondence between increased soluble carbohydrate concentrations and decreased levels for nuclear gene transcripts was found. The difference in soluble carbohydrate concentration between leaves grown at elevated and current ambient CO₂ concentrations diminished with crop development, whereas the difference in transcript levels increased. In the flag leaf, soluble carbohydrate concentrations declined markedly with the onset of grain filling; yet transcript levels also declined. The results suggest that, whereas the hypothesis may hold well in model laboratory systems, many other factors modified its significance in this field wheat crop.

Nie, G.Y., S.P. Long, R.L. Garcia, B.A. Kimball, R.L. Lamorte, P.J. Pinter, G.W. Wall, and A.N. Webber. 1995. Effects of free-air CO₂ enrichment on the development of the photosynthetic apparatus in wheat, as indicated by changes in leaf proteins. *Plant, Cell and Environment* 18(8):855-864.

A spring wheat crop was grown at ambient and elevated (550 $\mu\text{mol mol}^{-1}$) CO₂ concentrations under free-air CO₂ enrichment (FACE) in the field. Four experimental blocks, each comprising 21-m-diameter FACE and control experimental areas, were used. CO₂ elevation was maintained day and night from crop emergence to final grain harvest. This experiment provided a unique opportunity to examine the hypothesis that CO₂ elevation in the field would lead to acclimatory changes within the photosynthetic apparatus under open field conditions and to assess whether acclimation was affected by crop developmental stage, leaf ontogeny and leaf age. Change in the photosynthetic apparatus was assessed by measuring changes in the composition of total leaf and thylakoid polypeptides separated by SDS-PAGE. For leaves at completion of emergence of the blade, growth at the elevated CO₂ concentration had no apparent effect on the amount of any of the major proteins of the photosynthetic apparatus regardless of the leaf examined. Leaf 5 on the main stem was in full sunlight at emergence, but then became shaded progressively as 3-4 further leaves formed above with continued development of the crop. By 35 d following completion of blade emergence, leaf 5 was in shade. At this point, the chlorophyll *a*/*b* ratio had declined by 26% both in plants grown at the control CO₂ concentration and in those grown at the elevated CO₂ concentration, which is indicative of shade acclimation. The ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) content declined by 45% in the control leaves, but by 60% in the leaves grown at the elevated CO₂

concentration. The light-harvesting complex of photosystem II (LHCII) and the chlorophyll content showed no decrease and no difference between treatments, indicating that the decrease in Rubisco was not an effect of earlier senescence in the leaves at the elevated CO₂ concentration. Following completion of the emergence of the flag-leaf blade, the elevated-CO₂ treatment inhibited the further accumulation of Rubisco which was apparent in control leaves over the subsequent 14 d. From this point onwards, the flag leaves from both treatments showed a loss of Rubisco, which was far more pronounced in the elevated-CO₂ treatment, so that by 36 d the Rubisco content of these leaves was just 70% of that of the controls and by 52 d it was only 20%. At 36 d, there was no decline in chlorophyll, LHCII or the chloroplast ATPase coupling factor (CFI) in the elevated CO₂ concentration treatment relative to the control. By 52 d, all of these proteins showed a significant decline relative to the control. This indicates that the decreased concentration of Rubisco at this final stage probably reflected earlier senescence in the elevated-CO₂ treatment, but that this was preceded by a CO₂-concentration-dependent decline in Rubisco.

Nielsen, M.V. 1995. Photosynthetic characteristics of the coccolithophorid *emiliania-huxleyi* (prymnesiophyceae) exposed to elevated concentrations of dissolved inorganic carbon. *Journal of Phycology* 31(5):715-719.

Light-saturated photosynthesis (P-max) of *Emiliania huxleyi* (Lohmann) Hay et Mohler is known to be carbon-limited at natural concentrations of dissolved inorganic carbon (DIC). In the present study, light-limited and light-saturated photosynthetic rates of *E. huxleyi* were studied at three concentrations of DIC (2.4, 7.4, and 12.4 mM) for high-calcite (C-in/C-tot = 0.48) and low-calcite (C-in/C-tot = 0.08) cells of the same strain. The photosynthetic efficiency (α) and the maximum quantum yield ($\Phi(\text{max})$) increased by more than a factor of 2 from the lowest to the highest DIC level. P-max, α , and $\Phi(\text{max})$ were always higher for the high-calcite than for the low-calcite cells at identical DIC levels. This may indicate that the calcification process acts as an extra supplier of CO₂ for photosynthesis making the CO₂ shortage at natural DIC levels a little smaller for high-calcite than for low-calcite *E. huxleyi*. A dependency of $\Phi(\text{max})$ on DIC has not previously been shown for marine phytoplankton. $\Phi(\text{max})$ is a key parameter in recent biooptical models of phytoplankton productivity, and the results from the present study are therefore important for modeling the productivity of *E. huxleyi*.

Niewiadomska, E., C. Gaucher-Veilleux, N. Chevrier, Y. Mauffette, and P. Dizengremel. 1999. Elevated CO₂ does not provide protection against ozone considering the activity of several antioxidant enzymes in the leaves of sugar maple. *Journal of Plant Physiology* 155(1):70-77.

Seedlings of sugar maple (*Acer saccharum* Marsch.) were exposed for 46 days to 700 ppm of CO₂, 200 ppb of ozone, and 700 ppm of CO₂ + 200 ppb of ozone. A significant increase in the activity of H₂O₂ scavenging enzymes, i.e. ascorbate peroxidase [EC 1.11.1.11] and catalase [EC 1.11.1.6], was measured due to the action of O₃. This increase was rather negatively affected by elevated CO₂. A tendency of decreased activity of glutathione reductase [EC 1.6.4.2] and superoxide dismutase [EC 1.15.1.1] due to the action of O₃ was detected. Elevated CO₂ does not provide enhanced tolerance to oxidative stress in the seedlings of sugar maple. Changes in the activity of antioxidant enzymes were more pronounced in the young leaves (developed during the experiment) than in the old leaves (developed before starting the experiment). Stimulation of chloroplastic FeSOD by elevated CO₂ was observed, indicating oxidative stress in chloroplasts evoked by elevated CO₂ level. This effect did not result in enhanced protection against the detrimental effect of ozone, most probably due to compartmentation of CO₂ and O₃ effects within the cell.

Niinemets, U., J.D. Tenhunen, N.R. Cantá, M.M. Chaves, T. Faria, J.S. Pereira, and J.F. Reynolds. 1999. Interactive effects of nitrogen and phosphorus on the acclimation potential of foliage photosynthetic properties of cork oak, *Quercus suber*, to elevated atmospheric CO₂ concentrations. *Global Change Biology* 5(4):455-470.

Leaf gas-exchange and chemical composition were investigated in seedlings of *Quercus suber* L. grown for 21 months either at elevated (700 $\mu\text{mol mol}^{-1}$) or normal (350 $\mu\text{mol mol}^{-1}$) ambient atmospheric CO₂ concentrations, [CO₂], in a sandy nutrient-poor soil with either 'high' N (0.3 mol N m⁻³) in the irrigation solution) or with 'low' N (0.05 mol N m⁻³) and with a constant suboptimal concentration of the other macro- and micronutrients. Although elevated [CO₂] yielded the greatest total plant biomass in 'high' nitrogen treatment, it resulted in lower leaf nutrient concentrations in all cases, independent of the nutrient addition regime, and in greater nonstructural carbohydrate concentrations. By contrast, nitrogen treatment did not affect foliar N concentrations, but resulted in lower phosphorus concentrations, suggesting that under lower N, P use-efficiency in foliar biomass production was lower. Phosphorus deficiency was evident in all treatments, as photosynthesis became CO₂ insensitive at intercellular CO₂ concentrations larger than approximate to 300 $\mu\text{mol mol}^{-1}$, and net assimilation rates measured at an ambient [CO₂] of 350 $\mu\text{mol mol}^{-1}$ or at 700 $\mu\text{mol mol}^{-1}$ were not significantly different. Moreover, there was a positive correlation of foliar P with maximum Rubisco (Ribulose-1,5-bisphosphate carboxylase/oxygenase) carboxylase activity (V_{cmax}), which potentially limits photosynthesis at low [CO₂], and the capacities of photosynthetic electron transport (J_{max}) and phosphate utilization (P_{max}), which are potentially limiting at high [CO₂]. None of these potential limits was correlated with foliar nitrogen concentration, indicating that photosynthetic N use-efficiency was directly dependent on foliar P availability. Though the tendencies were towards lower capacities of potential limitations of photosynthesis in high [CO₂] grown specimens, the effects were statistically insignificant, because of (i) large within-treatment variability related to foliar P, and (ii) small decreases in P/N ratio with increasing [CO₂], resulting in balanced changes in other foliar compounds potentially limiting carbon acquisition. The results of the current study indicate that under P-deficiency, the down-regulation of excess biochemical capacities proceeds in a similar manner in leaves grown under normal and elevated [CO₂], and also that foliar P/N ratios for optimum photosynthesis are likely to increase with increasing growth CO₂ concentrations.

Nijs, I., T. Behaeghe, and I. Impens. 1995. Leaf nitrogen content as a predictor of photosynthetic capacity in ambient and global change conditions. *Journal of Biogeography* 22(2-3):177-183.

Leaf assimilation capacity in *Lolium perenne*, grown in elevated CO₂ level (700 $\mu\text{mol mol}^{-1}$) and/or increased air temperature (ambient + 4 degrees C) could be predicted from leaf N content expressed on an area basis, although the linear relationships between maximum carboxylation rate (V_{cmax}) or maximum electron transport rate (J_{max}) and leaf N depended on treatment. The model, based on Farquhar, Von Caemmerer & Berry (1980) showed negative long-term effects of increased air temperature on V_{cmax} and J_{max} while longterm exposure to increased CO₂ level affected only V_{cmax}. Acclimation responses to these global changes therefore could not be explained by changes in N-content alone, but also in terms of changes in photosynthetic nitrogen use efficiency. Stimulation of photosynthesis by elevated CO₂ was not affected by reduction of leaf N in leaves developed in ambient air temperature, while part of the CO₂ benefit was lost in leaves developed in increased air temperature. This suggests that N-deficient ecosystems maintain the potential to respond to elevated CO₂ concentration, unless other processes than the primary carbon metabolism become limiting at low N supply. Similar to nitrogen content, changes in photon flux density did not change the CO₂ benefit either, unless a transition occurred from one limiting process to another (electron transport to carboxylation or vice versa). Hypotheses on interaction between CO₂ level, nitrogen status of the leaf and light intensity are formulated to support these findings.

Nijs, I., R. Ferris, H. Blum, G. Hendrey, and I. Impens. 1997. Stomatal regulation in a changing climate: a field study using Free Air Temperature Increase (FATI) and Free Air CO₂ enrichment (FACE). *Plant, Cell and Environment* 20(8):1041-1050.

This study investigates effects of climate warming (+2.5 degrees C above ambient) and elevated CO₂ concentration (600 $\mu\text{mol mol}^{-1}$) on the stomatal functioning and the water relations of *Lolium perenne*, using Free Air Temperature Increase (FATI) and Free Air CO₂ Enrichment (FACE). Compared to growth at ambient temperature, whole-season temperature increase reduced leaf stomatal conductance, but only at the top of the canopy (-14.6 and -8.8% at ambient and elevated CO₂, respectively). However, because higher canopy temperature raised the leaf-to-air vapour pressure difference, leaf transpiration rate increased (+28% at ambient and +48% at elevated CO₂) and instantaneous leaf water use efficiency, derived from short-term measurements of assimilation and transpiration rate, declined (-11% at ambient and -13% at elevated CO₂). Nevertheless, at the stand level, growth at +2.5 degrees C reduced transpiration due to fewer tillers per plant and a smaller leaf area per tiller. This sparser vegetation was also more closely coupled to the atmosphere and maintained a drier internal microclimate. To assess whether the stomatal behaviour observed in this experiment could be explained by prevailing concepts of stomatal functioning, three models were applied (Cowan 1977; Ball,

Woodrow & Berry 1987; Leuning 1995), The latter model accounted for the highest proportion of variability in the data (58%) and was insensitive to CO₂ and temperature regime, which suggests that the principles of stomatal regulation are not affected by changes in CO₂ or climate.

Nijs, I., and I. Impens. 1993. Effects of long-term elevated atmospheric carbon-dioxide on lolium-perenne and trifolium-repens, using a simple photosynthesis model. *Vegetatio* 104:421-431.

Changes in gross canopy photosynthetic rate (PGC), produced by long-term exposure to an elevated atmospheric CO₂ level (626 +/- 50 $\mu\text{mol mol}^{-1}$), were modelled for Lolium perenne L. cv. Vigor and Trifolium repens L. cv. Blanca, using a simple photosynthesis model, based on biochemical and physiological information (leaf gross CO₂ uptake in saturating light, P(max), and leaf quantum efficiency, alpha) and structural vegetation parameters (leaf area index, LAI, canopy extinction coefficient, k, leaf transmission, M). Correction of PGC for leaf respiration allowed comparison with previously measured canopy net CO₂ exchange rates, with the average divergence from model prediction amounting to about 6%. Sensitivity analysis showed that for a three-week old canopy, the PGC increase in high CO₂ could be attributed largely to changes in P(max) and alpha, while differences in canopy architecture were no longer important for the PGC-stimulation (which they were in the early growth stages). As a consequence of this increasing LAI with canopy age, the gain of daytime CO₂ uptake is progressively eroded by the increasing burden of canopy respiration in high- CO₂ grown Lolium perenne. Modelling canopy photosynthesis in different regrowth stages after cutting (one week, two weeks,...), revealed that the difference in a 24-h CO₂ balance between the ambient and the high CO₂ treatment is reduced with regrowth time and completely disappears after 6 weeks.

Nijs, I., and I. Impens. 1996. Effects of elevated CO₂ concentration and climate-warming on photosynthesis during winter in Lolium perenne. *Journal of Experimental Botany* 47(300):915-924.

Long-term effects of atmospheric carbon dioxide concentration (ambient or 700 $\mu\text{mol mol}^{-1}$) and air temperature (simulation of field conditions or +4 degrees C) on leaf photosynthetic rate were examined in Lolium perenne L. cv. Vigor, exposed to natural illumination during winter. Photosynthetic capacity was compared over a range of air temperatures and photon flux densities of photosynthetically active radiation which were representative of winter climate (5-15 degrees C and 0-500 $\mu\text{mol m}^{-2} \text{s}^{-1}$), with CO₂ level during measurement similar to that during the experimental period. Long-term exposure to increased air temperature reduced leaf CO₂ fixation capacity by 23% (averaged over all measurement conditions), resulting from a decline in light-saturated uptake rate, but not in incident- light quantum efficiency. CO₂-stimulation was largely absent in plants grown in ambient temperature, but pronounced in plants grown under +4 degrees C, where it compensated for two-thirds of the 23% drop. This enhancing effect of elevated CO₂ level on leaf CO₂ uptake rate observed in the warmer treatment, was strongly dependent on measurement temperature, increasing from 5% at 5 degrees C, to up to 32% at 15 degrees C. Measurements of chlorophyll fluorescence and dry matter corresponded with the observed changes in assimilation capacity, which could not be attributed to a deteriorated nitrogen status of the leaves as there was a

similar N content on an area basis. Several hypotheses are considered to explain the observed CO₂- temperature interactions.

Nijs, I., and I. Impens. 1997. An analysis of the balance between root and shoot activity in Lolium perenne cv Melvina. Effects of CO₂ concentration and air temperature. *New Phytologist* 135(1):81-91.

This study investigated the mechanisms which control the partitioning between roots and shoots in plants subjected to changes in environment. Two types of analyses were used: firstly, an examination of the cost and revenue associated with investment in different plant parts, and secondly, a test of the principle of functional equilibrium between roots and shoots, i.e. whether root dry matter x root specific activity balances shoot dry matter x shoot specific activity. Measurements were made on individual plants of Lolium perenne in sunlit controlled environments, grown from germination to canopy closure under optimal nitrogen supply. At the final harvest, increased air temperature (+4 degrees C above ambient) reduced whole-plant dry matter by 12% relative to the control, whereas elevated CO₂ mole fraction (700 $\mu\text{mol mol}^{-1}$) led to a 38% gain. The combined treatment yielded an intermediate result (+19%). Plants grown at +4 degrees C maintained balanced activity between roots and shoots throughout the experimental period, irrespective of CO₂ concentration. This required enhanced allocation to roots in young plants to compensate for a strong negative effect of higher temperature on root specific activity, which suggests that plants conserve balanced activity by adjusting dry matter partitioning. The extra cost involved with the adjustment at +4 degrees C significantly enhanced the cost:revenue ratio of plant investment. In ambient temperature, the balance between roots and shoots departed from equilibrium, slightly at ambient but substantially at elevated CO₂: the plants accumulated excess carbon relative to nitrogen, and this imbalance increased with plant age. At elevated CO₂, the cost:revenue ratio increased in young plants but this was later reversed owing to loss of root specific activity, which explains the gradually declining CO₂ stimulation with time. The strategies in equilibrating root and shoot functioning observed in the different treatments are discussed in the light of whole plant performance.

Nijs, I., I. Impens, and P. Vanhecke. 1992. Diurnal changes in the response of canopy photosynthetic rate to elevated CO₂ in a coupled temperature-light environment. *Photosynthesis Research* 32(2):121-130.

The relative increase with elevated CO₂ of canopy CO₂ uptake rate (A), derived from continuous measurements during the day, was examined in full-cover vegetative Lolium perenne canopies after 17 days of regrowth. The stands were grown at ambient (358 +/- 50- $\mu\text{mol mol}^{-1}$) and increased (626 +/- 50- $\mu\text{mol mol}^{-1}$) CO₂ concentration in sunlit growth chambers. Over the entire range of temperature and light conditions (which were strongly coupled and increased simultaneously), A was on average twice as large in high compared to ambient CO₂. This response (called M = A in high CO₂/A in ambient CO₂) could not be explained by changes in canopy conductance for CO₂ diffusion (GC). In spite of interaction and strong coupling between temperature and light intensity, there was evidence that temperature rather than light determined M. Further, high CO₂ treatment was found to alleviate the afternoon depression in A observed in ambient CO₂. A temperature

optimum shift or/and a larger carbohydrate sink capacity through altered root/shoot ratio are proposed in explanation.

Nijs, I., F. Kockelbergh, H. Teughels, H. Blum, G. Hendrey, and I. Impens. 1996. Free air temperature increase (FATI): A new tool to study global warming effects on plants in the field. *Plant, Cell and Environment* 19(4):495-502.

A new technique, called Free Air Temperature Increase (FATI), was developed to artificially induce increased canopy temperature in field conditions without the use of enclosures. This acronym was chosen in analogy with FACE (Free Air CO₂ Enrichment), a technique which produces elevated CO₂ concentrations [CO₂] in open field conditions. The FATI system simulates global warming in small ecosystems of limited height, using infrared heaters from which all radiation below 800 nm is removed by selective cut-off filters to avoid undesirable photomorphogenetic effects. An electronic control circuit tracks the ambient canopy temperature in an unheated reference plot with thermocouples, and modulates the radiant energy from the lamps to produce a 2.5 degrees C increment in the canopy temperature of an associated heated plot (continuously day and night). This pre-set target differential is relatively constant over time due to the fast response of the lamps and the use of a proportional action controller (the standard deviation of this increment was <1 degrees C in a 3 week field study with 1007 measurements). Furthermore, the increase in leaf temperature does not depend on the vertical position within the canopy or on the height of the stand. Possible applications and alternative designs are discussed.

Nijs, I., H. Teughels, H. Blum, G. Hendrey, and I. Impens. 1996. Simulation of climate change with infrared heaters reduces the productivity of *Lolium perenne* L. in summer. *Environmental and Experimental Botany* 36(3):271-280.

Field-grown perennial ryegrass was subjected to climate warming and elevated CO₂ concentration during summer in free air conditions (no enclosure of the vegetation). Increased foliage temperature (2.5 degrees C above fluctuating ambient) was induced by heating the stand with infrared radiation sources, modulated by an electronic control device (FATI, Free Air Temperature Increase). Enhanced CO₂ was produced by a FACE system (Free Air CO₂ Enrichment). Exposure to simulated climate warming drastically reduced above-ground harvestable dry matter (52% loss). The nitrogen allocated to the leaf fraction was thus concentrated into less dry matter, which enhanced the nitrogen concentration on a mass basis (+17%) but also per unit leaf area (+47%). As a consequence, CO₂ assimilation rates were not affected in these slower growing plants in the +2.5 degrees C treatment, and the photochemical efficiency of non-cyclic electron transport of photosystem II was also unaffected. Although the plants were grown in the field without root restrictions, long-term exposure to elevated CO₂ concentration induced noticeable acclimation of the photosynthetic apparatus (40% loss of fixation potential), which largely outweighed the direct stimulation in this summer period. Part of the reduced rates could be attributed to lower N concentration on a leaf area basis. The results are compared with responses of this species in sunlit conditioned greenhouses, which indicates that experiments in enclosures may underestimate effects in the field. This also emphasizes the need to validate other plant responses to climate warming and CO₂ enrichment

in free air conditions.

Niklaus, P.A. 1998. Effects of elevated atmospheric CO₂ on soil microbiota in calcareous grassland. *Global Change Biology* 4(4):451-458.

Microbial responses to three years of CO₂ enrichment (600 μ mol L⁻¹) in the field were investigated in calcareous grassland. Microbial biomass carbon (C) and soil organic C and nitrogen (N) were not significantly influenced by elevated CO₂. Microbial C:N ratios significantly decreased under elevated CO₂ (-15%, $P = 0.01$) and microbial N increased by +18% ($P = 0.04$). Soil basal respiration was significantly increased on one out of 7 sampling dates (+14%, $P = 0.03$; December of the third year of treatment), whereas the metabolic quotient for CO₂ (qCO_2) = basal respiration/microbial C) did not exhibit any significant differences between CO₂ treatments. Also no responses of microbial activity and biomass were found in a complementary greenhouse study where intact grassland turfs taken from the field site were factorially treated with elevated CO₂ and phosphorus (P) fertilizer (1 g P m⁻² y⁻¹). Previously reported C balance calculations showed that in the ecosystem investigated growing season soil C inputs were strongly enhanced under elevated CO₂. It is hypothesized that the absence of microbial responses to these enhanced soil C fluxes originated from mineral nutrient limitations of microbial processes. Laboratory incubations showed that short-term microbial growth (one week) was strongly limited by N availability, whereas P was not limiting in this soil. The absence of large effects of elevated CO₂ on microbial activity or biomass in such nutrient-poor natural ecosystems is in marked contrast to previously published large and short-term microbial responses to CO₂ enrichment which were found in fertilized or disturbed systems. It is speculated that the absence of such responses in undisturbed natural ecosystems in which mineral nutrient cycles have equilibrated over longer periods of time is caused by mineral nutrient limitations which are ineffective in disturbed or fertilized systems and that therefore microbial responses to elevated CO₂ must be studied in natural, undisturbed systems.

Niklaus, P.A., and C. Körner. 1996. Responses of soil microbiota of a late successional alpine grassland to long term CO₂ enrichment. *Plant and Soil* 184(2):219-229.

We investigated microbial responses in a late successional sedge-dominated alpine grassland to four seasons of CO₂ enrichment. Part of the plots received fertilizer equivalent to 4.5 g N m⁻² a⁻¹. Soil basal respiration (R_{mic}), the metabolic quotient for CO₂ (qCO_2) = R_{mic}/C_{mic} , microbial C and N (C_{mic} and N_{mic}) as well as total soil organic C and N showed no response to CO₂ enrichment alone. However, when the CO₂ treatment was combined with fertilizer addition R_{mic} and qCO_2 were statistically significantly higher under elevated CO₂ than under ambient conditions (+57% and +71%, respectively). Fertilizer addition increased microbial N pools by 17%, but this was not influenced by elevated CO₂. Microbial C was neither affected by elevated CO₂ nor fertilizer. The lack of a CO₂-effect in unfertilized plots was surprising in the light of our evidence (based on C balance) that enhanced soil C inputs must have occurred under elevated CO₂ regardless of fertilizer treatment. Based on these data and other published work we suggest that microbial responses to elevated CO₂ in such stable, late-successional ecosystems are limited by the availability

of mineral nutrients and that results obtained with fertile or heavily disturbed substrates are unsuitable to predict future microbial responses to elevated CO₂ in natural systems. However, when nutrient limitation is removed (e.g. by wet nitrogen deposition) microbes make use of the additional carbon introduced into the soil system. We believe that the response of natural ecosystems to elevated CO₂ must be studied in situ in natural, undisturbed systems.

Niklaus, P.A., P.W. Leadley, J. Stocklin, and C. Korner. 1998. Nutrient relations in calcareous grassland under elevated CO₂. *Oecologia* 116(1-2):67-75.

Plant nutrient responses to 4 years of CO₂ enrichment were investigated in situ in calcareous grassland. Beginning in year 2, plant aboveground C:N ratios were increased by 9% to 22% at elevated CO₂ ($P < 0.01$), depending on year. Total amounts of N removed in biomass harvests during the first 4 years were not affected by elevated CO₂ (19.9 $\pm$ 1.3 and 21.1 $\pm$ 1.3 g N m⁻²) at ambient and elevated CO₂, indicating that the observed plant biomass increases were solely attained by dilution of nutrients. Total aboveground P and tissue N:P ratios also were not altered by CO₂ enrichment (12.5 $\pm$ 2 g N g⁻¹ P in both treatments). In contrast to non-legumes (>98% of community aboveground biomass), legume C/N was not reduced at elevated CO₂ and legume N:P was slightly increased. We attribute the less reduced N concentration in legumes at elevated CO₂ to the fact that virtually all legume N originated from symbiotic N₂ fixation (%Ndfa approximate to 90%), and thus legume growth was not limited by soil N. While total plant N was not affected by elevated CO₂, microbial N pools increased by +18% under CO₂ enrichment ($P = 0.04$) and plant available soil N decreased. Hence, there was a net increase in the overall biotic N pool, largely due increases in the microbial N pool. In order to assess the effects of legumes for ecosystem CO₂ responses and to estimate the degree to which plant growth was P-limited, two greenhouse experiments were conducted, using firstly undisturbed grassland monoliths from the field site, and secondly designed 'microcosm' communities on natural soil. Half the microcosms were planted with legumes and half were planted without. Both monoliths and microcosms were exposed to elevated CO₂ and P fertilization in a factored design. After two seasons, plant N pools in both unfertilized monoliths and microcosm communities were unaffected by CO₂ enrichment, similar to what was found in the field. However, when P was added total plant N pools increased at elevated CO₂. This community-level effect originated almost solely from legume stimulation. The results suggest a complex interaction between atmospheric CO₂ concentrations, N and P supply. Overall ecosystem productivity is N-limited, whereas CO₂ effects on legume growth and their N₂ fixation are limited by P.

Niklaus, P.A., D. Spinnler, and C. Korner. 1998. Soil moisture dynamics of calcareous grassland under elevated CO₂. *Oecologia* 117(1-2):201-208.

Water relations of nutrient-poor calcareous grassland under long-term CO₂ enrichment were investigated. Understanding CO₂ effects on soil moisture is critical because productivity in these grasslands is water limited. In general, leaf conductance was reduced at elevated CO₂, but

responses strongly depended on date and species. Evapotranspiration (measured as H₂O gas exchange) revealed only small, non-significant reductions at elevated CO₂, indicating that leaf conductance effects were strongly buffered by leaf boundary layer and canopy conductance (leaf area index was not or only marginally increased under elevated CO₂). However, these minute and non-significant responses of water vapour loss accumulated over time and resulted in significantly higher soil moisture in CO₂-enriched plots (gravimetric spot measurements and continuous readings using a network of time-domain reflectometry probes). Differences strongly depended on date, with the smallest effects when soil moisture was very high (after heavy precipitation) and effects were largest at intermediate soil moisture. Elevated CO₂ also affected diurnal soil moisture courses and rewetting of soils after precipitation. We conclude that ecosystem-level controls of the water balance (including soil feedbacks) overshadow by far the physiological effects observed at the leaf level. Indirect effects of CO₂ enrichment mediated by trends in soil moisture will have far-ranging consequences on plant species composition, soil bacterial and faunal activity as well as on soil physical structure and may indirectly also affect hydrology and trace gas emissions and atmospheric chemistry.

Nikolaidis, N.P., H.L. Hu, and C. Ecsedy. 1994. Effects of climatic variability on the hydrologic response of a fresh-water watershed. *Aquatic Sciences* 56(2):161-178.

A generalized watershed model was used to evaluate the effects of global climate changes on the hydrologic responses of freshwater ecosystems. The Enhanced Trickle Down (ETD) model was applied to W-3 watershed located near Danville, Vermont. Eight years of field data was used to perform model calibration and verification and the results were presented in Nikolaidis et al., (1993). Results from the Goddard Institute for Space Studies (GISS) and the Geophysical Fluid Dynamics Laboratory (GFDL) general circulation models which simulated the doubling of present day atmospheric CO₂ scenarios were used to perform the hydrologic simulations for the W-3 watershed. The results indicate that the W-3 watershed will experience increases in annual evapotranspiration and decreases in annual outflow and soil moisture. Stochastic models that simulate collective statistical properties of meteorological time series were developed to generate data to drive the ETD model in a Monte- Carlo fashion for quantification of the uncertainty in the model predictions due to input time series. This coupled deterministic and stochastic model was used to generate probable scenarios of future hydrology of the W-3 watershed. The predicted evapotranspiration and soil moisture under doubling present day atmospheric CO₂ scenarios exceed the present day uncertainty due to input time series by a factor greater than 2. The results indicate that the hydrologic response of the W-3 watershed will be significantly different than its present day response. The Enhanced Trickle Down model can be used to evaluate land surface feedbacks and assessing water quantity management in the event of climate change.

Nilsen, E.T., P.W. Rundel, and M.R. Sharifi. 1996. Diurnal gas exchange characteristics of two stem photosynthesizing legumes in relation to the climate at two contrasting sites in the California desert. *Flora* 191(2):105-116.

The diurnal and seasonal patterns of climate, shoot water potential, stem

photosynthesis (Pn), stem conductance, and stem intercellular CO₂ were measured for two legume shrubs in the southern California desert at two elevations at four seasons of the year. One species (*Senna armata*), is restricted to the Mojave desert and was studied at 950 m elevation, while the other species (*Caesalpinia virgata*) is endemic to the Sonoran desert and was studied at 180 m elevation. The Sonoran desert site was characterized by higher temperatures, higher vapor pressure deficits, and more consistent solar radiation than the Mojave desert site. During the summer, the differences between the microclimates of the two sites were maximal. Both species have high predawn and midday shoot water potentials compared with other desert species, most likely because they have vertical stem orientation and low stem conductance. Stem Pn was positive all year, but Pn(max) decreased for *C. virgata* during the summer. Stem temperature, and its impact on vapor pressure deficit, was the most important regulator of stem photosynthesis. Although there were large changes in stem Pn between winter and summer, there was little change in intercellular CO₂ among seasons inferring no change in water use efficiency. Stem Pn most likely provides most of the carbon gain for both species because leaves are small and ephemeral, and stems are present and actively gaining carbon all year.

Ning, B., Y. Kubo, A. Inaba, and R. Nakamura. 1997. Physiological responses of Chinese pear 'Yali' fruit to CO₂-enriched and/or O₂-reduced atmospheres. *Journal of the Japanese Society for Horticultural Science* 66(3-4):613-620.

Respiration and ethylene production rates of Chinese pear 'Yali' fruit (*Pyrus ussuriensis* Maxim. var. *sinensis* Kikuchi) stored in CO₂-enriched and/or O₂-reduced atmospheres. In addition, several types of polyethylene film packaging were also applied to the long-term storage of 'Yali' fruit. 1. Oxygen uptake and ethylene production in 'Yali' fruit at 20 degrees C decreased with increasing CO₂ concentration up to 40%. Ethylene production under 60% CO₂ was markedly inhibited, whereas O₂ uptake was promoted; a physiological disorder in the flesh developed. 2. Under the same storage condition, oxygen uptake and ethylene production consistently decreased with decreasing O₂ concentration. However, when O₂ was decreased to less than 5%, CO₂ output exceeded O₂ uptake, suggesting that anaerobic respiration was occurring. 3. Respiration was inhibited in fruit kept at 10 or 20 degrees C under 5% CO₂ + 3% O₂ during the first 4 days of storage and then increased suddenly thereafter accompanied by the development of a physiological disorder. 4. The storage life of the fruit packed in a film with soda lime at 10 degrees C, in which O₂ became to about 8%, was prolonged by about a month, as compared to that of those packed in a perforated bag. The gas concentration higher than 5% CO₂ and/or lower than 5% O₂ within a plastic bag caused an accumulation of ethanol and the development of disorder in flesh, thus shortening storage life of fruit. Our results suggest that 'Yali' fruit is sensitive to both CO₂-enriched and O₂-reduced atmospheres, and that 2% CO₂ and 8% O₂ are about optimal for its long-term storage.

Ning, L., B.E. Petersen, G.E. Edwards, L.S. Daley, and J.B. Callis. 1997. Recovery of digital information stored in living plant leaf photosynthetic apparatus as fluorescence signals. *Applied Spectroscopy* 51(1):1-9.

A CCD (charge-coupled device)-equipped, imaging spectroscopic instrument is discussed that can be reversible and rapidly reconfigured

to image photosynthetic fluorescence, allowing two-dimensional spatial estimates of fluorescence quantum yield (Y'). Y' images of leaf areas with immediately functional photosynthetic apparatus appear smooth and uniform and are much less affected by variations in chlorophyll content and light path through the leaf. However, areas of the leaf where the photosynthetic apparatus has different light history, pathology, or other damage generate different Y' value images. This characteristic allowed storage and recovery of images from leaves. Extending this finding, we prepared binary data coding for the value of pi to 99 decimal places (100 digits), on living leaves. The images containing the binary codes for these digits can be "read" by eye, because the human brain interprets visual data with great skill. However, it was necessary to enhance the images to facilitate instrument "reading". A program was developed to enhance the images and "read" the data images with no errors. The photosynthetic mechanism involved (nonphotochemical quenching), the role of leaf age and germplasm variation, and the potential applications of this finding in terms of bioelectronics are discussed.

Nitschelm, J.J., A. Luscher, U.A. Hartwig, and C. VanKessel. 1997. Using stable isotopes to determine soil carbon input differences under ambient and elevated atmospheric CO₂ conditions. *Global Change Biology* 3(5):411-416.

Quantitative estimates of soil C input under ambient (35 Pa) and elevated (60 Pa) CO₂-partial pressure (pCO₂) were determined in a Free-Air Carbon dioxide Enrichment (FACE) experiment. To facilitate C-13-tracing, *Trifolium repens* L. was grown in a soil with an initial delta(13)C distinct by at least 5 parts per thousand from the delta(13)C of *T. repens* grown under ambient or elevated pCO₂. A shift in delta(13)C of the soil organic C was detected after one growing season. Calculated new soil C inputs in soil under ambient and elevated pCO₂ were 2 and 3 t ha⁻¹, respectively. Our findings suggest that under elevated CO₂ conditions, soil C sequestration may be altered by changes in plant biomass production and quality.

Niu, G., T. Kozai, M. Hayashi, and M. Tateno. 1997. Time course simulations of CO₂ concentration and net photosynthetic rates of potato plantlets cultured under different lighting cycles. *Transactions of the Asae* 40(6):1711-1718.

Potato (*Solanum tuberosum* L. cv. Benimaru) plantlets were cultured under four lighting cycles with the same ratio of photo/dark period (16 h/8 h, 4 h/2 h, 1 h/0.5 h, and 0.25 h/0.125 h) photoautotrophically (without sugar in the medium) and photomixotrophically (with sugar in the medium) in vitro for 28 days. Simulations of time courses of CO₂ concentration in the vessel (C-i) for plantlets cultured photoautotrophically, and photomixotrophically and dry weight accumulations of the plantlets cultured photoautotrophically were conducted using the same model and parameter values as those in Niu and Kozai (1997). While underestimation and overestimation of the time courses of C-i in some treatments were observed the simulated values of C-i and the dry weight accumulation of the plantlets generally agreed with the measured values. The simulated responses of net photosynthetic

rate of the plantlets to C-i indicated that in the early, culture period, plantlets have higher photosynthetic ability under photoautotrophic than under photomixotrophic culture conditions. The quantitative relationship between daily net photosynthetic rate (daily net production) and vessel ventilation rate per plantlet was simulated under various CO₂ levels outside the vessel for given sizes of potato plantlets cultured in vitro photoautotrophically, to aid appropriate CO₂ enrichment and vessel design in commercial micropropagation systems.

Nobel, P.S. 1991. Environmental productivity indexes and productivity for *Opuntia ficus-indica* under current and elevated atmospheric CO₂ levels. *Plant, Cell and Environment* 14(7):637-646.

The productivity of the prickly-pear cactus *Opuntia ficus-indica*, which is cultivated worldwide for its fruits and stem segments, was predicted based on the responses of its net CO₂ uptake to soil water status, air temperature and photosynthetic photon flux density (PPFD). Each of these environmental factors was represented by an index with a maximum value of unity when that factor was not limiting net CO₂ uptake over a 24-h period. The water index, the temperature index, and the PPFD index were determined for 87 sites in the contiguous United States using data from 189 weather stations and for 148 sites worldwide using data from 1464 weather stations. The product of these three indices, the environmental productivity index (EPI), was used to predict the productivity of *O. ficus-indica* under current climatic conditions and under those accompanying a possible increase in the atmospheric CO₂ level to 650- μ mol mol⁻¹. Sites with temperatures always above -10-degrees-C and hence suitable for prickly-pear cultivation numbered 37 in the United States and 110 worldwide; such sites increased by 43 and 5%, respectively, for the global warming accompanying the elevated CO₂. Productivity of *O. ficus-indica* was at least 15 tonnes dry weight hectare⁻¹ year⁻¹, comparable to that of many agronomic crops, for 20 sites with temperatures always above -10-degrees-C in the contiguous United States and for 12 such sites worldwide under current climatic conditions; such sites increased by 85 and 117%, respectively, under the elevated CO₂ condition, mainly because of direct effects of the atmospheric CO₂ level on net CO₂ uptake. In summary, simulations based on EPI indicate that *O. ficus-indica* may presently be advantageously cultivated over a substantial fraction of the earth's surface, such regions increasing markedly with a future doubling in atmospheric CO₂ levels.

Nobel, P.S. 1996. Responses of some North American CAM plants to freezing temperatures and doubled CO₂ concentrations: Implications of global climate change for extending cultivation. *Journal of Arid Environments* 34(2):187-196.

Environmental influences on the cultivation of Crassulacean acid metabolism (CAM) plants, which are especially well adapted to arid regions with limited rainfall, were evaluated with respect to two aspects of global climate change. Cellular uptake of a vital stain, which occurs in living cells only, was halved at -6 $\pm$ 1 degrees C for the cultivated CAM species *Agave salmiana*, *Opuntia ficus indica* and *Stenocereus queretaroensis* growing at day/night air temperatures of 30 degrees C/20 degrees C compared with -12 degrees C for the wild species *Opuntia humifusa*. When plants were grown at reduced temperatures of 10 degrees C/0 degrees C, stain uptake was halved at about -8 degrees C for the cultivated species but at -24 degrees C for *O. humifusa*. The greater

low-temperature sensitivity and the lesser low-temperature acclimation of the cultivated species severely limit the regions where they can presently be grown, but such regions will expand as air temperatures rise accompanying global climate change. When the atmospheric CO₂ concentration was doubled from the current ambient value of 360 μ mol mol⁻¹ to 720 μ mol mol⁻¹, net CO₂ uptake over 24-h periods increased 36% for *A. salmiana* and *S. queretaroensis*; about one-third of the increase resulted from higher net CO₂ uptake rates in the last 4 h of daytime and two-thirds from higher rates during the first 8 h of the night. The doubled atmospheric CO₂ concentration predicted to occur before the end of the twenty-first century will increase CO₂ uptake and hence biomass productivity of such CAM species, further expanding the regions where they may be profitably cultivated. Nobel, P.S. 1996. Shading, osmoticum, and hormone effects on organ development for detached cladodes of *Opuntia ficus-indica*. *International Journal of Plant Science* 157(6):722-728.

To help understand what conditions lead to the development of new organs on shoots of *Opuntia ficus-indica*, a widely cultivated prickly pear cactus, detached cladodes were kept in a glasshouse and were shaded, exposed to full sunlight, or exposed to full sunlight and injected with various osmotica and hormones. Daughter cladodes emerged more slowly on cladodes detached in January (mean time of 12.6 wk) than in May (4.2 wk). In the field, new organ development was more rapid and more fruits were produced compared with cladodes detached in January and kept in a glasshouse. Shading by 94% essentially eliminated the development of daughter cladodes for cladodes harvested in both seasons over the 18-wk observation period. Daughter cladodes had a lower percentage dry mass and a higher water potential than the detached cladodes on which they developed, suggesting that water entered them primarily via the phloem. Compared with detached cladodes injected weekly with 1% of the cladode fresh mass of water for 6 wk, injection of 1.5 M sucrose accelerated daughter cladode development by 1.4 wk 750 mM KCl by 3.0 wk, and 750 mM KNO₃ by 4.8 wk. Injection of 20 μ M gibberellic acid (GA(3) and GA(4)) virtually eliminated the development of daughter cladodes. Injection of 800 μ M indole-3-acetic acid accelerated cladode development by 3.1 wk and 800 μ M kinetin by 4.0 wk, both resulting in a greater biomass for the new organs. Thus production of daughter cladodes by detached cladodes of *O. ficus-indica* was enhanced by a higher tissue osmotic pressure, indole-acetic acid, and kinetin and was inhibited by shading and gibberellic acid.

Nobel, P.S., M.Y. Cui, and A.A. Israel. 1994. Light, chlorophyll, carboxylase activity and CO₂ fixation at various depths in the chlorenchyma of *Opuntia ficus-indica* (L.) miller under current and elevated CO₂. *New Phytologist* 128(2):315-322.

Mature cladodes of *Opuntia ficus-indica* (L.) Miller have a thick chlorenchyma (about 4 mm) with a relatively high chlorophyll content (0.65 g m⁻²), suggesting that light may be greatly attenuated and hence CO₂ fixation negligible in the inner part of this tissue. Indeed, blue light (400-470 nm) and red light (670-685 nm) were 99 % attenuated in the

outer 2 mm of the chlorenchyma when the cladodes developed under both current and elevated CO₂ concentrations. Nevertheless, the nocturnal acidity increase and C-14 accumulation following a brief exposure to (CO₂)-C-14 night decreased only 22 to 47 % for a layer 2-3 mm deep in the chlorenchyma of this CAM plant. Under a particular growth CO₂, the activities of both ribulose- 1,5-bisphosphate carboxylase/oxygenase and phosphoenolpyruvate carboxylase were similar for each of the outer three 1-mm-thick layers of the chlorenchyma. Therefore, although the light level and total chlorophyll decreased sharply with depth and the chlorophyll a/b ratio also decreased, substantial CO₂ fixation apparently occurs throughout most of the chlorenchyma. When *O. ficus-indica* was grown under 720 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, the chlorenchyma was 20 % thicker but contained 11 % less chlorophyll and had a lower absorptance than under the current CO₂ concentration (370 μmol^{-1}). Greater nocturnal acidity increases and C-14 accumulation following exposure to (CO₂)-C- 14 at night occurred at the doubled CO₂ concentration despite 29-39% reductions in the activities of the two carboxylating enzymes, the lower absorptance, and a 24 % increase in the cladode reflectance from 400 to 700 nm.

Nobel, P.S., M.Y. Cui, P.M. Miller, and Y.Q. Luo. 1994. Influences of soil volume and an elevated CO₂ level on growth and CO₂ exchange for the crassulacean acid metabolism plant *Opuntia ficus-indica*. *Physiologia Plantarum* 90(1):173-180.

Effects of the current (38 Pa) and an elevated (74 Pa) CO₂ partial pressure on root and shoot areas, biomass accumulation and daily net CO₂ exchange were determined for *Opuntia ficus-indica* (L.) Miller, a highly productive Crassulacean acid metabolism species cultivated worldwide. Plants were grown in environmentally controlled rooms for 18 weeks in pots of three soil volumes (2 600, 6 500 and 26 000 cm³), the smallest of which was intended to restrict root growth. For plants in the medium-sized soil volume, basal cladodes tended to be thicker and areas of main and lateral roots tended to be greater as the CO₂ level was doubled. Daughter cladodes tended to be initiated sooner at the current compared with the elevated CO₂ level but total areas were similar by 10 weeks. At 10 weeks, daily net CO₂ uptake for the three soil volumes averaged 24% higher for plants growing under elevated compared with current CO₂ levels, but at 18 weeks only 3% enhancement in uptake occurred. Dry weight gain was enhanced 24% by elevated CO₂ during the first 10 weeks but only 8% over 18 weeks. Increasing the soil volume 10-fold led to a greater stimulation of daily net CO₂ uptake and biomass production than did doubling the CO₂ level. At 18 weeks, root biomass doubled and shoot biomass nearly doubled as the soil volume was increased 10-fold; the effects of soil volume tended to be greater for elevated CO₂. The amount of cladode nitrogen per unit dry weight decreased as the CO₂ level was raised and increased as soil volume increased, the latter suggesting that the effects of soil volume could be due to nitrogen limitations.

Nobel, P.S., and V.G. Decortazar. 1991. Growth and predicted productivity of *Opuntia ficus-indica* for current and elevated carbon-dioxide. *Agronomy Journal* 83(1):224-230.

Opuntia ficus-indica (L.) Mill., a prickly pear cactus cultivated worldwide for its fruits and stem segments, can have an annual dry weight productivity exceeding that of many crops. Using a recently introduced environmental productivity index (EPI), the influences of water status, temperature, and photosynthetically active radiation (PAR) on its productivity can be predicted. This investigation calculated the water index, the temperature index, and the PAR index, whose product equals EPI, for 169 sites distributed approximately uniformly across the contiguous USA for present climatic conditions as well as for those associated with an elevated CO₂ concentration of 650- $\mu\text{L L}^{-1}$. The effect of elevated CO₂ on growth of *O. ficus-indica* was directly measured, and low temperature limitations on productivity were considered. The dry weight gain of *O. ficus-indica* during 6 mo in an environmental growth chamber was 23% greater at 650 compared with 350- $\mu\text{L L}^{-1}$ CO₂ and increased as the duration of the wet period increased, in agreement with predictions of the water index (the fraction of maximal net CO₂ uptake during a 24-h period for the prevailing plant water status). For closely spaced plants that lead to a high productivity per unit ground area, EPI averaged about 0.10, except in desert regions where the water index lowered EPI, in the far North or South and at high elevations where the temperature index lowered EPI, and in the Northeast and Northwest where the PAR index lowered EPI. The predicted annual dry weight productivity for *O. ficus-indica* was 12.8 Mg ha⁻¹ yr⁻¹ under current conditions, and 16.3 Mg ha⁻¹ yr⁻¹ under those associated with 650- $\mu\text{L L}^{-1}$ CO₂. Both productivities are relatively high compared with other agronomic plants. The percentage of sites where temperatures fall below - 15-degrees- C at least once during the 10 years simulated, which would be lethal to most prickly pear cacti, was reduced from 49 to 18% by the general warming expected to accompany an approximate doubling of the atmospheric CO₂ concentration.

Nobel, P.S., and A.A. Israel. 1994. Cladode development, environmental responses of CO₂ uptake, and productivity for *Opuntia ficus-indica* under elevated CO₂. *Journal of Experimental Botany* 45(272):295-303.

Opuntia ficus-indica, an extremely productive CAM plant cultivated in many countries, was exposed to 36, 52, and 72-73 Pa CO₂ in field plots and open-top chambers. Initiation of new cladodes (stem segments) was monitored until the canopy closed, after which bimonthly harvests maintained the plants for one year at a cladode area per unit ground area that is optimal for biomass production. Doubling the CO₂ partial pressure slightly increased the number of first-order daughter cladodes growing on the basal (planted) cladodes after 3 months and nearly doubled the number and area of second-order cladodes. When the CO₂ level was doubled, cladodes were 5% thicker after a few months and 11 to 16% thicker after one year. Although the productivity enhancement by elevated CO₂ tended to decrease during the year, the annual above-ground dry-mass gain was 37 to 40% higher when the CO₂ level was doubled, reaching 65 tons hectare⁻¹ year⁻¹ in a field plot. Well-watered cladodes at day/night air temperatures of 25 degrees C/15 degrees C and a total daily photosynthetic photon flux (PPF) of 15 mol m⁻² d⁻¹ in controlled environment chambers had 74% more net CO₂ uptake over 24 h at 73 Pa than at 37 Pa CO₂. With doubled CO₂, the percentage enhancement of net CO₂ uptake increased as the PPF was lowered, as the temperature was raised, and during drought. Using an environmental productivity index based on such factors, net CO₂ uptake and hence productivity of *O. ficus-indica* can be predicted for elevated CO₂ levels and other variations accompanying global climate change.

Nobel, P.S., A.A. Israel, and N. Wang. 1996. Growth, CO₂ uptake, and responses of the carboxylating enzymes to inorganic carbon in two highly productive CAM species at current and doubled CO₂ concentrations. *Plant, Cell and Environment* 19(5):585-592.

In *Agave salmiana* Otto ex Salm. var. *salmiana* grown for 41/2 months in open-top chambers, 55% more leaves unfolded and 52% more fresh mass was produced at 730 than at 370 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. A doubling of the CO₂ concentration also stimulated growth in another highly productive CAM species, *Opuntia ficus-indica* (L.) Miller, leading to earlier initiation and 37% more daughter cladodes. Substantial net CO₂ uptake occurred earlier in the afternoon and lasted longer through the night for *A. salmiana* at 730 than at 370 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, resulting in 59% more total daily net CO₂ uptake. The Michaelis constant (HCO₃⁻) for PEPCase was 15% lower for *A. salmiana* and 44% lower for *O. ficus-indica* when the CO₂ concentration was doubled; the percentage of Rubisco in the activated state in vivo was on average 64% higher at the doubled CO₂ concentration. Thus the substantial increases in net CO₂ uptake and biomass production that occurred in these two CAM species when the ambient CO₂ concentration was doubled resulted mainly from higher inorganic carbon levels for their carboxylating enzymes, a greater substrate affinity for PEPCase, and a greater percentage of Rubisco in the activated state.

Noble, R., K.F. Jensen, B.S. Ruff, and K. Loats. 1992. Response of acer-saccharum seedlings to elevated carbon-dioxide and ozone. *Ohio Journal of Science* 92(3):60-62.

Newly germinated seedlings of *Acer saccharum* were grown in atmospheres of elevated carbon dioxide (CO₂) or ozone (O₃) for 85 days. Net photosynthesis measured on initial leaves and recently formed leaves tended (though not always statistically significant) to increase with an increase in CO₂. Biomass measured at the end of the study also increased with and increase in CO₂. Ozone at 0.15 ppm did not have a significant impact on either net photosynthesis or growth; however, with O₃-treatment, biomass increased at elevated CO₂ levels.

Noctor, G., A.C.M. Arisi, L. Jouanin, and C.H. Foyer. 1999. Photorespiratory glycine enhances glutathione accumulation in both the chloroplastic and cytosolic compartments. *Journal of Experimental Botany* 50(336):1157-1167.

Transformed poplars overexpressing gamma-glutamylcysteine synthetase (gamma-ECS) in the chloroplast (Lggs) were used to investigate chloroplastic biosynthesis of glutathione (GSH). In Lggs leaves, GSH contents were! enhanced by up to 3.7-fold. In general, the highest GSH contents were observed in lines with highest gamma-glutamylcysteine (gamma-EC) contents. These lines had relatively low glycine. In darkness, foliar GSH decreased and gamma-EC increased. Illumination of pre-darkened Lggs in air resulted in a 5-fold decrease in the gamma-EC:GSH ratio. This light-induced decrease was largely abolished if leaves were illuminated at high CO₂. Consequently, the gamma-EC:GSH ratio of illuminated leaves was much higher at high CO₂ than

in air. At high CO₂ total foliar amino acids were higher, but glycine and serine were lower, than in air. These results suggest that photorespiratory glycine is used in chloroplastic GSH synthesis. Despite this, net CO₂ fixation was similar in Lggs to untransformed poplars. Pre-illuminated leaf discs from Lggs, and poplars overexpressing gamma-ECS in the cytosol (ggs), were incubated in darkness with a range of metabolites. After 15 h, discs from both types of transformant incubated on water had accumulated high levels of gamma-EC and showed marked increases in the $\gamma\text{-EC:GSH}$ ratio. Feeding glycine, serine, glycollate or phosphoserine, attenuated the dark-induced changes in the gamma-EC:GSH ratio, whereas 3-phosphoglycerate (PGA), phosphoenolpyruvate, glycerate, and hydroxypyruvate did not. Glycine produced from glycollate was therefore required for maximal GSH accumulation in both the chloroplastic and cytosolic compartment. Production of glycine from PGA failed to meet the demand of increased GSH synthetic capacity.

Nonhebel, S. 1996. Effects of temperature rise and increase in CO₂ concentration on simulated wheat yields in Europe. *Climatic Change* 34(1):73-90.

A crop-growth-simulation model based on SUCROS87 was used to study effects of temperature rise and increase of atmospheric CO₂ concentration on wheat yields in several regions in Europe. The model simulated potential and water-limited crop production (growth with ample supply of nutrients and in the absence of damage by pests, diseases and weeds). Historic daily weather data from 13 sites in Western Europe were used as starting point. For potential production (optimal water) a 3 degrees C temperature rise led to a yield decline due to a shortening of the growing period on all locations. Doubling of the CO₂ concentration caused an increase in yield of 40% due to higher assimilation rates. It was found that effects of higher temperature and higher CO₂ concentration were nearly additive and the combination of both led to a yield increase of 1-2 ton ha⁻¹. A very small CO₂-temperature interaction was found: the effect of doubled CO₂ concentration on crop yield was larger at higher temperatures. The inter-annual yield variability was hardly affected. When water was limiting crop-production effects of temperature rise and higher CO₂ levels were different than for the potential production. Rise in temperature led to a smaller yield reduction, doubled CO₂ concentration to a larger yield increase and combination of both led to a large yield increase (3 ton ha⁻¹) in comparison with yields simulated for the present situation. Both rise in temperature and increase in the CO₂ concentration reduced water requirements of the crop. Water shortages became smaller, leading to a reduction in inter-annual variability. It is concluded that when no major changes in precipitation pattern occur a climate change will not affect wheat yields since negative effects of higher temperatures are compensated by positive effects of CO₂ enrichment.

Norby, R.J. 1994. Issues and perspectives for investigating root responses to elevated atmospheric carbon-dioxide. *Plant and Soil* 165(1):9-20.

A thorough assessment of how plants and ecosystems will respond to increasing concentrations of atmospheric CO₂ requires that the

responses of root systems and associated belowground processes be understood. Static measures of root-to-shoot ratio have not been satisfactory for describing the integrated responses of plants to CO₂-enriched atmospheres, but research with a process orientation has suggested that elevated CO₂ can stimulate root growth or root activity and provide a positive feedback on plant growth. There are, however, critical questions concerning the relevance of root data from short-term studies with potted plants when scaling to questions about plants in the field. Data on root responses to CO₂ enrichment in the field are fragmentary, but they allow us to more clearly define research questions for further investigation. Three perspectives for analyzing the significance of root responses as a component of the overall response of the terrestrial biosphere to increasing atmospheric CO₂ are suggested: (1) roots as a platform for nutrient acquisition and a mediator of whole-plant response to CO₂; (2) carbon storage in roots as a component of whole-plant carbon storage; and (3) effects of CO₂ enrichment on root turnover and the implications for carbon storage as soil organic matter. The relative importance of these different perspectives will vary depending on the ecosystem of interest and the larger-scale issues being considered.

Norby, R.J. 1996. Oaks in a high-CO₂ world. *Annales Des Sciences Forestieres* 53(2-3):413-429.

The concentration of carbon dioxide in the atmosphere is one environmental factor that is certain to influence the physiology and productivity of oak trees everywhere. Direct assessment of the impact of increasing CO₂ is very difficult, however, because of the long-term nature of CO₂ effects and the myriad potential interactions between CO₂ and other environmental factors that can influence the physiological and ecological relationships of oaks. The CO₂ responses of at least 11 *Quercus* species have been investigated, primarily in experiments with seedlings. The growth response varies considerably among these experiments, and there appears to be no basis for differentiating the response of oaks as a group from those of other woody plants. The more important challenge is to find a basis for addressing questions about the responses of oak forest ecosystems from experimental data on individual seedlings and saplings. A series of experiments with white oak (*Quercus alba* L.) seedlings and saplings was focused toward larger-scale questions, such as whether N limitations would preclude growth responses to elevated CO₂ and whether short-term physiological responses could be sustained over longer time scales. These experiments suggested three issues that are particularly important for addressing forest responses: leaf area dynamics, fine root production, and biotic interactions. By focusing seedling and sapling experiments toward these issues, we gain insight into the important processes that will influence ecosystem response and, at least in a qualitative sense, the sensitivity of those processes to elevated CO₂.

Norby, R.J. 1998. Nitrogen deposition: a component of global change analyses. *New Phytologist* 139(1):189-200.

The global cycles of carbon and nitrogen are being perturbed by human activities that increase the transfer from large pools of non-reactive

forms of the elements to reactive forms that are essential to the functioning of the terrestrial biosphere. The cycles are closely linked at all scales, and global change analyses must consider C and N cycles together. The increasing amount of N originating from fossil fuel combustion and deposited to terrestrial ecosystems as nitrogen oxides could increase the capacity of ecosystems to sequester C, thereby removing some of the excess carbon dioxide from the atmosphere and slowing the development of greenhouse warming. Several global and ecosystem models have calculated the amount of C sequestration that can be attributed to N deposition, based on assumptions about the allocation of N among ecosystem components with different C:N ratios. They support the premise that, since industrialization began, N deposition has been responsible for an increasing terrestrial C sink, but there is great uncertainty whether ecosystems will continue to retain exogenous N. Whether terrestrial ecosystems continue to sequester additional C will depend in part on their response to increasing concentrations of atmospheric carbon dioxide, widely thought to be constrained by limited N availability. Ecosystem models generally support the conclusion that responses to increasing concentrations of carbon dioxide will be greater, and the range of possible responses will be wider, in ecosystems where increased N inputs originate as atmospheric deposition. The interactions between N deposition and increasing carbon dioxide concentrations could be altered considerably, however, by additional factors, including N saturation of ecosystems, changes in community composition, and climate change. Nitrogen deposition is also linked to global change issues through the volatile losses of nitrous oxide, which is a potent greenhouse gas, and the role of nitrogen oxides in the production of tropospheric ozone, which could interact with plant responses to elevated carbon dioxide. Any consideration of the role of N deposition in global change issues must also balance the projected responses against the serious detrimental impact of excess N on the environment.

To enable experiments on the interactive effects of elevated atmospheric CO₂ and increased air temperature on physiological processes in trees to be carried out, we altered the standard design of open-top chambers by replacing blowers with evaporative coolers and in-line heaters, with a feedback control system to maintain ambient or elevated air temperatures within the chambers. Ambient and elevated (+ 4 degrees C) temperature regimes were attained consistently and reliably throughout the growing season, with high reproducibility between chambers. From May through December the average of nearly 300,000 temperature measurements was 18.5 degrees C in ambient air, 18.9 +/- 0.6 degrees C in six ambient chambers, and 22.4 +/- 0.9 degrees C in six elevated temperature chambers. The difference in soil temperature between ambient and elevated chambers was 1.2 degrees C. Absolute humidity (vapour pressure) in the chambers was higher than that of ambient air, but it was generally similar between temperature treatments. Vapour pressure deficit therefore was higher in elevated temperature

chambers than in ambient chambers, and this difference is considered an inseparable part of the temperature treatment. The addition of a temperature control system to open-top chambers removes what has been an important flaw in this important tool for global change research.

Norby, R.J., C.A. Gunderson, S.D. Wullschleger, E.G. Oneill, and M.K. McCracken. 1992. Productivity and compensatory responses of yellow-poplar trees in elevated CO₂. *Nature* 357(6376):322-324.

INCREASED forest growth in response to globally rising CO₂ concentrations could provide an additional sink for the excess carbon added to the atmosphere from fossil fuels 1,2. The response of trees to increased CO₂, however, can be expected to be modified by the interactions of other environmental resources and stresses, higher-order ecological interactions and internal feedbacks inherent in the growth of large, perennial organisms 3,4. To test whether short-term stimulation of tree growth by elevated CO₂ can be sustained without inputs from other environmental resources, we grew yellow-poplar (*Liriodendron tulipifera* L.) saplings for most of three growing seasons with continuous exposure to ambient or elevated concentrations of atmospheric CO₂. Despite a sustained increase in leaf-level photosynthesis and lower rates of foliar respiration in CO₂-enriched trees, whole-plant carbon storage did not increase. The absence of a significant growth response is explained by changes in carbon allocation patterns, specifically a relative decrease in leaf production and an increase in fine root production. Although these compensatory responses reduced the potential increase in carbon storage in increased CO₂ concentrations, they also favour the efficient use of resources over the longer term.

1717

Norby, R.J., and E.G. Oneill. 1991. Leaf-area compensation and nutrient interactions in CO₂-enriched seedlings of yellow-poplar (*Liriodendron tulipifera* L.). *New Phytologist* 117(4):515-528.

The responses of yellow-poplar (*Liriodendron tulipifera* L.) seedlings to elevated levels of atmospheric CO₂ were investigated to identify attributes governing growth and physiological responses to CO₂. Based on the pattern of leaf initiation and nutrient requirements of the species, it was predicted that (1) CO₂ enrichment would enhance growth of yellow-poplar seedlings both through accelerated leaf area production and through higher rates of carbon assimilation per unit leaf area; and (2) growth enhancement of yellow-poplar by CO₂ enrichment would be reduced by nutrient limitations. The hypotheses were tested in an experiment in which yellow-poplar plants were grown from seed for 24 weeks in controlled-environment chambers. The experimental design comprised three atmospheric CO₂ concentrations (371, 493, and 787 cm³ m⁻³), two levels of mineral nutrients (unfertilized or weekly additions of complete nutrient solution), and three harvests (6, 12, and 24 weeks). Plant growth rate, water use, foliar gas exchange, component dry weights, and nutrient contents were measured. Both hypotheses were rejected. Whole-plant dry weight increased similarly with CO₂ enrichment in plants provided with additional mineral nutrients and in unfertilized plants, although the fertilized plants grew 10-fold larger. The increase in dry weight resulting from elevated CO₂ occurred only in root systems. Although leaves were produced continuously during the experiment, leaf area was slightly reduced in elevated CO₂, and the whole-plant growth response was wholly attributable to an increase in carbon assimilation per unit leaf area. Although the compensation between photosynthesis and leaf area reduced the potential growth response to CO₂, the reduction in leaf area ratio was associated with a significant increase in water-use efficiency. This unexpected result

demonstrated the importance of feedbacks and interactions between resources in shaping the response of a plant to CO₂.

Norby, R.J., S.D. Wullschleger, C.A. Gunderson, D.W. Johnson, and R. Ceulemans. 1999. Tree responses to rising CO₂ in field experiments: implications for the future forest. *Plant, Cell and Environment* 22(6):683-714.

The need to assess the role of forests in the global cycling of carbon and how that role will change as the atmospheric concentration of CO₂ increases has spawned many experiments over a range of scales. Experiments using open-top chambers have been established at many sites to test whether the short-term responses of tree seedlings described in controlled environments would be sustained over several growing seasons under field conditions. Here we review the results of those experiments, using the framework of the interacting cycles of carbon, water and nutrients, because that is the framework of the ecosystem models that are being used to address the decades-long response of forests. Our analysis suggests that most of what was learned in seedling studies was qualitatively correct. The evidence from field-grown trees suggests a continued and consistent stimulation of photosynthesis of about 60% for a 300 p.p.m. increase in [CO₂], and there is little evidence of the long-term loss of sensitivity to CO₂ that was suggested by earlier experiments with tree seedlings in pots. Despite the importance of respiration to a tree's carbon budget, no strong scientific consensus has yet emerged concerning the potential direct or acclimation response of woody plant respiration to CO₂ enrichment. The relative effect of CO₂ on above-ground dry mass was highly variable and greater than that indicated by most syntheses of seedling studies. Effects of CO₂ concentration on static measures of response are confounded with the acceleration of ontogeny observed in elevated CO₂. The trees in these open-top chamber experiments were in an exponential growth phase, and the large growth responses to elevated CO₂ resulted from the compound interest associated with an increasing leaf area. This effect cannot be expected to persist in a closed-canopy forest where growth potential is constrained by a steady-state leaf area index. A more robust and informative measure of tree growth in these experiments is the annual increment in wood mass per unit leaf area, which increased 27% in elevated CO₂. There is no support for the conclusion from many studies of seedlings that root-to-shoot ratio is increased by elevated CO₂; the production of fine roots may be enhanced, but it is not clear that this response would persist in a forest. Foliar nitrogen concentrations were lower in CO₂-enriched trees, but to a lesser extent than was indicated in seedling studies and only when expressed on a leaf mass basis. The prediction that leaf litter C/N ratio would increase was not supported in field experiments. Also contrasting with seedling studies, there is little evidence from the field studies that stomatal conductance is consistently affected by CO₂; however, this is a topic that demands more study. Experiments with trees in open-top chambers under field conditions have provided data on longer-term, larger-scale responses of trees to elevated CO₂ under field conditions, confirmed some of the conclusions from previous seedling studies, and challenged other conclusions. There remain important obstacles to using these experimental results to predict forest responses to rising CO₂, but the studies are valuable nonetheless for guiding ecosystem model development and revealing the critical questions that must be addressed in new larger-scale CO₂ experiments.

Norby, R.J., S.D. Wullschlegel, C.A. Gunderson, and C.T. Nietch. 1995. Increased growth efficiency of quercus-alba trees in a CO₂-enriched atmosphere. *New Phytologist* 131(1):91-97.

Forests have a prominent role in the global carbon cycle, but their response to a changing atmosphere cannot be measured directly. Experimental observations of small trees in CO₂-enriched atmospheres must be interpreted carefully if they are to be relevant to the potential responses of forest trees. We grew white oak (*Quercus alba* L.) saplings for four complete growing seasons in open-top chambers with different partial pressures of atmospheric CO₂. White oak saplings produced 58% more dry mass in 50 Pa CO₂ and 135% more in 65 Pa, compared with plants in ambient (35 Pa) CO₂. Although this result might suggest a substantial potential for increased carbon storage in forests, the large difference in growth rate could be attributed to a stimulation of growth very early in the experiment. There was not a sustained effect of CO₂ on relative growth rate after the first year, and the increased absolute growth rate could persist only so long as leaf area could increase, a condition that would not occur indefinitely in a forest. Nevertheless, annual stem wood production per unit area (growth efficiency) was 37% greater in elevated CO₂. This increase in growth efficiency, a response that is consistent across diverse studies, implies a potential increase in carbon sequestration by forests, subject to critical assumptions about forest canopy development in a CO₂-enriched atmosphere.

Norris, T.S., and B.J. Bailey. 1996. Use of simulation analysis to improve the design of open-top chambers. *Agricultural and Forest Meteorology* 78(3-4):259-275.

A greenhouse climate simulation model, employing linked first-order integral and differential equations, was adapted to predict the microclimate within carbon-dioxide-enriched open-top chambers (OTCs) suitable for climate change research. The simulation model was validated using experimental measurements from a prototype OTC test rig constructed at Silsoe Research Institute; this model was then used to investigate the effect of employing a controlled combination of air recirculation and ventilation on carbon dioxide consumption for a chamber containing wheat plants. Control criteria for a controlled-ventilation OTC were investigated using the simulation and verified experimentally; results showed that a 2 degrees C temperature excess limit within the chamber could be achieved in practice for a chamber exhibiting minimal wind incursion through the open-top, provided that a mechanical ventilation rate of 6 air changes minute⁻¹ was provided during periods of peak solar flux. Furthermore, the simulation suggested that, by applying controlled ventilation and recirculation to OTCs, it is feasible to reduce the daily consumption of enrichment gas to achieve 560 $\mu\text{mol mol}^{-1}$ concentration within a 3 m-diameter and 3 m-high chamber located at an exposed site to 15 kg in comparison to the estimated 100 kg required when continuous ventilation is employed.

North, G.B., T.L. Moore, and P.S. Nobel. 1995. Cladode development for *Opuntia ficus-indica* (Cactaceae) under current and doubled CO₂ concentrations. *American Journal of Botany* 82(2):159-166.

Morphological and anatomical changes for first-order daughter cladodes (flattened stem segments) of a prickly pear cactus, *Opuntia ficus-indica*, were monitored to determine the effects of a doubled atmospheric CO₂ concentration on their development and mature form. For daughter cladodes developing in controlled environment chambers for 60 d, maximal elongation rates were similar under a photosynthetic photon flux density (PPFD) of 6 $\text{mol m}^{-2} \text{d}^{-1}$ and a CO₂ concentration of 370 $\mu\text{l liter}^{-1}$, an increased PPFD (10 $\text{mol m}^{-2} \text{d}^{-1}$), and an increased PPFD and a doubled CO₂ concentration. These maximal rates, however, occurred at 20, 15, and 12 d, respectively. The maximal relative growth rate under the doubled CO₂ concentration was about twice that under the other conditions. For cladodes at 60 d as well as after 4 and 16 mo in open-top chambers, doubling the CO₂ concentration had no effect on final length or width. At 4 mo, cladodes under doubled CO₂ were 27% thicker, perhaps allowing the earlier production of second-order daughter cladodes. The chlorenchyma was then 31% thicker and composed of longer cells. At 16 mo, the difference in cladode thickness diminished, but the chlorenchyma remained thicker under doubled CO₂, which may contribute to greater net CO₂ uptake for *O. ficus-indica* under elevated CO₂ concentrations. Two other persistent differences were a 20% lower stomatal frequency and a 30% thicker cuticle with more epicuticular wax for cladodes under doubled CO₂, both of which may help reduce transpirational water loss.

Norton, L.R., L.G. Firbank, and H. Blum. 1999. Effects of free-air CO₂ Enrichment (FACE) on experimental grassland communities. *Functional Ecology* 13:38-44.

1. Experimental grassland communities (turves) were exposed to elevated (60 Pa) and ambient (35 Pa) CO₂ partial pressures (pCO₂) in a Free-air Carbon Dioxide Enrichment (FACE) experiment between 30 March 1995 and 4 July 1996. The vegetation was cut once during the experiment prior to the final harvest (harvest 2). 2. No significant treatment effects on total plant biomass at the whole turf level were detected, although biomass was typically about 25% higher under fumigation in year 1 and about 15% higher in year 2. 3. Biomass for two of the six sown species was significantly higher at harvest 2 than at harvest 1. There were no significant differences between individual species biomass under the two CO₂ treatments at either harvest 1 or 2 or in terms of overall cumulative biomass. However, in four of the five sown species in both years biomass tended to be higher in the fumigated than in the control rings (*Cerastium holosteoides*, *Phleum pratense*, *Plantago lanceolata* and *Poa trivialis*). In contrast, *Lolium perenne* showed increased biomass under the control treatment relative to the fumigated treatment in both years. Owing to the high variance both within and between rings for each of the two treatments the statistical power of most, but not all, of the analyses carried out was poor. 4. The relative proportions of each species in the turves under fumigated and control treatments was broadly similar after the first summer, with differences in the second year being mainly owing to the negative response of *L. perenne* to CO₂ fumigation.

Norton, L.R., L.G. Firbank, A.J. Gray, and A.R. Watkinson. 1999. Responses to elevated temperature and CO₂ in the perennial grass *Agrostis curtisii* in relation to population origin. *Functional Ecology*

1. Evolutionary responses to climate change will depend on the presence of heritable variation within species populations for traits that increase fitness under the changing conditions. Patterns of ecotypic differentiation in relation to latitude in some species suggest that such variation exists in relation to temperature responses. Response to elevated CO₂, whether heritable or not, is not expected to be related to latitudinal or climatic differences within temperate regions. 2. To test these ideas, seeds were collected from 10 populations of the outbreeding perennial grass *Agrostis curtisii* across its range in Europe from south Wales to Portugal. Plants were grown under ambient and elevated temperature and CO₂ conditions, in a factorial design, in solardomes; two half sibs from each population were planted in separate pots in each of the two replicate domes with each combination of treatments. One half sib was harvested at the end of the first summer, the second at the end of the second summer. 3. Survival was uniformly high and flowering uniformly low across treatments and populations. 4. Responses to temperature and CO₂ treatments varied over time for almost all populations. Treatment effects were not significant on plants harvested in year 1, although there was a trend towards higher shoot biomass under the elevated temperature and CO₂ treatment. In year 2 shoot biomass was significantly higher under the elevated temperature treatment across all populations and there was a strong trend towards decreased biomass under elevated CO₂. 5. There were no significant correlations of plant response to either CO₂ or temperature with climate at origin. 6. These results warn of the dangers of extrapolating evolutionary plant responses to CO₂ from short-term experiments.

Norton, L.R., L.G. Firbank, and A.R. Watkinson. 1995. Ecotypic differentiation of response to enhanced CO₂ and temperature levels in *Arabidopsis thaliana*. *Oecologia* 104(3):394-396.

Five ecotypes of *Arabidopsis thaliana*, from widely dispersed origins, were grown under combinations of ambient and elevated atmospheric CO₂ concentrations and ambient and elevated temperatures within solardomes. Total above-ground plant biomass was measured when the majority of plants across all ecotypes and treatments had formed seed pods. There were substantial differences in biomass between the ecotypes across all treatments. Temperature had no effect on biomass whilst CO₂ had a significant effect both alone and in interaction with ecotype. The CO₂ x ecotype interaction was mostly due to the enhancement of a single ecotype from the Cape Verde Islands.

Novero, R., D.H. Smith, F.D. Moore, J.F. Shanahan, and R. Dandria. 1991. Field-grown tomato response to carbonated water application. *Agronomy Journal* 83(5):911-916.

Direct release of CO₂ gas to achieve a cost-effective method of atmospheric CO₂ enrichment has not been proven feasible under field conditions. We hypothesized that greater efficiency of application would

occur by applying CO₂ via carbonated water and that application would also result in beneficial modifications of the soil environment. Our objectives were to evaluate crop, soil, and atmospheric CO₂ responses to application of carbonated water under pressure through a drip irrigation system. Studies were conducted under mulched and unmulched conditions in 1988 using tomato (*Lycopersicon esculentum* Mill.). In 1989, carbonated water was applied at approximately 2-, 4-, and 6-d intervals to determine the effect of irrigation frequency. In 1988, a positive yield response of 9% was obtained in the presence of mulch. No response was observed in open beds. Fruit yields were increased at all three irrigation frequencies in 1989, with increases in fresh-market and total fruit yields averaging 16.4 and 15.9%, respectively. Atmospheric enrichment was observed during carbonated water application, but residual enrichment between irrigations was difficult to detect. Significant increase in soil-air CO₂ from carbonated water application was noted throughout the intervals between successive irrigation events. Carbonated water application also decreased soil pH for periods of up to 5 d after irrigation and increased apparent uptake of P, K, Ca, Mg, Zn, Fe, Mn, Cu, and B. Based on the limited duration of enrichment relative to the entire growing season for any of the carbonated water treatments, the yield responses observed could not be attributed solely to atmospheric enrichment. Thus, we conclude that yield increases resulted from the combined effects of limited atmospheric CO₂ enrichment and soil environment modifications leading to improved nutrient uptake.

Nowak, E.J., and C.E. Martin. 1995. Effect of elevated CO₂ on nocturnal malate accumulation in the CAM species *Tillandsia ionantha* and *Crassula arborescens*. *Photosynthetica* 31(3):441-444.

The effect of elevated CO₂ on overnight malate accumulation in the CAM epiphyte *Tillandsia ionantha* and the CAM terrestrial species *Crassula arborescens* was compared. Both species showed an increase in nocturnal accumulation of malate with increasing CO₂ concentrations. This study is the first to show an increase in nighttime malate accumulation with increasing levels of CO₂ at near-ambient concentrations in a CAM plant. The results indicate that some CAM plants can respond to increasing levels of CO₂ in the atmosphere, potentially leading to an increase in productivity.

Nunes, M.A., J.D.C. Ramalho, and M.A. Dias. 1993. Effect of nitrogen supply on the photosynthetic performance of leaves from coffee plants exposed to bright light. *Journal of Experimental Botany* 44(262):893-899.

Although *Coffea arabica* L. grows naturally in shaded habitats, it can be cultivated under high light intensity, but not without severe photoinhibition mainly during the period of transfer from the nursery into the field. The present work examines some of the changes in the photosynthetic performance induced by exposure to high light and the possibility of using enhanced nitrogen levels to overcome photoinhibition. For that purpose, young plants of *Coffea arabica* L. (cv. Catuai) grown in a shaded greenhouse were treated with 0, 1 and 2 mmol of nitrogen and 4 weeks later exposed to full solar irradiation, outside. Visible damage due to exposure to full sunlight appeared within 2 d in all plants, resulting in a reduced photosynthetic leaf area and drastic shedding of leaves in the unfertilized plants. These effects were considerably less in plants with the highest N dose. After 130 d of exposure, there was 100% mortality in plants receiving no extra

nitrogen, compared with 30% in the plants treated with 2 mmol nitrogen. Photosynthesis rates, leaf conductance and transpiration presented minimum values after 4 d of light stress. Large changes in the photosynthetic capacity (measured at high CO₂ concentration and high light intensity), quantum efficiency and fluorescence yield (F(v)/F(m)) indicate that net photosynthesis rate in the air had been reduced by both stomatal closure and by changes at the photochemical level. All indicators show that N-fertilized plants were less affected by photoinhibition.

Nungesser, M.K., L.A. Joyce, and A.D. McGuire. 1999. Effects of spatial aggregation on predictions of forest climate change response. *Climate Research* 11(2):109-124.

We investigated the influence of spatial aggregation on modeled forest responses to climate change by applying the profess- based Terrestrial Ecosystem Model (TEM) to a fine resolution spatial grid (100 km(2)) and to a coarse resolution spatial grid (2500 km(2)). Three climate scenarios were simulated: baseline (present) climate with ambient CO₂ and 2 future climates derived from the general circulation models OSU and GFDL-Q with elevated atmospheric CO₂. For baseline climate, the aggregation error of the national (U.S.) study area was very small, -0.4%. Forest-level aggregation error ranged from -1.6 to 11.8%, with the largest aggregation error occurring in boreal forest types. Coarse grid resolution inputs underestimated production for boreal and forested boreal wetland forests and overestimated net primary production (NPP) for temperate conifer, temperate deciduous, and temper ate forested wetland forests. Aggregation error for coarse grid cells ranged between -25.6 and 27.3%. Aggregation errors were especially large in transition regions between temperate and boreal forest types. An analysis that homogenized inputs for the 10 km grid cells within a 50 km grid indicated that aggregation of forest types and air temperature from fine to coarse grid cells contributed most to the spatial aggregation error. The aggregation error for the OSU climate was similar to the GFDL-Q climate and both results were similar to the aggregation error of the baseline climate in magnitude, sign, and spatial pattern. While aggregation error was similar across the baseline, GFDL-Q and OSU scenarios, NPP response to the GFDL-Q and OSU climates increased 13 to 30% above the baseline NPP. Within each climate scenario, the estimated NPP response to climate change differed by less than 1% between the coarse and fine resolutions. Except for transition regions and regions with substantial variability in air temperature, our simulations indicate that the use of 0.5 degrees resolution provides an acceptable level of aggregation error at the 3 scales of analysis in this study. Improvements could be made by focusing computational intensity in heterogeneous regions and avoid computational intensity in regions that are relatively homogeneous with respect to vegetation and air temperature.

Nussbaumer, U., J. Ascher, A. Kraft, and H. Insam. 1997. Litter decomposition of a tropical understory species (*Ctenanthe lubbersiana*) grown under ambient and elevated CO₂. *Acta Oecologica-International Journal of Ecology* 18(3):377-381.

A CO₂ evolution and a dissolved organic carbon (DOC)-die-away test were used to determine the inherent decomposability of plant litter of *Ctenanthe lubbersiana* grown under ambient (340 ppm) and elevated CO₂ (610 ppm). The CO₂ evolution of leaf litter in a 10 day decomposition assay was retarded by 7% (P = 0.046). In the DOG-die-away test, the decomposition of a leaf litter hot water extract was retarded by 8% (P = 0.039). The decomposition of the solid litter fraction was retarded by 16% (P = 0.101). The decomposition rate of petioles was not affected by elevated CO₂. Despite the differences were small, the results suggest possible effects on ecosystem C cycling.

Obenland, D.M., L.H. Aung, and R.E. Rij. 1994. Timing and control of methanethiol emission from broccoli florets induced by atmospheric modification. *Journal of Horticultural Science* 69(6):1061-1065.

Storage of broccoli (*Brassica oleracea* L., Italica Group) under conditions of low O₂ concentration extends its shelf life. Excessively low O₂, however, leads to the formation of an offensive odour which is primarily due to the emission of methanethiol. In this study, we investigated the initial induction and control of methanethiol production of broccoli florets exposed to various levels of O₂ and CO₂ over short-term periods of 10 h or less. Lowering the O₂ concentration surrounding the broccoli florets by continuously flowing N₂ through the sample containers acted to initiate the production of methanethiol within 1 h after the O₂ concentration had reached 0.5 %. After initiation the rate of production showed a slow but steady increase during the 10 h of experimentation. In contrast, introduction of O₂ into the sample containers while the broccoli florets were actively producing methanethiol led to a rapid 79% drop in the amount of methanethiol detected within 15 min, followed by a complete absence of methanethiol within another 15 min. Resumption of N₂ flow acted to reinstate methanethiol production, with the initiation requiring a lesser amount of time than that required for the initial induction of methanethiol production. Experiments with elevated CO₂ concentrations of up to 26.5% determined that CO₂ is an inhibitor of methanethiol production.

Oechel, W.C., S. Cowles, N. Grulke, S.J. Hastings, B. Lawrence, T. Prudhomme, G. Riechers, B. Strain, D. Tissue, and G. Vourlitis. 1994. Transient nature of co₂ fertilization in arctic tundra. *Nature* 371(6497):500-503.

THERE has been much debate about the effect of increased atmospheric CO₂ concentrations on plant net primary production(1,3) and on net ecosystem CO₂ flux(3-10). Apparently conflicting experimental findings could be the result of differences in genetic potential(11-15) and resource availability(16-20), different experimental conditions(21-24) and the fact that many studies have focused on individual components of the system(2,21,25-27) rather than the whole ecosystem. Here we present results of an in situ experiment on the response of an intact native ecosystem to elevated CO₂. An undisturbed patch of tussock tundra at Toolik Lake, Alaska, was enclosed in greenhouses in which the CO₂ level, moisture and temperature could be controlled(28), and was subjected to ambient (340 p.p.m.) and elevated (680 p.p.m.) levels of CO₂ and temperature (+4 degrees C). Air humidity, precipitation and soil water table were maintained at ambient control levels. For a doubled CO₂ level alone, complete homeostasis of the CO₂ flux was re-established within three years, whereas the regions exposed to a combination of higher temperatures and doubled CO₂ showed persistent fertilization effect on net ecosystem carbon sequestration over this time.

This difference may be due to enhanced sink activity from the direct effects of higher temperatures on growth (16,29-33) and to indirect effects from enhanced nutrient supply caused by increased mineralization (10,11,19,27,34). These results indicate that the responses of native ecosystems to elevated CO₂ may not always be positive, and are unlikely to be straightforward. Clearly, CO₂ fertilization effects must always be considered in the context of genetic limitation, resource availability and other such factors.

Oechel, W.C., G. Riechers, W.T. Lawrence, T.J. Prudhomme, N. Grulke, and S.J. Hastings. 1992. CO₂It an automated, null-balance system for studying the effects of elevated CO₂ and global climate change on unmanaged ecosystems. *Functional Ecology* 6(1):86-100.

An automated, CO₂-controlled, long-term greenhouse system ('CO₂LT') has been developed to provide replicated in situ ecosystem-level manipulation of atmospheric CO₂ concentration and temperature for intact plots of tussock tundra, and to measure the instantaneous ecosystem-level CO₂ exchange rates within each of the plots under the treatments imposed. This is a computer-controlled, closed, null-balance greenhouse system consisting of 12 chambers with individual control of CO₂ concentration and temperature. Carbon dioxide can be maintained in each chamber at concentrations from well below ambient (150-200- μ mol l⁻¹) to more than 900- μ mol l⁻¹. Air temperature can be fixed, set to track ambient, or can track ambient temperature with a specified offset allowing studies of the interaction of CO₂ and temperature. Despite the complications involved in tracking a naturally fluctuating environment, the CO₂LT system performs very well. Temperatures in individual chambers average within 1-degrees-C of ambient or target temperatures over a 24-h period and carbon dioxide concentration control rivals that of laboratory-based, control-environment systems. Photon flux density within the chambers is within 93% of ambient values. Comparison to unenclosed tundra indicates minimal chamber effects on depth of thaw, air, leaf, or soil temperatures, or net ecosystem CO₂ flux. Chamber effects are generally small, and the experimental design allows separation and interpretation of treatment effects despite any unavoidable chamber effects. Both diurnal and seasonal patterns of net ecosystem CO₂ flux can be accurately tracked with this system. Field measurements indicate net ecosystem CO₂ loss under current environmental conditions, a possible response to recent climate change. Field measurements also indicate initial enhancement of net ecosystem CO₂ uptake with elevated atmospheric CO₂. Photosynthetic adjustment to elevated CO₂ lowers ecosystem response to that of ambient chambers by mid-season. Also indicated is the possibility of delayed senescence of photosynthetic capacity at elevated CO₂.

Oechel, W.C., and G.L. Vourlitis. 1994. The effects of climate-change on land atmosphere feedbacks in arctic tundra regions. *Trends in Ecology and Evolution* 9(9):324-329.

Recently reported high-latitude warming has the potential to affect arctic ecosystem structure and function in the short and long term. Arctic ecosystems are known sources of atmospheric CH₄, and recent CO₂ flux measurements indicate that these ecosystems are now, at least regionally, net sources of atmospheric CO₂. It appears that over the short term (decades to centuries), arctic ecosystems may represent a positive feedback on global atmospheric CO₂ concentrations and associated

greenhouse gas-induced climate change. In addition, short-term feedbacks may be large enough to affect both local and global surface temperatures. Over the long term, changes in the structure, function and composition of arctic ecosystems may increase C accumulation relatively more than the amount lost, thus restoring the sink status of arctic ecosystems.

Oechel, W.C., G.L. Vourlitis, S. Brooks, T.L. Crawford, and E. Dumas. 1998. Intercomparison among chamber, tower, and aircraft net CO₂ and energy fluxes measured during the Arctic System Science Land-Atmosphere-Ice Interactions (ARCSS-LAII) Flux Study. *Journal of Geophysical Research-Atmospheres* 103(D22):28993-29003.

Measurements of net ecosystem CO₂ exchange (NEE) and energy balance were made using chamber-, tower-, and aircraft-based measurement techniques in Alaskan arctic tundra ecosystems during the 1994-1995 growing seasons (June-August). One of our objectives was to quantify the interrelationships between the NEE and the energy balance measurements made from different sampling techniques. Qualitative and quantitative intercomparisons revealed that on average the correspondence between the mass and energy fluxes measured by these sampling methods was good despite potential spatial and temporal mismatches in sampling scale. Quantitative comparisons using least squares linear regression analyses with the tower-based measurements of NEE as the independent variable indicate that the chamber- and aircraft-based NEE measurements were generally lower relative to the tower-based measurements (slope = 0.76-0.86). Similarly, tower-aircraft comparisons of latent (L-e) and sensible (H) heat exchange indicated that the aircraft-based measurements were lower than the tower-based measurements (slope = 0.72-0.80). Qualitative comparisons, however, indicate that the correspondence among the chamber-, tower- and aircraft-measured fluxes varied both seasonally and interannually, suggesting the lack of a consistent bias between the sampling techniques. The results suggest that differences observed between the chamber, tower, and aircraft flux measurements were primarily due to the failure to account for the spatial distribution of surface types in the tower and aircraft sampling footprint, problems involved in the comparison of temporal and spatial averages, and temporal (e.g., seasonal and interannual) variance in rates of mass and energy flux for a given point. Other potential sources of variance include the underestimation of nocturnal NEE by the tower-based eddy covariance system, and the periodic occurrence of an elevated CO₂ plume in the atmosphere over the Prudhoe Bay oil field. Even with these potential sources of variation, the results reveal that the various methods give comparable estimates of NEE and energy flux within a range of temporal or spatial variability.

Oechel, W.C., G.L. Vourlitis, S.J. Hastings, R.P. Ault, and P. Bryant. 1998. The effects of water table manipulation and elevated temperature on the net CO₂ flux of wet sedge tundra ecosystems. *Global Change Biology* 4(1):77-90.

lit situ manipulations were conducted in a naturally drained lake on the arctic coastal plain near Prudhoe Bay, Alaska (70 degrees 21.98' N, 148 degrees 33.72' W) to assess the potential shortterm effects of decreased water table and elevated temperature on net ecosystem CO₂ flux. The

experiments were conducted over a 2-year period, and during that time, water table depth of drained plots was maintained on average 7 cm lower than the ambient water table, and surface temperatures of plots exposed to elevated temperature were increased on average 0.5 degrees C. Water table drainage, and to a lesser extent elevated temperature, resulted in significant increases in ecosystem respiration (ER) rates, and only small and variable changes in gross ecosystem productivity (GEP). As a result, drained plots were net sources of approximate to 40 gC m⁻² season⁻¹ over both years of manipulation, while control plots were net sinks of atmospheric CO₂ of about 10 gC m⁻² season⁻¹ (growing season length was an estimated 125 days). Control plots exposed to elevated temperatures accumulated slightly more carbon than control plots exposed to ambient temperatures. The direct effects of elevated temperature on net CO₂ flux, ER, and GEP were small, however, elevated temperature appeared to interact with drainage to exacerbate the amount of net carbon loss. These data suggest that many currently saturated or nearly saturated wet sedge ecosystems of the north slope of Alaska may become significant sources of CO₂ to the atmosphere if climate change predictions of increased evapotranspiration and reduced soil water status are realized. There is ample evidence that this may be already occurring in arctic Alaska, as a change in net carbon balance has been observed for both tussock and wet-sedge tundra ecosystems over the last 2-3 decades, which coincides with a recent increase in surface temperature and an associated decrease in soil water content. In contrast, if precipitation increases relatively more than evapotranspiration, then increases in soil moisture content will likely result in greater carbon accumulation.

Oechel, W.C., G.L. Vourlitis, S.J. Hastings, and S.A. Bochkarev. 1995. Change in arctic CO₂ flux over 2 decades - effects of climate-change at barrow, Alaska. *Ecological Applications* 5(3):846-855.

A significant difference in net ecosystem carbon balance of wet sedge ecosystems in the Barrow, Alaska region was observed between CO₂ flux measurements obtained during the International Biological Program in 1971 and measurements made during the 1991-1992 growing seasons. Currently, high-center polygons are net sources of CO₂ to the atmosphere of approximate to 14 gC . m⁻². yr⁻¹, while low-center polygons are losing approximate to 3.6 gC . m⁻². yr⁻¹, and ice wedge habitats are accumulating 4.0 gC . m⁻². yr⁻¹. On average, moist meadow habitats characteristic of the IBP-II site are currently sources of approximate to 1.3 gC . m⁻². yr⁻¹ to the atmosphere compared to the reported accumulation of approximate to 25 gC . m⁻². yr⁻¹ determined in 1971. This difference in ecosystem function over the last two decades may be due to the recently reported increase in surface temperatures resulting in decreases in the soil moisture status. These results point to the importance of long-term research sites and databases for determining the potential effects of climate change on ecosystem function.

Oeschger, H. 1992. Atmospheric CO₂ - global change and regulation mechanisms. *Berichte Der Bunsen-Gesellschaft-Physical Chemistry Chemical Physics* 96(3):252-257.

For the estimate of the distribution in the carbon system of the CO₂ emitted into the atmosphere due to human activities, the exchange of

carbon between atmosphere and ocean, and between atmosphere and biosphere needs to be considered. Information on this spreading of excess CO₂ can be obtained from measurements of a.o. CO₂, C-13/C-12, C-14/C in the atmosphere, of natural and nuclear weapon produced C-14 in the ocean and in the biota and of other natural or anthropogenic tracers. - Based essentially on such information, models for the CO₂ uptake by the carbon system have been developed which are capable of reproducing the result of the drop in the rate of increase of CO₂ emissions from 4.5% to 2% per year following the oil-embargo in 1973. - Of special interest regarding the understanding of the carbon cycle and its role in controlling the climate of the Earth are the observations in polar ice cores covering the past 160,000 years, corresponding to one and a half glaciation cycles. They show variations of atmospheric CO₂, CH₄, and N₂O parallel to the climatic variations. Measurements of C-13/C-12 in shells of foraminifera support the hypothesis that these CO₂ changes are caused by changes in the ocean's biological pump, i.e. the flux of detrital organic carbon from the surface to the deep ocean, which affects the total inorganic carbon in the surface ocean and the partial pressure of CO₂.

Ogasawara, N., H. Inden, and T. Asahira. 1996. Effects of lighting cycle on *Caladium* plantlets grown under ventilated and airtight culture vessels in relation to net daily CO₂ uptakes. *Journal of the Japanese Society for Horticultural Science* 65(1):129-134.

Caladium plantlets were cultured in vitro under a long lighting cycle (16 hr light/8 hr dark) and a short lighting cycle (2 hr light/1 hr dark). When gas exchange between the inside and outside of the culture vessel was allowed, the short lighting cycle enhanced growth, but when the culture vessel was airtight, the lighting cycle had no effect on growth. The estimated net daily CO₂ uptake under the short lighting cycle is greater than that under the long lighting cycle only when gas exchange occurs between the inside and outside of the vessel. These results demonstrate that the enhancement of growth by the short lighting cycle is due to an increase in the amount of available CO₂ resulting from the reduced escape of CO₂ from the vessel.

Ojala, A., P. Kankaala, J. Haapamaki, and T. Tulonen. 1995. Immediate responses of photosynthesis and dark respiration of late summer stands of *Equisetum fluviatile* L to increasing concentrations of atmospheric CO₂. *Journal of Applied Botany-Angewandte Botanik* 69(5-6):169-176.

Short-term responses of net photosynthesis, apparent dark respiration and gross photosynthesis of *Equisetum fluviatile* to increasing concentrations of atmospheric CO₂ were studied by using transplanted stands of natural origin. Three transplantations with biomasses of 274, 407, and 401 g dry weight m⁻² were established six weeks before the measurements in late August. Net photosynthesis and apparent dark respiration was measured from the change of CO₂ concentration inside polycarbonate chambers with diameter of 0.455 m and volume of 0.207 m³. Altogether 50 experiments for determination of CO₂ influx rates and 24 for efflux rates were run without any pre-treatment to higher CO₂ and each of them lasted 20-30 min. The response of net photosynthesis of *E. fluviatile* to CO₂ enrichment was less clear than the response to temperature or irradiance. Nevertheless, the stands showed an increase of ca. 25 % in net photosynthesis when the CO₂ concentration in air was increased from ambient to 500-600 ppm. When the CO₂ concentration was > 600 ppm the increase was ca. 60 %. A multilinear regression model combining solar radiation, temperature and CO₂ concentration

could only explain 46.4 % of the variation in the observed rates of net photosynthesis. The apparent dark respiration was positively correlated with temperature but inversely related to CO₂ concentration. When the CO₂ concentration was doubled from ambient the stands of *E. fluviatilis* reduced their apparent dark respiration by ca. 50 %. Under higher CO₂ concentration *E. fluviatilis* appeared more effective than in the ambient concentration, as the production lost through respiration decreased. When the concentration of atmospheric CO₂ was < 500 ppm, 57.5 % of gross production was respired whereas above 500 ppm of CO₂ the corresponding proportion was only 34.2 %. As the enrichment with CO₂ resulted in decreased respiration rates and it was known from long-term growth and photosynthesis experiments that neither shoot growth in length in *E. fluviatilis* is stimulated by higher CO₂ concentrations nor do the stands show down-regulation of photosynthesis after several weeks of CO₂ enrichment, it was concluded that the extra carbon fixed was allocated to storage through growth of below-ground biomass.

Ojima, D.S., W.J. Parton, D.S. Schimel, J.M.O. Scurlock, and T.G.F. Kittel. 1993. Modeling the effects of climatic and CO₂ changes on grassland storage of soil-C. *Water, Air, and Soil Pollution* 70(1-4):643-657.

We present results from analyses of the sensitivity of global grassland ecosystems to modified climate and atmospheric CO₂ levels. We assess 31 grassland sites from around the world under two different General Circulation Models (GCM) double CO₂ climates. These grasslands are representative of mostly naturally occurring ecosystems, however, in many regions of the world, grasslands have been greatly modified by recent land use changes. In this paper we focus on the ecosystem dynamics of natural grasslands. The climate change results indicate that simulated soil C losses occur in all but one grassland ecoregion, ranging from 0 to 14% of current soil C levels for the surface 20 cm. The Eurasian grasslands lost the greatest amount of soil C (approximately 1200 g C m⁻²) and the other temperate grasslands losses ranged from 0 to 1000 g C m⁻², averaging approximately 350 g C m⁻². The tropical grasslands and savannas lost the least amount of soil C per unit area ranging from no change to 300 g C m⁻² losses, averaging approximately 70 g C m⁻². plant production varies according to modifications in rainfall under the altered climate and to altered nitrogen mineralization rates. The two GCM's differed in predictions of rainfall with a doubling of CO₂, and these differences are reflected in plant production. Soil decomposition rates responded most predictably to changes in temperature. Direct CO₂ enhancement effects on decomposition and plant production tended to reduce the net impact of climate alterations alone.

Olaizola, M., E.O. Duerr, and D.W. Freeman. 1991. Effect of CO₂ enhancement in an outdoor algal production system using tetraselmis. *Journal of Applied Phycology* 3(4):363-366.

One of the objectives of microalgal culture is to provide reliable production technology for important live aquaculture feed organisms. Presented here are the results of experiments designed to provide a better understanding of the relationship between inorganic carbon availability and algal production. Our results suggest that through additions of CO₂ gas we were able to maintain sufficient dissolved carbon to stabilize outdoor algal cultures. Increases in the rate of addition of CO₂ increased levels of dissolved CO₂, total dissolved inorganic carbon (SIGMA-

CO₂), and decreased pH in the growth medium. This translated into improved buffering capacity of the culture medium and higher growth rate. A minimum of 2.4 mM SIGMA-CO₂ was found necessary to maintain a maximal growth rate of 0.7 doublings/day. We also found that the increased productivity more than offsets the cost of adding the CO₂.

Olesniewicz, K.S., and R.B. Thomas. 1999. Effects of mycorrhizal colonization on biomass production and nitrogen fixation of black locust (*Robinia pseudoacacia*) seedlings grown under elevated atmospheric carbon dioxide. *New Phytologist* 142(1):133-140.

Interactive effects of elevated atmospheric CO₂ and arbuscular mycorrhizal (AM) fungi on biomass production and N-2 fixation were investigated using black locust (*Robinia pseudoacacia*). Seedlings were grown in growth chambers maintained at either 350 µmol mol⁻¹ or 710 µmol mol⁻¹ CO₂. Seedlings were inoculated with *Rhizobium* spp. and were grown with or without AM fungi. The N-15 isotope dilution method was used to determine N source partitioning between N₂ fixation and inorganic fertilizer uptake. Elevated atmospheric CO₂ significantly increased the percentage of fine roots that were colonized by AM fungi. Mycorrhizal seedlings grown under elevated CO₂ had the greatest overall plant biomass production, nodulation, N and P content, and root N absorption. Additionally, elevated CO₂ levels enhanced nodule and root mass production, as well as N₂ fixation rates, of nonmycorrhizal seedlings. However, the relative response of biomass production to CO₂ enrichment was greater in non-mycorrhizal seedlings than in mycorrhizal seedlings. This study provides strong evidence that arbuscular mycorrhizal fungi play an important role in the extent to which plant nutrition of symbiotic N-2-fixing tree species is affected by enriched atmospheric CO₂.

Olszyk, D.M., H.G.S. Centeno, L.H. Ziska, J.S. Kern, and R.B. Matthews. 1999. Global climate change, rice productivity and methane emissions: comparison of simulated and experimental results. *Agricultural and Forest Meteorology* 97(2):87-101.

Irrigated rice production is a major food source for a large portion of the world's population, and a major anthropogenic source of the greenhouse gas methane (CH₄). Potential impacts of global climate change [elevated carbon dioxide (CO₂) and/or elevated temperature] on rice can be predicted with simulation models, but experiments are necessary to determine how well these models mimic the responses of the field crop. This paper compares grain yield, biomass, and methane emissions from experiments at the international Rice Research Institute (IRRI) at Los Banos, the Philippines, with potential responses based on simulations using the ORYZA1 process model and the climate data from those experiments. Yield and biomass were compared for the 1995 and 1996 dry seasons (DS) and the 1994 wet season (WS). Emissions of CH₄ from rice fields were evaluated for the 1995 WS and 1996 DS. Simulated and experimental responses (adjusted for effects of the open-top chambers on plant growth) differed with climate change scenario, response parameter, and season. Under current climate conditions (ambient CO₂ and ambient temperature), simulated grain yield was 14% lower than the adjusted experimental grain yield in the 1996 DS, but was 17 and 37% higher than experimental grain yield in the 1995 DS and 1994 WS, respectively. With current climate, simulations underestimated experimental aboveground, belowground, and total biomass. The

simulated CH₄ emissions were the same as the experimental emissions, assuming CH₄ emissions were 2.9% of the simulated total biomass carbon. With elevated CO₂ and ambient temperature, simulations predicted greater increases (compared with current climate) in grain yield, aboveground biomass, and total biomass, but generally smaller increases in belowground biomass and CH₄ emissions than the significant (at $p < 0.05$) increases that were found experimentally. With ambient CO₂ and elevated temperature, both simulations and experiments generally showed either no change or a decrease in grain yield and biomass, but none of the responses in the experiments were statistically significant. Simulated ambient CO₂ and elevated temperature resulted in a smaller decrease in CH₄ emissions than the significant decrease found in the experiments. For both elevated CO₂ and elevated temperature, simulated grain yield increased in all three seasons, whereas there were no significant effects on experimental grain yield. The simulations predicted smaller increases in belowground biomass and CH₄ emissions with elevated CO₂ and elevated temperature than the significant increases in the experiments. To better correspond to experimental results, this study suggested that current simulation models could be improved in terms of effects of temperature on grain yield and use of belowground biomass to estimate CH₄ emissions. Olszyk, D.M., and C. Wise. 1997. Interactive effects of elevated CO₂ and O₃ on rice and flacca tomato. *Agriculture Ecosystems & Environment* 66(1):1-10.

Atmospheric concentrations of both carbon dioxide (CO₂) and ozone (O₃) are increasing, with potentially dramatic effects on plants. This study was conducted to determine interactive effects of CO₂ and O₃ on rice (*Oryza sativa* L. cv. IR 74) and a 'wilty' mutant of tomato (*Lycopersicon esculentum* Mill. flacca). Plants were grown from seed in a glasshouse and exposed for 28 days to ambient or elevated CO₂ (approximate to 400 or 700 $\mu\text{mol mol}^{-1}$ CO₂) and/or ambient or elevated O₃ (peak/valley pattern of exposure with cumulative totals of approximate to 1 or 44 $\mu\text{mol l}^{-1}$ h). Elevated CO₂ alleviated O₃-associated decreases in allocation of biomass to roots, as indicated by a decreased root:shoot ratio ($p < 0.05$), and also reduced injury from O₃ as indicated by leaf greenness readings for one experiment ($p < 0.05$). By itself, elevated CO₂ resulted in increases in total plant and individual organ (root, leaf, stem) dry weights and root:shoot ratio and elevated O₃ resulted in increases in main culm leaf number and a decrease in stem dry weight ($p < 0.05$). Elevated CO₂ had no significant effect on the tendency for O₃-induced biomass reductions of flacca tomato. For flacca, elevated CO₂ alone increased shoot and root biomass ($p < 0.05$), and elevated O₃ alone tended to decrease biomass for both parameters, but only at $p = 0.09$ and 0.11 , respectively. This study was preliminary, as the environmental conditions in these experiments may have altered O₃ and CO₂ responses of the plants. However, these results provided additional evidence that elevated CO₂ inhibits adverse effects of O₃ on plants, and that the interactive response may be mediated by stomata. Olszyk, D., C. Wise, E. VanEss, M. Apple, and D. Tingey. 1998. Phenology and growth of shoots, needles, and buds of Douglas- fir seedlings with elevated CO₂ and (or) temperature. *Canadian Journal of*

Botany-Revue Canadienne De Botanique 76(12):1991-2001.

Increased atmospheric CO₂ and global warming may affect overall tree growth, but impacts of these combined stresses are largely unknown in terms of multiple growing season impacts on specific flushes. Thus, the effects of ambient or elevated CO₂ (approximately 200 $\mu\text{mol mol}^{-1}$ above ambient) and ambient or elevated temperature (approximately 4 degrees C above ambient) were evaluated for both main and second (lammas) flushes of Douglas-fir (*Pseudotsuga menziesii* (Mirb.) France). Established seedlings were grown for three full growing seasons in outdoor, sunlit chambers, which maintained diel and seasonal variation in climate. A reconstructed forest soil was used with a seasonal wet and dry cycle and without added fertilizer. Compared with ambient CO₂ elevated CO₂ had no impact on overall phenology and growth of terminal shoots, needles, or buds. In contrast, compared with ambient temperature, elevated temperature resulted in higher shoot and needle growth rates early in the season; reduced final terminal shoot length; and either reduced, increased, or unchanged final needle length, depending on season. Initiation of the lammas flush was delayed and (or) decreased at elevated temperature. Leading terminal bud break and growth occurred earlier; however, resting bud length was reduced, and bud width tended to increase with elevated temperature. Thus, at least during early seedling growth, elevated temperatures may reduce both main- and lammas- flush growth, thereby altering tree productivity, whereas elevated CO₂ may have little effect on main or lammas growth at either the current or elevated temperature.

Olszyk, D., C. Wise, E. VanEss, and D. Tingey. 1998. Elevated temperature but not elevated CO₂ affects long-term patterns of stem diameter and height of Douglas-fir seedlings. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 28(7):1046-1054.

Global climatic change may impact forest productivity, but data are lacking on potential effects of elevated CO₂ and temperature on tree growth. We determined changes in shoot growth for Douglas-fir (*Pseudotsuga menziesii* (Mirb.) France) seedlings exposed to ambient or elevated CO₂ (+approximate to 179 $\mu\text{mol mol}^{-1}$), and ambient or elevated temperature (+approximate to 3.5 degrees C). Seedlings were grown for 4 years (three complete growing seasons) in outdoor, sunlit chambers. In each season, height growth was initiated earlier and, in two seasons, ceased earlier for elevated compared with ambient temperature trees. Elevated temperature reduced intermediate and final plant heights. Stem diameter growth began earlier each season at the elevated compared with the ambient temperature, but temperature had no effect on final stem diameter. Elevated temperature tended to reduce leaf ($p = 0.07$) but not woody biomass. Elevated CO₂ had no significant effects on stem diameter, height, and leaf or woody biomass, and there were no significant CO₂ x temperature interactions. Thus, elevated temperatures (but not elevated CO₂) associated with climate change may decrease seedling canopy growth as indicated by reduced height and leaf biomass but have little or no effect on overall woody growth as indicated by stem diameter and woody biomass.

Oltchev, A., A. Ibrom, K. Morgenstern, H. Kreilein, and G. Gravenhorst. 1999. Evaluation of the response of a spruce forest

ecosystem on climatic changes: Results of modelling experiments. *Physics and Chemistry of the Earth Part B-Hydrology Oceans and Atmosphere* 24(1-2):103-110.

The physical and chemical environment of forests will change in the future. How forests will react to new conditions is not known yet. In order to get an idea of the sensitivity of present forests to possible atmospheric changes, it is helpful to investigate the physiological response of forest ecosystem to a change of key environmental parameters. In order to estimate the response of a mountain spruce forest to different atmospheric conditions during the summer a six-layer non-steady-state SVAT model (SLODSVAT) was used. Eight scenarios were used for modelling energy and mass exchange during an eleven day summer period, combining different combinations of microclimatic conditions. All atmospheric scenarios were examined for three various CO₂ mixing ratio levels: 350ppm (current condition), 450ppm and 550ppm. A scenario "0" assuming the current climatic features at different CO₂ contents was considered as well. Structural and physiological adaptation of the forest to the new atmospheric conditions were not taken into account. For all scenarios the modelling results show increased net CO₂ flux into the forest with increasing ambient CO₂ concentration. Maximum net CO₂ uptake was simulated for dry climate scenarios. Transpiration and evapotranspiration rates had similar trends independently of the ambient CO₂ concentration used: at cold and wet conditions they decreased, while at warm and dry conditions transpiration and evapotranspiration rates increased. The influence of CO₂ concentrations on transpiration rates is of minor importance if compared to changes of temperature, water vapour pressure, cloud amount and atmospheric precipitation as considered in this investigation. Ommen, O.E., A. Donnelly, S. Vanhoutvin, M. van Oijen, and R. Manderscheid. 1999. Chlorophyll content of spring wheat flag leaves grown under elevated CO₂ concentrations and other environmental stresses within the 'ESPACE-wheat' project. *European Journal of Agronomy* 10(3-4):197-203.

Spring wheat cv. Minaret was grown in open-top chambers at four sites across Europe. The effect of different treatments (CO₂ enrichment, O-3 fumigation, drought stress and temperature) on the chlorophyll content of the flag leaf was investigated using the MINOLTA SPAD-502 meter. Under optimum growth conditions the maximum chlorophyll content, which was reached at anthesis, was consistent among the sites ranging from 460 to 500 mg chlorophyll m⁻². No significant effect of elevated CO₂ or O-3 was observed at anthesis. Leaf senescence, indicated by the chlorophyll breakdown after anthesis, was relatively constant in the control chambers. Under control conditions, thermal time until 50% chlorophyll loss was reached was 600 degrees C day. Elevated CO₂ caused a faster decline in chlorophyll content (thermal time until 50% chlorophyll loss was reduced to 500-580 degrees C day) indicating a faster rate of plant development at two experimental sites. The effect of ozone on chlorophyll content depended on the time and dose of O-3 exposure. During grain filling, high O-3 concentrations induced premature senescence of the flag leaves (up to -130 degrees C day). This deleterious effect was mitigated by elevated CO₂. Drought stress led to faster chlorophyll breakdown irrespective of CO₂ treatment. (C) 1999 Elsevier Science B.V. All rights reserved.

Oneill, E.G. 1994. Responses of soil biota to elevated atmospheric carbon-dioxide. *Plant and Soil* 165(1):55-65.

Increasing concentrations of atmospheric CO₂ could have dramatic effects upon terrestrial ecosystems including changes in ecosystem structure, nutrient cycling rates, net primary production, C source-sink relationships and successional patterns. All of these potential changes will be constrained to some degree by below ground processes and mediated by responses of soil biota to indirect effects of CO₂ enrichment. A review of our current state of knowledge regarding responses of soil biota is presented, covering responses of mycorrhizae, N-fixing bacteria and actinomycetes, soil microbiota, plant pathogens, and soil fauna. Emphasis will be placed on consequences to biota of increasing C input through the rhizosphere and resulting feedbacks to above ground systems. Rising CO₂ may also result in altered nutrient concentrations of plant litter, potentially changing decomposition rates through indirect effects upon decomposer communities. Thus, this review will also cover current information on decomposition of litter produced at elevated CO₂.

Ong, B.L., C.K.K. Koh, and Y.C. Wee. 1998. Effects of CO₂ on growth and photosynthesis of *Pyrrosia piloselloides* (L.) Price gametophytes. *Photosynthetica* 35(1):21-27.

The effects of CO₂ concentration on spore germination, growth, and net photosynthetic rate (P-N) of gametophytes of a tropical epiphytic fern, *Pyrrosia piloselloides*, were investigated over a 100-d period. Increasing CO₂ concentration stimulated spore germination and enhanced gametophytic growth. The appearance of sexual organs and formation of sporophytes were accelerated with higher CO₂ during growth. Radiant energy saturated P-N and dark respiration rate also increased with increasing CO₂ concentrations during growth.

Ormrod, D.P., V.M. Lesser, D.M. Olszyk, and D.T. Tingey. 1999. Elevated temperature and carbon dioxide affect chlorophylls and carotenoids in douglas-fir seedlings. *International Journal of Plant Science* 160(3):529-534.

The objective of this study was to determine whether increased temperature and CO₂ concentration would decrease or increase the concentrations of foliar pigments in 5-yr-old seedlings of Douglas-fir *Pseudotsuga menziesii* [Mirb.] France var. *menziesii*. Seedlings were grown for 3 yr in sunlit, controlled environment chambers under ambient conditions or with a 179 μ L L⁻¹ elevation of CO₂ and/or a 3.5 degrees C elevation of temperature. Current- and previous-year needles were extracted with methanol for determination of chlorophylls and b, total carotenoids, and UV-absorbing compounds. Interactive effects of elevated temperature and CO₂ on the measured responses were not significant. Current-year needles from the elevated CO₂ treatment had the lowest chlorophyll and carotenoid concentrations, whereas needles of both age classes in the elevated temperature treatment had the highest concentrations of chlorophylls; current-year needles had the highest carotenoid concentration at elevated temperature. Neither temperature

nor CO₂ affected the concentrations of UV-absorbing compounds or needle fresh mass significantly. Chlorophyll a was correlated with carotenoids across all treatments ($r = 0.75-0.89$) in both needle age classes and with chlorophyll b in most treatments.

Osborne, C.P., B.G. Drake, J. LaRoche, and S.P. Long. 1997. Does long-term elevation of CO₂ concentration increase photosynthesis in forest floor vegetation? Indian strawberry in a Maryland forest (vol 114, pg 337, 1997). *Plant Physiology* 114(4):1571.

As the partial pressure of CO₂ (pCO₂) in the atmosphere rises, photorespiratory loss of carbon in C-3 photosynthesis will diminish and the net efficiency of light-limited photosynthetic carbon uptake should rise. We tested this expectation for Indian strawberry (*Duchesnea indica*) growing on a Maryland forest floor. Open-top chambers were used to elevate the pCO₂ of a forest floor habitat to 67 Pa and were paired with control chambers providing an ambient pCO₂ of 38 Pa. After 3.5 years, *D. indica* leaves grown and measured in the elevated pCO₂ showed a significantly greater maximum quantum efficiency of net photosynthesis (by 22%) and a lower light compensation point (by 42%) than leaves grown and measured in the control chambers. The quantum efficiency to minimize photorespiration, measured in 1% O-2, was the same for controls and plants grown at elevated pCO₂. This showed that the maximum efficiency of light-energy transduction into assimilated carbon was not altered by acclimation and that the increase in light-limited photosynthesis at elevated pCO₂ was simply a function of the decrease in photorespiration. Acclimation did decrease the ribulose-1,5-bisphosphate carboxylase/oxygenase and light-harvesting chlorophyll protein content of the leaf by more than 30%. These changes were associated with a decreased capacity for light-saturated, but not light-limited, photosynthesis. Even so, leaves of *D. indica* grown and measured at elevated pCO₂ showed greater light-saturated photosynthetic rates than leaves grown and measured at the current atmospheric pCO₂. In situ measurements under natural forest floor lighting showed large increases in leaf photosynthesis at elevated pCO₂, relative to controls, in both summer and fall. The increase in efficiency of light-limited photosynthesis with elevated pCO₂ allowed positive net photosynthetic carbon uptake on days and at locations on the forest floor that light fluxes were insufficient for positive net photosynthesis in the current atmospheric pCO₂.

Osborne, C.P., J. LaRoche, R.L. Garcia, B.A. Kimball, G.W. Wall, P.J. Pinter, R.L. LaMorte, G.R. Hendrey, and S.P. Long. 1998. Does leaf position within a canopy affect acclimation of photosynthesis to elevated CO₂? Analysis of a wheat crop under free-air CO₂ enrichment. *Plant Physiology* 117(3):1037-1045.

Previous studies of photosynthetic acclimation to elevated CO₂ have focused on the most recently expanded, sunlit leaves in the canopy. We examined acclimation in a vertical profile of leaves through a canopy of wheat (*Triticum aestivum* L.). The crop was grown at an elevated CO₂ partial pressure of 55 Pa within a replicated field experiment using free-air CO₂ enrichment. Gas exchange was used to estimate in vivo carboxylation capacity and the maximum rate of ribulose-1,5-bisphosphate-limited photosynthesis. Net photosynthetic CO₂ uptake was measured for leaves in situ within the canopy. Leaf contents of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), light-harvesting-complex (LHC) proteins, and total N were determined. Elevated CO₂ did not affect carboxylation capacity in the most recently expanded leaves but led to a decrease in lower, shaded leaves during grain development. Despite this acclimation, in situ photosynthetic CO₂ uptake remained higher under elevated CO₂. Acclimation at elevated CO₂ was accompanied by decreases in both Rubisco and total leaf N contents and an increase in LHC content. Elevated CO₂ led to a larger increase in LHC/Rubisco in lower canopy leaves than in the uppermost leaf. Acclimation of leaf photosynthesis to elevated CO₂ therefore depended on both vertical position within the canopy and the developmental stage.

Osborne, J.L., C.S. Awmack, S.J. Clark, I.H. Williams, and V.C. Mills. 1997. Nectar and flower production in *Vicia faba* L (field bean) at ambient and elevated carbon dioxide. *Apidologie* 28(1):43-55.

Atmospheric CO₂ has been predicted to double by the year 2100. Elevated CO₂ causes an increase in photosynthetic rate and extra assimilate is allocated to plant growth, seed and fruit production. Increased investment in flowers may have implications for pollination in entomophilous plants. Floral nectar standing crop, flower production and longevity were examined in *Vicia faba*, field bean, at ambient and

elevated CO₂. Nectar standing crop did not differ significantly between treatments but plants grown at elevated CO₂ produced approximately 25% more flowers per plant and these lived 17% longer than those grown at ambient CO₂. A plant grown at elevated CO₂ may thus produce more nectar in total and, together with its increased floral display, may be more attractive to pollinators, but pollen flow will not necessarily be improved.

Osorio, J., M.L. Osorio, M.M. Chaves, and J.S. Pereira. 1998. Water deficits are more important in delaying growth than in changing patterns of carbon allocation in *Eucalyptus globulus*. *Tree Physiology* 18(6):363-373.

Potted cuttings of three *Eucalyptus globulus* Labill. clones (AR3, CN44, MP11) were either well watered or subjected to one of two soil water deficit regimes for six months in a greenhouse. Reductions in lateral branching, leaf production and leaf expansion were the leading contributors to the large differences observed in biomass production between well-watered and water-stressed plants. Although no significant differences among clones were observed in dry matter accumulation or in the magnitude of the response to soil water deficits, sensitivity of lateral branching, leaf initiation and whole-plant foliage to water stress was significantly lower in CN44 than in AR3 and MP11. When the confounding effect of differences in plant size resulting from the different watering regimes was removed, allometric analysis indicated that the genotypes differed in biomass allocation patterns. In addition to a drought-induced reduction in leaf number, water deficits also resulted in smaller leaves because leaf expansion was inhibited during dehydration events. Resumption of leaf expansion following stress relief occurred in all of the clones, but was particularly evident in severely stressed plants of Clone AR3, possibly as a result of the osmotic adjustment observed in this genotype.

Overdieck, D. 1993. Effects of atmospheric co₂ enrichment on co₂ exchange-rates of beech stands in small model-ecosystems. *Water, Air, and Soil Pollution* 70(1-4):259-277.

CO₂ enrichment experiments were performed during two vegetation periods on young beech stands in four closed mini-greenhouses. The houses were climatized according to the outside microclimate (+/- 0.5-degrees-C, +/- 15 % rel. air humidity, wind speed approximately to outside in the range of 0.5 - 2.5 m s⁻¹, max. 17 % PAR reduction). The model ecosystems - consisting of 36 young beech (2.5 yr-old) in a soil block of 0.38 m³ and an air volume of 0.64 m³ - were exposed to CO₂ concentrations of the unchanged ambient air (350 +/- 34 ppmv, control) and of 700 ppmv (698 +/- 10 ppmv). Plant growth parameters were measured non destructively and at the end of the 1st season samples were

taken for weighing the phytomass. CO₂ gas exchange of the stands taken as a whole were continuously measured with two entire mini-greenhouses and, in addition, a compact mini-cuvette system (CMS 400, Walz) was used for measuring dark respiration and CO₂ net assimilation rates of single leaves in both stands. Under the influence of the additional CO₂ supply stem diameter (2 cm above the first lateral roots) was increased by 13.5 %, stem height by 27.4 %, and the number of leaves/tree by 33 % at the end of the 2nd season. The number of buds was not significantly different and the effect on mean area per leaf was insignificant. Leaf area index was by 1.4 units greater. All dry weights of the main organs were increased after the 1st season: leaf 60 %, stem 34 %, bud 54 %. Roots < 2 mm phi weighed 1.5-fold more and roots > 2 mm phi 1.7-fold more under elevated CO₂. CO₂ gas exchange of two systems was measured. Whole system CO₂ losses during night as well as photosynthetic CO₂ gains during days were greater at 700 ppmv than in the control system. However, if one balances CO₂ gains with CO₂ losses over a period of five days in August both model-ecosystems taken as a whole were sinks for CO₂. During this selected time period of 5 days at the peak of the season the beech stand at 350 ppmv was the greater sink. At 350 ppmv CO₂ (control) the average leaf respiration for 20-degrees- C amounted to 0.31 +/- 0.18 and at 700 ppmv to 0.57 +/- 0.42 mumol CO₂ m⁻² s⁻¹ (n = 35/40, t = 3.48, alpha < 0.05), and correlated positively with leaf temperature. At light saturation the mean net assimilation rate was 4.48 mumol m⁻² (leaf area) s⁻¹ in the control and 6.21 mumol m⁻² s⁻¹ at the high CO₂ concentration corresponding with an enhancement factor of 1.39 for the selected time period. Results from the whole stand and from single leaf measurements are compared by means of mathematical modelling procedures in order to quantify CO₂ enrichment effects on beech model ecosystems.

Overdieck, D. 1993. Elevated co₂ and the mineral-content of herbaceous and woody- plants. *Vegetatio* 104:403-411.

The CO₂ enrichment effects (300-650 mumol mol⁻¹) on mineral concentration (N, P, K, Ca, Mg, Mn, Fe, Zn), absolute total mineral contents per individual and of whole stands of four herbaceous (*Trifolium repens* L., *Trifolium pratense* L., *Lolium perenne* L., *Festuca pratensis* HUDS.) and two woody species (*Acer pseudo-platanus* L., *Fagus sylvatica* L.) were investigated. In general, the mineral concentration of the plant tissues decreased (all six species: N > Ca > K > Mg) with the exception of P. Mn and Fe were only determined for the tree species. Both decreased in concentration (Mn > Fe). Zn was only analysed for *Trifolium pratense* and *Festuca pratensis* and decreased significantly in the grass. Despite of decreases in concentrations of as much as 20 % in some cases there were increases in absolute amounts per individual and, therefore, in the whole vegetation up to 25 % because of the enhanced dry matter accumulation at elevated CO₂ supply.

Overdieck, D. 1996. CO₂ gas exchange and mass production during germination of radish at elevated atmospheric CO₂ concentration. *Journal of Applied Botany-Angewandte Botanik* 70(5-6):205-210.

The influence of elevated CO₂ concentration (similar to 700 mu mol mol⁻¹) on dry mass accumulation and CO₂ net assimilation of

germinating *Raphanus sativus* L.-seeds was investigated during growth over 10 days at low light during the day (16 h, photosynthetic photon flux density (PPFD): 20-70 $\mu\text{mol m}^{-2}\text{s}^{-1}$) and at darkness (8 h). Investigations at similar to 360 (unchanged ambient air) and at similar to 400 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ served as controls. At germination and development in a WALZ- mini-cuvette (part of CMS 400) with constant microclimatic conditions (20 degrees C, PPFD during day: 20-60 $\mu\text{mol m}^{-2} \text{s}^{-1}$), vapor pressure deficit: similar to 0.5 kPa dry mass decreased by 14% in the course of the experiment without measurable influence of CO_2 concentration. In a subsequent experiment with continuous CO_2 gas exchange measurements on groups of 10 germinating radishes over 10 days at similar to 360 ($n = 6$) and at similar to 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ ($n = 5$) and, except for PPFD (70 $\mu\text{mol m}^{-2} \text{s}^{-1}$), under unchanged microclimatic conditions no measurable CO_2 effect on dark respiration ($R(d)$) could be found. In light and in both CO_2 treatments maximum respiration was reached at day 3 or 4; whereas during darkness its level remained unchanged until the 10(th) day. At 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ during the day compensation of respiratory CO_2 losses by photosynthetic gains was reached one day earlier than in the control. CO_2 net assimilation during the light phase of the 10(th) day was enhanced by the elevated CO_2 supply by a factor of 2.2 relative to the control. Results of CO_2 gas exchange measurements on groups of 10 germinating radish seeds taken day by day from phytotron chambers with the same microclimatic conditions as before (similar to 400 and similar to 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, $n = 3/\text{day}$ and CO_2 concentration) again showed no CO_2 effect on dark respiration; however, a positive effect on CO_2 net assimilation clearly occurred once more in light (with an enhancement factor after 10 days of similar to 1.5). The mean dry mass balance - calculated by means of all CO_2 gas exchange rates and the C-content [%] of seeds and seedlings of the last experiment - resulted after 10 days in a photosynthetically not yet compensated loss of 8.7% from the starting seed dry mass at 400 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ and of only 3.3% at 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. The reported positive CO_2 effect on growth and net production of radish reported in literature could, therefore, be explained at least in the germinating phase by enhanced CO_2 net assimilation with unchanging CO_2 losses by simultaneous dark respiration.

Overdieck, D., and M. Forstreuter. 1994. Evapotranspiration of beech stands and transpiration of beech leaves subject to atmospheric CO_2 enrichment. *Tree Physiology* 14(7-9):997-1003.

Beech trees (*Fagus sylvatica* L.) show reduced stomatal conductance and increased leaf area index in response to increased atmospheric CO_2 concentration. To determine whether the reduction in stomatal conductance results in lower stand evapotranspiration, we compared transpiration on a leaf-area basis and stand evapotranspiration on a ground-area basis in young European beech trees growing in greenhouses at ambient (360 $\pm$ 34 $\mu\text{mol mol}^{-1}$) and elevated (698 $\pm$ 10 $\mu\text{mol mol}^{-1}$) CO_2 concentrations. Trees were grown in homogenized natural soil at constant soil water supply for two growing seasons. At light saturation, leaf transpiration rates were, on average, 18% lower in the elevated CO_2 treatment than in the ambient CO_2 treatment. Mean transpiration coefficients (transpiration/net CO_2 uptake) of leaves were 179 and 110 in the ambient and elevated CO_2 treatments, respectively, indicating improved water use efficiency in trees in the elevated CO_2 treatment. Total leaf conductance was decreased by 32% at light saturation. The elevated CO_2 treatment resulted in a 14% reduction in stand evapotranspiration. In both CO_2 treatments, evapotranspiration increased linearly at a rate of 0.2 kg $\text{H}_2\text{O m}^{-2} \text{ day}^{-1}$ for each 1-degrees-C rise in air temperature between 14 and 25-degrees-C. We conclude that, under Central European conditions, water losses from deciduous forest stands will be reduced by a doubling

of tropospheric CO_2 concentration.

Owensby, C.E. 1993. Potential impacts of elevated CO_2 and aboveground and belowground litter quality of a tallgrass prairie. *Water, Air, and Soil Pollution* 70(1-4):413-424.

Increased atmospheric CO_2 will likely impact the productivity of arid and semiarid ecosystems through increased C, N, and water use efficiencies at the individual plant level. Tallgrass prairie has had increased above- and belowground biomass production under elevated CO_2 , primarily due to increased water use efficiency. There is an apparent decreased N requirement to sustain increased productivity in CO_2 -enriched tallgrass prairie, and C:N ratios of plant litter above and below ground have increased. The tallgrass prairie ecosystem level response to elevated CO_2 on the C cycle could potentially increase C storage. Reduced litter quality associated with elevated CO_2 in tallgrass prairie has the potential to reduce decomposition rates, and ruminant digestion rate of plant biomass apparently has been lowered. Reduced intake by ruminants would shunt more of the plant biomass directly into the detrital food chain, thereby slowing decomposition further. The potential impact is for increased C to be retained as soil organic matter in the tallgrass prairie.

Owensby, C.E., L.M. Auen, and P.I. Coyne. 1994. Biomass production in a nitrogen-fertilized, tallgrass prairie ecosystem exposed to ambient and elevated levels of CO_2 . *Plant and Soil* 165(1):105-113.

Increased biomass production in terrestrial ecosystems with elevated atmospheric CO_2 may be constrained by nutrient limitations as a result of increased requirement or reduced availability caused by reduced turnover rates of nutrients. To determine the short-term impact of nitrogen (N) fertilization on plant biomass production under elevated CO_2 , we compared the response of N-fertilized tallgrass prairie at ambient and twice-ambient CO_2 levels over a 2-year period. Native tallgrass prairie plots (4.5 m diameter) were exposed continuously (24 h) to ambient and twice-ambient CO_2 from 1 April to 26 October. We compared our results to an unfertilized companion experiment on the same research site. Above- and belowground biomass production and leaf area of fertilized plots were greater with elevated than ambient CO_2 in both years. The increase in biomass at high CO_2 occurred mainly aboveground in 1991, a dry year, and belowground in 1990, a wet year. Nitrogen concentration was lower in plants exposed to elevated CO_2 , but total standing crop N was greater at high CO_2 . Increased root biomass under elevated CO_2 apparently increased N uptake. The biomass production response to elevated CO_2 was much greater on N-fertilized than unfertilized prairie, particularly in the dry year. We conclude that biomass production response to elevated CO_2 was suppressed by N limitation in years with below-normal precipitation. Reduced N concentration in above- and belowground biomass could slow microbial degradation of soil organic matter and surface litter, thereby exacerbating N limitation in the long term.

Owensby, C.E., P.I. Coyne, and L.M. Auen. 1993. Nitrogen and phosphorus dynamics of a tallgrass prairie ecosystem exposed to elevated carbon-dioxide. *Plant, Cell and Environment* 16(7):843-850.

A tallgrass prairie ecosystem was exposed to ambient and twice-ambient CO₂ concentrations in open-top chambers and compared to unchambered ambient CO₂ during the entire growing season from 1989 through 1991. Dominant species were *Andropogon gerardii* (C4), *A. scoparius* (C4), *Sorghastrum nutans* (C4) and *Poa pratensis* (C3). Nitrogen and phosphorus concentrations in *A. gerardii*, *P. pratensis* and dicotyledonous herbs above ground biomass were estimated by periodic sampling throughout the growing season in 1989 and 1990. In 1991, N and P concentrations in peak biomass were estimated by an early August harvest. N and P concentrations in root production as a function of treatment were estimated using root ingrowth bags that remained in place throughout the growing season. Total N and P in above- and belowground biomass were calculated as products of concentration and peak biomass by species groups. N concentration in *A. gerardii* and dicotyledonous herb aboveground biomass was lower and total N higher in elevated CO₂ plots than in ambient CO₂ plots. N concentration in *P. pratensis* aboveground biomass was lower in elevated CO₂ plots than in ambient, but total N did not differ among treatments in 2 out of 3 years. In 1990, N concentration in root ingrowth bag biomass was lower and total N greater in elevated CO₂ than in ambient CO₂ plots. Root ingrowth bag biomass N concentration did not differ among treatments in 1991, but total N was greater in elevated CO₂ plots than in ambient CO₂ plots. P concentration was lower under elevated CO₂ compared to ambient in 1989, but did not differ substantially among treatments in 1990 or 1991. In all years, total P in aboveground *A. gerardii* and root ingrowth bag biomass was greater under elevated CO₂ than ambient. P concentration and total P in *P. pratensis* was similar among treatments.

Owensby, C.E., P.I. Coyne, J.M. Ham, L.M. Auen, and A.K. Knapp. 1993. Biomass production in a tallgrass prairie ecosystem exposed to ambient and elevated CO₂. *Ecological Applications* 3(4):644-653.

Responses to elevated CO₂ have not been measured for natural grassland ecosystems. Global carbon budgets will likely be affected by changes in biomass production and allocation in the major terrestrial ecosystems. Whether ecosystems sequester or release excess carbon to the atmosphere will partly determine the extent and rate that atmospheric CO₂ concentration rises. Elevated CO₂ also may change plant community species composition and water status. We determined above- and belowground biomass production, plant community species composition, and measured and modeled water status of a tallgrass prairie ecosystem in Kansas exposed to ambient and twice-ambient CO₂ concentrations in open-top chambers during the entire growing season from 1989 through 1991. Dominant species were *Andropogon gerardii*, *A. scoparius*, and *Sorghastrum nutans* (C-4 metabolism) and *Poa pratensis* (C-3). Aboveground biomass and leaf area were estimated by periodic sampling throughout the growing season in 1989 and 1990. In 1991, peak biomass and leaf area were estimated by an early August harvest. Relative root production among treatments was estimated using root ingrowth bags which remained in place throughout the growing season. Latent heat flux was simulated with and without water stress. Botanical composition was estimated annually. Compared to ambient CO₂ levels, elevated CO₂ increased production of C-4 grass species, but not of C-3 grass species. Species composition of C-4 grasses did not change, but *Poa pratensis* (C-3) declined, and C-3 forbs increased in the stand with elevated CO₂ compared to ambient. Open-top chambers appeared to reduce latent heat flux and increase water-use efficiency similar to the elevated CO₂ treatment when water stress was not severe,

but under severe water stress, the chamber effect on water-use efficiency was limited. In natural ecosystems with periodic moisture stress, increased water-use efficiency under elevated CO₂ apparently would have a greater impact on productivity irrespective of photosynthetic pathway.

1767

Owensby, C.E., J.M. Ham, A.K. Knapp, and L.M. Auen. 1999. Biomass production and species composition change in a tallgrass prairie ecosystem after long-term exposure to elevated atmospheric CO₂. *Global Change Biology* 5(5):497-506.

To determine the long-term impact of elevated CO₂ on primary production of native tallgrass prairie, we compared the responses of tallgrass prairie at ambient and twice-ambient atmospheric CO₂ levels over an 8-year period. Plots in open-top chambers (4.5 m diameter) were exposed continuously (24 h) to ambient and elevated CO₂ from early April to late October each year. Unchambered plots were monitored also. Aboveground peak biomass was determined by clipping each year in early August, and root growth was estimated by harvesting roots from root ingrowth bags. Plant community composition was censused each year in early June. In the last 2 years of the study, subplots were clipped on 1 June or 1 July, and regrowth was harvested on 1 October. Volumetric soil water content of the 0-100 cm soil layer was determined using neutron scattering, and was generally higher in elevated CO₂ plots than ambient. Peak aboveground biomass was greater on elevated CO₂ plots than ambient CO₂ plots with or without chambers during years with significant plant water stress. Above-ground regrowth biomass was greater under elevated CO₂ than under ambient CO₂ in a year with late-season water stress, but did not differ in a wetter year. Root ingrowth biomass was also greater in elevated CO₂ plots than ambient CO₂ plots when water stress occurred during the growing season. The basal cover and relative amount of warm-season perennial grasses (C4) in the stand changed little during the 8-year period, but basal cover and relative amount of cool-season perennial grasses (C3) in the stand declined in the elevated CO₂ plots and in ambient CO₂ plots with chambers. Forbs (C3) and members of the Cyperaceae (C3) increased in basal cover and relative amount in the stand at elevated compared to ambient CO₂. Greater biomass production under elevated CO₂ in C4-dominated grasslands may lead to a greater carbon sequestration by those ecosystems and reduce peak atmospheric CO₂ concentrations in the future.

Owensby, C.E., J.M. Ham, A.K. Knapp, D. Bremer, and L.M. Auen. 1997. Water vapour fluxes and their impact under elevated CO₂ in a C4-tallgrass prairie. *Global Change Biology* 3(3):189-195.

We measured leaf-level stomatal conductance, xylem pressure potential, and stomate number and size as well as whole plant sag now and canopy-level water vapour fluxes in a C4-tallgrass prairie in Kansas exposed to ambient and elevated CO₂. Stomatal conductance was reduced by as much as 50% under elevated CO₂ compared to ambient. In addition, there was a reduction in stomate number of the C4 grass, *Andropogon gerardii* Vitman, and the C3 dicot herb, *Salvia pitcheri* Torr., under elevated CO₂ compared to ambient. The result was an improved water status for plants exposed to elevated CO₂ which was

reflected by a less negative xylem pressure potential compared to plants exposed to ambient CO₂. Sap flow rates were 20 to 30% lower for plants exposed to elevated CO₂ than for those exposed to ambient CO₂. At the canopy level, evapotranspiration was reduced by 22% under elevated CO₂. The reduced water use by the plant canopy under elevated CO₂ extended the photosynthetically-active period when water became limiting in the ecosystem. The result was an increased above- and belowground biomass production in years when water stress was frequent.

Pacala, S.W., and D.H. Deutschman. 1995. Details that matter: The spatial distribution of individual trees maintains forest ecosystem function. *Oikos* 74(3):357-365.

This paper shows that the processes controlling tree-scale spatial heterogeneity in forests have large effects on system-level properties such as standing crop, and on community-level properties such as successional species turnover. A "mean field" version of the forest simulation model SORTIE is developed in which horizontal spatial heterogeneity is eliminated while vertical structure is retained. The mean-field model maintains only approximately one half the standing crop and loses successional diversity approximately twice as fast as the full spatial model. Data from natural stands support the spatial model. A partial differential equation limit of the mean-field simulator is also derived. The results are set in the context of ongoing efforts to develop models intended to predict the biosphere's response to global change. The importance of processes governing fine-scale spatial heterogeneity implies that biospheric models will agree with nature only if they are phenomenological (e.g. fitted to data) at large scale, or if spatial scaling rules are discovered that allow one to derive system-level properties from individual-level processes.

Pachepsky, L.B., and B. Acock. 1996. An adequate model of photosynthesis. 2. Dependence of parameters on environmental factors. *Agricultural Systems* 50(2):227-238.

Models of photosynthesis are commonly written as functions of light, temperature and CO₂ concentration ([CO₂]). In an ideal model, the parameter values would be independent of these environmental factors. However, there is no ideal photosynthesis model, so it is necessary to know how the parameters vary in response to the environment. Three of the most popular models of photosynthesis were fitted to experimental data for tomato plants, including light response curves measured at temperatures of 18, 25 and 32 degrees C and [CO₂] of 100, 350, 700 and 1000 vpm. Statistical analysis of parameter values allowed us to find their dependencies on environmental factors. Light utilization efficiency proved to be constant at ambient and elevated [CO₂]. Values of alpha at 100 mu l l(-1) [CO₂] were approximately half of those at 350, 700 and 1000 mu l l(-1) [CO₂]. Leaf conductance for CO₂ transfer tau depended on temperature as well as on [CO₂]. Two other parameters, one connected with respiration, R and Farquhar's 'curvature factor' theta, were both linearly dependent on temperature.

Pachepsky, L.B., and B. Acock. 1996. A model 2DLEAF of leaf gas

exchange: Development, validation, and ecological application. *Ecological Modelling* 93(1-3):1-18.

A two-dimensional model (2DLEAF) of leaf photosynthesis and transpiration has been developed that explicitly accounts for gas diffusion through the boundary layer and the intercellular space as well as for stomatal regulation. The model has been validated for tomato. It was used to study the effect of stomatal density on photosynthesis and transpiration rate. It has been demonstrated by varying stomatal density in the model that the stomatal density measured on tomato leaves provides the maximal photosynthesis rate for both 300 and 600 mu l l(-1) [CO₂]. The transpiration rate varied in direct proportion to stomatal density at all values of stomatal aperture, but transpiration efficiency (photosynthesis rate/transpiration rate) was higher at 600 mu l l(-1) [CO₂] with a normal stomatal density than at 300 mu l l(-1) [CO₂] with a stomatal density reduced 25%. Such calculations with 2DLEAF can be useful for analysis of contradicting data presented in publications on possible changes in stomatal density in a future high [CO₂] atmosphere.

Pachepsky, L.B., J.D. Haskett, and B. Acock. 1995. A two-dimensional model of leaf gas exchange with special reference to leaf anatomy. *Journal of Biogeography* 22(2-3):209-214.

This model of leaf gas exchange includes (1) two-dimensional CO₂, O-2 and water vapour diffusion in intercellular space schematized according to leaf anatomy, (2) CO₂ assimilation by mesophyll cells as described by Farquhar's model of photosynthesis and (3) stomatal movements as a regulating factor. Parameters describing the leaf cross-section and gas diffusion properties replace the empirical parameters of earlier models. The model was tested for soybean and performed well in representing light, CO₂ concentration ([CO₂]), and temperature response curves as well as the dependence of transpiration on temperature and water vapour deficit. The model allows the calculation of the steady state distribution of CO₂ and water vapour concentrations in the intercellular space and the boundary layer. The direct calculation of diffusion in leaves showed that stomatal aperture effectively regulates the transpiration rate but usually has a much smaller effect on the rate of assimilation.

Pajari, B. 1995. Soil respiration in a poor upland site of scots pine stand

subjected to elevated-temperatures and atmospheric carbon concentration. *Plant and Soil* 169:563-570.

Soil respiration rates under elevated temperature and atmospheric CO₂ concentrations were studied in eastern Finland (62 degrees 47'N, 30 degrees 58'E, 144 m.a.s.l.) around naturally regenerated 20 - 30 years old Scots pine trees, enclosed in open top chambers. The production of CO₂ varied spatially and temporally, but clearly followed the changes in temperature measured at the soil surface. However, soil respiration in the open control was higher than that in chambers; i.e. the chamber itself changed the conditions by increasing the temperature, altering the movement of water, and thereby soil moisture. Nevertheless, an elevation in the concentration of atmospheric CO₂ raised soil respiration and brought it nearer to the level in the open control. An increase in temperature seemed to inhibit this rise, possibly because of an imbalance between temperature and moisture.

Pal, R.K., and R.W. Buescher. 1993. Respiration and ethylene evolution of certain fruits and vegetables in response to carbon-dioxide in controlled- atmosphere storage. *Journal of Food Science and Technology-Mysore* 30(1):29-32.

Respiration was depressed by 10-30% CO₂ in ripening bananas, pink tomatoes and pickling cucumbers; increased by 20-30% in carrot roots and unaffected by CO₂ exposure in guava, orange and onion bulb. Changes in respiration seldom coincided with changes in C₂H₄ evolution. Evolution of C₂H₄ from guavas and tomatoes was substantially reduced by all levels of CO₂. However, 30% CO₂ accelerated C₂H₄ evolution in bananas, carrot roots, cucumbers, onions and potatoes which may have been due to an early injury response.

Palet, A., M. Ribascarbo, J.M. Argiles, and J. Azconbieto. 1991. Short-term effects of carbon-dioxide on carnation callus cell respiration. *Plant Physiology* 96(2):467-472.

The addition of potassium bicarbonate to the electrode cuvette immediately stimulated the rate of dark O₂ uptake of photomixotrophic and heterotrophic carnation (*Dianthus caryophyllus* L.) callus, of *Elodea canadensis* (Michx.) leaves, and of other plant tissues. This phenomenon occurred at pH values lower than 7.2 to 7.8, and the stimulation depended on the concentration of gaseous CO₂ in the solution. These stimulatory responses lasted several minutes and then decreased, but additional bicarbonate or gaseous CO₂ again stimulated respiration, suggesting a reversible effect. Carbonic anhydrase in the solution increased the stimulatory effect of potassium bicarbonate. The CO₂/bicarbonate dependent stimulation of respiration did not occur in animal tissues such as rat diaphragm and isolated hepatocytes, and was inhibited by salicylhydroxamic acid in carnation callus cells and *E. canadensis* leaves. This suggested that the alternative oxidase was engaged during the stimulation in plant tissues. The cytochrome pathway was severely inhibited by CO₂/bicarbonate either in the absence or in the presence of the uncoupler carbonyl-cyanide m-chlorophenyl hydrazone. The activity of cytochrome c oxidase of callus tissue homogenates was also inhibited by CO₂/bicarbonate. The results suggested that high carbon dioxide levels (mainly free CO₂) Partially inhibited the cytochrome pathway (apparently at the oxidase level), and this block in electron transport elicited a large transient engagement of the alternative oxidase when present uninhibited.

Palutikof, J.P., C.M. Goodess, and X. Guo. 1994. Climate-change, potential evapotranspiration and moisture availability in the mediterranean basin. *International Journal of Climatology* 14(8):853-869.

Simple methods for estimating potential evapotranspiration, requiring only temperature and day length data, are compared by reference to the results from the Penman method. A modification of the Blaney and Criddle method, in which the c parameter is calculated from seasonal regression equations with the mean monthly temperature as the independent variable, is proposed and tested. It is found to work sufficiently well in the area of interest, the Mediterranean Basin. For a network of 248 Mediterranean temperature stations, present-day seasonal mean potential evapotranspiration is estimated by this method. Using the results from four equilibrium-mode general circulation models, seasonal mean scenarios of potential evapotranspiration per 1-degree-C rise in global mean temperature caused by the enhanced greenhouse effect are presented. Comparison of scenarios of the change in potential evapotranspiration and scenarios of the change in precipitation indicates an unfavourable shift in moisture availability due to the enhanced greenhouse effect, throughout the Mediterranean region.

Pan, Q., Z. Wang, and B. Quebedeaux. 1998. Responses of the apple plant to CO₂ enrichment: changes in photosynthesis, sorbitol, other soluble sugars, and starch. *Australian Journal of Plant Physiology* 25(3):293-297.

There is no information on the effects of elevated [CO₂] on whole-plant photosynthesis and carbohydrate metabolism in apple (*Malus domestica* Borkh.) and other sorbitol-translocating plants. Experiments were conducted in controlled growth chambers to evaluate how increases in [CO₂] affect plant photosynthesis and carbon partitioning into soluble sugars and starch in apple leaves. Apple plants (cv. Gala), 1-year-old, were exposed to [CO₂] of 200, 360, 700, 1000, and 1600 μ mol L⁻¹ up to 8 d. Whole-plant net photosynthetic rates were analysed daily after [CO₂] treatments. Newly expanded mature leaves were sampled at 1, 2, 4, and 8 d after [CO₂] treatments for sorbitol, sucrose, glucose, fructose, and starch analysis. Midday whole-plant net photosynthetic rates increased linearly with increasing [CO₂], but the differences in whole-plant photosynthesis between CO₂-enrichment and ambient [CO₂] treatments were less significant as apple plants acclimated to high atmospheric [CO₂] for 8 d. Increases in [CO₂] significantly increased sorbitol and starch, but did not affect sucrose concentrations. As a result, the ratios of starch to sorbitol and starch to sucrose at 8 d after [CO₂] treatments were increased from 0.05 and 0.06 to 0.8 and 1.6 as [CO₂] increased from ambient [CO₂] (360 μ mol L⁻¹) to 1000 μ mol L⁻¹ [CO₂], respectively. The sorbitol to sucrose ratio also increased from 1.3 to 2.2 as [CO₂] increased from 360 to 1000 μ mol L⁻¹. Elevated [CO₂] enhanced the photosynthesis of apple plants and altered carbohydrate accumulation in mature leaves in favour of starch and sorbitol over sucrose.

Pitelka, K. Hibbard, L.L. Pierce, S.W. Running, D.S. Ojima, W.J. Parton, and D.S. Schimel. 1998. Modeled responses of terrestrial ecosystems to elevated atmospheric CO₂: a comparison of simulations by the biogeochemistry models of the Vegetation/Ecosystem Modeling and Analysis Project (VEMAP). *Oecologia* 114(3):389-404.

Although there is a great deal of information concerning responses to increases in atmospheric CO₂ at the tissue and plant levels, there are substantially fewer studies that have investigated ecosystem-level responses in the context of integrated carbon, water, and nutrient cycles. Because our understanding of ecosystem responses to elevated CO₂ is incomplete, modeling is a tool that can be used to investigate the role of plant and soil interactions in the response of terrestrial ecosystems to elevated CO₂. In this study, we analyze the responses of net primary production (NPP) to doubled CO₂ from 355 to 710 ppmv among three biogeochemistry models in the Vegetation/Ecosystem Modeling and Analysis Project (VEMAP): BIOME-BGC (BioGeochemical Cycles), Century, and the Terrestrial Ecosystem Model (TEM). For the conterminous United States, doubled atmospheric CO₂ causes NPP to increase by 5% in Century, 8% in TEM, and 11% in BIOME-BGC. Multiple regression analyses between the NPP response to doubled CO₂ and the mean annual temperature aid annual precipitation of biomes or grid cells indicate that there are negative relationships between precipitation and the response of NPP to doubled CO₂ for all three models. In contrast, there are different relationships between temperature and the response of NPP to doubled CO₂ for the three models: there is a negative relationship in the responses of BIOME-BGC, no relationship in the responses of Century, and a positive relationship in the responses of TEM. In BIOME-BGC, the NPP response to doubled CO₂ is controlled by the change in transpiration associated with reduced leaf conductance to water vapor. This change affects soil water, then leaf area development and, finally, NPP. In Century, the response of NPP to doubled CO₂ is controlled by changes in decomposition rates associated with increased soil moisture that results from reduced evapotranspiration. This change affects nitrogen availability for plants, which influences NPP. In TEM, the NPP response to doubled CO₂ is controlled by increased carboxylation which is modified by canopy conductance and the degree to which nitrogen constraints cause down-regulation of photosynthesis. The implementation of these different mechanisms has consequences for the spatial pattern of NPP responses, and represents, in part, conceptual uncertainty about controls over NPP responses. Progress in reducing these uncertainties requires research focused at the ecosystem level to understand how interactions between the carbon, nitrogen, and water cycles influence the response of NPP to elevated atmospheric CO₂.

Panina, L.I., I.V. Motorina, M.N. Mamedov, and S.A. Makhmudov. 1997. Physicochemical conditions of the development of the tertiary trachybasalt-phonolite formation in the Talysh zone (Azerbaijan). *Geologiya I Geofizika* 38(4):730-739.

It has been established by mineral thermobarogeochemistry that the magmas initial of the trachybasalt-phonolite series in the Talysh zone were crystallized according to Bowen's scheme at the following temperatures and order of phenocryst formation: O1 (>1350 degrees C) --> Cpx (1280-1170 degrees C) --> Ap (1240-1030 degrees C) --> P1 (1190-1035 degrees C). The fluid phase at the time of olivine phenocryst crystallization was composed of 90 mol. % CO₂ and 10 mol. % N₂, while at the stage of pyroxene and plagioclase formation it was 100 mol. % N₂. A drastic change in fluid composition is related to a discontinuity in time and place of phenocryst formation: olivine

crystallization in deep-seated conditions, and formation of pyroxene and plagioclase in shallow depth of the Earth's crust. A microprobe study of silicate melt inclusions has shown that the evolution of the initial magma proceeded by means of differentiation and fractionation of minerals. In the process of crystallization the derivative melts were enriched in SiO₂ (up to 64%), Al₂O₃ (up to 21%), alkalis (up to 10-11 wt.%) and were depleted in femic components (totalled to few per cent). Residual rhyolite-dacite alkali-enriched melts (67- 73% SiO₂, 14-17% Al₂O₃, 4-8% alkalis) appeared in the final stages of magma evolution. The presence of alkalis brings us back to the problem of the mantle, <<basalt>>, origin of some siliceous rocks, as well as of the possibility to overcome an <<impassable>> barrier between quartz-normative acid melts and alkaline leucite-bearing rocks.

Paoletti, E., G. Nourrisson, J.P. Garrec, and A. Raschi. 1998. Modifications of the leaf surface structures of *Quercus ilex* L in open, naturally CO₂-enriched environments. *Plant, Cell and Environment* 21(10):1071-1075.

Two Italian CO₂ springs allowed us to study the long-term effect of a 350-2600 $\mu\text{mol mol}^{-1}$ increase in CO₂ concentrations on the surface structures of leaves of *Quercus ilex* L. Carbon dioxide increased the quantity of cuticular waxes, above an apparent threshold of 750 $\mu\text{mol mol}^{-1}$ CO₂. Leaf wettability was not modified by CO₂ concentrations. Reduction in stomatal frequency was observable up to 750 $\mu\text{mol mol}^{-1}$ CO₂, the slope being almost the same as that estimated for the increase in CO₂ concentration from preindustrial times to the present. At higher concentrations, CO₂ seemed to exert no more impact on stomatal frequency.

Papadopoulos, A.P., and X.M. Hao. 1997. Effects of three greenhouse cover materials on tomato growth, productivity, and energy use. *Scientia Horticulturae* 70(2-3):165-178.

Effects of single-layered glass (glass), double inflated polyethylene film (D-poly), and rigid-twin wall acrylic panels (acrylic), as greenhouse covers on tomato (*Lycopersicon esculentum* Mill) growth, productivity and energy use were investigated over two spring seasons in 1993 and 1994. There was no significant difference in early marketable yield (harvested until April 30) between the D-poly and glass houses. Early marketable yield in the acrylic houses was similar to that in the glass houses, but higher than that in the D-poly houses in 1994. Mid-season yield in the D-poly houses was lower than in the glass houses. Final marketable yield in the D-poly and acrylic houses was similar to that in the glass houses. Fruit size during the early and mid-season in the D-poly houses was smaller than in the glass or acrylic houses. This reduction in fruit size shifted 6-12% of grade #1 fruit from extra large to large. Fruit size in the glass and acrylic houses was similar. In 1993, there was a higher BER (blossom-end rot) incidence in the glass houses than in D-poly or acrylic houses, but a higher percentage of grade #1 fruit in the D-poly houses than in the glass or acrylic houses. The D-poly and acrylic houses saved 30% in heating energy compared to the glass houses. (C) 1997 Elsevier Science B.V.

Parton, W.J., D.S. Ojima, and D.S. Schimel. 1994. Environmental change in grasslands - assessment using models. *Climatic Change* 28(1-2):111-141.

Modeling studies and observed data suggest that plant production, species distribution, disturbance regimes, grassland biome boundaries and secondary production (i.e., animal productivity) could be affected by potential changes in climate and by changes in land use practices. There are many studies in which computer models have been used to assess the impact of climate changes on grassland ecosystems. A global assessment of climate change impacts suggest that some grassland ecosystems will have higher plant production (humid temperate grasslands) while the production of extreme continental steppes (e.g., more arid regions of the temperate grasslands of North America and Eurasia) could be reduced substantially. All of the grassland systems studied are projected to lose soil carbon, with the greatest losses in the extreme continental grassland systems. There are large differences in the projected changes in plant production for some regions, while alterations in soil C are relatively similar over a range of climate change projections drawn from various General Circulation Models (GCM's). The potential impact of climatic change on cattle weight gains is unclear. The results of modeling studies also suggest that the direct impact of increased atmospheric CO₂ on photosynthesis and water use in grasslands must be considered since these direct impacts could be as large as those due to climatic changes. In addition to its direct effects on photosynthesis and water use, elevated CO₂ concentrations lower N content and reduce digestibility of the forage.

Parton, W.J., J.M.O. Scurlock, D.S. Ojima, D.S. Schimel, and D.O. Hall. 1995. Impact of climate-change on grassland production and soil carbon worldwide. *Global Change Biology* 1(1):13-22.

The impact of climate change and increasing atmospheric CO₂ was modelled for 31 temperate and tropical grassland sites, using the CENTURY model. Climate change increased net primary production, except in cold desert steppe regions, and CO₂ increased production everywhere. Climate change caused soil carbon to decrease overall, with a loss of 4 Pg from global grasslands after 50 years. Combined climate change and elevated CO₂ increased production and reduced global grassland C losses to 2 Pg, with tropical savannas becoming small sinks for soil C. Detection of statistically significant change in plant production would require a 16% change in measured plant production because of high year to year variability in plant production. Most of the predicted changes in plant production are less than 10%.

Pasquier-Cardin, A., P. Allard, T. Ferreira, C. Hatte, R. Coutinho, M. Fontugne, and M. Jaudon. 1999. Magma-derived CO₂ emissions recorded in C-14 and C-13 content of plants growing in Furnas caldera, Azores. *Journal of Volcanology and Geothermal Research* 92(1-2):195-207.

The environmental impact of fumarolic and soil emanations of magma-derived carbon dioxide across Furnas caldera has been investigated by measuring the C-14 and C-13 content of 40 specimens of different C3 plants (leaves) growing within and outside the degassing areas. The results demonstrate a significant to large C-14 depletion in many of the

plants due to assimilation of C-14-free endogenous CO₂ during photosynthesis and leading to artificial radiocarbon ageing of up to 4400 years. The extent of C-14 ageing broadly correlates with the intensity of gas manifestations at the sampling sites, as inferred from field observations and measurements of excess CO₂ concentrations in the volcanic ground. It also provides a time-integrated measure of the amount of volcanic CO₂ locally admixed to the ambient air; at several sites this accounts for 15 to 40% of total CO₂ (420 to 600 ppm) in enriched air. In some of the plant species (Azalea, Camellia and fern) C-14 depletion is correlated with an enrichment of C-13 due to assimilation of magma-derived CO₂ with a 4 parts per thousand higher $\delta^{13}C$ than normal atmosphere. The rate of C-13 enrichment averages ca. 0.18 parts per thousand by percent of volcanic carbon fixed in the plant and includes enhanced C-13 discrimination during photosynthesis as a consequence of increased ambient pCO₂ (inferred at - 0.0306 parts per thousand per added ppm of volcanic CO₂). Furnas is one of the few Volcanoes where clear C-13 enrichment in plants due to endogenous degassing has been evidenced. Our results can be used to estimate the local intensity of volcanic soil gas fluxes in the emanating areas of Furnas caldera. They also have implications for radiocarbon dating of past eruptive events in the caldera, since plants artificially aged by previous degassing could be trapped in volcanic deposits. Pataki, D.E., R. Oren, and D.T. Tissue. 1998. Elevated carbon dioxide does not affect average canopy stomatal conductance of *Pinus taeda* L. *Oecologia* 117(1-2):47-52.

While photosynthetic responses of C-3 plants to elevated CO₂ are fairly well documented, whole-plant water use under such conditions has been less intensively studied. Woody species, in particular, have exhibited highly variable stomatal responses to high CO₂ as determined by leaf-level measurements. In this study, sap flux of *Pinus taeda* L. saplings was periodically monitored during the 4th year of an open-top chamber CO₂ fumigation experiment. Water use per unit sapwood area did not differ between treatments. Furthermore, the ratio of leaf area to sapwood area did not change under high CO₂, so that average canopy stomatal conductance (on a unit leaf area basis) remained unaffected by the CO₂ treatment. Thus, the only effect of high CO₂ was to increase whole-plant water use by increasing sapling leaf area and associated conducting sapwood area. Such an effect may not directly translate to forest-level responses as the feedback effects of higher leaf area at the canopy scale cannot be incorporated in a chamber study. These feedbacks include the potential effect of higher leaf area index on rainfall and light interception, both of which may reduce average stomatal conductance in intact forest canopies.

Paterson, E., J.M. Hall, E.A.S. Rattray, B.S. Griffiths, K. Ritz, and K. Killham. 1997. Effect of elevated CO₂ on rhizosphere carbon flow and soil microbial processes. *Global Change Biology* 3(4):363-377.

Direct effects of increased above-ground CO₂ concentration on soil microbial processes are unlikely, due to the high pCO₂ of the soil atmosphere in most terrestrial ecosystems. However, below-ground microbial processes are likely to be affected through altered plant inputs at elevated CO₂. A major component of plant input is derived from litter

fall and root turnover. Inputs also derive from rhizodeposition (loss of C-compounds from active root systems) which may account for up to 40% of photoassimilate. This input fuels the activity of complex microbial communities around roots. These communities are centrally important not only to plant-microbe interactions and consequent effects on plant growth, but also, through their high relative activity and abundance, to microbially mediated processes in soil generally. This review focuses on approaches to measure C-flow from roots, in particular, as affected by increased atmospheric CO₂ concentration. The available evidence for impacts on microbial communities inhabiting this niche, which constitutes an interface for possible perturbations on terrestrial ecosystems through the influence of environmental change, will also be discussed. While methodologies for measuring effects of increased CO₂ concentration on plant growth, physiology and C-partitioning are abundant and widely reported, there is relatively little information on plant-mediated effects on soil microbial communities and processes. Importantly, many studies have also neglected to recognize that any secondary effects on microbial communities may have profound effects on plant parameters measured in relation to environmental change. We critically review approaches which have been used to measure rhizodeposition under conditions of increased atmospheric CO₂ concentration, and then consider evidence for changes in microbial communities and processes, and the methodologies which have been recently developed, and are appropriate to study such changes.

Paterson, E., A. Hodge, B. Thornton, P. Millard, and K. Killham. 1999. Carbon partitioning and rhizosphere C-flow in *Lolium perenne* as affected by CO₂ concentration, irradiance and below-ground conditions. *Global Change Biology* 5(6):669-678.

Plant responses to increasing atmospheric CO₂ concentrations have received considerable interest. However, major uncertainties in relation to interactive effects of CO₂ with above- and below-ground conditions remain. This microcosm study investigated the impacts of CO₂ concentration on plant growth, dry matter partitioning and rhizodeposition as affected by: (i) photon flux density (PFD), and (ii) growth matrix. Plants were grown in a sandy loam soil for 28 d under two photon flux densities: 350 (low PFD) and 1000 $\mu\text{mol m}^{-2}\text{s}^{-1}$ (high PFD) and two CO₂ concentrations: 450 (low CO₂) and 720 $\mu\text{mol mol}^{-1}$ (high CO₂). Partitioning of recent assimilate amongst plant and rhizosphere C-pools was determined by use of (CO₂)-C-14 pulse-labelling. In treatments with high PFD and/or high CO₂, significant ($P < 0.05$) increases in dry matter production were found in comparison with the low PFD/low CO₂ treatment. In addition, significant ($P < 0.05$) reductions in shoot %N and SLA were found in treatments imposing high PFD and/or high CO₂. Root weight ratio (RWR) was unaffected by CO₂ concentration, however, partitioning of C-14 to below ground pools was significantly ($P < 0.05$) increased. In a separate study, *L. perenne* was grown for 28 d in microcosms percolated with nutrient solution, in either a sterile sand matrix or nonsterile soil, under high or low CO₂. Dry matter production was significantly ($P < 0.01$) increased for both sand and soil grown seedlings. Dry matter partitioning was affected by matrix type. C-14-allocation below ground was increased for sand grown plants. Rhizodeposition was affected by CO₂ concentration for growth in each matrix, but was increased for plants grown in the soil matrix, and decreased for those in sand. The results illustrate that plant responses to CO₂ are potentially affected by (i) PFD, and (ii) by feedbacks from the growth matrix. Such feedbacks are discussed in relation to soil nutrient status and interactions with the rhizosphere microbial biomass.

Paterson, E., E.A.S. Rattray, and K. Killham. 1996. Effect of elevated atmospheric CO₂ concentration on C-partitioning and rhizosphere C-flow for three plant species. *Soil Biology and Biochemistry* 28(2):195-201.

The effects of elevated atmospheric CO₂ concentration on the partitioning of dry matter and recent assimilate was investigated for three plant species (rye grass, wheat and Bermuda grass). This was evaluated in plant-soil microcosm systems maintained at specific growth conditions, under two CO₂ regimes (450 and 720 $\mu\text{mol mol}^{-1}$). The distribution of recent assimilate between plant, microbial and soil pools was determined by (CO₂)-C-14 pulse chase, for each plant species at both CO₂ concentrations. Growth of rye grass and wheat (both C-3) was Ca. doubled at the higher CO₂ concentration. Dry matter partitioning was also significantly affected, with an increased root-to-shoot ratio for wheat (0.72-1.03), and a decreased root-to-shoot ratio for rye grass (0.68-0.47) at elevated CO₂. For Bermuda grass (C-4), growth and partitioning of dry matter and C-14 were not affected by CO₂ concentration. C-14-allocation to the rhizospheres of rye-grass and wheat was found to be increased by 62 and 19%, respectively, at the higher CO₂ concentration. The partitioning of C-14 within the rhizospheres of the two C-3 species was also found to be affected by CO₂ concentration. At the higher CO₂ concentration, proportionately less C-14 was present in the microbial fraction, relative to that in the soil. This indicates altered microbial utilisation of root-released compounds at the higher CO₂ concentration, which may be a consequence of altered quantity or quality of rhizodeposits derived from recent assimilate.

Patterson, B.W., X.J. Zhang, Y.P. Chen, S. Klein, and R.R. Wolfe. 1997. Measurement of very low stable isotope enrichments by gas chromatography mass spectrometry: Application to measurement of muscle protein synthesis. *Metabolism-Clinical and Experimental* 46(8):943-948.

Measurement of muscle protein synthesis using stable isotopically labeled tracers usually requires isotope ratio mass spectrometry (IRMS) because of the need to measure very low enrichments of stable isotopically labeled tracers (tracer to tracee ratio [TTR], 0.005% to 0.10%). This approach is laborious, requiring purification of the metabolite of interest and combustion to a gas for IRMS analysis, and is best suited for use with C-13 tracers. We have developed an approach whereby low enrichments can be conveniently measured by a conventional gas chromatography/mass spectrometry (GC/MS) instrument. The approach includes three critical elements: (1) use of a highly substituted tracer containing three or more labeled atoms, to measure enrichment above a very low natural abundance of highly substituted isotopomers; (2) use of a highly substituted natural abundance isotopomer as a base ion for comparison rather than the most abundant $m + 0$ isotopomer, to reduce the dynamic range of the isotopomer ratio measurement; and (3) a sensitive mass spectrometric analysis that measures the natural abundance of the isotopomer used as a tracer with a high signal to noise ratio ($> 100:1$). This approach was used to measure the rate of synthesis of muscle protein following a primed continuous infusion of L-[C-13(6)]-phenylalanine (PHE) in eight fasted dogs and L-[H-2(3)]-leucine in five fasted human subjects. Values for [C-13(6)]-PHE enrichment by GC/MS rates were virtually identical to those obtained by a conventional approach using high-

performance liquid chromatography (HPLC) to isolate PHE, combustion to CO₂, and measurement of (CO₂)-C-13 enrichment by IRMS (IRMS enrichment = 0.9988 x GC/MS enrichment, R-2 = .891), resulting in identical values for muscle fractional synthesis rates ([FSRs] mean +/- SEM: 2.7 +/- 0.2 and 2.5 +/- 0.2%/d for GC/MS and IRMS, respectively). Human muscle synthesis rates measured by GC/MS analysis of [H-2(3)]-leucine enrichment (1.90 +/- 0.17%/d) were similar to published values based on IRMS analysis using a 1-C-13-leucine tracer. We conclude that compared with the IRMS approach, the GC/MS approach offers faster throughput, has a lower sample requirement, and is suitable for a wider variety of tracers such as H-2. The principles outlined here should be applicable to the measurement of low enrichments by GC/MS in a wide variety of stable isotope tracer applications. Copyright (C) 1997 by W.B. Saunders Company.

Patterson, D.T. 1995. Effects of environmental-stress on weed/crop interactions. *Weed Science* 43(3):483-490.

All environmental factors that influence plant growth potentially can affect the ability of weeds and crops to exploit the environmental resources for which plants compete. Stressful levels of environmental factors such as temperature, light, and water and nutrient availability influence weed/crop interactions directly and also may interfere with (or enhance) weed control. Weed and crop species differing in photosynthetic pathway (C-3 VS C-4) are likely to respond differently to many of these factors. Long-term changes in the atmospheric concentrations of CO₂ and other radiatively-active "greenhouse gases" may exert direct physiological and indirect climatic effects on weed/crop interactions and influence weed management strategies. This review focuses on the effects of temperature, light, soil nutrients, water stress, and CO₂ concentration on weed/crop interactions with consideration of the potential impact of climate change.

Patterson, D.T. 1995. Weeds in a changing climate. *Weed Science* 43(4):685-700.

Current and projected increases in the concentrations of CO₂ and other radiatively-active gases in the Earth's atmosphere lead to concern over possible impacts on agricultural pests. All pests would be affected by the global warming and consequent changes in precipitation, wind patterns, and frequencies of extreme weather events which may accompany the "greenhouse effect." However, only weeds are likely to respond directly to the increasing CO₂ concentration. Higher CO₂ will stimulate photosynthesis and growth in C-3 weeds and reduce stomatal aperture and increase water use efficiency in both C-3 and C-4 weeds. Respiration, and photosynthate composition, concentration, and translocation may be affected. Perennial weeds may become more difficult to control, if increased photosynthesis stimulates greater production of rhizomes and other storage organs. Changes in leaf surface characteristics and excess starch accumulation in the leaves of C-3 weeds may interfere with herbicidal control. Global warming and other climatic changes will affect the growth, phenology, and geographical distribution of weeds. Aggressive species of tropical and subtropical origins, currently restricted to the southern U.S., may expand northward. Any direct or indirect consequences of the CO₂ increase that differentially affect the growth or fitness of weeds and crops will alter

weed-crop competitive interactions, sometimes to the detriment of the crop and sometimes to its benefit.

Paul, M.J., and S.P. Driscoll. 1997. Sugar repression of photosynthesis: The role of carbohydrates in signalling nitrogen deficiency through source:sink imbalance. *Plant, Cell and Environment* 20(1):110-116.

The aim of this work was to examine whether carbohydrates are involved in signalling N deficiency through source:sink imbalance. Photosynthetic metabolism in tobacco was studied over 8 d during the withdrawal of N from previously N- sufficient plants in which the source:sink ratio was manipulated by shading leaves on some of the plants. In N- sufficient plants over this timescale, there was a small decline in photosynthetic rate, Rubisco protein and amino acid content, with a larger decrease in carbohydrate content. Withdrawal of N from the growing medium induced a large decrease in the rate of photosynthesis (35% reduction after 8 d under the growing conditions, with a reduction also apparent at high and low measuring CO₂), which was caused by a large decrease in the amount of Rubisco protein (62% after 8 d) and Rubisco activity. Higher amounts of hexoses preceded the loss of photosynthetic activity and sucrose and starch accumulation. Reduction of the source:sink ratio by shading prevented the loss of photosynthetic activity and the increase in hexoses and other carbohydrates. These data indicate that the reduction of photosynthesis that accompanies N deficiency in intact plants has the characteristics of sugar repression of photosynthesis observed in model systems, but that the accumulation of hexose prior to the decline in photosynthesis is small. The possibility that sugar repression of photosynthesis under physiological conditions depends more crucially on the C:N status of leaves than the carbohydrate status alone is discussed.

Paustian, K., E.T. Elliott, H.P. Collins, C.V. Cole, and E.A. Paul. 1995. Use of a network of long-term experiments for analysis of soil carbon dynamics and global change: The North American model. *Australian Journal of Experimental Agriculture* 35(7):929-939.

Soils contain a large proportion of the carbon (C) in the terrestrial biosphere, yet the role of soils as a sink or a source of net atmospheric C flux is uncertain. In agricultural systems, soil C is highly influenced by management practices and there is considerable interest in adapting management systems to promote soil C sequestration, thereby helping to mitigate atmospheric CO₂ increases. Long-term field experimental sites represent a unique source of information on soil C dynamics, and networks of such sites provide a key ingredient for making large-scale assessments of soil C change across ranges in climate and soil conditions and management regimes. Currently, there are collaborative efforts to develop such site networks in Australia, Europe, and North America. A network of long-term experiments in North America was established to provide baseline information on the effects of management (i.e. tillage, crop rotations, fertilisation, organic amendments) on soil organic matter. Historical data on soils, primary productivity, climate, and management

were synthesised by scientists from the individual field sites, representing a total of 35 long-term field experiments. An additional cross-site soil sampling campaign was carried out to provide uniform comparisons of soil C and nitrogen (N), both within and across sites. Long-term field experiments are a principle component necessary for regional assessments of soil C dynamics. We describe a general methodology for combining long-term data with process-oriented simulation models and regional-level, spatially resolved databases. Such analyses are needed to assess past and present changes in soil C at regional to global scales and to make projections of the potential impacts of changes in climate, CO₂, and landuse patterns on soil C in agroecosystems.

Paustian, K., E.T. Elliott, G.A. Peterson, and K. Killian. 1996. Modelling climate, CO₂ and management impacts on soil carbon in semi-arid agroecosystems. *Plant and Soil* 187(2):351-365.

In agroecosystems, there is likely to be a strong interaction between global change and management that will determine whether soil will be a source or sink for atmospheric C. We conducted a simulation study of changes in soil C as a function of climate and CO₂ change, for a suite of different management systems, at four locations representing a climate sequence in the central Great Plains of the US. Climate, CO₂ and management interactions were analyzed for three agroecosystems: a conventional winter wheat-summer fallow rotation, a wheat-corn-fallow rotation and continuous cropping with wheat. Model analyses included soil C responses to changes in the amount and distribution of precipitation and responses to changes in temperature, precipitation and CO₂ as projected by a general circulation model for a 2xCO₂ scenario. Overall, differences between management systems at all the sites were greater than those induced by perturbations of climate and/or CO₂. Crop residue production was increased by CO₂ enrichment and by a changed climate. Where the frequency of summer fallowing was reduced (wheat-corn-fallow) or eliminated (continuous wheat), soil C increased under all conditions, particularly with increased (640 μmol L⁻¹) CO₂. For wheat-fallow management, the model predicted declines in soil C under both ambient conditions and with climate change alone. Increased CO₂ with wheat-fallow management yielded small gains in soil C at three of the sites and reduced losses at the fourth site. Our results illustrate the importance of considering the role of management in determining potential responses of agroecosystems to global change. Changes in climate will determine changes in management as farmers strive to maximize profitability. Therefore, changes in soil C may be a complex function of climate driving management and management driving soil C levels and not be a simple direct effect of either climate or management.

Pearson, M., R.T. Besford, and D.W. Hand. 1994. The effects of oxides of nitrogen and carbon-dioxide enrichment on growth and content of ribulose-1, 5-bisphosphate carboxylase-oxygenase and nitrite reductase in glasshouse lettuce. *Journal of Horticultural Science* 69(2):257-266.

Different systems of CO₂ enrichment and heating were used to produce glasshouse atmospheres with varying concentrations of NO(x) and CO₂ (ambient NO(x) and CO₂, ambient NO(x) and 1000 vpm CO₂, and three concentrations of NO(x) varying between 0.5 and 2.5 vpm with concurrent CO₂ concentrations between 1000- 2500 vpm). The growth

response of winter lettuce in these environments was assessed for three contrasting cultivars (Ambassador, Berlo and Pascal). Contents of ribulose-1, 5-bisphosphate carboxylase-oxygenase (RuBPCo) and nitrite reductase (NiR) in the leaf tissue were also determined using immunoblotting and enzyme-linked immunosorbent assay (ELISA). 'Ambassador' produced the heaviest "head" weights, but on marketable criteria 'Berlo' performed better. CO₂ enrichment enhanced yields, but the High NO(x) treatments reduced growth relative to that in the Low NO(x) and unpolluted environments. Growth assessments suggested a greater tolerance of NO(x) in cvs Berlo and Pascal than in cv. Ambassador. Immunoblots showed that the antibodies used here were specific. Using these antibodies in ELISA, 'Pascal' was found to contain more RuBPCo and NiR on a leaf area basis than 'Ambassador'. There were reductions in RuBPCo and NiR contents in response to growth in elevated CO₂. Elevated CO₂ caused a reduction in RuBPCo and NiR in 'Ambassador', but in 'Pascal' only RuBPCo levels were reduced. This may account for the greater relative tolerance of 'Pascal' and the sensitivity of 'Ambassador' to NO(x) pollution.

Pearson, M., and G.L. Brooks. 1995. The influence of elevated CO₂ on growth and age-related-changes in leaf gas-exchange. *Journal of Experimental Botany* 46(292):1651-1659.

Rumex obtusifolius plants were grown for several months in daylight environment chambers (Solardomes) force-ventilated with air containing 350 or 600 μmol mol⁻¹ CO₂. Elevated CO₂ was found to accelerate the natural ontogenic decline in photosynthesis, but did not reduce leaf duration. In both CO₂ treatments photosynthetic rates declined progressively with increasing leaf age, the decline being greater for plants grown in elevated CO₂ such that rates became lower than in ambient CO₂. The degree of CO₂-induced photosynthetic down-regulation as determined by A/C-I analysis was found to be dependent on leaf age. The major contribution to the decline in photosynthesis was likely to be a reduction in Rubisco activity as changes in stomatal and mesophyll limitations were small. Instantaneous water use efficiency (WUE(i)) was greater for plants in elevated CO₂, but these values declined rapidly with leaf age, whereas in ambient CO₂ values were always lower, but were maintained for longer. Growth analysis indicated an increased root: shoot ratio for plants grown in elevated CO₂, this occurring almost entirely as a result of increased root growth. Greater root proliferation and increased WUE(i) are characteristics which should give this persistent and troublesome weed an increased competitive under projected conditions of climate change.

Pearson, M., and G.L. Brooks. 1996. The effect of elevated CO₂ and grazing by *Gastrophysa viridula* on the physiology and regrowth of *Rumex obtusifolius*. *New Phytologist* 133(4):605-616.

Plants of *Rumex obtusifolius* L. were grown in Solardomes under ambient and elevated (+ 250 μmol mol⁻¹) mole fractions of CO₂ and were exposed to two levels of herbivory by *Gastrophysa viridula* Degeer larvae. The herbivory treatment lasted 1 month, thereafter half of the plants were harvested and over the following month during a period of regrowth physiological measurements were made on the remaining plants. At the termination of the herbivory treatment uninfested plants

showed no damage, whereas the low and high herbivore treatments caused 20-40% and 50-70% loss of leaf area as a proportion of total leaf area, respectively. The CO₂ treatment did not affect the degree of defoliation. Total leaf area was not significantly affected by either CO₂ or herbivory. Uninfested plants grown in elevated concentrations of CO₂ showed increased growth, root- to-shoot ratios (RS), rates of photosynthesis and reduced stomatal conductance compared with uninfested plants grown in ambient CO₂. A/C-i analysis revealed that plants grown in elevated CO₂ showed reductions in V_c(max). For plants grown in ambient CO₂ the high herbivory treatment led to increased rates of photosynthesis and decreased rates of dark respiration per unit leaf area, and caused increases in stomatal conductance and RS. For plants grown in elevated CO₂ the high herbivory treatment increased plant biomass and RS. The increases in RS in response to elevated CO₂ and herbivory appeared to be additive. Defoliation did not reduce the degree of photosynthetic down-regulation caused by growth in elevated concentrations of CO₂, but appeared to reduce the rate of ontogenic decline in photosynthesis in ambient CO₂.

Pearson, M., W.J. Davies, and T.A. Mansfield. 1995. Asymmetric responses of adaxial and abaxial stomata to elevated CO₂ - impacts on the control of gas-exchange by leaves. *Plant, Cell and Environment* 18(8):837-843.

The response of adaxial and abaxial stomatal conductance in *Ruier obtusifolius* to growth at elevated atmospheric concentrations of CO₂ (250 $\mu\text{mol mol}^{-1}$ above ambient) was investigated over two growing seasons. The conductance of both the adaxial and abaxial leaf surfaces was found to be reduced by elevated concentrations of CO₂. Elevated CO₂ caused a much greater reduction in conductance for the adaxial surface than for the abaxial surface. The absence of effects upon stomatal density indicated that the reductions were probably the result of changes in stomatal aperture. Partitioning of gas exchange between the leaf surfaces revealed that increased concentrations of CO₂ caused increased rates of photosynthesis only via the abaxial surface. Additionally, leaf thickness was found to increase during growth at elevated concentrations of CO₂. The tendency for these amphistomatous leaves to develop a distribution of conductance approaching that of hypostomatous leaves clearly reduced their maximum photosynthetic potential. This conclusion was supported by measurements of stomatal limitation, which showed greater values for the adaxial surfaces, and greater values at elevated CO₂. This reduction in photosynthesis may in part be caused by higher diffusive limitations imposed because of increased leaf thickness, in an uncoupled canopy, asymmetrical stomatal responses of the kind identified here may appreciably reduce transpiration. Species which show symmetrical responses are less likely to show reduced transpirational rates, and a redistribution of water loss between species may occur. The implications of asymmetrical stomatal responses for photosynthesis and canopy transpiration are discussed.

Pearson, S., T.R. Wheeler, P. Hadley, and A.E. Wheldon. 1997. A validated model to predict the effects of environment on the growth of lettuce (*Lactuca sativa* L): Implications for climate change. *Journal of Horticultural Science* 72(4):503-517.

A mechanistic model is described that predicts the effects of changes to

the environment on the growth, yield and maturity of lettuce. The model assumes that lettuce has structural and storage carbon pools. The storage pool is supplied by photosynthesis and depleted by respiratory losses and the conversion of assimilate to the structural pool. The model incorporated both instantaneous effects of temperature and CO₂, and long term effects of thermal time on photosynthetic rate. The rate of structural dry-matter production was related to a simple temperature dependent partitioning coefficient. The model was calibrated on eight separate crops of lettuce and validated With independent data from seven sources. The validated model was then used to simulate changes in head weight and time to maturity with systematic changes in temperature (-2 to +5 degrees C in 1 K steps) and carbon dioxide (350 to 700 ppm in 50 ppm steps) superimposed on baseline meteorological data from Rothamsted (1984-1995). These predicted that changes to temperature of up to +3 degrees C would reduce the production time from about 96 to 79 d for April plantings, and from 63 to 52 d for August plantings. Head weight would increase by approximately 32% with an increase in CO₂ of from 350 to 700 ppm, whilst the magnitude of this response varied little with planting date. For any sowing date, increasing temperature was predicted to have little effect on final head weight, however, head weight was predicted to decrease with later transplanting. The potential effects of changes to climate on lettuce production are discussed.

Pedersen, O., and K. SandJensen. 1997. Transpiration does not control growth and nutrient supply in the amphibious plant *Mentha aquatica*. *Plant, Cell and Environment* 20(1):117-123.

Mentha aquatica L. was grown at different nutrient availabilities in water and in air at 60% RH. The plants were kept at 600 mmol m^{-3} free CO₂ dissolved in water (40 times air equilibrium) and at 30 mmol m^{-3} CO₂ in air to ensure CO₂ saturation of growth in both environments. We quantified the transpiration-independent water transport from root to shoot in submerged plants relative to the transpiration stream in emergent plants and tested the importance of transpiration in sustaining nutrient flux and shoot growth. The acropetal water flow was substantial in submerged *Mentha aquatica*, reaching 14% of the transpiration stream in emergent plants. The transpiration-independent mass flow of water from the roots, measured by means of tritiated water, was diverted to leaves and adventitious shoots in active growth. The plants grew well and at the same rates in water and air, but nutrient fluxes to the shoot were greater in plants grown in air than in those that were submerged when they were rooted in fertile sediments. Restricted O₂ supply to the roots of submerged plants may account for the smaller nutrient concentrations, though these exceeded the levels required to saturate growth. In hydroponics, the root medium was aerated and circulated between submerged and emergent plants to minimize differences in medium chemistry, and here the two growth forms behaved similarly and could fully exploit nutrient enrichment. It is concluded that the lack of transpiration from leaf surfaces in a vapour-saturated atmosphere, or under water, is not likely to constrain the transfer of nutrients from root to shoot in herbaceous plants. Nutrient deficiency under these environmental conditions is more likely to derive from restricted development and function of the roots in waterlogged anoxic soils or from low porewater concentrations of nutrients.

Peiris, D.R., J.W. Crawford, C. Grashoff, R.A. Jefferies, J.R.

Porter, and B. Marshall. 1996. A simulation study of crop growth and development under climate change. *Agricultural and Forest Meteorology* 79(4):271-287.

Climate changes of the order predicted by Global Circulation Models have important implications for arable crop production. We have studied the impact in Scotland using simulation models for three crops of contrasting developmental type: faba or field bean, potato, spring and winter wheat. The models used were the FABEAN, SCRI water-constrained potato model and AFRCWHEAT2 models respectively. Consideration has been made of the natural year-to-year variation in weather which causes yield variability by using 100 years of input weather data produced by a weather generator. The models were run for four Scottish sites and five Scottish soils. Based on GCM predictions, we used eight scenarios of future climate which combine both temperature and rainfall changes. Current temperature (T-0) and rainfall (R(0)) were used as a baseline, and each of T-0 + 1 degrees C, T-0 + 2 degrees C, T-0 + 3 degrees C were used with rainfall unchanged at R(0), and increased by seasonally adjusted amounts ranging from 0 to 1.5 mm per wet day. Possible enhancements due to CO₂ fertilisation were not included in the study. Increased temperatures increase crop development rate, which shortens the growing season for wheat and faba bean, but, given a fixed harvest date, lengthens the season for potatoes. Yields of potato increased by up to 33% over all our sites and scenarios, whereas wheat yields decreased by 5-15% and faba bean by 11-41%. Rainfall increases of the amount suggested here do not affect the yield of potatoes or spring wheat, but winter wheat yields are reduced, due to leaching, and faba bean yields increase through alleviation of water shortage. Faba beans also show a reduction in yield variability as a result of increased rainfall. Changes in variability in wheat and potato were less pronounced and tended to reflect the increase in variability which was assumed to accompany the increased rainfall. Predictions for the changes in the frequencies of high and low yields are also presented. The results give an indication of the level of changes in crop production which would be expected in these future climates.

Peisker, M., I. Heinemann, and M. Pfeffer. 1998. A study on the relationship between leaf conductance, CO₂ concentration and carboxylation rate in various species. *Photosynthesis Research* 56(1):35-43.

Leaf conductance $g(L)$ is strongly influenced by environmental factors like CO₂, irradiance and air humidity. According to Ball et al. (1987), $g(L)$ is correlated with an index calculated as the product of net CO₂ exchange rate A and ambient water vapour concentration $W-a$, divided by ambient CO₂ concentration $c(a)$. However, this empirical model does not apply to high values of $g(L)$ observed at $c(a)$ below CO₂ compensation concentration Γ . Therefore, we applied modified indices in which A is replaced by estimates for the rate of carboxylation. Such estimates, $P-1$ and $P-2$, were determined by adding to A the quotient of Γ and the sum of gas phase resistance $r(g)$ and intracellular resistance for CO₂ exchange $r(i)$, $P-1 = A + \Gamma / (r(g) + r(i))$, or the quotient of Γ and $r(i)$, $P-2 = A + \Gamma / r(i)$. If $P-2$ is chosen, $c(a)$ in the Ball index has to be replaced by the intercellular CO₂ concentration $c(i)$. By using the modified indices $P-1 \cdot W-a/c(a)$ and $P-2 \cdot W-a/c(i)$, we analysed data from the C-3 species *Nicotiana tabacum* and *Nicotiana plumbaginifolia*, the C-3-C-4 intermediate species *Diplotaxis tenuifolia*, and the C-4 species *Zea mays*. The data were collected at widely varying levels of irradiance and CO₂ concentration. For all species uniform relationships between $g(L)$ and the new indices were found for the whole range of CO₂ concentrations below and above Γ . Correlations between $g(L)$ and $P-1 \cdot W-a/c(a)$ were closer than those between $g(L)$ and $P-2 \cdot W-a/c(i)$ because $P-1/c(a)$ implicitly contains $g(L)$. Highly significant correlations were also obtained for the

relationships between $g(L)$ and the ratios $P-1/c(a)$ and $P-2/c(i)$.

Peker, H., M.P. Srinivasan, J.M. Smith, and B.J. McCoy. 1992. Caffeine extraction rates from coffee beans with supercritical carbon-dioxide. *Aiche Journal* 38(5):761-770.

The extraction of caffeine from whole coffee beans with supercritical carbon dioxide was studied in a continuous-flow extraction apparatus. Decaffeination rates were determined as a function of CO₂ flow rate, temperature and pressure by continuously monitoring the caffeine in the effluent with a flame ionization detector. Soaking the raw beans in water prior to decaffeination enhanced the rate of extraction, which increased markedly with water content. Using CO₂ saturated with water also increased the rate of extraction. The rate of decaffeination increased with pressure and temperature and was influenced by both intraparticle diffusion in the water-soaked beans and external mass transfer. A mathematical model based on a linear-driving-force approximation of mass transfer and partitioning of caffeine between the water and the supercritical CO₂ describes the time-dependent process. The partition coefficient for caffeine distributed between water and supercritical CO₂, the only parameter determined from the dynamic extraction rate data, increases with temperature and pressure.

Peng, C.H., and M.J. Apps. 1998. Simulating carbon dynamics along the Boreal Forest Transect Case Study (BFTCS) in central Canada - 2. Sensitivity to climate change. *Global Biogeochemical Cycles* 12(2):393-402.

The effects of climate change and doubling atmospheric CO₂ on carbon dynamics of the boreal forest in the area of the Boreal Forest Transect Case Study in central Canada were investigated using the process-based plant-soil model CENTURY 4.0. The results presented here suggest that (1) across the transect climate change would result in increased total carbon in vegetation biomass but decreased overall carbon in soil; (2) increased atmospheric CO₂ concentration under current climatic patterns would result in increased total carbon in vegetation and in soil organic matter; and (3) combined climate change and elevated CO₂ would increase both net primary productivity and decomposition rates relative to the current climate condition, but their combined action would be a reduction of soil carbon losses relative to those due to climate change alone. The interactive effects of climate change and elevated CO₂, however, are not a simple additive combination of the individual responses. The responses to climate change and elevated CO₂ vary across the climate gradient from southern to northern sites on the transect. The present simulations indicate that the northern sites are more sensitive to climate change than the southern sites are, but these simulations do not consider likely changes in the disturbance regime or changes in forest species distribution.

Peng, C.H., and M.J. Apps. 1999. Modelling the response of net

primary productivity (NPP) of boreal forest ecosystems to changes in climate and fire disturbance regimes. *Ecological Modelling* 122(3):175-193.

This study reports on the use of the process-based ecosystem model CENTURY 4.0 to investigate the patterns of net primary productivity (NPP) along a transect across the boreal forests of central Canada and the influence of climate change, CO₂ fertilization and changing fire disturbance regimes on changes in NPP over time. Simulated NPP was tested against observed NPP data from northern sites near Thompson (Manitoba) and southern sites near Prince Albert (Saskatchewan) and shown to be consistent with the data. The temporal dynamics of NPP were very different for the southern, central and northern sites, consistent with the hypothesis that different climate-driven processes regulate forest growth in the various regions of the boreal forest transect case study (BFTCS). The simulations suggest that climate change would result in increased NPP for most sites across the transect. According to the model results, increases in atmospheric CO₂ also show increased NPP. The combined influence of climate change and elevated CO₂ appear to interact in a positive, but non-linear manner. Statistical analysis of the simulation results indicate that changes in NPP are also positively correlated with changes in net N mineralization ($R^2 = 0.89$). This supports the conclusion that feedback via N cycling - a coupling of aboveground production with changes in belowground decomposition - is very important for understanding the NPP dynamics of the boreal forest under a changing climate. It was also found that NPP increases with greater fire frequency under current climate conditions, at least over the range of fire return intervals considered (50- 200 years). The influence of other changes in disturbance regimes (e.g. altered fire severity and concurrent changes in climate or CO₂ fertilization), however, were not considered. (C) 1999 Elsevier Science B.V. Peng, C.H., J. Guiot, and E. Van Campo. 1998. Past and future carbon balance of European ecosystems from pollen data and climatic models simulations. *Global and Planetary Change* 18(3-4):189-200.

As climate changes, there is considerable uncertainty whether northern hemisphere ecosystems will act as atmospheric CO₂ sinks or sources. Here, we used statistical models calibrated on field measurements, past terrestrial biomes and climates inferred from pollen and future climatic change scenarios simulated by General Circulation Models (GCMs), to investigate the processes controlling past, present and future CO₂ fluxes in the European ecosystems. Our results suggest that climatic change can significantly affect spatial and temporal variations of net primary production and soil respiration, and alter the net ecosystem exchange of CO₂. Most of the potential terrestrial biomes in Europe will likely change from a net CO₂ sink, which provided a negative feedback for atmospheric CO₂ during the last 13 000 yr BP, to a net CO₂ source, providing a positive feedback following global warming. The results further illustrate that there is no analogue in the recent past (Late Quaternary) for the probable future ecosystem dynamics. (C) 1998 Elsevier Science B.V. All rights reserved.

Penuelas, J., C. Biel, and M. Estiarte. 1995. Growth, biomass allocation, and phenology responses of pepper to elevated CO₂ concentrations and different water and nitrogen supply. *Photosynthetica* 31(1):91-99.

Fifty-day old plants of *Capsicum annuum* L. with two developed leaves were placed into controlled environment chambers at atmospheric (350 cm³ m⁻³, ACO(2)) and elevated (700 cm³ m⁻³, ECO(2)) CO₂ concentrations under different nitrogen and water supply. Plant response to ECO(2) and the modulating effect of the availability of nitrogen and water were evaluated. CO₂ effects were significant only after 40 d of treatment. An increase in plant growth and yield was found in ECO(2) plants only under a good supply of both water (HW) and nitrogen (HN). Chlorophyll concentration responded only to N supply. Root/shoot ratio was higher under ECO(2) only under low N (LN) and low water (LW) supply. Leaf area and specific leaf area decreased under ECO₂. Flowering and fructification took place earlier in ECO(2) under HN and HW. Thus, all CO₂ effects were modulated by the N and water supply and the duration of exposure.

Penuelas, J., C. Biel, R. Save, and M. Estiarte. 1995. Detrimental effects of fluctuating high CO₂ concentrations on peppers. *Photosynthetica* 31(3):361-370.

Plants of pepper (*Capsicum annuum* L.) were grown in controlled environment chambers at ambient (360 μmol mol⁻¹) and fluctuating pulse-enriched CO₂ concentrations (700 μmol mol⁻¹) daily average, ranging from 500 to 3500 μmol mol⁻¹ = ECO(2)) under two water regimes. A decrease in plant growth and yield together with frequent visual injuries was found in plants growing under ECO(2). Root/shoot ratio was greater, chlorophyll concentration and respiration rates were lower, and stomatal conductance and relative importance of alternative pathway respiration were higher under ECO(2). The negative effects of ECO(2) were more intense under high water availability. The symptoms produced by ECO(2) were similar to those of resource limitation, and were alleviated with increased nutrient supply. Constant elevated CO₂ concentrations (700 μmol mol⁻¹) increased pepper production and did not produce any of the injuries described for this erratic ECO(2) treatment. Thus, it is probably the erratic nature of the CO₂ concentration and not the gas itself that was causing the injury.

Penuelas, J., and M. Estiarte. 1997. Trends in plant carbon

concentration and plant demand for N throughout this century. *Oecologia* 109(1):69-73.

Atmospheric CO₂ concentration has increased by 25% over the preindustrial level. A parallel increase in C concentration and decreases in N concentration and $\delta(13\text{C})$ of plants grown throughout this century have been observed in plant specimens stored in herbaria. We tested our previous results in a study of 12 more species collected in the western Mediterranean throughout this century (1920-1930, 1945-1955, and 1985-1990) and tree rings of *Quercus pubescens* from the same area. These changes were accompanied by apparent increases in condensed tannin concentration. A decreasing trend in $\delta(15\text{N})$ both in herbarium material and tree rings was also found, indicating that ecosystems might cope with higher plant N demand by decreasing N losses and increasing N fixation and mineralization. These results may contribute to a better understanding of the effects of global change on carbon and nitrogen cycling.

Penuelas, J., M. Estiarte, B.A. Kimball, S.B. Idso, P.J. Pinter, G.W. Wall, R.L. Garcia, D.J. Hansaker, R.L. LaMorte, and D.L. Hendrix. 1996. Variety of responses of plant phenolic concentration to CO₂ enrichment. *Journal of Experimental Botany* 47(302):1463-1467.

A wide range of responses to elevated CO₂ was found for leaf total phenolic concentration of one grass species (wheat) growing in a Free-Air CO₂ Enrichment (FACE) system and two woody species (orange and pine trees) growing in Open-Top Chambers (OTC). The total phenolic concentration of wheat flag leaves grown at elevated [CO₂] was increased for most of the grain-filling stages studied; there was no significant change in phenolic concentration of CO₂-enriched orange tree leaves and CO₂-enriched pine tree needles had reduced total phenolic concentration. There was an inverse relationship between the increase in leaf total phenolic concentration and increase in biomass of these pine trees. Different rates of increase in growth (carbon sink) produced by different environmental conditions or different resource availabilities apart from CO₂ itself must be considered in order to understand the response of carbon-based-secondary-compounds to elevated CO₂.

Penuelas, J., M. Estiarte, and J. Llusia. 1997. Carbon-based secondary compounds at elevated CO₂. *Photosynthetica* 33(2):313-316.

From literature sources we compiled the data on carbon-based-secondary compounds CBSC (phenolics and terpenoids) and biomass of 17 plant species grown at different CO₂ concentrations under low and high nutrient availabilities. With a low nutrient availability a possible inverse correlation was found between the biomass and CBSC changes. On the contrary, under a high nutrient availability, both the CBSC and biomass increased with elevated CO₂. The wide variation in the CBSC production among species and compounds (larger responses in phenolics than in terpenoids) indicates that the allocation to CBSC may not completely be governed by changes in CO₂ and nutrient availabilities per se. Yet the comparison shows that elevated CO₂ generally loads the carbon into CBSC [their leaf concentration increased an overall average of 14 % at 700 $\mu\text{mol}(\text{CO}_2) \text{mol}^{-1}$] which may improve our

understanding of the carbon storage and cycling in ecosystems under the "global change" of climate.

Penuelas, J., S.B. Idso, A. Ribas, and B.A. Kimball. 1997. Effects of long-term atmospheric CO₂ enrichment on the mineral concentration of *Citrus aurantium* leaves. *New Phytologist* 135(3):439-444.

Leaf mineral concentration of *Citrus aurantium* (sour orange tree) was measured at bi-monthly intervals from 30 to 85 months of exposure in a long-term study on the effects of a 300 $\mu\text{mol} \text{mol}^{-1}$ enrichment of atmospheric CO₂, under conditions of high nutrient and water supply. There were clear seasonal trends in the concentrations of most of the elements studied. There were initial decreases in the leaf concentrations of N and the xylem-mobile, phloem-immobile elements Mn, Ca and Mg, as well as a significant and sustained increase in the leaf concentration of B, and no changes in the concentrations of K, Fe, Na, P, S, Zn and Cu. Interestingly, the initial reductions in the leaf concentrations of Mn, N, Ca and Mg gradually disappeared with time.

Penuelas, J., and J. Llusia. 1997. Effects of carbon dioxide, water supply, and seasonality on terpene content and emission by *Rosmarinus officinalis*. *Journal of Chemical Ecology* 23(4):979-993.

Rosmarinus officinalis L. plants were grown under carbon dioxide concentrations of 350 and 700 $\mu\text{mol} \text{mol}^{-1}$ (atmospheric CO₂ and elevated CO₂) and under two levels of irrigation (high water and low water) from October 1, 1994 to May 31, 1996. Elevated CO₂ led to increasingly larger monthly growth rates than the atmospheric CO₂ treatments. The increase was 9.5% in spring 1995, 23% in summer 1995, and 53% in spring 1996 in the high-water treatments, whereas in low-water treatments the growth response to elevated CO₂ was constrained until the second year spring, when there was a 47% increase. The terpene concentration was slightly larger in the elevated CO₂ treatments than in atmospheric CO₂ treatments and reached a maximum 37% difference in spring 1996. There was no significant effect of water treatment, likely as a result of a mild low water treatment for a Mediterranean plant. Terpene concentration increased throughout the period of study, indicating possible age effects. The most abundant terpenes were alpha-pinene, cineole, camphor, borneol, and verbenone, which represented about 75% of the total. No significant differences were found in the terpene composition of the plants in the different treatments or seasons. The emission of volatile terpenes was much larger in spring (about 75 $\mu\text{g} \text{g}^{-1} \text{wt/hr}$) than in autumn (about 10 $\mu\text{g} \text{g}^{-1} \text{wt/hr}$), partly because of higher temperature and partly because of seasonal effect, but no significant difference was found because of CO₂ or water treatment. The main terpene emitted was alpha-pinene, which represented about 50% of the total. There was no clear correlation between content and emission, either quantitatively or qualitatively. More volatile terpenes were proportionally more important in the total emission than in total content and in autumn than in spring.

Penuelas, J., and R. Matamala. 1993. Variations in the mineral composition of herbarium plant species collected during the last 3 centuries. *Journal of Experimental Botany* 44(266):1523-1525.

Mineral content (dry weight basis) was determined for herbarium specimens of 12 C3 plants (trees, shrubs and herbs) collected during the last 250 years in N.E. Spain. Present values of Al, Ca, Cu, Sr, Fe, P, Mg, Mn, K, Na, S, and Zn were always lower than in any other period of the last three centuries. Only one C4 plant was analysed. It presented a similar pattern to the C3 plants. These results are in accordance with experimental results that have shown that the mineral content of plants grown in elevated CO₂ is generally lowered. Increased atmospheric CO₂ and other anthropogenic environmental changes are suggested as possible causes of the changes in mineral content.

Percival, D.C., J.T.A. Proctor, and M.J. Tsujita. 1996. Whole-plant net CO₂ exchange of raspberry as influenced by air and root-zone temperature, CO₂ concentration, irradiation, and humidity. *Journal of the American Society for Horticultural Science* 121(5):838-845.

The influence of irradiance, CO₂, and temperature on whole-plant net CO₂ exchange rate (NCER) of *Rubus idaeus* L. 'Heritage' micropropagated raspberries was examined. Within the set of environmental conditions examined, irradiation was the most important factor, accounting for 58% of the whole-plant irradiance/CO₂ concentration/temperature NCER model variation, followed by CO₂ concentration (28%) and temperature (2.5%). Net photosynthesis (Pn) required irradiance levels >600 $\mu\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ PPFD for saturation, greatly increased under CO₂ enrichment (up to 1500 $\mu\text{L} \cdot \text{L}^{-1}$), and was optimum at a whole-plant temperature of 20 degrees C. Temperature effects were partitioned in an experiment using varying air and root-zone temperatures (15, 20, 25, 30, and 35 degrees C) under saturated light and ambient CO₂ levels (350 $\mu\text{L} \cdot \text{L}^{-1}$). Air and root-zone temperature influenced Pn, with maximum rates occurring at an air x root-zone temperature of 17/25 degrees C. The contribution of air and root-zone temperature to the NCER model varied, with air and root-zone temperature contributing 75% and 24%, respectively, to the total model variation ($R^2 = 0.96$). Shoot dark respiration increased with air and root-zone temperature, and root respiration rates depended on air and root-zone temperature and shoot assimilation rate. Humidity also influenced Pn with a saturated vapor pressure deficit threshold >0.25 kPa resulting in a Pn decrease. Quantifying the physiological response of raspberries to these environmental parameters provides further support to recent findings that cool shoot/warm root conditions are optimum for raspberry plant growth.

Perezsoba, M., T.A. Dueck, G. Puppi, and P.J.C. Kuiper. 1995. Interactions of elevated CO₂, NH₃ and O₃ on mycorrhizal infection, gas-exchange and N-metabolism in saplings of Scots pine. *Plant and Soil* 176(1):107-116.

Four-year-old saplings of Scots pine (*Pinus sylvestris* L.) were exposed for 11 weeks in controlled-environment chambers to charcoal-filtered air, or to charcoal-filtered air supplemented with NH₃ (40 $\mu\text{g} \cdot \text{m}^{-3}$), O₃ (110 $\mu\text{g} \cdot \text{m}^{-3}$) during day/ 40 $\mu\text{g} \cdot \text{m}^{-3}$ during night) or NH₃ + O₃. All treatments were carried out at ambient (350 $\mu\text{L} \cdot \text{L}^{-1}$) and at elevated CO₂ concentration (700 $\mu\text{L} \cdot \text{L}^{-1}$). Total tree biomass,

mycorrhizal infection, net CO₂ assimilation (P_n), stomatal conductance (g(s)), transpiration of the shoots and NH₃ metabolism of the needles were measured. In ambient CO₂ (1) gaseous NH₃ decreased mycorrhizal infection, without significantly affecting tree biomass or N concentration and it enhanced the activity of glutamine synthetase (GS) and glutamate dehydrogenase (GDH) in one-year-old needles; (2) ozone decreased mycorrhizal infection and the activity of GS in the needles, while it increased the activity of GDH; (3) exposure to NH₃ + O₃ lessened the effects of single exposures to NH₃ and O₃ on reduction of mycorrhizal infection and on increase in GDH activity. Similar lessening effects on mycorrhizal infection as observed in trees exposed to NH₃ + O₃ at ambient CO₂, were measured in trees exposed to NH₃ + O₃ at elevated CO₂. Exposure to elevated CO₂ without pollutants did not significantly affect any of the parameters studied, except for a decrease in the concentration of soluble proteins in the needles. Elevated CO₂ + NH₃ strongly decreased root branching and mycorrhizal infection and temporarily stimulated P_n and g(s). The exposure to elevated CO₂ + NH₃ + O₃ also transiently stimulated P_n. The possible mechanisms underlying and integrating these effects are discussed. Elevated CO₂ clearly did not alleviate the negative effects of NH₃ and O₃ on mycorrhizal infection. The significant reduction of mycorrhizal infection after exposure to NH₃ or O₃, observed before significant changes in gas exchange or growth occurred, suggest the use of mycorrhizal infection as an early indicator for NH₃ and O₃ induced stress.

Perezsoba, M., L.J.M. Vandereerden, I. Stulen, and P.J.C. Kuiper. 1994. Gaseous ammonia counteracts the response of Scots pine needles to elevated atmospheric carbon-dioxide. *New Phytologist* 128(2):307-313.

Four-year-old saplings of Scots pine (*Pinus sylvestris* L.) were exposed for 8 wk in controlled-environment chambers to charcoal-filtered air (FB), FA supplemented with 754 $\mu\text{g} \cdot \text{m}^{-3}$ (650 $\mu\text{L} \cdot \text{L}^{-1}$) CO₂, FA supplemented with 100 $\mu\text{g} \cdot \text{m}^{-3}$ NH₃ and FA + CO₂ + NH₃. Elevated CO₂ induced a significant increase in the concentrations of NH₄⁺ and NO₃⁻ in the soil solution, while exposure to NH₃ enhanced the soil NH₄⁺ concentration. Elevated CO₂ significantly increased needle biomass and area, and decreased specific leaf area (SLA) and N concentration in the needles. The activity of peroxidase (POD) was decreased, while the activities of glutamine synthetase (GS) and glutamate dehydrogenase (GDH) were only slightly affected. Gaseous NH₃ enhanced the concentration of N, soluble proteins and the GS activity in the needles, while it decreased the POD and GDH activities. The effects of elevated CO₂ + NH₃ on needle biomass production, N metabolism and POD activity were smaller than the effects of single exposures to elevated CO₂ or NH₃, suggesting that elevated CO₂ and NH₃ counteract each other and disturb needle physiology. The possible mechanisms underlying the negative interactions of elevated CO₂ and NH₃ are discussed. The expected stimulation of biomass production by elevated CO₂ may be reduced in the presence of atmospheric NH₃.

Perruchoud, D., F. Joos, A. Fischlin, I. Hajdas, and G. Bonani. 1999. Evaluating timescales of carbon turnover in temperate forest soils with radiocarbon data. *Global Biogeochemical Cycles* 13(2):555-573.

Timescales of soil organic carbon (SOC) turnover in forests were investigated with soil radiocarbon data. The C-12/C-14 ratios were measured by accelerated mass spectroscopy on soil sampled from a deciduous temperate forest in Switzerland during 1969-1995. The resulting Delta(14)C values (125-174 parts per thousand) were in line with previously published C-14 soil data. We applied FORCLIM-D, a model of nonliving organic matter decomposition including nine litter and two soil compartments to estimate SOC turnover times for this forest type. Carbon 14 aging in woody vegetation was explicitly accounted for. Parameters were calibrated to match radiocarbon ratios observed for forest soils at Meathop Wood, United Kingdom [Harkness et al., 1986]. We estimated that roughly 50-94% (best estimate, 49%) of foliar litter carbon and 11-74% (73%) of fine root litter carbon are eventually respired as CO₂ at Meathop Wood; the rest is transferred to soil humus, where it undergoes further decomposition. Turnover times for the 0-20 cm mineral soil layer ranged from 9-50 years (25 years) for a fast overturning soil compartment comprising 38-74% (68%) of bulk SOC and 155-10,018 years (3,570 years) for a slowly overturning compartment. For the Swiss site, SOC turnover times were in the same range. Parameter uncertainties were correlated and induced by uncertainties in C-14 observations from small-scale spatial inhomogeneities, sample preparation and by lack of reliable C-14 observations for the "prebomb" test period. Model-based estimates of soil organic C turnover derived from C-14 data must be used cautiously since they depend on the underlying model structure: bypassing litter in FORCLIM-D overestimated SOC turnover by a factor of 2.5. Such an error might remain undetected in studies lacking samples from the late 1960s and early 1970s. Thus litter C turnover should be included when estimating SOC turnover in temperate forests from C-14 data.

Peterson, J.V., and M.A. Maun. 1999. The role of mycorrhizal fungi in growth enhancement of dune plants following burial in sand. *Functional Ecology* 13(4):560-566.

1. Burial in sand of *Agropyron psammophilum* and *Panicum virgatum* plants had a stimulating effect on carbon dioxide exchange rate, leaf area and biomass, irrespective of whether sand used for burial did or did not contain mycorrhizal fungi. 2. Plants of both *A. psammophilum* and *P. virgatum* species grown in mycorrhiza-containing sand and then buried with mycorrhiza-containing sand had the highest CO₂ exchange rate, leaf area and biomass. 3. The growth stimulation following a burial episode is probably a composite response of several factors. The major contribution of mycorrhizal fungi will possibly be the exploitation of resources in the burial deposit.

Pesheva, I., M. Kodama, M.L. Dionisiosese, and S. Miyachi. 1994. Changes in photosynthetic characteristics induced by transferring air-grown cells of *Chlorococcum littorale* to high-CO₂ conditions. *Plant and Cell Physiology* 35(3):379-387.

When air-grown cells of *Chlorococcum littorale* were enriched with CO₂, growth was enhanced after a lag period of one to two days at 20% CO₂, and 3 to 6 days at 40% CO₂. Changes in the rate of photosynthesis measured as oxygen evolution and CO₂ fixation, were similar to those observed for growth. During the initial inhibition of photosynthesis in

40% CO₂, the activity of PSII was suppressed. In contrast, PSI activity was greatly enhanced. Air-grown cells of *C. littorale* possessed comparatively high carbonic anhydrase (CA) activity which was localized inside the cells and on the cell surface. Under high CO₂ concentrations extracellular CA activity was greatly suppressed and intracellular activity almost completely abolished. Phosphoenolpyruvate carboxylase activity was also suppressed in high CO₂-grown cells. Ribulose-1,5-bisphosphate carboxylase activity was higher in high-CO₂ grown cells than in air-grown cells. The above results indicated that the lag phase induced by 40% CO₂ was due to suppression of PSII activity.

Peterson, A.G., J.T. Ball, Y. Luo, C.B. Field, P.S. Curtis, K.L. Griffin, C.A. Gunderson, R.J. Norby, D.T. Tissue, M. Forstreuter, A. Rey, and C.S. Vogel. 1999. Quantifying the response of photosynthesis to changes in leaf nitrogen content and leaf mass per area in plants grown under atmospheric CO₂ enrichment. *Plant, Cell and Environment* 22(9):1109-1119.

Previous modelling exercises and conceptual arguments have predicted that a reduction in biochemical capacity for photosynthesis (A(area)) at elevated CO₂ may be compensated by an increase in mesophyll tissue growth if the total amount of photosynthetic machinery per unit leaf area is maintained (i.e. morphological upregulation). The model prediction was based on modelling photosynthesis as a function of leaf N per unit leaf area (N-area), where N-area = N-mass x LMA. Here, N-mass is percentage leaf N and is used to estimate biochemical capacity and LMA is leaf mass per unit leaf area and is an index of leaf morphology. To assess the relative importance of changes in biochemical capacity versus leaf morphology we need to control for multiple correlations that are known, or that are likely to exist between CO₂ concentration, N-area, N-mass, LMA and A(area). Although this is impractical experimentally, we can control for these correlations statistically using systems of linear multiple-regression equations. We developed a linear model to partition the response of A(area), to elevated CO₂ into components representing the independent and interactive effects of changes in indexes of biochemical capacity, leaf morphology and CO₂ limitation of photosynthesis. The model was fitted to data from three pine and seven deciduous tree species grown in separate chamber-based field experiments. Photosynthetic enhancement at elevated CO₂ due to morphological upregulation was negligible for most species. The response of A(area), in these species was dominated by the reduction in CO₂ limitation occurring at higher CO₂ concentration. However, some species displayed a significant reduction in potential photosynthesis at elevated CO₂ due to an increase in LMA that was independent of any changes in N-area. This morphologically based inhibition of A(area) combined additively with a reduction in biochemical capacity to significantly offset the direct enhancement of A(area) caused by reduced CO₂ limitation in two species. This offset was 100% for *Acer rubrum*, resulting in no net effect of elevated CO₂ on A(area) for this species, and 44% for *Betula pendula*. This analysis shows that interactions between biochemical and morphological responses to elevated CO₂ can have important effects on photosynthesis.

Peterson, A.G., J.T. Ball, Y.Q. Luo, C.B. Field, P.B. Reich, P.S. Curtis, K.L. Griffin, C.A. Gunderson, R.J. Norby, D.T. Tissue, M.

Forstreuter, A. Rey, and C.S. Vogel. 1999. The photosynthesis leaf nitrogen relationship at ambient and elevated atmospheric carbon dioxide: a meta-analysis. *Global Change Biology* 5(3):331-346.

Estimation of leaf photosynthetic rate (A) from leaf nitrogen content (N) is both conceptually and numerically important in models of plant, ecosystem, and biosphere responses to global change. The relationship between A and N has been studied extensively at ambient CO₂ but much less at elevated CO₂. This study was designed to (i) assess whether the A-N relationship was more similar for species within than between community and vegetation types, and (ii) examine how growth at elevated CO₂ affects the A-N relationship. Data were obtained for 39 C3 species grown at ambient CO₂ and 10 C3 species grown at ambient and elevated CO₂. A regression model was applied to each species as well as to species pooled within different community and vegetation types. Cluster analysis of the regression coefficients indicated that species measured at ambient CO₂ did not separate into distinct groups matching community or vegetation type. Instead, most community and vegetation types shared the same general parameter space for regression coefficients. Growth at elevated CO₂ increased photosynthetic nitrogen use efficiency for pines and deciduous trees. When species were pooled by vegetation type, the A-N relationship for deciduous trees expressed on a leaf-mass basis was not altered by elevated CO₂, while the intercept increased for pines. When regression coefficients were averaged to give mean responses for different vegetation types, elevated CO₂ increased the intercept and the slope for deciduous trees but increased only the intercept for pines. There were no statistical differences between the pines and deciduous trees for the effect of CO₂. Generalizations about the effect of elevated CO₂ on the A-N relationship, and differences between pines and deciduous trees will be enhanced as more data become available.

Peterson, R.B. 1991. Effects of O₂ and CO₂ concentrations on quantum yields of photosystem-I and photosystem-II in tobacco leaf tissue. *Plant Physiology* 97(4):1388-1394.

The interactive effects of irradiance and O₂ and CO₂ levels on the quantum yields of photosystems I and II have been studied under steady-state conditions at 25-degrees-C in leaf tissue of tobacco (*Nicotiana tabacum*). Assessment of radiant energy utilization in photosystem II was based on changes in chlorophyll fluorescence yield excited by a weak measuring beam of modulated red light. Independent estimates of photosystem I quantum yield were based on the light-dark in vivo absorbance change at 830 nanometers, the absorption band of P700+. Normal (i.e. 20.5%, v/v) levels of O₂ generally enhanced photosystem II quantum yield relative to that measured under 1.6% O₂ as the irradiance approached saturation. Photorespiration is suspected to mediate such positive effects of O₂ through increases in the availability of CO₂ and recycling of orthophosphate. Conversely, at low intercellular CO₂ concentrations, 41.2% O₂ was associated with lower photosystem II quantum yield compared with that observed at 20.5% O₂. Inhibitory effects of 41.2% O₂ may occur in response to negative feedback on photosystem II arising from a build-up in the thylakoid proton gradient during electron transport to O₂. Covariation between quantum yields of photosystems I and II was not affected by concentrations of either O₂ or CO₂. The dependence of quantum yield of electron transport to CO₂ measured by gas exchange upon photosystem II quantum yield as determined by fluorescence was unaffected by CO₂ concentration.

Petschel-Held, G., H.J. Schellnhuber, T. Bruckner, F.L. Toth, and K. Hasselmann. 1999. The tolerable windows approach: Theoretical and methodological foundations. *Climatic Change* 41(3-4):303-331.

The tolerable windows (TW) approach is presented as a novel scheme for integrated assessment of climate change. The TW approach is based on the specification of a set of guardrails for climate evolution which refer to various climate-related attributes. These constraints, which define what we call tolerable windows, can be purely systemic in nature - like critical thresholds for the North Atlantic Deep Water formation - or of a normative type - like minimum standards for per-capita food production worldwide. Starting from this catalogue of knock-out criteria and using appropriate modeling techniques, those policy strategies which are compatible with all the constraints specified are sought to be identified. In addition to the discussion of the basic elements and the general theory of the TW approach, a modeling exercise is carried out, based on simple models and assumptions adopted from the German Advisory Council on Global Change (WBGU). The analysis shows that if the global mean temperature is restricted to 2 degrees C beyond the preindustrial level, the cumulative emissions of CO₂ are asymptotically limited to about 1550 Gt C. Yet the temporal distribution of these emissions is also determined by the climate and socio-economic constraints: using, for example, a maximal tolerable rate of temperature change of 0.2 degrees C/dec and a smoothly varying emissions profile, we obtain the maximal cumulative emissions, amounting to 370 Gt C in 2050 and 585 Gt C in 2100.

Pettersson, R., and A.J.S. McDonald. 1992. Effects of elevated carbon-dioxide concentration on photosynthesis and growth of small birch plants (*Betula pendula* Roth.) at optimal nutrition. *Plant, Cell and Environment* 15(8):911-919.

Small birch plants (*Betula Pendula* Roth.) were grown from seed for periods of up to 70 d in a climate chamber at optimal nutrition and at present (350 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) concentrations of atmospheric CO₂. Nutrients were sprayed over the roots in Ingstad-type units. Relative growth rate and net assimilation rate were slightly higher at elevated CO₂, whereas leaf area ratio was slightly lower. Smaller leaf area ratio was associated with lower values of specific leaf area. Leaves grown at elevated CO₂ had higher starch concentrations (dry weight basis) than leaves grown at present levels of CO₂. Biomass allocation showed no change with CO₂, and no large effects on stem height, number of side shoots and number of leaves were found. However, the specific root length of fine roots was higher at elevated CO₂. No large difference in the response of carbon assimilation to intercellular CO₂ concentration (A/C(i) curves) were found between CO₂ treatments. When measured at the growth environments, the rates of photosynthesis were higher in plants grown at elevated CO₂ than in plants grown at present CO₂. Water use efficiency of single leaves was higher in the elevated treatment. This was mainly attributable to higher carbon assimilation rate at elevated CO₂. The difference in water use efficiency diminished with leaf age. The small treatment difference in relative growth rate was maintained throughout the experiment, which meant that the difference in plant size became progressively greater. Thus, where plant nutrition is sufficient to maintain maximum growth, small birch plants may potentially increase in size more rapidly at elevated CO₂.

Pettersson, R., and A.J.S. McDonald. 1994. Effects of nitrogen supply on the acclimation of photosynthesis to elevated CO₂. *Photosynthesis Research* 39(3):389-400.

A common observation in plants grown in elevated CO₂ concentration is that the rate of photosynthesis is lower than expected from the dependence of photosynthesis upon CO₂ concentration in single leaves of plants grown at present CO₂ concentration. Furthermore, it has been suggested that this apparent down regulation of photosynthesis may be larger in leaves of plants at low nitrogen supply than at higher nitrogen supply. However, the available data are rather limited and contradictory. In this paper, particular attention is drawn to the way in which whole plant growth response to N supply constitutes a variable sink strength for carbohydrate usage and how this may affect photosynthesis. The need for further studies of the acclimation of photosynthesis at elevated CO₂ in leaves of plants whose N supply has resulted in well-defined growth rate and sink activity is emphasised, and brief consideration is made of how this might be achieved.

Pettersson, R., A.J.S. McDonald, and I. Stadenberg. 1993. Response of small birch plants (betula-pendula roth) to elevated CO₂ and nitrogen supply. *Plant, Cell and Environment* 16(9):1115-1121.

Small birch plants were grown for up to 80 d in a climate chamber at varied relative addition rates of nitrogen in culture solution, and at ambient (350 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) concentrations of CO₂. The relative addition rate of nitrogen controlled relative growth rate accurately and independently of CO₂ concentration at sub- optimum levels. During free access to nutrients, relative growth rate was higher at elevated CO₂. Higher values of relative growth rate and net assimilation rate were associated with higher values of plant N-concentration. At all N-supply rates, elevated CO₂ resulted in higher values of net assimilation rate, whereas leaf weight ratio was independent of CO₂. Specific leaf area (and leaf area ratio) was less at higher CO₂ and at lower rates of N-supply. Lower values of specific leaf area weight partly because of starch accumulation. Nitrogen productivity (growth rate per unit plant nitrogen) was higher at elevated CO₂. At sub-optimal N-supply, the higher net assimilation rate at elevated CO₂ was offset by a lower leaf area ratio. Carbon dioxide did not affect root/shoot ratio, but a higher fraction of plant dry weight was found in roots at lower N-supply. In the treatment with lower N-supply, five times as much root length was produced per amount of plant nitrogen in comparison with optimum plants. The specific fine root length at all N-supplies was greater at elevated CO₂. These responses of the root system to lower N- supply and elevated CO₂ may have a considerable bearing on the acquisition of nutrients in depleted soils at elevated CO₂. The advantage of maintaining steady-state nutrition in small plants while investigating the effects of elevated CO₂ on growth is emphasized.

Pfirrmann, T., J.D. Barnes, K. Steiner, P. Schramel, U. Busch, H. Kuchenhoff, and H.D. Payer. 1996. Effects of elevated CO₂, O-3 and K deficiency on Norway spruce (Picea abies): Nutrient supply, content and leaching. *New Phytologist* 134(2):267-278.

Two clones of 5-yr-old Norway spruce (Picea abies [L.] Karst.) were exposed to two atmospheric concentrations of CO₂ (350 and 750 $\mu\text{mol mol}^{-1}$) and of O-3 (20 and 75 nmol mol^{-1}) in a phytotron at the GSF-Forschungszentrum (Munich) over the course of a single season (April-October). The phytotron was programmed to recreate an artificial climate similar to that at a high elevation site in the Inner Bavarian forest, and trees were grown in 401 containers of soil (pH 3.5) fertilized to achieve two levels of potassium nutrition; well fertilized and K-deficient. Foliar nutrient analyses performed at the beginning of the exposure indicated that the fertilization programmes achieved their goal without significantly altering the levels of other nutrients or the soil pH. At the beginning of the fumigation, foliar K concentrations were 7-9 mg g⁻¹ d. wt for well fertilized trees and 4-5 mg g⁻¹ d. wt for trees receiving no supplemental K. Over the course of the season, differences between K treatments intensified so that by the end of the experiment there was a five to sixfold difference between foliar K concentrations. This was associated with slight, but significant ($P < 0.05$), decreases in S and Zn (and of Cu in the 1989 needle year age class) and higher levels of C, N and Mg in K-deficient trees. Foliar N concentrations were low for all trees (9-15 mg g⁻¹ needle d. wt) but were similar to levels found in the field. Elevated O-3 was found to decrease significantly the C ($P < 0.05$) and N ($P < 0.001$) content of both current-year (1989) and previous-year (1988) needles independent of CO₂ concentration, but apart from some minor changes in the concentrations of Cu and Mn in the current-year needles no other effects of the pollutant on plant nutrient status were found. In contrast, CO₂ enrichment resulted in significantly ($P < 0.01$) lower concentrations of K and P (effects on Mg were also on the borderlines of statistical significance) in current-year needles, but there was no influence on the nutrient composition of the previous-year needles (although effects on N were on the borderlines of statistical significance). CO₂ enrichment also increased ($P < 0.05$) the C:N ratio of both current-year and previous-year needles. One factor contributing to the decline in foliar K at elevated CO₂ appeared to be a marked increase (25-30%) in the rate at which cations were leached from the canopy by repeated simulated acid mist (pH 4.0) events, and this effect occurred independently of the O-2 concentration. The information presented will aid the interpretation of parallel studies examining the effects of elevated CO₂ and/or O-2 on seasonal changes in photosynthesis, non-structural carbohydrate content, antioxidants, tree growth and water use efficiency, and sheds further light on the growing scepticism concerning the role of O-2 in the development of Mg and K-deficiency symptoms characteristic of certain types of forest decline in central Europe.

Phillips, D.L., J.J. Lee, and R.F. Dodson. 1996. Sensitivity of the US corn belt to climate change and elevated CO₂. 1. Corn and soybean yields. *Agricultural Systems* 52(4):481-502.

Climate models indicate that increasing atmospheric concentrations of CO₂ and other greenhouse gases could alter climate globally. The EPIC (Erosion Productivity Impact Calculator) model was used to examine the sensitivity of corn and soybean yields over the US corn belt to changes in temperature, precipitation, wind and atmospheric CO₂ concentration. A statistically representative sample of 100 corn and soybean production sites was selected from the 1987 National Resources Inventory (NRI). One-hundred-year simulations were run for each site under 36 different

climate/CO₂ scenarios. The results were area weighted according to the NRI area expansion factor's to produce a regionally aggregated estimate of yields. EPIC did an excellent job of reproducing current regional mean expected yields under the baseline scenario. There were 3% decreases in both corn and soybean yields in response to a 2 degrees C temperature increase at baseline precipitation levels, with larger and smaller temperature effects under drier and wetter conditions, respectively. Crop yields increased and decreased in response to increases and decreases of 10% or 20% precipitation. A 10% precipitation increase roughly balanced the negative effect of the 2 degrees C temperature increase. Whether the precipitation changes resulted from altered precipitation event frequency or amount per event had little effect on mean crop yields; however interannual yield variability was higher when precipitation decreases were due to frequency rather than intensity. The opposite was true, though to a lesser extent, for precipitation increases. Potential evapotranspiration responded linearly to changes in mean wind speed, leading to modest changes of 1-3 days of water stress per growing season, yield increases of up to 2% for decreased wind, and yield decreases of up to 6% for increased wind. Elevated CO₂ concentrations of 625 ppmv gave the greatest yield increases, +17% for corn and +27% for soybean at baseline temperature and precipitation levels. The relative CO₂ effect was larger under drier conditions. Copyright (C) 1996 Published by Elsevier Science Ltd

Phillips, O.L., and A.H. Gentry. 1994. Increasing turnover through time in tropical forests. *Science* 263(5149):954-958.

Tree turnover rates were assessed at 40 tropical forest sites. Averaged across inventoried forests, turnover, as measured by tree mortality and recruitment, has increased since the 1950s, with an apparent pantropical acceleration since 1980. Among 22 mature forest sites with two or more inventory periods, forest turnover also increased. The trend in forest dynamics may have profound effects on biological diversity.

Picon, C., A. Ferhi, and J.M. Guehl. 1997. Concentration and delta C-13 of leaf carbohydrates in relation to gas exchange in Quercus robur under elevated CO₂ and drought. *Journal of Experimental Botany* 48(313):1547-1556.

The variations of leaf carbohydrate concentration, carbon isotope discrimination (Delta) of leaf soluble carbohydrate, gas-exchange and growth during a soil drying cycle under 350 and 700 mu mol mol⁻¹ CO₂ concentrations ([CO₂]) in Quercus robur seedlings were analysed. In well-watered conditions, a doubling of [CO₂] caused an increase of CO₂ assimilation rate (A) (+47%) and a decrease of stomatal conductance for water vapour (g) (-25%), and doubled the intrinsic water-use efficiency (A/g). The values of Delta were not affected by elevated [CO₂] which was consistent with the 2-fold increase of A/g.

Elevated [CO₂] also significantly increased sucrose and starch leaf concentrations as well as aerial growth and plant dry weight. The stimulating effect of CO₂ enrichment on A and A/g was maintained in moderate drought conditions, but disappeared in the most severe drought conditions. Drought induced an increase of hexose concentrations in both [CO₂], but this effect was more pronounced under elevated [CO₂], which may contribute to increase osmoregulation. From the onset of drought, starch was depleted in both [CO₂]. Carbon isotope discrimination decreased in response to drought, which corresponded to an increase in A/g according to the two-step model of isotopic discrimination. In contrast, the A/g values derived from instantaneous leaf gas-exchange measurements decreased along the drying cycle. The discrepancy observed between the two independent estimates of water-use efficiency is discussed in terms of time-scale integration. The results obtained with the isotopic approach using soluble carbohydrate suggest a predominant stomatal limitation of CO₂ assimilation in response to drought.

Picon, C., J.M. Guehl, and G. Aussenac. 1996. Growth dynamics, transpiration and water-use efficiency in Quercus robur plants submitted to elevated CO₂ and drought. *Annales Des Sciences Forestieres* 53(2-3):431-446.

Seedlings of pedunculate oak (Quercus robur L) were grown for one growing season under ambient (350 mu mol mol⁻¹) and elevated (700 mu mol mol⁻¹) atmospheric CO₂ concentration ([CO₂]) either in well-watered or in droughted (the water supply was 40% of the well-watered plants transpiration in both [CO₂]) conditions. In the droughted conditions, gravimetric soil water content (SWC) was on average 4.10(-2) g g⁻¹ lower under elevated [CO₂]. In well-watered conditions, biomass growth was 39% higher in the elevated [CO₂] treatment than under ambient [CO₂]. However relative growth rate (RGR) was stimulated by the elevated [CO₂] only for 17 days, in July, at the end of the stem elongation phase (third growing flush), which corresponded also to the phase of maximum leaf expansion rate. Both the number of leaves per plant and the plant leaf area were 30% higher in the elevated [CO₂] treatment than under ambient [CO₂]. In the droughted conditions, no significant enhancement in biomass growth and in plant leaf area was brought about by the elevated [CO₂]. Transpiration rate was lower in the elevated [CO₂] conditions, but whole plant water use was similar in the two [CO₂] treatments, reflecting a compensation between leaf area and stomatal control of transpiration. Transpiration efficiency (W = biomass accumulation/plant water use) was improved by 47% by the elevated [CO₂] in well-watered conditions but only by 18% in the droughted conditions. Carbon isotope discrimination (Delta) was decreased by drought and was increased by the elevated [CO₂]. A negative linear relationship was found between transpiration efficiency divided by the atmospheric [CO₂] and Delta, as predicted by theory.

Picon, C., J.M. Guehl, and A. Ferhi. 1996. Leaf gas exchange and carbon isotope composition responses to drought in a drought-avoiding (Pinus pinaster) and a drought-tolerant (Quercus petraea) species under present and elevated atmospheric CO₂ concentrations. *Plant, Cell and Environment* 19(2):182-190.

The responses of predawn leaf water potential ($\Psi_i(wp)$), leaf conductance to water vapour diffusion (g), CO_2 assimilation rate (A) and carbon isotope competition ($\delta(13)C$) to a soil drying cycle were assessed in *Pinus pinaster*, a drought-avoiding species with high stomatal sensitivity to drought, and *Quercus petraea*, a drought-tolerant species with lower stomatal sensitivity to drought, under present (350 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) atmospheric CO_2 concentrations ($[CO_2]$). In *P. pinaster*, decreasing A in response to drought was associated with increasing plant intrinsic water use efficiency (A/g) and with decreasing calculated intercellular $[CO_2]$ (C_i), suggesting a stomatal limitation of A . In contrast, in *Q. petraea*, A/g declined and C_i increased during the drying cycle, which suggests a non-stomatal origin for the decrease in A . In *P. pinaster*, a negative relationship was observed between the gas exchange-derived values of C_i/C_a and $\delta(13)C$, which conforms to the classical two-step carbon isotope discrimination model. In *Q. petraea*, the relationship between C_i/C_a and $\delta(13)C$ was positive. Possible causes of this discrepancy are discussed. Lower g values were observed under elevated $[CO_2]$ than under present $[CO_2]$ in *Q. petraea*, whereas g was unaffected in *P. pinaster*. A stimulation of A by elevated $[CO_2]$ was found in *P. pinaster* but not in *Q. petraea*. In both species, A/g was markedly higher under elevated than under present $[CO_2]$. Whether the differences in the g response to elevated $[CO_2]$ found here can be generalized to other drought-avoiding and non-avoiding species remains to be assessed.

Plants of maritime pine (*Pinus pinaster* Ait.) were acclimated for 2 years under ambient (350 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) CO_2 concentrations ($[CO_2]$). In the summer of the second growing season, the plants were subjected to a soil drying cycle for 6 days. Drought reduced plant transpiration rate and net CO_2 assimilation rate (A) by about 80 %. Elevated $[CO_2]$ induced a substantial increase of A (+105 % and +229 % in well-watered and in droughted plants, respectively) and of the needle starch (+145 %) and sucrose (+20 %) concentrations, whatever the watering regime. Drought did not significantly affect starch acid sucrose concentrations, while hexose concentrations were slightly increased in the most severe drought condition (predawn water potential value equal to -1.5 MPa). The stimulating effect of elevated $[CO_2]$ on A was maintained along the drying cycle, whereas no significant CO_2 effect was observed on the soluble carbohydrate concentration. These compounds did not contribute to an enhancement of osmotic adjustment under elevated $[CO_2]$ in *P. pinaster*. ((C) Inra/Elsevier, Paris.).

Pinter, P.J., S.B. Idso, D.L. Hendrix, R.R. Rokey, R.S. Rauschkolb, J.R. Mauney, B.A. Kimball, G.R. Hendrey, K.F. Lewin, and J. Nagy. 1994. Effect of free-air CO_2 enrichment on the chlorophyll content of cotton leaves. *Agricultural and Forest Meteorology* 70(1-4):163-169.

In vivo chlorophyll concentrations were estimated using a Minolta SPAD 502 meter on upper-canopy leaves of cotton plants exposed to air enriched to an atmospheric CO_2 concentration of approximately 550

$\mu\text{mol mol}^{-1}$ in a free-air CO_2 enrichment (FACE) study. Measurements were made on 27 days during the final 90 days of the 1991 growing season. In both well-watered and moderately water-stressed plants, leaves in the FACE plots had greater chlorophyll a concentrations than leaves in the ambient air control plots (about 370 $\mu\text{mol } CO_2 \text{ mol}^{-1}$): season-long chlorophyll a averages were 7.1% greater in the 'wet' treatment and 8.2% greater in the 'dry' treatment. This finding differs from what has been observed in a number of studies where experimental plants were grown in small pots. It is, however, typical of what has been observed in studies employing larger pots and open fields, and is a compelling rationale for conducting additional studies of this nature in FACE projects.

Pinter, P.J., B.A. Kimball, J.R. Mauney, G.R. Hendrey, K.F. Lewin, and J. Nagy. 1994. Effects of free-air carbon-dioxide enrichment on par absorption and conversion efficiency by cotton. *Agricultural and Forest Meteorology* 70(1-4):209-230.

Anticipated changes in global climate and atmospheric CO_2 concentrations have very important, albeit poorly understood consequences for production agriculture. Effects of these changes on plants have usually been examined in controlled- environment enclosures, glass-houses, or open-top field chambers. Beginning in 1989, an innovative experimental free- air CO_2 enrichment (FACE) facility was operated in central Arizona to evaluate crop response to increased CO_2 levels within a large, open-field production environment. Cotton (*Gossypium hirsutum* L.) was grown for three consecutive seasons under exposed to either ambient (control, about 370 $\mu\text{mol mol}^{-1}$) or elevated (FACE, 550 $\mu\text{mol mol}^{-1}$) CO_2 concentrations. Deficit irrigation regimes supplying 75% (beginning in July 1990) or 67% (beginning in mid-May 1991) of the crop's evapotranspiration requirement were included as additional treatment variables. Plant growth was monitored by periodic sampling. Canopy reflectances in visible (blue, 0.45-0.52 μm ; green, 0.05-0.59 μm ; red, 0.61-0.68 μm) and near-infrared (NIR; 0.79-0.89 μm) wavebands were measured frequently with an Exotech radiometer and related to absorbed photosynthetically active radiation (PAR; 0.4-0.7 μm) measured with a line quantum sensor. Dry biomass of plants in the FACE treatment was significantly ($P < 0.05$) greater than control values during each year of the study. The FACE plant canopy also absorbed significantly more PAR than controls during the early and middle portion of the 1990 and 1991 seasons. Light use efficiency (LUE, biomass produced per unit absorbed PAR) was significantly higher in FACE plots during each year. In the well-watered irrigation treatment, the 3 year mean LUE was 1.97 g MJ⁻¹ for FACE and 1.56 g MJ⁻¹ for controls. The deficit irrigation treatment in 1991 produced significantly smaller plants, which absorbed less PAR and had lower LUE than plants in the well-watered treatment ($P < 0.05$). No interaction was observed between CO_2 and irrigation treatments. FACE research under realistic field conditions revealed positive consequences of increased CO_2 on cotton plant biomass, PAR absorption, and LUE. It also demonstrated the effectiveness of this new technology for examining community-level plant responses to possible changes in global environment.

Pirjola, L. 1999. Effects of the increased UV radiation and biogenic

VOC emissions on ultrafine sulphate aerosol formation. *Journal of Aerosol Science* 30(3):355-367.

A sectional model (AEROFOR) for the formation of sulphuric acid-water particles has been developed. The model includes gas-phase chemistry and aerosol dynamics. An increased UV-B irradiation penetrating into the troposphere due to stratospheric ozone depletion causes via the SO₂ oxidation route an enhanced nucleation potential for new H₂SO₄-H₂O particles as well as the growth of particles to CCN size. Using AEROFOR we show that after a nucleation event the nucleated particle concentration is linearly dependent on increased UV-B irradiation with a positive slope. On the other hand, due to increased CO₂ concentration photosynthetic rates of plants will increase, and it is likely that enhanced photosynthesis in forests will increase emissions of biogenic volatile organic compounds (BVOC) such as isoprene and monoterpenes. We show that the nucleated particle concentration decreases with increasing BVOC emission, but this dependence is not linear. We investigate the strength of these opposite effects and fit a straight line for such UV-B and BVOC conditions which yield a certain particle number density. The coupling between O₃, OH and particle concentrations as a function of UV-B and BVOC emission is also demonstrated. (C) 1999 Elsevier Science Ltd. All rights reserved.

Plaut, Z., and E. Federman. 1991. Acclimation of CO₂ assimilation in cotton leaves to water- stress and salinity. *Plant Physiology* 97(2):515-522.

Cotton (*Gossypium hirsutum* L. cv Acala SJ2) plants were exposed to three levels of osmotic or matric potentials. The first was obtained by salt and the latter by withholding irrigation water. Plants were acclimated to the two stress types by reducing the rate of stress development by a factor of 4 to 7. CO₂ assimilation was then determined on acclimated and nonacclimated plants. The decrease of CO₂ assimilation in salinity-exposed plants was significantly less in acclimated as compared with nonacclimated plants. Such a difference was not found under water stress at ambient CO₂ partial pressure. The slopes of net CO₂ assimilation versus intercellular CO₂ partial pressure, for the initial linear portion of this relationship, were increased in plants acclimated to salinity of -0.3 and -0.6 megapascal but not in nonacclimated plants. In plants acclimated to water stress, this change in slopes was not significant. Leaf osmotic potential was reduced much more in acclimated than in nonacclimated plants, resulting in turgor maintenance even at -0.9 megapascal. In nonacclimated plants, turgor pressure reached zero at approximately -0.5 megapascal. The accumulation of Cl⁻ and Na⁺ in the salinity-acclimated plants fully accounted for the decrease in leaf osmotic potential. The rise in concentration of organic solutes comprised only 5% of the total increase in solutes in salinity- acclimated and 10 to 20% in water-stress-acclimated plants. This acclimation was interpreted in light of the higher protein content per unit leaf area and the enhanced ribulose biphosphate carboxylase activity. At saturating CO₂ Partial pressure, the declined inhibition in CO₂ assimilation of stress-acclimated plants was found for both salinity and water stress.

Pleijel, H., J. Sild, H. Danielsson, and L. Klemetsson. 1998. Nitrous oxide emissions from a wheat field in response to elevated carbon dioxide concentration and open-top chamber enclosure. *Environmental Pollution* 102:167-171.

Soil emissions of nitrous oxide (N₂O) were measured using static field chambers, which were installed in a wheat field. The treatments were: open-top chambers with ambient CO₂ concentrations (OTC350), open-top chambers with 700 ppm CO₂ (OTC700) and ambient air plots without open-top chambers (AA). Measurements of N₂O emissions were made weekly starting at anthesis. The measurements continued for ten weeks, until two weeks after the harvest of the mature crop. During the first eight weeks the N₂O emissions were higher in the OTC350 treatment compared to OTC700. At the last two measurements, after the plants were harvested, the N₂O emissions of the chamber treatments were similar to each other and higher than during the preceding period. The accumulation of grain protein per unit area was higher in OTC700 compared with OTC350. These results suggest that a competition for soil nitrogen exists between plants and the microbial community. The AA plots emitted less N₂O during the green canopy period compared with the chamber treatments. After harvest, the emissions from AA increased up to the same magnitude as the chamber treatments. The lower emissions of the ambient air plots during the pre- harvest period can be explained partly by lower ambient temperatures and drier soil.

Polderdijk, J.J., and G.J.P.M. van den Boogaard. 1998. Effect of reduced levels of O₂ and elevated levels of CO₂ on the quality of bunched radishes. *Gartenbauwissenschaft* 63(6):250-253.

In two trials bunched radishes were stored at 12 degrees C and different levels of O₂ (21%, 10%, 5%, 1%, 0.5%) combined with different levels of CO₂ (0%, 1%, 5%, 10%, 15%, 20%). Decreased levels of O₂ and increased levels of CO₂ proved to inhibit the yellowing of the leaves and the growth of new roots. The incidence of decay was inhibited by increased CO₂ concentrations. Levels of 1% and 0.5% O₂ caused abnormal discolouration of the radishes and increased the incidence of decay. Off-odours and/or off-taste were found at O₂ levels of 0.5% and/or CO₂ levels of 20%.

Polglase, P.J., and Y.P. Wang. 1992. Potential CO₂-enhanced carbon storage by the terrestrial biosphere. *Australian Journal of Botany* 40(4-5):641-656.

Geochemical models that deduce latitudinal source/sink relationships of atmospheric CO₂ suggest that, in tropical regions, there is almost zero net exchange of CO₂ between the atmosphere and the terrestrial biosphere. The implication is that CO₂-enhanced carbon storage (CO₂-ECS) by tropical biomes is negating the output of CO₂ from deforestation. We describe here a 10-biome model for CO₂-ECS, in which carbon accumulation in living vegetation is coupled to the Rothamsted soil carbon model. A biotic growth factor (beta) was used to describe the relationship between literature estimates of net primary production (NPP) and atmospheric CO₂ concentration. Using beta = 0.3 as a reference state, CO₂-ECS by the global biosphere in 1990 was 1.1

Gt. When more appropriate values of beta were used (derived from a theoretical response of vegetation to increasing temperature and CO₂), CO₂-ECS was 1.3 Gt, of which tropical biomes accounted for 0.7 Gt. There are many uncertainties in this (and other) models; total CO₂-ECS is particularly sensitive to changes in NPP. Unless published surveys have underestimated tropical NPP by a factor of about 2, then it is unlikely that CO₂-ECS could have negated the 1.5- 3.0 Gt of carbon that are estimated to have been emitted by tropical deforestation in 1990.

Polle, A., M. Eiblmeier, L. Sheppard, and M. Murray. 1997. Responses of antioxidative enzymes to elevated CO₂ in leaves of beech (*Fagus sylvatica* L.) seedlings grown under a range of nutrient regimes. *Plant, Cell and Environment* 20(10):1317-1321.

To study whether responses of antioxidative enzymes to enhanced atmospheric CO₂ concentrations are affected by plant nutrition, the activities of superoxide dismutase, catalase and peroxidase were investigated in leaves of 3-year-old beech trees grown with low (0.1 x optimum), intermediate (0.5 x optimum) and high (2 x optimum) nutrient supply rates in open-top chambers at either ambient (approximate to 355 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. These treatments resulted in foliar C/N ratios of about 20 in the presence of high and > 30 in the presence of low nutrient supply rates. Pigment and malondialdehyde contents were determined to assess plant stress levels. Low nutrient supply rates caused pigment loss, whereas elevated CO₂ had no effect on pigmentation. Guaiacol peroxidase activities did not respond to either CO₂ or nutrient treatment. Catalase activity decreased with decreasing nutrient supply rate and also in response to elevated CO₂. Superoxidase dismutase activity was affected by both nutrient supply and CO₂ concentration. In leaves from trees grown with the high-nutrient treatment, superoxide dismutase activity was low irrespective of CO₂ concentration. In chlorotic leaves, superoxide dismutase activity was increased, suggesting an enhanced need for detoxification of reactive oxygen species. Leaves from plants grown under elevated CO₂ with medium nutrient supply rates showed decreased malondialdehyde contents and superoxide dismutase activities. This suggests that the intrinsic oxidative stress of leaves was decreased under these conditions. These results imply that intrinsic oxidative stress is modulated by the balance between N and C assimilation.

Polle, A., T. Pfirrmann, S. Chakrabarti, and H. Rennenberg. 1993. The effects of enhanced ozone and enhanced carbon-dioxide concentrations on biomass, pigments and antioxidative enzymes in spruce needles (*picea-abies* L). *Plant, Cell and Environment* 16(3):311-316.

During one growing period, 5-year-old spruce trees (*Picea abies* L., Karst.) were exposed in environmental chambers to elevated concentrations of carbon dioxide (750 $\text{cm}^3 \text{m}^{-3}$) and ozone (0.08 $\text{cm}^3 \text{m}^{-3}$) as single variables or in combination. Control concentrations of the gases were 350 $\text{cm}^3 \text{m}^{-3}$ CO₂ and 0.02 $\text{cm}^3 \text{m}^{-3}$ ozone. To investigate whether an elevated CO₂ concentration can prevent adverse ozone effects by reducing oxidative stress, the activities of the protective

enzymes superoxide dismutase, catalase and peroxidase were determined. Furthermore, shoot biomass, pigment and protein contents of two needle age classes were investigated. Ozone caused pigment reduction and visible injury in the previous year's needles and growth reduction in the current year's shoots. In the presence of elevated concentrations of ozone and CO₂, growth reduction in the current year's shoots was prevented, but emergence of visible damage in the previous year's needles was only delayed and pigment reduction was still found. Elevated concentrations of ozone or CO₂ as single variables caused a significant reduction in the activities of superoxide dismutase and catalase in the current year's needles. Minimum activities of superoxide dismutase and catalase and decreased peroxidase activities were found in both needle age classes from spruce trees grown at enhanced concentrations of both CO₂ and ozone. These results suggest a reduced tolerance to oxidative stress in spruce trees under conditions of elevated concentrations of both CO₂ and ozone.

Polley, H.W. 1997. Implications of rising atmospheric carbon dioxide concentration for rangelands. *Journal of Range Management* 50(6):562-577.

Extensive rangelands and other vegetation types that we know today formed while atmospheric carbon dioxide (CO₂) concentration was low (50 to 75% of today's concentration). Fossil fuel burning and deforestation and other land use changes during the last 200 years have increased CO₂ concentration by about 30%, to the present 360 parts per million (ppm). Atmospheric CO₂ will continue to rise during the next century, possibly to concentrations that are unprecedented for the last several million years. Much of the potential importance of CO₂ concentration to vegetation derives from its influence on plant carbon balance and water relations. Plants grow by assimilating CO₂ that diffuses into leaves through stomatal pores. Inevitably associated with CO₂ uptake is transpirational loss of water vapor through stomata. Transpiration rates usually decline as CO₂ increases, while, in many plants, photosynthesis and growth increase. These "primary" responses to CO₂ can lead to a multitude of changes at the plant and ecosystem levels, ranging from alteration of the chemical composition of plant tissues to changes in ecosystem function and the species composition of plant communities. The direct physiological responses of plants to CO₂ and expression of these responses at higher scales differ among species and growing conditions. Growth response to CO₂ is usually highest in rapidly-growing plants that quickly export the carbohydrates formed in leaves and use them for storage or new growth and allocate a high proportion of fixed carbon to produce leaves. Growth is also more responsive to CO₂ in plants with the C-3 (most woody plants and 'cool-season' grasses) than C-4 photosynthetic pathway (most 'warm-season' grasses). These and other differences among species could lead to changes in the composition of rangeland vegetation, but generalizations are difficult. On many rangelands, species abundances are determined more by morphological and phenological attributes that influence plant access to essential resources like nitrogen and light and reaction to fire, grazing, and other disturbances than by physiological traits that are sensitive to CO₂ concentration. Species composition probably will be most responsive to CO₂ on moderately water-limited and disturbed rangelands where multiple positive effects of CO₂ on plant water relations can be expressed and competition for light is minimized. Greatest initial changes in species composition likely will occur on C-3/C-4 grasslands and at the transition between grasslands and woodlands. Plant production should also increase on water-limited rangelands, but CO₂ may have little influence on production when nutrient elements like nitrogen are severely limiting.

Polley, H.W., H.B. Johnson, B.D. Marino, and H.S. Mayeux. 1993. Increase in C3 plant water-use efficiency and biomass over glacial to present CO₂ concentrations. *Nature* 361(6407):61-64.

ATMOSPHERIC CO₂ concentration was 160 to 200 $\mu\text{mol mol}^{-1}$ during the Last Glacial Maximum (LGM; about 18,000 years ago)¹, rose to about 275 $\mu\text{mol mol}^{-1}$ 10,000 years ago^{2,3}, and has increased to about 350 $\mu\text{mol mol}^{-1}$ since 1800 (ref. 4). Here we present data indicating that this increase in CO₂ has enhanced biospheric carbon fixation and altered species abundances by increasing the water-use efficiency of biomass production of C3 plants, the bulk of the Earth's vegetation. We grew oats (*Avena sativa*), wild mustard (*Brassica kaber*) and wheat (*Triticum aestivum* cv. Seri M82 and Yaqui 54), all C3 annuals, and selected C4 grasses along daytime gradients of Glacial to present atmospheric CO₂ concentrations in a 38-m-long chamber. We calculated parameters related to leaf photosynthesis and water-use efficiency from stable carbon isotope ratios (C-13/C-12) of whole leaves. Leaf water-use efficiency and above-ground biomass/plant of C3 species increased linearly and nearly proportionally with increasing CO₂ concentrations. Direct effects of increasing CO₂ on plants must be considered when modelling the global carbon cycle and effects of climate change on vegetation.

Polley, H.W., H.B. Johnson, and H.S. Mayeux. 1992. Growth and gas-exchange of oats (*avena-sativa*) and wild mustard (*brassica-kaber*) at subambient CO₂ concentrations. *International Journal of Plant Science* 153(3):453-461.

A repeated sequence of monocultures and mixtures of oats (*Avena sativa* L.) and wild mustard (*Brassica kaber* (DC.) Wheeler) was grown along a daytime gradient of CO₂ concentrations ([CO₂]) from near 330 to a minimum of 150 $\mu\text{mol mol}^{-1}$. The objectives were to determine effects of subambient [CO₂] on leaf gas exchange, biomass production, and competitive interactions of these C3 species. A decrease in stomatal conductance did not prevent a nearly linear increase in leaf internal [CO₂] and net assimilation of oat leaves as [CO₂] increased. Net assimilation of oats and wild mustard increased from 5.0 and 2.5 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ at 150 $\mu\text{mol mol}^{-1}$, respectively, to 16.1 and 15.9 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ at 330 $\mu\text{mol mol}^{-1}$ CO₂, respectively, when measured at 1,200-1,500 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ incident light. Aboveground biomass per plant of wild mustard and oats increased 106% and 198%, respectively, and leaf area rose more than two- and threefold, respectively, from 154 to 331 mmol mol^{-1} CO₂. The CO₂-induced increase in aboveground biomass of plants of each species did not vary among monocultures and mixtures. Responses of oats and wild mustard to higher subambient [CO₂] were large relative to reported responses of C3 species to comparable increases above the current atmospheric [CO₂]. This suggests that past changes in atmospheric [CO₂], including the 27% rise since the beginning of the nineteenth century, may have profoundly altered the productivity of C3 plants.

Polley, H.W., H.B. Johnson, and H.S. Mayeux. 1994. Increasing CO₂ - comparative responses of the C-4 grass *Schizachyrium* and grassland invader *Prosopis*. *Ecology* 75(4):976-988.

The woody C-3 *Prosopis glandulosa* (honey mesquite) and C-4 perennial grass *Schizachyrium scoparium* (little bluestem) were grown along a gradient of daytime carbon dioxide concentrations from near 340 to 200 $\mu\text{mol mol}^{-1}$ air in a 38 m long controlled environment chamber. We sought to determine effects of historical and prehistorical increases in atmospheric CO₂ concentration on growth, resource use, and competitive interactions of a species representative of C-4-dominated grasslands in the southwestern United States and the invasive legume *P. glandulosa*. Increasing CO₂ concentration stimulated N-2 fixation by individually grown *P. glandulosa* and elicited in C-3 seedlings a similar relative increase in leaf intercellular CO₂ concentration, net assimilation rate, and intrinsic water use efficiency (leaf net assimilation rate/stomatal conductance). Aboveground biomass of *P. glandulosa* was not altered by CO₂ concentration, but belowground biomass and whole-plant water and nitrogen use efficiencies increased linearly with CO₂ concentration in seedlings that were grown alone. Biomass produced by *P. glandulosa* that was grown with *S. scoparium* was not affected by CO₂ concentration. Stomatal conductance declined and leaf assimilation rates of *S. scoparium* at near maximum incident light increased at higher CO₂ concentration, but there was no effect of CO₂ concentration on biomass production or whole-plant water use efficiency of the C-4 grass. Rising CO₂ concentration, especially the 27% increase since the beginning of the 19th century, may have contributed to more abundant *P. glandulosa* on C-4 grasslands by stimulating the shrub's growth or reducing the amount of resources that the C-3 required. Much of the potential response of *P. glandulosa* to CO₂ concentration, however, appears to be contingent on the shrub's escaping competition with neighboring grasses.

Polley, H.W., H.B. Johnson, and H.S. Mayeux. 1995. Nitrogen and water requirements of C3 plants grown at glacial to present carbon-dioxide concentrations. *Functional Ecology* 9(1):86-96.

1. Nitrogen- and water-use efficiencies in biomass production were determined for three C3 plant species at carbon dioxide concentrations ([CO₂]) that spanned glacial to present atmospheric levels [200-350 $\mu\text{mol CO}_2$ (mol air)⁻¹]. The species were annual grasses *Bromus tectorum* and *Triticum aestivum* (two cultivars) and a woody perennial *Prosopis glandulosa* (alone and in mixtures with the C4 grass, *Schizachyrium scoparium*). 2. Changes in nitrogen- and water- use efficiencies were used to investigate effects of increasing [CO₂] on the relative requirements of C3 plants for these frequently limiting resources. 3. Water-use efficiency (biomass produced/evapotranspiration; WUE) increased at higher [CO₂] in all species but relative responses to [CO₂] varied among species, cultivars and watering regimes. 4. Intrinsic WUE (net assimilation/stomatal conductance to water), calculated from stable carbon isotopes in plants, increased by about the same relative amount as did [CO₂] in all species. 5. Nitrogen-use efficiency (biomass produced/plant N; NUE) rose at higher [CO₂] only in well-watered *B. tectorum* and in *P. glandulosa* grown alone. 6. The more consistent increase in WUE than NUE in these species at higher [CO₂] implies that rising [CO₂] may have reduced the amount of water relative to nitrogen that some C3 plants require and

thereby altered the composition and function of terrestrial ecosystems.

Polley, H.W., H.B. Johnson, and H.S. Mayeux. 1997. Leaf physiology, production, water use, and nitrogen dynamics of the grassland invader *Acacia smallii* at elevated CO₂ concentrations. *Tree Physiology* 17(2):89-96.

Invasion by woody legumes can alter hydrology, nutrient accumulation and cycling, and carbon sequestration on grasslands. The rate and magnitude of these changes are likely to be sensitive to the effects of atmospheric CO₂ enrichment on growth and water and nitrogen dynamics of leguminous shrubs. To assess potential effects of increased atmospheric CO₂ concentrations on plant growth and acquisition and utilization of water and nitrogen, seedlings of *Acacia smallii* Isely (huisache) were grown for 13 months at CO₂ concentrations of 385 (ambient), 690, and 980 $\mu\text{mol mol}^{-1}$. Seedlings grown at elevated CO₂ concentrations exhibited parallel declines in leaf N concentration and photosynthetic capacity; however, at the highest CO₂ concentration, biomass production increased more than 2.5-fold as a result of increased leaf photosynthetic rates, leaf area, and N₂ fixation. Measurements of leaf gas exchange and aboveground biomass production and soil water balance indicated that water use efficiency increased in proportion to the increase in atmospheric CO₂ concentration. The effects on transpiration of an accompanying decline in leaf conductance were offset by an increase in leaf area, and total water loss was similar across CO₂ treatments. Plants grown at elevated CO₂ fixed three to four times as much N as plants grown at ambient CO₂ concentration. The increase in N₂ fixation resulted from an increase in fixation per unit of nodule mass in the 690 $\mu\text{mol mol}^{-1}$ CO₂ treatment and from a large increase in the number and mass of nodules in plants in the 980 $\mu\text{mol mol}^{-1}$ CO₂ treatment. Increased symbiotic N₂ fixation by woody invaders in response to CO₂ enrichment may result in increased N deposition in litterfall, and thus increased productivity on many grasslands.

Polley, H.W., H.B. Johnson, H.S. Mayeux, D.A. Brown, and J.W.C. White. 1996. Leaf end plant water use efficiency of C-4 species grown at glacial to elevated CO₂ concentrations. *International Journal of Plant Science* 157(2):164-170.

Leaf gas exchange was measured on C-4 plants grown from near glacial to current CO₂ concentrations (200-350 $\mu\text{mol mol}^{-1}$) and from the current concentration to possible future levels (near 700 and 1000 $\mu\text{mol mol}^{-1}$) to test the prediction that intrinsic water use efficiency (CO₂ assimilation [A]/stomatal conductance to water [g]) would rise by a similar relative amount as CO₂ concentration. Studied were species differing in growth form or life history, the perennial grass *Schizachyrium scoparium* (little bluestem), perennial shrub *Atriplex canescens* (four-wing saltbush), and annual grass *Zea mays* (maize). Contrary to our prediction, leaf A/g of the C-4 species examined was stimulated proportionally more by a given relative increase in CO₂ over subambient than by elevated concentrations. The ratio of the relative increase in A/g to that in CO₂ exceeded unity in *S. scoparium* and, in 1 of 2 yr, in *Z. mays* as CO₂ rose from 200 to 350 $\mu\text{mol mol}^{-1}$, but

declined to near zero in *S. scoparium* and *A. canescens* as CO₂ rose from 700 to 1000 $\mu\text{mol mol}^{-1}$. At higher CO₂ concentrations, A/g of the C-4 perennials was similar to that expected for C-3 plants. Since much of the potential response of C-4 plants to CO₂ often derives from higher water use efficiency (WUE), these results indicated that potential productivity of some C-4 plants increased relatively more since glaciation than it will in the future. There also were large (>100%) differences in A/g and plant WUE (production/transpiration) at a given CO₂ level among the plants examined that could influence the relative productivities of C-4 species or growth forms and their interactions with C-3 plants.

Polley, H.W., H.B. Johnson, H.S. Mayeux, C.R. Tischler, and D.A. Brown. 1996. Carbon dioxide enrichment improves growth, water relations and survival of droughted honey mesquite (*Prosopis glandulosa*) seedlings. *Tree Physiology* 16(10):817-823.

Low water availability reduces the establishment of the invasive shrub *Prosopis* on some grasslands. Water deficit survival and traits that may contribute to the postponement or tolerance of plant dehydration were measured on seedlings of *P. glandulosa* Torr. var. *glandulosa* (honey mesquite) grown at CO₂ concentrations of 370 (ambient), 710, and 1050 $\mu\text{mol mol}^{-1}$. Because elevated CO₂ decreases stomatal conductance, the number of seedlings per container in the elevated CO₂ treatments was increased to ensure that soil water content was depleted at similar rates in all treatments. Seedlings grown at elevated CO₂ had a greater root biomass and a higher ratio of lateral root to total root biomass than those grown at ambient CO₂ concentration; however, these seedlings also shed more leaves and retained smaller leaves. These changes, together with a reduced transpiration/leaf area ratio at elevated CO₂, may have contributed to a slight increase in xylem pressure potentials of seedlings in the 1050 $\mu\text{mol mol}^{-1}$ CO₂ treatment during the first 37 days of growth (0.26 to 0.40 MPa). Osmotic potential was not affected by CO₂ treatment. Increasing the CO₂ concentration to 710 and 1050 $\mu\text{mol mol}^{-1}$ more than doubled the percentage survival of seedlings from which water was withheld for 65 days. Carbon dioxide enrichment significantly increased survival from 0% to about 40% among seedlings that experienced the lowest soil water content. By increasing seedling survival of drought, rising atmospheric CO₂ concentration may increase abundance of *P. glandulosa* on grasslands where low water availability limits its establishment.

Polley, H.W., H.B. Johnson, C.R. Tischler, and H.A. Torbert. 1999. Links between transpiration and plant nitrogen: Variation with atmospheric CO₂ concentration and nitrogen availability. *International Journal of Plant Science* 160(3):535-542.

Transpiration is closely linked to plant nitrogen (N) content, indicating that global or other changes that alter plant N accumulation or the relative requirements of plants for water and N will affect transpiration. We studied effects of N availability and atmospheric CO₂ concentration, two components of global biogeochemistry that are changing, on relationships between whole-plant transpiration and N in two perennial C-3 species, *Pseudoroegneria spicata* (a tussock grass) and *Gutierrezia microcephala* (a half-shrub). Two indices of plant N requirement were used: N accretion (N in live and dead tissues) and N loss in litter (N in dead tissues). Transpiration was analyzed as the product of N accretion or loss by plants and the ratio of transpiration to N accretion or loss. The two indices of plant N requirement led to different conclusions as to the effects of N availability on plant use of water relative to N. Transpiration scaled proportionally with N accretion, but transpiration per unit of N loss declined at high N. Carbon dioxide enrichment had little effect on the ratio of transpiration to N accretion and no effect on transpiration per unit of N loss. The two species accumulated similar amounts of N, but the half-shrub used more than twice as much water as the grass. Nitrogen availability and CO₂ concentration influenced whole-plant transpiration more by changing plant N accumulation than by altering the stoichiometry between transpiration and plant N. Species differences in total water use, by contrast, reflected differences in the scaling of transpiration to plant N. A better understanding of species differences in water and N dynamics may thus be required to predict transpiration reliably.

Polley, H.W., H.S. Mayeux, H.B. Johnson, and C.R. Tischler. 1997. Viewpoint: Atmospheric CO₂, soil water, and shrub/grass ratios on rangelands. *Journal of Range Management* 50(3):278-284.

The abundance of woody plants on grasslands and savannas often is controlled by the availability of water and its location in soil. Water availability to plants is limited by precipitation, but the distribution of soil water and period over which it is available in these ecosystems are influenced by the transpiration rates of grasses. We discuss implications of recent and projected increases in atmospheric CO₂ concentration for transpiration, soil water availability, and the balance of grasses and shrubs. An increase in CO₂ concentration often reduces potential transpiration/leaf area by reducing stomatal conductance. On grasslands where effects of stomatal closure on transpiration are not negated by an increase in leaf temperature and leaf area, rising CO₂ concentration should slow the depletion of soil water by grasses and potentially favor shrubs and other species that might otherwise succumb to water stress. Predicted effects of CO₂ are supported by results from CO₂-enrichment studies in the field and are compatible with recent models of interactions between resource levels and vegetation pattern and structure.

Polley, H.W., C.R. Tischler, H.B. Johnson, and R.E. Pennington. 1999. Growth, water relations, and survival of drought-exposed seedlings from six maternal families of honey mesquite (*Prosopis glandulosa*): responses to CO₂ enrichment. *Tree Physiology* 19(6):359-366.

Low water availability is a leading contributor to mortality of woody

seedlings on grasslands, including those of the invasive shrub *Prosopis*. Increasing atmospheric CO₂ concentration could favor some genotypes of this species over others if there exists intraspecific variation in the responsiveness of survivorship to CO₂. To investigate such variation, we studied effects of CO₂ enrichment on seedling survival in response to uniform rates of soil water depletion in six maternal families of honey mesquite (*P. glandulosa* Torr. var. *glandulosa*). Three families each from the arid and mesic extremes of the species' distribution in the southwestern United States were studied in environmentally controlled glasshouses. Relative water content at turgor loss and osmotic potential were not affected by CO₂ treatment. Increased atmospheric CO₂ concentration, however, increased growth, leaf production and area, and midday xylem pressure potential, and apparently reduced transpiration per unit leaf area of seedlings as soil dried. Consequently, CO₂ enrichment about doubled the fraction of seedlings that survived soil water depletion. Maternal families of honey mesquite differed in percentage survival of drought and in several other characteristics, but differences were of similar or of smaller magnitude compared with differences between CO₂ treatments. There was no evidence for genetic variation in the responsiveness of survivorship to CO₂. By increasing seedling survival of drought, increasing atmospheric CO₂ concentration could increase the abundance of honey mesquite where establishment is limited by water availability. Genetic types with superior ability to survive drought today, however, apparently will maintain that advantage in the future.

Pons, T.L., and R.W. Pearcy. 1994. Nitrogen reallocation and photosynthetic acclimation in response to partial shading in soybean plants. *Physiologia Plantarum* 92(4):636-644.

The first trifoliolate of soybean was shaded when fully expanded, while the plant remained in high light; a situation representative for plants growing in a closed crop. Leaf mass and respiration rate per unit area declined sharply in the first few days upon shading and remained rather constant during the further 12 days of the shading treatment. Leaf nitrogen per unit area decreased gradually until the leaves were shed. Leaf senescence was enhanced by the shading treatment in contrast to control plants growing in low light. Shaded leaves on plants grown at low nutrient availability senesced earlier than shaded leaves on plants grown at high nutrient availability. The light saturated rate of photosynthesis decreased also gradually during the shading treatment, but somewhat faster than leaf N, whereas chlorophyll contents declined somewhat slower than leaf N. Partitioning of N in the leaf over main photosynthetic functions was estimated from parameters derived from the response of photosynthesis to CO₂. It appeared that the N exported from the leaf was more at the expense of compounds that make up photosynthetic capacity than of those involved in photon absorption, resulting in a change in partitioning of N within the photosynthetic apparatus. Photosynthetic nitrogen use efficiency increased during the shading treatment, which was for the largest part due to the decrease in leaf N content, to some extent to the decrease in respiration rate and only for a small part to change in partitioning of N within the photosynthetic apparatus.

Poorter, H. 1993. Interspecific variation in the growth-response of

plants to an elevated ambient CO₂ concentration. *Vegetatio* 104:77-97.

The effect of a doubling in the atmospheric CO₂ concentration on the growth of vegetative whole plants was investigated. In a compilation of literature sources, the growth stimulation of 156 plant species was found to be on average 37%. This enhancement is small compared to what could be expected on the basis of CO₂-response curves of photosynthesis. The causes for this stimulation being so modest were investigated, partly on the basis of an experiment with 10 wild plant species. Both the source-sink relationship and size constraints on growth can cause the growth-stimulating effect to be transient. Data on the 156 plant species were used to explore interspecific variation in the response of plants to high CO₂. The growth stimulation was larger for C₃ species than for C₄ plants. However the difference in growth stimulation is not as large as expected as C₄ plants also significantly increased in weight (41% for C₃ vs. 22 % for C₄). The few investigated CAM species were stimulated less in growth (15%) than the average C₄ species. Within the group of C₃ species, herbaceous crop plants responded more strongly than herbaceous wild species (58% vs. 35%) and potentially fast-growing wild species increased more in weight than slow-growing species (54% vs. 23%). C₃ species capable of symbiosis with N₂-fixing organisms had higher growth stimulations compared to other C₃ species. A common denominator in these 3 groups of more responsive C₃ plants might be their large sink strength. Finally, there was some tendency for herbaceous dicots to show a larger response than monocots. Thus, on the basis of this literature compilation, it is concluded that also within the group of C₃ species differences exist in the growth response to high CO₂.

Poorter, H. 1998. Do slow-growing species and nutrient-stressed plants respond relatively strongly to elevated CO₂? *Global Change Biology* 4(6):693-697.

Mainly based on a simulation model, Lloyd & Farquhar (1996; *Functional Ecology*, 10, 4-32) predict that inherently slow-growing species and nutrient-stressed plants show a relatively strong growth response to an increased atmospheric CO₂ concentration. Compiling published experiments, I conclude that these predictions are not supported by the available data. On average, inherently fast-growing species are stimulated proportionately more in biomass than slow-growing species and plants grown at a high nutrient supply respond more strongly than nutrient-stressed plants.

Poorter, H., and R. De Jong. 1999. A comparison of specific leaf area, chemical composition and leaf construction costs of field plants from 15 habitats differing in productivity. *New Phytologist* 143(1):163-176.

Laboratory experiments have shown a large difference in specific leaf area (SLA, leaf area:leaf mass) between species from nutrient-poor and nutrient-rich habitats, but no systematic difference in the construction costs (the amount of glucose required to construct 1 g biomass). We examined how far these patterns are congruent with those from field-grown plants. An analysis was made of the vegetation in a range of

grasslands and heathlands differing in productivity. The SLA of the dominant species in 15 different habitats was determined, as well as chemical composition and construction costs of bulk samples of leaves. SLA in the field was generally lower than in the laboratory, but showed consistency in that the ranking across species remained the same. Species from highly productive habitats had higher SLA than those from sites of low productivity, although individual species sometimes deviated substantially from the general trend. Construction costs were similar for plants from different habitats. This was mainly due to the positive correlation between an expensive class of compounds (proteins) and a cheap one (minerals).

Poorter, H., R.M. Gifford, P.E. Kriedemann, and S.C. Wong. 1992. A quantitative-analysis of dark respiration and carbon content as factors in the growth-response of plants to elevated CO₂. *Australian Journal of Botany* 40(4-5):501-513.

An analysis of elevated CO₂ effects (2-4 times ambient) on dark respiration rate and carbon content was undertaken for a wide range of plant species, using both published reports and new data. On average, leaf respiration per unit leaf area was slightly higher for plants grown at high CO₂ (16%), whereas a small decrease was found when respiration was expressed on a leaf weight basis (14%). For the few data on root respiration, no significant change due to high CO₂ could be detected. Carbon content of leaves and stem showed a small increase (1.2 and 1.7% respectively), whereas C-content of roots was not significantly affected. In both data sets direction of responses was variable. A sensitivity analysis of carbon budgets under elevated CO₂ identified changes in respiration rate, and to a lesser extent carbon content, as important factors affecting the growth response to elevated CO₂ in quite a number of cases. Any comprehensive analysis of growth responses to increased CO₂ should therefore include measurements of these two variables.

Poorter, H., Y. VanBerkel, R. Baxter, J. DenHertog, P. Dijkstra, R.M. Gifford, K.L. Griffin, C. Roumet, J. Roy, and S.C. Wong. 1997. The effect of elevated CO₂ on the chemical composition and construction costs of leaves of 27 C-3 species. *Plant, Cell and Environment* 20(4):472-482.

We determined the proximate chemical composition as well as the construction costs of leaves of 27 species, grown at ambient and at a twice-ambient partial pressure of atmospheric CO₂. These species comprised wild and agricultural herbaceous plants as well as tree seedlings. Both average responses across species and the range in response were considered. Expressed on a total dry weight basis, the main change in chemical composition due to CO₂ was the accumulation of total non- structural carbohydrates (TNC). To a lesser extent, decreases were found for organic N compounds and minerals. Hardly any change was observed for total structural carbohydrates (cellulose plus hemicellulose), lignin and lipids. When expressed on a TNC-free basis, decreases in organic N compounds and minerals were still present. On this basis, there was also an increase in the concentration of soluble phenolics. In terms of glucose required for biosynthesis, the increase in costs for one chemical compound - TNC - was balanced by a decrease in the costs for organic N compounds. Therefore, the construction costs,

the total amount of glucose required to produce 1 g of leaf, were rather similar for the two CO₂ treatments; on average a small decrease of 3% was found. This decrease was attributable to a decrease of up to 30% in the growth respiration coefficient, the total CO₂ respired [mainly for NAD(P)H and ATP] in the process of constructing 1 g of biomass. The main reasons for this reduction were the decrease in organic N compounds and the increase in TNC.

Popova, L.P., T.D. Tsonev, G.N. Lazova, and Z.G. Stoinova. 1996. Drought- and ABA-induced changes in photosynthesis of barley plants. *Physiologia Plantarum* 96(4):623-629.

The changes caused by drought stress and abscisic acid (ABA) on photosynthesis of barley plants (*Hordeum vulgare* L. cv. Alfa) have been studied. Drought stress was induced by allowing the leaves to lose 12% of their fresh weight. Cycloheximide (CHI), an inhibitor of stress-induced ABA accumulation, was used to distinguish alterations in photosynthetic reactions that are induced after drought stress in response to elevated ABA levels from those that are caused directly by altered water relations. Four hours after imposition of drought stress or 2 h after application of ABA, the bulk of the leaf's ABA content measured by enzyme-amplified ELISA, increased 14- and 16-fold, respectively. CHI fully blocked the stress-induced ABA accumulation. Gas exchange measurements and analysis of enzyme activities were used to study the reactions of photosynthesis to drought stress and ABA. Leaf dehydration or ABA treatment led to a noticeable decrease in both the initial slope of the curves representing net photosynthetic rate versus intercellular CO₂ concentration and the maximal rate of photosynthesis; dehydration of CHI treated plants showed much slower inhibition of the latter. The calculated values of the intercellular CO₂ concentration, CO₂ compensation point and maximal carboxylating efficiency of ribulose 1,5-bisphosphate (RuBP) carboxylase support the suggestion that biochemical factors are involved in the response of photosynthesis to ABA and drought stress. RuBP carboxylase activity was almost unaffected in ABA- and CHI-treated, non-stressed plants. A drop in enzyme activity was observed after leaf dehydration of the control and ABA-treated plants. When barley plants were supplied with ABA, the activity of carbonic anhydrase (CA, EC 4.2.2.1) increased more than 2-fold. Subsequent dehydration caused an over 1.5-fold increase in CA activity of the control plants and a more than 2.5-fold increase in ABA-treated plants. Dehydration of CHI-treated plants caused no change in enzyme activity. It is suggested that increased activity of CA is a photosynthetic response to elevated ABA concentration.

Porte, A., and D. Loustau. 1998. Variability of the photosynthetic characteristics of mature needles within the crown of a 25-year-old *Pinus pinaster*. *Tree Physiology* 18(4):223-232.

Photosynthetic characteristics of 1- and 2-year-old needles were determined in excised shoots of maritime pine (*Pinus pinaster* Ait.) with an open gas exchange system. We used the nonlinear least mean squares method to derive values for quantum yield of electron transport (α), maximum carboxylation velocity (V_{cmax}), and maximum electron transport rate ($J(max)$), from photosynthetic response curves to light and CO₂. Crown height had no significant effect on any of the parameters; however, V_{cmax} and $J(max)$, as well as α were 43, 26 and 35% higher,

respectively, in 1-year-old needles than in 2-year-old needles. The main effect of irradiance on needles was a small decline in leaf concentrations of nitrogen and phosphorus from the top to the bottom of the canopy. Only $J(max)$ demonstrated a linear relationship with both nitrogen content ($R^2 = 0.42$) and irradiance at the shoot level. Because needle age accounted for most of the variability in photosynthesis, we incorporated needle age into the photosynthesis model of Farquhar et al. (1980). The modified model underestimated the daily assimilation rate of 1-year-old needles in the field, especially when assimilation rates were high.

Portielje, R., and L. Lijklema. 1995. Carbon-dioxide fluxes across the air-water-interface and its impact on carbon availability in aquatic systems. *Limnology and Oceanography* 40(4):690-699.

Diffusion of CO₂ across the air-water interface was analyzed with a model that simulates both transport and reaction of CO₂ in a stagnant boundary layer. The atmospheric C influx was determined in relation to several environmental variables: pH, total dissolved inorganic C, temperature, and the thickness of the stagnant boundary layer in relation to ambient windspeed. We used the model to calculate the atmospheric CO₂ influx into six experimental ditches for a period of 6 or 8 months, starting in early spring. Three of the six ditches were dominated by aquatic macrophytes and three by benthic algae. Each series received three levels of external N and P input. A comparison with net C assimilation during the same period, as estimated from continuous oxygen measurements, showed that, especially in the ditches dominated by submersed macrophytes, a sizable fraction of the C requirements during this period could have been obtained from atmospheric CO₂. In the ditches dominated by benthic algae, this fraction was considerably less, but nonetheless substantial, and was related to the level of N and P loading. Increased primary production due to enhanced external N and P loading increased the atmospheric C input due to the resultant higher pH values. The trophic state with respect to N and P and the availability of C are therefore interrelated.

Pospisilova, J., and J. Catsky. 1999. Development of water stress under increased atmospheric CO₂ concentration. *Biologia Plantarum* 42(1):1-24.

The increase in water use efficiency (the ratio of photosynthetic to transpiration rates) is likely to be the commonest positive effect of long-term elevation in CO₂ concentration (CE). This may not necessarily lead to decrease in long-term water use owing to increased leaf area. However, some plant species seem to cope better with drought stress under CE, because increased production of photosynthates might enhance osmotic adjustment and decreased stomatal conductance and transpiration rate under CE enable plants to maintain a higher leaf water potential during drought. In addition, at the same stomatal conductance, internal CO₂ concentration might be higher under CE which results in higher photosynthetic rate. Therefore plants under CE of the future atmosphere will probably survive eventual higher drought stress and some species may even be able to extend their biotope into less favourable sites.

Pospisilova, J., J. Solarova, and J. Catsky. 1992. Photosynthetic responses to stresses during invitro cultivation. *Photosynthetica* 26(1):3-18.

Present knowledge of photosynthesis, biomass production and water relations of plantlets cultivated in vitro and their responses to environmental conditions is reviewed. Acclimation of plantlets, firstly to very special in vitro conditions and secondly after transplanting to ex vitro conditions, is considered. Low irradiance and CO₂ concentration inside cultivation vessels restrict photosynthetic rate and accumulation of biomass by plantlets in situ. Nevertheless the photosynthetic apparatus is often fully developed. Therefore net photosynthetic rate and hence biomass accumulation can increase immediately after artificial increase in CO₂ concentration inside the vessels (this enables autotrophic cultivation of plantlets as one of important future technologies) or after transplanting to glasshouse or field. On the other hand, under very high humidity and low irradiance in vitro, efficient regulation of gas exchange does not operate. The development of functional stomata and cuticle requires some weeks of acclimation to natural conditions.

Pospisilova, J., H. Synkova, D. Haisel, J. Catsky, N. Wilhelmova, and F. Sramek. 1999. Effect of elevated CO₂ concentration on acclimation of tobacco plantlets to ex vitro conditions. *Journal of Experimental Botany* 50(330):119-126.

Nicotiana tabacum L, plants grown in vitro were transferred to ex vitro conditions and grown for 28 d in a greenhouse under normal CO₂ concentration (C, 330 pmol mol⁻¹) or elevated CO₂ concentration (E, 1000 pmol mol⁻¹). Stomatal conductances of abaxial and adaxial epidermes measured under optimal conditions were not significantly affected by growth under E, but the stomatal regulation of gas exchange was better. Leaf photosynthetic rate (A) of elevated CO₂ plants was similar to that of control plants when both were measured under normal CO₂, but higher when both were measured under elevated CO₂. The A of elevated CO₂ plants was much higher than the A of control plants when measured under their respective growth CO₂ concentration, which resulted in their higher growth rate. Chlorophyll a and b contents, and activities of whole electron transport chain and of photosystem (PS) II were not markedly affected by growth under E, and the maximum efficiency of PSII measured as the ratio of variable to maximum fluorescence was even slightly increased. Hence no down-regulation of photosynthesis occurred in transplanted plants grown for 4 weeks under E. The contents of p-carotene and of xanthophyll cycle pigments (violaxanthin + antheraxanthin+zeaxanthin) were lower in E plants. The degree of de-epoxidation of xanthophyll cycle pigments was not changed or was even lower after transfer to ex vitro conditions, which indicated that no photoinhibition occurred. Therefore, CO₂ enrichment can improve acclimation of in vitro-grown plantlets to ex vitro conditions.

Plantlets of *Nicotiana tabacum* L. cv, Petit Havana SR1 were grown in vitro on Murashige and Skoog medium containing 2% saccharose, and then transplanted ex vitro into pots with coarse sand and Hewitt nutrient solution. In the first day after transplantation, the antitranspirant abscisic acid (ABA; 0.01, 0.05 or 0.10 mM) was added to the substrate. Leaf stomatal conductance (g(s)), which was high in plants during the first days after transplantation similarly as in plantlets grown in vitro, was considerably decreased by ABA-treatment. However, in the further days g(s) decreased more quickly in control than in ABA-treated plants, and after 2 or 3 weeks g(s) was significantly lower than that of plantlets grown in vitro but similar in control and ABA-treated plants. Two weeks after transplantation, net photosynthetic rate, chlorophyll a + b content, maximal photochemical efficiency, and actual quantum yield of photosystem II in plant leaves were higher in comparison with those in plantlets grown in vitro. ABA- treatment had slight positive or insignificant effect on photosynthetic parameters and enhanced plant growth. Thus ABA application can alleviate 'transplant shock' and speed up acclimation of plantlets to ex vitro conditions.

Possingham, H.P. 1993. Impact of elevated atmospheric CO₂ on biodiversity - mechanistic population-dynamic perspective. *Australian Journal of Botany* 41(1):11-21.

Biodiversity is characteristically defined on three levels: genetic diversity, species diversity and ecosystem diversity. In this paper I consider the impact of elevated CO₂ and associated climate change on the biodiversity of terrestrial systems at the species level. I attempt to understand the impact of a rapidly changing physical environment mechanistically. The direct impact of elevated CO₂ is emphasised. A changing physical environment will cause behavioural and physiological responses in organisms that will affect population dynamics and interspecific relationships. In the short term, extinctions will occur via the direct interaction of species with their changing environment. Species exposed to new diseases, and species dependent on mutualists or keystone species that become extinct or change geographical range, may become extinct rapidly through interactions with other species. I hypothesise that the effect of environmental change on competitive interactions will play a minor role in causing declines in biodiversity. Existing literature on the impact of climate change on terrestrial ecosystems emphasises the way in which ecosystems and species should track suitable climates across the landscape. Here I argue that each species will be affected in one, or a combination, of the following ways: range change to track shifting climate zones, tolerating the environmental change, microevolutionary change, and extinction.

Post, W.M., J. Pastor, A.W. King, and W.R. Emanuel. 1992. Aspects

of the interaction between vegetation and soil under global change. *Water, Air, and Soil Pollution* 64(1-2):345-363.

Responses of terrestrial ecosystems to a world undergoing a change in atmospheric CO₂ concentration presents a formidable challenge to terrestrial ecosystem scientists. Strong relationships among climate, atmosphere, soils and biota at many different temporal and spatial scales make the understanding and prediction of changes in net ecosystem production (NEP) at a global scale difficult. Global C cycle models have implicitly attempted to account for some of this complexity by adapting lower pool sizes and smaller flux rates representing large regions and long temporal averages than values appropriate for a small area. However, it is becoming increasingly evident that terrestrial ecosystems may be experiencing a strong transient forcing as a result of increasing levels of atmospheric CO₂ that will require a finer temporal and spatial representation of terrestrial systems than the parameters for current global C cycle models allow. To adequately represent terrestrial systems, in the global C cycle it is necessary to explicitly model the response of terrestrial systems to primary environmental factors. While considerable progress has been made experimentally and conceptually in aspects of photosynthetic responses, and gross and net primary production, the application of this understanding to NEP at individual sites is not well developed. This is an essential step in determining effects of plant physiological responses on the global C cycle. We use a forest stand succession model to explore the effects of several possible plant responses to elevated atmospheric CO₂ concentration. These simulations show that ecosystem C storage can be increased by increases in individual tree growth rate, reduced transpiration, of increases in fine root production commensurate with experimental observations.

Potosnak, M.J., S.C. Wofsy, A.S. Denning, T.J. Conway, J.W. Munger, and D.H. Barnes. 1999. Influence of biotic exchange and combustion sources on atmospheric CO₂ concentrations in New England from observations at a forest flux tower. *Journal of Geophysical Research-Atmospheres* 104(D8):9561-9569.

Hourly data for concentrations and fluxes of CO₂ at 30 m in Harvard Forest (Petersham, Massachusetts) are analyzed using linear modeling to obtain regionally representative CO₂ concentrations at a continental site. The time series is decomposed into contributions due to regional combustion, local canopy exchange, monthly average regional biotic exchange (as modulated by the daily cycle of growth and decay of the planetary boundary layer (PBL)), and the regional monthly background concentration. Attributions are derived using time series analysis, data for a tracer for combustion (CO or acetylene (C₂H₂)), and measurements of indicators of proximate canopy exchange (CO₂ flux and momentum flux). Results are compared to observations at Cold Bay, Alaska. Combustion contributes on average 4-5 ppm to ambient CO₂ at Harvard Forest in winter and 2-3 ppm in summer. Regional biotic emissions elevate daily mean CO₂ by 4-6 ppm in winter, and the covariance of the biotic cycle of uptake and emission with PBL height enhances daily mean CO₂ by 1-2 ppm in summer; minimum values in late afternoon average 10 ppm lower than at Cold Bay in summer. The study shows that regionally representative concentrations of CO₂ can be determined at continental sites if suitable correlates (tracers, fluxes of CO₂, and momentum) are measured simultaneously with CO₂ itself.

Potter, C.S., and S.A. Klooster. 1999. Detecting a terrestrial biosphere sink for carbon dioxide: Interannual ecosystem modeling for the mid-1980s. *Climatic Change* 42(3):489-503.

There is considerable uncertainty as to whether interannual variability in climate and terrestrial ecosystem production is sufficient to explain observed variation in atmospheric carbon content over the past 20-30 years. In this paper, we investigated the response of net CO₂ exchange in terrestrial ecosystems to interannual climate variability (1983 to 1988) using global satellite observations as drivers for the NASA- CASA (Carnegie-Ames-Stanford Approach) simulation model. This computer model of net ecosystem production (NEP) is calibrated for interannual simulations driven by monthly satellite vegetation index data (NDVI) from the NOAA Advanced Very High Resolution Radiometer (AVHRR) at 1 degree spatial resolution. Major results from NASA-CASA simulations suggest that from 1985 to 1988, the northern middle-latitude zone (between 30 and 60 degrees N) was the principal region driving progressive annual increases in global net primary production (NPP; i.e., the terrestrial biosphere sink for carbon). The average annual increase in NPP over this predominantly northern forest zone was on the order of +0.4 Pg (10¹⁵ g) C per year. This increase resulted mainly from notable expansion of the growing season for plant carbon fixation toward the zonal latitude extremes, a pattern uniquely demonstrated in our regional visualization results. A net biosphere source flux of CO₂ in 1983-1984, coinciding with an El Nino event, was followed by a major recovery of global NEP in 1985 which lasted through 1987 as a net carbon sink of between 0.4 and 2.6 Pg C per year. Analysis of model controls on NPP and soil heterotrophic CO₂ fluxes (R-h) suggests that regional warming in northern forests can enhance ecosystem production significantly. In seasonally dry tropical zones, periodic drought and temperature drying effects may carry over with at least a two-year lag time to adversely impact ecosystem production. These yearly patterns in our model-predicted NEP are consistent in magnitude with the estimated exchange of CO₂ by the terrestrial biosphere with the atmosphere, as determined by previous isotopic (delta(13)C) deconvolution analysis. Ecosystem simulation results can help further target locations where net carbon sink fluxes have occurred in the past or may be verified in subsequent field studies.

Potvin, C., and D. Tousignant. 1996. Evolutionary consequences of simulated global change: Genetic adaptation or adaptive phenotypic plasticity. *Oecologia* 108(4):683-693.

During the next century, natural and agricultural systems might need to adjust to a rapid increase in atmospheric CO₂ concentration and global temperature. Evolution of genotypes adapted to this global change could play a central role in plants' response. The main purpose of this study was to determine the relative importance of phenotypic and genotypic responses of plants to global change. To do so, we selected two populations of the short-lived *Brassica juncea*, one under ambient conditions and another one under conditions simulating global change. After seven generations of selection, differences between the two populations were examined using a reciprocal transplant garden. We monitored 14 different traits and found evidence for genetic adaptation only once, for vegetative biomass early in the growth cycle. Of the 14 traits, 11 responded plastically to the environment, but only one of these plastic changes had a possible adaptive value. Overall, the long-term evolutionary consequences of global change will depend on the response of fitness-related traits. None of the five reproductive traits measured showed any evolutionary responses. The main conclusion of our study is that *Brassica juncea* was apparently unable to respond evolutionarily to simulated global change either by genetic adaptation or by adaptive

phenotypic plasticity. The Limit to selection was apparently due to inbreeding depression induced by the harsh conditions of the "predicted" environment.

Potvin, C., and L. Vasseur. 1997. Long-term CO₂ enrichment of a pasture community: Species richness, dominance, and succession. *Ecology* 78(3):666-677.

The present study addresses responses of a pasture community to CO₂ enrichment in situ. It focused on two levels of organization. We examined changes in both community properties and species-specific responses during long-term exposure to high CO₂ concentration. The underlying hypothesis is that CO₂ enrichment could change community composition. At the community level, we observed higher species richness and lesser dominance under enriched than ambient CO₂. Two species were apparently central in explaining our results, *Agropyron repens* and *Plantago major*. The cover of this first species increased only under ambient CO₂. Conversely, the cover of the latter species decreased under ambient CO₂ but remained stable under enriched CO₂. Species were pooled into dicots and monocots to examine space acquisition. Changes in monocot cover through time were more tightly coupled with that of dicots under ambient than high CO₂. Enrichment with CO₂ appeared to have a positive effect on the early-successional species, preventing the complete dominance by late-successional species. In fact, under elevated CO₂ early- and late-successional species were coexisting. Therefore, our results suggest the possibility that succession patterns might be altered by CO₂ enrichment apparently because enriched CO₂ stimulates the growth of dicots.

Poulin, M.J., R. Belrhliid, Y. Piche, and R. Chenevert. 1993. Flavonoids released by carrot (*daucus-carota*) seedlings stimulate hyphal development of vesicular-arbuscular mycorrhizal fungi in the presence of optimal CO₂ enrichment. *Journal of Chemical Ecology* 19(10):2317-2327.

Carbon dioxide has been previously identified as a critical volatile factor that stimulates hyphal growth of *Gigaspora margarita*, a vesicular-arbuscular mycorrhizal fungus, and we determined the optimal concentration at 2.0%. The beneficial effect of CO₂ on fungal development is also visible in the presence of stimulatory (quercetin, myricetin) or inhibitory (naringenin) flavonoids. Sterile root exudates from carrot seedlings stimulate the hyphal development of *G. margarita* in the presence of optimal CO₂ enrichment. Three flavonols (quercetin, kaempferol, rutin or quercetin 3-rutinoside) and two flavones (apigenin, luteolin) were identified in carrot root exudates by means of HPLC retention time. Flavonols like quercetin and kaempferol are known to have stimulatory effects on hyphal growth of *G. margarita*.

Prade, K., and V. Hagelgans. 1993. Enrichment of N₂ and Ar in the

atmosphere of CO₂-consuming soils. *Zeitschrift Fur Pflanzenernahrung Und Bodenkunde* 156(5):421-426.

The phenomenon of unexplained N₂/Ar-enrichment in soil air is quite frequently to be encountered in soil air studies on anthropogenically influenced sites. In the present study two anthropogenic deposits and a calcareous fluvisol were investigated for their soil air composition. While in the alkaline deposits extreme enrichments of N₂ and Ar (N₂ + Ar: up to 99%, v/v) were found as persistent site characteristics, the fluvisol showed only slight (about 1%, v/v) transient N₂/Ar-enrichments in summer. All sites, which did not show substantial vertical seepage percolation, exhibited enhanced CO₂-Solubility either due to strong calcite precipitation or dissolution. So, it was concluded that intensive continuous depletion of CO₂ was responsible for the subsequent convective influx of atmospheric air. From the results obtained it was concluded that an encasement of the concerned soil volume rather impermeable to gas transport as well as intense dissolution of CO₂ in the pore water are prerequisites for substantial N₂/Ar-enrichments in soil air.

Prakash, O., A. Sood, M. Sharma, and P.S. Ahuja. 1999. Grafting micropropagated tea [*Camellia sinensis* (L.) O. Kuntze] shoots on tea seedlings - a new approach to tea propagation. *Plant Cell Reports* 18(10):883-888.

Tea microshoots excised from well-established multiple shoot cultures grown in vitro and 8-week-old, three- to five-leaved seedlings from a local chinery stock (Banuri-96) and UPASI-9 (from southern India) were selected as scions and root stocks, respectively, for grafting. In addition, 4-month- and 12-month-old seedlings of Banuri-96 were also used as root stocks. Cut ends of root stocks and scions were pretreated with varying concentrations of BAP and NAA for 10 min. A treatment of BAP (5 mg/l) and NAA (5 mg/l) to both scion and stocks in water renewed foliar development at a relatively early stage (40-60 days). The grafted plants were kept in hardening chambers with CO₂-enriched air. No significant difference was observed between autograft (scion and root stock of Banuri clone) and heterograft (scion of the Banuri clone and root stock of UPASI-9). Of the three types (in terms of age) of seedling-raised root stocks employed, grafts on young tea (4-month-old) performed the best (88.33%). Grafts made in early summer established relatively faster and at a high rate of success. The percentage survival of plants transferred to the field was 88.33%.

Pregitzer, K.S., D.R. Zak, P.S. Curtis, M.E. Kubiske, J.A. Teeri, and C.S. Vogel. 1995. Atmospheric CO₂, soil-nitrogen and turnover of fine roots. *New Phytologist* 129(4):579-585.

In most natural ecosystems a significant portion of carbon fixed through photosynthesis is allocated to the production and maintenance of fine roots, the ephemeral portion of the root system that absorbs growth-limiting moisture and nutrients. In turn, senescence of fine roots can be the greatest source of C input to forest soils. Consequently, important questions in ecology entail the extent to which increasing atmospheric CO₂ may alter the allocation of carbon to, and demography of, fine roots. Using microvideo and image analysis technology, we demonstrate that elevated atmospheric CO₂ increases the rates of both fine root production and mortality. Rates of root mortality also increased substantially as soil nitrogen availability increased, regardless of CO₂ concentration. Nitrogen greatly influenced the proportional allocation of carbon to leaves vs. fine roots. The amount of available nitrogen in the soil appears to be the most important factor regulating fine root

demography in *Populus* trees.

Prentice, I.C., M.T. Sykes, M. Lautenschlager, S.P. Harrison, O. Denissenko, and P.J. Bartlein. 1993. Modeling global vegetation patterns and terrestrial carbon storage at the last glacial maximum. *Global Ecology and Biogeography Letters* 3(3):67-76.

Global patterns of potential natural vegetation were simulated for present and last glacial maximum (LGM) climates. The LGM simulation showed good agreement with available evidence, most importantly in the humid tropics. Simple calculations based on these simulations indicate that terrestrial carbon storage increased by 300-700 Pg C after the LGM. The range is due to uncertainties in the mean carbon storage values for different biomes, and in the amount of carbon in boreal peats. These results are consistent with the global change in ocean delta-C-13, inferred from measurements on benthic foraminifera, reflecting the increased storage of isotopically light carbon on land.

Price, D.T., and M.J. Apps. 1995. The boreal forest transect case-study - global change effects on ecosystem processes and carbon dynamics in boreal Canada. *Water, Air, and Soil Pollution* 82(1-2):203-214.

The Boreal Forest Transect Case Study (BFTCS) is a multi-disciplinary ecological study organised around a 1000 km transect located in central Canada. The transect is oriented along an ecoclimatic gradient in a region likely to undergo significant environmental change within the next few decades, and crosses the climate-sensitive boreal forest biome, including the transitions north and south into tundra and grassland respectively. Originally conceived as an extension to the BOREal Ecosystem Atmosphere Study (BOREAS), the 10-year BFTCS project projects the intensive canopy-scale measurements and modelling advances obtained from BOREAS to a wider range of sites with a longer-term perspective. In addition to considering ecophysiological processes with time-frames of the order of one year or shorter, BFTCS addresses the effects of larger scale, longer term processes including vegetation succession and ecosystem disturbances. The BFTCS currently provides practical linkages among ecosystem monitoring, field experiments and regional scale modelling. It will ultimately provide a knowledge-base of key processes and their environmental sensitivities, and assessments of possible climate feedbacks, which can be used to assess the possible consequences of global change both regionally and globally.

Prince, T.A., and M.S. Cunningham. 1991. Forcing characteristics of easter lily bulbs exposed to elevated-ethylene and elevated-carbon dioxide and low-oxygen atmospheres. *Journal of the American Society for Horticultural Science* 116(1):63-67.

Exposure of bulbs of Easter Lily (*Lilium longiflorum* Thunb.) to a maximum of 2-mu-l ethylene/liter during vernalization delayed flowering by 5 to 7 days and decreased the number of flower buds. Ethylene exposure for 5 days at 21C after vernalization accelerated shoot

emergence and flowering by up to 3 days. No floral or plant abnormalities were observed after bulb exposure to ethylene. Exposure to atmospheres with 0%, 0.5%, or 1% O₂ at 21C for up to 2 weeks before or 10 days after vernalization did not significantly impair subsequent bulb forcing. Storage in 1% O₂ at 21C for 1 week before vernalization resulted in nearly one additional secondary bud initiated per plant. Exposure to up to 15% CO₂ at 21C for up to 2 weeks before or 10 days after vernalization did not significantly impair subsequent forcing.

Prior, L.D., D. Eamus, and G.A. Duff. 1997. Seasonal and diurnal patterns of carbon assimilation, stomatal conductance and leaf water potential in *Eucalyptus tetrodonta* saplings in a wet-dry savanna in northern Australia. *Australian Journal of Botany* 45:241-258.

Seasonal and diurnal trends in carbon assimilation, stomatal conductance and leaf water potential were studied using 1-3 m tall saplings of *Eucalyptus tetrodonta* (F.Muell.). The study site was in an unburnt savanna near Darwin, where rainfall is strongly seasonal. Mean daily maximum assimilation rates ranged from 14.5 mu mol m⁻² s⁻¹ in May to 4.8 mu mol m⁻² s⁻¹ in October. There was a linear relationship between daily maximum assimilation rates and pre-dawn leaf water potential ($r = 0.62$, $n = 508$) and a log-log linear relationship between daily maximum stomatal conductance and pre-dawn leaf water potential ($r = 0.68$, $n = 508$). Assimilation rates and stomatal conductance were always higher in the morning than in the afternoon, irrespective of season. Stomatal conductance responded more strongly to leaf-to-air vapour pressure difference when pre-dawn leaf water potentials were moderately low (-0.5 to -1.5 MPa) than when they were very low (< -1.5 MPa) or high (> -0.5 MPa). Assimilation decreased sharply when temperature exceeded 35 degrees C. Seasonal trends in assimilation rate could be attributed primarily to stomatal closure, but diurnal trends could not. High leaf temperatures were a major cause of lower assimilation rates in the afternoon. Approximately 90% of leaves were lost by the end of the dry season, and above-ground growth was very slow. It is hypothesised that *E. tetrodonta* saplings allocate most photosynthate to root and lignotuber growth in order to tolerate seasonal drought and the high frequency of fire in northern Australian savannas.

Prior, S.A., S.G. Pritchard, G.B. Runion, H.H. Rogers, and R.J. Mitchell. 1997. Influence of atmospheric CO₂ enrichment, soil N, and water stress on needle surface wax formation in *Pinus palustris* (Pinaceae). *American Journal of Botany* 84(8):1070-1077.

Interactive effects of increasing atmospheric CO₂ with resource limitations on production of surface wax in plants have not been studied. *Pinus palustris* seedlings were grown for 1 yr at two levels of soil N (40 or 400 kg N.ha⁻¹.yr⁻¹) and water stress (-0.5 or -1.5 MPa xylem pressure potential) in open-top field chambers under two levels of CO₂ (365 or 720 mu mol/mol). Needle surface wax content was determined at 8 mo (fall) and 12 mo (spring) and epicuticular wax morphology was examined using scanning electron microscopy (SEM) at 12 mo. Wax content expressed on both a leaf area and dry mass basis was increased due to main effects of low N and water stress. No main effects of CO₂ were observed; however, a CO₂ x N interaction at 12 mo indicated that under low soil N the elevated CO₂ treatment had less wax (surface area or dry mass basis) compared to its ambient counterpart. Morphologically, low N needle surfaces appeared rougher compared to those of high N needles due to more extensive wax ridges. Although the

main effect of water treatment on wax density was not reflected by changes in wax morphology, the CO₂ x N interaction was paralleled by alterations in wax appearance. Decreases in density and less prominent epicuticular wax ridges resulting from growth under elevated CO₂ and limiting N suggest that dynamics of plant/atmosphere and plant/pathogen interactions may be altered.

Prior, S.A., and H.H. Rogers. 1995. Soybean growth-response to water-supply and atmospheric carbon- dioxide enrichment. *Journal of Plant Nutrition* 18(4):617-636.

Growth response of soybean [*Glycine max* (L.) Merr. 'Bragg'] grown in open top field chambers at five carbon dioxide (CO₂) concentrations ranging from 349 to 946 $\mu\text{mol mol}^{-1}$ and under two water regimes was examined. During reproductive growth, plants grown under CO₂ enrichment exhibited increases in total leaf area and dry weight. Water stress inhibited growth at all CO₂ levels, but the relative enhancement of growth due to CO₂ enrichment under water-stressed (WS) conditions was greater than under well-watered (WW) conditions. Water-stressed plants grown under 946 $\mu\text{mol mol}^{-1}$ CO₂ were larger than WW plants grown under 349 $\mu\text{mol mol}^{-1}$ CO₂. Reproductive yield increases were represented by increases in seed number rather than larger seeds. Although water stress reduced yield, the relative increase in seed number in response to elevated CO₂ was greater for WS plants. Leaf tissue analysis suggested that a phosphorus deficiency may have restricted the seed dry weight response to elevated CO₂. The mean relative growth rate (RGR) and mean net assimilation rate (NAR) increased with CO₂ concentration in the first interval (5 to 14 days after planting) and diminished with time thereafter for each CO₂ level. At the second interval (14 to 63 days), the direct effect of NAR was offset by lower leaf area ratio (LAR). However, the LAR was greater for WS plants but the response of RGR to CO₂ was similar under both water treatments. At the third interval (63 to 98 days), the RGR for WS plants remained constant across CO₂ treatments, whereas under WW conditions a level response of NAR coupled with a negative response of LAR resulted in a decrease in RGR under CO₂-enriched conditions. The decrease in LAR was attributed to a decrease in specific leaf area. Leaf weight ratio was unaffected by CO₂.

Prior, S.A., H.H. Rogers, G.B. Runion, and G.R. Hendrey. 1994. Free-air CO₂ enrichment of cotton - vertical and lateral root distribution patterns. *Plant and Soil* 165(1):33-44.

The objective of this investigation was to determine how free- air carbon dioxide enrichment (FACE) of cotton (*Gossypium hirsutum* L.) affects root distribution in a natural soil environment. For two years cotton was grown on a Trix clay loam under two atmospheric CO₂ concentrations (370 and 550 $\mu\text{mol mol}^{-1}$) and two water treatments [wet, 100% of evapotranspiration (ET) replaced and dry, 75% (1990) and 67% (1991)

of ET replaced] at Maricopa, AZ. At early vegetative and mid-reproductive growth, 90 cm soil cores were taken at 0, 0.25, and 0.5 m perpendicular to row center; root variables were ascertained at three 30 cm depth increments. The effect of water stress alone or its interaction with CO₂ on measured variables during both samplings were rare and showed no consistent pattern. There was a significant CO₂ x position interaction for root length density at the vegetative stage (both years) and reproductive stage (1990 only); the positive effects of extra CO₂ were more evident at interrow positions (0.25 and 0.5 m). A CO₂ x depth x position interaction at the vegetative phase (1990) indicated that FACE increased root dry weight densities for the top soil depth increment at all positions and at the middle increment at the 0.5 m position. Similar trends were seen at the reproductive sampling for this measure as well as for root length density at both sample dates in 1990. In 1991, a CO₂ x depth interaction was noted at both periods; CO₂ enhancement of root densities (i.e., both length and dry weight) were observed within the upper and middle depths. Although variable in response, increases for root lineal density under high CO₂ were also seen. In general, results also revealed that the ambient CO₂ treatment had a higher proportion of its root system growing closer to the row center, both on a root length and dry weight basis. On the other hand, the FACE treatment had proportionately more of its roots allocated away from row center (root length basis only). Results from this field experiment clearly suggest that increased atmospheric CO₂ concentration will alter root distribution patterns in cotton.

Prior, S.A., H.H. Rogers, G.B. Runion, B.A. Kimball, J.R. Mauney, K.F. Lewin, J. Nagy, and G.R. Hendrey. 1995. Free-air carbon-dioxide enrichment of cotton - root morphological-characteristics. *Journal of Environmental Quality* 24(4):678-683.

The response of plants to rising global CO₂ concentration is of critical research interest but one neglected aspect is its effect on roots. Root morphological changes in cotton [*Gossypium hirsutum* (L.) 'Delta Pine 77'] were examined in a 2- yr held study. The test crop was grown under two water regimes (wet, 100% of evapotranspiration [ET] replaced and dry, 75% [1990] and 67% [1991] of ET replaced) and two atmospheric CO₂ concentrations (ambient = 370 $\mu\text{mol mol}^{-1}$) and free-air CO₂ enrichment [FACE] = 550 $\mu\text{mol mol}^{-1}$). A FACE technique that allows for CO₂ exposure under held conditions with minimal alteration of plant microclimate was used. Excavated root systems were partitioned into taproot and lateral roots at two growth phases (vegetative and reproductive). Vertical root- pulling resistance was determined at the second sampling; this measure was higher because of CO₂ enrichment but was unaffected by water stress. Water stress affected root variables only at the second sampling; water stress reduced taproot variables more than lateral variables. The larger diameter taproots seen at all sample dates under FACE exhibited large increases in dry weight and volume. FACE often increased lateral root number and lateral dry weights were higher at all sample dates. The development of more robust taproot systems in CO₂-enriched environments may allow for greater carbohydrate storage for utilization during periods such as hop filling and to ensure root growth for continued exploration of the soil profile to meet nutrient and water demands during peak demand periods.

Prior, S.A., H.H. Rogers, G.B. Runion, and J.R. Mauney. 1994.

Effects of free-air CO₂ enrichment on cotton root-growth. *Agricultural and Forest Meteorology* 70(1-4):69-86.

The rise in atmospheric CO₂ concentration is predicted to have a positive effect on agro-ecosystem productivity. However, an area which requires further investigation centers on responses of crop root systems to elevated atmospheric CO₂ under field conditions. The advent of free-air CO₂ enrichment (FACE) technology provides a new method of CO₂ exposure with minimal alteration of plant microclimate. In 1990 and 1991, cotton (*Gossypium hirsutum* (L.) 'Deltapine 77') was grown under two atmospheric CO₂ levels (370 and 550 $\mu\text{mol mol}^{-1}$) and two water regimes (wet (100% of ET replaced) and dry (75% of ET replaced in 1990 and 67% in 1991)). Plant root samples were collected at early vegetative and mid-reproductive growth. Taproots of CO₂-enriched plants displayed greater volume, dry weight, length, and tissue density. Water treatment effects were noted for length, volume and dry weight of roots at the second sampling in 1991. In general, whole soil profile root densities (both length and dry weight densities) and root weight per unit length at the initial sampling were increased under CO₂ enrichment at each of three positions (0.00, 0.25, and 0.50 m) from row center to the middle of the inter-row space. At the second sampling, root length density and root dry weight density were generally unaffected by water stress, whereas root weight per unit length was somewhat higher. In addition, extra CO₂ increased whole profile root length density only at the 0.50 m inter-row position, whereas whole profile root dry weight density and root weight per unit length were generally higher under elevated CO₂ at all three positions. The results from this field experiment strongly indicated that increased atmospheric CO₂ level would enhance plant root growth.

Prior, S.A., H.H. Rogers, G.B. Runion, H.A. Torbert, and D.C. Reicosky. 1997. Carbon dioxide-enriched agroecosystems: Influence of tillage on short-term soil carbon dioxide efflux. *Journal of Environmental Quality* 26(1):244-252.

Increasing atmospheric carbon dioxide (CO₂) concentration can increase biomass production that may influence carbon (C) dynamics in terrestrial ecosystems. Soil CO₂ efflux as affected by crop residues from high CO₂ environments managed under different tillage systems has not been explored. This study examined the effects of tillage systems in a legume soybean [*Glycine max* (L.) Merr.] and nonlegume grain sorghum [*Sorghum bicolor*] (L.) Moench. CO₂-enriched agroecosystem on the rates of short-term CO₂ evolution from a Blanton loamy sand (loamy siliceous, thermic Grossarenic Paleudults). In the spring of 1993, CO₂ efflux observations initiated within 5 s after a tillage event were compared to no-tillage conditions for 8 d in plots where both crop species had been grown in open top field chambers under two CO₂ conditions (ambient and twice ambient) for two seasons (1992 and 1993). Added CO₂ increased yields, residue, and root biomass; higher percent ground cover was also observed in CO₂-enriched plots prior to the tillage treatment. Differences in C/N ratio of the residue may have influenced CO₂ efflux rates; C/N ratio was highest for sorghum and was increased by elevated CO₂. Efflux patterns were characterized by flushes of CO₂ following initial tillage and rainfall events. Species x tillage and CO₂ x species interactions were noted on several days and for total CO₂ efflux values. Our results suggest that short-term CO₂ fluxes may be greater for tilled soybean and for soybean grown under elevated CO₂; however, short-term flux rates in the sorghum crop were affected by tillage, but not by CO₂ level. These short-term results should be viewed with caution when predicting long-term C turnover in agroecosystems.

Prior, S.A., H.H. Rogers, N. Sionit, and R.P. Patterson. 1991. Effects of elevated atmospheric CO₂ on water relations of soya bean. *Agriculture Ecosystems & Environment* 35(1):13-25.

Soya bean (*Glycine max* (L.) Merr. 'Bragg') plants were grown in large containers in open-top field chambers under five atmospheric CO₂ concentrations (349-946 $\mu\text{mol mol}^{-1}$) and two water regimes. Rate of soil water depletion for the high CO₂ treatments started to decrease under well-watered conditions during anthesis and by early pod formation under water-stressed conditions. During reproductive growth, normal and stressed plants at 349- $\mu\text{mol mol}^{-1}$ (ambient level) received irrigation water 29 and 12 times, respectively, compared with 21 and 9 times, respectively, at 946- $\mu\text{mol mol}^{-1}$ CO₂. At both anthesis and pod fill, plants grown under CO₂ enrichment exhibited greater leaf area. Nevertheless, water use per plant either remained constant (stressed plants at anthesis) or else declined (well-watered plants at pod fill; both moisture levels during pod fill) in response to CO₂ enrichment. At pod fill, leaves of CO₂-enriched plants generally displayed a higher stomatal resistance, except near the end of the sampling period when a sudden increase in resistance was observed under low CO₂ owing to low soil water availability. Midday xylem potential for well-watered plants was greater than values for stressed plants and was unaffected by CO₂ treatment. Under low moisture conditions, elevated CO₂ had no effect on xylem potential at anthesis; however, during pod fill potential increased significantly with increasing CO₂ concentration, as elevated CO₂ decreased water use rates, lowering soil water stress. Alleviation of water stress during critical reproductive phases was strongly suggested.

Prior, S.A., G.B. Runion, R.J. Mitchell, H.H. Rogers, and J.S. Amthor. 1997. Effects of atmospheric CO₂ on longleaf pine: Productivity and allocation as influenced by nitrogen and water. *Tree Physiology* 17(6):397-405.

Longleaf pine (*Pinus palustris* Mill.) seedlings were exposed to two concentrations of atmospheric CO₂ (365 or 720 $\mu\text{mol mol}^{-1}$) in combination with two N treatments (40 or 400 kg N ha⁻¹ year⁻¹) and two irrigation treatments (target values of -0.5 or -1.5 MPa xylem pressure potential) in open-top chambers from March 1993 through November 1994. Irrigation treatments were imposed after seedling establishment (i.e., 19 weeks after planting). Seedlings were harvested at 4, 8, 12, and 20 months. Elevated CO₂ increased biomass production only in the high-N treatment, and the relative growth enhancement was greater for the root system than for the shoot system. In water-stressed trees, elevated CO₂ increased root biomass only at the final harvest. Root:shoot ratios were usually increased by both the elevated CO₂ and low-N treatments. In the elevated CO₂ treatment, water-stressed trees had a higher root:shoot ratio than well-watered trees as a result of a drought-induced increase in the proportion of plant biomass in roots. Well-watered seedlings consistently grew larger than water-stressed seedlings only in the high-N treatment. We conclude that available soil N was the controlling resource for the growth response to elevated CO₂ in this study. Although some growth enhancement was observed in water-stressed trees in the elevated CO₂ treatment, this response was contingent on available soil N.

Prior, S.A., H.A. Torbert, G.B. Runion, G.L. Mullins, H.H. Rogers, and J.R. Mauney. 1998. Effects of carbon dioxide enrichment on cotton nutrient dynamics. *Journal of Plant Nutrition* 21(7):1407-1426.

The rise in atmospheric carbon dioxide (CO₂) concentration is predicted to have positive effects on agro-ecosystem productivity. However, an area which requires further study centers on nutrient dynamics of crops grown under elevated CO₂ in the field. In 1989 and 1990, cotton [*Gossypium hirsutum* (L.) Deltapine 77] was grown under two CO₂ levels [370 $\mu\text{mol mol}^{-1}$ =ambient and 550 $\mu\text{mol mol}^{-1}$ =free-air CO₂ enrichment(FACE)]. At physiological maturity, nutrient concentration and content of nitrogen (N), phosphorus (P), potassium (K), calcium (Ca), magnesium (Mg), copper (Cu), iron (Fe), manganese (Mn), and zinc (Zn) were determined for whole plant and individual plant organs. While the effects of added CO₂ on whole plant nutrient concentrations and contents were consistent, some differences among plant organs were observed between years. FACE often decreased tissue nutrient concentration, but increased total nutrient accumulation. Results indicate that under elevated CO₂, field grown cotton was more nutrient efficient in terms of nutrient retrieval from the soil and nutrient utilization in the plant. This implies more efficient fertilizer utilization, better economic return for fertilizer expenditures, and reduced environmental impact from agricultural fertilization practices in the future.

Prior, S.A., H.A. Torbert, G.B. Runion, H.H. Rogers, C.W. Wood, B.A. Kimball, R.L. LaMorte, P.J. Pinter, and G.W. Wall. 1997. Free-air carbon dioxide enrichment of wheat: Soil carbon and nitrogen dynamics. *Journal of Environmental Quality* 26(4):1161-1166.

The predicted positive impact of elevated atmospheric carbon dioxide (CO₂) concentration on crop biomass production suggests that more C will reach the soil. An aspect of soil C sequestration that requires further study is the effect of elevated CO₂ on C and N dynamics; this relationship is the key to understanding potential longterm C storage in soil. Soil samples (0-5, 5-10, and 10-20 cm increments) were collected after 2 yr of wheat (*Triticum aestivum* L.) production under two CO₂ levels [370 (ambient) and 550 $\mu\text{mol mol}^{-1}$ (free-air CO₂ enrichment) (FACE)] and two water treatments [100% of ET replaced (wet) and 50% of ET replaced (dry)] on a Trix clay loam [fine, loamy, mixed (calcareous), hyperthermic Typic Torrifluvents] at Maricopa, AZ. Organic C, total N, potential C and N mineralization, and C turnover were determined during a 60-d incubation study. Organic C content increased at all three soil depths under FACE and the total N content increased at the 5 to 10 and 10 to 20 cm depths. In general, increased N mineralization under dry conditions corresponded well with patterns of higher C mineralization and turnover. Nitrogen mineralization was unaffected by CO₂ treatment, indicating that factors other than N may limit C mineralization and turnover. Soil respiration and C turnover patterns were not affected by CO₂ treatment level at the 0 to 5 cm depth; however, these measures were lower under FACE at the lower depths. Soil respiration and C turnover at the 10 to 20 cm depth were increased by water stress under ambient CO₂; these measures under both water levels for FACE were similar to the ambient CO₂/wet treatment, suggesting that more C storage in wheat cropping systems is likely under elevated CO₂ regardless of water treatment.

Pritchard, S.G., C. Mosjidis, C.M. Peterson, G.B. Runion, and H.H. Rogers. 1998. Anatomical and morphological alterations in longleaf pine needles resulting from growth in elevated CO₂: Interactions with soil resource availability. *International Journal of Plant Science* 159(6):1002-1009.

Studies of anatomical changes in longleaf pine (*Pinus palustris* Mill.) needles for plants exposed to elevated atmospheric CO₂ may provide insight into the potential influences of global CO₂ increases on plant productivity. Longleaf pine seedlings were grown in open-top field chambers supplied with either ambient (similar to 365 $\mu\text{mol mol}^{-1}$) or elevated (similar to 720 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ for 20 mo. Two levels of soil nitrogen (40 and 400 g ha⁻¹ yr⁻¹) and two soil moisture regimes (-0.5 or -1.5 MPa predawn xylem pressure potential) were used in combination with CO₂ treatments. Needle tissue was collected 12 and 20 mo after treatment initiation and subjected to light and scanning electron microscopy. There was no effect of elevated CO₂ on stomatal distribution or the proportion of internal leaf area allocated to a given tissue type at either sampling date. Although the relationships between vascular, transfusion, mesophyll, and epidermal tissue cross-sectional areas to total leaf cross-sectional areas appear nonplastic, leaves grown in elevated CO₂ with low N availability exhibit anatomical characteristics suggestive of reduced capacity to assimilate carbon, including decreased mesophyll cell surface area per unit needle volume (in low-N soil). Significantly greater (8%) needle fascicle volume as a result of growth in elevated CO₂ was observed after 12 mo because of thicker needles. After 20 mo of exposure, there was a trend indicating smaller fascicle volume (8%) in plants grown with elevated CO₂ compared with those grown in ambient conditions, resulting from shorter needles and smaller mesophyll, vascular tissue, and epidermal cell cross-sectional areas. These results indicate short-term stimulation and longterm inhibition of needle growth in longleaf pine as a result of exposure to elevated CO₂ and suggest at the leaf level that pine species are less responsive to elevated CO₂ than are dicotyledons, including other tree species.

Pritchard, S.G., C.M. Peterson, S.A. Prior, and H.H. Rogers. 1997. Elevated atmospheric CO₂ differentially affects needle chloroplast ultrastructure and phloem anatomy in *Pinus palustris*: Interactions with soil resource availability. *Plant, Cell and Environment* 20(4):461-471.

The response of forest species to increasing atmospheric CO₂, particularly under resource limitations, will require study in order to predict probable changes which may occur at the plant, community and ecosystem levels. Longleaf pine (*Pinus palustris* Mill.) seedlings were grown for 20 months at two levels of CO₂ (365 and 720 $\mu\text{mol mol}^{-1}$) in two levels of soil nitrogen (4 and 40 g m⁻²), and with two levels of soil moisture (-0.5 and -1.5 MPa xylem pressure potential). Leaf tissue was collected in the spring (12 months exposure) and autumn (20 months exposure) and examined using transmission electron microscopy (TEM) and light microscopy. During early spring, elevated CO₂ magnified effects of N and water treatment on starch accumulation and in some cases contributed to altered organization of mesophyll chloroplasts. Disruption of chloroplast integrity was pronounced under elevated CO₂, low N and water stress. In autumn, needles contained little starch; however, chloroplasts grown under high CO₂ exhibited

stress symptoms including increased plastoglobuli and shorter grana, A trend for reduced needle phloem cross-sectional area resulting from fewer sieve cells was also observed under elevated CO₂. These results suggest that, in nature, longleaf pine seedlings may not benefit from a doubling of CO₂, especially when soil resources are limiting.

Pritchard, S., C. Peterson, G.B. Runion, S. Prior, and H. Rogers. 1997. Atmospheric CO₂ concentration, N availability, and water status affect patterns of ergastic substance deposition in longleaf pine (*Pinus palustris* Mill.) foliage. *Trees-Structure and Function* 11(8):494-503.

Leaf chemistry alterations due to increasing atmospheric CO₂ will reflect plant physiological changes and impact ecosystem function. Longleaf pine was grown for 20 months at two levels of atmospheric CO₂ (720 and 365 $\mu\text{mol mol}^{-1}$), two levels of soil N (4 g m⁻² year⁻¹ and 40 g m⁻² year⁻¹), and two soil moisture levels (-0.5 and -1.5 MPa) in open top chambers. After 20 months of exposure, needles were collected and ergastic substances including starch grains and polyphenols were assessed using light microscopy, and calcium oxalate crystals were assessed using light microscopy, scanning electron microscopy, and transmission electron microscopy. Polyphenol content was also determined using the Folin-Denis assay and condensed tannins were estimated by precipitation with protein. Evaluation of phenolic content histochemically was compared to results obtained using the Folin-Denis assay. Total leaf polyphenol and condensed tannin content were increased by main effects of elevated CO₂, low soil N and well-watered conditions. Elevated CO₂ and low soil N decreased crystal deposition within needle phloem. Elevated CO₂ had no effect on the percentage of cells within the mesophyll, endodermis, or transfusion tissue which contained visible starch inclusions. With respect to starch accumulation in response to N stress, mesophyll > endodermis > transfusion tissue. The opposite was true in the case of starch accumulation in response to main effects of water stress: mesophyll < endodermis < transfusion tissue. These results indicate that N and water conditions significantly affect deposition of leaf ergastic substances in longleaf pine, and that normal variability in leaf tissue quality resulting from gradients in soil resources will be magnified under conditions of elevated CO₂.

Pritchard, S.G., H.H. Rogers, S.A. Prior, and C.M. Peterson. 1999. Elevated CO₂ and plant structure: a review. *Global Change Biology* 5(7):807-837.

Consequences of increasing atmospheric CO₂ concentration on plant structure, an important determinant of physiological and competitive success, have not received sufficient attention in the literature. Understanding how increasing carbon input will influence plant developmental processes, and resultant form, will help bridge the gap between physiological response and ecosystem level phenomena. Growth in elevated CO₂ alters plant structure through its effects on both primary and secondary meristems of shoots and roots. Although not well established, a review of the literature suggests that cell division, cell expansion, and cell patterning may be affected, driven mainly by increased substrate (sucrose) availability and perhaps also by differential expression of genes involved in cell cycling (e.g. cyclins) or cell expansion (e.g. xyloglucan endotransglycosylase). Few studies, however,

have attempted to elucidate the mechanistic basis for increased growth at the cellular level. Regardless of specific mechanisms involved, plant leaf size and anatomy are often altered by growth in elevated CO₂, but the magnitude of these changes, which often decreases as leaves mature, hinges upon plant genetic plasticity, nutrient availability, temperature, and phenology. Increased leaf growth results more often from increased cell expansion rather than increased division. Leaves of crop species exhibit greater increases in leaf thickness than do leaves of wild species. Increased mesophyll and vascular tissue cross-sectional areas, important determinates of photosynthetic rates and assimilate transport capacity, are often reported. Few studies, however, have quantified characteristics more reflective of leaf function such as spatial relationships among chlorenchyma cells (size, orientation, and surface area), intercellular spaces, and conductive tissue. Greater leaf size and/or more leaves per plant are often noted; plants grown in elevated CO₂ exhibited increased leaf area per plant in 66% of studies, compared to 28% of observations reporting no change, and 6% reported a decrease in whole plant leaf area. This resulted in an average net increase in leaf area per plant of 24%. Crop species showed the greatest average increase in whole plant leaf area (+37%) compared to tree species (+14%) and wild, nonwoody species (+15%). Conversely, tree species and wild, nontrees showed the greatest reduction in specific leaf area (-14% and -20%) compared to crop plants (-6%). Alterations in developmental processes at the shoot apex and within the vascular cambium contributed to increased plant height, altered branching characteristics, and increased stem diameters. The ratio of internode length to node number often increased, but the length and sometimes the number of branches per node was greater, suggesting reduced apical dominance. Data concerning effects of elevated CO₂ on stem/branch anatomy, vital for understanding potential shifts in functional relationships of leaves with stems, roots with stems, and leaves with roots, are too few to make generalizations. Growth in elevated CO₂ typically leads to increased root length, diameter, and altered branching patterns. Altered branching characteristics in both shoots and roots may impart competitive relationships above and below the ground. Understanding how increased carbon assimilation affects growth processes (cell division, cell expansion, and cell patterning) will facilitate a better understanding of how plant form will change as atmospheric CO₂ increases. Knowing how basic growth processes respond to increased carbon inputs may also provide a mechanistic basis for the differential phenotypic plasticity exhibited by different plant species/functional types to elevated CO₂.

Prusky, D., H. Hamdan, R. Ardi, and N.T. Keen. 1996. Induction of biosynthesis of epicatechin in avocado suspension cells treated with an enriched CO₂ atmosphere. *Physiological and Molecular Plant Pathology* 48(3):171-178.

Exposure to an atmosphere of 30% carbon dioxide caused increased levels of phenylalanine ammonia-lyase (PAL) activity in avocado cell suspension cultures. The carbon dioxide treatment also enhanced chalcone synthase activity by 30% and resulted in a 1.5-2 fold greater accumulation of epicatechin than in untreated cells. It was concluded that the level of epicatechin in avocado suspension cells can be increased by carbon dioxide, and this increase appears to be regulated by PAL and CHS activation. Prusky, D., R.A. Plumbly, I. Kobiler, G. Zauberman, and Y. Fuchs. 1993. The effect of elevated CO₂ levels on the symptom expression of *Colletotrichum-gloeosporioides* on avocado fruits. *Plant Pathology* 42(6):900-904.

Exposure of freshly harvested avocado fruits to different concentrations of CO₂ (11, 16 and 30%) for different lengths of time (4, 17 and 26 h) affected the decay development caused by *Colletotrichum gloeosporioides*. The delay in symptom development depended on the treatment given, the temperature regime of the fruit and time after harvest for treatment application. The most appropriate treatment was the application of 30% CO₂ for 24 h at a temperature of 20-25 degrees C on the day of harvest. Treatment for shorter time periods, at lower temperatures or 50 h after harvest, resulted in a reduced response and, in some cases, enhanced symptom expression. Concentrations of 11 or 16% CO₂ were less effective than 30% CO₂ as the fruits became more mature. It is concluded that treatment of avocado fruits with high levels of CO₂ for a short period has the potential to provide an alternative means of controlling anthracnose.

Pukhalskaya, N.V. 1997. Generative development of barley at an elevated atmospheric concentration of CO₂ and varying temperature conditions. *Russian Journal of Plant Physiology* 44(2):152-157.

Ear development in barley (*Hordeum vulgare* L.) was studied at normal (350 µl/l) and elevated (700 µl/l) atmospheric CO₂ concentrations and two temperature regimes. Plant productivity was found to increase by 63 and 47% at temperatures of 20/14 and 23/17 degrees C (day/night), respectively. Analysis of production showed that elevated CO₂ may induce an increase in the number of spikelets in the inflorescence primordium and in the size of the primordium beginning from the early stages of development. At 20/14 degrees C, a high level of CO₂ significantly elevated the yield of the main ear, increasing the number of caryopses by 18-28% and the grain weight in the main ear by 42-49%. At 23/17 degrees C, a double concentration of CO₂ increased plant production due to increased tiller formation (by 75-106%). It was found that the CO₂ concentration did not affect pollen fertility in barley at low temperature, but at elevated temperature, the number of sterile pollen grains increased. Thus, the experiments showed that an elevated CO₂ concentration affected the development of the barley ear during its whole ontogeny, including the early stages.

Pukhal'skaya, N.V., and L.V. Osipova. 1999. Drought resistance of wheat plants in an atmosphere enriched with CO₂. *Russian Journal of Plant Physiology* 46(2):219-226.

Wheat (*Triticum aestivum* L.) plants were grown under natural (350 µl/l) and elevated (700 µl/l) CO₂ concentrations. Watering was discontinued for a portion of the plants during floret development in the primordial ear (the sixth stage of morphogenesis after Kuperman). The evapo-transpiration of the stand, leaf water deficit, membrane permeability for electrolytes, and final grain yield were evaluated. At the beginning of the growth period of the normally watered plants, the elevated CO₂ concentration reduced the evapo-transpiration of the stand, providing for slower tissue dehydration during drought. Under equal stress "doses," the drought-induced decrease in the grain yield was deeper in the CO₂-enriched atmosphere (37%) than in normal air (27%),

although the elevated CO₂ level alleviated some metabolic damages (increased membrane permeability in particular). However, the total grain yield was higher in the CO₂-enriched atmosphere under both normal watering (by 49%) and drought conditions (by 25%). It was concluded that, under a high CO₂ concentration in the air, plant sensitivity to tissue dehydration declined. However, this change was not always correlated with plant drought resistance.

Pukhalskaya, N.V., N. Romin, and E.N. Akanov. 1997. Growth and CO₂ exchange in wheat seedlings grown at an elevated concentration of CO₂. *Russian Journal of Plant Physiology* 44(2):147-151.

The effect of an elevated concentration of CO₂ (700 µl/l) on the growth and gas exchange of wheat (*Triticum aestivum* L.) seedlings was studied on the 4th day (germination), the 8th day (etiolated seedlings), and the 13th day (2-leaf stage) after sowing. The elevated concentration of CO₂ activated respiration of seeds germinating in the air but did not significantly affect their growth, gas exchange, and the time of shoot formation when the seeds were in soil. The increase in CO₂ concentration lowered the rate of respiration in etiolated seedlings by 25-40% and in the 13-day-old seedlings by 30-35%. In the 13-day-old seedlings, the elevated concentration of CO₂ in the air increased the rate of photosynthesis and, as a result, augmented twofold the net (per day) assimilation of CO₂ and activated growth processes. Thus, it was found that the CO₂ concentration in the air significantly affected the growth and gas exchange of the seedlings before the formation of assimilating machinery.

Pulleman, M., and A. Tietema. 1999. Microbial C and N transformations during drying and rewetting of coniferous forest floor material. *Soil Biology and Biochemistry* 31(2):275-285.

Microbial C and N transformation rates in air-dried and subsequently rewetted coniferous forest floor material were examined in a laboratory incubation study. Gross N transformation rates were determined through parallel (NH₄⁺)-N-15 and (NO₃⁻)-N-15 enrichment experiments. After drying of the litter for 12 d to a water content of 10% of dry weight, CO₂ respiration, net N mineralization and nitrification rates were strongly restricted. Microbial biomass C was reduced to 67% of the amount in the continuously moist material. Remoistening of the dry litter to a water content of 340% resulted in a flush in C and net N mineralization within a few hours after rewetting. The increase in net N mineralization could be attributed to a larger increase in gross N mineralization relative to the increase in gross N immobilization. Gross N immobilization had increased to the same rate as gross N mineralization after 26 h, and a small secondary peak in respiration and microbial C was observed 48 h after rewetting. It was concluded that both biomass-derived substrate with a low C-to-N ratio and 'nonbiomass'-derived substrate with a high C-to-N ratio have been released, and metabolized, as a result of the drying-rewetting treatment. Despite the very extreme drying treatment, the mineralization flush after rewetting could not compensate for the large reduction in CO₂ and mineral N production during dry conditions due to its short duration. Since there was no increase in nitrification rate after drying and rewetting, the NO₃⁻ concentration at the end of the incubation was strongly reduced due to the extremely slow net nitrification rates during desiccation. Pushnik, J.C., R.S. Demaree, J.L.J. Houps, W.B. Flory, S.M. Bauer, and P.D. Anderson. 1995. The effect of elevated carbon dioxide on a Sierra-Nevadan dominant species: *Pinus ponderosa*. *Journal of Biogeography* 22(2-3):249-254.

The impact of increasing atmospheric CO₂ has not been fully evaluated on western coniferous forest species. Two year old seedlings of *Pinus ponderosa* were grown in environmentally controlled chambers under increased CO₂ conditions (525 μ mol L⁻¹ and 700 μ mol L⁻¹) for 6 months. These trees exhibited morphological, physiological and biochemical alterations when compared to our controls (350 μ mol L⁻¹). Analysis of whole plant biomass distribution has shown no significant treatment effect to the root to shoot ratios. However, while stem diameter and height growth generally increased with elevated CO₂, needles exhibited an increased overall specific needle mass and a decreased total needle area. Morphological changes at the needle level included decreased mesophyll to vascular tissue ratio and variations in starch storage in chloroplasts. The elevated CO₂ increased internal CO₂ concentrations and assimilation of carbon. Biochemical assays revealed that ribulose-bis-phosphate carboxylase (RuBPCase) specific activities increased on per unit area basis with CO₂ treatment levels. Sucrose phosphate synthase (SPS) activities exhibited an increase of 55% in the 700 μ mol L⁻¹ treatment. These results indicate that the sink-source relationships of these trees have shifted carbon allocation toward above ground growth, possibly due to transport limitations.

Pushnik, J.C., D. Garcia-Ibancieta, S. Bauer, P.D. Anderson, J. Bell, and J.L.J. Houps. 1999. Biochemical responses and altered genetic expression patterns in ponderosa pine (*Pinus ponderosa* Doug ex P. Laws) grown under elevated CO₂. *Water, Air, and Soil Pollution* 116(1-2):413-422.

Biochemical and gene expression changes in response to elevated atmospheric CO₂ were investigated in five maternal half-sibling breeding families of Ponderosa pine. Seedlings were grown in a common garden located at Lawrence Livermore National Laboratory, in open-topped chambers (OTC) for two years. Chamber atmospheres were maintained at ambient, ambient + 175 μ mol L⁻¹ CO₂, or ambient + 350 μ mol L⁻¹ CO₂. Growth measurements showed significant increases in stem volumes and volume enhancement ratios in three of the five families studied when grown under elevated CO₂. Biochemical and gene expression studies were undertaken to gain a mechanistic understanding of these phenotypic responses. Biochemical studies focused on sucrose phosphate synthase (SPS) specific activities at increase CO₂ levels. Kinetic evaluations of SPS showed an increase in V-Max. Specific SPS probes revealed increases in the transcriptional levels of one SPS gene with exposure to increasing CO₂. RT-PCR differential gene displays showed that overall only a small fraction of visualized gene transcripts responded to elevated CO₂ (8-10%). There were also significant differences between the gene expression patterns of the different families, some of which correlated with alterations in growth at elevated CO₂ levels.

Qi, J.E., J.D. Marshall, and K.G. Mattson. 1994. High soil carbon-dioxide concentrations inhibit root respiration of douglas-fir. *New Phytologist* 128(3):435-442.

Total and basal respiration (R(t) and R(b), respectively) of intact and undisturbed roots of one-year-old Douglas fir seedlings, *Pseudotsuga menziesii* var. *glauca* [Beissn] France, were measured at experimentally varied soil carbon dioxide concentrations ([CO₂]). Use of specially designed root boxes and a CO₂ gas-flow compensating system designed around an infrared gas analyzer (IRGA) allowed controlled delivery of CO₂ to roots and simultaneous measurements of CO₂ released by roots. Root respiration rate responded to each inlet [CO₂], independent of whether the previous concentration had been higher or lower, within two to three hours (paired t test = 0.041, P = 0.622, and n = 13). Total and basal respiration rates decreased exponentially as soil [CO₂] rose from 130 ppm, well below atmospheric [CO₂], to 7015 ppm, a concentration not uncommon in field soils. Analyses of variance (ANOVA) showed that the effects of soil [CO₂] on rates of total and basal root respiration were statistically significant. Root respiration rates decreased by 4 to 5 nmol CO₂ g⁻¹ dry weight of roots s⁻¹ for every doubling of [CO₂] according to the following equations: $\ln(R(t))$ (nmol CO₂ g⁻¹ s⁻¹) = $5.24 - 0.30 \cdot \ln[CO_2]$ with $r = 0.78$, $P < 0.0001$, and $n = 70$; and $\ln(R(b))$ (nmol CO₂ g⁻¹ s⁻¹) = $6.29 - 0.52 \cdot \ln[CO_2]$ with $r = 0.82$, $P < 0.0001$, and $n = 35$. The sensitivity of root respiration to [CO₂] suggests that some previous laboratory measurements of root respiration at atmospheric [CO₂], which is 3 to 10-fold lower than [CO₂] in field soils, overestimated root respiration in the field. Further, the potential importance of soil [CO₂] indicates that it should be accounted for in models of below-ground carbon budgets.

Rabbinge, R., H.C. Vanlatesteijn, and J. Goudriaan. 1993. Assessing the greenhouse-effect in agriculture. *Ciba Foundation Symposia* 175:62-79.

Evidence that concentrations of CO₂ and trace gases in the atmosphere have increased is irrefutable. Whether or not these increased concentrations will lead to climate changes is still open to debate. Direct effects of increased CO₂ concentrations on physiological processes and individual plants have been demonstrated and the consequences for crop growth and production under various circumstances are evaluated with simulation models. The consequences of CO₂ enrichment are considerable under optimal growing conditions. However, the majority of crops are grown under sub-optimal conditions where the effects of changes in CO₂ are often less. The same holds for the possible indirect effects of environmental changes such as temperature rise. Studies on individual plants under optimal conditions are therefore not sufficient for evaluating the effects at a farm, regional, national or supra-national level. Simulation studies help to bridge the gap between the various aggregation levels and provide a basis for various studies of policy options at various aggregation levels.

Rabha, B.K., and D.C. Uprety. 1998. Effects of elevated CO₂ and moisture stress on *Brassica juncea*. *Photosynthetica* 35(4):597-602.

The interactive effect of elevated CO₂ (EC) and moisture stress (MS) on

Brassica juncea cv. Pusa Bold was studied using open- top chambers. The EC markedly increased net photosynthetic rate and internal CO₂ concentration and reduced variable and maximal chlorophyll fluorescence. Under MS, EC increased water potential and relative water content, and reduced transpiration rate. The greater allocation of biomass to the roots, which serve as a strong sink for assimilated carbon under EC, helped in better root growth.

Raddatz, R.L., and C.F. Shaykewich. 1998. Impact of warm summers on the actual evapotranspiration from spring wheat grown on the eastern Canadian prairies. *Canadian Journal of Soil Science* 78(1):171-179.

How do warm summers (June-July-August) influence the actual evapotranspiration totals from cropped land sown to spring wheat on the eastern Canadian Prairies? The eastern Prairies is a semi-arid region where over 60% of the land is cultivated. Over a third of the cropped land is usually sown to spring wheat. A comparison of mean summer temperatures and modelled evapotranspiration, for the years 1988 to 1996, demonstrated that with the current environmental conditions and farming practices, warm summers have lower actual evapotranspiration totals from spring wheat than cool summers. The average daily actual evapotranspiration rate is generally higher in years with higher mean summer temperatures; however, the crop growth- period is shorter. The net effect is lower total actual evapotranspiration from spring wheat. This suggests that climate warming on the eastern Canadian Prairies, if the current trend continues and all other factors remain equal, will reduce, on average, the total actual evapotranspiration from spring wheat. A reduction in the growth-period actual evapotranspiration from lands sown to spring wheat will likely decrease the total actual evapotranspiration for the entire warm season as growth-period evapotranspiration currently makes up about three-quarters of the seasonal total. However, the magnitude and timing of the reduction is far from certain. The consequence for agriculture may be a reduction in the average spring wheat yield because yield is positively correlated with the actual evapotranspiration total from the crop.

Seedlings of Vicia faba L. were grown in open-top growth chambers at present (P=350 μmol-1) and at elevated (E=700 μmol mol-1) atmospheric CO₂ concentration. The effects Of CO₂ enrichment on the first phase of growth after germination were examined over 45d. There were no positive effects Of CO₂ enrichment on growth of the seedlings during this early phase. No differences were observed in leaf area or in total dry weight. No differences were found in morphology or anatomy of the leaves. The numbers of stomatal and epidermal cells, thickness of leaf, of epidermis and of mesophyll cell-layers were unaffected by CO₂ enrichment. Also, no differences were observed in leaf concentrations of chlorophyll, reducing carbohydrates or starch. These results contrast markedly with results from similar experiments on poplar hybrids and Phaseolus vulgaris obtained in the same growth facility. It seems that the intital growth is under internal control such that the atmospheric CO₂ concentration has no effects. The lack of response in this case may be attributed to the presence and longevity of the large cotyledons which provided available substrate for growth.

Rafarel, C.R., T.W. Ashenden, and T.M. Roberts. 1995. An improved Solardome system for exposing plants to elevated CO₂ and temperature. *New Phytologist* 131(4):481-490.

Ventilated Solardomes (hemispherical glasshouses) have been used for 20 yr for studying the effects of gaseous pollutants on plants. This paper describes a computer-operated facility for studying the effects of CO₂ x temperature regimes on plants. The eight chambers were set up for factorial design experiments - with two levels of CO₂ (ambient and ambient+340 ppmv), two levels of temperature (ambient and 3 degrees C tracked continuously above ambient) and two replicates of each CO(2)xtemperature treatment. Monitoring of environmental conditions within the chambers over a 2 yr period has shown highly effective control of CO₂ and temperature regimes. Even with high-quality and u.v.-B transmitting glass, the irradiance in the PAR region was reduced by 18 % within the domes. Variation in temperature across the radii of the domes increased with higher photosynthetic photon flux density (PPFD). Vapour pressure deficits (VPDs) in the ambient temperature domes compared well with outside conditions but were higher in the elevated temperature domes. The watering regime within the domes affected intermittently the relationship between 'dome' and 'outside' VPDs. The Solardome facility has been used extensively for studies of the impacts of climate change within the UK Programme on Terrestrial Initiative on Global Environmental Research (TIGER).

Raich, J.W., and A. Tufekciogul. 2000. Vegetation and soil respiration: Correlations and controls. *Biogeochemistry* 48(1):71-90.

Soil respiration rates vary significantly among major plant biomes, suggesting that vegetation type influences the rate of soil respiration. However, correlations among climatic factors, vegetation distributions, and soil respiration rates make cause-effect arguments difficult. Vegetation may affect soil respiration by influencing soil microclimate and structure, the quantity of detritus supplied to the soil, the quality of that detritus, and the overall rate of root respiration. At the global scale, soil respiration rates correlate positively with litterfall rates in forests, as previously reported, and with aboveground net primary productivity in grasslands, providing evidence of the importance of detritus supply. To determine the direction and magnitude of the effect of vegetation type on soil respiration, we collated data from published studies where soil respiration rates were measured simultaneously in two or more plant communities. We found no predictable differences in soil respiration between cropped and vegetation-free soils, between forested and cropped soils, or between grassland and cropped soils, possibly due to the diversity of crops and cropping systems included. Factors such as temperature, moisture availability, and substrate properties that simultaneously influence the production and consumption of organic matter are more important in controlling the overall rate of soil respiration than is vegetation type in most cases. However, coniferous forests had similar to 10% lower rates of soil respiration than did adjacent broad-leaved forests growing on the same soil type, and grasslands had, on average, similar to 20% higher soil respiration rates than did comparable forest stands, demonstrating that vegetation type does in some cases significantly affect rates of soil respiration.

Raiesi, F.G., and P. Buurman. 1998. Effects of CO₂ enrichment on quality of leaf litter and on soil C dynamics in a Mediterranean forest ecosystem. *Fresenius Environmental Bulletin* 7(5A-6A):429-436.

We discuss the effect of long-term elevated CO₂ on quality and decomposability of litter from mature trees, and its influence on soil organic matter (SOM) dynamics by evaluating the available data from mineral CO₂ springs in Central Italy. Results from the vegetation around these natural CO₂ springs demonstrate that elevated CO₂ did not affect litter quality. Consequently, C and N mineralization rates remained unaffected by CO₂ level. However, there were significant differences in litter quality and decomposition between species. Results from soil analysis indicate that elevated CO₂ increased the total organic C content and C pool sizes in the F layer, but not in HA and 0-10 cm layers. Neither were soil N, C/N ratio and the decomposition of SOM affected by elevated CO₂. Soil N mineralization in the forest floor seems to be enhanced by CO₂ enrichment.

Ranasinghe, S., and G. Taylor. 1996. Mechanism for increased leaf growth in elevated CO₂. *Journal of Experimental Botany* 47(296):349-358.

The effect of exposure to elevated CO₂ on the processes of leaf cell

production and leaf cell expansion was studied using primary leaves of *Phaseolus vulgaris* L. Cell division and expansion were separated temporally by exposing seedlings to dim red light for 10 d (when leaf cell division was completed) followed by exposure to bright white light for 14 d (when leaf growth was entirely dependent on cell expansion). When plants were exposed to elevated CO₂ during the phase of cell expansion, epidermal cell size and leaf area development were stimulated. Three pieces of evidence suggest that this occurred as a result of increased cell wall loosening and extensibility, (i) cell wall extensibility (WEx, measured as tensiometric extension using an Instron) was significantly increased, (ii) cell wall yield turgor (Y, MPa) was reduced and (iii) xyloglucan endotransglycosylase (XET) enzyme activity was significantly increased. When plants were exposed to elevated CO₂ during the phase of cell division, the number of epidermal cells was increased whilst final cell size was significantly reduced and this was associated with reduced final leaf area, WEx and XET activity. When plants were exposed to elevated CO₂ during both phases of cell division and expansion, leaf area development was not affected. For this treatment, however, the number of epidermal cells was increased, but cell expansion was inhibited, despite exposure to elevated CO₂ during the expansion phase. Assessments were also made of the spatial patterns of WEx across the expanding leaf lamina and the data suggest that exposure to elevated CO₂ during the phase of leaf expansion may lead to enhanced extensibility particularly at basal leaf margins which may result in altered leaf shape. The data show that both cell production and expansion were stimulated by elevated CO₂, but that leaf growth was only enhanced by exposure to elevated CO₂ in the cell expansion phase of leaf development. Increased leaf cell expansion is, therefore, an important mechanism for enhanced leaf growth in elevated CO₂, whilst the importance of increased leaf cell production in elevated CO₂ remains to be elucidated.

Randerson, J.T., M.V. Thompson, and C.B. Field. 1999. Linking C-13-based estimates of land and ocean sinks with predictions of carbon storage from CO₂ fertilization of plant growth. *Tellus Series B-Chemical and Physical Meteorology* 51(3):668-678.

The residence times of carbon in plants, litter, and soils are required for partitioning land and ocean sinks using measurements of atmospheric delta(13)CO(2) and also for estimating terrestrial carbon storage in response to net primary production (NPP) stimulation by elevated levels of atmospheric CO₂. While C-13-based calculations of the land sink decline with increasing estimates of terrestrial carbon residence times (through the fossil fuel-induced isotopic disequilibrium term in equations describing the global atmospheric budgets of (CO₂)-C-13 and CO₂), estimates of land sinks based on CO₂ fertilization of plant growth are directly proportional to carbon residence times. Here we used a single model of terrestrial carbon turnover, the Carnegie Ames- Stanford Approach (CASA) biogeochemical model, to simultaneously estimate 1984-1990 terrestrial carbon storage using both approaches. Our goal was to identify the fraction of the (CO₂)-C-13-based land sink attributable to CO₂ fertilization. Uptake from CO₂ fertilization was calculated using a beta factor of 0.46 to describe the response of NPP to increasing concentrations of atmospheric CO₂ from 1765 to 1990. Given commonly used parameters in the C-13-based sink calculation and assuming a deforestation flux of 0.8 Pg C/yr, CO₂ fertilization accounts for 54% of the missing terrestrial carbon sink from 1984 to 1990. CO₂ fertilization can account for all of the missing terrestrial sink only when the terrestrial mean residence time (MRT) and the land isodisequilibrium forcing are greater than many recent estimates.

Randlett, D.L., D.R. Zak, K.S. Pregitzer, and P.S. Curtis. 1996. Elevated atmospheric carbon dioxide and leaf litter chemistry: Influences on microbial respiration and net nitrogen mineralization. *Soil Science Society of America Journal* 60(5):1571-1577.

Elevated atmospheric CO₂ has the potential to influence rates of C and N cycling in terrestrial ecosystems by altering plant litter chemistry and slowing rates of organic matter decomposition. We tested the hypothesis that the chemistry of leaf litter produced at elevated CO₂ would slow C and N transformations in soil. Soils were amended with *Populus* leaf litter produced under two levels of atmospheric CO₂ (ambient and twice-ambient) and soil N availability (low and high). Kinetic parameters for microbial respiration and net N mineralization were determined on soil with and without litter during a 32-wk lab incubation. Product accumulation curves for CO₂-C and inorganic N were fit to a first order rate equation [$y = A(1 - e^{-(kt)})$] using nonlinear regression analyses. Although CO₂ treatment affected soluble sugar concentration in leaf litter (ambient = 120 g kg⁻¹, elevated = 130 g kg⁻¹), it did not affect starch concentration or C/N ratio. Microbial respiration, microbial biomass, and leaf litter C/N ratio were affected by soil N availability but not by atmospheric CO₂. Net N mineralization was a linear function of time and was not significantly different for leaves grown at ambient (50 mg N kg⁻¹) and elevated CO₂ (35 mg N kg⁻¹). Consequently, we found no evidence for the hypothesis that leaf litter produced at elevated atmospheric CO₂ will dampen the rates of C and N cycling in soil.

Rao, M.V., and L.J. Dekok. 1994. Interactive effects of high CO₂ and SO₂ on growth and antioxidant levels in wheat. *Phyton-Annales Rei Botanicae* 34(2):279-290.

The impact of elevated CO₂ and/or SO₂ on the growth and antioxidant levels of wheat (*Triticum aestivum* L. cv. Urban) plants has been studied. High CO₂ (0.7 ml l⁻¹) significantly enhanced shoot biomass and photosynthetic capacity, while exposure to SO₂ (0.14 ml l⁻¹) resulted in a decreased shoot biomass and in an injured photosynthetic apparatus, illustrated by a loss of chlorophyll and a decreased ratio of variable to maximal fluorescence ($F(v)/F(m)$) and $A(max)$. However, combined exposure of plants to high CO₂ and SO₂ eliminated the negative effects of SO₂. Sulfate accumulation was almost equal in plants exposed to SO₂ and, high CO₂ and SO₂. A significant increase in ascorbate, glutathione and their redox state was observed in plants exposed to high CO₂ and SO₂, compared to that of plants exposed to solely SO₂. The absence of the negative effects of SO₂ in the presence of high CO₂ might be related to a high redox state of ascorbate and glutathione. Abbreviations: $A(max)$, maximum rate of oxygen evolution at saturated light and CO₂ ($\mu\text{mol m}^{-2} \text{s}^{-1}$); ASA, reduced ascorbic acid; DHA, dehydroascorbic acid; $F(m)$, maximum emission of photosystem-II chlorophyll fluorescence; $F(v)$, variable component of $F(m)$; GSH, reduced glutathione; GSSG, oxidized glutathione.

Rao, M.V., B.A. Hale, and D.P. Ormrod. 1995. Amelioration of ozone-induced oxidative damage in wheat plants grown under high-carbon dioxide - role of antioxidant enzymes. *Plant Physiology*

109(2):421-432.

O₃-induced changes in growth, oxidative damage to protein, and specific activities of certain antioxidant enzymes were investigated in wheat plants (*Triticum aestivum* L. cv Roblin) grown under ambient or high CO₂. High CO₂ enhanced shoot biomass of wheat plants, whereas O₃ exposure decreased shoot biomass. The shoot biomass was relatively unaffected in plants grown under a combination of high CO₂ and O₃. O₃ exposure under ambient CO₂ decreased photosynthetic pigments, soluble proteins, and ribulose-1,5-bisphosphate carboxylase/oxygenase protein and enhanced oxidative damage to proteins, but these effects were not observed in plants exposed to O₃ under high CO₂. O₃ exposure initially enhanced the specific activities of superoxide dismutase, peroxidase, glutathione reductase, and ascorbate peroxidase irrespective of growth in ambient or high CO₂. However, the specific activities decreased in plants with prolonged exposure to O₃ under ambient CO₂ but not in plants exposed to O₃ under high CO₂. Native gels revealed preferential changes in the isoform composition of superoxide dismutase, peroxidases, and ascorbate peroxidase of plants grown under a combination of high CO₂ and O₃. Furthermore, growth under high CO₂ and O₃ led to the synthesis of one new isoform of glutathione reductase. This could explain why plants grown under a combination of high CO₂ and O₃ are capable of resisting O₃-induced damage to growth and proteins compared to plants exposed to O₃ under ambient CO₂.

Rastetter, E.B., and G.R. Shaver. 1992. A model of multiple-element limitation for acclimating vegetation. *Ecology* 73(4):1157-1174.

In this paper we present a simple model of multiple-element limitation of plant production and biomass accumulation. The primary aim of this model is to develop a theoretical framework for examining multiple-element limitation vs. single-element limitation and for examining the relationship between short-term and long-term responses to changes in element availability. In the model we assume that there is an "optimal" ratio of mineral elements in vegetation biomass, and that the vegetation continually adjusts its relative element uptake capacities to compensate for shifts away from this optimum. We examine the responses of this model to changes in element availability in the plant environment, where "availability" is defined either as fixed concentrations of non-depletable elements or as fixed replenishment rates of depletable elements. The model results suggest that the nature of the controls on element availability has a major impact on whether single- or multiple-element limitation prevails, even when plants can acclimate so as to maintain an "optimal" nutritional balance. Single-element limitation occurs when the replenishment rate of an essential element to the available pool is limited and sustainable plant uptake of that element equals the replenishment rate. Furthermore, when single-element limitation prevails, there is little or no correlation between short-term responses to a change in element availability and long-term, equilibrium responses. In general, previous experimental studies and models of plant growth in response to changes in relative availability of multiple, essential elements have either not specified how those resources are controlled, or have examined only one

type of control. Our results help to explain the diversity of results of past studies of multiple-element limitation, suggest some improvements in experimental design for future studies, and have important implications for the extrapolation of the results of controlled experiments to field situations.

Ratanachinakorn, B., A. Klieber, and D.H. Simons. 1997. Effect of short-term controlled atmospheres and maturity on ripening and eating quality of tomatoes. *Postharvest Biology and Technology* 11(3):149-154.

Mature green, breaker, and pink 'Bermuda' tomatoes (*Lycopersicon esculentum* Mill.) were treated in air, 0.5% O₂ for 1 day, or 80% CO₂ for 1 or 2 days at 22 degrees C before ripening in air at 22 degrees C. Headspace ethanol (EtOH) and acetaldehyde (AA), soluble solids (SS), titratable acidity (TA), and pH were measured, and sensory quality was determined using descriptive analysis with a trained panel. Some ripening delay of 1-2 days was observed due to low O₂ and 2 days of high CO₂. EtOH and AA production increased more with increasing fruit maturity and with low O₂ at these maturities; both volatiles dissipated to trace amounts before fruit were eating ripe in all treatments. Aroma and taste were not enhanced by any treatment/ripeness combinations, although 80% CO₂ for 2 days marginally increased the sweetness and blandness of the fruit. Soluble solids, titratable acidity and pH were not different between treatments or ripening stages. (C) 1997 Elsevier Science B.V.

Rathgeber, C., J. Guiot, P. Roche, and L. Tessier. 1999. *Quercus humilis* increase of productivity in the Mediterranean area. *Annals of Forest Science* 56(3):211-219.

Several recent studies have shown an increasing long-term growth trend for various forest tree species in western Europe. Nevertheless such studies have not yet, been performed in Mediterranean Europe. The aim of this work is to analyse changes in productivity of some Mediterranean forest ecosystems compared with other mediterranean forest ecosystems. Sixteen *Quercus humilis* (Miller) populations were sampled in south-east France. Tree ring widths were measured for each tree according to three radius, and annual basal area increments were calculated. Two growth indexes (IP and IC) were calculated with two different standardization techniques, in order to remove age and interstation productivity effects. From the IP and IC indexes we can see that there was a productivity increase during the last century, this increase being evaluated at 100 % (IC index). These results indicate that the Mediterranean forest ecosystems have shown a high productivity increase over the last century, as have the mediterranean forest ecosystems. The best hypothesis to explain this increasing long-term growth trend is a direct CO₂ fertilization along with N deposition fertilization. ((C) Inra/Elsevier, Paris.).

Ratray, E.A.S., E. Paterson, and K. Killham. 1995. Characterization of the dynamics of C-partitioning within lolium-perenne and to the rhizosphere microbial biomass using C-14 pulse-chase. *Biology and Fertility of Soils* 19(4):280-286.

The dynamics of C partitioning with *Lolium perenne* and its associated rhizosphere was investigated in plant-soil microcosms using C-14 pulse-chase labelling. The CO₂(C-14) pulse was introduced into the shoot chamber and the plants allowed to assimilate the label for a fixed period. The microcosm design facilitated independent monitoring of shoot and root/soil respiration during the chase period. Partitioning between above- and below-ground pools was determined between 30 min and 168 h after the pulse, and the distribution was found to vary with the length of the chase period. Initially (30 min after the pulse), C-14 was predominantly (99%) in the shoot biomass and declined thereafter. The results indicate that translocation of recent photoassimilate is rapid, with C-14 detected below ground within 30 min of pulse application. The translocation rate of C-14 below ground was maximal (6.2% h⁻¹) between 30 min and 3h after the pulse, with greatest incorporation into the microbial biomass detected at 3 h. After 3 h, the microbial biomass C-14 pool accounted for 74% of the total C-14 rhizosphere pool. By 24 h, approximately 30% of C-14 assimilate had been translocated below ground; thereafter C-14 translocation was greatly reduced. Partitioning of recent assimilate changed with increasing CO₂ concentration. The proportion of C-14 translocated below ground almost doubled from 17.76% at the ambient atmospheric CO₂ concentration (450 ppm) to 33.73% at 750 ppm CO₂ concentration. More specifically, these changes occurred in the root biomass and the total rhizosphere pools, with two- and threefold C-14 increases at an elevated CO₂ concentration compared to ambient, respectively. The pulse- labelling strategy developed in this study provided sufficient sensitivity to determine perturbations in C dynamics in *L. perenne*, in particular rhizosphere C pools, in response to an elevated atmospheric CO₂ concentration.

Raveh, E., M. Gersani, and P.S. Nobel. 1995. Co₂ uptake and fluorescence responses for a shade-tolerant cactus *hylocereus-undatus* under current and doubled co₂ concentrations. *Physiologia Plantarum* 93(3):505-511.

Hylocereus undatus (Haworth) Britton and Rose growing in controlled environment chambers at 370 and 740 $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ air}$ showed a C₃ acid metabolism (CAM) pattern of CO₂ uptake, with 34% more total daily CO₂ uptake under the doubled CO₂ concentration and most of the increase occurring in the late afternoon. For both CO₂ concentrations, 90% of the maximal daily CO₂ uptake occurred at a total daily photosynthetic photon flux density (PPFD) of only 10 $\text{mol m}^{-2} \text{ day}^{-1}$ and the best day/night air temperatures were 25/15 degrees C. Enhancement of the daily net CO₂ uptake by doubling the CO₂ concentration was greater under the highest PPFD (30 $\text{mol m}^{-2} \text{ day}^{-1}$) and extreme day/night air temperatures (15/5 and 45/35 degrees C). After 24 days of drought, daily CO₂ uptake under 370 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ was 25% of that under 740 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. The ratio of variable to maximal chlorophyll fluorescence (F_v/F_m) decreased as the PPFD was raised above 5 $\text{mol m}^{-2} \text{ day}^{-1}$, at extreme day/night temperatures and during drought, suggesting that stress occurred under these conditions. F_v/F_m was higher under the doubled CO₂ concentration, indicating that the current CO₂ concentration was apparently limiting for photosynthesis. Thus net CO₂ uptake by the shade-tolerant *H. undatus*, the photosynthetic efficiency of which was greatest at low PPFDs, showed a positive response to doubling the CO₂ concentration, especially under stressful environmental conditions.

Raven, J.A. 1994. Carbon fixation and carbon availability in marine-phytoplankton. *Photosynthesis Research* 39(3):259-273.

It is widely believed that inorganic C does not limit the rate of short-term photosynthesis, the net productivity, or the maximum biomass, of marine phytoplankton. This lack of inorganic C restriction is less widely believed to hold for phytoplankton in many low alkalinity freshwaters or for seaweed in nutrient-enriched rock pools. These views are examined in the context of the physical chemistry of the inorganic C system in natural waters and of the ways in which various taxa of phytoplankton deal with inorganic C and discriminate between C-12 and C-13. Using this information to interpret data obtained in the ocean or in freshwater suggests that short-term photosynthesis, production rate, and achieved biomass, of phytoplankton are rarely limited by inorganic C supply but, rather, that the widely suggested factors of limited light, nitrogen or phosphorus supply are the resource inputs which restrict productivity. Global change, by increasing atmospheric CO₂ partial pressure and global mean temperatures, is likely to increase the mean CO₂ concentration in the atmosphere, but the corresponding change in the oceans will be much less. There are, however, genotypic differences in the handling of inorganic C among the diversity of marine phytoplankton, and in impact on use of limiting nutrients, so increases in the mean CO₂ and HCO₃⁻ concentrations in surface ocean waters could cause changes in species composition. However, the rarity of inorganic C limitation of marine phytoplankton short-term photosynthesis, net productivity, or the maximum biomass, in today's ocean means that global change is unlikely to increase these three values in the ocean.

Rawson, H.M. 1992. Plant-responses to temperature under conditions of elevated CO₂. *Australian Journal of Botany* 40(4-5):473-490.

A literature survey of the interactive effects of CO₂ enrichment and temperature on plant development and growth, indicated that the responses cannot be interpreted within a simple framework. For example, although plant development is generally accelerated by increased temperature, CO₂ enrichment can accelerate it even further in some instances, or CO₂ enrichment may have neutral or even retarding effects in other cases. Where the temperature and CO₂ effects are additive, it is argued that CO₂ is operating in the same way as radiation to reduce a carbon limitation. If this were true, CO₂ enrichment would be most likely to accelerate development in tropical regions during the low-radiation monsoon season. Similarly, while it would be expected that CO₂-enrichment would have increasingly enhancing effects with increasing temperature on phytomass growth, this is not invariably the case. In extreme examples which followed the expected trend, plants grown in twice-normal CO₂-enriched atmospheres performed progressively better than those grown at current levels of CO₂ by 8.7% for every 1-degrees-C rise in temperature. However, the difference between the two CO₂ treatments more commonly increased by only around 2% for every 1-degrees-C rise in temperature. Of examples examined, both sunflower and nodulated cowpea showed the reverse response to temperature, while non-nodulated cowpea, supplied with luxuriant levels of nutrition, showed no interaction with temperature but a strong interaction between CO₂ and radiation. Other aspects of the

environment such as nutrition and radiation strongly modify the responses to temperature. It is also clear that plant factors such as stage of development can alter the response to CO₂. Long-term studies with several species are required which will take into account many environmental variables within a realistic envelope. One methodology for doing this is presented. There was no evidence among species that responses to CO₂ arise through any consistent change in morphology such as via increased branching or increased leaf number. Plant plasticity is such that responses can be expressed in a variety of ways determined by other environmental variables.

Rawson, H.M. 1995. Yield responses of 2 wheat genotypes to carbon-dioxide and temperature in-field studies using temperature-gradient tunnels. *Australian Journal of Plant Physiology* 22(1):23-32.

Clear, plastic-coated, temperature gradient tunnels (TGTs), 8 X 1.25 X 1.25 m were designed and built to examine how temperature and CO₂ affect the yield of wheat in the field. Each of the three modules of each TGT was maintained at a different temperature above the ambient temperature using solar heating during the day and electric heating at night. The maximum day-time increment above ambient for the warmest module was 5 degrees C and full-season averages were close to 2 degrees C. TGTs were paired, with air in one being enriched to 700 μ mol L⁻¹ CO₂, and in the other being maintained at ambient CO₂. Crops were planted in the TGTs at two sites in either summer (December) or winter (April and July) and they remained there until maturity. CO₂ enrichment increased the yield in summer plantings by up to 36%. In winter plantings, with mean temperatures between sowing and anthesis of around 10 degrees C, the responses to CO₂ were small averaging only 7% (range 1-12%). Though yield declined with increasing temperature in the TGTs in summer, there was a clear trend for an increasing response to CO₂ at these higher temperatures, i.e. yield declined less. In summer, there was no convincing evidence for a different relative response to CO₂ in two isolines which differed in maturity date, though the later line yielded more under the highest temperature regime (mean of 22-24 degrees C between sowing and anthesis). In winter there was a strong trend for the isoline requiring less vernalisation to respond more to CO₂. It is suggested that early progress towards flowering might predispose wheat to a greater CO₂ response. Overall, the data indicated that the positive response to CO₂ in grain yield is likely to increase at approximately 1.8% per 1 degrees C in wheat crops that are not limited by water. Extrapolation indicated that the temperature at which there was no response to CO₂ was 5 degrees C. All yield responses reflected biomass responses as harvest index was unchanged by CO₂.

Read, J.J., and J.A. Morgan. 1996. Growth and partitioning in *Pascopyrum smithii* (C-3) and *Bouteloua gracilis* (C-4) as influenced by carbon dioxide and temperature. *Annals of Botany* 77(5):487-496.

This study investigated how CO₂ and temperature affect dry weight (d.wt) accumulation, total nonstructural carbohydrate (TNC) concentration, and partitioning of C and N among organs of two important grasses of the shortgrass steppe, *Pascopyrum smithii* Rydb. (C-3) and *Bouteloua gracilis* (H.B.K.) Lag. ex Steud. (C-4). Treatment combinations comprised two temperatures (20 and 35 degrees C) at two

concentrations of CO₂ (380 and 750 $\mu\text{mol mol}^{-1}$), and two additional temperatures of 25 and 30 degrees C at 750 $\mu\text{mol mol}^{-1}$ CO₂. Plants were maintained under favourable nutrient and soil moisture and harvested following 21, 35, and 49 d of treatment. CO₂-induced growth enhancements were greatest at temperatures considered favourable for growth of these grasses. Compared to growth at 380 $\mu\text{mol mol}^{-1}$ CO₂, final d.wt of CO₂-enriched *P. smithii* increased 84% at 20 degrees C but only 4% at 35 degrees C. Final d.wt of *B. gracilis* was unaffected by CO₂ at 20 degrees C, but was enhanced by 28% at 35 degrees C. Root:shoot ratios remained relatively constant across CO₂ levels, but increased in *P. smithii* with reduction in temperature. These partitioning results were adequately explained by the theory of balanced root and shoot activity. Favourable growth temperatures led to CO₂-induced accumulations of TNC in leaves of both species, and in stems of *P. smithii*, which generally reflected responses of above-ground d.wt partitioning to CO₂. However, CO₂-induced decreases in plant tissue N concentrations were more evident for *P. smithii*. Roots of CO₂-enriched *P. smithii* had greater total N content at 20 degrees C, an allocation of N below-ground that may be an especially important adaptation for C-3 plants. Tissue N contents of *B. gracilis* were unaffected by CO₂. Results suggest CO₂ enrichment may lead to reduced N requirements for growth in C-3 plants and lower shoot N concentration, especially at favourable growth temperatures. Read, J.J., J.A. Morgan, N.J. Chatterton, and P.A. Harrison. 1997. Gas exchange and carbohydrate and nitrogen concentrations in leaves of *Paspopyrum smithii* (C-3) and *Bouteloua gracilis* (C-4) at different carbon dioxide concentrations and temperatures. *Annals of Botany* 79(2):197-206.

Paspopyrum smithii (C-3) and *Bouteloua gracilis* (C-4) are important forage grasses native to the Colorado shortgrass steppe. This study investigated photosynthetic responses of these grasses to long-term CO₂ enrichment and temperature in relation to leaf nonstructural carbohydrate (TNC) and [N]. Glasshouse-grown seedlings were transferred to growth chambers and grown for 49 d at two CO₂ concentrations (380 and 750 $\mu\text{mol mol}^{-1}$) at 20 and 35 degrees C, and two additional temperatures (25 and 30 degrees C) at 750 $\mu\text{mol mol}^{-1}$ CO₂. Leaf CO₂ exchange rate (CER) was measured at a plant's respective growth temperature and at two CO₂ concentrations of approx. 380 and 700 $\mu\text{mol mol}^{-1}$. Long-term CO₂ enrichment stimulated CER in both species, although the response was greater in the CER *P. smithii*. Doubling the [CO₂] from 380 to 750 $\mu\text{mol mol}^{-1}$ stimulated CER of *P. smithii* slightly more in plants grown and measured at 30 degrees C compared to plants grown at 20, 25 or 35 degrees C. CO₂-enriched plants sometimes exhibited lower CER when compared to ambient-grown controls measured at the same [CO₂], indicating photosynthetic acclimation to CO₂ growth regime. In *P. smithii*, such reductions in CER were associated with increases in TNC and specific leaf mass, reductions in leaf [N] and, in one instance, a reduction in leaf conductance compared to controls. In *B. gracilis*, photosynthetic acclimation was observed more often, but significant changes in leaf metabolite levels from growth at different [CO₂] were generally less evident. Temperatures considered optimal for growth (C-3: 20 degrees C; C-4: 35 degrees C) sometimes led to CO₂-induced accumulations of TNC in both species, with starch accumulating in the leaves of both species, and fructans accumulating only in *P. smithii*. Photosynthesis of both species is likely to be enhanced in future CO₂-enriched and warmer environments, although responses will sometimes be attenuated by acclimation. (C) 1997 Annals of Botany Company.

Reddy, A.R., K.R. Reddy, and H.F. Hodges. 1998. Interactive effects of elevated carbon dioxide and growth temperature on photosynthesis in cotton leaves. *Plant Growth Regulation* 26(1):33-40.

Cotton (*Gossypium hirsutum* L., cv DPL 5415) plants were grown in naturally lit environment chambers at day/night temperature regimes of 26/18 (T26/18), 31/23 (T-31/23) and 36/28 degrees C (T-36/28) and CO₂ concentrations of 350 (C-350), 450 (C-450) and 700 $\mu\text{mol mol}^{-1}$ (C-700). Net photosynthesis rates, stomatal conductance, transpiration, RuBP carboxylase activity and the foliar contents of starch and sucrose were measured during different growth stages. Net CO₂ assimilation rates increased with increasing CO₂ and temperature regimes. The enhancement of photosynthesis was from 24 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (with C-350 and T-26/18) to 41 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ (with C-700 and T-36/28). Stomatal conductance decreased with increasing CO₂ while it increased up to T-31/23 and then declined. The interactive effects of CO₂ and temperature resulted in a 30% decrease in transpiration. Although the leaves grown in elevated CO₂ had high starch and sucrose concentrations, their content decreased with increasing temperature. Increasing temperature from T-26/18 to 36/28 increased RuBP carboxylase activity in the order of 121, 172 and 190 $\mu\text{mol mg}^{-1} \text{ chI h}^{-1}$ at C-350, C-450 and C-700 respectively. Our data suggest that leaf photosynthesis in cotton benefited more from CO₂ enrichment at warm temperatures than at low growth temperature regimes.

Reddy, K.R., G.H. Davidonis, A.S. Johnson, and B.T. Vinyard. 1999. Temperature regime and carbon dioxide enrichment alter cotton boll development and fiber properties. *Agronomy Journal* 91(5):851-858.

Temperature and atmospheric carbon dioxide concentration [CO₂] affect cotton (*Gossypium hirsutum* L.) growth and development, but the interaction of these two factors on boll and fiber properties has not been studied. An experiment was conducted in naturally lit plant growth chambers to determine the influence of temperature and atmospheric [CO₂] on cotton (cv. DPL-51) boll and fiber growth parameters. Five temperature regimes were evaluated: the 1995 temperature at Mississippi State, MS; the 1995 temperature minus 2 degrees C; and the 1995 temperature plus 2, 5, and 7 degrees C. Daily and seasonal variation and amplitudes were maintained. Atmospheric [CO₂] treatments were 360 (ambient) and 720 $\mu\text{mol L}^{-1}$. Boll number, boll growth, and fiber properties were measured. Boll size and maturation periods decreased as temperature increased. Boll growth increased with temperature to 25 degrees C and then declined at the highest temperature. Boll maturation period, size, and growth rates were not affected by atmospheric [CO₂]. The most temperature-sensitive aspect of cotton development is boll retention. Almost no bolls were retained to maturity at 1995 plus 5 or 7 degrees C, but squares and bolls were continuously produced even at those high temperatures. Therefore, the upper limit for cotton boll survival is 32 degrees C, or 5 degrees C warmer than the 1995 U.S. Mid-South ambient temperatures. The 720 $\mu\text{mol L}^{-1}$ atmospheric [CO₂] had about 40% more squares and bolls across temperatures than the 360 $\mu\text{mol L}^{-1}$ [CO₂]. Fibers were longer when bolls grew at less than optimal temperatures (25 degrees C) for boll growth. As temperature increased, fiber length distributions were more uniform. Fiber fineness and maturity increased linearly with the increase in temperature up to 26 degrees C, but decreased at 32 degrees C. Short-fiber content declined linearly from 17 to 26 degrees C, but was higher at higher temperature.

As for boll growth and developmental parameters, elevated atmospheric [CO₂] did not affect any of the fiber parameters. Changes in temperature, however, had a dramatic effect on boll set and tiber properties. The relationships between temperature and boll growth and developmental rate functions and fiber properties provide the necessary functional parameters to build fiber models under optimum water and nutrient conditions.

Reddy, K.R., H.F. Hodges, and J.M. McKinion. 1995. Carbon-dioxide and temperature effects on pima cotton development. *Agronomy Journal* 87(5):820-826.

Predicting plant responses to changing atmospheric CO₂ and to the possible global warming are important concerns. Effects of CO₂ on developmental events are poorly documented, as is the interaction of CO₂ and other major climate variables on crop development. The objective of this experiment was to determine the effects of an altered CO₂ environment and interactions of CO₂ and temperature on pima cotton developmental rates. Pima cotton (*Gossypium barbadense* L. cv. S-6) was grown from seed in sun-lit plant growth chambers. Air temperatures were controlled from 20/12 to 40/32 degrees C (day/night) in 5-degree increments. Daytime CO₂ was maintained at 350 or 700 μ L L⁻¹. In a second experiment, the temperature was maintained at 30/22 degrees C day/night and the plants were grown in 350, 450, or 700 μ L L⁻¹ CO₂. Days required to develop nodes on the mainstem, days from emergence to first square, number of vegetative and fruiting branches, number of fruiting sites produced, number of bolls and squares produced, and number of bolls and squares retained by the plants were determined. Rates of mainstem node formation and the time required to produce the first square and first flower were not sensitive to atmospheric CO₂, but were very sensitive to temperature. Prefruiting branch nodal positions required longer to develop than nodes with fruiting branches. Carbon dioxide levels did not affect the time required to produce nodes. Number of branches produced was sensitive to both temperature and CO₂. The larger number of bolls set on the lower branches of plants grown at high CO₂ provided a larger sink for photosynthate than plants grown at low CO₂. This may be the reason for the observed reduction in number of fruit at the upper nodes of high-CO₂-grown plants. More bolls and squares were produced and retained on plants grown in high-CO₂ environments, except that none were produced in either CO₂ environment at 40/32 degrees C. Our results indicate that high-temperature-tolerant cotton cultivars would be more productive in the present-day CO₂ world, and they would be essential in the future if global temperature increases.

Reddy, K.R., H.F. Hodges, and J.M. McKinion. 1995. Carbon-dioxide and temperature effects on pima cotton growth. *Agriculture Ecosystems & Environment* 54(1-2):17-29.

Temperature and CO₂ are major environmental variables that affect plant growth and development. Limited information is available concerning how these factors affect plants, as well as specific interactions between the two. We conducted two experiments in controlled environmental chambers where temperature and CO₂ were controlled and other environmental factors were not limiting. The purpose was to determine how cotton grew and responded to a range of temperatures and CO₂ concentrations. During vegetative development,

stem growth was quite sensitive to CO₂ resulting in more effective early-season light capture. Plants did not develop more nodes when exposed to additional CO₂, while node number increased more at higher temperatures. Individual leaf growth was about 18% greater at optimum temperature in 450 μ L L⁻¹ than in 350 μ L L⁻¹ CO₂, but did not increase from 450 μ L L⁻¹ CO₂ to 700 μ L L⁻¹ CO₂. However, the time required for a leaf to reach mature size was not influenced by CO₂. Leaf area, on the whole plant basis, was about 33% greater on plants grown at optimum temperature in high CO₂ than in ambient CO₂. The greater leaf area on a whole plant basis was achieved by a combination of larger leaves and additional leaves produced primarily on the branches. There was a 28% increase in number of bolls produced at 700 μ L L⁻¹ CO₂ at optimum temperature compared with bolls produced at 350 μ L L⁻¹ CO₂. There was not, however, an increase in boll size due to high CO₂. At 35.5-degrees-C, little growth response to high CO₂ environments occurred at 700 μ L L⁻¹ CO₂ compared with 350 μ L L⁻¹ CO₂, but approximately a 45% increase occurred in the plants grown at 18.9-26.9-degrees-C. Less total biomass was produced at 35.5-degrees-C than at 26.9-degrees-C and no bolls were produced in either CO₂ environment at the higher temperature. The most important response to temperature and CO₂ occurred at high temperatures where the effects of elevated CO₂ on plant growth were masked by apparent high-temperature injury that limited growth of all plant organs, particularly, reproductive growth.

Reddy, K.R., H.F. Hodges, and J.M. McKinion. 1997. A comparison of scenarios for the effect of global climate change on cotton growth and yield. *Australian Journal of Plant Physiology* 24(6):707-713.

If global surface temperatures change as projected because of radiative and physiological effects of a changing environment, we should expect important changes in crop production in the 21st Century. Experiments were conducted at ambient and twice ambient atmospheric CO₂ concentrations at five temperatures. The 1995 temperature in Mississippi was used as a reference with the other temperatures being 1995 minus 2 degrees C, and 1995 plus 2, 5 and 7 degrees C. Daily and seasonal variation and amplitudes were maintained. Seedlings had 4-6 times as much leaf area and dry weight at 20 d after emergence when grown at 28 degrees C as at 23 degrees C (1995 ambient) average temperature during that growth period. Number of days to first square, flower, and open boll decreased as temperature increased. Double atmospheric CO₂ did not affect these developmental rates. Temperatures above 28 degrees C, or 1995 average whole-season temperatures, were detrimental to mid- and late-season boll retention and growth. No fruits were retained to maturity at 1995 plus 5 or 7 degrees C. However, whole season vegetative growth was not significantly reduced by temperature 5-7 degrees C above the 1995 ambient conditions. Twice ambient CO₂ caused about 40% increase in vegetative dry matter accumulation across temperatures. In a separate experiment, similar results were obtained on fruiting cotton grown at a range of temperatures based on long-term average US Midsouth July temperatures. Therefore, if global warming occurs as predicted, food and fibre production in such high- temperature and humid environments may be more limited to vegetative structures and the animals that consume vegetative structures.

Reddy, K.R., H.F. Hodges, and J.M. McKinion. 1997. Modeling temperature effects on cotton internode and leaf growth. *Crop Science* 37(2):503-509.

Cotton (*Gossypium hirsutum* L.) is grown commercially in temperatures that vary greatly during the season. The purpose of this study was to develop potential growth and developmental rates of cotton leaves and internodes as a function of temperature in a temperature-limiting environment. That information may be used with growth duration and appropriate stress factors to develop a crop canopy development model. Plants were grown in sunlit plant growth chambers in five temperatures, 20/12 degrees C to 40/32 degrees C (day/night), at ambient (350 μ mol L⁻¹ CO₂) and twice ambient carbon dioxide levels in well-watered and fertilized conditions. Plants were monitored daily for leaf unfolding dates, areas of leaves, and lengths of internodes at leaf unfolding, and growth of leaves and internodes. Durations of leaf and internode expansion were also determined. Leaf unfolding interval rates of both mainstem and fruiting branches increased as temperature increased; the rate of mainstem leaf unfolding interval increased more than the rate of branch leaf unfolding. Irrespective of sizes, leaves, and internodes fit a single relationship of relative expansion rates and age for each temperature condition. Enriching CO₂ to twice the ambient level did not change these relationships. Increasing temperature increased maximum growth rate, decreased the decay in the rate of expansion due to age, and reduced growth duration of both leaves and internodes. Internodes typically took less time than leaves to elongate at all temperatures. Leaf area and internode length at leaf unfolding increased as temperature increased to 27 to 30 degrees C, then decreased at higher temperatures.

Reddy, K.R., R.R. Robana, H.F. Hodges, X.J. Liu, and J.M. McKinion. 1998. Interactions of CO₂ enrichment and temperature on cotton growth and leaf characteristics. *Environmental and Experimental Botany* 39(2):117-129.

Studies on the interactive effects of atmospheric CO₂ and temperature on growth and leaf morphology, particularly on stomatal index and density are limited. Upland cotton was grown in naturally-lit plant growth chambers at 30/22 degrees C day/night temperatures from planting until squaring or the fifth or sixth leaf emerged. Five growth chambers were maintained at ambient (350 μ mol L⁻¹) CO₂ and another five at twice ambient (700 μ mol L⁻¹) CO₂ throughout the experiment. Day/night temperature treatments of 20/12, 25/17, 30/22, 35/27 and 40/32 degrees C were imposed at each CO₂ treatment for 42 days after squaring. The plants were irrigated with half-strength Hoagland's nutrient solution three times per day. Growth of plant parts was determined at the end of the experiment. Stomatal characteristics, nonstructural carbohydrates and specific leaf weight were measured on the fully expanded tenth mainstem leaf. Stomatal density and index were not affected by elevated CO₂. Stomata and epidermal cell numbers per leaf increased in high CO₂ and were positively correlated with final leaf sizes irrespective of CO₂ level. Our results suggest that plants do not acclimate to elevated CO₂ by changing stomatal density within a single generation. Leaves had greater area and accumulated more biomass when grown in high CO₂. Growth stimulation expressed as dry weight at 700 μ mol L⁻¹ over dry weight at 350 μ mol L⁻¹ CO₂ was uniform across temperatures. Temperature optimum for vegetative and reproductive growth was 30/22 degrees C and was not altered by CO₂ enrichment. Fruit retention was severely curtailed at the two higher temperatures compared to 30/22 degrees C in both CO₂ environments. Increased carbohydrate storage in leaves may be an added advantage for initiation and growth of vegetative structures such as branches at all temperatures. However, it is unlikely that high temperature effects on flower abortion will be ameliorated by high CO₂. Species/cultivars that retain fruits at high temperatures would be more productive both in the present-day cotton producing environments and are even more desirable in the future warmer world. Reddy, S.R.C., and C. Price. 1999. Carbon sequestration and conservation of tropical forests under uncertainty. *Journal of Agricultural Economics* 50(1):17-35.

Concern for global warming has focused attention on the role of tropical forests in the reduction of ambient CO₂ levels and mitigation of climate change. Deforestation is a major land use change in the tropics, with forest resources undergoing degradation through the influence of logging and conversion to other uses. Land use change is a product of varied local and regional resource use policies. Management of forest resources is one such major temporal factor, influencing resource stability and the carbon pool. Under a given management policy, both the long period of forest growth, and the slow turnover and decay of the carbon pool, enhance the relevance of stand level management policies as cost-effective mechanisms mitigating climate change. Apart from regional level uncertainties like the nature of land use and the estimation of carbon storage in vegetation and soil, the carbon flux of tropical forests is greatly influenced by uncertainty in regenerative capacity of forests and in harvest and management policies. A case study from India is used to develop a transition matrix model of natural forest management, and to explore the economic implications of maintaining and expanding existing carbon sinks. The study further explores the significance of investments in additional carbon sink in plantation forests, given continued uncertainty in natural forest management.

Reddy, V.R., K.R. Reddy, and B. Acock. 1995. Carbon-dioxide and temperature interactions on stem extension, node initiation, and fruiting in cotton. *Agriculture Ecosystems & Environment* 55(1):17-28.

Understanding the response of agricultural crops to rising carbon dioxide concentration (CO₂) and temperature is critical for modeling the effects of future climate change on crop productivity. The objective of this study was to evaluate the direct and interactive effects of temperature and CO₂ on mainstem and branch expansion rates, node initiation rates, and fruiting in cotton to be used for the development of a cotton simulation model. Cotton plants (*Gossypium hirsutum* L., cv. DPL 50) were grown in plant growth chambers exposed to natural light levels with temperature and CO₂ as treatments. The average temperatures were 17.8, 18.7, 22.7, 26.6, and 30.6 degrees C during a 70 day experimental period with CO₂ treatments of 350 and 700 μ mol L⁻¹ at each temperature. Plant height and number of mainstem nodes increased with increase in temperature and CO₂. A nine-fold increase was observed in number of fruiting branches with increase in temperature from 17.8 to 30.6 degrees C, however, no significant differences were observed in fruiting branch number due to doubling of CO₂ except at 30.6 degrees C. The number of days from emergence to first square was strongly influenced by temperature, and CO₂ had no effect on this process. The number of squares and bolls were increased at higher temperatures, and the rate of increase was greater at 700 μ mol L⁻¹ CO₂.

Reddy, V.R., K.R. Reddy, and H.F. Hodges. 1995. Carbon-dioxide

enrichment and temperature effects on cotton canopy photosynthesis, transpiration, and water-use efficiency. *Field Crops Research* 41(1):13-23.

The objectives of this study were to evaluate effects of ambient and double ambient [CO₂] at a range of growing temperatures on photosynthesis, respiration, transpiration, water-use efficiency and dry matter accumulation of cotton plants (*Gossypium hirsutum* L., cv. DPL 50). In Experiment I, plants were grown outdoors until first bloom, then transferred into naturally lit growth chambers and grown for 22 days at 30/ 18 degrees C with five CO₂ concentrations varying from 350 to 900 μ mol(-1). In Experiment II, air temperatures were maintained at 20/12, 25/17, 30/22, and 35/27 degrees C day/night during a 70-day experimental period with [CO₂] of 350 and 700 μ mol(-1) at each temperature. Photosynthesis increased with [CO₂] from 350 to 700 μ mol(-1) and with temperature. Plants grown at 35/27 degrees C produced fewer bolls due to abscission compared with plants grown at optimum temperatures (30/20 degrees C). At higher [CO₂], water-use efficiency increased at all temperatures due mainly to increased canopy photosynthesis but also to more limited extent to reduced canopy transpiration. Increased photosynthesis at higher [CO₂] resulted in greater dry matter accumulation at all temperatures except at 20/12 degrees C. Respiration increased as dry matter and temperature increased. Plants grown at higher [CO₂] had less respiration per unit dry matter but more per unit area. These results indicate that future increases in [CO₂] are likely to benefit cotton production by increasing carbon assimilation under temperatures favorable for cotton growth. Reduced fruit weights at higher temperatures indicate potential negative effects on production if air temperatures increase as projected in a high-CO₂ world.

Reddy, V.R., K.R. Reddy, and Z. Wang. 1997. Cotton responses to nitrogen, carbon dioxide, and temperature interactions (Reprinted from Plant nutrition for sustainable food production and environment, 1997). *Soil Science and Plant Nutrition* 43:1125-1130.

Several studies were conducted to evaluate how increases in the global atmospheric carbon dioxide concentration [CO₂] and temperature affect growth and development rates, dry matter production, photosynthesis, and water use efficiency of cotton and how these responses are influenced by leaf N levels. In one study, cotton (cv. DPL 50) plants were grown at four temperatures (20/12, 25/17, 30/22, and 35/27 degrees C day/night) until harvest at 70 days after emergence (DAE). Each temperature treatment was combined with [CO₂] of 350 or 700 μ mol L⁻¹. In another study, cotton (cv. DES 119) grown at two [CO₂] received five N treatments (0, 1, 2, 6, and 10 mM NO₃ in Hoagland's nutrient solution) at 17 DAE and every 2 days thereafter. Canopy gross photosynthetic rates increased with increasing [CO₂] and temperature. The increased photosynthesis resulted in higher plant growth and dry matter accumulation rates except at the highest temperature. At 70 DAE, the maximum canopy dry matter accumulation rate occurred in 30/22 degrees C. The 35/27 degrees C treatment induced fruit abortion, resulting in greater dry matter accumulation in vegetative structures. Increases in plant dry weights by CO₂ enrichment were greater in the two high temperature regimes than in the two lower temperature regimes. Water-use efficiency increased with increased [CO₂] and decreased with increased temperature. Increases in water-use efficiency were due mainly to increased photosynthesis and partly to reduced canopy transpiration. Increase in leaf N concentration increased cotton photosynthesis and vegetative growth rates, and the increases were higher at 700 μ mol L⁻¹ than at 350 μ mol L⁻¹ [CO₂].

Reece, C.F., S.V. Krupa, H.J. Jager, S.W. Roberts, S.J. Hastings, and W.C. Oechel. 1995. Evaluating the effects of elevated levels of atmospheric trace gases on herbs and shrubs - a prototype dual array field exposure system. *Environmental Pollution* 90(1):25-31.

In the context of global climate change, an understanding of the long-term effects of increasing concentrations of atmospheric trace gases (carbon dioxide, CO₂, ozone, O₃, oxides of nitrogen, NO_x etc.) on both cultivated and native vegetation is of utmost importance. Over the years, under field conditions, various trace gas-vegetation exposure methodologies with differing advantages and disadvantages have been used. Because of these variable criteria, with elevated O₃ or CO₂ levels, at the present time the approach of free-air experimental-release of the gas into study plots is attracting much attention. However, in the case of CO₂, this approach (using 15 m diameter study plot with a single circular array of vent pipes) has proven to be cost prohibitive (about \$59000- 98000/year/replicate) due to the consumption of significant quantities of the gas to perform the experiment (CO₂ level elevated to 400 ppm above the ambient). Therefore, in this paper, we present a new approach consisting of a dual concentric exposure array of vertical risers or vent pipes. The purpose of the outer array (17 m diameter) is to vent ambient air outward and toward the incoming wind thus providing an air curtain to reduce the velocity of that incoming wind to simulate the mode or the most frequently occurring wind speed at the study site. The inner array (15 m diameter) vents the required elevated levels of trace gases (CO₂, O₃, etc.) into the study plot. This dual array system is designed to provide spatial homogeneity (shown through diffusion modeling) of the desired trace-gas levels within the study plot and to also reduce its consumption. As an example, while in the single- array free-air CO₂-release system the consumption of CO₂ to elevate its ambient concentration by 400 ppm is calculated to be about 980 tons/year/replicate, it is estimated that in the dual array system it would be approximately 590 tons/year/replicate. Thus, the dual array system may provide substantial cost savings (\$24000-39000/year/replicate) in the CO₂ consumption (\$60-100/ton of CO₂) alone. Similarly, benefits in the requirements of other trace gases (O₃, NO_x, etc.) are expected, in future multivariate studies on global climate change.

Reekie, E.G., and F.A. Bazzaz. 1991. Phenology and growth in 4 annual species grown in ambient and elevated CO₂. *Canadian Journal of Botany-Revue Canadienne De Botanique* 69(11):2475-2481.

The objectives of this study were (i) to test the hypothesis that changes in phenology with CO₂ are a function of the effect of CO₂ upon growth and (ii) to determine if CO₂-induced changes in phenology can influence competitive outcome. We examined the effect of 350, 525, and 700- μ mol L⁻¹ CO₂ on *Guara brachycarpa*, *Gailardia pulchella*, *Oenothera lacinata*, and *Lupinus texensis*. Plants were grown as individuals in 150-, 500-, or 1000-mL pots and in competition in 1000-mL pots. Growth and development were monitored at twice-weekly intervals, by recording the number of leaves and noting the presence or absence of stem elongation, branching, flower buds, and open flowers. Elevated CO₂ affected both growth and phenology, but the direction and magnitude of effects varied with species and soil volume. Elevated CO₂ did not appear to affect development through its effect on growth. Those treatments in which there were significant effects of CO₂ on growth were generally different from those treatments in which CO₂ affected phenology. Rather than affecting phenology by changing plant size, CO₂ appeared to affect phenology by modifying the size at which plants

switched from one stage to the next. The level of CO₂ changed competitive outcome; the importance of *Lupinus* increased whereas that of *Oenothera* decreased with increased CO₂. These changes were more closely related to the effect of CO₂ on growth than its effect on phenology.

Reekie, E.G., C. MacDougall, I. Wong, and P.R. Hicklenton. 1998. Effect of sink size on growth response to elevated atmospheric CO₂ within the genus *Brassica*. *Canadian Journal of Botany-Revue Canadienne De Botanique* 76(5):829-835.

Many plants grown at elevated CO₂ concentrations exhibit enhanced photosynthetic rates. However, this increase in photosynthesis is often reduced after prolonged exposure to elevated CO₂. This reduction may be related to the capacity of plants to utilize the extra photosynthate produced at elevated CO₂. This study examined the effect of source to sink ratio on the capacity of plants to respond to elevated CO₂. Seven species or cultivars within the genus *Brassica* were germinated and grown at either 350 or 1000 ppm CO₂. Broccoli (*Brassica oleracea* L.) and cauliflower (*B. oleracea* L.) have large carbon sinks in the reproductive structures; Chinese broccoli (*Brassica campestris* L.) and marrow stem kale (*B. oleracea*) have carbon sinks in the stem; turnip (*B. campestris*) stores carbon in the root; rape (*Brassica napus* L.) and white mustard (*Brassica alba* (L.) Rabenh.) have no obvious carbon storage structures and were assumed to have a lower sink strength relative to the above cultivars. Plants were harvested at three stages of development and total plant weight, leaf area ratio, and allocation to leaf, root, and stem determined. As young seedlings, all cultivars responded positively to elevated CO₂. The long-term growth response of different cultivars to CO₂ was independent of sink location, but was dependent on sink size. Cultivars with no obvious carbon storage structures showed no significant growth enhancement by elevated CO₂ by the end of the experiment. However, neither leaf area ratio nor biomass allocation pattern were reliable predictors of response to CO₂ suggesting that assessing differences in source to sink ratio is not necessarily straightforward.

Reekie, J.Y.C., P.R. Hicklenton, and E.G. Reekie. 1994. Effects of elevated CO₂ on time of flowering in 4 short-day and 4 long-day species. *Canadian Journal of Botany-Revue Canadienne De Botanique* 72(4):533-538.

This study was undertaken to determine if the effect of elevated CO₂ on flowering phenology is a function of the photoperiodic response of the species involved. Four long-day plants, *Achillea millefolium*, *Callistephus chinensis*, *Campanula isophylla*, and *Trachelium caeruleum*, and four short-day plants, *Dendranthema grandiflora*, *Kalanchoe blossfeldiana*, *Pharbitis nil*, and *Xanthium pensylvanicum*, were grown under inductive photoperiods (9 h for short day and 17 h for long day) at either 350 or 1000 $\mu\text{L/L}$ CO₂. Time of visible flower bud formation, flower opening, and final plant biomass were assessed. Elevated CO₂ advanced flower opening in all four long-day species and delayed flowering in all four short-day species. In the long-day species, the effect of CO₂ was primarily on bud initiation; all four species formed buds earlier at high CO₂. Bud development, the difference in time between flower opening and bud initiation, was advanced in only one long-day species, *Callistephus chinensis*. Mixed results were obtained for the short-day species. Elevated CO₂ exerted no effects on

bud initiation but delayed bud development in *Dendranthema* and *Kalanchoe*. In *Xanthium*, bud initiation rather than bud development was delayed. Data on bud initiation and development were not obtained for *Pharbitis*. The negative effect of CO₂ upon phenology in the short-day species was not associated with negative effects on growth. Elevated CO₂ increased plant size in both long-day and short-day species.

Reekie, J.Y.C., P.R. Hicklenton, and E.G. Reekie. 1997. The interactive effects of carbon dioxide enrichment and daylength on growth and development in *Petunia hybrida*. *Annals of Botany* 80(1):57-64.

Plants were grown at either 350 or 1000 $\mu\text{L/L}$ CO₂ and in one of three photoperiod treatments: continuous short days (SD), continuous long days (LD), or short switched to long days at day 41 (SD-LD). All plants received 9 h of light at 450 $\mu\text{mol m}^{-2} \text{s}^{-1}$ and LD plants received an additional 4 h of light at 8 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Growth of SD plants responded more positively to elevated CO₂ than did LD plants, due largely to differences in the effect of CO₂ on unit leaf rate. High CO₂ increased height and decreased branching under SD conditions, but had no effect under LD conditions. Elevated CO₂ also increased the number of buds and open flowers, the effect for flower number being greater in short than in long days. The specific leaf area of plants grown at 1000 $\mu\text{L/L}$ CO₂ was reduced regardless of daylength. High CO₂ also decreased leaf and increased reproductive allocation, the magnitude of these effects being greater under SD conditions. Bud formation and flower opening was advanced under high CO₂ conditions in SD plants but bud formation was delayed and there was no effect on flower opening under LD conditions. The effects of CO₂ on plants switched from SD to LD conditions were largely intermediate between the two continuous treatments, but for some parameters, more closely resembled one or the other. The results illustrate that daylength is an important factor controlling response of plants to elevated CO₂. (C) 1997 Annals of Botany Company.

Reeves, D.W., H.H. Rogers, S.A. Prior, C.W. Wood, and G.B. Runion. 1994. Elevated atmospheric carbon-dioxide effects on sorghum and soybean nutrient status. *Journal of Plant Nutrition* 17(11):1939-1954.

Increasing atmospheric carbon dioxide (CO₂) concentration could have significant implications on technologies for managing plant nutrition to sustain crop productivity in the future. Soybean (*Glycine max* [L.] Merr.) (C₃ species) and grain sorghum (*Sorghum bicolor* [L.] Moench) (C₄ species) were grown in a replicated split-plot design using open-top field chambers under ambient (357 $\mu\text{mol/mol}$) and elevated (705 $\mu\text{mol/mol}$) atmospheric CO₂. At anthesis, leaf disks were taken from upper mature leaves of soybean and from the third leaf below the head of sorghum for analysis of plant nutrients. Leaf greenness was measured with a Minolta SPAD-502 chlorophyll meter. Concentrations of chlorophylls a and b and specific leaf weight were also measured. Above-ground dry matter and seed yield were determined at maturity. Seed yield of sorghum increased 17.5% and soybean seed yield increased 34.7% with elevated CO₂. There were no differences in extractable chlorophyll concentration or chlorophyll meter readings due to CO₂ treatment, but meter readings were reduced 6% when sorghum was grown in chambers as compared in the open. Leaf nitrogen (N)

concentration of soybean decreased from 54.5 to 39.1 g/kg at the higher CO₂ concentration. Neither the chambers nor CO₂ had an effect on concentrations of other plant nutrients in either species. Further work under field conditions is needed to determine if current critical values for tissue N in crops, especially C3 crops, should be adjusted for future increases in atmospheric CO₂ concentration.

Refouvelet, E., and F. Daguin. 1999. Polymorphic glutamate dehydrogenase in lilac vitroplants as revealed by combined preparative IEF and native PAGE: Effect of ammonium deprivation, darkness and atmospheric CO₂ enrichment upon isomerization. *Physiologia Plantarum* 105(2):199-206.

The activity and polymorphism of glutamate dehydrogenase (GDH) were studied in basal callus of Lilac (*Syringa vulgaris* L.) vitroplants. Native PAGE alone revealed seven bands staggered at regular intervals. Preparative liquid-vein IEF allowed the separation of six to ten GDH fractions with charges ranging between 5.18 and 7.08. Analysis of these GDH fractions in native PAGE indicated that up to seven GDH bands can be detected for each fraction. This suggests the existence of seven isoforms of the enzyme with subunits presenting different isoelectric points. Dark- and ammonium-controlled forms were found to be the more acidic and faster migrating ones in native PAGE. The results support for the first time that atmospheric CO₂ enrichment increases GDH activity dramatically and modifies isomerization of the enzyme.

Reich, P.B. 1995. Phenology of tropical forests - patterns, causes, and consequences. *Canadian Journal of Botany-Revue Canadienne De Botanique* 73(2):164-174.

Leaf phenology of tropical forests is distinct from other biomes. Unlike the marked temperature-related periodicity of temperate forests, development tends to be continuous in aseasonal lowland tropical rain forests and becomes more episodic in response to increasing annual drought in tropical dry forests. Hence, in tropical rain forests, foliar development (production, senescence, and longevity) is largely under internal rather than environmental control. In contrast, tropical forests with marked annual dry seasons display associated seasonality of leaf production and shedding. This developmental seasonality can be explained by overlaying the influence of seasonality on trees' internally regulated development and appears to be controlled by acclimative physiological processes and not by sensitivity to photo-, thermo-periodic, or direct environmental cues. Consequences of tropical phenology stem from both the variety of leaf and species ecophysiological types common to a given moisture regime and their relative synchrony of development, and include the following: larger diversity of ecophysiological species types in rain than dry forests; differential rates of herbivory in dry than wet seasons and for synchronous versus asynchronous leaf flushes; ecosystems with greater canopy foliar mass per hectare in rain than dry forests; and several leaf adaptations perhaps unique to tropical forests, such as delayed greening and seasonal leaf phenotypes. Tropical forests may vary in sensitivity to predicted climate change. Phenology of rain forests should change little unless water balance changes markedly, and developmental events in rain forests may be relatively insensitive to moderate changes in CO₂ or temperature. Phenology of dry forests could be more sensitive, and in

opposite directions, to elevated CO₂ and temperatures. Elevated CO₂ might delay the onset of leaf shedding and stimulate longer life span if stand level transpiration is reduced, whereas higher temperatures could lead to more rapid water depletion, longer leafless periods, and more strongly synchronized phenology.

Reich, P.B., J. Oleksyn, and M.G. Tjoelker. 1996. Needle respiration and nitrogen concentration in Scots Pine populations from a broad latitudinal range: A common garden test with field-grown trees. *Functional Ecology* 10(6):768-776.

1. Models of tree function and forest ecosystem carbon budgets often assume that potential global changes in temperature and/or other factors may alter tissue nitrogen (N) and dark respiration rates (R(d)). However, little is known of patterns of co-variation in tissue N and R(d) among intraspecific populations originating along climatic gradients, and of whether an N-based model of R(d) can link these two variables. To address these issues, we studied N and R(d) in fully expanded needles of 10-year-old trees of 14 Scots Pine (*Pinus sylvestris*) populations of wide-ranging origin (43 degrees to 60 degrees N), grown under common garden conditions. 2. For 11 lowland populations (elevation <200 m) from the contiguous part of the species range (48 degrees to 60 degrees N) grown at a field site in Kornik, western Poland (52 degrees N), there were greater needle %N in populations from increasing latitude of origin or decreasing mean annual temperature (r greater than or equal to 0.93, $P < 0.01$). Similar %N and latitude of origin correlations were observed in another year at this site and in retrospective analyses of published data for different sets of Scots Pine populations grown in common gardens at 48 degrees, 52 degrees C and 62 degrees N latitudes. Needle R(d) rates of the 11 lowland populations growing at Kornik and measured at a common temperature (20 degrees C) were greater, by as much as 50%, for more northerly than southerly populations. Mean R(d) rates were positively correlated to latitude of origin and to mean annual temperature ($P < 0.05$, $r = 0.7$ to 0.8). R(d) and needle %N were positively correlated ($P < 0.01$, $r = 0.75$), with one relationship fitting all data. Across the entire range from 1.15 to 1.55 needle %N, R(d) increased from 4.5 to 6.9 nmol g⁻¹ s⁻¹. 3. Mean needle %N and R(d) values for two montane southern populations (43 degrees and 44 degrees N, elevation greater than or equal to 885 m) growing in the same common garden at Kornik were consistent with the relationships between mean annual temperature, needle %N and R(d) observed for the more northerly populations but did not fit the latitudinal patterns. This suggests that temperature and/or associated climate variables are likely the driving force for observed genetic variation in Scots Pine needle %N and R(d) across latitudinal and altitudinal gradients. 4. Results of these common garden studies support the idea of a general relationship between needle dark respiration and N concentration, and indicate that there is intraspecific genetic variation in physiology that is selected by climate that persists in a common environment, resulting in higher needle %N and respiration in plants originating from colder habitats. Such patterns need to be better understood and quantified, and merit consideration in modelling of current and potential global change effects on plant function and global carbon cycles.

W.F. Postl, and F. Halbwachs. 1997. The influence of ambient and elevated ozone concentrations on photosynthesis in *Populus nigra*. *Plant, Cell and Environment* 20(8):1061-1069.

Light-saturated net leaf photosynthesis ($A(\text{sat})$), CO_2 response curves (A/C_i), current photochemical capacity (F_v/F_m) and pigment contents were measured in leaves of *Populus nigra* (Clone T107) which had been exposed to ozone stress in open-top chambers for the entire growth period. Surprisingly, not only elevated ($\text{ao}(+)$, i.e. ambient air + 50 $\text{mm}^3 \text{m}^{-3}$ ozone) but also ambient (aa) ozone concentrations led to a reduction in $A(\text{sat})$ in comparison with leaves exposed to air containing almost no ozone ($\text{cf}(-)$, i.e. charcoal filtered ambient air). The very small change in leaf conductance (g_l) indicated that the decrease in $A(\text{sat})$ was not due to stomatal limitation. This finding was supported by the fact that, a decrease in carboxylation efficiency (CE) correlated with a loss in $A(\text{sat})$. In comparison to cf -leaves, aa leaves showed no change in current photochemical capacity (F_v/F_m) throughout the whole experiment. However, a marked decline in F_v/F_m in $\text{ao}(+)$ leaves was observed at a time when $A(\text{sat})$ and CE were already decreased by about 45% and 60% respectively. As the chlorophyll b content of leaves is known to correlate with the amount of LHC and PSII centres, it was used to normalize fluorescence parameters in relation to PSII centres present. The normalized values for F_m and F_o increased with the dosage of ozone in $\text{ao}(+)$ leaves but not in aa leaves, indicating a change of the pigment content of PSII in the former, but not in the latter. These data led to the conclusion that ozone interacts primarily with components of the Calvin cycle, which results in a decrease in $A(\text{sat})$ with subsequent feedback on the current photochemical capacity of PSII centres.

Reicosky, D.C., D.W. Reeves, S.A. Prior, G.B. Runion, H.H. Rogers, and R.L. Raper. 1999. Effects of residue management and controlled traffic on carbon dioxide and water loss. *Soil & Tillage Research* 52(3-4):153-165.

Management of crop residues and soil organic matter is of primary importance in maintaining soil fertility and productivity and in minimizing agricultural impact on the environment. Our objective was to determine the effects of traffic and tillage on short-term carbon dioxide (CO_2) and water (H_2O) fluxes from a representative soil in the southeastern Coastal Plain (USA). The study was conducted on a Norfolk loamy sand (FAO classification, Luxic Ferralsols; USDA classification, fine-loamy siliceous, thermic Typic Kandiudults) cropped to a corn (*Zea mays* L.)- soybean (*Glycine max* (L.) Merr) rotation with a crimson clover (*Trifolium incarnatum* L.) winter cover crop for eight years. Experimental variables were with and without traffic under conventional tillage (CT) (disk harrow twice, chisel plow, field cultivator) and no tillage (NT) arranged in a split-plot design with four replicates. A wide-frame tractive vehicle enabled tillage without wheel traffic. Short-term CO_2 and H_2O fluxes were measured with a large portable chamber. Gas exchange measurements were made on both CT and NT at various times associated with tillage and irrigation events. Tillage-induced COP and H_2O fluxes were larger than corresponding fluxes from untilled soil. Irrigation caused the CO_2 fluxes to increase rapidly from both tillage systems, suggesting that soil gas fluxes were initially limited by lack of water. Tillage-induced CO_2 and H_2O fluxes were consistently higher than under NT. Cumulative CO_2 flux from CT at the end of 80 h was nearly three times larger than from NT while the corresponding H_2O loss was 1.6 times larger. Traffic had no significant effects on the magnitude of CO_2 fluxes, possibly reflecting this soil's natural tendency to reconsolidate. The immediate impact of intensive

surface tillage of sandy soils on gaseous carbon loss was larger than traffic effects and suggests a need to develop new management practices for enhanced soil carbon and water management for these sensitive soils. (C) 1999 Elsevier Science B.V. All rights reserved.

Reid, C.D., and E.L. Fiscus. 1998. Effects of elevated $[\text{CO}_2]$ and/or ozone on limitations to CO_2 assimilation in soybean (*Glycine max*). *Journal of Experimental Botany* 49(322):885-895.

Soybean (*Glycine max*) was grown in open-top field chambers at ambient (360 $\mu\text{mol mol}^{-1}$) or doubled $[\text{CO}_2]$ either in charcoal-filtered air (20 nmol mol^{-1} $[\text{O}_3]$) or in non-filtered air supplemented to 1.5 x ambient $[\text{O}_3]$ (70 nmol mol^{-1}) to determine the major limitations to assimilation under conditions of elevated $[\text{CO}_2]$ and/or $[\text{O}_3]$. Through plant ontogeny, assimilation versus intercellular CO_2 concentration (A/C_i) responses were measured to assess the limitations to assimilation imposed by the capacity for Rubisco carboxylation, RuBP regeneration, and stomatal diffusion. In the vegetative stages, no significant treatment effects of elevated $[\text{CO}_2]$ and/or $[\text{O}_3]$ were observed on Rubisco carboxylation efficiency (CE), light and CO_2 -saturated assimilation capacity ($A(\text{max})$), and chlorophyll content (Chl). However, for plants grown in elevated $[\text{CO}_2]$, the assimilation rate at growth $[\text{CO}_2]$ (A) was 60% higher than at ambient $[\text{CO}_2]$ up to the seed maturation stage, and the potential rate of assimilation by Rubisco capacity ($A(p)$) was increased. Also in elevated $[\text{CO}_2]$: A was 51% of $A(p)$; the relative stomatal limitation (%Stomata) was 5%; and the relative RuBP regeneration limitation (%RuBP) was 44%. In ambient $[\text{CO}_2]$, O_3 gradually decreased A per unit leaf area, but had little effect on A , and the relative limitations to assimilation where A remained 51% of $A(p)$, %Stomata was 27%, and %RuBP was 22%. During reproduction, CE declined for plants grown in elevated $[\text{CO}_2]$ and/or $[\text{O}_3]$; $A(p)$ was unaffected by elevated $[\text{CO}_2]$, but was reduced by $[\text{O}_3]$ at ambient $[\text{CO}_2]$; A increased to 72% of $A(p)$ in elevated $[\text{CO}_2]$ and/or $[\text{O}_3]$ - fumigated air; the %Stomata increased; and the %RuBP decreased, to become non significant in elevated $[\text{CO}_2]$ from the beginning of seed growth on, and in O_3 -fumigated air at ambient $[\text{CO}_2]$ at the seed maturation stage. The decrease in %RuBP occurred concomitantly with an increase in $A(\text{max})$ and Chl . Significant $[\text{CO}_2] \times [\text{O}_3]$ interactions support the lack of an O_3 effect on assimilation and its limitations at elevated $[\text{CO}_2]$ during seed maturation. These data suggest that elevated $[\text{CO}_2]$ alleviated some of the effects of O_3 on photosynthesis.

Reid, C.D., E.L. Fiscus, and K.O. Burkey. 1998. Combined effects of chronic ozone and elevated CO_2 on Rubisco activity and leaf components in soybean (*Glycine max*). *Journal of Experimental Botany* 49(329):1999-2011.

Content and activity of Rubisco and concentrations of leaf nitrogen, chlorophyll and total non-structural carbohydrates (TNC) were determined at regular intervals during the 1993 and 1994 growing seasons to understand the effects and interactions of $[\text{O}_3]$ and elevated $[\text{CO}_2]$ on biochemical limitations to photosynthesis during ontogeny. Soybean (*Glycine max* var. Essex) was grown in open-top field chambers in either charcoal-filtered air (CF, 20 nmol mol^{-1}) or non-

filtered air supplemented with 1.5 x ambient [O-3] (c. 80 nmol mol⁻¹) at ambient (AA, 360 μ mol mol⁻¹) or elevated [CO₂] (700 μ mol mol⁻¹). Sampling period significantly affected all the variables examined. Changes included a decrease in the activity and content of Rubisco during seed maturation, and increased nitrogen (N), leaf mass per unit area (LMA) and total non- structural carbohydrates (TNC, including starch and sucrose) through the reproductive phases. Ontogenetic changes were most rapid in O-3-treated plants. At ambient [CO₂], O-3 decreased initial activity (14-64% per unit leaf area and 14-29% per unit Rubisco) and content of Rubisco (9-53%), and N content per unit leaf area. Ozone decreased LMA by 17-28% of plants in CF-AA at the end of the growing season because of a 24-41% decrease in starch and a 59-80% decrease in sucrose. In general, elevated [CO₂] in CF or O-3-fumigated air, reduced the initial activity of Rubisco and activation state while having little effect on Rubisco content, N and chlorophyll content, per unit leaf area. Elevated CO₂ decreased Rubisco activity by 14-34% per unit leaf area and 15-25% per unit Rubisco content of plants in grown CF-AA, and increased LMA by 27-74% of the leaf mass per unit area in CF-AA because of a 23-148% increase in starch. However, the data suggest that, at elevated [CO₂], increases in starch and sucrose are not directly responsible for the deactivation of Rubisco. Also, there was little evidence of an adjustment of Rubisco activity in response to starch and sucrose metabolism. Significant interactions between elevated [CO₂] and [O-3] on all variables examined generally resulted in alleviation or amelioration of the O-3 effects at elevated CO₂. These data provide further support to the idea that elevated atmospheric CO₂ will reduce or prevent damage from pollutant O-3.

Reid, C.D., E.L. Fiscus, and K.O. Burkey. 1999. Effects of chronic ozone and elevated atmospheric CO₂ concentrations on ribulose-1,5-bisphosphate in soybean (*Glycine max*). *Physiologia Plantarum* 106(4):378-385.

Ribulose-1,5-bisphosphate (RuBP) pool size was determined at regular intervals during the growing season to understand the effects of tropospheric ozone concentrations, elevated atmospheric carbon dioxide concentrations and their interactions on the photosynthetic limitation by RuBP regeneration. Soybean (*Glycine max* [L.] Merr. cv. Essex) was grown from seed to maturity in open-top field chambers in charcoal-filtered air (CF) either without (22 nmol O-3 mol⁻¹) or with added O-3 (83 nmol mol⁻¹) at ambient (AA, 369 μ mol CO₂ mol⁻¹) or elevated CO₂ (710 μ mol mol⁻¹). The RuBP pool size generally declined with plant age in all treatments when expressed on a unit leaf area and in all treatments but CF-AA when expressed per unit ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco; EC 4.1.1.39) binding site. Although O-3 in ambient CO₂ generally reduced the RuBP pool per unit leaf area, it did not change the RuBP pool per unit Rubisco binding site. Elevated CO₂, in CF or O-3-fumigated air, generally had no significant effect on RuBP pool size, thus mitigating the negative O-3 effect. The RuBP pools were below 2 mol mol⁻¹ binding site in all treatments for most of the season, indicating limiting RuBP regeneration capacity. These low RuBP pools resulted in increased RuBP regeneration. Fia faster RUBP turnover, but only in CF air and during vegetative and flowering stages at elevated CO₂. Also, the low RuBP pool sizes did not always reflect RuBP consumption rates or the RuBP regeneration limitation relative to potential carboxylation (%RuBP). Rather, %RuBP increased linearly with decrease in the RuBP pool turnover time. These data suggest that amelioration of damage from O-3 by elevated atmospheric CO₂ to the RuBP regeneration may be in response to changes in the Rubisco carboxylation.

Reid, C.D., and B.R. Strain. 1994. Effects of CO₂ enrichment on whole-plant carbon budget of seedlings of *Fagus grandifolia* and *Acer saccharum* in low irradiance. *Oecologia* 98(1):31-39.

Carbon exchange rates (CER) and whole-plant carbon balances of beech (*Fagus grandifolia*) and sugar maple (*Acer saccharum*) were compared for seedlings grown under low irradiance to determine the effects of atmospheric CO₂ enrichment on shade-tolerant seedlings of co-dominant species. Under contemporary atmospheric CO₂, photosynthetic rate per unit mass of beech was lower than for sugar maple, and atmospheric CO₂ enrichment enhanced photosynthesis for beech only. Aboveground respiration per unit mass decreased with CO₂ enrichment for both species while root respiration per unit mass decreased for sugar maple only. Under contemporary atmospheric CO₂, beech had lower C uptake per plant than sugar maple, while C losses per plant to nocturnal aboveground and root respiration were similar for both species. Under elevated CO₂, C uptake per plant was similar for both species, indicating a significant relative increase in whole-seedling CER with CO₂ enrichment for beech but not for sugar maple. Total C loss per plant to aboveground respiration was decreased for beech only because increase in sugar maple leaf mass counterbalanced a reduction in respiration rates. Carbon loss to root respiration per plant was not changed by CO₂ enrichment for either species. However, changes in maintenance respiration cost and nitrogen level suggest changes in tissue composition with elevated CO₂. Beech had a greater net daily C gain with CO₂ enrichment than did sugar maple in contrast to a lower one under contemporary CO₂. Elevated CO₂ preferentially enhances the net C balance of beech by increasing photosynthesis and reducing respiration cost. In all cases, the greatest C lost was by roots, indicating the importance of belowground biomass in net C gain. Relative growth rate estimated from biomass accumulation was not affected by CO₂ enrichment for either species possibly because of slow growth under low light. This study indicates the importance of direct effects of CO₂ enrichment when predicting potential change in species distribution with global climate change.

Reid, C.D., D.T. Tissue, E.L. Fiscus, and B.R. Strain. 1997. Comparison of spectrophotometric and radioisotopic methods for the assay of Rubisco in ozone-treated plants. *Physiologia Plantarum* 101(2):398-404.

Radioisotopic and spectrophotometric assays for ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) initial and final activities and Rubisco content were compared in plants chronically exposed to ozone (O-3) in a greenhouse and the field. In a greenhouse experiment, *Glycine max* was treated in exposure chambers with either charcoal-filtered air (CF air) or 100 nl O-3 l⁻¹ for 6 h daily during vegetative growth. Samples were collected after 7 days of exposure. In a field experiment, *G. max* was treated in open-top chambers with either CF air or nonfiltered air with O-3 added at 1.5 times ambient O-3 for 12 h daily. Average daily O-3 concentrations were 21 and 92 nl l⁻¹ in the CF and O-3 treatments, respectively samples were collected during vegetative and reproductive growth. Both assays generally yielded comparable Rubisco initial and final activities for greenhouse-grown

plants regardless of the O-3 treatment. However for field-grown plants, Rubisco initial and final activities averaged 15 and 23% lower when assayed by the spectrophotometric rather than the radioisotopic method. For Rubisco content estimated by the spectrophotometric method, lower r^2 values for the regression of Rubisco activity vs concentration of carboxyarabinitol-1,5-bisphosphate were observed in O-3- than in CF-treated plants. Both assays yielded comparable Rubisco contents in the greenhouse and in the field although the variation was larger with the spectrophotometric method in field-grown plants. Growth conditions, field vs greenhouse, were more critical to the spectrophotometric assay performance than the O-3 treatments for measurement of Rubisco activity and content.

Reinert, R.A., G. Eason, and J. Barton. 1997. Growth and fruiting of tomato as influenced by elevated carbon dioxide and ozone. *New Phytologist* 137(3):411-420.

'Tiny Tim' tomato plants were exposed to five CO₂ treatments (375 (ambient), 450, 525, 600 or 675 $\mu\text{mol mol}^{-1}$) in combination with O-3 (O or 80 nmol mol^{-1}). Biomass was evaluated following 3, 5, 7 and 13 wk exposure. Biomass following 13 wk exposure also included weekly harvests of mature tomato fruit beginning week 8. Carbon dioxide enrichment significantly enhanced total vegetative plant d. wt at each harvest, as well as cumulative yield of mature fruit, whereas O-3 significantly suppressed total Vegetative plant d. wt at each harvest and reduced total cumulative fruit yield. The magnitude of these changes varied with the development of tomato from early growth to mature fruit yield. Carbon dioxide enrichment reduced the detrimental effects of O-3 on total vegetative plant d. wt of tomato following 3, 5, 7 and 13 wk exposure. Final mature fruit yield was 24% higher under enriched CO₂ treatments than in ambient CO₂. Ozone suppressed final yield by 31% following exposure to 80 nmol mol^{-1} O-3 when compared with exposure to charcoal-filtered (CF) air. The impacts of both CO₂ and O-3 on yield were, however, dependent upon the presence or absence of the other gas. In the absence of O-3, yields were very similar for the ambient and elevated CO₂ treatments, but in the presence of O-3, yields under ambient CO₂ were greatly suppressed whereas yields under elevated CO₂ were similar to those in the absence of O-3. Thus, enriched CO₂ ameliorated most of the suppressive effect of O-3 on yield of mature fruit.

Reinert, R.A., and M.C. Ho. 1995. Vegetative growth of soybean as affected by elevated carbon- dioxide and ozone. *Environmental Pollution* 89(1):89-96.

The effects of elevated carbon dioxide (CO₂) and ozone (O-3) on soybean (*Glycine max* (L.) Merr. cv. Centennial) growth and biomass partitioning were evaluated under greenhouse conditions. Soybeans were exposed to CO₂ concentrations at 350 (ambient), 450, 550, and 650 $\mu\text{l liter}^{-1}$ (ppm) for 24 h day⁻¹ for 5 weeks. Ozone treatments of 0 and 120 nl liter^{-1} (ppb) for 6 h day⁻¹ for 5 days week⁻¹ for 5 weeks were added in combination with the CO₂ treatments. Plant dry weight and biomass partitioning were assessed each week. Dry weight of leaf, stem, and root, as well as the total plant dry weight increased with exposure to

increasing levels of CO₂. Dry weight of leaf, root and total plant were suppressed significantly by the O-3 treatment. Stem dry weight was not affected by O-3. Suppression of root dry weight due to O-3 at each weekly harvest was significantly dependent on the CO₂ concentration. Root growth was enhanced by CO₂ at 650 $\mu\text{l liter}^{-1}$ compared with ambient CO₂ (350 $\mu\text{l liter}^{-1}$) at 5 weeks of age. At ambient CO₂ in the presence of O3 the roots were only about 63% of the weight of the root grown in the absence of O-3. At 550 and 650 $\mu\text{l liter}^{-1}$ CO₂ the biomass of soybean roots in the presence of 120 nl liter^{-1} O-3 was 88.2 and 88.4% of the control, respectively. Thus, CO₂ limited the amount of root growth suppression caused by O-3. The partitioning of leaf, stems and root dry weight in relation to total plant dry weight remained relatively constant across each CO₂ concentration. Thus, CO₂ did not affect biomass partitioning among leaves, stems and roots of soybean.

Reining, E. 1994. Acclimation of C-3 photosynthesis to elevated co₂ - hypotheses and experimental-evidence. *Photosynthetica* 30(4):519-525.

Acclimation of the photosynthesis of C-3 plants to elevated atmospheric CO₂ concentrations is frequently observed. Some hypotheses frequently proposed to explain this phenomenon are: (1) stomatal closure; (2) inhibition of photosynthesis by starch accumulation, and (3) reduced activity or concentration of ribulose-1,5-bisphosphate carboxylase/oxygenase. These hypotheses are compared with experimental evidence from the literature.

Reining, F. 1995. The effect of elevated co₂ concentrations on the competition between lamium-galeobdolon and stellaria-holostea. *Photosynthetica* 31(4):501-508.

The effect of enhanced air CO₂ concentrations (c(520) and c(650) = 520 and 650 $\text{cm}^3 \text{m}^{-3}$) on the growth of *Lamium galeobdolon* and *Stellaria holostea* and on the competition between the two species was examined. After five months growth under CO₂ enrichment the dry masses of both species increased when the plants were grown in monoculture, but the increase in biomass was much more pronounced in *Stellaria*. When the plants were grown together in competition, the measured shoot masses of *Stellaria* were again higher under c(520) and c(650) than at ambient CO₂ concentration (c(390) = 390 $\text{cm}^3 \text{m}^{-3}$), while the shoot masses of *lamium* strongly decreased at c(650). The effect of CO₂ enrichment on the two plant species in monoculture differed significantly from that observed in mixed cultures. In terms of plant relative yield. *Stellaria* benefitted slightly but insignificantly from competition, while *Lamium* was significantly suppressed under c(650). Total community production of the mixed culture was optimum at c(520), while that of the monocultures was highest at c(650). At c(390) and c(520), growth of *Stellaria* depended strongly on irradiance in all types of culture. At c(650) no such dependence could be demonstrated.

Reitz, S.R., D.N. Karowe, M.M. Diawara, and J.T. Trumble. 1997. Effects of elevated atmospheric carbon dioxide on the growth and linear furanocoumarin content of celery. *Journal of Agricultural and Food Chemistry* 45(9):3642-3646.

The effects of elevated atmospheric carbon dioxide on the growth and development of celery (*Apium graveolens*) were examined to determine if anticipated global increases in CO₂ will affect the nutritional quality and secondary chemistry of celery. The size (fresh and dry mass), nitrogen and carbon composition, and concentrations of linear furanocoumarins of celery grown under ambient (363 μ L L⁻¹) and elevated (718 μ L L⁻¹) carbon dioxide were analyzed. Growth under elevated CO₂ resulted in larger petioles, reduced nitrogen content, and higher C:N ratios in both leaves and petioles. However, CO₂ treatment did not affect plant water content or carbon content. Moreover, in contrast to the carbon-nutrient balance hypothesis, the increased C:N ratios of plants grown under elevated CO₂ were not associated with increased concentrations of potentially harmful linear furanocoumarins. Levels of linear furanocoumarins in the petioles of plants from each treatment did not exceed concentrations reported to cause acute or chronic contact dermatitis.

Rennenberg, H., and A. Gessler. 1999. Consequences of N deposition to forest ecosystems - Recent results and future research needs. *Water, Air, and Soil Pollution* 116(1-2):47-64.

Wet and dry deposition of atmospheric nitrogen (N) compounds into forest ecosystems and their effect on physical, chemical and microbial processes in the soil has attracted considerable attention for many years. Still the consequences of atmospheric N deposition on N metabolism of trees and its interaction with soil microbial processes has only recently been studied. Atmospheric N deposited to the leaves is thought to enter the general N metabolism of the leaves, but the processes involved, the interaction with different metabolic pathways, and the connection between injury by atmospheric N and its metabolic conversion are largely unknown. Laboratory and field experiments have shown that N of atmospheric NO₂ and NH₃, deposited to the leaves of trees, is subject to long-distance transport in the phloem to the roots. This allocation can result in considerable decline of N uptake by the roots. Apparently, the flux of N from the soil into the roots can be down-regulated to an extent that equals N influx into the leaves. This down-regulation is not mediated by generally enhanced amino-N contents, but by elevated levels of particular amino acids. Field experiments confirm these results from laboratory studies: Nitrate (NO₃) uptake by the roots of trees at a field sites exposed to high loads of atmospheric N is negligible, provided concentrations of Gln in the roots are high. At the ecosystem level, consequences of reduced N uptake by the roots of trees exposed to high loads of atmospheric N are (1) an increased availability of N for soil microbial processes, (2) enhanced emission of gaseous N-oxides from the soil, and (3) elevated leaching of NO₃ into the ground water. How recent forest management practices aimed at transforming uniform monocultures to more structured species-rich forests will interact with these processes remains to be seen. Possible implications of these forest management practices on N metabolism in trees and N conversion in the soil are discussed particularly in relation to atmospheric N deposition.

Repo, T., H. Hanninen, and S. Kellomaki. 1996. The effects of long-term elevation of air temperature and CO₂ on the frost hardiness of Scots pine. *Plant, Cell and Environment* 19(2):209-216.

The frost hardiness of 20 to 25-year-old Scots pine (*Pinus sylvestris* L.) saplings was followed for 2 years in an experiment that attempted to simulate the predicted climatic conditions of the future, i.e. increased atmospheric CO₂ concentration and/or elevated air temperature. Frost hardiness was determined by an electrolyte leakage method and visual damage scoring on needles. Elevated temperatures caused needles to harden later and dehardening earlier than the controls. In the first year, elevated CO₂ enhanced hardening at elevated temperatures, but this effect disappeared the next year. Dehardening was hastened by elevating CO₂ in both springs. The frost hardiness was high (<-40 degrees C), even at elevated temperatures, in midwinter, at which time the electrolyte leakage method underestimated the frost hardiness compared with the visual scoring. In addition to the significant differences between treatments, there was also significant variation between trees in frost hardiness within treatments. These results suggest that the risks of frost damage are marked in the predicted climatic conditions in Finland, and, more specifically, they depend on how the occurrence of the frost episodes changes with respect to climatic warming during the annual cycle, especially in the autumn and spring. We also conclude that the conditions in midwinter are not critical for frost injury to trees in the future.

Retamales, J., T. Cooper, J. Streif, and J.C. Kania. 1992. Preventing cold-storage disorders in nectarines. *Journal of Horticultural Science* 67(5):619-626.

A storage experiment was aimed at preventing low temperature storage disorders in nectarine fruits, of cvs July Red and Autumn Grand. Fruit was either cooled immediately after harvest or kept at 20-degrees-C for 48 h, before transfer to controlled atmosphere (CA) conditions at 0-degrees-C. Combinations of 0, 10, 15 and 20% CO₂ with 8 and 16% O₂ were assayed. The fruit was evaluated following cold storage, 31 days after harvest, and after four and eight days under 'shelf conditions' (ripening at 15-18-degrees-C). Warming of the fruit at 20-degrees-C before cold storage prevented woolliness in the absence of elevated CO₂ levels but did not affect internal browning and increased reddish discoloration; further, it enhanced water loss and ripening, increasing fruit softening markedly. Conversely, high CO₂ delayed fruit ripening in CA storage, keeping the fruit firmer, and preventing the development of woolliness, internal browning and reddish discoloration during ripening, the best results being mostly obtained with 20% CO₂. O₂ levels assayed did not show clear effects, but decreased O₂ concentration in absence of high CO₂ showed some benefit in 'July Red'. No deleterious effect of CO₂ concentrations even as high as 20% could be detected. Thus, even though high CO₂ in CA conditions showed promise for controlling disorders and preventing over-ripening, further work is needed on other cultivars, and lower O₂ concentrations should be investigated before making a general recommendation.

Retuerto, R., L. Rochefort, and F.I. Woodward. 1996. The influence of plant density on the responses of *Sinapis alba* to CO₂ and windspeed. *Oecologia* 108(2):241-251.

Plants in nature live in populations of variable density, a characteristic which may influence individual plant responses to the environment. We investigated how the responses of *Sinapis alba* plants to different wind speeds and CO₂ concentrations could be modified by plant density. In our wind- density experiment the expectation that mechanical and physiological effects of wind will be ameliorated by growing in high density, as a result of positive plant interactions, was realised. Although individual plants were smaller at higher densities, the effect of increasing windspeed was much less than at lower plant densities. A similar reduced sensitivity of individual plant growth under high densities was also observed under CO₂ enrichment. When measured as a population or stand response, there was no effect of density on the CO₂ responses, with all stands showing very similar increases in total biomass with CO₂ enrichment. In the wind speed experiment, total biomass per stand increased significantly with density, although there was no effect of density on the wind speed response. Specific leaf area decreased with increasing wind speed and this response was significantly affected by the density at which the plants grew.

Retuerto, R., and F.I. Woodward. 1993. The influences of increased CO₂ and water-supply on growth, biomass allocation and water-use efficiency of *sinapis-alba* L grown under different wind speeds. *Oecologia* 94(3):415-427.

We examined how independent and interactive effects of CO₂ concentrations, water supply and wind speed affect growth rates, biomass partitioning, water use efficiency, diffusive conductance and stomatal density of plants. To test the prediction that wind stress will be ameliorated by increased CO₂ and/or by unrestricted water supply we grew *Sinapis alba* L. plants in controlled chambers under combinations of two levels of CO₂ (350 ppmv, 700 ppmv), two water regimes and two wind speeds (0.3 ms⁻¹, 3.7 ms⁻¹). We harvested at ten different dates over a period of 60 days. A growth analysis was carried out to evaluate treatment effects on plant responses. Plants grown both in increased CO₂ and in low wind conditions had significantly greater stem length, leaf area and dry weights of plant parts. Water supply significantly affected stem diameter, root weight and leaf area. CO₂ enrichment significantly increased the rate of biomass accumulation and the relative ratio of biomass increase to leaf area expansion. High wind speed significantly reduced plant growth rates and the rate of leaf area expansion was reduced more than the rate of biomass accumulation. Regression analysis showed significant CO₂ effects on the proportion of leaf and stem dry weight to total dry weight. A marked plant-age effect was dependent on water supply, wind speed and CO₂ concentration. A reduced water supply significantly decreased the stomatal conductance, and water use efficiency significantly increased with a limited water supply, low wind and increased CO₂. We found significant CO₂ x wind effects for water diffusion resistance, adaxial number of stomata and water use efficiencies and significant wind x water effect for water use efficiency. In conclusion, wind stress was ameliorated by growing in unrestricted water but not by growing in increased CO₂.

Reuveni, J., and B. Bugbee. 1997. Very high CO₂ reduces photosynthesis, dark respiration and yield in wheat. *Annals of Botany* 80(4):539-546.

Although terrestrial CO₂ concentrations, [CO₂], are not expected to reach 1000 μmol mol⁻¹ for many decades, CO₂ levels in closed systems such as growth chambers and glasshouses, can easily exceed this concentration. CO₂ levels in life support systems in space can exceed 10 000 μmol mol⁻¹ (1 %). Here we studied the effect of six CO₂ concentrations, from ambient up to 10000 μmol mol⁻¹, on seed yield, growth and gas exchange of two wheat cultivars (USU-Apogee and Veery- 10). Elevating [CO₂] from 350 to 1000 μmol mol⁻¹ increased seed yield (by 33 %), vegetative biomass (by 25 %) and number of heads m⁻² (by 34 %) of wheat plants. Elevation of [CO₂] from 1000 to 10000 μmol mol⁻¹ decreased seed yield (by 37 %), harvest index (by 14%), mass per seed (by 9 %) and number of seeds per head (by 29 %). This very high [CO₂] had a negligible, non-significant effect on vegetative biomass, number of heads m⁻² and seed mass per head. A sharp decrease in seed yield, harvest index and seeds per head occurred by elevating [CO₂] from 1000 to 2600 μmol mol⁻¹. Further elevation of [CO₂] from 2600 to 10000 μmol mol⁻¹ caused a further but smaller decrease. The effect of CO₂ on both wheat cultivars was similar for all growth parameters. Similarly there were no differences in the response to high [CO₂] between wheat grown hydroponically in growth chambers under fluorescent lights and those grown in soilless media in a glasshouse under sunlight and high pressure sodium lamps. There was no correlation between high [CO₂] and ethylene production by flag leaves or by wheat heads. Therefore, the reduction in seed set in wheat plants is not mediated by ethylene. The photosynthetic rate of whole wheat plants was 8 % lower and dark respiration of the wheat heads 25 % lower when exposed to 2600 μmol mol⁻¹ CO₂ compared to ambient [CO₂]. It is concluded that the reduction in the seed set can be mainly explained by the reduction in the dark respiration in wheat heads, when most of the respiration is functional and is needed for seed development. Reuveni, J., J. Gale, and M. Zeroni. 1997. Differentiating day from night effects of high ambient [CO₂] on the gas exchange and growth of *Xanthium strumarium* L exposed to salinity stress. *Annals of Botany* 79(2):191-196.

Sodium chloride, at a concentration of 88 mol m⁻³ in half strength Hoagland nutrient solution, increased dry weight per unit area of *Xanthium strumarium* L. leaves by 19%, and chlorophyll by 45% compared to plants grown without added NaCl at ambient (350 μmol mol⁻¹) CO₂ concentration. Photosynthesis, per unit leaf area, was almost unaffected. Even so, over a 4-week period, growth (dry weight increment) was reduced in the salt treatment by 50%. This could be ascribed to a large reduction in leaf area (>60%) and to an approx. 20% increase in the rate of dark respiration (R_d). Raising ambient [CO₂] from zero to 2000 μmol mol⁻¹ decreased R_d in both control and salinized plants (by 20% at 1000, and by 50% at 2000 μmol mol⁻¹ CO₂ concentration) compared to R_d in the absence of ambient CO₂. High night-time [CO₂] had no significant effect on growth of non-salinized plants, irrespective of day-time ambient [CO₂]. Growth reduction caused by salt was reduced from 51% in plants grown in 350 μmol mol⁻¹ throughout the day, to 31% in those grown continuously

in 900 $\mu\text{mol mol}^{-1}$ $[\text{CO}_2]$. The effect of $[\text{CO}_2]$ at night on salinized plants depended on the daytime CO_2 concentration. Under 350 $\mu\text{mol mol}^{-1}$ day-time $[\text{CO}_2]$, 900 $\mu\text{mol mol}^{-1}$ at night reduced growth over a 4-week period by 9% ($P < 0.05$) and 1700 $\mu\text{mol mol}^{-1}$ reduced it by 14% ($P < 0.01$). However, under 900 $\mu\text{mol mol}^{-1}$ day-time $[\text{CO}_2]$, 900 vs. 350 $\mu\text{mol mol}^{-1}$ $[\text{CO}_2]$ at night increased growth by 17% ($P < 0.01$). It is concluded that there is both a functional and an otiose (functionless) component to R_d , which is increased by salt. Under conditions of low photosynthesis (such as here, in the low day-time $[\text{CO}_2]$ regime) the otiose component is small and high night-time $[\text{CO}_2]$ partly suppresses functional R_d , thereby reducing salt tolerance. In plants growing under conditions which stimulate photosynthesis (e.g. with increased daytime $[\text{CO}_2]$), elevated $[\text{CO}_2]$ at night suppresses mainly the otiose component of respiration, thus increasing growth. Consequently, in regions of adequate water and sunlight, the predicted further elevation of the world atmospheric $[\text{CO}_2]$ may increase plant salinity tolerance. 1979

Reuveni, J., A.M. Mayer, and J. Gale. 1995. High ambient carbon-dioxide does not affect respiration by suppressing the alternative, cyanide-resistant pathway. *Annals of Botany* 76(3):291-295.

Total dark respiration ($v(t)$), cytochrome pathway ($v(\text{eyt})$), alternative pathway ($v(\text{alt})$) and residual ($v(\text{res})$) respiration were measured in *Lemna gibba* plants, by the use of pathway inhibitors. NaCN was used to inhibit $v(\text{eyt})$ and SHAM (salicylhydroxamic acid) to inhibit $v(\text{alt})$. Residual respiration ($v(\text{res})$) was about 5% of $v(t)$. The effect of high (100 Pa) and low (0 Pa) carbon dioxide partial pressure ($[\text{CO}_2]$) on $v(t)$, $v(\text{eyt})$ and $v(\text{alt})$ was determined from both CO_2 efflux and O_2 uptake measurements. The higher $[\text{CO}_2]$ suppressed $v(t)$ by about 30%. When respiration operated through the cytochrome pathway only, in the absence of $v(\text{alt})$, it was suppressed by about 12% as measured by the O_2 uptake of submerged *Lemna* fronds or by about 40% as measured by CO_2 efflux from floating fronds. The higher $[\text{CO}_2]$ treatment had only a small effect on respiration, when $v(\text{alt})$ alone operated. There was no evidence of a specific suppression of the $v(\text{alt})$ pathway by high $[\text{CO}_2]$. Succinic dehydrogenase activity of the mitochondria of roots of *Medicago sativum* was reduced by 18%, when the mitochondria were pre-treated with 120 as compared to 34 Pa $[\text{CO}_2]$. There was no such effect on cytochrome c oxidase activity of mitochondria under the same conditions. It is concluded that there is no evidence for the hypothesis that the high $[\text{CO}_2]$ suppression of respiration is a result of a CO_2 effect on the non-phosphorylating alternative respiration pathway. Rey, A., and P.G. Jarvis. 1997. Growth response of young birch trees (*Betula pendula* Roth.) after four and a half years of CO_2 exposure. *Annals of Botany* 80(6):809-816.

A field experiment consisting of 18 birch trees grown in open top chambers in ambient and elevated CO_2 concentrations was set up with the aim of testing whether the positive growth response observed in many short-term studies is maintained after several growing seasons. We present the results of growth and biomass after 4.5 years of CO_2 exposure, one of the longest studies so far on deciduous tree species. We

found that elevated CO_2 led to a 58% increase in biomass at the end of the experiment. However, estimation of stem mass during the growing season showed that elevated CO_2 did not affect relative growth rate during the fourth growing season, and therefore, that the large accumulation of biomass was the result of an early effect on relative growth rate in previous years. Trees grown in elevated CO_2 invested more carbon into fine roots and had relatively less leaf area than trees grown in ambient CO_2 . In contrast with previous studies, acceleration of growth did not involve a significant decline in nutrient concentrations of any plant tissue. It is likely that increased fine root density assisted the trees in meeting their nutrient demands. Changes in the species composition of the ectomycorrhizal fungi associated with the trees grown in elevated CO_2 in favour of late successional species supports the hypothesis of an acceleration of the ontogeny of the trees in elevated CO_2 . Rey, A., and P.G. Jarvis. 1998. Long-term photosynthetic acclimation to increased atmospheric CO_2 concentration in young birch (*Betula pendula*) trees. *Tree Physiology* 18(7):441-450.

To study the long-term response of photosynthesis to elevated atmospheric CO_2 concentration in silver birch (*Betula pendula* Roth.), 18 trees were grown in the field in open-top chambers supplied with 350 or 700 $\mu\text{mol mol}^{-1}$ CO_2 for four consecutive growing seasons. Maximum photosynthetic rates, stomatal conductance and CO_2 response curves were measured over the fourth growing season with a portable photosynthesis system. The photosynthesis model developed by Farquhar et al. (1980) was fitted to the CO_2 response curves. Chlorophyll, soluble proteins, total nonstructural carbohydrates, nitrogen and Rubisco activity were determined monthly. Elevated CO_2 concentration stimulated photosynthesis by 33% on average over the fourth growing season. However, comparison of maximum photosynthetic rates at the same CO_2 concentration (350 or 700 $\mu\text{mol mol}^{-1}$) revealed that the photosynthetic capacity of trees grown in an elevated CO_2 concentration was reduced. Analysis of the response curves showed that acclimation to elevated CO_2 concentration involved decreases in carboxylation efficiency and RuBP regeneration capacity. No clear evidence for a redistribution of nitrogen within the leaf was observed. Down-regulation of photosynthesis increased as the growing season progressed and appeared to be related to the source-sink balance of the trees. Analysis of the main leaf components revealed that the reduction in photosynthetic capacity was accompanied by an accumulation of starch in leaves (100%), which was probably responsible for the reduction in Rubisco activity (27%) and to a lesser extent for reductions in other photosynthetic components: chlorophyll (10%), soluble protein (9%), and N concentrations (12%) expressed on an area basis. Despite a 21% reduction in stomatal conductance in response to the elevated CO_2 treatment, stomatal limitation was significantly less in the elevated, than in the ambient, CO_2 treatment. Thus, after four growing seasons exposed to an elevated CO_2 concentration in the field, the trees maintained increased photosynthetic rates, although their photosynthetic capacity was reduced compared with trees grown in ambient CO_2 .

Reyenga, P.J., S.M. Howden, H. Meinke, and G.M. McKeon. 1999. Modelling global change impacts on wheat cropping in south-east Queensland, Australia. *Environmental Modelling & Software* 14(4):297-306.

The wheat module, I-WHEAT, from the APSIM cropping system model was used to investigate the impacts of changes in atmospheric CO₂ concentrations on wheat crops by modifying radiation use efficiency, transpiration efficiency, specific leaf area and critical nitrogen concentrations. The effects of several combinations of atmospheric CO₂, climate change and crop adaptation strategies on wheat production in the Burnett region were studied. Mean wheat yields were increased under doubled CO₂, with the response relative to ambient CO₂ greatest in dry years. Higher temperatures under the climate change scenarios moderated the yield gains achieved with increasing CO₂ and in some instances reversed them under the reduced rainfall scenario. The status of the region as a producer of prime hard wheat may be at risk due to reduced grain protein levels under doubled CO₂ and the increased likelihood of "heat shock" in the climate scenarios used. Reynolds, J.F., J.L. Chen, P.C. Harley, D.W. Hilbert, R.L. Dougherty, and J.D. Tenhunen. 1992. Modeling the effects of elevated CO₂ on plants - extrapolating leaf response to a canopy. *Agricultural and Forest Meteorology* 61(1-2):69-94.

The response of canopies to short-duration exposure to elevated CO₂ was examined by using a detailed submodel of single-leaf ps exchange combined with a model of canopy structure and light penetration. The leaf model included a mechanistic ps exchange model and leaf energy balance equations, and the canopy model included a detailed description of spatial variability in environmental conditions within the canopy. The structure of the canopy model was designed to facilitate implementation of different leaf aggregation schemes. To compare six aggregation methods of increasing simplicity, daily carbon gain, and water use were simulated for *Quercus coccifera* under current ambient and future doubled CO₂. Analyses of simulated canopy responses confirmed the importance of including (1) leaf energy balance and (2) distinguishing between sunlit and shaded leaves. A multi-layer canopy model with Gaussian integration for sunlit leaves and a single leaf class for shaded leaves in each layer gave excellent results. A multi-layer model with one shaded and one sunlit leaf class gave a reasonable approximation, and the single-layer model with one sunlit and one shaded leaf class resulted in errors of up to 15%. Vertical gradients in leaf nitrogen content and leaf and stem area index had greater effects on canopy assimilation and transpiration than did gradients of stem or leaf inclination or leaf width. However, predictions of the relative response of CO₂ assimilation and transpiration to doubled CO₂ are rather robust and were not greatly affected by simplifications of the canopy model.

Rice, C.W., F.O. Garcia, C.O. Hampton, and C.E. Owensby. 1994. Soil microbial response in tallgrass prairie to elevated CO₂. *Plant and Soil* 165(1):67-74.

Terrestrial responses to increasing atmospheric CO₂ are important to the global carbon budget. Increased plant production under elevated CO₂ is expected to increase soil C which may induce N limitations. The objectives of this study were to determine the effects of increased CO₂ on 1) the amount of carbon and nitrogen stored in soil organic matter and microbial biomass and 2) soil microbial activity. A tallgrass prairie ecosystem was exposed to ambient and twice-ambient CO₂ concentrations in open-top chambers in the field from 1989 to 1992 and compared to unchambered ambient CO₂ during the entire growing season. During 1990 and 1991, N fertilizer was included as a treatment. The soil microbial response to CO₂ was measured during 1991 and 1992. Soil organic C and N were not significantly affected by enriched atmospheric CO₂. The response of microbial biomass to CO₂ enrichment was dependent upon soil water conditions. In 1991, a dry year, CO₂ enrichment significantly increased microbial biomass C and N. In 1992, a wet year, microbial biomass C and N were unaffected by the CO₂ treatments. Added N increased microbial C and N under CO₂ enrichment. Microbial activity was consistently greater under CO₂ enrichment because of better soil water conditions. Added N stimulated microbial activity under CO₂ enrichment. Increased microbial N with CO₂ enrichment may indicate plant production could be limited by N availability. The soil system also could compensate for the limited N by increasing the labile pool to support increased plant production with elevated atmospheric CO₂. Longer-term studies are needed to determine how tallgrass prairie will respond to increased C input.

Riedo, M., D. Gyalistras, A. Fischlin, and J. Fuhrer. 1999. Using an ecosystem model linked to GCM-derived local weather scenarios to analyse effects of climate change and elevated CO₂ on dry matter production and partitioning, and water use in temperate managed grasslands. *Global Change Biology* 5(2):213-223.

Local effects of climate change (CC) and elevated CO₂ (2 x CO₂, 660 μmol mol⁻¹) on managed temperate grasslands were assessed by forcing a dynamic ecosystem model with weather scenarios. The aims of the study were to compare the relative importance of individual and combined effects of CC, 2 x CO₂, and photosynthetic acclimation, and to assess the importance of local site conditions. The model was driven by hourly means for temperature (T), precipitation (P), global radiation (G), vapour pressure (VP), and wind speed (U). Local climate scenarios were derived by statistical downscaling techniques from a 2 x CO₂ simulation with the General Circulation Model of the Canadian Climate Centre (CCC-GCMII). Simulations over 14 growing seasons to account for year-to-year variability of climate were carried out for a low, relatively dry site, and a high, more humid site. At both sites, shoot dry matter responded positively to 2 x CO₂ with the site at low elevation being more sensitive than the higher site. The effect of assumed changes in climate was negative at the lower, but positive at the higher site. Shoot dry matter was more sensitive to the effects of 2 x CO₂ than to CC. Both effects combined increased shoot dry matter by up to 20%. This was attributed to direct effects of 2 x CO₂ and increased T, and indirect stimulation via increased soil N availability. Biomass partitioning to roots increased with 2 x CO₂ but decreased with CC, while an intermediate response resulted from the combination. Leaf area index (LAI) increased under 2 x CO₂, but not enough to compensate fully for a decrease in leaf conductance. Under the 2 x CO₂ scenario

evapotranspiration (ET) decreased, but increased under CC. Photosynthetic acclimation reduced the effect of 2 x CO₂ on shoot growth, but had little effect on ET. The seasonal water use efficiency (WUE) was improved under 2 x CO₂, and reduced under CC. With the combination of both factors, the change was small but still positive, especially at the high elevation site with more favourable soil water conditions. This reflects the stronger positive yield response in combination with a smaller increase in ET under cooler, more humid conditions. The results for the combination of factors suggest that except for shoot growth, effects of 2 x CO₂ and CC tend to offset each other. While CC determines the sign of the ET response, the sign of the biomass response is determined by 2 x CO₂. The results highlight the importance of a site-specific analysis of ecosystem responses by using a flexible approach based on a combination of state-of-the-art downscaling, spatially resolved data sets, and a mechanistic model to obtain quantitative and reproducible assessments of climate change impacts at the ecosystem level.

Riedo, M., D. Gyalistras, A. Grub, M. Rosset, and J. Fuhrer. 1997. Modelling grassland responses to climate change and elevated CO₂. *Acta Oecologica-International Journal of Ecology* 18(3):305-311.

A mechanistic model for productive grassland was used to simulate the annual production of above-and belowground plant biomass in relation to fluxes of C, N, and water, and to test the sensitivity of yield, shoot/root ratio, evapotranspiration, and water use efficiency (WUE) to climate change scenarios (CC) and to elevated CO₂ (2 x CO₂) with or without consideration of photosynthetic acclimation of the plants. Validation with data from two Swiss sites revealed satisfactory agreement between simulation and measurement for yield, energy fluxes, and N- dynamics. Local weather scenarios were derived from the results of two General Circulation Models (GCM) for 2 x CO₂ by a statistical down-scaling procedure. Biomass production changed by a maximum of 8% in response to CC without 2 x CO₂ effects, by 1-17% in response to 2 x CO₂ alone, and by 6-20% in response to the combination of CC and 2 x CO₂. With plant acclimation, biomass Production increased only up to 8% with elevated CO₂, as compared to a maximum increase of 20% in the absence of plant acclimation. Reduced yield with CC was obtained for sites with low soil water holding capacity. Decreased evapotranspiration and increased WUE with 2 x CO₂ were partially offset by CC. The simulations indicated that productivity of managed grassland is sensitive to different assumptions about changes in climate, CO₂ concentration, and photosynthetic acclimation, and that the effects of elevated CO₂ are modified by CC and depend on local soil conditions.

Righetti, B., E. Magnanini, and F. Rossi. 1993. Photosynthetic carbon-dioxide uptake and oxygen accumulation during in-vitro culture of actinidia-deliciosa CV tomuri. *Environmental and Experimental Botany* 33(4):523-528.

Proliferating cultures of Actinidia deliciosa cv Tomuri were grown in vitro under a photosynthetic photon flux density (PPFD) of 120 μmol m²/s. Some jars were daily enriched with 2000 μmol/l CO₂ administered at the end of the dark period. Head space analysis revealed that CO₂ accumulated up to 9500 μmol/l during the dark period and was drastically reduced by photosynthetic activity to 150-200 μmol/l during the

photoperiod without any significant difference between CO₂-enriched and non-enriched cultures. Oxygen concentration assayed at the end of the photoperiod showed a steady increase during the 44 days of culture and was not reduced to atmospheric values by respiratory processes during the dark period. CO₂ enrichment enhanced O₂ production and accumulation to 32.5% at the end of the culture period. Oxygen photoreduction and its photo-oxidative damage to green tissue cells are discussed.

Righetti, B., D.M. Reid, and T.A. Thorpe. 1996. Growth and tissue senescence in Prunus avium shoots grown in vitro at different CO₂/O₂ ratios. *In Vitro Cellular & Developmental Biology-Plant* 32(4):290-294.

The rate of metabolism and biosynthetic processes make in vitro cultures very sensitive to environmental changes, and therefore subject to physiological and morphological alterations leading to senescence in the short term. The effects of three different calibrated atmospheric compositions were studied during in vitro culture of Prunus avium shoots. At 0.034% CO₂-21% O₂ (vol/vol), which stimulate the natural atmosphere, the highest growth rate and chlorophyll content were recorded. When grown at 0.09% CO₂-8% O₂ (vol/vol), a favorable condition for photosynthesis and growth, cultures showed a higher percentage of dry matter and elevated ethylene production, but total chlorophyll was lower. These shoots were also highly lignified and fibrous with red pigmentation along the leaves and stems. At 0% CO₂-21% O₂ (vol/vol), in contrast, growth and ethylene formation were inhibited; chlorophyll content was lowest in comparison with the other two environmental conditions, but greening of tissues was observed after the first half of the culture period. Senescence symptoms, as indicated by decreased chlorophyll, appeared after about 18 d of culture for tissues grown in CO₂-containing atmospheres. These experiments provided evidence that in CO₂-enriched cultures biomass production steadily increased even when chlorophyll decreased. A possible role of CO₂ in promoting tissue-senescence through activation of photooxidative events and ethylene synthesis is discussed.

Rigler, E., and S. Zechmeister-Boltenstern. 1998. Influence of nitrogen and carbon dioxide on ethylene and methane production in two different forest soils. *Microbiological Research* 153(3):227-237.

The impact of nitrogen and CO, on ethylene and methane production was investigated in two different forest soils. The soils were adjusted to a water tension of 30 kPa. Nitrogen was added in the form of KNO₃ or (NH₄)(2)SO₄ and CO₂ was added in 5 different concentrations. To half of the samples, C₂H₂ was added to inhibit ethylene uptake. After 0, 24, and 96 hours, ethylene and methane concentrations were measured by gas chromatography. Ethylene net production increased with increasing N and CO₂ concentrations. In the presence of acetylene, ethylene production was unaffected by the investigated amendments. Therefore, we suppose that the increasing ethylene net production rates are due to decreasing ethylene uptake rates. In the deciduous forest soil, there was no ethylene net production rate, as uptake rates exceeded production rates. Methane net production rates in the spruce forest soil increased with increasing N additions possibly due to a lowered C:N ratio and a decreased methane oxidation. Ethylene production rates in the presence

of acetylene were slightly enhanced. In the deciduous forest soil, methane uptake rates decreased with nitrogen possibly due to the inhibition of the methanomonooxygenase. CO₂ seemed to increase methane production in the presence of acetylene but had no significant effect on methane net production. Acetylene might serve as a substrate for methanogenesis.

Rigler, E., and S. Zechmeister-Boltenstern. 1999. Oxidation of ethylene and methane in forest soils - effect of CO₂ and mineral nitrogen. *Geoderma* 90(1-2):147-159.

The influence of inorganic nitrogen and CO₂ on microbial C₂H₄ and CH₄ consumption was evaluated in two forest soils (montane spruce forest and colline deciduous forest) under laboratory conditions at 25 degrees C. The soils were adjusted to a water tension of - 30 kPa. Nitrogen was added as KNO₃ or (NH₄)₂SO₄, while CO₂ enrichment ranged from 1-20%. At 0, 24, and 96 h, the amounts of CH₄ and C₂H₄ consumed were determined. In both soils, we observed a parallel response of C₂H₄ and CH₄ to all kinds and concentrations of amendments, plausibly due to co- metabolism of C₂H₄ by either methanotrophs or nitrifiers. Ammonium-N inhibited hydrocarbon oxidation in the deciduous forest soil, but promoted it in the acidic spruce forest soil. Ammonium addition narrowed the C:N ratio of the spruce forest soil which was characterized by low pH but high humus content. Therefore, the general living conditions for microorganisms might have been improved. Conversely, NO₃- inhibited hydrocarbon oxidation in both soils, here a non-specific ion toxicity ('salt-effect') is discussed. CO₂ also had an inhibitory effect on hydrocarbon microbial uptake at high concentrations, with its production increasing at elevated CO₂ levels. We conclude that the impact of nitrogen inputs and of enhanced CO₂ on the sink strength for hydrocarbons depends on the amount and the kind of addition as well as on soil type. Riis, T., and K. Sand-Jensen. 1997. Growth reconstruction and photosynthesis of aquatic mosses: Influence of light, temperature and carbon dioxide at depth. *Journal of Ecology* 85(3):359-372.

1 The mosses *Sphagnum subsecundum* and *Drepanocladus exannulatus* dominate the vegetation in the oligotrophic, softwater Lake Grane Langso, Denmark, even at great depths where light and temperature are low. We used seasonal changes in morphology to reconstruct the annual growth and the longevity of the mosses and measurements of photosynthesis and respiration to evaluate the importance of light, temperature and CO₂ for the growth patterns at depth in the lake. 2 The reconstruction technique revealed that the mosses had a relatively fast growth rate (90- 250 mm shoot(-1) year(-1)) and were short lived (0.7- 2.9 years). The shoots of both moss species grew faster in deep than in shallow water. Growth experiments in summer confirmed that *Sphagnum* grew more slowly and decayed more rapidly in shallow than in deep water. 3 Fast growth of mosses in deep waters can be accounted for by lower temperature, extensive CO₂ supersaturation and nutrient enrichment in the hypolimnion during summer stratification. Maximum rate of light-saturated photosynthesis in July was 3.3-fold higher and of

dark respiration 1.3-fold lower in *Sphagnum* from 9.5m incubated at the ambient 8 degrees C than in *Sphagnum* from 0.7m incubated at 20 degrees C. The net daily carbon fixation was greater in deep than in shallow water despite the much lower irradiance at depth. Extensive CO₂ supersaturation stimulated photosynthesis several-fold relative to the rates observed in air-saturated water. Tissues of *Sphagnum* were richer in nitrogen in deep than in shallow water during summer, but the importance of nutrient availability to annual moss growth remains unclear. 4 Reconstruction techniques are recommended for comparative studies on annual and interannual growth patterns of mosses within lakes and among lakes of different altitude, latitude and water chemistry. This information can be based on just a single collection and can therefore include remote sites with adverse climate.

Rillig, M.C., and M.F. Allen. 1998. Arbuscular mycorrhizae of *Gutierrezia sarothrae* and elevated carbon dioxide: Evidence for shifts in C allocation to and within the mycobiont. *Soil Biology and Biochemistry* 30(14):2001-2008.

In a complete 2 x 2 factorial greenhouse experiment we examined the responses of arbuscular mycorrhizal (AM) and non- mycorrhizal fungi to *Gutierrezia sarothrae* shrubs grown in elevated atmospheric carbon dioxide (750 μ l l(-1)) and fertilized with N. AM percent infection did not change significantly with elevated CO₂, but arbuscular infection increased 14-fold in the low-N treatment. Extraradical hyphal length increased on an absolute basis in elevated CO₂, and also per infected root length. In the high-N treatments, increasing CO₂ caused a decrease in hyphal length per infected root length, and an increase in vesicular infection. There was a significant positive response of AM infection intensity to increasing CO₂ for the high N treatment, and a similar trend in the low N treatment. Infection intensity was positively correlated with arbuscular infection and with vesicular infection. Nonmycorrhizal fungi did not respond to any of the treatment combinations, as measured by percent root infection and external hyphal length. Our results indicate that C allocation to the AM fungi was increased in elevated CO₂, and that the mycobiont in turn increased C allocation to external hyphae. (C) 1998 Elsevier Science Ltd. Rillig, M.C., and M.F. Allen. 1999. What is the role of arbuscular mycorrhizal fungi in plant-to- ecosystem responses to Elevated atmospheric CO₂? *Mycorrhiza* 9(1):1-8.

We advocate the concept of an arbuscular mycorrhiza (AM) as a temporally and spatially complex symbiosis representing a suite of hosts and fungi, as against the more traditional "dual organism" view. We use the hierarchical framework presented in Fig. 1 as a basis for organizing many unanswered questions, and several questions that have not been asked, concerning the role of AM in responses to elevated atmospheric CO₂. We include the following levels: plant host, plant population, plant community, functional group and ecosystem. Measurements of the contributions of AM fungi at the various levels require the use of different response variables. For example, hyphal nutrient translocation rates or percent AM root infection may be important measures at the individual plant level, but hyphal biomass or glomalin production and turnover are more relevant at the ecosystem level. There is a discrepancy

between our knowledge of the multifaceted role of AM fungi in plant and ecosystem ecology and most of the current research aimed at elucidating the importance of this symbiosis in global-change scenarios. Our framework for more integrated and multifactorial research on mycorrhizal involvement in regulating CO₂ responses may also serve to enhance communication between researchers working at different scales on large global-change ecosystem projects.

Rillig, M.C., M.F. Allen, J.N. Klironomos, N.R. Chiariello, and C.B. Field. 1998. Plant species-specific changes in root-inhabiting fungi in a California annual grassland: responses to elevated CO₂ and nutrients. *Oecologia* 113(2):252-259.

Five co-occurring plant species from an annual mediterranean grassland were grown in monoculture for 4 months in pots inside open-top chambers at the Jasper Ridge Biological Preserve (San Mateo County, California). The plants were exposed to elevated atmospheric CO₂ and soil nutrient enrichment in a complete factorial experiment. The response of root-inhabiting non-mycorrhizal and arbuscular mycorrhizal fungi to the altered resource base depended strongly on the plant species. Elevated CO₂ and fertilization altered the ratio of non-mycorrhizal to mycorrhizal fungal colonization for some plant species, but not for others. Percent root infection by non-mycorrhizal fungal increased by over 500% for *Linanthus parviflorus* in elevated CO₂, but decreased by over 80% for *Bromus hordeaceus*. By contrast, the mean percent infection by mycorrhizal fungi increased in response to elevated CO₂ for all species, but significantly only for *Avena barbata* and *B. hordeaceus*. Percent infection by mycorrhizal fungi increased, decreased, or remained unchanged for different plant hosts in response to fertilization. There was evidence of a strong interaction between the two treatments for some plant species and non-mycorrhizal and mycorrhizal fungi. This study demonstrated plant species- and soil fertility-dependent shifts in belowground plant resource allocation to different morphogroups of fungal symbionts. This may have consequences for plant community responses to elevated CO₂ in this California grassland ecosystem.

Rillig, M.C., M.F. Allen, J.N. Klironomos, and C.B. Field. 1998. Arbuscular mycorrhizal percent root infection and infection intensity of *Bromus hordeaceus* grown in elevated atmospheric CO₂. *Mycologia* 90(2):199-205.

Using *Bromus hordeaceus*, a grass from a Mediterranean annual grassland in California, we measured changes in infection intensity, rather than the more traditional % root infection, as an indicator of response to elevated atmospheric CO₂ and soil nutrient enrichment. Intensity was measured as the number of intraradical hyphae intersecting a microscope cross-hair for specific root diameter size classes. We found an increase in intensity of infection when plants were exposed to elevated CO₂, and we found a decrease in infection intensity when plants were fertilized. This finding is significant in that it provides evidence for an increase in carbon allocation to the mycobiont under elevated CO₂ even in the absence of change in percent infection, or mycorrhizal root length. Previous studies may therefore have overlooked an important response of arbuscular mycorrhizal fungi to this treatment,

leading to an underestimation of the importance of mycorrhizae under elevated CO₂. Infection intensity may also change in response to many other treatments and environmental variables that the symbiosis is exposed to, highlighting the potential usefulness of intensity as a response variable in mycorrhizal research.

Rillig, M.C., C.B. Field, and M.F. Allen. 1999. Fungal root colonization responses in natural grasslands after long-term exposure to elevated atmospheric CO₂. *Global Change Biology* 5(5):577-585.

Arbuscular mycorrhizae, ubiquitous mutualistic symbioses between plant roots and fungi in the order Glomales, are believed to be important controllers of plant responses to global change, in particular to elevated atmospheric CO₂. In order to test if any effects on the symbiosis can persist after long-term treatment, we examined root colonization by arbuscular mycorrhizal (AM) and other fungi of several plant species from two grassland communities after continuous exposure to elevated atmospheric CO₂ for six growing seasons in the field. For plant species from both a sandstone and a serpentine annual grassland there was evidence for changes in fungal root colonization, with changes occurring as a function of giant host species. We documented decreases in percentage nonmycorrhizal fungal root colonization in elevated CO₂ for several plant species. Total AM root colonization (%) only increased significantly for one out of the five plant species in each grassland. However, when dividing AM fungal hyphae into two groups of hyphae (fine endophyte and coarse endophyte), we could document significant responses of AM fungi that were hidden when only total percentage colonization was measured. We also documented changes in elevated CO₂ in the percentage of root colonized by both AM hyphal types simultaneously. Our results demonstrate that changes in fungal root colonization can occur after long-term CO₂ enrichment, and that the level of resolution of the study of AM fungal responses may have to be increased to uncover significant changes to the CO₂ treatment. This study is also one of the first to document compositional changes in the AM fungi colonizing roots of plants grown in elevated CO₂. Although it is difficult to relate the structural data directly to functional changes, possible implications of the observed changes for plant communities are discussed.

Rillig, M.C., C.B. Field, and M.F. Allen. 1999. Soil biota responses to long-term atmospheric CO₂ enrichment in two California annual grasslands. *Oecologia* 119(4):572-577.

Root, arbuscular-mycorrhizal (AM), soil faunal (protozoa and microarthropods), and microbial responses to field exposure to CO₂ for six growing seasons were measured in spring 1997 in two adjacent grassland communities. The grasslands showed contrasting root responses to CO₂ enrichment: whereas root length was not affected in the sandstone grassland, it was greater in the serpentine grassland, as was specific root length. AM fungal hyphal lengths were greater in the sandstone, but were unaffected in the serpentine community. This lent support to the hypothesis that there may be a tradeoff in resource allocation to more fine roots or greater mycorrhizal extraradical hyphal length. AM root infection was greater in both communities at elevated CO₂, as was the proportion of roots containing arbuscules. Our data on total hyphal lengths, culturable and active fungi, bacteria, and protozoa supported the hypothesis that the fungal food chain was more strongly stimulated than the bacterial chain. This study is one of the first to test

these hypotheses in natural multi-species communities in the field.

Rillig, M.C., K.M. Scow, J.N. Klironomos, and M.F. Allen. 1997. Microbial carbon-substrate utilization in the rhizosphere of *Gutierrezia sarothrae* grown in elevated atmospheric carbon dioxide. *Soil Biology and Biochemistry* 29(9-10):1387-1394.

Differences in rhizosphere microbial community function in response to *Gutierrezia sarothrae* plants grown in elevated CO₂ (750 μ l(-1)) and fertilized with nitrogen were studied using the Biolog microplate analysis of sole C substrate utilization. Compared to ambient CO₂ under elevated CO₂, polymers were more slowly oxidized by the microbial community, amides showed no change in usage, and all other substrate groups were more rapidly utilized, although there was no significant change in the number of viable bacteria. No microbial community responses to N fertilization were detected. The results indicate that potential functional changes in the soil microbial community in response to elevated CO₂ have to be taken into account in future experiments. Differential use of rhizo-deposits in elevated CO₂ may have important consequences for biogeochemistry and plant growth. (C) 1997 Elsevier Science Ltd.

Ringelberg, D.B., J.O. Stair, J. Almeida, R.J. Norby, E.G. O'Neill, and D.C. White. 1997. Consequences of rising atmospheric carbon dioxide levels for the belowground microbiota associated with white oak. *Journal of Environmental Quality* 26(2):495-503.

The consequences for belowground microbiota under conditions of rising atmospheric CO₂ are largely unknown. In this research we examined the microbiota associated with white oak (*Quercus alba* L.). It was our hypothesis that an increase in CO₂ level would induce a change in the rhizosphere-associated microbial abundance and community composition. To provide an in situ estimation of microbial abundance and community composition, ester-linked polar lipid fatty acid (PLFA) technology was utilized. This technology, based on the quantitative measurement of membrane lipid fatty acids, has been utilized in the accurate identification and description of bacterial isolates and communities. Initial experiments demonstrated that a clear distinction in lipid patterns and microbial biomass existed between sterile roots and those of roots containing an associated viable microbiota. Statistical approaches were then used to determine what differences existed between individual PLFA and PLFA patterns obtained from white oak fine roots and bulk soils. An analysis of variance (ANOVA) showed significant differences to exist in the relative percentages of individual prokaryotic PLFA collected under ambient vs. elevated CO₂ and between those associated with fine roots and bulk soils. Multivariate statistics showed distinct differences in the patterns of prokaryotic PLFA detected in the rhizosphere vs. the surrounding bulk soil, but did not identify differences related to elevated CO₂ exposures. An artificial neural network recognized PLFA patterns unique to three different CO₂ exposures: similar to 35, similar to 50, and similar to 65 Pa. Results of the three statistical tests were viewed as supportive of the hypothesis describing significant differences in individual PLFA and patterns of PLFA as a result of elevated CO₂ exposure.

RiviereRolland, H., P. Contard, and T. Betsche. 1996. Adaptation of pea to elevated atmospheric CO₂: Rubisco, phosphoenolpyruvate carboxylase and chloroplast phosphate translocator at different levels of nitrogen and phosphorus nutrition. *Plant, Cell and Environment* 19(1):109-117.

Resource allocation in high CO₂ was studied with respect to plant nutrition. Pea (*Pisum sativum*) was grown in CO₂-enriched air (1000 cm³ m⁻³ CO₂) during the entire vegetative phase, or grown in ambient air (340 cm³ m⁻³ CO₂), with different levels of nitrogen or phosphorus supply. Rubisco specific activity, abundance and small subunit transcript levels were unaltered at high N but declined at reduced N depending upon the degree of N deprivation. It is proposed that (a) a threshold value for the N status occurs in pea above which Rubisco is not down-regulated by high CO₂ and (b) a high leaf level of soluble carbohydrates is not a sufficient condition to down-regulate Rubisco in high CO₂. Phosphoenolpyruvate (PEP) carboxylase decreased, and chloroplast phosphate (P)- translocator increased, in high CO₂. In contrast to Rubisco, down-regulation of PEP carboxylase was alleviated by low N and enhanced by low P. The increase in the P-translocator was little affected by N but was accentuated by low P. The increase in the P-translocator is considered to be one way of alleviating low P conditions in the chloroplast and thus re- balancing carbon partitioning between starch and soluble carbohydrates and amino acids. It is proposed that acclimation of PEP carboxylase and P-translocator reflects adaptation to metabolic perturbations caused by high CO₂.

Robertz, P. 1999. Effects of long-term CO₂ enrichment and nutrient availability in Norway spruce. I. Phenology and morphology of branches. *Trees-Structure and Function* 13(4):188-198.

Branches of 30-year-old Norway spruce [*Picea abies* (L.) Karst.] trees were enclosed in ventilated, transparent plastic bags and flushed with air containing ambient (A approximate to 370 μ mol CO₂ mol⁻¹) or ambient plus 340 μ mol CO₂ mol⁻¹ (EL). Light-saturated photosynthesis was on average 56% higher in EL compared to A. Branch phenology and morphology were strongly related to nitrogen concentration (mg g⁻¹ dry mass) in the foliage and to elevated temperatures in the bags, but no direct effect of EL was found. In 1995, budbreak occurred on average 4 days earlier in the bags compared to the control branches, which was partly explained by the temperature elevation in the bags. No nutrient or EL effect on budbreak was found. Increases in temperature and nitrogen supply increased shoot growth: together they explained 76% of the variation in the extension rate, 63% of the variation in extension duration and 65% of the variation in final length of leading shoots. Shoot morphology was altered both by increased nitrogen availability and by the enclosure induced environmental changes inside the bags, leading to reduced mutual shading between needles. Specific needle area (SNA) was lower in EL, but this was related to lower nitrogen concentrations. Total dry mass of the branches was unaffected by EL. It is concluded that treating individual branches of Norway spruce with elevated CO₂ does not increase branch growth. The nutrient status of the branch and climate determine its growth, i.e., its sink strength for carbon. Increased export of carbohydrates to the rest of the tree is probable in EL treated branches.

Roberntz, P., and S. Linder. 1999. Effects of long-term CO₂ enrichment and nutrient availability in Norway spruce. II. Foliar chemistry. *Trees-Structure and Function* 14(1):17-27.

Branches on 30-year-old Norway spruce trees [*Picea abies* (L.) Karst.] were exposed to ambient (AMB) or ambient plus 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ (EL) for 4 years (except winters), using the branch bag technique (BB). The trees were growing on plots with low (control) and high (irrigated-fertilised) availability of soil nutrients. The seasonal variation in foliar macronutrients and non-structural carbohydrates in current and 1-year-old shoots was monitored throughout the treatment period. When the branches were harvested at the end of treatment, macronutrients were analysed in five age classes of foliage. The concentration of all elements, except magnesium, generally increased in AMB, i.e. a 'bag effect', but decreased as an effect of EL, i.e. a 'CO₂ effect'. At the final harvest K, P, N and S were reduced in young needles by EL, whereas Mg was reduced in older needles on both plots. A change in needle morphology by EL possibly caused a dilution effect in irrigated-fertilised needles, but not in control needles. Reductions in K and Mg are suggested to be an effect of increased phloem transport from the branch, in consequence of higher rates of carbon fixation in EL. Foliage in BBs had higher concentration of Ca, but there was no significant effect of the EL-treatment, indicating that elevated CO₂ had no effect on stomatal conductance. Quinic acid concentration decreased, but shikimic acid concentration increased in BBs, independently of CO₂ treatment. Concentrations of starch and sugars increased in the EL-treatment, but pinitol decreased.

Roberntz, P., and J. Stockfors. 1998. Effects of elevated CO₂ concentration and nutrition on net photosynthesis, stomatal conductance and needle respiration of field-grown Norway spruce trees. *Tree Physiology* 18(4):233-241.

To study the effects of elevated CO₂ on gas exchange, nonstructural carbohydrate and nutrient concentrations in current-year foliage of 30-year-old Norway spruce (*Picea abies* (L.) Karst.) trees, branches were enclosed in ventilated, transparent plastic bags and flushed with ambient air (mean 370 $\mu\text{mol CO}_2 \text{ mol}^{-1}$; control) or ambient air + 340 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ (elevated CO₂) during two growing seasons. One branch bag was installed on each of 24 selected trees from control and fertilized plots. To reduce the effect of variation among trees, results from each treated branch were compared with those from a control branch on the same whorl of the same tree. Elevated CO₂ increased rates of light-saturated photosynthesis on average by 55% when measured at the treatment CO₂ concentration. The increase was larger in shoots with high needle nitrogen concentrations than in shoots with low needle nitrogen concentrations. However, shoots grown in elevated CO₂ showed a decrease in photosynthetic capacity compared with shoots grown in ambient CO₂. When measured at the internal CO₂ concentration of 200 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, photosynthetic rates of branches in the elevated CO₂ treatments were reduced by 8 to 32%. The elevated CO₂ treatment caused a 9 to 20% reduction in carboxylation efficiency and an 18% increase in respiration rates. In response to elevated CO₂, starch, fructose and glucose concentrations in the needles increased on average 33%, whereas concentrations of potassium,

nitrogen, phosphorus, magnesium and boron decreased. Needle nitrogen concentrations explained 50-60% of the variation in photosynthesis and CO₂ acclimation was greater at low nitrogen concentrations than at high nitrogen concentrations. We conclude that the enhanced photosynthetic rates found in shoots exposed to elevated CO₂ increased carbohydrate concentrations, which may have a negative feedback on the photosynthetic apparatus and stimulate cyanide-resistant respiration. We also infer that the decrease in nutrient concentrations of needles exposed to elevated CO₂ was the result of retranslocation of nutrients to other parts of the branch or tree.

Roberts, S.W., W.C. Oechel, P.J. Bryant, S.J. Hastings, J. Major, and V. Nosov. 1998. A field fumigation system for elevated carbon dioxide exposure in chaparral shrubs. *Functional Ecology* 12(4):708-719.

1. Modifications and improvements in the hardware and software of a free-air CO₂ enrichment (FACE) system are described. The modifications were undertaken to minimize the amount of structure required and to improve software control of CO₂ set points. 2. A new low-cost CO₂ flow controller which provides increased reliability is described. 3. Analysis of system performance during a 79-day evaluation period of operation (13 h day⁻¹) showed that for 1 min averages, the system is capable of maintaining a 550 p.p.m. $\pm$ 10% CO₂ set point during 78% of the operating time and a 550 p.p.m. $\pm$ 20% set point during 95% of the operating time. Ten-minute averages were within $\pm$ 10% and 20% during 87% and 96% of the operating time, respectively. 4. Continuous measurements of the spatial variation in CO₂ concentration inside the FACE ring over an 18-day period showed that of the total 16-m diameter treatment area, the central 11-m diameter portion remains within the 550 p.p.m. $\pm$ 10% set point. 5. Daily course gas-exchange measurements in matched individuals of the chaparral shrub *Adenostoma fasciculatum* just prior to and following a 6-week fumigation period at 550 p.p.m. CO₂ in the FACE treatment ring showed the FACE plants with reduced photosynthetic rates and higher (less stressful) water potentials compared with control A. *fasciculatum* plants measured at the same times and conditions, indicating the responsiveness of this species to elevated CO₂ conditions.

Robertson, E.J., and R.M. Leech. 1995. Significant changes in cell and chloroplast development in young wheat leaves (triticum-aestivum CV hereward) grown in elevated CO₂. *Plant Physiology* 107(1):63-71.

Cell and chloroplast development were characterized in young *Triticum aestivum* cv Hereward leaves grown at ambient (350 $\mu\text{mol L}^{-1}$) or at elevated (650 $\mu\text{mol L}^{-1}$) CO₂. In elevated CO₂, cell and chloroplast expansion was accelerated by 10 and 25%, respectively, in the first leaf of 7-d-old wheat plants without disruption to the leaf developmental pattern. Elevated CO₂ did not affect the number of chloroplasts in relation to mesophyll cell size or the linear relationship between chloroplast number or size and mesophyll cell size. No major changes in leaf anatomy or in chloroplast ultrastructure were detected as a result of growth in elevated CO₂, but there was a marked reduction in starch accumulation. In leaf sections fluorescently tagged antisera were used to visualize and quantitate the amount of cytochrome f, the α - and β -subunits of the coupling factor 1 in ATP synthase, D1 protein of the photosystem II reaction center, the 33-kD protein of the extrinsic oxygen-evolving complex, subunit II of photosystem I, and ribulose-1,5-

bisphosphate carboxylase/oxygenase. A significant finding was that in 10 to 20% of the mesophyll cells grown in elevated CO₂ the 33-kD protein of the extrinsic oxygen-evolving complex of photosystem II and cytochrome f were deficient by 75%, but the other proteins accumulated normally.

Robertson, E.J., M. Williams, J.L. Harwood, J.G. Lindsay, C.J. Leaver, and R.M. Leech. 1995. Mitochondria increase 3-fold and mitochondrial proteins and lipid change dramatically in postmeristematic cells in young wheat leaves grown in elevated CO₂. *Plant Physiology* 108(2):469-474.

A dramatic stimulation in mitochondrial biogenesis during the very early stages of leaf development was observed in young wheat plants (*Triticum aestivum* cv Hereward) grown in elevated CO₂ (650 μ mol L⁻¹). An almost 3-fold increase in the number of mitochondria was observed in the very young leaf cells at the base of the first leaf of a 7-d-old wheat plant. In the same cells large increases in the accumulation of a mitochondrial chaperonin protein and the mitochondrial 2-oxoglutarate dehydrogenase complex and pyruvate dehydrogenase complex were detected by immunolabeling. Furthermore, the basal segment also shows a large increase in the rate of radiolabeling of diphosphatidylglycerol, a lipid confined to the inner mitochondrial membrane. This dramatic response in very young leaf cells to elevated CO₂ suggests that the numerous documented positive effects of elevated CO₂ on wheat leaf development are initiated as early as 12 h postmitosis.

Robinson, C.H., A. Michelsen, J.A. Lee, S.J. Whitehead, T.V. Callaghan, M.C. Press, and S. Jonasson. 1997. Elevated atmospheric CO₂ affects decomposition of *Festuca vivipara* (L) Sm litter and roots in experiments simulating environmental change in two contrasting arctic ecosystems. *Global Change Biology* 3(1):37-49.

Mass loss, together with nitrogen and carbon loss, from above-ground material and roots of *Festuca vivipara* were followed for 13 months in a high Arctic polar semidesert and a low Arctic tree-line dwarf shrub heath. *Festuca vivipara* for the study was obtained from plants cultivated at two different CO₂ concentrations (350 and 500 μ mol L⁻¹) in controlled environment chambers in the UK. Each of the four resource types (shoots or roots from plants grown in elevated or ambient CO₂ concentrations) was subsequently placed in an experiment simulating aspects of environmental change in each Arctic ecosystem. Air, litter and soil temperatures were increased using open-topped polythene tents at both sites, and a 58% increase in summer precipitation was simulated at the high Arctic site. Mass loss was greatest at the low Arctic site, and from the shoot material, rather than the roots. Shoots grown under an elevated CO₂ concentration decomposed more slowly at the high Arctic site, and more quickly at the low Arctic one, than shoots grown at ambient CO₂. After 13 months, greater amounts of C and N remained in above-ground litter from plants grown under elevated, rather than

ambient, CO₂ at the polar semi-desert site, although lower amounts of C remained in elevated CO₂ litter at the low Arctic ecosystem. In the high Arctic, roots grown in the 500 μ mol L⁻¹ CO₂ concentration decomposed significantly more slowly than below-ground material derived from the ambient CO₂ chambers. Elevated CO₂ concentrations significantly increased the initial C:N ratio, % soluble carbohydrates and alpha-cellulose content, and significantly decreased the initial N content, of the above-ground material compared to that derived from the ambient treatment. Initially, the C:N ratio and percentage N were similar in both sets of roots derived from the two different CO₂ treatments, but soluble carbohydrate and alpha-cellulose concentrations were higher, and percentage lignin lower, in the elevated CO₂ treatments. The tent treatments significantly retarded shoot decomposition in both ecosystems, probably because of lower litter bag moisture contents, although the additional precipitation treatment had no effect on mass loss from the above-ground material. The results suggest that neither additional summer precipitation (up to 58%), nor soil temperature increase of 1 degrees C, which may occur by the end of the next century as an effect of a predicted 4 degrees C rise in air temperature, had an appreciable effect on root decomposition in the short term in a high Arctic soil. However, at the low Arctic site, greater root decomposition, and a lower pool of root N remaining, were observed where soil temperature was increased by 2 degrees C in response to a 4 degrees C rise in air temperature. These results suggest that decomposition below-ground in this ecosystem would increase as an effect of predicted climate change. These data also show that there is a difference in the initial results of decomposition processes between the two Arctic ecosystems in response to simulated environmental change.

Robinson, D., and J.P. Conroy. 1999. A possible plant-mediated feedback between elevated CO₂, denitrification and the enhanced greenhouse effect. *Soil Biology and Biochemistry* 31(1):43-53.

Natural abundances (δ) of N-15 were used to detect effects of elevated atmospheric CO₂ concentration ([CO₂]) and soil wetness on soil N transformations in the presence or absence of plants. An elevated [CO₂] of 1000 μ mol L⁻¹ reduced water use by the perennial C-4 grass *Panicum coloratum* and stimulated root and whole-plant growth. Soil remained wetter between infrequent irrigations than in soil supporting *P. coloratum* grown in an ambient [CO₂] (350 μ mol L⁻¹). The $\delta(15)$ N value of soil nitrate increased from -2.4 to +9.6 parts per thousand as nitrate was depleted from the soil, but remained unchanged in unplanted soil. The change in $\delta(15)$ N of soil nitrate was greatest in frequently watered soil regardless of [CO₂], and in infrequently watered soil only in elevated [CO₂]. It was least in the infrequently watered, ambient [CO₂] treatment. Isotope mass balances and N-15/N-14 fractionation theory identified denitrification as the most probable cause of this effect, through the effect of elevated [CO₂] on soil wetness. Nitrification, nitrogen assimilation, leaching or ammonia volatilisation were unlikely causes. The data suggest a positive, plant-induced effect of elevated atmospheric [CO₂] on denitrification. The possibility exists, therefore, for a positive feedback between elevated atmospheric [CO₂], a greater soil-to-atmosphere N₂O flux and an exacerbation of the enhanced greenhouse effect. Robinson, M.F., J. Heath, and T.A. Mansfield. 1998. Disturbances in stomatal behaviour caused by air pollutants. *Journal of Experimental Botany* 49:461-469.

Many atmospheric pollutants, even when present at relatively low concentrations, may interfere with the control of stomatal aperture, and they thus have the potential to upset the water balance of the leaf or the whole plant. Although at high concentrations pollutants such as SO₂ and O₃ usually cause stomatal closure, at low concentrations stomatal conductance is often increased. As well as creating a risk of loss of control of water relations, this is likely to increase the dose of the pollutant entering the mesophyll. It is, however, difficult to generalize about the nature of the physiological disturbances caused by pollutants because of variation in the responses between plants. In some cases the effects may be peculiar to one, or just a few, species. Two mechanisms underlying the interference with stomatal control have recently been identified, one involving O₃ and the other CO₂. In *Aster tripolium* (sea aster) stomata in detached epidermal strips close as the external Na⁺ concentration is increased, and it has been proposed that this phenomenon is involved in the regulation of salt loading of shoot tissues. Ozone has been shown to have the capacity to interfere with Na⁺-induced stomatal closure, and the possibility that it therefore disrupts an aspect of salinity tolerance in this species is worthy of further research. Elevated CO₂, on the other hand, has been found to interfere with the control of water relations of beech (*Fagus sylvatica*): for a given degree of drought, stomatal conductance and rates of soil water depletion were significantly higher in elevated CO₂ than in ambient air. It is normally assumed that atmospheric CO₂-enrichment will lead to increased plant productivity and improved water economy, while also providing some protection against other atmospheric pollutants through partial stomatal closure. However, the response of beech indicates that in some species there may also be detrimental effects of CO₂-enrichment on plant-water relations.

Rocheffort, L., and F.A. Bazzaz. 1992. Growth-response to elevated CO₂ in seedlings of 4 cooccurring birch species. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 22(11):1583-1587.

Seedlings of four birch species were examined to evaluate the presence and extent of phylogenetic constraints on the response of species to global CO₂ change. The species differ in their habitat preferences and their successional status. Seedlings were grown for 3 months at near ambient (380 µL L⁻¹) and double (690 µL L⁻¹) CO₂ concentrations in glasshouses. We found the following: (i) yellow birch (*Betula alleghaniensis* Britton) was the only species whose survival differed among CO₂ treatments. Survival was slightly increased by elevated CO₂. (ii) All growth parameters considered in all four species were significantly stimulated by enriched CO₂ Conditions, but the magnitude of response was different among species. The most shade-intolerant, fast-growing species (grey birch; *Betula populifolia* Marsh.) took greater advantage of the elevated CO₂ resource than the more shade-tolerant, later successional species (e.g., yellow birch). (iii) Patterns of allocation, shoot architecture, and leaf nitrogen content were affected differently by CO₂ concentrations for the different species. (iv) The presence and identity of a neighbor did not influence the magnitude or pattern of response to CO₂ in birches of a given community. Our results suggest that congeneric species might be more similar in their response to global CO₂ in comparison to unrelated species of the same ecosystem that had been studied by others, despite the fact that these closely related birch

species differ in their habitat preferences and successional status.

Roden, J.S., and M.C. Ball. 1996. The effect of elevated [CO₂] on growth and photosynthesis of two eucalyptus species exposed to high temperatures and water deficits. *Plant Physiology* 111(3):909-919.

Two species of eucalyptus (*Eucalyptus macrorhyncha* and *Eucalyptus rossii*) were grown for 8 weeks in either ambient (350 µL L⁻¹) or elevated (700 µL L⁻¹) CO₂ concentrations, either well watered or without water additions, and subjected to a daily, 3-h high-temperature (45 degrees C, maximum) and high-light (1250 µmol photons m⁻² s⁻¹), maximum stress period. Water-stressed seedlings of *E. macrorhyncha* had higher leaf water potentials when grown in elevated [CO₂]. Growth analysis indicated that increased [CO₂] may allow eucalyptus species to perform better during conditions of low soil moisture. A down-regulation of photosynthetic capacity was observed for seedlings grown in elevated [CO₂] when well watered but not when water stressed. Well-watered seedlings grown in elevated [CO₂] had lower quantum efficiencies as measured by chlorophyll fluorescence (the ratio of variable to maximal chlorophyll fluorescence [F_v/F_m]) than seedlings grown in ambient [CO₂] during the high-temperature stress period. However, no significant differences in F_v/F_m were observed between CO₂ treatments when water was withheld. The reductions in dark-adapted F_v/F_m for plants grown in elevated [CO₂] were not well correlated with increased xanthophyll cycle photoprotection. However, reductions in the F_v/F_m were correlated with increased levels of nonstructural carbohydrates. The reduction in quantum efficiencies for plants grown in elevated [CO₂] is discussed in the context of feedback inhibition of electron transport associated with starch accumulation and variation in sink strength.

Roden, J.S., and M.C. Ball. 1996. Growth and photosynthesis of two eucalypt species during high temperature stress under ambient and elevated [CO₂]. *Global Change Biology* 2(2):115-128.

Two species of eucalypt (*Eucalyptus macrorhyncha* and *E. rossii*) were grown under conditions of high temperatures (45 degrees C, maximum) and high light (1500 µmol m⁻² s⁻¹, maximum) at either ambient (350 µL L⁻¹) or elevated (700 µL L⁻¹) CO₂ concentrations for 8 weeks. The growth enhancement, in terms of total dry weight, was 41% and 103% for *E. macrorhyncha* and *E. rossii*, respectively, when grown in elevated [CO₂]. A reduction in specific leaf area and increased concentrations of non-structural carbohydrates were observed for leaves grown in elevated [CO₂]. Plants grown in elevated [CO₂] had an overall increase in photosynthetic CO₂ assimilation rate of 27%; however, when measured at the same CO₂ concentration a down-regulation of photosynthesis was evident especially for *E. macrorhyncha*. During the midday period when temperatures and irradiances were maximal, photosynthetic efficiency as measured by chlorophyll fluorescence (F_v/F_m) was lower in *E. macrorhyncha* than in *E. rossii*. Furthermore, F_v/F_m was lower in leaves of *E. macrorhyncha* grown under elevated than under ambient [CO]. These reductions in F_v/F_m were accompanied by increases in both photochemical (q(p)) and nonphotochemical quenching (q(N) and NPQ), and by increases in the concentrations of xanthophyll cycle pigments with an increased

proportion of the total xanthophyll cycle pool comprising of antheraxanthin and zeaxanthin. Thus, increased atmospheric [CO₂] may enhance photoinhibition when environmental stresses such as high temperatures limit the capacity of a plant to respond with growth to elevated [CO₂].

Roden, J.S., J.J.G. Egerton, and M.C. Ball. 1999. Effect of elevated [CO₂] on photosynthesis and growth of snow gum (*Eucalyptus pauciflora*) seedlings during winter and spring. *Australian Journal of Plant Physiology* 26(1):37-46.

Snow gum (*Eucalyptus pauciflora* Sieb. ex Spreng.) seedlings were grown from autumn through spring in open top chambers located in a pasture naturally subject to freezing temperatures in either ambient or elevated (350 μ L L⁻¹ above ambient) CO₂ concentrations. Sustained reduction in quantum efficiency, as measured by chlorophyll fluorescence (F-v/F-m), in over-wintering leaves may be related to seasonal down-regulation of photosynthesis, combined with cumulative effects of freeze-induced damage to the photosynthetic apparatus, with the effect being greater in leaves grown under elevated [CO₂]. Down-regulation of photosynthesis apparently occurred in response to seasonal limitations to growth which were not overcome by elevation of [CO₂] despite temperatures being favorable for photosynthesis during most of the photoperiod. Elevated [CO₂] had no effect on growth of over-wintering seedlings, but enhanced growth in spring when minimum temperatures rose consistently above freezing. As there were no effects of elevated [CO₂] on allocation, the stimulation of growth in spring was attributable to increase in net assimilation rates. Thus seasonal differences in photoinhibition were consistent with seasonal differences in the capacity for growth, with plants grown under elevated [CO₂] having to dissipate more excess excitation energy over-winter.

Roden, J.S., D.J. Wiggins, and M.C. Ball. 1997. Photosynthesis and growth of two rain forest species in simulated gaps under elevated CO₂. *Ecology* 78(2):385-393.

Two species common to the temperate rain forests of New South Wales, Australia (*Doryphora sassafras* and *Acmena smithii*) were grown for 2 wk in either ambient (350 μ L/L) or elevated (700 μ L/L) CO₂ concentrations and low light (30 μ mol photons $\cdot$ m⁻² $\cdot$ s⁻¹) after which the seedlings were exposed for over 9 wk to a midday 2-h highlight period (1250 μ mol photons $\cdot$ m⁻² $\cdot$ s⁻¹, maximum) to simulate a tree fall gap. For both species, plants grown in elevated CO₂ had greater biomass than plants grown in ambient CO₂. However, relative increases in biomass were greater in *Acmena*, which is an early-successional species, than *Doryphora*, which is a late-successional species. *Doryphora sassafras* also had greater reductions in photosynthetic efficiency, as measured by chlorophyll fluorescence techniques (F-v/F-m) upon exposure to the high-light treatment than *Acmena*. Recovery in quantum efficiencies over time was observed for *Doryphora*, implying physiological acclimation to the new light environment. Plants grown in elevated CO₂ had lower values of F-v/F-m than plants grown in ambient CO₂, but these differences between CO₂ treatments were only significant for the late-successional *Doryphora*.

Although exposure to the simulated tree fall gap dramatically increased the conversion of pigments of the xanthophyll cycle, as well as increased the total pool size of xanthophyll cycle pigments relative to total chlorophyll concentration, there were no differences in either parameter between CO₂ treatments. Leaves of *Doryphora* and those seedlings grown in elevated CO₂ had greater starch concentrations than *Acmena* and those seedlings grown in ambient CO₂, respectively. The reduction in quantum efficiencies for plants grown in elevated CO₂ and exposed to a simulated tree fall gap is discussed in the context of the importance of gap phase regeneration for species in rain forest ecosystems and the potential effects of global change on those processes.

Roderick, M.L., S.L. Berry, and I.R. Noble. 1999. The relationship between leaf composition and morphology at elevated CO₂ concentrations. *New Phytologist* 143(1):63-72.

The composition and morphology of leaves exposed to elevated [CO₂] usually change so that the leaf nitrogen (N) per unit dry mass decreases and the leaf dry mass per unit area increases. However, at ambient [CO₂], leaves with a high leaf dry mass per unit area usually have low leaf N per unit dry mass. Whether the changes in leaf properties induced by elevated [CO₂] follow the same overall pattern as that at ambient [CO₂] has not previously been addressed. Here we address this issue by using leaf measurements made at ambient [CO₂] to develop an empirical model of the composition and morphology of leaves. Predictions from that model are then compared with a global database of leaf measurements made at ambient [CO₂]. Those predictions are also compared with measurements showing the impact of elevated [CO₂]. In the empirical model both the leaf dry mass and liquid mass per unit area are positively correlated with leaf thickness, whereas the mass of C per unit dry mass and the mass of N per unit liquid mass are constant. Consequently, both the N:C ratio and the surface area:volume ratio of leaves are positively correlated with the liquid content. Predictions from that model were consistent with measurements of leaf properties made at ambient [CO₂] from around the world. The changes induced by elevated [CO₂] follow the same overall trajectory. It is concluded that elevated [CO₂] enhances the rate at which dry matter is accumulated but the overall trajectory of leaf development is conserved.

Rodriguez, D., M. Van Oijen, and A.H.M.C. Schapendonk. 1999. LINGRA-CC: a sink-source model to simulate the impact of climate change and management on grassland productivity. *New Phytologist* 144(2):359-368.

A simulation model for the prediction of grassland (*Lolium perenne*) productivity under conditions of climate change is described and validated for grass growing in the Wageningen Rhizolab, Wageningen, The Netherlands. In this work the model was used to study the impact of different management strategies on the productivity of grassland under present and increased atmospheric CO₂ concentrations. In LINGRA-CC simulated key processes are light utilization, leaf formation, leaf elongation, tillering and carbon partitioning. The daily growth rate is determined by the minimum of a sink and a source term. As in a previous model (LINGRA), the potential growth of the sink depends on the mean daily temperature, and can be modified by the effects of the availability of assimilates on tillering. The growth of roots is calculated

from the amount of carbohydrates the shoot is unable to utilize when the number or activity of the sinks is small (overflow hypothesis). The main difference between LINGRA and LINGRA-CC is the way the source of assimilates for growth is calculated. Assimilate production depends on intercepted radiation, and a photosynthetic light-use efficiency (LUE) calculated as a function of CO₂, temperature, light intensity and the Rubisco concentration of upper leaves. Other differences are that in LINGRA-CC, the specific shoot area for new growth depends on the level of reserves. Data from two independent experiments with *L. perenne* swards, grown in enclosures at two levels of CO₂ during 1994 and 1995, were used to calibrate and validate the model, respectively. The model predicted well the observed amounts of harvested biomass, and the dynamics of the leaf area index, tiller number and specific shoot area. LINGRA-CC was used to study the effects of different combinations of cutting interval and cutting height on biomass production, at ambient (350 µmol mol⁻¹ CO₂) and double (700 µmol mol⁻¹ CO₂) CO₂ conditions. Under both ambient and doubled CO₂, maximum biomass was produced with cuttings of leaf area index >1, and at cutting intervals of 20 and 17 d for ambient and increased CO₂ environments, respectively. Under high CO₂ conditions the curling interval for maximum yield was 15% shorter than at ambient CO₂. However, the gain in harvested biomass obtained by reducing the cutting interval by 3 d under high CO₂ conditions was negligible.

Rogers, A., B.U. Fischer, J. Bryant, M. Frehner, H. Blum, C.A. Raines, and S.P. Long. 1998. Acclimation of photosynthesis to elevated CO₂ under low-nitrogen nutrition is affected by the capacity for assimilate utilization. Perennial ryegrass under free-air CO₂ enrichment. *Plant Physiology* 118(2):683-689.

Acclimation of photosynthesis to elevated CO₂ has previously been shown to be more pronounced when N supply is poor. Is this a direct effect of N or an indirect effect of N by limiting the development of sinks for photoassimilate? This question was tested by growing a perennial ryegrass (*Lolium perenne*) in the field under elevated (60 Pa) and current (36 Pa) partial pressures of CO₂ (pCO₂) at low and high levels of N fertilization. Cutting of this herbage crop at 4- to 8-week intervals removed about 80% of the canopy, therefore decreasing the ratio of photosynthetic area to sinks for photoassimilate. Leaf photosynthesis, *in vivo* carboxylation capacity, carbohydrate, N, ribulose-1,5-bisphosphate carboxylase/oxygenase, sedoheptulose-1,7-bisphosphatase, and chloroplastic fructose-1,6-bisphosphatase levels were determined for mature lamina during two consecutive summers, just before the cut, when the canopy was relatively large, growth at elevated pCO₂ and low N resulted in significant decreases in carboxylation capacity and the amount of ribulose-1,5-bisphosphate carboxylase/oxygenase protein. In high N there were no significant decreases in carboxylation capacity or proteins, but chloroplastic fructose-1,6-bisphosphatase protein levels increased significantly. Elevated pCO₂ resulted in a marked and significant increase in leaf carbohydrate content at low N, but had no effect at high N. This acclimation at low N was absent after the harvest, when the canopy size was small. These results suggest that acclimation under low N is caused by limitation of sink development rather than being a direct effect of N supply on photosynthesis.

Rogers, G.S., P.W. Gras, I.L. Batey, P.J. Milham, L. Payne, and J.P. Conroy. 1998. The influence of atmospheric CO₂ concentration on the protein, starch and mixing properties of wheat flour. *Australian Journal of Plant Physiology* 25(3):387-393.

Wheat (*Triticum aestivum* L.) cultivars Hartog and Rosella were grown at CO₂ concentrations of 280 µmol L⁻¹ (representing the pre-industrial CO₂ concentration), 350 µmol L⁻¹ (ambient) and 900 µmol L⁻¹ (an extreme projection of atmospheric CO₂ concentration). The plants were grown in naturally lit glasshouses in 7 L pots containing soil to which basal nutrients had been added and the pH adjusted to 6.5. Hartog yielded 2.4 g of grain per plant when grown at 280 µmol L⁻¹ CO₂. This yield was increased by 38% and 75% at CO₂ concentrations of 350 µmol L⁻¹ and 900 µmol L⁻¹ respectively. These changes were due to increases in both grain number and individual grain weight as the level of CO₂ was raised. The yield of Rosella was unaffected by altering the CO₂ concentration. Increasing the CO₂ concentration reduced grain protein concentration of cv. Hartog from 17.4% at 280 µmol L⁻¹ CO₂ to 16.5% and 16% at CO₂ concentrations of 350 µmol L⁻¹ and 900 µmol L⁻¹ respectively. The grain protein concentration of cv. Rosella was reduced from 10.7% to 10.2% by increasing the CO₂ concentration from 280 µmol L⁻¹ to 350 µmol L⁻¹; however, an additional increase in the CO₂ concentration to 900 µmol L⁻¹ had no effect on grain protein concentration. In Hartog flour, the highest proportion of polymeric protein in the flour (7.7%) occurred at 280 µmol L⁻¹ CO₂. This was reduced to 6.3% at 350 µmol L⁻¹ CO₂ but then increased again to 7.0% at 900 µmol L⁻¹ CO₂. These changes in concentration of polymeric protein were correlated (*r*²=0.58) with changes in mixing properties. The mixing time required to produce optimum dough strength was greatest at 900 µmol L⁻¹ CO₂ (181 s), then 141 s and 151 s at 350 µmol L⁻¹ CO₂ and 280 µmol L⁻¹ CO₂ respectively. These changes in mixing time could not be explained by changes in grain protein concentration. The proportion of 'B' starch granules (<10 µm diameter) increased from 25% of total weight of starch at 280 µmol L⁻¹ CO₂ to 30% at CO₂ concentrations 350 and 900 µmol L⁻¹. There were generally no effects of CO₂ concentration on dough mixing properties or starch granule size distribution for Rosella.

Rogers, G.S., P.J. Milham, M. Gillings, and J.P. Conroy. 1996. Sink strength may be the key to growth and nitrogen responses in N-deficient wheat at elevated CO₂. *Australian Journal of Plant Physiology* 23(3):253-264.

The influence of elevated CO₂ (350, 550 and 900 µmol L⁻¹) and N supplies ranging from deficient to excess (0-133 mg N kg⁻¹ soil week⁻¹) on the leaf N concentration and shoot growth of wheat (*Triticum aestivum* L.), cultivar Hartog, was investigated. Shoot growth was 30% greater at 550 µmol L⁻¹ compared to ambient CO₂ at all levels of N supply. When the CO₂ concentration was increased to 900 µmol L⁻¹, there was no increase in shoot growth at low N supply but it more than doubled at high N supply (67 mg N kg⁻¹ soil week⁻¹). Growth effects were closely matched by changes in sink development, suggesting that sink strength, mediated through N supply controlled the shoot growth response to elevated CO₂. The shoot N concentration was lower at each level of CO₂ enrichment and the greatest effect (30% reduction) occurred at 900 µmol L⁻¹ CO₂, 33 mg N kg⁻¹ soil week⁻¹. The effect of high CO₂ on shoot N concentration diminished as N supply increased and, at the highest N addition rate, there was only a 7% reduction. Changes in foliar N concentration due to CO₂ enrichment were closely correlated with lower soluble protein concentration, accounting for 58% of the total leaf N reduction. Ribulose-1,5-

bisphosphate carboxylase/oxygenase (Rubisco) levels were also reduced at high CO₂ and N was allocated away from Rubisco and into other soluble proteins at high CO₂ when N supply was low. Nonstructural carbohydrate concentration (dry weight basis) was greatest at 900 $\mu\text{mol CO}_2 \text{ L}^{-1}$ and low N supply and may have reduced Rubisco concentration via a feed-back response. Critical foliar N concentrations (N concentration at 90 % of maximum shoot growth) were reduced from 43 mg g^{-1} at ambient CO₂ to 39 and 38 mg g^{-1} at 550 and 900 $\mu\text{mol CO}_2 \text{ L}^{-1}$, respectively. Elevated CO₂, at N supplies of 0-17 mg N kg^{-1} soil week⁻¹, reduced flour protein concentration by 9-13 %.

Rogers, G.S., P.J. Milham, M.C. Thibaud, and J.P. Conroy. 1996. Interactions between rising CO₂ concentration and nitrogen supply in cotton .1. Growth and leaf nitrogen concentration. *Australian Journal of Plant Physiology* 23(2):119-125.

The influence of sink development on the response of shoot growth in cotton (*Gossypium hirsutum* L. cv. Siokra BT1-4) was investigated by growing plants at three levels of CO₂ concentration: 350 (ambient), 550 and 900 $\mu\text{mol CO}_2 \text{ L}^{-1}$ and six levels of nitrogen (N) supply ranging from deficient to excess (0-133 mg N kg^{-1} soil week⁻¹). Changes in leaf N concentration were also investigated. At 59 days after sowing, there was an average 63% increase in shoot growth at 550 $\mu\text{mol CO}_2 \text{ L}^{-1}$ compared with ambient CO₂-grown plants, with no significant growth increase at 900 $\mu\text{mol CO}_2 \text{ L}^{-1}$ and, this response was closely matched by sink development (flower number and stem weight). Low N supply restricted the responses of both sink development and shoot growth to high CO₂. At elevated CO₂, leaf N concentration was reduced by an average 27% at low to adequate N supply. The high CO₂-induced reduction in leaf N concentration, however, disappeared when the N supply was increased to a high level of 133 mg N kg^{-1} soil week⁻¹. These CO₂ effects on leaf N concentration were smaller when N was expressed per unit leaf area, apparently due to a combination of the effects of elevated CO₂ or high N supply reducing specific leaf area and, to an N uptake limitation at low to moderate levels of N supply. The critical foliar N concentrations (leaf N concentration at 90% of maximum shoot growth) were reduced from 42 to 38 and 36 mg g^{-1} when CO₂ concentrations were increased from 350 to 550 and 900 $\mu\text{mol CO}_2 \text{ L}^{-1}$ respectively, indicating that changes in fertiliser management may be required under changing CO₂ concentrations.

Rogers, H.H., and R.C. Dahlman. 1993. Crop responses to CO₂ enrichment. *Vegetatio* 104:117-131.

Carbon dioxide is rising in the global atmosphere, and this increase can be expected to continue into the foreseeable future. This compound is an essential input to plant life. Crop function is affected across all scales from biochemical to agro-ecosystem. An array of methods (leaf cuvettes, field chambers, free-air release systems) are available for experimental studies of CO₂ effects. Carbon dioxide enrichment of the air in which crops grow usually stimulates their growth and yield. Plant structure and physiology are markedly altered. Interactions between CO₂ and environmental factors that influence plants are known to occur. Implications for crop growth and yield are enormous. Strategies designed to assure future global food security must include a consideration of crop responses to elevated atmospheric CO₂. Future research should include these targets: search for new insights, development of new techniques, construction of better simulation models, investigation of belowground processes, study of interactions, and the elimination of major discrepancies in the scientific knowledge base.

Plant root response to atmospheric CO₂ enrichment can be great. Results from this controlled environment investigation demonstrate substantial effects on root system architecture, micromorphology and physiology. The most pronounced effects were an increase in root length (110%) and root dry weight (143%). Root diameter, stele diameter, cortex width, root/shoot and root weight ratios all increased; root numbers did not increase. The long-term implications for belowground processes could be enormous.

Rogers, H.H., S.A. Prior, G.B. Runion, and R.J. Mitchell. 1996. Root to shoot ratio of crops as influenced by CO₂. *Plant and Soil* 187(2):229-248.

Crops of tomorrow are likely to grow under higher levels of atmospheric CO₂. Fundamental crop growth processes will be affected and chief

among these is carbon allocation. The root to shoot ratio (R:S, defined as dry weight of root biomass divided by dry weight of shoot biomass) depends upon the partitioning of photosynthate which may be influenced by environmental stimuli. Exposure of plant canopies to high CO₂ concentration often stimulates the growth of both shoot and root, but the question remains whether elevated atmospheric CO₂ concentration will affect roots and shoots of crop plants proportionally. Since elevated CO₂ can induce changes in plant structure and function, there may be differences in allocation between root and shoot, at least under some conditions. The effect of elevated atmospheric CO₂ on carbon allocation has yet to be fully elucidated, especially in the context of changing resource availability. Herein we review root to shoot allocation as affected by increased concentrations of atmospheric CO₂ and provide recommendations for further research. Review of the available literature shows substantial variation in R:S response for crop plants. In many cases (59.5%) R:S increased, in a very few (3.0%) remained unchanged, and in others (37.5%) decreased. The explanation for these differences probably resides in crop type, resource supply, and other experimental factors. Efforts to understand allocation under CO₂ enrichment will add substantially to the global change response data base.

Rogers, H.H., G.B. Runion, and S.V. Krupa. 1994. Plant-responses to atmospheric CO₂ enrichment with emphasis on roots and the rhizosphere. *Environmental Pollution* 83(1-2):155-189.

Empirical records provide incontestable evidence of global changes; foremost among these changes is the rising concentration of CO₂ in the earth's atmosphere. Plant growth is nearly always stimulated by elevation of CO₂. Photosynthesis increases, more plant biomass accumulates per unit of water consumed, and economic yield is enhanced. The profitable use of supplemental CO₂ over years of greenhouse practice points to the value of CO₂ for plant production. Plant responses to CO₂ are known to interact with other environmental factors, e.g. light, temperature, soil water, and humidity. Important stresses including drought, temperature, salinity, and air pollution have been shown to be ameliorated when CO₂ levels are elevated. In the agricultural context, the growing season has been shortened for some crops with the application of more CO₂; less water use has generally, but not always, been observed and is under further study; experimental studies have shown that economic yield for most crops increases by about 33% for a doubling of ambient CO₂ concentration. However, there are some reports of negligible or negative effects. Plant species respond differently to CO₂ enrichment, therefore, clearly competitive shifts within natural communities could occur. Though of less importance in managed agro-ecosystems, competition between crops and weeds could also be altered. Tissue composition can vary as CO₂ increases (e.g. higher C:N ratios) leading to changes in herbivory, but tests of crop products (consumed by man) from elevated CO₂ experiments have generally not revealed significant differences in their quality. However, any CO₂-induced change in plant chemical or structural make-up could lead to alterations in the plant's interaction with any number of environmental factors- physicochemical or biological. Host-pathogen relationships, defense against physical stressors, and the capacity to overcome resource shortages could be impacted by rises in CO₂. Root biomass is known to increase but, with few exceptions, detailed studies of root growth and function are lacking. Potential enhancement of root growth could translate into greater rhizodeposition, which, in turn, could lead to shifts in the rhizosphere itself. Some of the direct effects of CO₂ on vegetation have been reasonably well-studied, but for others work has been inadequate. Among these neglected areas are plant roots and the rhizosphere.

Therefore, experiments on root and rhizosphere response in plants grown in CO₂-enriched atmospheres will be reviewed and, where possible, collectively integrated. To this will be added data which have recently been collected by us. Having looked at the available data base, we will offer a series of hypotheses which we consider as priority targets for future research.

Rolland, C., V. Petitcolas, and R. Michalet. 1998. Changes in radial tree growth for *Picea abies*, *Larix decidua*, *Pinus cembra* and *Pinus uncinata* near the alpine timberline since 1750. *Trees-Structure and Function* 13(1):40-53.

Changes in radial growth of the four coniferous species growing in the French Alps near the upper treeline are investigated. Thirty-seven populations of Norway spruce [*Picea abies* (L.) Karst.], European larch (*Larix decidua* Mill.), Swiss stone pine (*Pinus cembra* L.) and mountain pine (*Pinus uncinata* Mill. ex Mirb.) were sampled by taking 1320 cores and analysing tree-ring widths. Sites were chosen in various climatic conditions (macroclimate and aspect) and on two kinds of bedrock in order to take into account the ecological behaviour of these species. Belledonne, Moyenne-Tarentaise: Haute-Maurienne and Briançonnais areas were sampled along increasing gradients of summer aridity and winter continentality. The calculation of time series after removing the age trend brings strong evidence for an increase in radial growth during the two last centuries, but with different stages and fluctuations for each species. This growth trend is significantly enhanced since 1860 for the spruce, and since 1920 for the two pine species. Furthermore, it also appears on *Larix decidua* with the same pattern despite periodical growth reduction due to attacks of the larch bud moth (*Zeiraphera diniana* Gn.). The analysis of ring-widths at a given cambial age reveals that this enhanced phenomenon is observed especially during the tree's early years (25-75 years). The analysis of four regional climatic series, and three longer series of temperature (in farther single sites) reveals synchronous decadal fluctuations and an evident secular increase in minimum temperatures (especially in January and from July to October), that may be involved in tree-growth enhancement. Thermic amplitudes are significantly reduced during the whole growing period, what is more pronounced in Belledonne, the most oceanic region. Long term growth changes are well described by stepwise regression models, especially for the pine species. These models involved both a linear trend (CO₂ concentration or N-deposition) and low frequency of Turin monthly temperatures. However, they show different patterns than those observed from response functions at a yearly scale.

Ronen-Tarazi, M., D.J. Bonfil, D. Schatz, and A. Kaplan. 1998. Cyanobacterial mutants impaired in bicarbonate uptake isolated with the aid of an inactivation library. *Canadian Journal of Botany-Revue Canadienne De Botanique* 76(6):942-948.

An inactivation library consisting of genomic fragments ligated within a modified bluescript vector was used to isolate several new high CO₂ requiring mutants of *Synechococcus* PCC7942. The mutants described here were impaired in the ability to accumulate C₄ internally when supplied with HCO₃⁻. The relevant genomic regions bearing novel genes

involved in the ability to transport and to accumulate Ci within the cells and thus to grow under low-CO₂ conditions are presented. Some of the mutants were also impaired in ability to adjust to an elevated pH in their medium. We show that the use of inactivation libraries enabled cloning of genes encoding membrane-located proteins; we point to mutations introduced by the single cross-recombination events resulting in the formation of some of these mutants. Possible artifacts that may result in incorrect identification of genes, the inactivation of which could have led to the observed phenotype, are discussed.

Ronentarazi, M., J. Liemanhurwitz, C. Gabay, M.I. Orus, and A. Kaplan. 1995. The genomic region of *rbclS* in *synechococcus* sp pcc-7942 contains genes involved in the ability to grow under low CO₂ concentration and in chlorophyll biosynthesis. *Plant Physiology* 108(4):1461-1469.

Several genes involved in the ability of *Synechococcus* sp. PCC 7942 to grow under different CO₂ concentrations were mapped in the genomic region of *rbclS* (the operon encoding the large and small subunits of ribulose-1,5-bisphosphate carboxylase/oxygenase). Insertion of a cartridge encoding kanamycin resistance within open reading frame (ORF) 78, designated *ccmJ*, located 7 kb upstream of *rbclS*, resulted in a kanamycin-resistant, high-CO₂-requiring mutant, M3, which does not contain normal carboxysomes. *ccmJ* shows significant homology to *csoS1* encoding a carboxysomal shell polypeptide in *Thiobacillus neopolitanus*. Analysis of the polypeptide pattern of a carboxysome-enriched fraction indicated several differences between the wild type and the mutant. The amount of the ribulose-1,5-bisphosphate carboxylase/oxygenase subunits was considerably smaller in the carboxysomal fraction of the mutant when compared to the wild type. On the basis of the sequence analyses, ORF286 and ORF466, located downstream of *ccmJ* were identified as *chit* and *chlN*, respectively, which are involved in chlorophyll biosynthesis in the dark.

Rosenthal, Y. 1998. Variations of ecosystem gas exchange in the rain forest mesocosm at Biosphere 2 in response to elevated CO₂. *Global Change Biology* 4(5):539-547.

The effects of elevated CO₂ on tropical ecosystems were studied in the artificial rain forest mesocosm at Biosphere 2, a large-scale and ecologically diverse experimental facility located in Oracle, Arizona. The ecosystem responses were assessed by comparing the whole-system net gas exchange (NEE) upon changing CO₂ levels from 900 to 450 ppmV. The day-NEE was significantly higher in the elevated CO₂ treatment. In both experiments, the NEE rates were similar to values observed in natural analogue systems. Variations in night-NEE, reflecting both soil CO₂ efflux and plants respiration, covaried with temperature but showed no clear correlation with atmospheric CO₂ levels. After correcting for

changes in CO₂ efflux we show that the rain forest net photosynthesis increased in response to increasing atmospheric CO₂. The photosynthetic enhancement was expressed in higher quantum yields, maximum assimilation rates and radiation use efficiency. The results suggest that photosynthesis in large tropical trees is CO₂ sensitive, at least following short exposures of days to weeks. Taken at face value, the data suggest that as a result of anthropogenic emissions of CO₂, tropical rain forests may shift out of steady state, and become a carbon sink at least for short periods. However, a better understanding of the unique conditions and phenomena in Biosphere 2 is necessary before these results are broadly useful.

Rosenthal, Y., B. Farnsworth, F.V.R. Romo, G.H. Lin, and B.D.V. Marino. 1999. High quality, continuous measurements of CO₂ in Biosphere 2 to assess whole mesocosm carbon cycling. *Ecological Engineering* 13(1-4):249-262.

Accurate measurements of atmospheric CO₂ concentrations are performed routinely in a variety of experimental settings including open fields and forests, leaf gas-exchange chambers, phytotrons and specialized growth chambers. However, the accurate monitoring of large scale structurally and biologically complex experimental systems, operating as materially closed systems, is not widely reported. Here we report the design elements, material specifications and other details for high precision monitoring of CO₂ in Biosphere 2, a large scale ecologically diverse experimental facility located in Oracle, AZ. The results are used to illustrate how carbon balance in a temporarily isolated sub-system of the facility is used to assess carbon dynamics under different environmental conditions such as variable atmospheric CO₂ levels, temperature, light, and soil moisture. The analytical system described here should be applicable for any settings in which continuous, high accuracy measurements of CO₂ in a complex system are needed for quantitative research. Rosenzweig, C., and D. Hillel. 1993. Agriculture in a greenhouse world. *Research & Exploration* 9(2):208-221.

While agriculture in some temperate regions may benefit from global climate change, tropical and subtropical regions may suffer. Even where potential production will improve, the required adjustments may disrupt ecosystems and land-use patterns. Agricultural zones will shift toward high latitudes, while heat stress and increased droughts will reduce productivity in lower latitudes. On the positive side, higher CO₂ may enhance photosynthesis and water-use efficiency. Future hazards include sea-level rise, insect infestation, and greater evaporation losses. Some agricultural activities augment the greenhouse effect by releasing CO₂, CH₄, and N₂O. Understanding the potential impacts of climate change is a prerequisite to developing societal responses.

Rosenzweig, C., J. Phillips, R. Goldberg, J. Carroll, and T. Hodges. 1996. Potential impacts of climate change on citrus and potato production in the US. *Agricultural Systems* 52(4):455-479.

Potential impacts of global climate change on fruit and vegetable yield

in the US were investigated through simulations of citrus and potato. Simulated treatments included combinations of three increased temperature regimes (+1.5, +2.5 and +5.0 degrees C), and estimates of the impact of three levels of atmospheric carbon dioxide (440, 530, and 600 ppm) in addition to control runs representing current climatic conditions. Adaptive planting dates of -28, -14, +14 and +28 days were included in the potato simulations for current and increased temperature regimes. Twenty-two sites were simulated for citrus yields and 12 sites for potato, using climate records from 1951 to 1980. Response surfaces were developed for all combinations of increased temperature and CO₂. Results of citrus simulations without CO₂-induced yield improvement indicate that production may shift slightly northward in the southern states, but yields may decline in southern Florida and Texas due to excessive heat during the winter. CO₂ effects tended to counteract the decline in simulated citrus yields. Fall potato production under current management practices appears vulnerable to an increase in temperature in the northern states; increased CO₂ and changes in planting date were estimated to have minimal compensating impacts on simulated potato yields.

Rosenzweig, C., and F.N. Tubiello. 1996. Effects of changes in minimum and maximum temperature on wheat yields in the central US - A simulation study. *Agricultural and Forest Meteorology* 80(2-4):215-230.

Recent observations and general circulation models indicate that future temperature changes linked to global warming might be characterized by a marked asymmetry between daytime maxima and nighttime minima. We investigate the importance of such a pattern in determining future wheat (*Triticum aestivum*) yields in the Central United States by using a dynamic crop growth model, CERES-Wheat, modified to include physiological effects of temperature and CO₂ on canopy photosynthesis. Simulations are run at four sites spanning a north-south transect of the Central US; four mean temperatures increases (1-4 degrees C) are applied to baseline daily climate data (1951-1980). The effects of two different scenarios of temperature change (minimum and maximum temperatures equally raised; minima increased three times as much as maxima in agreement with recent observations) are analyzed under both current (330 ppm) and elevated (550 ppm) CO₂ concentrations. The main mechanisms controlling the simulated wheat responses are direct and indirect temperature effects on wheat phenological development. Negative effects of temperature on simulated wheat yields are reduced when minima increase more than maxima. Yield changes are consistently negative under temperature change and current CO₂ concentration, while they range from positive to negative under temperature change and elevated CO₂ concentration. Responses vary across the transect, with larger negative effects occurring at the southernmost site.

Ross, D.J., S. Saggar, K.R. Tate, C.W. Feltham, and P.C.D. Newton. 1996. Elevated CO₂ effects on carbon and nitrogen cycling in grass/clover turves of a Psammaque soil. *Plant and Soil* 182(2):185-198.

Effects of elevated CO₂ (525 and 700 mu L L(-1)), and a control (350 mu L L(-1) CO₂), on biochemical properties of a Mollic Psammaque

soil in a well-established pasture of C3 and C4 grasses and clover were investigated with continuously moist turves in growth chambers over four consecutive seasonal temperature regimes from spring to winter inclusive. After a further 'spring' period, half of the turves under 350 and 700 mu L L(-1) were subjected to 'summer' drying and were then re-wetted before a further 'autumn' period; the remaining turves were kept continuously moist throughout these additional three consecutive 'seasons'. The continuously moist turves were then pulse-labelled with C-14-CO₂ to follow C pathways in the plant/soil system during 35 days. Growth rates of herbage during the first four 'seasons' averaged 4.6 g m(-2) day(-1) under 700 mu L L(-1) CO₂ and were about 10% higher than under the other two treatments. Below-ground net productivity at the end of these 'seasons' averaged 465, 800 and 824 g m(-2) in the control, 525 and 700 mu L L(-1) treatments, respectively. In continuously moist soil, elevated CO₂ had no overall effects on total, extractable or microbial C and N, or invertase activity, but resulted in increased CO₂-C production from soil, and from added herbage during the initial stages of decomposition over 21 days; rates of root decomposition were unaffected. CO₂ produced h(-1) mg(-1) microbial C was about 10% higher in the 700 mu L L(-1) CO₂ treatment than in the other two treatments. Elevated CO₂ had no clearly defined effects on N availability, or on the net N mineralization of added herbage. In the labelling experiment, relatively more C-14 in the plant/soil system occurred below ground under elevated CO₂, with enhanced turnover of C-14 also being suggested. Drying increased levels of extractable C and organic-N, but decreased mineral-N concentrations; it had no effect on microbial C, but resulted in lowered microbial N in the control only. In soil that had been previously 'summer'-dried, CO₂ production was again higher, but net N mineralization was lower, under elevated CO₂ than in the control after 'autumn' pasture growth. Over the trial period of 422 days, elevated CO₂ generally appears to have had a greater effect on soil C turnover than on soil C pools in this pasture ecosystem.

Ross, D.J., K.R. Tate, and P.C.D. Newton. 1995. Elevated co₂ and temperature effects on soil carbon and nitrogen cycling in ryegrass/white clover turves of an endoaquept soil. *Plant and Soil* 176(1):37-49.

Effects of elevated CO₂ (700 mu L L(-1)) and a control (350 mu L L(-1) CO₂) on the productivity of a 3-year-old ryegrass/white clover pasture, and on soil biochemical properties, were investigated with turves of a Typic Endoaquept soil in growth chambers. Temperature treatments corresponding to average winter, spring, and summer conditions in the field were applied consecutively to all of the turves. An additional treatment, at 700 mu L L(-1) CO₂ and a temperature 6 degrees C higher throughout than in the other treatments, was included. Under the same temperature conditions, overall herbage yields in the '700 mu L L(-1) CO₂' treatment were ca. 7% greater than in the control at the end of the 'summer' period. Root mass (to ca 25 cm depth) in the '700 mu L L(-1) CO₂' treatment was then about 50% greater than in the control, but in the '700 mu L L(-1) CO₂ + 6 degrees C' treatment it was 6% lower than in the control. Based on decomposition results, herbage from the '700 mu L L(-1) + 6 degrees C' treatment probably contained the highest proportion of readily decomposable components. Elevated CO₂ had no consistent effect on soil total C and N, microbial C and N, or extractable C concentrations in any of the treatments. Under the same temperature conditions, it did, however, enhance soil respiration (CO₂-C production) and invertase activity. The effects of elevated CO₂ on rates of net N mineralization were less distinct, and the apparent availability of N for the sward was not affected. Under elevated CO₂, soil in the higher-temperature treatment had a higher microbial C:N ratio; it also had a greater potential to degrade plant materials. Data interpretation was

complicated by soil spatial variability and the moderately high background levels of organic matter and biochemical properties that are typical of New Zealand pasture soils. More rapid cycling of C under CO₂ enrichment is, nevertheless, indicated. Further long-term experiments are required to determine the overall effect of elevated CO₂ on the soil C balance.

RossKarstens, G.S., G. Ebert, and P. Ludders. 1996. Diurnal time courses of CO₂ gas exchange in closed and open gas systems for coffee (*Coffea arabica* L.), pomegranate (*Punica granatum* L.), citrus (*Citrus limonia* Osb.), grape (*Vitis vinifera* L.), and banana (*Musa x paradisiaca* L.) in vitro plantlets under different environment conditions. *Journal of Applied Botany-Angewandte Botanik* 70(3-4):155-162.

Continuous measurements were made of CO₂ gas exchange over a period of three days on ill vitro plantlets of coffee (*Coffea arabica* L.), pomegranate (*Punica granatum* L.), citrus (*Citrus limonia* Osb.), grape (*Vitis vinifera* L.), and banana (*Musa x paradisiaca* L.). The gas used for measurements contained CO₂ concentrations of 350, 600, 1000 or 2000 $\mu\text{l l}^{-1}$. Measurements in the closed system for coffee plantlets grown in medium containing different sucrose concentrations showed a strong decrease of the CO₂ concentration in the cuvette atmosphere during the light period almost reaching the CO₂ compensation point (70 $\mu\text{l l}^{-1}$ CO₂). During the dark period a continuous increase was observed. Measured in the open system diurnal time courses of in vitro pomegranate and citrus plantlets showed that CO₂ assimilation rates were strongly influenced by light intensity and temperature. A positive balance of CO₂ gas exchange was found for pomegranate plantlets only with light intensities beyond 100 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photosynthetic photon flux density (PPFD). Citrus plantlets were independent of the sucrose concentration in the medium and showed a positive CO₂ balance at 350 $\mu\text{l l}^{-1}$ CO₂ gas concentration. Banana plantlets revealed negative balances under all conditions examined.

RossKarstens, G.S., G. Ebert, and P. Ludders. 1996. Influence of CO₂ concentration, light intensity, and sucrose concentration on net photosynthesis of citrus plantlets during in vitro propagation. *Journal of Applied Botany-Angewandte Botanik* 70(5-6):188-193.

Light curves of the CO₂ gas exchange of in vitro plantlets of citrus (*Citrus limonia* Osb. (Rutaceae)) were measured continuously in an open system using different CO₂ concentrations (350, 1000, and 2000 $\mu\text{l l}^{-1}$ CO₂). The plantlets were grown in media with sucrose concentrations from 0 to 5% under light intensities of 60, 100, and 260 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Before starting the measurements the plantlets were pretreated with 1000 $\mu\text{l l}^{-1}$ CO₂ for several weeks. Control plantlets were grown for the same period in gas tight vessels. CO₂ concentration of the gas atmosphere inside the plant vessels had a stronger influence on CO₂ gas exchange of citrus plantlets than sucrose concentration of the medium. Net photosynthesis of plantlets grown under various light intensities differed only little when using the same CO₂ concentration for measurement as used for growing. After pretreatment with 1000 $\mu\text{l l}^{-1}$ CO₂ during growth, net photosynthesis of plantlets measured under 350 $\mu\text{l l}^{-1}$ CO₂ was higher compared to control plantlets.

Roth, S.K., and R.L. Lindroth. 1994. Effects of CO₂-mediated changes in paper birch and white-pine chemistry on gypsy-moth performance. *Oecologia* 98(2):133-138.

We examined the effects of CO₂-mediated changes in the foliar chemistry of paper birch (*Betula papyrifera*) and white pine (*Pinus strobus*) on performance of the gypsy moth (*Lymantria dispar*). Trees were grown under ambient or enriched CO₂ conditions, and foliage was subjected to plant chemical assays and insect bioassays. Enriched CO₂ atmospheres reduced foliar nitrogen levels and increased condensed tannin levels in birch but not in pine. Foliar carbohydrate concentrations were not markedly altered by CO₂ environment. Gypsy moth performance was significantly affected by CO₂ level, species, and the CO₂ x species interaction. Under elevated CO₂ conditions, growth was reduced for larvae fed birch, while development was prolonged for larvae fed pine. Although gypsy moths performed better overall on birch than pine, birch-fed larvae were influenced more by CO₂-mediated changes in host quality.

Roth, S.K., and R.L. Lindroth. 1995. Elevated atmospheric CO₂ effects on phytochemistry, insect performance and insect parasitoid interactions. *Global Change Biology* 1(3):173-182.

This study was conducted to examine the effects of CO₂-mediated changes in tree chemistry on the performance of the gypsy moth (*Lymantria dispar* L.) and the parasitoid *Cotesia melanoscela* (Ratz.). We used carbon-nutrient balance theory to develop hypotheses regarding changes in tree chemistry and the performance of both insects under elevated CO₂. As predicted, levels of foliar nitrogen declined and concentrations of carbon-based compounds (e.g. starch and phenolics) increased under elevated CO₂. Gypsy moth performance (e.g. growth, development) was altered by CO₂-mediated changes in foliar chemistry, but the magnitude was small and varied across tree species. Larvae feeding on high CO₂ aspen exhibited the largest reduction in performance, relative to larvae feeding on birch, oak, or maple. Parasitism by *C. melanoscela* significantly prolonged gypsy moth development and reduced growth rates. Overall, the effect of parasitism on gypsy moth performance did not differ between CO₂ treatments. Altered gypsy moth performance on high CO₂ foliage in turn affected parasitoid performance, but the response was variable: parasitoid mortality increased and adult female size declined slightly under high CO₂, while development time and adult male size were unaffected. Our results suggest that CO₂-induced changes in plant chemistry were buffered to the extent that effects on third trophic level interactions were weak to non-existent for the system examined in this study.

Roth, S., R.L. Lindroth, J.C. Volin, and E.L. Kruger. 1998. Enriched atmospheric CO₂ and defoliation: effects on tree chemistry and insect performance. *Global Change Biology* 4(4):419-430.

We examined the effects of CO₂ and defoliation on tree chemistry and performance of the forest tent caterpillar, *Malacosoma disstria*. Quaking aspen (*Populus tremuloides*) and sugar maple (*Acer saccharum*) trees

were grown in open-top chambers under ambient or elevated concentrations of CO₂. During the second year of growth, half of the trees were exposed to free-feeding forest tent caterpillars, while the remaining trees served as nondefoliated controls. Foliage was collected weekly for phytochemical analysis. Insect performance was evaluated on foliage from each of the treatments. At the sampling date coincident with insect bioassays, levels of foliar nitrogen and starch were lower and higher, respectively, in high CO₂ foliage, and this trend persisted throughout the study. CO₂-mediated increases in secondary compounds were observed for condensed tannins in aspen and gallotannins in maple. Defoliation reduced levels of water and nitrogen in aspen but had no effect on primary metabolites in maple. Similarly, defoliation induced accumulations of secondary compounds in aspen but not in maple. Larvae fed foliage from the enriched CO₂ or defoliated treatments exhibited reduced growth and food processing efficiencies, relative to larvae on ambient CO₂ or nondefoliated diets, but the patterns were host species-specific. Overall, CO₂ and defoliation appeared to exert independent effects on foliar chemistry and forest tent caterpillar performance.

Roth, S., E.P. McDonald, and R.L. Lindroth. 1997. Atmospheric CO₂ and soil water availability: consequences for tree-insect interactions. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 27(8):1281-1290.

The consequences of elevated CO₂ for interactions between trees and associated insects will be influenced by the availability of other plant resources. We investigated the effects of CO₂ and water availability on phytochemistry of quaking aspen (*Populus tremuloides* Michx.) and sugar maple (*Acer saccharum* Marsh.) and the associated performance of the forest tent caterpillar (*Malacosoma disstria* Hbn.). Seedlings were grown under ambient or elevated CO₂ concentrations and under well-watered or drought conditions. We measured rates of gas exchange and subjected foliage to phytochemical assays. Bioassays were conducted to quantify larval performance on foliage from the various treatments. In general, elevated CO₂ increased photosynthetic rates and had no effect on stomatal conductance, while drought reduced both parameters. Foliar nitrogen levels declined and secondary metabolite concentrations increased under enriched CO₂, but starch and sugar levels were unaffected. All phytochemicals measured, with the exception of simple sugars, declined or did not change in response to drought. CO₂- and drought-mediated changes in phytochemistry reduced forest tent caterpillar growth and food processing efficiencies, but the patterns were host-species specific. This work demonstrates that CO₂ effects on forest trees will be mediated by the availability of water and that the direction and magnitude of responses will depend on the tree species involved, which will, in turn, affect patterns of host use by herbivorous insects.

Rothschild, L.J. 1994. Elevated CO₂ - impact on diurnal patterns of photosynthesis in natural microbial ecosystems. *Life Sciences and Space Research XXV (3)* 14(11):285-289.

Algae, including blue-green algae (cyanobacteria), are the major source of fixed carbon in many aquatic ecosystems. Previous work has shown that photosynthetic carbon fixation is often enhanced in the presence of

additional carbon dioxide (CO₂). This study was undertaken to determine if this CO₂ fertilization effect extended to microbial mats, and, if so, at what times during the day might the addition of CO₂ affect carbon fixation. Four microbial mats from diverse environments were selected, including mats from a hypersaline pond (area 5, Exportadora de Sal, Mexico), the marine intertidal (Lyngbya, Laguna Ojo de Liebre, Mexico), an acidic hot spring (Cyanidium, Nymph Creek, Yellowstone National Park), and an acidic stream at ambient temperature (Zygonium, Yellowstone National Park). Carbon fixation in the absence of additional CO₂ essentially followed the rising and falling sunlight levels, except that during the middle of the day there was a short dip in carbon fixation rates. The addition of CO₂ profoundly enhanced carbon fixation rates during the daylight hours, including during the midday dip. Therefore, it is unlikely that the midday dip was due to photoinhibition. Surprisingly, enhancement of carbon fixation was often greatest in the early morning or late afternoon, times when carbon fixation would be most likely to be light limited.

Rotter, R., and S.C. Van de Geijn. 1999. Climate change effects on plant growth, crop yield and livestock. *Climatic Change* 43(4):651-681.

A review is given of the state of knowledge in the field of assessing climate change impacts on agricultural crops and livestock. Starting from the basic processes controlling plant growth and development, the possible impacts and interactions of climatic and other biophysical variables in different agro- environments are highlighted. Qualitative and quantitative estimations of shifts in biomass production and water relations, inter-plant competition and crop species adaptability are discussed. Special attention is given to the problems encountered when scaling up physiological responses at the leaf- and plant level to yield estimates at regional to global levels by using crop simulation models in combination with geo-referenced, agro-ecological databases. Some non-linear crop responses to environmental changes and their relations to adaptability and vulnerability of agro-ecosystems are discussed.

Rotzel, C., P.W. Leadley, and C. Korner. 1997. Non-destructive assessment of the effects of elevated CO₂ on plant community structure in a calcareous grassland. *Acta Oecologica-International Journal of Ecology* 18(3):231-239.

Calcareous grassland was exposed to ambient or elevated CO₂ using a Screen-Aided CO₂ Control (SACC) system starting in March 1994. The effects of elevated CO₂ on plant community structure were studied using the point intercept method. Measurements were made in March 1994 prior to the start of CO₂ exposure and again in June 1994 at peak plant biomass. There were no significant differences in the initial structure of the communities based on their assigned CO₂ treatments in March. After 9 weeks of exposure of the community to elevated CO₂, the total number of intercepts per plot was not significantly different between CO₂ treatments; however, *Carex flacca* and *Cirsium acaule* had marginally significant ($P = 0.055$ and $P = 0.06$) increases in the % sward of the community at elevated CO₂ (number of intercepts for a single species divided by the total number of intercepts for all species). Measurements of leaf extension in *Carex flacca* showed that at least part of the increase in % sward at elevated CO₂ could be explained by

greater leaf length per plant ($P = 0.02$). These measurements and other experiments with calcareous grassland species and communities suggest that rising atmospheric CO₂ concentrations will probably alter the structure of calcareous grassland communities.

Rouhier, H., G. Billes, L. Billes, and P. Bottner. 1996. Carbon fluxes in the rhizosphere of sweet chestnut seedlings (*Castanea sativa*) grown under two atmospheric CO₂ concentrations: C-14 partitioning after pulse labelling. *Plant and Soil* 180(1):101-111.

Partitioning of C-14 was assessed in sweet chestnut seedlings (*Castanea sativa* Mill.) grown in ambient and elevated atmospheric [CO₂] environments during two vegetative cycles. The seedlings were exposed to (CO₂)-C-14 atmosphere in both high and low [CO₂] environments for a 6-day pulse period under controlled laboratory conditions. Six days after exposure to (CO₂)-C-14, the plants were harvested, their dry mass and the radioactivity were evaluated. C-14 concentration in plant tissues, root-soil system respiratory outputs and soil residues (rhizodeposition) were measured. Root production and rhizodeposition were increased in plants growing in elevated atmospheric [CO₂]. When measuring total respiration, i.e. CO₂ released from the root/soil system, it is difficult to separate CO₂ originating from roots and that coming from the rhizospheric microflora. For this reason a model accounting for kinetics of exudate mineralization was used to estimate respiration of rhizospheric microflora and roots separately. Root activity (respiration and exudation) was increased at the higher atmospheric CO₂ concentration. The proportion attributed to root respiration accounted for 70 to 90% of the total respiration. Microbial respiration was related to the amount of organic carbon available in the rhizosphere and showed a seasonal variation dependent upon the balance of root exudation and respiration. The increased carbon assimilated by plants grown under elevated atmospheric [CO₂] stayed equally distributed between these increased root activities.

Rouhier, H., G. Billes, A. Elkohen, M. Mousseau, and P. Bottner. 1994. Effect of elevated CO₂ on carbon and nitrogen distribution within a tree (*castanea-sativa* mill) soil system. *Plant and Soil* 162(2):281-292.

Two-year-old sweet chestnut trees were grown outside in normal or double CO₂ atmospheric concentration. In spring and in autumn of two growing seasons, a six day labelling pulse of C-14 labelled CO₂ was used to follow the carbon assimilation and distribution in the plant-soil system. Doubling atmospheric CO₂ had a significant effect on the tree net carbon uptake. A large proportion of the additional C uptake was 'lost' through the root system. This suggests that increased C uptake under elevated CO₂ conditions increases C cycling without necessarily increasing C storage in the plant. Total root derived material represented a significant amount of the 'extra-assimilated' carbon due to the CO₂ treatment and was strongly correlated with the phenological stage of the tree. Increasing root rhizodeposition led to a stimulation of microbial activity, particularly near the end of the growing season. When plant rhizodeposition was expressed as a function of the root dry weight, the effect of increasing CO₂ resulted in a higher root activity. The C to N ratios were significantly higher for trees grown under elevated CO₂ except for the fine root compartment. An evaluation of the plant-soil system nitrogen dynamics showed, during the second season of CO₂ treatment, a decrease of soil N mineralization rate and total N uptake for trees grown at elevated CO₂ levels.

Rouhier, H., and D.J. Read. 1998. Plant and fungal responses to elevated atmospheric carbon dioxide in mycorrhizal seedlings of *Pinus sylvestris*. *Environmental and Experimental Botany* 40(3):237-246.

The effects of elevated CO₂ concentration upon the mycorrhizal relationships of Scots pine (*Pinus sylvestris*) seedlings were investigated. Plants were grown for 4 months with their shoots exposed to ambient (C-AMB = 360 μ mol l⁻¹) or elevated (C-ELEV = 700 μ mol l⁻¹) CO₂ environments while their root systems, either colonised by the mycorrhizal fungi *Paxillus involutus* or *Suillus bovinus*, or left in the non-mycorrhizal condition, were maintained in sealed dishes. In one series of these plants the effects of C-ELEV upon the extent of mycorrhizal development and upon their growth and nutrition were determined, while another series were transferred from the dishes after 1 month, to transparent observation chambers before being returned to the two CO₂ environments. In these chambers, the effects of C-ELEV upon development of the external mycelial systems of the two mycorrhizal fungi was determined by measuring the advance of the hyphal fronts of the mycorrhizal fungi across non-sterile peat from the colonised plants. The dry mass and number of mycorrhizal tips were significantly higher in C-ELEV than in the C-AMB condition in plants colonised by both fungi in the dishes. Yields of whole plants and of shoots were higher in the C-ELEV treatment whether or not they were grown in the mycorrhizal condition, but the greater yields were not associated in these sealed systems with enhanced nutrient gain. The dry mass of non-mycorrhizal plants was greater than that of those colonised by mycorrhizal fungi under elevated CO₂. This is thought to be attributable to the energetic cost of production of the larger mycorrhizal systems in this treatment. The extent of development of the mycorrhizal mycelial systems of both fungi was greatly increased in C-ELEV relative to that in C-AMB environments. It is hypothesised that increased allocation of carbon to mycorrhizal root systems and their associated mycelia would provide the potential for enhancement of nutrient acquisition in open systems of greater fertility. Rouhier, H., and D.J. Read. 1998. The role of mycorrhiza in determining the response of *Plantago lanceolata* to CO₂ enrichment. *New Phytologist* 139(2):367-373.

Plantago lanceolata L. was grown for 104 d with (M) or without (NM) arbuscular mycorrhizal colonization under conditions of ambient (C-AMB = 350 μ mol l⁻¹) and elevated (C-ELEV = 540 μ mol l⁻¹) CO₂. Sequential harvests (H) were taken at 41 (H-1), 76 (H-2) and 104 d (H-3) to determine the time-course of mycorrhizal influence on the response of the plant to CO₂ enrichment. Total yields of M plants were greater than those of NM from H-2 onwards. Plants in the M-ELEV treatment were significantly larger than those in the M-AMB at 104 d. There were significant but much smaller differences in yield between NMELEV and NMAMB. The differences in total yield arose through impact of C-ELEV on both shoots and roots. Total root length was greater in M-ELEV than in M-AMB only at H-3, but total length of mycorrhizal root was greater at H-2 and H-3. The percentages of root length colonized and that occupied by arbuscules and vesicles were greater in M-ELEV than in M-AMB at the last two harvests, indicating increased sequestration of carbon in internal fungal structures. Though extraradical

hyphal lengths were greater in M-ELEV than in M-AMB at H-2 and H-3, the differences were not significant. Phosphorus inflow and P content of M plants were higher than those of NM plants at H-2 and H-3, and were higher in M-ELEV than in M-AMB at H-3. ANOVA revealed no significant interactions between CO₂ and mycorrhizal treatment. The results are discussed in relation to carbon sequestration in mycorrhizal systems and likely impacts of CO₂ enrichment on *P. lanceolata* grown under field conditions. The importance of sequential harvesting for realistic determination of responses to CO₂ is stressed.

Rouhier, H., and D.J. Read. 1999. Plant and fungal responses to elevated atmospheric CO₂ in mycorrhizal seedlings of *Betula pendula*. *Environmental and Experimental Botany* 42(3):231-241.

The effects of elevated CO₂ concentrations upon carbon allocation in mycorrhizal (M) and non-mycorrhizal (NM) birch (*Betula pendula*) seedlings were investigated. M plants, colonised by the fungus *Paxillus involutus*, and NM plants, were exposed for 3 months to ambient (350 $\mu\text{mol l}^{-1}$) or elevated (700 $\mu\text{mol l}^{-1}$) CO₂ environments. The assimilation and distribution of carbon within the different compartments of the plant-substrate-fungal system were investigated using radioactive carbon as a tracer. In addition, the impact of elevated CO₂ upon extension growth of the ectomycorrhizal mycelium of the fungus was determined in transparent observation chambers. Yields of whole plants and of shoots were significantly decreased under elevated CO₂ whether they were grown with or without their fungal symbionts. Neither the dry mass production of roots of mycorrhizal plants, nor the amount of carbon allocated to shoots, roots and mycorrhizal tips were affected by elevated CO₂. While the number of mycorrhizal root tips was decreased with CO₂ enrichment, their relative importance in the total root system was unchanged. There was a significant increase in the extent of development of the external mycelium under elevated CO₂. A greater proportion of the radioactive carbon was allocated to the soil compartment under elevated CO₂. This increase, probably arising through increased rhizodeposition, was greater in NM than M plants. The responses are discussed in terms of nutrient availability in the growth media and the possible role of increased carbon allocation to mycorrhizal mycelium in nature. Roumet, C., M.P. Bel, L. Sonie, F. Jardon, and J. Roy. 1996. Growth response of grasses to elevated CO₂: A physiological plurispecific analysis. *New Phytologist* 133(4):595-603.

The effect of CO₂ enrichment on the growth and the economy of carbon and nitrogen of 11 Mediterranean grass species was investigated in order to determine the underlying causes of the large variation observed between species in their responses to elevated CO₂. Plants were grown for 26-43 d (depending on species growth rate) under productive conditions at ambient (350 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) concentrations of CO₂. Plant parameters were determined at a common biomass of 0.15 g to determine the CO₂ effect independent of ontogenic effects. The effect of CO₂ on RGR ranged from -6.7 to 22.5%, with a mean stimulation of 10.3%. Averaged over the 11 species, the growth enhancement resulted from an increase in net assimilation rate per unit leaf d. wt. (NAR(w)) of 10.6%. This was the result of a

large increase (18.7%) in NAR per unit leaf area (NAR(a)) associated with a 8.1% decrease in the specific leaf area (SLA). This decrease in SLA was due to a large increase of the non-structural carbohydrates. The increase in shoot activity was balanced by a 7.6% increase in the specific absorption rate of nitrogen (SAR). As a result, plant nitrogen content was not modified. Leaf nitrogen productivity was significantly increased (14.9%). Shoot vs. root allocation of biomass and nitrogen was not modified. An analysis across the 11 species of the relationships between the stimulation of RGR and the alteration in RGR components showed a significant correlation only with increases in NAR(w), SAR and nitrogen productivity. The co-ordinated increase in these three parameters constitutes a single response syndrome, whose intensity is responsible for most of the species variability.

Roumet, C., G. Laurent, and J. Roy. 1999. Leaf structure and chemical composition as affected by elevated CO₂: genotypic responses of two perennial grasses. *New Phytologist* 143(1):73-81.

Genotypic variability was studied in two Mediterranean grass species, *Bromus erectus* and *Dactylis glomerata*, with regard to the response to CO₂ of leaf total non-structural carbohydrate concentration ([TNC](1f)), specific leaf area (SLA), and leaf carbon and nitrogen concentrations ([C](1f) and [N](1f), respectively). Fourteen genotypes of each species were grown together on intact soil monoliths at ambient and elevated CO₂ concentrations (350 and 700 $\mu\text{mol mol}^{-1}$, respectively). In both species, the most consistent effect of elevated CO₂ was an increase in [TNC](1f) and a decrease in leaf nitrogen concentration when expressed either as total dry mass [N-m](1f), structural dry mass [N(m)st](1f) or leaf area [N-a](1f). The SLA decreased only in *D. glomerata*, due to an accumulation of total nonstructural carbohydrates and to an increase in leaf density. No genotypic variability was found for any variable in *B. erectus*, suggesting that genotypes responded in a similar way to elevated CO₂. In *D. glomerata*, a genotypic variability was found only for [Cst], [N-m](1f), [N(m)st](1f) and [N-a](1f). Since [N-m](1f) is related to plant growth and is a strong determinant of plant-herbivore interactions, our results suggest evolutionary consequences of elevated CO₂ through competitive interactions or herbivory.

Roumet, C., and J. Roy. 1996. Prediction of the growth response to elevated CO₂: A search for physiological criteria in closely related grass species. *New Phytologist* 134(4):615-621.

Using 11 closely related grass species, we tested the capacity of physiological criteria to predict the growth response to elevated CO₂ and to categorize the species with regard to their CO₂ response. A growth analysis was conducted under productive conditions both at ambient (350 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) CO₂. The relative growth rate stimulation was regressed against each of the growth rate components measured at ambient CO₂. Growth response to CO₂ was positively correlated with specific leaf area (SLA, the leaf surface area per unit of leaf weight), leaf area ratio (the leaf area per unit of total plant dry weight) and negatively correlated with net assimilation rate and leaf nitrogen concentration, both per unit of leaf area. We suggest that SLA has a predominant role in these relationships. Different hypotheses are proposed and discussed in order to explain why species with low

SLA are less responsive to elevated CO₂. Neither biomass allocation, relative growth rate, shoot or root specific activities per unit of mass, nor chemical composition were significantly correlated with growth response to CO₂. The four predictive criteria mentioned above coherently differentiate the five wild annual species (higher SLA, stronger growth response to CO₂) from the four wild perennials. The two perennial crop species, with the highest SLA, were more responsive than the wild species.

Rousopoulos, D., A. Liakatas, and W.J. Whittington. 1998. Cotton responses to different light-temperature regimes. *Journal of Agricultural Science* 131:277-283.

A series of experiments investigating the interactive effects of light and temperature on vegetative growth, earliness, fruiting, yield and fibre properties in three cultivars of cotton, was undertaken in growth rooms. Two constant day/night temperature regimes with a difference of 4 degrees C (30/20 and 26/16.5 degrees C) were used throughout the growing season in combination with two light intensities (75 and 52.5 W m⁻²). The results showed that significant interactions occurred for most of the characters studied. Although the development of leaf area was mainly temperature-dependent, plants at harvest had a larger leaf area when high temperature was combined with low rather than with high light intensity. Leaf area was least in the low temperature-low light regime. However, the plants grown under the high temperature-low light combination weighed the least. Variations in the number of nodes and internode length were largely dependent on temperature rather than light. Light did, however, affect the numbers of branches, sympodia and monopodia. The first two of these were highest in the high light-high temperature regime and the third in the low light- low temperature regime. All other characters, except time to certain developmental stages and fibre length, were reduced at the lower light intensity. Variation in temperature modified the light effect and vice versa, in a character-dependent manner. More specifically, square and boll dry weights, as well as seed cotton yield per plant, were highest in high light combined with low temperature, where the most and heaviest bolls were produced. But flower production was favoured by high light and high temperature, suggesting increased boll retention at low temperature, especially when combined with low light. Low temperature and high light also maximized lint percentage. Fibres were shortest in the high temperature-high light regime, where fibre strength, micronaire index and maturity ratio were at a maximum. However, the finest and the most uniform fibres were produced when high light was combined with low temperature. Cultivar differences were significant mainly in leaf area and dry matter production at flowering.

Rowlandbamford, A.J., L.H. Allen, J.T. Baker, and K.J. Boote. 1990. Carbon-dioxide effects on carbohydrate status and partitioning in rice. *Journal of Experimental Botany* 41(233):1601-1608.

The atmospheric carbon dioxide (CO₂) concentration has been rising and is predicted to reach double the present concentration sometime during the next century. The objective of this investigation was to determine the long-term effects of different CO₂ concentrations on carbohydrate status and partitioning in rice (*Oryza sativa* L. cv. IR-30). Rice plants were grown season-long in outdoor, naturally sunlit,

environmentally controlled growth chambers with CO₂ concentrations of 160, 250, 330, 500, 660, and 900 μ -mol CO₂ mol⁻¹ air. In leaf blades, the priority between the partitioning of carbon into storage carbohydrates or into export changed with development stage and CO₂ concentration. During vegetative growth, leaf sucrose and starch concentrations increased with increasing CO₂ concentration but tended to level off above 500 μ -mol mol⁻¹ CO₂. Similarly, photosynthesis also increased with CO₂ concentrations up to 500 μ -mol mol⁻¹ and then reached a plateau at higher concentrations. The ratio of starch to sucrose concentration was positively correlated with the CO₂ concentration. At maturity, increasing CO₂ concentration resulted in an increase in total non-structural carbohydrate (TNC) concentration in leaf blades, leaf sheaths and culms. Carbohydrates that were stored in vegetative plant parts before heading made a smaller contribution to grain dry weight at CO₂ concentrations below 330 μ -mol mol⁻¹ than for treatments at concentrations above ambient. Increasing CO₂ concentration had no effect on the carbohydrate concentration in the grain at maturity.

Rowlandbamford, A.J., J.T. Baker, L.H. Allen, and G. Bowes. 1991. Acclimation of rice to changing atmospheric carbon-dioxide concentration. *Plant, Cell and Environment* 14(6):577-583.

The effects were studied of season-long (75 and 88 d) exposure of rice (*Oryza sativa* L. cv. IR-30) to a range of atmospheric CO₂ concentrations in outdoor, computer-controlled, environment chambers under natural solar radiation. The CO₂ concentrations were maintained at 160, 250, 330, 500, 660 and 900- μ -mol mol⁻¹ air. Photosynthesis increased with increasing growth CO₂ concentrations up to 500- μ -mol mol⁻¹, but levelled off at higher CO₂ values. Specific leaf area also increased significantly with increasing CO₂. Although leaf dry weight and leaf area index increased, the overall response was not statistically significant. Leaf nitrogen content dropped slightly with elevated CO₂, but the response was not statistically significant. The specific activity of ribulose biphosphate carboxylase/oxygenase (rubisco) declined significantly over the CO₂ concentration range 160 to 900- μ -mol mol⁻¹. When expressed on a leaf area basis, rubisco activity decreased by 66%. This was accompanied by a 32% decrease in the amount of rubisco protein as a fraction of the total soluble leaf protein, and by 60% on a leaf area basis. For leaves in the dark, the total rubisco activity (CO₂/Mg²⁺-activated) was reduced by more than 60%. This indicates that rice accumulated an inhibitor in the dark, probably 2-carboxyarabinitol 1-phosphate (CA-1-P). However, the inhibitor did not seem to be involved in the acclimation response. The degree of carbamylation of the rubisco enzyme was unchanged by the CO₂ growth regime, except at 900- μ -mol mol⁻¹ where it was reduced by 24%. The acclimation of rice to different atmospheric CO₂ conditions involved the modulation of both the activity and amount of rubisco protein in the leaf.

RowlandBamford, A.J., J.T. Baker, L.H. Allen, and G. Bowes. 1996. Interactions of CO₂ enrichment and temperature on carbohydrate accumulation and partitioning in rice. *Environmental and Experimental Botany* 36(1):111-124.

The objective of this study was to determine the long-term effects of CO₂ concentration and temperature on carbohydrate partitioning and

status in rice (*Oryza sativa* L. cv. IR-30). The plants were grown season-long in sunlit, controlled- environment chambers with CO₂ concentrations of 330 or 660 $\mu\text{mol mol}^{-1}$, and daytime air temperatures of 28, 34 or 40 degrees C. In leaf blades, the priority between partitioning of carbon into storage or into export changed with CO₂ concentration and temperature. Leaf sucrose concentration increased with CO₂ enrichment at all temperature regimes. Over the season, elevated CO₂ resulted in an increase in total non- structural carbohydrate (TNC) concentration in leaf blades, leaf sheaths and culms at all temperature treatments. Elevated CO₂ had no effect on carbohydrate concentration in the grain at maturity, however, grain TNC concentration was significantly lowered by increasing temperature. Under the highest temperature regime, the plants in the 330 $\mu\text{mol mol}^{-1}$ CO₂ treatment died during stem extension while the CO₂ enriched plants survived but produced sterile panicles. The results suggest that CO₂-enriched plants could survive and maintain carbohydrate production rates at higher temperatures than the non-enriched plants; however, the optimum temperature for TNC accumulation was 28 degrees C at both CO₂ concentrations.

Rozema, J. 1993. Plant-responses to atmospheric carbon-dioxide enrichment - interactions with some soil and atmospheric conditions. *Vegetatio* 104:173-190.

In general, C3 plant species are more responsive to atmospheric carbon dioxide (CO₂) enrichment than C4-plants. Increased relative growth rate at elevated CO₂ primarily relates to increased Net Assimilation Rate (NAR), and enhancement of net photosynthesis and reduced photorespiration. Transpiration and stomatal conductance decrease with elevated CO₂, water use efficiency and shoot water potential increase, particularly in plants grown at high soil salinity. Leaf area per plant and leaf area per leaf may increase in an early growth stage with increased CO₂, after a period of time Leaf Area Ratio (LAR) and Specific Leaf Area (SLA) generally decrease. Starch may accumulate with time in leaves grown at elevated CO₂. Plants grown under salt stress with increased (dark) respiration as a sink for photosynthates, may not show such acclimation to increased atmospheric CO₂ levels. Plant growth may be stimulated by atmospheric carbon dioxide enrichment and reduced by enhanced UV-B radiation but the limited data available on the effect of combined elevated CO₂ and ultraviolet B (280-320 nm) (UV-B) radiation allow no general conclusion. CO₂-induced increase of growth rate can be markedly modified at elevated UV-B radiation. Plant responses to elevated atmospheric CO₂ and other environmental factors such as soil salinity and UV-B tend to be species-specific, because plant species differ in sensitivity to salinity and UV-B radiation, as well as to other environmental stress factors (drought, nutrient deficiency). Therefore, the effects of joint elevated atmospheric CO₂ and increased soil salinity or elevated CO₂ and enhanced UV-B to plants are physiologically complex.

Rozema, J., F. Dorel, R. Janissen, G. Lenssen, R. Broekman, W. Arp, and B.G. Drake. 1991. Effect of elevated atmospheric CO₂ on growth, photosynthesis and water relations of salt-marsh grass species. *Aquatic Botany* 39(1-2):45-55.

The C3 grass species *Scirpus maritimus* L. and *Puccinellia maritima* (Huds.) Parl., and the C4 grass species *Spartina anglica* C.E. Hubbard and *Spartina patens* (Ait.) Muhl. were grown at ambient (340 p.p.m. CO₂) and elevated (580 p.p.m. CO₂) atmospheric CO₂ concentration, at low (10 mM NaCl) and high salinity (250 mM NaCl) under aerated and anaerobic conditions in the culture solution. The relative growth rate of both the C3 grass species was enhanced with atmospheric CO₂ enrichment, no such increase was found in the C4 grass species. High salinity reduced growth of the C3 species tested, but this relative growth reduction was not prevented by elevated CO₂ concentration. The growth increase at elevated CO₂ of *Scirpus maritimus* and *Puccinellia maritima* is greater under aerated than under anaerobic solution conditions. Water-use efficiency of all species was increased by elevated CO₂. In the case of *Scirpus* (C3), this increase was caused by increased net photosynthesis, for *Spartina patens* (C4) photosynthesis was not increased, but transpiration was reduced. The water potential of the shoot was less negative under conditions of CO₂ enrichment, in particular at increased salinity (250 mM NaCl).

Rozema, J., G.M. Lenssen, J.W.M. vandeStaij, M. Tosserams, A.J. Visser, and R.A. Broekman. 1997. Effects of UV-B radiation on terrestrial plants and ecosystems: Interaction with CO₂ enrichment. *Plant Ecology* 128(1-2):182-191.

UV-B radiation is just one of the environmental factors, that affect plant growth. It is now widely accepted that realistic assessment of plant responses to enhanced UV-B should be performed at sufficiently high Photosynthetically Active Radiation (PAR), preferably under field conditions. This will often imply, that responses of plants to enhanced UV-B in the field will be assessed under simultaneous water shortage, nutrient deficiency and variation of temperature. Since atmospheric CO₂ enrichment, global warming and increasing UV-B radiation represent components of global climatic change, interactions of UV-B with CO₂ enrichment and temperature are particularly relevant. Only few relevant UV-B x CO₂ interaction studies have been published. Most of these studies refer to greenhouse experiments. We report a significant CO₂ x UV-B interaction for the total plant dry weight and root dry weight of the C-3-grass *Elymus athericus*. At elevated CO₂ (720 $\mu\text{mol mol}^{-1}$), plant growth was much less reduced by enhanced UV-B than at ambient atmospheric CO₂ although there were significant (positive) CO₂ effects and (negative) UV-B effects on plant growth. Most other CO₂ x UV-B studies do not report significant interactions on total plant biomass. This lack of CO₂ x UV-B interactions may result from the fact that primary metabolic targets for CO₂ and UVB are different. UV-B and CO₂ may differentially affect plant morphogenetic parameters: biomass allocation, branching, flowering, leaf thickness, emergence and senescence. Such more subtle interactions between CO₂ and UV-B need careful and long term experimentation to be detected. In the case of no significant CO₂ x UV-B interactions, combined CO₂ and UV-B effects will be additive. Plants differ in their response to CO₂ and UV-B, they respond in general positively to elevated CO₂ and negatively to enhanced UV-B. Moreover, plant species differ in their responsiveness to CO₂ and UV-B. Therefore, even in case of additive CO₂ and UV-B effects, plant competitive relationships may change markedly under current climatic change with simultaneous enhanced atmospheric CO₂ and solar UV-B radiation.

Rudorff, B.F.T., C.L. Mulchi, C.S.T. Daughtry, and E.H. Lee. 1996.

Growth, radiation use efficiency, and canopy reflectance of wheat and corn grown under elevated ozone and carbon dioxide atmospheres. *Remote Sensing of Environment* 55(2):163-173.

Estimates of increases in future agricultural production in response to increases in carbon dioxide (CO₂) concentrations in the atmosphere are often based on the beneficial physiological effect of CO₂ enrichment on plant growth, especially in C-3 plants. However, these estimates fail to consider the negative impact of ozone (O-3) air pollution on crop production. Increases in tropospheric concentrations of both gases, CO₂ and O-3, have been observed over the past century, and both are predicted to continue to increase at even higher rates in the near future to levels when they may have a significant impact on agricultural production. Field studies with wheat (*Triticum aestivum* L.) in 1991 and 1992, and corn (*Zea mays* L.) in 1991 were conducted using open-top chambers to mimic atmospheric concentrations of CO₂ (similar to 500 μ mol L⁻¹ CO₂) and O-3 (similar to 40 nL L⁻¹ O-3 above ambient air [O-3] during 7h day⁻¹ 5 days week⁻¹) that are predicted to occur at the Earth surface during the first half of the 21st century. Wheat and corn (C-3 vs. C-4) produced clearly different responses to CO₂ enrichment, but similar responses to O-3 exposure. In wheat, O-3 exposure led to reduced grain yield, biomass, and radiation use efficiency (RUE, phytomass production per unit of energy received); in both years; but reduction in accumulated absorbed photosynthetically active radiation (AAPAR) was observed only in 1991. Conversely, CO₂ enrichment produced greater grain yield, dry biomass, and RUE. With CO₂ enrichment, the O-3-induced stress to wheat plants was apparently ameliorated since responses were equivalent to the control group (low O-3 and ambient CO₂) for all variables. In contrast, corn demonstrated no benefit to CO₂ enrichment for measured variables, and corn grain yield was the only parameter negatively influenced by O-3 exposure that is attributed to O-3-induced damage during the flowering process. Additionally, no treatment differences were observed for leaf area index (LAI) as determined nondestructively using the LICOR LAI-2000 Plant Canopy Analyzer. Also, treatment differences for normalized difference vegetation index (ND) were only observed for wheat plants from the high-O-3 and ambient-CO₂ treatment, at some growing stages. Otherwise, ND were not helpful for identifying damage due to O-3 fumigation or benefits due to CO₂ enrichment. Significant interactive effects of CO₂ vs. O-3 were observed only for wheat grain yield in 1991 ($p < 0.10$), indicated that the detrimental effect of O-3 air pollution was more than overcome under the CO₂-enriched environment.

Rudorff, B.F.T., C.L. Mulchi, P. Fenny, E.H. Lee, and R. Rowland. 1996. Wheat grain quality under enhanced tropospheric CO₂ and O-3 concentrations. *Journal of Environmental Quality* 25(6):1384-1388.

It is expected that the progressive increase of tropospheric trace gases such as CO₂ and O-3 will have a significant impact on agricultural production. The single and combined effects of CO₂ enrichment and tropospheric O-3 on grain quality characteristics in soft red winter wheat (*Triticum aestivum* L.) were examined in held studies using 3 m in diam. open-top chambers. Wheat cultivars 'Massey' (1991) and 'Saluda' (1992) were exposed to two CO₂ concentrations (350 vs. 590 μ mol CO₂ mol⁻¹; 12 h d⁻¹) in combination with two O-3 regimes (charcoal-filtered air vs. ambient air + 40 $\pm$ 20 nmol O-3 mol⁻¹, 7 h d⁻¹ Monday to Friday) from late March until maturity in June. Grain quality characteristics investigated included: test weight, milling and baking quality, flour yield, protein content, softness equivalent, alkaline water retention capacity, and cookie diameter. In general, exposure of plants to either elevated CO₂ or weekly chronic O-3 episodes caused only small changes in grain quality. Milling and baking quality score were not significantly changed in response to treatments in both years. Flour yield

was increased by elevated CO₂ but this increase was counteracted when elevated CO₂ was combined with chronic O-3 exposure. Flour protein contents were increased by enhanced O-3 exposure and reduced by elevated CO₂. Softness equivalent was increased by 2.4% by enhanced O-3 exposure but unaffected by O-3 under elevated CO₂. Although the single effect of either CO₂ enrichment or chronic O-3 exposure had some impact on grain quality characteristic, it was noted that the combined effect of these gases was minor. It is likely that the concomitant increase of CO₂ and O-3 in the troposphere will have no significant impact on wheat grain quality.

Rudorff, B.F.T., C.L. Mulchi, E.H. Lee, R. Rowland, and R. Pausch. 1996. Effects of enhanced O-3 and CO₂ enrichment on plant characteristics in wheat and corn. *Environmental Pollution* 94(1):53-60.

The effects of CO₂ enrichment and O-3 induced stress on wheat (*Triticum aestivum* L.) and corn (*Zea mays* L.) were studied in field experiments using open-top chambers to simulate the atmospheric concentrations of these two gases that are predicted to occur during the coming century. The experiments were conducted at Beltsville, MD, during 1991 (wheat and corn) and 1992 (wheat). Crops were grown under charcoal filtered (CF) air or ambient air +40 nL liter⁻¹ O-3 (7 h per day, 5 days per week) having ambient CO₂ concentration (350 μ mol liter⁻¹ CO₂) or +150 μ mol liter⁻¹ CO₂ (12 h per day). Averaged over O-3 treatments, the CO₂-enriched environment had a positive effect on wheat grain yield (26% in 1991 and 15% in 1992) and dry biomass (15% in 1991 and 9% in 1992). Averaged over CO₂ treatments, high O-3 exposure had a negative impact on wheat grain yield (-15% in 1991 and -11% in 1992) and drill biomass (-11% in 1991 and -9% in 1992). Averaged over CO₂ treatments, high O-3 exposure decreased corn grain yield by 9%. No significant interactive effects were observed for either crop. The results indicated that CO₂ enrichment had a beneficial effect in wheat (C-3 crop) but not in corn (C-4 crop). It is likely that the O-3-induced stress will be diminished under increased atmospheric CO₂ concentrations; however, maximal benefits in crop production in wheat in response to CO₂ enrichment will not be materialized under concomitant increases in tropospheric O-3 concentration. Rudorff, B.F.T., C.L. Mulchi, E. Lee, R. Rowland, and R. Pausch. 1996. Photosynthetic characteristics in wheat exposed to elevated O-3 and CO₂. *Crop Science* 36(5):1247-1251.

Tropospheric trace gases such as CO₂ and O-3 have progressively increased over the past century and are predicted to increase to levels at which they may have a significant impact on agricultural production. The effects of CO₂ enrichment and O-3 air pollution on leaf photosynthesis (P_n) and stomatal conductance (g_s) were investigated. Two soft red winter wheat (*Triticum aestivum* L.) cultivars, Massey in 1991 and Saluda in 1992, were studied in field experiments at Beltsville, MD, by means of open-top chambers to mimic atmospheric environments predicted for the first half of the 21st century. Plants were exposed to two levels of O-3 (charcoal filtered air and ambient air + an average of 40 nmol O-3 mol⁻¹) from Monday-Friday of every week. Ozone treatments were superimposed on two CO₂ treatments (350 μ mol CO₂ mol⁻¹ and 500 μ mol CO₂ mol⁻¹). Averaged over O-3

treatments, P-n was stimulated during the early and late growing season under enriched CO₂. Averaged over CO₂ treatments, high O-3 exposure had a negative impact on P-n early in the season of 1992 and a major impact late in the season of 1991 and 1992 due to premature senescence. Decreases in g(s) occurred under the enriched CO₂ environment and to a lesser extent with high O-3. Interactive effects on P-n, and g(s) were mostly absent. It is likely that if CO₂ and O-3 concentrations continue to increase, the beneficial effect of CO₂ enrichment on P-n may be partially negated by O-3-induced stress. Conversely, damaging effects of O-3 on P-n may be compensated by elevated atmospheric CO₂.

Rufty, T.W., R.B. Thomas, J.D. Cure, and W.W. Cure. 1994. Growth-response of cotton to CO₂ enrichment in differing light environments. *Physiologia Plantarum* 91(3):503-509.

Experiments were conducted to examine the growth responses of cotton (*Gossypium hirsutum* L. cv. Coker 315) to CO₂ enrichment under different light regimes. Plants were exposed to 350 or 700 $\mu\text{mol l}^{-1}$ CO₂ and six light treatments differing in photosynthetic period length (8 or 16 h) and in photosynthetic photon flux density (PPFD) for 32 days of vegetative growth. Higher PPFD (1100 $\mu\text{mol m}^{-2} \text{s}^{-1}$) was provided by a combination of high intensity discharge and incandescent lamps (HID), and lower PPFD (550 $\mu\text{mol m}^{-2} \text{s}^{-1}$) was provided by fluorescent and incandescent lamps (F) or HID and incandescent lamps with shade cloth (HIDs). Growth was generally much slower with the 8-h photosynthetic periods, but the growth stimulation by CO₂ enrichment was larger than with 16-h photosynthetic periods. After 28 to 32 days of treatment, the growth enhancement with CO₂ enrichment was 152 and 78% for 8- and 16-h photosynthetic periods, respectively, under HID; 100 and 77% in F, and 77 and 56% in HIDs. The higher PPFD of HID positively influenced the CO₂ effect only at the slower growth rate in the 8-h light period. The stimulation of leaf area expansion by CO₂ enrichment was also greater with the 8-h photosynthetic period for all light sources. These results, and others on net assimilation rate, shoot to root dry weight ratios and specific leaf weights, suggest that the growth response to CO₂ enrichment with the longer photosynthetic period was depressed by limiting factors, perhaps nutritional, in the growth environment. The results also show that extensive variability in CO₂ response can occur under light intensities which are often used in growth chamber experiments.

Ruget, F., O. Bethenod, and L. Combe. 1996. Repercussions of increased atmospheric CO₂ on maize morphogenesis and growth for various temperature and radiation levels. *Maydica* 41(3):181-191.

The effect of atmospheric CO₂ enhancement on maize production was studied through four crops in two glasshouse compartments, with and without CO₂ enrichment. Development (number of organs, duration of phenological phases) was measured during cultivation and growth (dry matter production) was measured at flowering and at final harvest. The main results were as follows: The number of initiated organs (florets and leaves) was not affected by the CO₂ enrichment. According to the runs, aerial and whole plant production were significantly or not increased in the enriched compartment. The production increase was significantly different between treatments under poor radiation or high plant demand conditions. The balance between supply and demand enabled or not the

effect of CO₂ enhancement to be expressed. Among the four crops, the light conversion efficiency was significantly modified by CO₂ enrichment only in one run. The dry matter increase was not equally partitioned between the organs. It was higher in stem, husks and cob than in leaves and grains. These organs have a morphogenetically limited size (through the number of grains). This controlled the expression of the effect of CO₂ enhancement in these runs and explained why the conversion efficiency only increased in one run, which was not morphogenetically limited. These crops proved the interactions between CO₂ concentration and the other main climatic factors (temperature and radiation) and the need to know the morphogenesis in order to be able to estimate the effects of CO₂ enrichment correctly.

Runion, G.B., E.A. Curl, H.H. Rogers, P.A. Backman, R. Rodriguezkabana, and B.E. Helms. 1994. Effects of free-air CO₂ enrichment on microbial-populations in the rhizosphere and phyllosphere of cotton. *Agricultural and Forest Meteorology* 70(1-4):117-130.

Cotton (*Gossypium hirsutum* L.) plants were exposed to free-air CO₂ enriched (FACE = 550 $\mu\text{mol mol}^{-1}$) or ambient (CONTROL = 370 $\mu\text{mol mol}^{-1}$) levels of atmospheric CO₂ and to wet (100% of evapotranspiration replaced) or dry (67% of ET replaced) soil water content treatments. Foliar, soil and root samples were collected in June and August 1991 to determine the effects of elevated CO₂ on selected groups of phyllosphere and rhizosphere microorganisms. Foliage and rhizosphere soil were analyzed for bacteria and/or fungi using dilution plating. Mycorrhizal colonization of cotton roots was assessed. Root-zone soil was analyzed for populations of nematodes, microarthropods and Rhizoctonia using various extraction methods. A dehydrogenase assay for total microbial respiration and a bioassay for cotton root infecting organisms were also conducted using root-zone soil. Populations of fungi on cotton leaves varied, by genera, in response to CO₂ enrichment, but none was affected by soil water content treatments; populations of foliar bacteria were not affected by either CO₂ or soil water content treatments. In August, higher total numbers of rhizosphere fungi were found under the wet compared with the dry soil water treatment, but differences related to CO₂ were not detected. There was a trend for infestation by *Rhizoctonia solani* to be higher under FACE in the August sample, but the soil bioassay demonstrated no increase in damping-off potential. There was a significant interaction between CO₂ concentration and soil water content for populations of saprophagous nematodes; populations were different between the CO₂ levels in the dry soil treatment only, with higher numbers under FACE. Microarthropod numbers were low; however, there was a trend for Collembola populations to be higher under FACE in the August sample and more fungi were isolated from Collembola in June. Total microbial activity was higher under FACE at both sample dates. Effects of elevated atmospheric CO₂ on plant-microbe interactions could have profound influence on the productivity of agro-ecosystems, and deserve further research.

Runion, G.B., J.A. Entry, S.A. Prior, R.J. Mitchell, and H.H. Rogers. 1999. Tissue chemistry and carbon allocation in seedlings of *Pinus palustris* subjected to elevated atmospheric CO₂ and water stress. *Tree Physiology* 19(4-5):329-335.

Longleaf pine (*Pinus palustris* Mill.) seedlings were grown in 45-l pots and exposed to ambient or elevated (365 or 730 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) CO_2 concentration in open-top chambers for 20 months. Two water-stress treatments (target values of -0.5 or -1.5 MPa xylem pressure potential) were imposed 19 weeks after initiation of the study. At harvest, tissues (needles, stems, taproots, coarse roots, and fine roots) were analyzed for carbon (C), nitrogen (N), nonpolar extractives (fats, waxes, and oils), nonstructural carbohydrates (sugars and starch), structural components (cellulose and lignin), and tannins. The greatest dry weights and lowest N concentrations occurred in tissues of plants grown at elevated CO_2 or with adequate water. Although allocation of C fractions among tissues was generally unaffected by treatments, concentrations of the analyzed compounds were influenced by treatments in needles and taproots, but not in stems and lateral roots. Needles and taproots of plants exposed to elevated CO_2 had increased concentrations of nonstructural carbohydrates. Among plant tissues, elevated CO_2 caused reductions in structural C concentrations and foliar concentrations of fats, waxes and oils.

Runion, G.B., R.J. Mitchell, T.H. Green, S.A. Prior, H.H. Rogers, and D.H. Gjerstad. 1999. Longleaf pine photosynthetic response to soil resource availability and elevated atmospheric carbon dioxide. *Journal of Environmental Quality* 28(3):880-887.

Gas exchange responses during a drought cycle were studied in longleaf pine (*Pinus palustris* Mill.) seedlings after prolonged exposure to varying levels of atmospheric CO_2 (approximate to 365 or approximate to 730 $\mu\text{mol CO}_2 \text{ mol}^{-1}$), soil N (40 or 100 $\text{kg N ha}^{-1} \text{ yr}^{-1}$), and water ("adequate" and "stressed"). Elevated atmospheric CO_2 concentration increased photosynthesis, tended to decrease stomatal conductance, and increased water-use efficiency (WUE). Although soil resource availability influenced gas exchange measurements, it generally did not affect the magnitude or direction of the response to CO_2 concentration. However, significant interactions among treatment variables were observed for plant xylem pressure potential. In seedlings grown with high N, a positive growth response to elevated atmospheric CO_2 increased whole-plant water use resulting in more severe plant water stress, despite increased leaf-level WUE; however, under low N conditions the lack of a growth response to elevated CO_2 reduced whole-plant water use, decreased water stress severity, and increased WUE. Photosynthetic response to CO_2 was greatest in the high N treatment at the beginning of the drought cycle, but diminished as water stress increased; however, plants grown with low N showed greater photosynthetic responses to CO_2 later in the drought cycle. Therefore, plant gas exchange rates interact with growth response in determining the severity of water stress under drought and, thus, the ability of elevated atmospheric CO_2 to ameliorate the effects of drought and allow plants to maintain increased rates of photosynthesis may be influenced by the availability of other resources, such as N and water.

Running, S.W., D.D. Baldocchi, D.P. Turner, S.T. Gower, P.S. Bakwin, and K.A. Hibbard. 1999. A global terrestrial monitoring network integrating tower fluxes, flask sampling, ecosystem modeling and EOS satellite data. *Remote Sensing of Environment* 70(1):108-127.

Accurate monitoring of global scale changes in the terrestrial biosphere has become acutely important as the scope of human impacts on biological systems and atmospheric chemistry grows. For example, the Kyoto Protocol of 1997 signals some of the dramatic socioeconomic and political decisions that may lie ahead concerning CO_2 emissions and global carbon cycle impacts. These decisions will rely heavily on accurate measures of global biospheric changes (Schimel 1998; IGBP TCWG, 1998). An array of national and international programs have inaugurated global satellite observations, critical field measurements of carbon and water fluxes, and global model development for the purposes of beginning to monitor the biosphere. The detection by these programs of interannual variability of ecosystem fluxes and of longer term trends will permit early indication of fundamental biospheric changes which might otherwise go undetected until major biome conversion begins. This article describes a blueprint for more comprehensive coordination of the various flux measurement and modeling activities into a global terrestrial monitoring network that will have direct relevance to the political decision making of global change. Rustad, L.E., and I.J. Fernandez. 1998. Experimental soil warming effects on CO_2 and CH_4 flux from a low elevation spruce-fir forest soil in Maine, USA. *Global Change Biology* 4(6):597-605.

The effect of soil warming on CO_2 and CH_4 flux from a spruce-fir forest soil was evaluated at the Howland Integrated Forest Study site in Maine, USA from 1993 to 1995. Elevated soil temperatures (similar to 5 degrees C) were maintained during the snow-free season (May-November) in replicated 15 x 15-m plots using electric cables buried 1-2 cm below the soil surface; replicated unheated plots served as the control. CO_2 evolution from the soil surface and soil air CO_2 concentrations both showed clear seasonal trends and significant ($P < 0.0001$) positive exponential relationships with soil temperature. Soil warming caused a 25-40% increase in CO_2 flux from the heated plots compared to the controls. No significant differences were observed between heated and control plot soil air CO_2 concentrations which we attribute to rapid equilibration with the atmosphere in the O horizon and minimal treatment effects in the B horizon. Methane fluxes were highly variable and showed no consistent trends with treatment.

Rusterholz, H.P., and A. Erhardt. 1998. Effects of elevated CO_2 on flowering phenology and nectar production of nectar plants important for butterflies of calcareous grasslands. *Oecologia* 113(3):341-349.

Effects of elevated CO_2 on flowering phenology and nectar production were investigated in *Trifolium pratense*, *Lotus corniculatus*, *Scabiosa columbaria*, *Centaurea jacea* and *Betonica officinalis*, which are all important nectar plants for butterflies. In glasshouse experiments, juvenile plants were exposed to ambient (350 $\mu\text{mol l}^{-1}$) and elevated (660 $\mu\text{mol l}^{-1}$) CO_2 concentrations for 60-80 days. Elevated CO_2 significantly enhanced the development of flower buds in *C. jacea*. *B. officinalis* flowered earlier and *L. corniculatus* produced more flowers under elevated CO_2 . In contrast, the number of flowers decreased in *T. pratense*. The amount of nectar per flower was not affected by elevated CO_2 in the tested legumes (*T. pratense* and *L. corniculatus*), but was significantly reduced (!) in the other forbs. Elevated CO_2 did not

significantly affect nectar sugar concentration and composition. However, *S. columbaria* and *C. jacea* produced significantly less total sugar under elevated CO₂. The nectar amino acid concentration remained unaffected in all investigated plant species, whereas the total of amino acids produced per flower was reduced in all non-legumes. In addition, the amino acid composition changed significantly in all investigated species except for *C. jacea*. The observed effects are unexpected and are a potential threat to flower visitors such as most butterflies which have no alternative food resources to nectar. Changes in nectar production due to elevated CO₂ could also have generally detrimental effects on the interactions of flowers and their pollinators.

Ryan, M.G. 1991. Effects of climate change on plant respiration. *Ecological Applications* 1(2):157-167.

Plant respiration is a large, environmentally sensitive component of the ecosystem carbon balance, and net ecosystem carbon flux will change as the balance between photosynthesis and respiration changes. Partitioning respiration into the functional components of construction, maintenance, and ion uptake will aid the estimation of plant respiration for ecosystems. Maintenance respiration is the component most sensitive to changes in temperature, CO₂, protein concentration and turnover, water stress, and atmospheric pollutants. For a wide variety of plant tissues, maintenance respiration, corrected for temperature, appears to be linearly related to Kjeldahl nitrogen content of live tissue. Total and maintenance respiration may decline under CO₂ enrichment, but the mechanism, independence from changes in protein content, and acclimation are unknown. Response of respiration to temperature can be modelled as a Q₁₀ relationship, if corrections for bias arising from daily and annual temperature amplitude are applied. Occurrence and control of the cyanide-resistant respiratory pathway and acclimation of respiration rates to different climates are poorly understood, but may substantially affect the reliability of model estimates of plant respiration.

Rygielwicz, P.T., and C.P. Andersen. 1994. Mycorrhizae alter quality and quantity of carbon allocated below ground. *Nature* 369(6475):58-60.

PLANTS and soils are a critically important element in the global carbon-energy equation. It is estimated that in forest ecosystems over two-thirds of the carbon is contained in soils and peat deposits(1). Despite the importance of forest soils in the global carbon cycle, fluxes of carbon associated with fundamental processes and soil functional groups are inadequately quantified, limiting our understanding of carbon movement and sequestration in soils. We report here the direct measurement of carbon id and through all major pools of a mycorrhizal (fungus-root) coniferous seedling (a complete carbon budget). The mycorrhizal symbiont reduces overall retention of carbon in the plant-fungus symbiosis by increasing carbon in roots and below-ground respiration and reducing its retention and release above ground. Below ground, mycorrhizal plants shifted allocation of carbon to pools that are rapidly turned over, primarily to fine roots and fungal hyphae, and host root and fungal respiration. Mycorrhizae alter the size of below-ground carbon pools, the quality and, therefore, the retention time of carbon

below ground. Our data indicate that if elevated atmospheric CO₂ and altered climate stressors alter mycorrhizal colonization in forests, the role of forests in sequestering carbon could be altered.

Rygielwicz, P.T., M.G. Johnson, L.M. Ganio, D.T. Tingey, and M.J. Storm. 1997. Lifetime and temporal occurrence of ectomycorrhizae on ponderosa pine (*Pinus ponderosa* Laws) seedlings grown under varied atmospheric CO₂ and nitrogen levels. *Plant and Soil* 189(2):275-287.

Climate change (elevated atmospheric CO₂, and altered air temperatures, precipitation amounts and seasonal patterns) may affect ecosystem processes by altering carbon allocation in plants, and carbon flux from plants to soil. Mycorrhizal fungi, as carbon sinks, are among the first soil biota to receive carbon from plants, and thereby influence carbon release from plants to soil. One step in this carbon release is via fine root and mycorrhizal turnover. It is necessary to know the lifetime and temporal occurrence of roots and mycorrhizae to determine the capacity of the soil ecosystem to sequester carbon assimilated aboveground. In this study, ponderosa pine (*Pinus ponderosa* Laws) seedlings were grown under three levels of atmospheric CO₂ (ambient, 525 and 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) and three levels of annual nitrogen additions (0, 100 and 200 kg N ha⁻¹) in open-top chambers. At a two-month frequency during 18 months, we observed ectomycorrhizal root tips observed using minirhizotron tubes and camera. The numbers of new mycorrhizal root tips, the numbers of tips that disappeared between two consecutive recording events, and the standing crop of tips at each event were determined. There were more mycorrhizal tips of all three types seen during the summer compared with other times of the year. When only the standing crop of mycorrhizal tips was considered, effects of the CO₂ and N addition treatments on carbon allocation to mycorrhizal tips was weakly evident. However, when the three types of tips were considered collectively, tips numbers flux of carbon through mycorrhizae was greatest in the: (1) high CO₂ treatment compared with the other CO₂ treatments, and (2) intermediate N addition treatment compared with the other N addition treatments. A survival analysis on the entire 18 month cohort of tips was done to calculate the median lifetime of the mycorrhizal root tips. Average median lifetime of the mycorrhizal tips was 139 days and was not affected by nitrogen and CO₂ treatments.

Ryle, G.J.A., and C.E. Powell. 1992. The influence of elevated CO₂ and temperature on biomass production of continuously defoliated white clover. *Plant, Cell and Environment* 15(5):593-599.

Clonal plants of white clover (*Trifolium repens* L.), grown singly in pots of Perlite and solely dependent for nitrogen on root nodule N₂ fixation, were maintained in controlled environments which provided four environments: 18/13-degrees-C day/night temperature at 340 and 680- $\mu\text{mol mol}^{-1}$ CO₂ and 20.5/15.5-degrees-C day/night temperature at 340 and 680- $\mu\text{mol mol}^{-1}$ CO₂. The daylength was 12h and the photon flux density 500 $\pm$ 25- $\mu\text{mol m}^{-2} \text{ s}^{-1}$ (PPFD). All plants were defoliated for about 80d, nominally every alternate day, to leave the youngest expanded leaf intact on 50% of stolons, plus expanding leaves (simulated grazing). Elevated CO₂ increased the yield of biomass removed at defoliation by a constant 45% during the second 40d of the experiment and by a varying amount in the first half of the experiment. Elevated temperature had little effect on biomass yield. Nitrogen, as a

proportion of the harvested biomass, was only fractionally affected by elevated CO₂ or temperature. In contrast, N₂ fixation increased in concert with the promoting effect of elevated CO₂ on biomass production. The increased yield of biomass harvested in 680 $\mu\text{mol mol}^{-1}$ CO₂ was primarily due to the early development and continued maintenance of more stolons. However, the stolons of plants grown in elevated CO₂ also developed leaves which were heavier and slightly larger in area than their counterparts in ambient CO₂. The conclusion is that, when white clover plants are maintained at constant mass by simulated grazing, they continue to respond to elevated CO₂ in terms of a sustained increase in biomass production.

Ryle, G.J.A., C.E. Powell, and V. Tewson. 1992. Effect of elevated co₂ on the photosynthesis, respiration and growth of perennial ryegrass. *Journal of Experimental Botany* 43(251):811-818.

Single, seed-grown plants of ryegrass (*Lolium perenne* L. cv. Melle) were grown for 49 d from the early seedling stage in growth cabinets at a day/night temperature of 20/15-degrees-C, with a 12 h photoperiod, and a CO₂ concentration of either 340 or 680- $\mu\text{mol l}^{-1}$ CO₂. Following complete acclimation to the environmental regimes, leaf and whole plant CO₂ effluxes and influxes were measured using infra-red gas analysis techniques. Elevated CO₂ increased rates of photosynthesis of young, fully expanded leaves by 35-46% and of whole plants by more than 50%. For both leaves and whole plants acclimation to 680- $\mu\text{mol l}^{-1}$ CO₂ reduced rates of photosynthesis in both CO₂ regimes, compared with plants acclimated to 340- $\mu\text{mol l}^{-1}$. There was no significant effect of CO₂ regime on respiration rates of either leaves or whole plants, although leaves developed in elevated CO₂ exhibited generally lower rates than those developed in 340- $\mu\text{mol l}^{-1}$ CO₂. Initially the seedling plants in elevated CO₂ grew faster than their counterparts in 340- $\mu\text{mol l}^{-1}$ CO₂, but this effect quickly petered out and final plant weights differed by only c. 10%. Since the total area of expanded and unexpanded laminae was unaffected by CO₂ regime, specific leaf area was persistently 13-40% lower in elevated CO₂ while, similarly, root/shoot ratio was also reduced throughout the experiment. Elevated CO₂ reduced tissue nitrogen contents of expanded leaves, but had no effect on the nitrogen contents of unexpanded leaves, sheaths or roots. The lack of a pronounced effect of elevated CO₂ on plant growth was primarily due to the fact that CO₂ concentration did not influence tiller (branch) numbers. In the absence of an effect on tiller numbers, any possible weight increment was restricted to the c. 2.5 leaves of each tiller. The reason for the lack of an effect on tillering is not known.

Sa, T.N., and D.W. Israel. 1998. Phosphorus-deficiency effects on response of symbiotic N-2 fixation and carbohydrate status in soybean to atmospheric CO₂ enrichment. *Journal of Plant Nutrition* 21(10):2207-2218.

The impact of phosphorus (P) deficiency on response of symbiotic N-2 fixation and carbohydrate accumulation in soybean (*Glycine max* [L.] Merr.) to atmospheric CO₂ enrichment was examined. Plants inoculated with *Bradyrhizobium japonicum* MN 110 were grown in growth chambers with controlled atmospheres of 400 and 800 $\mu\text{mol L}^{-1}$ CO₂ and supplied either 1.0 mM-P (P-sufficient) or 0.05 mM-P (P-deficient) nitrogen (N)-free nutrient solution. When plants were supplied with sufficient P, CO₂ enrichment significantly increased whole plant dry mass (83%), nodule mass (67%), total nitrogenase activity (58%), and N (35%) and P (47%) accumulation at 35 days after transplanting (DAT). Under sufficient P supply, CO₂ enrichment significantly increased starch concentrations in nodules compared to the normal atmospheric CO₂ treatment. Under normal CO₂ levels (400 $\mu\text{mol L}^{-1}$) nonstructural carbohydrate concentration (starch plus soluble sugar) was significantly higher in leaves of P-deficient plants than in leaves of P-sufficient plants in which nonstructural carbohydrate concentration exhibited a strong diurnal pattern. Under deficient P supply whole plant dry mass, symbiotic N-2-fixation parameters, and N and P accumulation were not enhanced by atmospheric CO₂ enrichment. Phosphorus deficiency decreased nonstructural carbohydrate accumulation in nodules at the end of a 10-day period in which functional activity was developing by 86% relative to P-sufficient controls. While P deficiency elicited significant increases in the nonstructural carbohydrate concentration in leaves, it caused significant decreases in the nonstructural carbohydrate concentration in nodules over the diurnal cycle from 30 to 31 DAT. Collectively, these results indicate that the lack of a symbiotic N-2-fixation response to atmospheric CO₂ enrichment by P-deficient plants may be related to the decreased carbohydrate status of nodules.

Saarin, T. 1998. Internal C : N balance and biomass partitioning of *Carex rostrata* grown at three levels of nitrogen supply. *Canadian Journal of Botany-Revue Canadienne De Botanique* 76(5):762-768.

The long-term effects of high nitrogen supply on the growth and partitioning of biomass in a common sedge species, *Carex rostrata* Stokes, were studied in a greenhouse experiment. Special attention was paid to free amino acids and soluble sugars, representing biochemically

available fractions of nitrogen and carbon, respectively, in the tissues of Carer. Plants were grown in peat in buckets, and nitrogen was added as ammonium nitrate (2, 5, and 10 g N m⁻² year⁻¹) five times during two growing seasons. Changes in biomass allocation patterns became evident towards the end of the second growing season. The biomass of shoots was highest in the high-N treatment, resulting in a high ratio of aboveground to belowground biomass. The high biomass of shoots was due to both the high density of current-year shoots and later senescence in the high-N treatment. No differences were observed in the belowground biomasses. Changes in allocation patterns were accompanied by changes in the soluble fractions of carbon and nitrogen. The concentration of free amino acids (FAA) was significantly higher (both shoots and roots) and the concentration of total nonstructural carbohydrates (TNC) lower (roots only) in the high-N treatment. The concentration of total nitrogen also increased with increasing supply of nitrogen. The results indicate that a high long-term supply of nitrogen may shift the internal carbon to nitrogen balance of Carer towards higher availability of nitrogen. Compared with the carbon to nitrogen ratio, the TNC:FAA ratio seems to be a better indicator of the internal carbon to nitrogen balance. A low TNC:FAA ratio may enhance the allocation of biomass to shoots and also increase the density of shoots.

Saarnio, S., J. Alm, P.J. Martikainen, and J. Silvola. 1998. Effects of raised CO₂ on potential CH₄ production and oxidation in, and CH₄ emission from, a boreal mire. *Journal of Ecology* 86(2):261-268.

1 In a glasshouse experiment we studied the effect of raised CO₂ concentration (720 p.p.m.) on CH₄ emission at natural boreal peat temperatures using intact cores of boreal peat with living vascular plants and Sphagnum mosses. After the end of the growing season half of the cores were kept unnaturally warm (17-20 degrees C). The potential for CH₄ production and oxidation was measured at the end of the emission experiment. 2 The vascular cores ('Sedge') consisted of a moss layer with sedges, and the moss cores ('Sphagnum') of Sphagnum mosses (some sedge seedlings were removed by cutting). Methane efflux was 6-12 times higher from the Sedge cores than from the Sphagnum cores. The release of CH₄ from Sedge cores increased with increasing temperature of the peat and decreased with decreasing temperature. Methane efflux from Sphagnum cores was quite stable independent of the peat temperatures. 3 In both Sedge and Sphagnum samples, CO₂ treatment doubled the potential CH₄ production but had no effect on the potential CH₄ oxidation. A raised concentration of CO₂ increased CH₄ efflux weakly and only at the highest peat temperatures (17-20 degrees C). 4 The results suggest that in cool regions, such as boreal wetlands, temperature would restrict decomposition of the extra substrates probably derived from enhanced primary production of mire vegetation under raised CO₂ concentrations, and would thus retard any consequent increase in CH₄ emission.

Saarnio, S., and J. Silvola. 1999. Effects of increased CO₂ and N on CH₄ efflux from a boreal mire: a growth chamber experiment. *Oecologia* 119(3):349-356.

Increases in the supply of atmospheric CO₂ and N are expected to alter the carbon cycle, including CH₄ emissions, in boreal peatlands. These

effects were studied in a glasshouse experiment with peat monoliths cored from an oligotrophic pine fen. The cores with living plants were kept in 720 ppm(v) and 360 ppm(v) CO₂ atmospheres for about 6 months under imitated natural temperature cycle. Fertilisation with NH₄NO₃ (3 g m⁻² for 25 weeks) was applied to 18 of the 36 monoliths. The rate of CH₄ flux was non-linearly dependent on the number of Eriophorum vaginatum shoots growing in the monoliths, probably due to the gas transport properties of the aerenchyma. The average CH₄ efflux rate, standardised by the number of shoots, was increased by a maximum of 10-20% in response to the raised CO₂ level. In the raised-NH₄NO₃ treatment, the increase in CH₄ release was lower. The effect of combined CO₂ + NH₄NO₃ on CH₄ release was negligible and even lower than in the single treatments. Both potential CH₄ production and oxidation rates at 5, 15 and 25 degrees C were higher near the surface than at the bottom of the core. As expected, the rates clearly depended on the incubation temperature, but the different treatments did not cause any consistent differences in either CH₄ production or oxidation. The determination of potential CH₄ production and oxidation in the laboratory is evidently too crude a method of differentiating substrate-induced differences in CH₄ production and oxidation in vivo. These results indicate that an increase in atmospheric CO₂ or N supply alone, at least in the short term, slightly enhances CH₄ effluxes from boreal peatlands; but together their effect may even be restrictive.

Saccardy, K., B. Pineau, O. Roche, and G. Cornic. 1998. Photochemical efficiency of Photosystem II and xanthophyll cycle components in Zea mays leaves exposed to water stress and high light. *Photosynthesis Research* 56(1):57-66.

The effects of two light treatments (photosynthetically active photon flux density of either 650 or 1950 $\mu\text{mol m}^{-2} \text{s}^{-1}$) on the photochemical efficiency of Photosystem II (PS II) (measured as variable to maximum fluorescence ratio) and on the xanthophyll cycle components was studied in wilted Zea mays leaves. For comparison, these parameters were followed under the same light conditions in well-hydrated leaves maintained either in normal or CO₂-free air. The net CO₂ assimilation of dehydrated leaves declined rapidly as their relative water content (RWC) decreased from 100 to 60% while the PS II efficiency measured after a prolonged dark period of 16 h declined only when RWC leaves was lower than 60%. Furthermore, drought caused an increase in the pool size of the xanthophyll cycle pigments and the presence of a sustained elevated level of zeaxanthin and antheraxanthin at the end of the long dark period. The leaf water deficit enhanced the sensitivity of PS II efficiency to light exposure. During illumination, strong inhibition of PS II efficiency and large violaxanthin deepoxidation was observed in wilted leaves even under moderate photon flux density compared to control leaves in the same conditions. After 2 h of darkness following the light treatment, the PS II efficiency that is dependent on the previous PPFD, decreased with leaf water deficit. Moreover, zeaxanthin epoxidation led to an accumulation of antheraxanthin in dehydrated leaves. All these drought effects on PS II efficiency and xanthophyll cycle components were also obtained in well-hydrated leaves by short-term CO₂ deprivation during illumination. We conclude that the increased susceptibility of PS II efficiency to light in wilted maize leaves is mainly explained by the decrease of CO₂ availability and the resulting low net CO₂ assimilation.

Sadowsky, M.J., and M. Schortemeyer. 1997. Soil microbial responses to increased concentrations of atmospheric CO₂. *Global Change Biology* 3(3):217-224.

Terrestrial ecosystems respond to an increased concentration of atmospheric CO₂. While elevated atmospheric CO₂ has been shown to alter plant growth and productivity, it also affects ecosystem structure and function by changing below-ground processes. Knowledge of how soil microbiota respond to elevated atmospheric CO₂ is of paramount importance for understanding global carbon and nutrient cycling and for predicting changes at the ecosystem-level. An increase in the atmospheric CO₂ concentration not only alters the weight, length, and architecture of plant roots, but also affects the biotic and abiotic environment of the root system. Since the concentration of CO₂ in soil is already 10-50 times higher than that in the atmosphere, it is unlikely that increasing atmospheric CO₂ will directly influence the rhizosphere. Rather, it is more likely that elevated atmospheric CO₂ will affect the microbe-soil-plant root system indirectly by increasing root growth and rhizodeposition rates, and decreasing soil water deficit. Consequently, the increased amounts and altered composition of rhizosphere-released materials will have the potential to alter both population and community structure, and activity of soil- and rhizosphere-associated microorganisms. This occurrence could in turn affect plant health and productivity and plant community structure. This review covers current knowledge about the response of soil microbes to elevated concentrations of atmospheric CO₂.

Saebo, A., T. Krekling, and M. Appelgren. 1995. Light quality affects photosynthesis and leaf anatomy of birch plantlets in-vitro. *Plant Cell Tissue and Organ Culture* 41(2):177-185.

Cultures in vitro of *Betula pendula* Roth were subjected to light of different spectral qualities. Photosynthetic capacity was highest when the plantlets were exposed to blue light (max recorded photosynthesis, 82 $\mu\text{mol CO}_2 \text{ dm}^{-2} \text{ h}^{-1}$) and lowest when irradiated with light high in red and/or far-red wave lengths (max recorded photosynthesis, 40 $\mu\text{mol CO}_2 \text{ dm}^{-2} \text{ h}^{-1}$). Highest chlorophyll content (2.2 mg dm^{-2} leaf area) was found in cultures irradiated with blue light, which also enhanced the leaf area. Morphometric analysis of light micrographs showed that the epidermal cell areas were largest in plantlets subjected to blue light and smallest in those subjected to red light. Morphometric analysis of electron micrographs of palisade cells, showed that the functional chloroplast area was largest in chloroplasts of leaves subjected to blue light and smallest in those exposed to red light. We suggest that light quality affects photosynthesis both through effects on the composition of the photosynthetic apparatus and on translocation of carbohydrates from chloroplasts.

Saebo, A., and L.M. Mortensen. 1995. Growth and regrowth of phleum-pratense, lolium-perenne, trifolium-repens and trifolium-pratense at normal and elevated co₂ concentration. *Agriculture Ecosystems & Environment* 55(1):29-35.

The effect of elevated CO₂ concentration (680 $\pm$ 52 $\mu\text{mol mol}^{-1}$) on growth of three cultivars of *Phleum pratense*, two of *Lolium perenne* and one of *Trifolium repens* and *Trifolium pratense* each, was studied during one growth season including three harvests. The study was performed in ten 9 m² field chamber units in a cool maritime climate under long days (15-18 h), on the southwest coast of Norway (59 degrees N, 6 degrees E). Tillering in *P. pratense* and *L. perenne* was not significantly affected in the first harvest (June/July), but was increased by 30% in the third harvest (September) in response to elevated CO₂ concentrations. The plant height was reduced by 16-24% in *P. pratense* and by 25-29% in *L. perenne* at high CO₂. The dry weight yield of the two grass species was negatively affected by elevated CO₂ in the two first harvests, however, no effect was found in the last harvest. The total harvestable dry matter was decreased by 18% in *P. pratense* and 13% in *L. perenne*. The dry matter of the stubble was increased at elevated CO₂, by 18% in *P. pratense* and 26% in *L. perenne*, leaving more of the yield in the meadow after harvest. Raising the CO₂ concentration increased the dry weight by 30% in both clover species. The results are discussed in relation to the climatic conditions during the season.

Saebo, A., and L.M. Mortensen. 1996. Growth, morphology and yield of wheat, barley and oats grown at elevated atmospheric CO₂ concentration in a cool, maritime climate. *Agriculture Ecosystems & Environment* 57(1):9-15.

The effects of elevated CO₂ concentration on the growth, yield and quality of spring wheat (*Triticum aestivum* L., cv. 'Sport'), barley (*Hordeum vulgare*, cv. 'Thule') and oats (*Avena sativa*, cv. 'Kapp') were studied. The study was performed from 20 April to 24 August in ten field chamber units each of 9 m² in a cool (12.6 degrees C) maritime climate under long days (14.6-18.1 h), on the southwest coast of Norway (59 degrees N, 6 degrees E). The total biomass increased at high CO₂ concentration, by 11% and 20% in wheat and barley, respectively. The proportion of small grains increased by 6% in wheat and 26% in barley, but the total grain yield was not affected. The weight of chaff increased by 9% and 19% in wheat and barley, respectively. Plant height was significantly reduced during the growing season at elevated CO₂, by 8-19% in barley and by 9-25% in oats until 6 July when no significant difference in height was found. After 6 July, barley plants at elevated CO₂ were significantly taller than at ambient CO₂ concentration and oats were not affected. Elongation in wheat was not affected by CO₂ concentration at any time in the growing season. No difference in developmental rate could be detected between plants at normal and elevated CO₂ concentrations. The protein content of the grain decreased by 8% in barley, but was not significantly affected in the other species.

Saebo, A., and L.M. Mortensen. 1996. The influence of elevated CO₂ concentration on growth of seven grasses and one clover species in a cool maritime climate. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 46(1):49-54.

The effect of elevated CO₂ concentration on the growth of eight common species and cultivars in Norwegian meadows-*Festuca pratensis* "Salten" and "Fure", *Festuca rubra* "Koket" and "Leik", *Festuca arundinaceae* "Vantage" *Festuca duruiscula* "Barfina", *Poa pratensis* "Lavang", *Agrostis capillaris* "Aros", *Dactylis glomerata* "Apelsvoll", and *Trifolium repens* "Grasslands Huia"-was studied during 11 weeks

(April 26-early July). The study was performed in ten 9 m(2) large field chamber units in a cool (11.3 degrees C) maritime climate under long days (15.1-18.1 h), on the south-west coast of Norway (59 degrees N, 6 degrees E). The different species responded differently to elevated CO₂ with respect to tillering, which was enhanced in *A. capillaris* (81%), *D. glomerata* (23%) and *F. pratensis* (36%), but was not significantly affected in the other species. The sward length was significantly decreased by high CO₂ concentration, by 20% in *P. pratensis*, 36% in *A. capillaris*, 29% in *D. glomerata*, 26% in *F. duriscula*, 36% in *F. pratensis* and 16% in *F. rubra*, but was not affected in *F. arundinacea*, *F. pratensis* "Salten" and *T. repens*. The dry matter was decreased at elevated CO₂ concentration in *A. capillaris* (14%), increased in *F. rubra* (10%) and not significantly affected in the other plants. The results are discussed in relation to climate and interspecific responses.

Saebo, A., and L.M. Mortensen. 1998. Influence of elevated atmospheric CO₂ concentration on common weeds in Scandinavian agriculture. *Acta Agriculturae Scandinavica Section B-Soil and Plant Science* 48(3):138-143.

This study investigated the influence of elevated CO₂ on three perennial weed species (*Achillea millefolium*, *Leontodon autumnalis* and *Rumex acetosa*) and seven annual species (*Chenopodium album*, *Matricaria matricarioides*, *Poa annua*, *Polygonum persicaria*, *Senecio vulgaris*, *Spergula arvensis* and *Stellaria media*). The study was carried out during the period 3 May to 5 August in ten field chamber units of 9 m(2) in a cool (12.6 degrees C) maritime climate under long days (15.8-18.1 h day(-1)) on the south-west coast of Norway (59 degrees N, 6 degrees E). Dry weights of the seven annual species were not significantly affected by the CO₂ concentration. Of the three perennial species, *L. autumnalis* increased in dry weight by 27% and *A. millefolium* by 19% at elevated compared with ambient CO₂ concentration. Plant height increased by 8% in *L. autumnalis* and decreased by 12 and 10% in *M. matricarioides* and *P. annua*, respectively. Leaf size increased by 32% and specific leaf area decreased by 23% in *P. persicaria* at elevated CO₂, while the other species were unaffected. The results are discussed in relation to competition between species and the influence of climate on the CO₂ responses.

Saetersdal, M., and H.J.B. Birks. 1997. A comparative ecological study of Norwegian mountain plants in relation to possible future climatic change. *Journal of Biogeography* 24(2):127-152.

Mountain plants constitute an important part of the Norwegian flora. They are also believed to be the plant group in Norway most threatened by the expected climatic warming due to an enhanced greenhouse effect in the near future. In this study the distributions of 107 mountain Norwegian vascular plants were modelled in relation to present-day climate using Gaussian legit regression. Most species are found to have a surprisingly broad amplitude to mean July and January temperatures, suggesting that a 2 degrees C increase in summer temperature and 4 degrees C increase in winter temperature (as expected with a 2 x CO₂ increase) may not have a dramatic direct effect on most of the species investigated. A comparative study between estimated July and January temperature optima and tolerances and other ecological attributes such as habitat characteristics, dispersal mechanisms, range sizes and other

climatic optima and tolerances was done using multivariate analysis. The results suggest that species most vulnerable to climatic warming, namely the species with narrow July and January temperature tolerances, are characterized by small range sizes and small population sizes, i.e. they are nationally rare species. Furthermore, these vulnerable species are found in all habitats along the major moisture gradient in alpine vegetation. A classification of the species into Rabinowitz's seven forms of rarity confirms that the species most vulnerable to climatic warming are characterized by being habitat specialists with a small geographic range size.

Sage, R.F. 1990. A model describing the regulation of ribulose-1,5-bisphosphate carboxylase, electron-transport, and triose phosphate use in response to light-intensity and CO₂ in C3 plants. *Plant Physiology* 94(4):1728-1734.

A model of the regulation of the activity of ribulose-1,5-bis-phosphate carboxylase, electron transport, and the rate of orthophosphate regeneration by starch and sucrose synthesis in response to changes in light intensity and partial pressures of CO₂ and O₂ is presented. The key assumption behind the model is that nonlimiting processes of photosynthesis are regulated to balance the capacity of limiting processes. Thus, at CO₂ partial pressures below ambient, when a limitation on photosynthesis by the capacity of rubisco is postulated, the activities of electron transport and phosphate regeneration are down-regulated in order that the rate of RuBP regeneration matches the rate of RuBP consumption by rubisco. Similarly, at subsaturating light intensity or elevated CO₂, when electron transport or Pi regeneration may limit photosynthesis, the activity of rubisco is downregulated to balance the limitation in the rate of RuBP regeneration. Comparisons with published data demonstrate a general consistency between modelled predictions and measured results.

Sage, R.F. 1994. Acclimation of photosynthesis to increasing atmospheric CO₂ - the gas-exchange perspective. *Photosynthesis Research* 39(3):351-368.

The nature of photosynthetic acclimation to elevated CO₂ is evaluated from the results of over 40 studies focusing on the effect of long-term CO₂ enrichment on the short-term response of photosynthesis to intercellular CO₂ (the A/C-i response). The effect of CO₂ enrichment on the A/C-i response was dependent on growth conditions, with plants grown in small pots (<5 L) or low nutrients usually exhibiting a reduction of A at a given C-i, while plants grown without nutrient deficiency in large pots or in the field tended to exhibit either little reduction or an enhancement of A at a given C-i following a doubling or tripling of atmospheric CO₂ during growth. Using theoretical interpretations of A/C-i curves to assess acclimation, it was found that when pot size or nutrient deficiency was not a factor, changes in the shape of A/C-i curves which are indicative of a reallocation of resources within the photosynthetic apparatus typically were not observed. Long-term CO₂ enrichment usually had little effect or increased the value of A at all C-i. However, a minority of species grown at elevated CO₂ exhibited gas exchange responses indicative of a reduced amount of

Rubisco and an enhanced capacity to metabolize photosynthetic products. This type of response was considered beneficial because it enhanced both photosynthetic capacity at high CO₂ and reduced resource investment in excessive Rubisco capacity. The ratio of intercellular to ambient CO₂ (the C_i/C_a ratio) was used to evaluate stomatal acclimation. Except under water and humidity stress, C_i/C_a exhibited no consistent change in a variety of C-3 species, indicating no stomatal acclimation. Under drought or humidity stress, C_i/C_a declined in high-CO₂ grown plants, indicating stomata will become more conservative during stress episodes in future high CO₂ environments.

Sage, R.F. 1995. Was low atmospheric CO₂ during the pleistocene a limiting factor for the origin of agriculture. *Global Change Biology* 1(2):93-106.

Agriculture originated independently in many distinct regions at approximately the same time in human history. This synchrony in agricultural origins indicates that a global factor may have controlled the timing of the transition from foraging to food-producing economies. The global factor may have been a rise in atmospheric CO₂ from below 200 to near 270 $\mu\text{mol mol}^{-1}$ which occurred between 15,000 and 12,000 years ago. Atmospheric CO₂ directly affects photosynthesis and plant productivity, with the largest proportional responses occurring below the current level of 350 $\mu\text{mol mol}^{-1}$. In the late Pleistocene, CO₂ levels near 200 $\mu\text{mol mol}^{-1}$ may have been too low to support the level of productivity required for successful establishment of agriculture. Recent studies demonstrate that atmospheric CO₂ increase from 200 to 270 $\mu\text{mol mol}^{-1}$ stimulates photosynthesis and biomass productivity of C-3 plants by 25% to 50%, and greatly increases the performance of C-3 plants relative to weedy C-4 competitors. Rising CO₂ also stimulates biological nitrogen fixation and enhances the capacity of plants to obtain limiting resources such as water and mineral nutrients. These results indicate that increases in productivity following the late Pleistocene rise in CO₂ may have been substantial enough to have affected human subsistence patterns in ways that promoted the development of agriculture. Increasing CO₂ may have simply removed a productivity barrier to successful domestication and cultivation of plants. Through effects on ecosystem productivity rising CO₂ may also have been a catalyst for agricultural origins by promoting population growth, sedentism, and novel social relationships that in turn led to domestication and cultivation of preferred plant resources.

Sage, R.F., J. Santrucek, and D.J. Grise. 1995. Temperature effects on the photosynthetic response of C-3 plants to long-term CO₂ enrichment. *Vegetatio* 121(1-2):67-77.

To assess the long-term effect of increased CO₂ and temperature on plants possessing the C-3 photosynthetic pathway, *Chenopodium album* plants were grown at one of three treatment conditions: (1) 23 degrees C mean day temperature and a mean ambient partial pressure of CO₂ equal to 350 μbar ; (2) 34 degrees C and 350 μbar CO₂; and (3) 34 degrees C and 750 μbar CO₂. No effect of the growth treatments was observed on the CO₂ response of photosynthesis, the temperature

response of photosynthesis, the content of Ribulose-1,5-bisphosphate carboxylase (Rubisco), or the activity of whole chain electron transport when measurements were made under identical conditions. This indicated a lack of photosynthetic acclimation in *C. album* to the range of temperature and CO₂ used in the growth treatments. Plants from every treatment exhibited similar interactions between temperature and CO₂ on photosynthetic activity. At low CO₂ (< 300 μbar), an increase in temperature from 25 to 35 degrees C was inhibitory for photosynthesis, while at elevated CO₂ (> 400 μbar), the same increase in temperature enhanced photosynthesis by up to 40%. In turn, the stimulation of photosynthesis by CO₂ enrichment increased as temperature increased. Rubisco capacity was the primary limitation on photosynthetic activity at low CO₂ (195 μbar). As a consequence, the temperature response of A was relatively flat, reflecting a low temperature response of Rubisco at CO₂ levels below its k(m) for CO₂. At elevated CO₂ (750 μbar), the temperature response of electron transport appeared to control the temperature dependency of photosynthesis above 18 degrees C. These results indicate that increasing CO₂ and temperature could substantially enhance the carbon gain potential in tropical and subtropical habitats, unless feedbacks at the whole plant or ecosystem level limit the long-term response of photosynthesis to an increase in CO₂ and temperature.

Sage, R.F., B. Schappi, and C. Korner. 1997. Effect of atmospheric CO₂ enrichment on Rubisco content in herbaceous species from high and low altitude. *Acta Oecologica-International Journal of Ecology* 18(3):183-192.

Atmospheric CO₂ enrichment reduces Rubisco content in many species grown in controlled environments; however, relatively few studies have examined CO₂ effects on Rubisco content of plants grown in their natural habitat. We examined the response of Rubisco content to atmospheric CO₂ enrichment (600-680 $\mu\text{mol mol}^{-1}$ in place of ppm) in 5 herbaceous species growing in a low altitude grassland (550 m) near Basel, Switzerland, and 3 herbaceous species from Swiss alpine grassland at 2 470 m. At low elevation, the dominant grass *Bromus erectus* and the subdominant dicot *Sanquisorba miller* exhibited 20% to 25% reduction of Rubisco content following high CO₂ exposure; no CO₂ effect was observed in the subdominants *Carex flacca*, *Lotus corniculatus* and *Trifolium repens*. At the Alpine site, the subdominant grass *Pea alpina* maintained 27% less Rubisco content when grown at high CO₂ while the co-dominant forb *Leontodon helveticus* had 19% less Rubisco in high CO₂: Rubisco content was unaffected in the tundra dominant *Carex curvula*. Because the degree of Rubisco modulation was similar between high and low elevation sites, it does not appear that differences in local partial pressure of CO₂ (altitude) or differences in stress in general induce different patterns of modulation of photosynthetic capacity in response to high CO₂. In addition, the degree of Rubisco reduction (<30%) was less than might be indicated by the low biomass response to CO₂ enrichment previously observed at these sites. Thus, plants in Swiss lowland and alpine grassland appear to maintain greater Rubisco concentration and photosynthetic capacity than whole plants can effectively exploit in terms of harvestable biomass.

Sage, R.F., T.D. Sharkey, and J.R. Seemann. 1990. Regulation of ribulose-1,5-bisphosphate carboxylase activity in response to light-intensity and CO₂ in the C₃ annuals *Chenopodium album* L and *Phaseolus vulgaris* L. *Plant Physiology* 94(4):1735-1742.

The light and CO₂ response of (a) photosynthesis, (b) the activation state and total catalytic efficiency (K(cata)) of ribulose-1,5-bisphosphate carboxylase (rubisco), and (c) the pool sizes of ribulose 1,5-bisphosphate, (RuBP), ATP, and ADP were studied in the C₃ annuals *Chenopodium album* and *Phaseolus vulgaris* at 25-degrees-C. The initial slope of the photosynthetic CO₂ response curve was dependent on light intensity at reduced light levels only (less than 450 micromoles per square meter per second in *C. album* and below 200 micromoles per square meter per second in *P. vulgaris*). Modeled simulations indicated that the initial slope of the CO₂ response of photosynthesis exhibited light dependency when the rate of RuBP regeneration limited photosynthesis, but not when rubisco capacity limited photosynthesis. Measured observations closely matched modeled simulations. The activation state of rubisco was measured at three light intensities in *C. album* (1750, 550, and 150 micromoles per square meter per second) and at intercellular CO₂ partial pressures (C(i)) between the CO₂ compensation point and 500 microbars. Above a C(i) of 120 microbars, the activation state of rubisco was light dependent. At light intensities of 550 and 1750 micromoles per square meter per second, it was also dependent on C(i), decreasing as the C(i) was elevated above 120 microbars at 550 micromoles per square meter per second and above 300 microbars at 1750 micromoles per square meter per second. The pool size of RuBP was independent of C(i) only under conditions when the activation state of rubisco was dependent on C(i). Otherwise, RuBP pool sizes increases as C(i) was reduced. ATP pools in *C. album* tended to increase as C(i) was reduced. In *P. vulgaris*, decreasing C(i) at a subsaturating light intensity of 190 micromoles per square meter per second increased the activation state of rubisco but had little effect on the K(cat). These results support modelled simulations of the rubisco response to light and CO₂, where rubisco is assumed to be down-regulated when photosynthesis is limited by the rate of RuBP regeneration.

Sagi, M., A. Dovrat, T. Kipnis, and H. Lips. 1998. Nitrate reductase, phosphoenolpyruvate carboxylase, and glutamine synthetase in annual ryegrass as affected by salinity and nitrogen. *Journal of Plant Nutrition* 21(4):707-723.

The concentration of organic acids, organic nitrogen (N), nitrate (NO₃), and total cations increased in annual ryegrass (*Lolium multiflorum* Lam.) with salinity and N concentration in the growth medium. Increasing salinity and N in the growth medium induced changes in the level of key enzymes of N assimilation and organic acids: nitrate reductase (NR, EC 1.6.6.1), phosphoenolpyruvate carboxylase (PEPc, EC 4.1.1.31), and glutamine synthetase (GS, EC 6.3.1.2). Plants grown in pots filled with sand were irrigated with nutrient solutions with an electroconductivity of 2 or 11.2 dS m⁻¹ and N applied as ammonium nitrate (NH₄NO₃), sodium nitrate (NaNO₃), or ammonium applied as ammonium nitrate (NH₄NO₃), sodium nitrate (NaNO₃), or ammonium (NH₄) as ammonium sulfate [(NH₄)₂SO₄] at concentrations of 0.5, 4.5 or 9.0 mM. Nitrate reductase, PEPc, and GS increased with salinity and N level. Shoot NR was highest in the presence of NH₄NO₃ irrespective of salinity level, while root NR activity responded best to NO₃. Enhancement of PEPc activity in both shoots and roots was highest with NH₄NO₃ and lowest with NH₄. Nitrogen source had no significant effect on GS activity in shoots or roots of ryegrass. Shoot NR

activity increased with NO₃ concentration in the tissue, as calculated from repression coefficients. The PEPc activity correlated positively with total cations and NO₃ concentrations in the plants, irrespective of the salinity level, suggesting that the increase in total cations and NO₃ induced by salinity may have triggered the changes in enzyme activities. The concentration of organic acids in both shoots and roots correlated positively with PEPc activity irrespective of the salinity level. The PEPc activity was higher in roots than in shoots, while organic acid concentration was higher in shoots. These results suggest that a significant part of the organic acids produced in the roots were used as carbon skeleton for transamination reactions. The increased activity of NR, PEPc, and GS in roots may constitute part of an adaptation strategy of the plant to increasing salinity in the medium. These enzymes have an important role in the metabolism of amino acids and the synthesis of organic N in annual ryegrass irrigated with saline water, and boosting them with suitable N fertilizers could increase the nutritional value and protein content of the crop.

Saito, M., T. Homma, Y. Nemoto, and H. Matsuoka. 1993. Intracellular potential change of *Tradescantia virginiana* L leaf in response to CO₂ stress. *Bioelectrochemistry and Bioenergetics* 32(2):133-143.

The response of a *Tradescantia virginiana* L. leaf to CO₂ stress was measured using a double-barrelled microelectrode (a potential recording electrode and an electrode carrying Lucifer yellow CH dye (LY)). After potential measurement, LY was allowed to diffuse out of the microelectrode by iontophoresis. The position of electrode tip was ascertained from the pattern of LY diffusion. The intracellular potential changed markedly in response to CO₂ stress. The most typical response pattern obtained during CO₂ exposure (ON response) was two-phase, initially changing in the positive direction and then in the negative direction. During the ON response, marked efflux of K⁺ and slight influx of Cl⁻ occurred initially, followed by efflux of Cl⁻ and influx of H⁺. On cessation of CO₂ exposure, the potential showed a similar two-phase pattern (OFF response) but the ion fluxes reversed. Therefore the effect Of CO₂ exposure is not just decrease in intracellular pH owing to dissolution Of CO₂.

Sala, A., and J.D. Tenhunen. 1996. Simulations of canopy net photosynthesis and transpiration in *Quercus ilex* L under the influence of seasonal drought. *Agricultural and Forest Meteorology* 78(3-4):203-222.

A mechanistically based C-3 leaf photosynthesis model combined with an empirical stomatal model and a canopy model of light interception and microclimate was used to simulate *Quercus ilex* canopy net photosynthesis and transpiration at l'Avic watershed (NE Spain). The model takes into account the sun-shade leaf differentiation of photosynthetic characteristics as affected by depth within the canopy. Based on field studies, simulations were carried out for two locations within the watershed along a gradient in elevation, microclimate and forest structure. Effective predictions of diurnal and seasonal courses of stomatal conductance of sun and shade leaves for different days during the year were obtained by changing a single model variable termed g(F). The value of g(F) determined from least squares of observed vs. simulated time courses was linearly related to pre-dawn xylem water

potential over critical ranges of the response curve. Response to $g(F)$ in the model may to a great extent be thought of as the integrated expression of canopy response to root system generated signals or control mechanisms. For development of predictive capability, $g(F)$ is extremely useful because it allows seasonal assessments of water use and carbon dioxide uptake with differing patterns in water availability. Based on simulated responses on representative clear, overcast and variable days throughout the year, only small differences in annual totals for net photosynthesis and transpiration were found between the two sites, despite large differences in soil drying. Annual estimates of canopy water loss were in close agreement with independent estimates of evapotranspiration using the hydrological input/output method.

Saleska, S.R., J. Harte, and M.S. Torn. 1999. The effect of experimental ecosystem warming on CO₂ fluxes in a montane meadow. *Global Change Biology* 5(2):125-141.

Climatic change is predicted to alter rates of soil respiration and assimilation of carbon by plants. Net loss of carbon from ecosystems would form a positive feedback enhancing anthropogenic global warming. We tested the effect of increased heat input, one of the most certain impacts of global warming, on net ecosystem carbon exchange in a Rocky Mountain montane meadow. Overhead heaters were used to increase the radiative heat flux into plots spanning a moisture and vegetation gradient. We measured net whole-ecosystem CO₂ fluxes using a closed-path chamber system, relatively nondisturbing bases, and a simple model to compensate for both slow chamber leaks and the CO₂ concentration-dependence of photosynthetic uptake, in 1993 and 1994. In 1994, we also measured soil respiration separately. The heating treatment altered the timing and magnitude of net carbon fluxes into the dry zone of the plots in 1993 (reducing uptake by approximate to 100 g carbon m⁻²), but had an undetectable effect on carbon fluxes into the moist zone. During a strong drought year (1994), heating altered the timing, but did not significantly alter the cumulative magnitude, of net carbon uptake in the dry zone. Soil respiration measurements showed that when differences were detected in dry zone carbon fluxes, they were caused by changes in carbon input from photosynthesis, not by temperature-driven changes in carbon output from soil respiration. When differences were detected in dry-zone carbon fluxes, they were caused by changes in carbon input from photosynthesis, not by a temperature-driven changes in carbon output from soil respiration. Regression analysis suggested that the reduction in carbon inputs from plants was due to a combination of two soil moisture effects: a direct physiological response to decreased soil moisture, and a shift in plant community composition from high-productivity species to low-productivity species that are more drought tolerant. These results partially support predictions that warming may cause net carbon losses from some terrestrial ecosystems. They also suggest, however, that changes in soil moisture caused by global warming may be as important in driving ecosystem response as the direct effects of increased soil temperature.

Sallanon, H., B. Dimon, P. Carrier, and P. Chagvardieff. 1995. Effects of CO₂ concentration and irradiance on growth and photosynthesis of *Juglans regia* plantlets grown in-vitro. *Photosynthetica* 31(2):241-249.

Walnut (*Juglans regia* L.) plantlets were incubated during micropropagation in standard vessels (quasi confined vessels) or in aerated vessels flushed with 360 or 20 000 cm³(CO₂) m⁻³ under irradiances of 70 (LI) and 250 (HI) μ mol m⁻² s⁻¹. Plantlet morphology was strongly affected by the environment: leaf surface was increased, but shoot elongation and number of stems were reduced after increasing the irradiance of culture. Gross photosynthesis (P-G) capacity measured by using the O-18(2) isotope and mass-spectrometry techniques was increased by increasing photosynthetic photon flux (PPF) and CO₂ concentration. Plantlets exhibited a potential for photorespiratory activity and Mehler-type reaction and a high rate of mitochondrial respiration in all vessel types and irradiances. When a long-term HI was applied, gas exchange rates (P-G and O-2 uptake) were reduced in most of the vessel and PPF conditions, except in quasi confined vessels. Under all the growth conditions, net photosynthetic rate (P-N) was zero or slightly positive and the dry matter accumulation was very similar. Changes in O-2 exchange, growth rate or enzyme activities linked to carbon fixation that were induced by changes in PFD and CO₂ concentration showed that the photosynthetic characteristics of plantlets were typical for hetero-mixotrophic tissues.

Sallanon, H., H. Isaka, B. Dimon, C. Ravel, and P. Chagvardieff. 1997. CO₂ exchanges and nutrient uptake during multiplication and rooting of micropropagated *Juglans regia* plantlets. *Plant Science* 124(1):107-116.

CO₂ gas exchanges in light and dark, PEPC and Rubisco activities and consumption of sugar and mineral nutrients (K⁺, Ca²⁺, Mg²⁺, NH₄⁺, NO₃⁻, PO₄³⁻, SO₄²⁻) were measured during multiplication and rooting stages of in vitro-cultivated *Juglans regia*. CO₂ gas exchanges in light and dark, and PEPC and Rubisco activities varied with plantlet age during a growth cycle. They were higher during the first part of the exponential stage of growth (defined in terms of dry weight increase). Respiratory gas exchanges were always higher than photosynthetic ones. The differences between the two stages of growth were reflected in respiration/photosynthesis and total Rubisco activity/initial Rubisco activity ratios, which were higher in the rooting than in the multiplication stage. This work underlines the need to consider the wide variations in photosynthetic and respiratory gas exchanges related to the plantlet development stage. Mineral absorption also displayed variations, both in the quantity and selectivity of the inorganic nutrients supplied. During the multiplication stage, fast exhaustion of PO₄³⁻ and NH₄⁺ occurred, whereas depletion of Ca²⁺, NH₄⁺, PO₄³⁻ and SO₄²⁻ were observed throughout the rooting stage. The inhibition of photosynthetic activity may be linked to the presence of sugar in the medium and also to ion deficiencies during the multiplication stage. Hence, this work also highlights the importance of mineral elements, suggesting a need to review nutrient medium compositions. (C) 1997 Elsevier Science Ireland Ltd.

Salt, D.T., G.L. Brooks, and J.B. Whittaker. 1995. Elevated carbon-dioxide affects leaf-miner performance and plant-growth in docks (*Rumex* spp). *Global Change Biology* 1(2):153-156.

Exposure of *R. crispus* and *R. obtusifolius* to elevated CO₂ (600 ppm) resulted in an increased C:N ratio of leaf tissue and greater leaf areas. Larvae of *P. nigritarsis* mining leaves of *X. obtusifolius* during exposure produced significantly bigger mines in elevated than in ambient (350

ppm) conditions. There were no significant treatment effects on pupal weight although in both host species mean weight was greater in ambient than in elevated conditions. These results are consistent with the hypothesis that insect herbivores compensate for increased C:N ratios by increased food consumption. This response by herbivores may partially offset predicted increases in plant biomass in a future high CO₂ environment.

Salt, D.T., P. Fenwick, and J.B. Whittaker. 1996. Interspecific herbivore interactions in a high CO₂ environment: Root and shoot aphids feeding on Cardamine. *Oikos* 77(2):326-330.

This study investigated the effects of elevated CO₂ on populations of root and/or shoot aphids and their effects on partitioning in Cardamine pratensis. Total plant biomass in elevated (approximate to 600 ppm) CO₂ of uninfested Cardamine plants was 52% higher than in ambient (approximate to 350 ppm) concentrations but CO₂ effects were not statistically significant. In elevated CO₂, feeding by shoot aphids (*Aphis fabae fabae*) alone and in combination with root aphids (*Pemphigus populitransversus*), and root aphids alone had no significant effect on plant biomass. No significant effects of elevated CO₂ were detected on population size of the shoot or root-feeding species. Interspecific effects were detected between the root and shoot species. Root aphid populations were significantly smaller in the presence of shoot aphids on the same plants. In this system plant growth was unaffected by an elevated CO₂ environment. Plant species which are more sensitive to elevated CO₂ may show a modified response to herbivore pressure in a future atmospheric environment.

Samarakoon, A.B., and R.M. Gifford. 1995. Soil water content under plants at high CO₂ concentration and interactions with the direct CO₂ effects: A species comparison. *Journal of Biogeography* 22(2-3):193-202.

Wheat, maize and cotton, grown as spaced plants in large pots of soil, differed in the way high (2 X ambient) CO₂ concentration affected the time-course of soil water use. For wheat, the tendency to conserve water owing to reduction in stomatal conductance in high CO₂ was largely offset by the stimulation of leaf area development as the soil column dried. However, when the soil was maintained continuously wet, soil water conservation occurred because in the absence of water stress high CO₂ did not maintain a greater leaf area. For maize, which has little or no photosynthetic response to CO₂ concentrations above ambient but a strong stomatal response, water was conserved and the soil profile dried more slowly. Maize leaf area and dry matter growth increased in response to damper soil under high CO₂, despite no growth response to CO₂ in the absence of water stress. For cotton, which has a strong photosynthetic but weak stomatal response to CO₂, the soil column dried faster under high CO₂. Despite this drier soil, cotton still showed the greatest response to high CO₂ of leaf area and dry matter growth of the three species compared. Under wet soil conditions, cotton exhibited a very large leaf area response to CO₂ leading to much greater water use per plant. This contrasts with both wheat and maize which conserved water at high CO₂ when wet. Despite these contrasting transpiration and growth responses, all three species exhibited a relatively similar increase in water use efficiency under high CO₂ for both wet and dry conditions. It is concluded that the secondary effect of high CO₂ on soil water content exerts a strong confounding influence on growth responses to

CO₂. In the longer term, the changed soil water status would influence hydrology, soil microbiology, nutrient relations and species composition. From indirect evidence it is proposed that the relative enhancement of growth owing to CO₂ enrichment is greater under drought conditions than in wet soil because of the effect of water deficit on the intercellular CO₂ concentration in the leaf, C-i. If water deficits cause C-i/C-a to decline then photosynthesis is operating in a more CO₂-sensitive region of the CO₂ response curve.

Samarakoon, A.B., and R.M. Gifford. 1996. Elevated CO₂ effects on water use and growth of maize in wet and drying soil. *Australian Journal of Plant Physiology* 23(1):53-62.

It is unclear from the literature as to whether growth of C-4 species is responsive to elevated atmospheric CO₂ concentration. Reports vary between no response to strong response. To explore the origin of this discrepancy, spaced plants of maize (*Zea mays*) were grown at atmospheric CO₂ concentrations of 362 or 717 $\mu\text{L L}^{-1}$ under continuously wet or drying soil regimes. The aims were to evaluate the comparative growth promotion from elevated CO₂ in a C-4 plant under the two contrasting water regimes and the causes of any such promotion, and also how water-use efficiency (WUE) is influenced by high CO₂ under the two water regimes. In wet soil, transpiration rate was reduced on average by 29% at high CO₂ but neither total dry matter nor plant height was significantly affected by CO₂ level. Leaf area was not influenced significantly, so daily water use per plant was 25% lower and WUE was increased entirely due to reduced water use at high CO₂. In soil that was drying from field capacity, plants in high CO₂ used about 30% less water than those in ambient CO₂ while the soil was still wet. This resulted in higher soil water content at high CO₂. Plant growth showed a marked response, accumulating 35% more leaf area and 50% more dry matter. Young internodes elongated up to 170% more, giving taller plants. The growth enhancement was largely due to higher average net assimilation rate indicating that C-4 photosynthesis responded to elevated CO₂ during drought. In drying soil the increase in WUE was due to both increased dry matter and reduced water use, the contribution from each depending on the stage of soil drying. We hypothesise therefore that literature examples where maize growth responded to elevated CO₂ may have involved (possibly unrecognised) minor water deficits.

Samarakoon, A.B., and R.M. Gifford. 1996. Water use and growth of

cotton in response to elevated CO₂ in wet and drying soil. *Australian Journal of Plant Physiology* 23(1):63-74.

Cotton (*Gossypium hirsutum* cv. Sicala 34) was grown at 352 ('low CO₂') or 710 ('high CO₂') $\mu\text{L L}^{-1}$ atmospheric CO₂ in continuously wet soil, or in drying soil, or in drying soil re-wetted after plant wilting. In wet soil, the approximately 15% reduction in transpiration per unit leaf area owing to high CO₂ was only half that for other species, whereas effects on growth and leaf area were relatively larger. Consequently, water use per plant was 45-50% higher for high CO₂ plants in contrast to other species for which the rate of water use is either the same or lower in high CO₂. Greater plant water use early in a drying cycle caused the soil to dry faster under high CO₂ than under low CO₂. The addition of the consequential greater water stress at high CO₂ in drying soil to the direct CO₂ effect on stomata caused the transpiration rate of high CO₂ plants to fall by up to 60% as the soil dried relative to plants drying at low CO₂. After re-wetting the dry soil, the reduction in transpiration rate at high CO₂ returned within hours to the value of 15% seen in wet soil. The results were inconsistent with the idea that water deficits increase the sensitivity of stomatal aperture to CO₂. Other consequences of drier soil under high CO₂ compared with low CO₂ were: (a) unlike in many other species, in cotton, the relative growth enhancement by high CO₂ is not higher under drying soil compared with wet soil owing to the opposite effect on soil water content; and (b) the increased water-use efficiency in drying soil relative to wet soil was greater in high CO₂ plants than in low CO₂. The confounding of indirect effects of soil water with the direct CO₂ effects may explain the wide variability of literature reports about CO₂ effects on stomatal conductance and water use.

Samarakoon, A.B., W.J. Muller, and R.M. Gifford. 1995. Transpiration and leaf-area under elevated CO₂ - effects of soil-water status and genotype in wheat. *Australian Journal of Plant Physiology* 22(1):33-44.

Transpiration rate, leaf area expansion, water use and water-use efficiency (WUE) of spaced plants of wheat (cvv. Matong and Quarrior), were examined at ambient and twice ambient CO₂ concentrations in wet and drying soil regimes. A hypothesis tested was that both stomatal conductance (g(s)) and leaf area development are so regulated by the plant in relation to soil water status that the reduction of approximately 40% in g(s) in high CO₂ has no permanent impact on whole-plant water use. Whereas, during a soil drying cycle, leaf area increase under elevated CO₂ counterbalanced closely for reduced g(s) in terms of soil water depletion as reported elsewhere, this counterbalance was neither exact at all times, nor did it apply when the soil was continuously wet. In wet soil, leaf area was not enhanced much by elevated CO₂, probably because, under the high radiation and nutritional conditions used, the tillering rate was almost maximal anyway. Quarrior, having a 40% lower g(s) than Matong genetically, did not counterbalance a reduced transpiration rate with a larger leaf area under either drying or wet soil conditions. These results support rejection, for wheat, of the hypothesis posed; elevated CO₂ increased leaf area mainly by virtue of the direct photosynthetic increase rather than changed soil water status. In wet soil, low g(s) Quarrior had a higher CO₂ effect on WUE (+ 73 to 82%) than did Matong (+ 54 to 65%). In drying soil, both cultivars had a similar increase in WUE at high CO₂ (+ 60 to 68%).

Sampson, D.A., E.J. Cooter, P.M. Dougherty, and H.L. Allen. 1996. Comparison of the UKMO and GFDL GCM climate projections in NPP simulations for southern loblolly pine stands. *Climate Research* 7(1):55-69.

We used the process model BIOMASS version 13.0 to simulate contemporary net primary production (NPP) and NPP response to climate projections for a doubling of atmospheric CO₂ concentration from 2 general circulation models (GCMs) that vary in their CO₂ sensitivity: the less sensitive GFDL and the more sensitive UKMO. Increased GCM sensitivity to CO₂ is reflected in increased predictions in the magnitude, variation, and range of the climate variables. Simulations used a 40 yr historical climate record, and 2 stand and site conditions to standardize the total NPP response estimates for eighteen 1x1 degrees grid cells across the southern United States. Contemporary NPP and NPP response estimates from the 18 cells were smoothed using a cell search algorithm to obtain an NPP response index matrix for the entire loblolly pine (*Pinus taeda*) forest-type. We conducted a sensitivity analysis of the environmental variables projected to change in a 2xCO₂ environment to help interpret simulation output. Contemporary NPP varied from 2.5 to 8.5 Mg C ha⁻¹ yr⁻¹ over the range of loblolly pine. High leaf area index (LAI) simulations had 1.5 to 2 times the productivity of low LAI simulations, but the regional patterns were similar; NPP was correlated with regional differences in precipitation and temperature. The NPP response to future climate and atmospheric changes depended on the GCM used, and on the stand and site condition assumed. Inter-annual estimates for the 18 cell simulations resulted in a +22 to +84% NPP response for the GFDL climate projections and a -30 to +94% NPP response for the UKMO climate projections. The 40-year average NPP response for the smoothed data ranged from +43 to +65% and -1 to +94% for the GFDL and the UKMO climate projections, respectively. Consequently, the magnitude and range of the 40-year average NPP response to the climate projections was directly correlated with the GCM CO₂ sensitivity. Although increased CO₂ sensitivity resulted in broader extremes in the predicted temperature response, precipitation response for the 2 models was similar. The NPP response was also correlated with the patterns in predicted climate change, with regional differences coupled to local climatic conditions. Climate projections from both models produced similar NPP responses when predicted temperatures and precipitation regimes were similar. Elevated ambient CO₂ had a greater effect on NPP response than temperature or precipitation in the sensitivity comparisons. Simulations indicate that a CO₂ fertilizer effect, assuming no CO₂ acclimation, more than compensates for declines in productivity over most of the loblolly pine forest-type associated with projected decreased precipitation and/or projected low to moderate increases in temperature and, therefore, increased maintenance respiration costs.

Sampson, R.N., M. Apps, S. Brown, C.V. Cole, J. Downing, L.S. Heath, D.S. Ojima, T.M. Smith, A.M. Solomon, and J. Wisniewski. 1993. Workshop summary statement - terrestrial biospheric carbon fluxes - quantification of sinks and sources of CO₂. *Water, Air, and Soil Pollution* 70(1-4):3-15.

Understanding the role of terrestrial ecosystems in the global carbon (C) cycle has become increasingly important as policymakers consider options to address the issues associated with global change, particularly climate change. Sound scientific theories are critical in predicting how these systems may respond in the future, both to climate change and human actions. In March 1993, 60 scientists from 13 nations gathered

in Bad Harzburg, Germany, to develop a state-of-the-science assessment of the present and likely future C fluxes associated with the major components of the earth's terrestrial biosphere. In the process, particular emphasis was placed on the potential for improving C sinks and managing long-term C sequestration. The majority of the week's work was conducted in eight working groups which independently considered a particular biome or subject area. The working groups considered: the Global Carbon Cycle; Boreal Forests and Tundra; Temperate Forests; Tropical Forests; Grasslands, Savannas and Deserts; Land and Water Interface Zones; Agroecosystems; and Biomass Management. This paper presents a brief overview of their major conclusions and findings. In addition, Table 1 brings together the best estimates from each group as to the current magnitude and estimated future direction of changes in the terrestrial C fluxes.

Samuelson, L.J., and J.R. Seiler. 1992. Fraser fir seedling gas-exchange and growth in response to elevated CO₂. *Environmental and Experimental Botany* 32(4):351-356.

Growth and gas exchange characteristics were examined in Fraser fir (*Abies fraseri* (Pursh.) Poir.) seedlings grown from seed in elevated (713 ppm) or ambient (374 ppm) CO₂ for 1 year (two artificial growing seasons) to determine the potential influence of a twice-ambient CO₂ concentration on this species. A subset of seedlings was transplanted from 172 cm³ pots into 1000 cm³ pots at 7 months to determine if CO₂ effects were dependent on rooting volume. At 5 and 12 months, net photosynthesis (P_{net}) and leaf conductance (g_l) were lower in elevated CO₂-grown seedlings grown in 172 cm³ pots than in ambient CO₂-grown seedlings when measured at either 346 or 796 ppm CO₂. For 12-month-old seedlings grown in 1000 cm³ pots, P_{net} was reduced by an elevated CO₂ growth environment only when measured at 346 ppm CO₂, although g_l was lower in these seedlings when measured at either CO₂ measurement level. Seedlings grown in both pot sizes and in elevated CO₂ for 1 year had greater height, diameter, and leaf, stem, root and total dry weights than seedlings grown in ambient CO₂. Specific leaf weight (SLW) was greater in elevated than in ambient CO₂-grown needles only in the large pot size treatment. These results suggest that Fraser fir seedling growth will increase in a future elevated CO₂ environment despite changes in gas exchange characteristics.

Samuelson, L.J., and J.R. Seiler. 1993. Interactive role of elevated CO₂, nutrient limitations, and water-stress in the growth-responses of red spruce seedlings. *Forest Science* 39(2):348-358.

Red spruce (*Picea rubens* Sarg.) seedlings were grown from seed for 5 mo in ambient (362 ppm) or elevated (711 ppm) CO₂ to determine the potential effect of an increase in global CO₂ concentration on seedling growth and establishment. CO₂ exposure treatments were crossed with two levels of soil fertility and water stress treatments to determine if seedling dry weight, size, and fixed growth responses to elevated CO₂ depended on nutrient and water supply. Seedling dry weight and size responses to elevated CO₂ at 5 mo did not depend on nutrient and water supply. Seedlings grown in both soil fertility treatments and water stress treatments responded similarly to CO₂ treatment. Water stress and CO₂ treatments did have an interactive influence on the fixed growth potential of the terminal leader. Leaf weight, leaf area, and height of the terminal leader of water-stressed seedlings were greater in seedlings exposed to elevated CO₂ during budset than seedlings exposed to ambient CO₂. Total new fixed growth (lateral plus terminal) and total terminal fixed growth (leaf plus stem) were greater in seedlings that formed shoot primordia in elevated CO₂ than in ambient CO₂. Red

spruce seedlings grown in elevated CO₂ for 5 mo had greater stem diameter, height, branching density, leaf weight, root weight, stem weight, total weight, and mean relative growth rate (RGR) from 3 to 5 mo than seedlings grown in ambient CO₂. Red spruce seedling responses to elevated CO₂ suggest that seedling establishment in natural environments may be enhanced when ambient CO₂ concentrations rise even if water and nutrient availabilities are limited.

Samuelson, L.J., and J.R. Seiler. 1994. Red spruce seedling gas-exchange in response to elevated CO₂, water-stress, and soil fertility treatments. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 24(5):954-959.

The interactive influences of ambient (374 µL.L⁻¹) or elevated (713 µL.L⁻¹) CO₂, low or high soil fertility, well-watered or water-stressed treatment, and rooting volume on gas exchange and growth were examined in red spruce (*Picea rubens* Sarg.) grown from seed through two growing seasons. Leaf gas exchange throughout two growing seasons and growth after two growing seasons in response to elevated CO₂ were independent of soil fertility and water-stress treatments, and rooting volume. During the first growing season, no reduction in leaf photosynthesis of seedlings grown in elevated CO₂ compared with seedlings grown in ambient CO₂ was observed when measured at the same CO₂ concentration. During the second growing season, net photosynthesis was up to 21% lower for elevated CO₂-grown seedlings than for ambient CO₂-grown seedlings when measured at 358 µL.L⁻¹. Thus, photosynthetic acclimation to growth in elevated CO₂ occurred gradually and was not a function of root-sink strength or soil-fertility treatment. However, net photosynthesis of seedlings grown and measured at an elevated CO₂ concentration was still over 2 times greater than the photosynthesis of seedlings grown and measured at an ambient CO₂ concentration. Growth enhancement by CO₂ was maintained, since seedlings grown in elevated CO₂ were 40% larger in both size and weight after two growing seasons.

Sanders, I.R., R. Streitwolf-Engel, M.G.A. van der Heijden, T. Boller, and A. Wiemken. 1998. Increased allocation to external hyphae of arbuscular mycorrhizal fungi under CO₂ enrichment. *Oecologia* 117(4):496-503.

Prunella vulgaris was inoculated with different arbuscular mycorrhizal fungi (AMF) and grown at two concentrations of CO₂ (ambient, 350 µL.L⁻¹, and elevated, 600 µL.L⁻¹) to test whether a plant's response to elevated CO₂ is dependent on the species of AMF colonizing the roots. Using compartments accessible only to AMF hyphae but not to roots, we also tested whether elevated CO₂ affects the growth of external AMF hyphae. Plant biomass was significantly greater at elevated than at ambient CO₂; the biomass of the root system, for example, increased by a factor of 2. The colonization of AMF inside the root remained constant, indicating that the total AMF inside the root system also increased by a factor of 2. The length of external AMF hyphae at elevated CO₂ was up to 5 times that at ambient CO₂, indicating that elevated CO₂ promoted allocation of AMF biomass to the external hyphae. The concentration and content of phosphorus in the stolons differed significantly between ambient and elevated CO₂ but this resulted in either an increase or a decrease, according to which AMF isolate occupied the roots. We hypothesized that an increase in external

hyphal growth at elevated CO₂ would result in increased P acquisition by the plant. To test this we supplied phosphorus, in a compartment only accessible to AMF hyphae. Plants did not acquire more phosphorus at elevated CO₂ when phosphorus was added to this compartment. Large increases in AMF hyphal growth could, however, play a significant role in the movement of fixed carbon to the soil and increase soil aggregation.

Santrucek, J., and R.F. Sage. 1996. Acclimation of stomatal conductance to a CO₂-enriched atmosphere and elevated temperature in *Chenopodium album*. *Australian Journal of Plant Physiology* 23(4):467-478.

Acclimation of stomatal conductance to different CO₂ and temperature regimes was determined in *Chenopodium album* L. plants grown at one of three treatment conditions: 23 degrees C and 350 $\mu\text{mol CO}_2\text{ mol}^{-1}$ air; 34 degrees C and 350 $\mu\text{mol mol}^{-1}$; and 34 degrees C and 750 $\mu\text{mol mol}^{-1}$. Stomatal conductance (g(s)) as a function of intercellular CO₂ (C-i) was determined for each treatment at 25 and 35 degrees C, and these data were used to estimate gains of the feedback loops linking changes in intercellular CO₂ with stomatal conductance and net CO₂ assimilation. Growth temperature affected the sensitivity of stomata to measurement temperature in a pattern that was influenced by intercellular CO₂. Stomatal conductance more than doubled at intercellular CO₂ varying between 200 and 600 $\mu\text{mol mol}^{-1}$ as leaf temperature increased from 25 to 35 degrees C for plants grown at 23 degrees C. In contrast, stomatal conductance was almost unaffected by measurement temperature in plants grown at 34 degrees C. Elevated growth CO₂ attenuated the response of stomatal conductance to CO₂, but growth temperature did not. Stomatal sensitivity to C-i was extended to higher C-i in plants grown in elevated CO₂. As a result, plants grown at 750 $\mu\text{mol mol}^{-1}$ CO₂ had higher C-i/C-a at ambient CO₂ values between 300 and 1200 $\mu\text{mol mol}^{-1}$ than plants grown at 350 $\mu\text{mol mol}^{-1}$ CO₂. The gain of the stomatal loop was reduced in plants grown at elevated CO₂ or at lower temperature when compared to plants grown at 350 $\mu\text{mol mol}^{-1}$ and 34 degrees C. Both photosynthetic and stomatal loop gains acclimated to elevated CO₂ in proportion so that their ratio, integrated over the range of C-i in which the plant operates, remained constant. Water use efficiency (WUE) more than doubled after a short-term doubling of ambient CO₂. However, the WUE of plant grown and measured at elevated CO₂ was only about 1.5 times that of plant transiently exposed to elevated CO₂, due to stomatal acclimation. An optimal strategy of water use was maintained for all growth treatments.

Santrucek, J., H. Santruckova, J. Kveton, M. Simkova, and K. Rohacek. 1994. The effect of elevated CO₂ concentration on photosynthetic CO₂ fixation, respiration and carbon economy of wheat plants. *Rostlinna Vyroba* 40(8):689-696.

Winter wheat plants were grown under controlled atmospheric and light conditions for 25 days to assess the response of photosynthesis, respiration and carbon allocation to elevated ambient CO₂ concentration. Daily balance of carbon fixation and loss was measured separately for shoots and roots including root exudation. Doubled CO₂ (700 $\mu\text{mol CO}_2\text{ mol}^{-1}$) stimulated photosynthetic CO₂ uptake and dark respiration rate when calculated on the leaf area basis. However,

total daily carbon gain per plant and total dry matter of shoot was lower for high-CO₂-grown plants due to reduced leaf area. After 23 days of exposition to high CO₂, photosynthesis was depressed probably due to limiting regeneration of ribulose biphosphate. Both stomatal resistance and water use efficiency were markedly higher in high-CO₂-grown plants. Higher evaporative demand in low-CO₂-grown plants promoted root elongation. Total root length was 160% of that in high-CO₂-grown plants. Root exudation of high-CO₂-grown plants was higher in the first days of plant development, but the inhibition of net photosynthesis was followed by a decrease in exudation.

Santruckova, H., J. Santrucek, J. Kveton, M. Simkova, D. Elhottova, and K. Rohacek. 1999. Carbon balance of a winter wheat-root microbiota system under elevated CO₂. *Photosynthetica* 36(3):341-354.

We examined the carbon budget of young winter wheat plants and their associated microorganisms as affected by a doubling of the atmospheric CO₂ concentration (700 $\mu\text{mol mol}^{-1}$). Plants were grown hydroponically in pre-sterilised sand at a controlled irradiance and temperature regime. Net photosynthesis (P-N) and respiration (R-D) rates of roots and shoots were measured continuously, plant growth and carbon distribution in the plant-root medium-associated microorganism system were determined destructively in interval-based analyses. P-N in elevated CO₂ grown plants (EC) was 123 % of that in the control (AC) plants when averaged over the whole life span (39-d-old plants, 34 d in EC), but the percentage varied with the developmental stage being 115, 88, and 167 % in the pre-tillering, tillering, and post-tillering phase, respectively. There was a transient depression of P-N, higher amplitude of day/night fluctuations of the chloroplast starch content, and depression of carbon content in rhizosphere of EC plants during the period of tillering. After 34 d in EC, carbon content in shoots, roots, and in rhizodepositions was enhanced by the factors 1.05, 1.28, and 1.96, respectively. Carbon partitioning between above and belowground biomass was not affected by EC, however, proportionally more C in the belowground partitioning was allocated into the root biomass. Carbon flow from roots to rhizodepositions and rhizosphere microflora was proportional to P-N; its fraction in daily assimilated carbon decreased from young (17 %) to older (3-4 %) plants.

Santruckova, H., and M. Simek. 1997. Effect of soil CO₂ concentration on microbial biomass. *Biology and Fertility of Soils* 25(3):269-273.

The effect of increasing soil CO₂ concentration was studied in six different soils. The soils were incubated in ambient air (0.05 vol.% CO₂) or in air enriched with CO₂ (up to 5.0 vol.% CO₂). Carbon dioxide evolution, microbial biomass, growth or death rate quotients and glucose decay rate were measured at 6, 12 and 24 h of CO₂ exposure. The decrease in soil respiration ranged from 7% to 78% and was followed by a decrease in microbial biomass by 10-60% in most cases. High CO₂ treatments did not affect glucose decay rate but the portion of C-gluc mineralized to CO₂ was lowered and a larger portion of C-gluc remained in soils. This carbon was not utilized by soil microorganisms.

Saralabai, V.C., M. Vivekanandan, and R.S. Babu. 1997. Plant responses to high CO₂ concentration in the atmosphere. *Photosynthetica* 33(1):7-37.

The impact of continuous rise in ambient CO₂ concentration (AC) in the atmosphere on different facets of growth of crop plants is assessed. The effects of CO₂ enrichment (EC) on plant growth, C-3 and C-4 photosynthesis, source-sink ratio, partitioning and translocation of metabolites, photosynthetic enzymes, respiratory rate, leaf area index, stomatal conductance (g(s)), transpiration rate, biomass production and water use efficiency are reviewed. The CO₂ fertilization effects are studied in both short-term (open top chambers) and long-term experiments. Long-term experiments suggest that ribulose-1,5-bisphosphate carboxylase is inactivated at high CO₂ concentrations. Also g(s) is lowered. One of the conspicuous effects of EC is the closure of stomata in C-3 plants. Photosystem (PS) 2 electron transport is more affected than PS1. Starch is the immediate product accumulated in the leaf of C-3 plants. The "CO₂ fertilization effect" does not confer any great advantage even in C-3 plants.

Sasek, T.W., and B.R. Strain. 1991. Effects of CO₂ enrichment on the growth and morphology of a native and an introduced honeysuckle vine. *American Journal of Botany* 78(1):69-75.

Japanese honeysuckle (*Lonicera japonica* Thunb.), introduced to the United States, and the native coral honeysuckle (*Lonicera sempervirens* L.) were compared to determine how intrinsic differences in their growth characteristics would affect their response to atmospheric carbon dioxide enrichment. Plants of both species grown from cuttings were harvested after 54 days of growth in controlled environment growth chambers at 350, 675, or 1,000- μ l/liter CO₂. The biomass of Japanese honeysuckle was increased 135% at 675- μ l/liter CO₂ and 76% at 1,000- μ l/liter CO₂ after 54 days. Morphologically, the main effect of CO₂ enrichment was to triple the number of branches and to increase total branch length six times. Enhanced and accelerated branching also increased total leaf area 50% at elevated CO₂ concentrations. In coral honeysuckle, total biomass was only 40% greater in the elevated CO₂ treatments. Branching was quadrupled but had not proceeded long enough to affect total leaf area. Main stem height was increased 36% at 1,000- μ l/liter CO₂. The much less significant height response of other woody erect growth forms suggests that vines may increase in importance during competition if atmospheric CO₂ concentrations increase as predicted. The impact of Japanese honeysuckle in the United States may become more serious.

Sato, H., N. Sakurai, S. Sendo, H. Saneoka, H. Nobuyasu, and K. Fujita. 1997. Factors affecting leaf area development in husk leaf of

flint corn. *Crop Science* 37(6):1826-1831.

Some corn (*Zea mays* L.) genotypes produce husk leaves (laminae extending from the husk) that on a per unit area basis, contribute more photosynthate to grain production than culm leaves. Furthermore, a high correlation between husk leaf area and dry weight has been observed, but little is known about the changes in cell components during development of husk leaves. A field experiment was conducted to quantify methanol (MeOH)-soluble fraction (cytosol) and incorporation of C-13-labeled photosynthate in cell walls from 9 d before silking (DBS) to silking. The ear leaf of flint corn (F-1 of N-19 by X-15) was subjected to (CO₂)-C-13, eight DBS. Leaf area, dry weight, and photosynthetic activity of the husk leaves, and sugar content of various cell components were measured continuously during the 9-d period. The husk leaf attained one-half of its maximum apparent photosynthetic rate (P-0.) when it had 8% of its maximum leaf area at 4 DES. At 9 DBS, neutral sugars in the MeOH-soluble fraction accounted for most of nonstarch carbohydrates within the husk leaf (68%), while hemicellulose and cellulose fractions accounted for <10%. At silking, however, sugars in the hemicellulose and cellulose fractions increased by 23 and 56%, respectively. Results of (CO₂)-C-13 labeling suggest that during rapid husk leaf development, MeOH-soluble fraction decreases, while the hemicellulose fraction fluctuates, and cellulose fraction increases.

Saurer, M., S. Maurer, R. Matyssek, W. Landolt, M.S. Gunthardtgoerg, and U. Siegenthaler. 1995. The influence of ozone and nutrition on delta-C-13 in betula-pendula. *Oecologia* 103(4):397-406.

In the cellulose of stems and leaves, delta(13)C was investigated in a birch clone (*Betula pendula*), which was exposed throughout the growing season to either <3 (control) or 90/40 nl O-3 1(-1) (day/night). Each regime was split into plants under high or low nutrient supply. delta(13)C was increased (becoming less negative), in stems rather than leaves, by both high nutrition (+2 parts per thousand) and O-3 stress (+1 parts per thousand). Whereas high nutrition raised the water-use efficiency (WUE) while lowering the CO₂ concentration in the inner leaf air space (c(i)), WUE decreased and c(i) increased under O-3 stress. Therefore, only the nutritional effect on the carbon isotope fractionation was reproduced by the model of Farquhar et al. (1982) which estimates WUE by means of delta(13)C based on C-i, C-i was not biased by 'patchiness' in respect to stomatal opening. The latter was verified by microscopical analysis and the complete water infiltration of the birch leaves through the stomata, independent of the diurnal course of the leaf conductance for water vapour. Under low nutrient supply, the activity of phosphoenol pyruvate carboxylase (PEPC) was roughly doubled by ozone to about 1.3% of the total carboxylation capacity (by PEPC + rubisco), and was increased to 1.7% under high nutrition. The fractionation model, extended to account for varying activities of the carboxylating enzymes, indicated that stimulated PEPC was the cause of elevated delta(13)C, although c(i) was increased under O-3 stress. The stimulation of PEPC and, as a consequence, elevated delta(13)C are discussed as part of a whole-plant acclimation to O-3 stress.

Saxe, H. 1994. Relative sensitivity of greenhouse pot plants to long-term exposures of no-containing and no2-containing air. *Environmental Pollution* 85(3):283-290.

Thirty-five cultivars of pot plants of 20 families were exposed for 50-64 days in a greenhouse facility to either 1 mul litre-1 NO with 0.5 mul litre-1 NO₂, or 1 mul litre-1 NO₂ with 0.1 mul litre-1 NO for 15 h each day, with air which was free from these gases as the reference. A sensitivity ranking of the pot plants was compiled, with the highest priority on visible injuries, followed by growth reductions, primarily as a response to the NO-dominated exposures, simulating the NO(x)-polluted environment in direct-fired, CO₂-enriched greenhouses. This treatment reduced the leaf dry weight more than the number and area of the leaves. Twenty-two cultivars were significantly injured, while two (*Hibiscus* sp., *Epipremnum pinnatum*, green) were significantly improved. The NO(x)-sensitivity of pot plants was highest in cultivars with variegated, small or narrow leaves, and in the Moraceae family. Nine cultivars (*Ficus elastica* 'Robusta', *F. benjamina*, *F. pumila* 'Sonny', *Dieffenbachia maculata* 'Camilla', *F. elastica* 'Tineke', *Epipremnum pinnatum* 'Marble Queen', *Begonia elatior* 'Nelson', *Cyclamen persica*, *Poinsettia* 'Mini') were specifically sensitive to the NO-containing exposure; six were specifically sensitive to the NO₂-containing exposure (*F. elastica* 'Robusta', *Asparagus* den. 'Sprenger', *Hedera helix* 'Shamrock', *Aspidium nidus*, *Aster novo-belgii*, *Hypoestes* phyl. 'Betina'); and 12 (*Soleirolia soleirolia*, *Asparagus* den. 'Sprenger', *H. helix* 'Ester', *Codiaeum Pictum*, *Rosa* 'Minimo Red', *F. benjamina* 'Starlight', *Saintpaulia ionantha* 'light blue', *F. pumila*, *Rhododendron simsii*, *H. helix* 'Shamrock', *Hibiscus* sp., *E. pinnatum*) were equally sensitive to mixtures dominated by either gas, as measured by at least one response parameter.

Saxe, H., D.S. Ellsworth, and J. Heath. 1998. Tree and forest functioning in an enriched CO₂ atmosphere. *New Phytologist* 139(3):395-436.

Forests exchange large amounts of CO₂ with the atmosphere and can influence and be influenced by atmospheric CO₂. There has been a recent proliferation of literature on the effects of atmospheric CO₂ on forest trees. More than 300 studies of trees on five different continents have been published in the last five years. These include an increasing number of field studies with a long-term focus and involving CO₂ x stress or environment interactions. The recent data on long-term effects of elevated atmospheric CO₂ on trees indicate a potential for a persistent enhancement of tree growth for several years, although the only relevant long-term datasets currently available are for juvenile trees. The current literature indicates a significantly larger average long-term biomass increment under elevated CO₂ for conifers (130%) than for deciduous trees (49%) in studies not involving stress components. However, stimulation of photosynthesis by elevated CO₂ in long-term studies was similar for conifers (62 %) and deciduous trees (53 %). Recent studies indicate that elevated CO₂ causes a more persistent stimulation of biomass increment and photosynthesis than previously expected. Results of seedling studies, however, might not be applicable to other stages of tree development because of complications of age- dependent and size-dependent shifts in physiology and carbon allocation, which are accelerated by elevated CO₂. In addition, there are many possible avenues to down-regulation, making the predicted canopy CO₂ exchange and growth of mature trees and forests in a CO₂-rich atmosphere uncertain. Although, physiological down-regulation of photosynthetic rates has been documented in field situations, it is rarely large enough to offset entirely photosynthetic gains in elevated CO₂. A persistent growth stimulation of individual mature trees has been demonstrated although this effect is more uncertain in trees in natural stands. Resource interactions can both constrain tree responses to elevated CO₂ and be altered by them. Although drought can reduce gas-exchange rates and offset the benefits of elevated CO₂, even in well watered trees, stomatal conductance is remarkably less responsive to

elevated CO₂ than in herbaceous species. Stomata of a number of tree species have been demonstrated to be unresponsive to elevated CO₂. We conclude that positive effects of CO₂ on leaf area can be at least as important in determining canopy transpiration as negative, direct effects of CO₂ on stomatal aperture. With respect to nutrition, elevated CO₂ has the potential to alter tree-soil interactions that might influence future changes in ecosystem productivity. There is continued evidence that in most cases nutrient limitations diminish growth and photosynthetic responses to elevated CO₂ at least to some degree, and that elevated CO₂ can accelerate the appearance of nutrient limitations with increasing time of treatment. In many studies, tree biomass responses to CO₂ are artefacts in the sense that they are merely responses to CO₂-induced changes in internal nutritional status of the tree. There are numerous interactions between CO₂ and factors of the biotic and abiotic environment. The importance of increasing atmospheric CO₂ concentrations for productivity is likely to be overestimated if these are not taken into account. Many interactions, however, are simply additive rather than synergistic or antagonistic. This appears to hold true for many parameters under elevated CO₂ in combination with temperature, elevated O₃, and other atmospheric pollutants. However, there is currently little evidence that elevated CO₂ will counteract O₃ damage. When the foliage content of C, mineral nutrients and secondary metabolites is altered by elevated CO₂, tree x insect interactions are modified. In most trees, mycorrhizal interactions might be less important for direct effects of CO₂ than for alleviating general nutrient deficiencies. Since many responses to elevated CO₂ and their interactions with stress show considerable variability among species/genotypes, one principal research need is for comparative studies of a large variety of woody species and ecosystems under realistic conditions. We still need more long-term experiments on mature trees and stands to address critical scaling issues likely to advance our understanding of responses to elevated CO₂ at different stages of forest development and their interactions with climate and environment. The only tools available at present for coping with the consequences of rising CO₂ are management of resources and selection of genotypes suitable for the future climate and environment.

ScarasciaMugnozza, G., P. DeAngelis, G. Matteucci, and R. Valentini. 1996. Long-term exposure to elevated [CO₂] in a natural *Quercus ilex* L community: Net photosynthesis and photochemical efficiency of PSII at different levels of water stress. *Plant, Cell and Environment* 19(6):643-654.

Naturally grown trees of Mediterranean evergreen oak (*Quercus ilex* L.), representing the climax species of the region, were enclosed in six large open-top chambers and exposed to ambient and elevated CO₂ concentrations during a 3 year period. Maximum daily net photosynthetic rates measured at the two different CO₂ concentrations were from 30 to 100% higher in elevated than in ambient [CO₂] throughout the experimental period. The increase in maximum daily photosynthesis was also accompanied by a 93% rise in the apparent quantum yield of CO₂ assimilation, measured during periods of optimum soil moisture conditions. Hence, no clear evidence of downregulation of net photosynthetic activity was found. Interactions between atmospheric CO₂ concentration and plant water stress were studied by following the natural evolution of drought in different seasons and years. At each level of water stress, the maximum rate of carbon assimilation was higher in elevated than in ambient [CO₂] by up to 100%. Analysis of in vivo chlorophyll fluorescence parameters in normal (21%) and low (2%) oxygen concentrations provided useful insights into

the functioning and stability of the photosynthetic processes, The photochemical efficiency of PSII (F-v/F-m) progressively decreased as drought conditions became more evident; this trend was accentuated under elevated [CO₂]. Thermal de-excitation processes were possibly more significant under elevated than under ambient [CO₂], in a combination of environmental stresses. This research suggests two possible conclusions: (i) a 'positive' interaction between elevated [CO₂] and carbon metabolism can be obtained through relief of water stress limitation in the summer months, and (ii) elevated [CO₂], under drought conditions, may also enhance the significance of slow- relaxing quenching.

Schaffer, B., C. Searle, A.W. Whiley, and R.J. Nissen. 1996. Effects of atmospheric CO₂ enrichment and root restriction on leaf gas exchange and growth of banana (Musa). *Physiologia Plantarum* 97(4):685-693.

The effects of atmospheric CO₂ enrichment and root restriction on photosynthetic characteristics and growth of banana (Musa sp, AAA cv. Gros Michel) plants were investigated. Plants were grown aeroponically in root chambers in controlled environment glasshouse rooms at CO₂ concentrations of 350 or 1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. At each CO₂ concentration, plants were grown in large (200 l) root chambers that did not restrict root growth or in small (20 l) root chambers that restricted root growth. Plants grown at 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ generally had a higher carboxylation efficiency than plants grown at 1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, although actual net CO₂ assimilation (A) was higher at the higher ambient CO₂ concentration due to increased intercellular CO₂ concentrations (C_i) resulting from CO₂ enrichment. Thus, plants grown at 1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ accumulated more leaf area and dry weight than plants grown at 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. Plants grown in the large root chambers were more photosynthetically efficient than plants grown in the small root chambers. At 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, leaf area and dry weights of plant organs were generally greater for plants in the large root chambers compared to those in the small root chambers. Atmospheric CO₂ enrichment may have compensated for the effects of root restriction on plant growth since at 1000 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ there was generally no effect of root chamber size on plant dry weight.

Schaffer, B., A.W. Whiley, C. Searle, and R.J. Nissen. 1997. Leaf gas exchange, dry matter partitioning, and mineral element concentrations in mango as influenced by elevated atmospheric carbon dioxide and root restriction. *Journal of the American Society for Horticultural Science*

122(6):849-855.

The effects of atmospheric CO₂ enrichment and root restriction on net CO₂ assimilation (A), dry mass partitioning, and leaf mineral element concentrations in 'Kensington' and 'Tommy Atkins' mango (*Mangifera indica* L.) were investigated. Trees were grown in controlled-environment glasshouse rooms at ambient CO₂ concentrations of 350 or 700 $\mu\text{mol mol}^{-1}$. At each CO₂ concentration, trees were grown in 8-L containers, which restricted root growth, or grown aeroponically in 200-L root mist chambers, which did not restrict root growth. Trees grown in 350 $\mu\text{mol mol}^{-1}$ CO₂ were more efficient at assimilating CO₂ than trees grown in 700 $\mu\text{mol mol}^{-1}$ CO₂. However, total plant and organ dry mass was generally higher for plants grown at 700 $\mu\text{mol mol}^{-1}$ CO₂ due to increased A as a result of a greater internal partial pressure of CO₂ (C_i) in leaves of plants in the CO₂ enriched environment. Root restriction reduced A resulting in decreased organ and plant dry mass. In root-restricted plants, reduced A and dry matter accumulation offset the increases in these variables resulting from atmospheric CO₂ enrichment. Atmospheric CO₂ enrichment and root restriction did not affect dry mass partitioning. Leaf mineral element concentrations were generally lower for trees grown at the higher ambient CO₂ concentration, presumably due to a dilution effect from an increased growth rate.

Schapendonk, A.H.C.M., P. Dijkstra, J. Groenwold, C.S. Pot, and S.C. vandeGeijn. 1997. Carbon balance and water use efficiency of frequently cut *Lolium perenne* L swards at elevated carbon dioxide. *Global Change Biology* 3(3):207-216.

The impact of doubled atmospheric [CO₂] on the carbon balance of regularly cut *Lolium perenne* L. swards was studied for two years under semi-field conditions in the Wageningen Rhizolab. CO₂ and H₂O vapour exchange rates of the swards were measured continuously for two years in transparent enclosures. The light utilization efficiencies of the swards ranged between 1.5 g CO₂ MJ⁻¹ global radiation (high light, ambient [CO₂]) and 2.8 g CO₂ MJ⁻¹ (low light, doubled [CO₂]). The above-ground net primary productivity (NPP) in the enclosures was greater by 29% in 1994 and 43% in 1995 in the doubled [CO₂] treatments, but only 20% and 25% more carbon was recovered in the periodical cuts. Thus, NPP increased significantly more than did the harvested aboveground biomass. The positive [CO₂] effect on net carbon assimilation is therefore associated with a preferential allocation of extra carbon to the roots and soil. In addition to higher canopy photosynthesis and leaf elongation rates, a small part of the positive [CO₂] effects on NPP could be attributed to a decrease of the specific respiration of the shoots. On a canopy basis however, respiration was equal or slightly higher at doubled [CO₂] due to the higher amount of standing biomass. Comparison of NPP and carbon recovered in different harvests showed that allocation to roots and soil was highest in spring, it was low in early summer and increased again in late summer and autumn. The total gross amount of carbon partitioned to the roots and soil during the two year period was 57% more at doubled [CO₂]. The total amount of carbon that was sequestered in the soil after subtraction of the respiratory losses was 458 g m⁻² and 779 g m⁻² in the ambient and doubled [CO₂] treatments, respectively. The average water use efficiency (WUE) of the swards was increased by a factor 1.5 at doubled [CO₂]. Both WUE and its positive interaction with [CO₂] varied between years and were positively correlated with global irradiance. At doubled [CO₂], the higher WUE was fully compensated for by a higher leaf area index. Therefore, total transpiration on a canopy basis was equal for the ambient and the doubled [CO₂] concentrations in both years.

Schapendonk, A.H.C.M., W. Stol, D.W.G. van Kraalingen, and B.A.M. Bouman. 1998. LINGRA, a sink/source model to simulate grassland productivity in Europe. *European Journal of Agronomy* 9(2-3):87-100.

A simulation model for the prediction of the productivity of *Lolium perenne* L. grasslands is described and validated. Simulated key processes are light utilization, leaf formation, leaf elongation, tillering, and carbon partitioning (storage, shoot, root). Source- and sink-limited growth are simulated independently. Sink-limited growth is characterized by temperature-dependent leaf expansion and tiller development, whereas source-limited growth is determined by photosynthetic light-use-efficiency of the canopy and the remobilization of stored carbohydrates in the stubble. At each integration step, commonly 1 day, the available amount of carbon from the source is compared with the carbon required by the sink. The actual growth is determined by the minimum value of either the sink or the source. If the source is in excess of the sink, the surplus is allocated to storage carbohydrates in the stubble. This storage carbon is available for remobilization at times that the sink requires more carbohydrates than are available from photosynthesis. In contrast to previous grassland models, LINGRA describes regrowth after defoliation in a mechanistic way, balanced by temperature-driven remobilization of stored carbohydrates. In order to validate LINGRA, an extensive set of experimental data was used, derived from measurements at 35 sites in Europe. The average error between the observed and predicted yields was 14% at the level of irrigated, and 19% at the level of non-irrigated, treatments for the whole of Europe. Schappi, B. 1996. Growth dynamics and population development in an alpine grassland under elevated CO₂. *Oecologia* 106(1):93-99.

Leaf expansion, population dynamics and reproduction under elevated CO₂ were studied for two dominant and four subdominant species in a high alpine grassland (2500 above sea level, Swiss Central Alps). Plots of alpine heath were exposed to 335 $\mu\text{mol l}^{-1}$ and 680 $\mu\text{mol l}^{-1}$ CO₂ in open-top chambers over three growing seasons. Treatments also included natural and moderately improved mineral nutrient supply (40 kg N ha⁻¹ year⁻¹ in an NPK fertilizer mix). Seasonal dynamics of leaf expansion, which was studied for the dominant graminoid *Carex curvula* only, were not affected by elevated CO₂ during two warm seasons or during a cool season. Improved nutrient supply increased both the expansion rate and the duration of leaf growth but elevated CO₂ did not cause any further stimulation. Plant and tiller density (studied in all species) increased under elevated CO₂ in the codominant *Leontodon helveticus* and the subdominant *Trifolium alpinum*, remained unchanged in two other minor species *Poa alpina* and *Phyteuma globulariifolium*, and decreased in *Carex curvula*. In *Potentilla aurea* elevated CO₂ compensated for a natural decline in shoot number. By year 3 the number of fertile shoots in *Leontodon* and individual seed weight in *Carex* were slightly increased under elevated CO₂, indicating CO₂ effects on sexual reproduction in these two dominant species. The results suggest that the effects of elevated CO₂ on the population dynamics of the species studied were not general, but species-specific and rather moderate effects. However, the reduction of tiller density in *Carex*

curvula, in contrast to the increases observed in *Leontodon helveticus* and *Trifolium alpinum*, indicates that elevated CO₂ may negatively affect the abundance of the species most characteristic of this alpine plant community.

Schappi, B., and C. Korner. 1996. Growth responses of an alpine grassland to elevated CO₂. *Oecologia* 105(1):43-52.

Alpine plant species have been shown to exhibit a more pronounced increase in leaf photosynthesis under elevated CO₂ than lowland plants. In order to test whether this higher carbon fixation efficiency will translate into increased biomass production under CO₂ enrichment we exposed plots of narrow alpine grassland (Swiss Central Alps, 2470 m) to ambient (355 $\mu\text{mol l}^{-1}$) and elevated (680 $\mu\text{mol l}^{-1}$) CO₂ concentration using open top chambers. Part of the plots received moderate mineral nutrient additions (40 kg ha⁻¹ year⁻¹) of nitrogen in a complete fertilizer mix). Under natural nutrient supply CO₂ enrichment had no effect on biomass production per unit land area during any of the three seasons studied so far. Correspondingly, the dominant species *Carex curvula* and *Leontodon helveticus* as well as *Trifolium alpinum* did not show a growth response either at the population level or at the shoot level. However, the subdominant generalistic species *Poa alpina* strongly increased shoot growth (+47%). Annual root production (in ingrowth cores) was significantly enhanced in *C. curvula* in the 2nd and 3rd year of investigation (+43%) but was not altered in the bulk samples for all species. Fertilizer addition generally stimulated above-ground (+48%) and below-ground (+26%) biomass production right from the beginning. Annual variations in weather conditions during summer also strongly influenced above-ground biomass production (19-27% more biomass in warm seasons compared to cool seasons). However, neither nutrient availability nor climate had a significant effect on the CO₂ response of the plants. Our results do not support the hypothesis that alpine plants, due to their higher carbon uptake efficiency, will increase biomass production under future atmospheric CO₂ enrichment, at least not in such late successional communities. However, as indicated by the response of *P. alpina*, species-specific responses occur which may lead to altered community structure and perhaps ecosystem functioning in the long-term. Our findings further suggest that possible climatic changes are likely to have a greater impact on plant growth in alpine environments than the direct stimulation of photosynthesis by CO₂. Counter-intuitively, our results suggest that even under moderate climate warming or enhanced atmospheric nitrogen deposition positive biomass responses to CO₂ enrichment of the currently dominating species are unlikely.

Schappi, B., and C. Korner. 1997. In situ effects of elevated CO₂ on the carbon and nitrogen status of alpine plants. *Functional Ecology* 11(3):290-299.

1. The effect of elevated CO₂ on tissue composition in an alpine grassland (Swiss Central Alps, 2500m) under both natural and increased nutrient supply (NPK) is summarized. 2. During 3 years of CO₂ enrichment the concentration of total non- structural carbohydrates (TNC) in leaves increased by 32% in *Leontodon helveticus* (largely sugar) and by 56% in *Trifolium alpinum* (largely starch) but did not

change significantly in the dominant sedge *Carex curvula* and in *Poa alpina*, currently a rare species at this site. 3. Enhanced mineral nutrient supply (unlike elevated CO₂) greatly stimulated growth but did not reduce the CO₂-induced TNC accumulation. 4. Under elevated CO₂ nitrogen concentrations (per g TNC-free dry matter) of green leaves decreased in *Leontodon* (-21%) and in *Trifolium* (-24%) but not or only slightly in *Carex* and in *Pea*. NPK addition compensated this CO₂ effect on a nitrogen concentration in *Trifolium* but not in the other species. 5. In below-ground tissue neither TNC nor nitrogen concentration responded to CO₂ fertilization. 6. The nitrogen pool per unit land area at peak season biomass remained unaffected by the CO₂ treatment. 7. Overall our results suggest that the late successional dominant sedge *Carex curvula* remains unaffected by elevated CO₂, independently of mineral nutrient supply, whereas the co-dominant and sub-dominant forbs *Leontodon helveticus* and *Trifolium alpinum* show both an increase of TNC as well as N depletion under elevated CO₂. 8. None of these changes in active plant tissue translate into compositional changes in naturally senesced litter suggesting caution with predictions of CO₂ effects on decomposition based on data from green plant material.

Schenk, U., H.J. Jager, and H.J. Weigel. 1996. Nitrogen supply determines responses of yield and biomass partitioning of perennial ryegrass to elevated atmospheric carbon dioxide concentrations. *Journal of Plant Nutrition* 19(10-11):1423-1440.

Perennial ryegrass (*Lolium perenne* L. cv. Parcour) grown at eight levels of nitrogen (N) fertilization (0-765 mg/pot) was exposed to ambient (390 ppm) and elevated (690 ppm) carbon dioxide (CO₂) concentrations for 83 days. Plants were cut three times and dry matter yields determined for each harvest. At final harvest, dry weight of root and stubble biomass was determined, as N concentrations of all plant fractions were determined. Carbon dioxide enrichment effects on yield and total plant biomass increased with increasing N fertilization. The weaker CO₂-related yield enhancement at low N supply was due to the plants inability to increase tiller number. Root fraction of total plant biomass at final harvest was increased by high CO₂ and decreased by N supply. Root biomass was significantly increased by CO₂ enrichment and for both CO₂ treatments the N supply for maximum root mass coincided with the N supply for reaching maximum total plant biomass. A significant correlation between root fraction of total plant dry matter and N concentration of total plant biomass, which was not changed by CO₂ enrichment, indicates that biomass partitioning between shoot and root is controlled by the internal N status of the plant.

Schenk, U., H.J. Jager, and H.J. Weigel. 1997. The response of perennial ryegrass white clover mini-swards to elevated atmospheric CO₂ concentrations: effects on yield and fodder quality. *Grass and Forage Science* 52(3):232-241.

In order to assess the effects of future elevated atmospheric CO₂ concentrations on yield, mineral content and the nutritive value of mixed swards of perennial ryegrass (*Lolium perenne* L.) and white clover (*Trifolium repens* L.), both species were grown as monocultures and as different mixtures and were exposed season-long to ambient (380 p.p.m.) and elevated (670 p.p.m.) CO₂ concentrations in open-top

chambers. Mini-swards were cut four times at about monthly intervals at a height of 5 cm, dry-matter yields were determined and content of macrolelements (N, P, K, S, Mg, Ca, Na) and crude fibre, crude protein and ash content were measured. The CO₂-related increase in seasonal yield amounted to 16-38% for white clover monocultures, 12-29% for mixed swards and 5-9% for ryegrass monocultures. The white clover content of all swards was significantly enhanced by elevated CO₂. The K and Na content of total yield was decreased by high CO₂ but did not fall below the minimum requirements for ruminants. As the Ca content of total yield was increased by elevated CO₂ and the P content was not changed, the Ca/P ratio of total yield was increased and exceeded values required for animal nutrition. The crude protein content of total yield was reduced by high CO₂ at the beginning of the growing season only and was increased by elevated CO₂ in the course of the experiment, whereas crude fibre content was decreased through out the season, sometimes falling below the minimum requirement for ruminants. Removal of N, P, S, Mg and Ca by cutting was significantly enhanced because of CO₂ enrichment. The results show that, besides the positive effect of rising atmospheric CO₂ on dry-matter yield of white clover/ryegrass swards, impacts on the nutritive value should be expected. Possible changes in species composition and implications for grassland management are briefly discussed.

Schenk, U., H.J. Jager, and H.J. Weigel. 1997. The response of perennial ryegrass/white clover swards to elevated atmospheric CO₂ concentrations. 1. Effects on competition and species composition and interaction with N supply. *New Phytologist* 135(1):67-79.

The effects of long-term carbon dioxide enrichment on competition for nutrients and light in a ryegrass/clover association were determined for simulated swards of perennial ryegrass (*Lolium perenne* L. cv. Parcour) and white clover (*Trifolium repens* L. cv. Karina), which were grown as monocultures and in three mixtures (25/75, 50/50, 75/25), according to the replacement design, at two levels of nitrogen (N) supply (no additional N and 200 kg N ha⁻¹) and at season-long ambient (380 ppm) and elevated (670 ppm) CO₂ concentrations, in open-top chambers. Stands were cut four times, at about monthly intervals, to a height of 5 cm. Plant material was separated into different species, fresh and dry weights were determined and the content of macrolelements (N, P, K, S, Mg) in both species was measured. In addition, plant height of both species at harvest dates and during several regrowth periods was monitored. Results indicate that both species made demand on different resources and profited from growth in a mixed sward. CO₂-related yield increase amounted to 16-42% for white clover whereas the effect of high CO₂ on ryegrass yield ranged between -33% and +9% depending on N supply, mixture and year. As a result the contribution of white clover to total yield in mixed swards was significantly enhanced by CO₂ enrichment at many harvests in both N supply treatments. Without additional N supply, shoot competition for light was intensified by CO₂ enrichment to the disadvantage of ryegrass, since clover petioles grew longer and ryegrass was shorter at elevated CO₂. With N fertilization, no marked effect of CO₂ enrichment on interspecific competition could be observed. Since clover and total yield were increased by CO₂ enrichment, nutrient requirements were also increased and potassium deficiency and increased intraspecific competition of clover for K was observed in the mixtures under elevated CO₂ which had the highest nutrient withdrawal. Although white clover profited much more from CO₂ enrichment in both N fertilization treatments, the suppression of ryegrass in mixed swards could only be observed under low N conditions. Generally, the effect of N fertilization on competitive interference between both species was much greater than the effect of

CO₂ enrichment and it is suggested that the effect of elevated CO₂ on the balance of species and the outcome of competition in a grass/clover sward is mainly dependent on the N status.

Schenk, U., R. Manderscheid, J. Hugen, and H.J. Weigel. 1995. Effects of CO₂ enrichment and intraspecific competition on biomass partitioning, nitrogen-content and microbial biomass carbon in soil of perennial ryegrass and white clover. *Journal of Experimental Botany* 46(289):987-993.

Seedlings of perennial ryegrass (*Lolium perenne* L. cv. Parcour) and white clover (*Trifolium repens* L. cv. Karina) grown at five different plant densities were exposed to ambient (390 ppm) and elevated (690 ppm) CO₂ concentrations. After 43 d the effects of CO₂ enrichment and plant density on growth of shoot and root, nitrogen concentration of tissue, and microbial biomass carbon (C-mic) in soil were determined. CO₂ enrichment of *Lolium perenne* increased shoot growth on average by 17% independent of plant density, while effects on root biomass ranged between -4% and +107% due to an interaction with plant density. Since tiller number per plant was unaffected by elevated CO₂, the small response of shoot growth to CO₂ enrichment was attributed to low sink strength. A significant correlation between nitrogen concentration of total plant biomass and root fraction of total plant dry matter, which was not changed by CO₂ enrichment, indicates that nitrogen status of the plant controls biomass partitioning and the effect of CO₂ enrichment on root growth. Effects of elevated CO₂ and plant density on shoot and root growth of *Trifolium repens* were not significantly interacting and mean CO₂ related increase amounted to 29% and 66%, respectively. However, growth enhancement due to elevated CO₂ was strongest when leaf area index was lowest. Total amounts of nitrogen in shoots and roots were bigger at 690 ppm than at 390 ppm CO₂. There was a significant increase in C-mic in experiments with both species whereas plant density had no substantial effect.

Scherzer, A.J., J. Rebbeck, and R.E.J. Boerner. 1998. Foliar nitrogen dynamics and decomposition of yellow-poplar and eastern white pine during four seasons of exposure to elevated ozone and carbon dioxide. *Forest Ecology and Management* 109(1-3):355-366.

Yellow-poplar (*Liriodendron tulipifera* L.) and eastern white pine (*Pinus strobus* L.) seedlings growing in two plantations were fumigated from 1992 to 1995 in open-top chambers with charcoal-filtered air (CF), ambient air (chamberless), one time ambient ozone (1X), twice ambient ozone (2X), or twice ambient ozone+twice ambient CO₂ (2X+CO₂). Across all treatments and years, concentrations of foliar nitrogen (N) in yellow-poplar averaged 26.3 mg g⁻¹ in June and decreased to 13.8 mg g⁻¹ just prior to leaf senescence. While leaves from all treatments exhibited similar seasonal reductions, actual N concentrations were greatly affected by treatment. Ozone (O-3) alone did not significantly alter foliar N concentrations; however, 2X+CO₂ decreased N concentrations by 18-40% depending on time of sampling. After one season of fumigation, 2X+CO₂-exposed leaves of yellow-poplar decayed significantly more slowly than leaves from all other treatments. In contrast, white pine needles demonstrated few differences in N

concentrations or decomposition during the first 3 years of fumigation. By the fourth season, 2X-CO₂-air significantly reduced N concentrations of current year needles. In needles grown in CF air N concentrations ranged from 14.8 mg g⁻¹ in June to 17.2 mg g⁻¹ in October. 2X+CO₂-air reduced N levels in white pine by 10- 23% depending on time of sampling. For both species, significant differences in N due to leaf age and canopy position must be taken into consideration when evaluating the data. Our experiments indicate that elevated CO₂ in the presence of elevated O-3 can reduce foliar N concentrations and reduce litter decay, thus affecting nutrient cycling. (C) 1998 Elsevier Science B.V.

Schier, G.A., and C.J. McQuattie. 1998. Effects of carbon dioxide enrichment on response of mycorrhizal pitch pine (*Pinus rigida*) to aluminum: growth and mineral nutrition. *Trees-Structure and Function* 12(6):340-346.

Carbon dioxide enrichment may increase the Al tolerance of trees by increasing root growth, root exudation and/or mycorrhizal colonization. The effect of elevated CO₂ on the response of mycorrhizal pitch pine (*Pinus rigida* Mill.) seedlings to Al was determined in two experiments with different levels of nutrients, 0.1- or 0.2-strength Clark solution. During each experiment, seedlings inoculated with the ectomycorrhizal fungus *Pisolithus tinctorius* (Pers.) Coker & Couch were grown 13 weeks in sand irrigated with nutrient solution (pH 3.8) containing 0, 6.25, 12.5, or 25 mg/l Al (0, 232, 463, or 927 µM Al) in growth chambers fumigated with 350 (ambient) or 700 (elevated) µl/l CO₂. At ambient CO₂ in the absence of Al, mean total dry weights (DW) of seedlings at the high nutrient level were 164% higher than those at the low level. Total DW at elevated CO₂, in the absence of Al, was significantly greater than that in ambient CO₂ at the low (+34%) and high (+16%) nutrient levels. Root and shoot DW at both nutrient levels decreased with increasing Al concentrations with Al reducing root growth more than shoot growth. Although visible symptoms of Al toxicity in roots and needles were reduced by CO₂ enrichment, there were no significant CO₂ x Al interactions for shoot or root DW. The percentage of seedling roots that became mycorrhizal was negatively related to nutrient level and was greater at elevated than at ambient CO₂ levels. Generally, elevated CO₂ had little effect on concentration of mineral nutrients in roots and needles. Aluminum reduced concentrations of most nutrients by inhibiting uptake.

Schimel, D.S. 1995. Terrestrial biogeochemical cycles - global estimates with remote-sensing. *Remote Sensing of Environment* 51(1):49-56.

The carbon and nitrogen cycles are crucial for understanding the changing Earth system, influencing atmospheric concentrations of greenhouse gases, primary productivity of the biosphere, and biogenic emissions of reactive trace species. The carbon budget of the terrestrial biosphere has attracted special attention because of its role in atmospheric changes in carbon dioxide. The terrestrial biosphere influences atmospheric CO₂ through three main modes: First, large, nearly balanced fluxes of CO₂ in photosynthesis and respiration exhibit a degree of interannual variability which can influence atmospheric CO₂, at least on annual to decadal time scales. Second, land use changes release CO₂ to the atmosphere. Third, poorly understood processes are

likely resulting in enhanced uptake of CO₂ in certain ecosystems, acting as a sink in the global carbon cycle. This sink may result from forest demographics, atmospheric N deposition, or direct CO₂ fertilization, or some synergistic combination of those processes. Global estimates of terrestrial carbon cycle components requires the use of remote observations; however, the appropriate remote sensing strategies are quite different for the various components.

Schimel, D.S. 1995. Terrestrial ecosystems and the carbon-cycle. *Global Change Biology* 1(1):77-91.

The terrestrial biosphere plays an important role in the global carbon cycle. In the 1994 Intergovernmental Panel Assessment on Climate Change (IPCC), an effort was made to improve the quantification of terrestrial exchanges and potential feedbacks from climate, changing CO₂, and other factors; this paper presents the key results from that assessment, together with expanded discussion. The carbon cycle is the fluxes of carbon among four main reservoirs: fossil carbon, the atmosphere, the oceans, and the terrestrial biosphere. Emissions of fossil carbon during the 1980s averaged 5.5 Gt C y⁻¹. During the same period, the atmosphere gained 3.2 Gt C y⁻¹, and the oceans are believed to have absorbed 2.0 Gt C y⁻¹. The regrowing forests of the Northern Hemisphere may have absorbed 0.5 Gt C y⁻¹ during this period. Meanwhile, tropical deforestation is thought to have released an average 1.6 Gt C y⁻¹ over the 1980s. While the fluxes among the four pools should balance, the average 1980s values lead to a 'missing sink' of 1.4 Gt C y⁻¹. Several processes, including forest regrowth, CO₂ fertilization of plant growth (c. 1.0 Gt C y⁻¹), N deposition (c. 0.6 Gt C y⁻¹), and their interactions, may account for the budget imbalance. However, it remains difficult to quantify the influences of these separate but interactive processes. Uncertainties in the individual numbers are large, and are themselves poorly quantified. This paper presents detail beyond the IPCC assessment on procedures used to approximate the flux uncertainties. Lack of knowledge about positive and negative feedbacks from the biosphere is a major limiting factor to credible simulations of future atmospheric CO₂ concentrations. Analyses of the atmospheric gradients of CO₂ and (CO₂)-C-13 concentrations provide increasingly strong evidence for terrestrial sinks, potentially distributed between Northern Hemisphere and tropical regions, but conclusive detection in direct biomass and soil measurements remains elusive. Current regional-to-global terrestrial ecosystem models with coupled carbon and nitrogen cycles represent the effects of CO₂ fertilization differently, but all suggest long-term responses to CO₂ that are substantially smaller than potential leaf- or laboratory whole plant-level responses. Analyses of emissions and biogeochemical fluxes consistent with eventual stabilization of atmospheric CO₂ concentrations are sensitive to the way in which biospheric feedbacks are modeled by c. 15%. Decisions about land use can have effects of 100s of Gt C over the next few centuries, with similarly significant effects on the atmosphere. Critical areas for future research are continued measurements and analyses of atmospheric data (CO₂ and (CO₂)-C-13) to serve as large-scale constraints, process studies of the scaling from the photosynthetic response to CO₂ to whole-ecosystem carbon storage, and rigorous quantification of the effects of changing land use on carbon storage.

Schindler, D.W., and S.E. Bayley. 1993. The biosphere as an increasing sink for atmospheric carbon - estimates from increased nitrogen deposition. *Global Biogeochemical Cycles* 7(4):717-733.

Estimates of carbon uptake and storage based on global nitrogen deposition, C:N ratios for typical terrestrial ecosystems, and recent ecosystem-scale nutrient studies indicate that 1.0-2.3 Gt C yr⁻¹ of carbon storage may be stimulated by anthropogenically caused increases in nitrogen deposition in the past century. Sixty four to eighty four percent of global nitrogen uptake appears to occur on northern continents, with the remainder largely in northern coastal oceans. Increased nitrogen input by terrestrial ecosystems causes increased accumulation of carbon as plant tissue, with C:N ratios generally 50 to 200:1. Calculations suggest that northern continents are a major sink for carbon and that nitrogen-stimulated carbon uptake may more or less balance global carbon losses to the atmosphere from deforestation and agriculture. Much of the uptake appears to occur in aggrading forests, and the question of how long it can continue has important consequences for global carbon budgets.

Schlesinger, W.H. 1993. Response of the terrestrial biosphere to global climate change and human perturbation. *Vegetatio* 104:295-305.

Despite 20 years of intensive effort to understand the global carbon cycle, the budget for carbon dioxide in the atmosphere is unbalanced. To explain why atmospheric CO₂ is not increasing as rapidly as it should be, various workers have suggested that land vegetation acts as a sink for carbon dioxide. Here, I examine various possibilities and find that the evidence for a sink of sufficient magnitude on land is poor. Moreover, it is unlikely that the land vegetation will act as a sink in the postulated warmer global climates of the future. In response to rapid human population growth, destruction of natural ecosystems in the tropics remains a large net source of CO₂ for the atmosphere, which is only partially compensated by the potential for carbon storage in temperate and boreal regions. Direct and inadvertent human effects on land vegetation might increase the magnitude of regional CO₂ storage on land, but they are unlikely to play a significant role in moderating the potential rate of greenhouse warming in the future.

Schmid, R., R. Forster, and M.J. Dring. 1992. Circadian-rhythm and fast responses to blue-light of photosynthesis in ectocarpus (phaeophyta, ectocarpales) .2. Light and co₂ dependence of photosynthesis. *Planta* 187(1):60-66.

Photosynthesis of *Ectocarpus siliculosus* (Dillwyn) Lyngb. under continuous saturating red irradiation follows a circadian rhythm. Blue-light pulses rapidly stimulate photosynthesis with high effectiveness in the troughs of this rhythm but the effectiveness of such pulses is much lower at its peaks. In an attempt to understand how blue light and the rhythm affected photosynthesis, the effects of inorganic carbon on photosynthetic light saturation curves were studied under different irradiation conditions. The circadian rhythm of photosynthesis was apparent only at irradiances which were not limiting for photosynthesis. The same was found for blue-light-stimulated photosynthesis, although

stimulation was observed also under very low red-light irradiances after a period of adaptation, provided that the inorganic-carbon concentration was not in excess. Double-reciprocal plots of light-saturated photosynthetic rates versus the concentration of total inorganic carbon (up to 10 mM total inorganic carbon) were linear and had a common constant for half-saturation (3.6 mM at pH 8) at both the troughs and the peaks of the rhythm and before and after blue-light pulses. Only at very low carbon concentrations was a clear deviation found from these lines for photosynthesis at the rhythm maxima (red and blue light), which indicated that the strong carbon limitation specifically affected photosynthesis at the peak phases of the rhythm. Very high inorganic carbon concentrations (20 mM) in the medium diminished the responses to blue light, although they did not fully abolish them. The kinetics of the stimulation indicate that the rate of photosynthesis is affected by two blue-light-dependent components with different time courses of induction and decay. The faster component seemed to be at least partially suppressed at red-light irradiances which were not saturating for photosynthesis. Lowering the pH of the medium had the same effects as an increase of the carbon concentration to levels of approx. 10 mM. This indicates that *Ectocarpus* takes up free CO₂ only and not bicarbonate, although additional physiological mechanisms may enhance the availability of CO₂.

Schmitt, V., A. Kussmaul, and A. Wild. 1999. Interaction of elevated CO₂ and ozone concentrations and irrigation regimes on leaf anatomy and carbohydrate status of young oak (*Quercus petraea*) trees. *Zeitschrift Fur Naturforschung C-A Journal of Biosciences* 54(9-10):812-823.

Young sessile oak (*Quercus petraea*) trees were exposed for one vegetation period in closed environmental chambers in a crossed factorial study on effects to varied CO₂ concentrations, ozone concentrations and irrigation treatments. Elevated CO₂ concentrations (ambient + 350 μ mol mol⁻¹) caused a significant increase in biomass production, alterations in leaf anatomy and chloroplast ultrastructure as well as an increase in leaf starch content, as compared to ambient CO₂ concentrations. The effects of elevated O₃ concentrations and drought stress were far less distinct. The leaf starch content was influenced by CO₂ and O₃ in a synergistic manner.

Schneider, S.H., and T.L. Root. 1996. Ecological implications of climate change will include surprises. *Biodiversity and Conservation* 5(9):1109-1119.

In addition to assessing the impacts of CO₂ doubling on environment and society, more consideration is needed to estimate extreme events or 'surprises'. This is particularly important at the intersection of disciplines like climate and ecology because the potential for large discontinuities is high given all the possible climate/biota interactions. The vast disparities in scales encountered by those working in traditional ecology (typically 20 m) and climatology (typically 200 km) make diagnoses of such interactions difficult, but these can be addressed by an emerging research paradigm we call strategic cyclical scaling (SCS). The need to anticipate outlier events and assign them subjective probabilities suggests emphasis on interdisciplinary research associations. The desire to reduce societal vulnerability to such events suggests the need to build adaptive management and diverse economic activities into social organizations. The effectiveness of adaptation responses to anticipated

climatic changes is complicated when consideration of transient changes, regional disturbances, large unforeseeable natural fluctuations and surprises are considered. Slowing down the rate of disturbances and decreasing vulnerability are advocated as the most prudent responses to the prospect of human-induced climatic changes.

Scholes, M.C., D. Powlson, and G.L. Tian. 1997. Input control of organic matter dynamics. *Geoderma* 79(1-4):25-47.

The amount and quality of inputs into soil organic matter will be altered by both climate and landuse change. The increase in growth of plants caused by increasing CO₂ concentration implies not only potential increases in yields but also increases in plant residues. Simulation models using doubled CO₂ levels predict global net primary productivity (NPP) to increase by 16.3%, over half of which will occur in the tropics. For tropical ecosystems increases in NPP will be dominated by the effects of elevated CO₂, with water and nitrogen availability and temperature playing a less significant role. Phosphorus limitation may determine whether the potential for increased plant growth will be realized. The distribution of C₃ and C₄ species in the tropics could be affected by landuse change and estimates of yield increases will be dependent on their proportions. The allocation of photosynthate to the root will increase under elevated CO₂, resulting in increased fine root dry weight and root length. Root sink strength and the turnover of roots and associated symbionts are critical knowledge gaps. Carbon:nitrogen ratios in tissues will increase resulting in decreased decomposition rates. The concentration of secondary compounds will be affected more by nitrogen limitations than a direct CO₂ effect. Changes in lignin, tannin and polyphenol levels are more important in the decomposability of tropical liners than changes in the C:N ratios. Decomposition models will have to be altered to take into account changes in plant composition. The role of models in predicting the effects of management practice on long-term fertility is addressed. (C) 1997 Elsevier Science B.V.

Scholes, R.J., and N. vanBreemen. 1997. The effects of global change on tropical ecosystems. *Geoderma* 79(1-4):9-24.

Alteration of land use will continue to be the dominant driver of environmental change in the tropics for the next several decades. It can take the form of fundamental vegetation cover transformation, or of intensification of existing land use without substantial change in cover type. Atmospheric composition changes and resultant climate changes could become ecologically significant within the next century. Changes in atmospheric composition in the tropics are essentially the same as those in higher latitudes, despite differences in the source and sink strengths for trace gases. Such changes can affect the functioning of tropical ecosystems through several processes, principally those related to carbon and nutrient assimilation and their interactions. Atmospheric composition may also have an indirect affect on tropical ecosystems via its effects on the climate. Predicted temperature increases in the tropics are less extreme than at high latitudes, but could still be biologically significant, especially at the tropical margins. The structure and productivity of ecosystems of the subhumid and dry tropics are very sensitive to changes in water balance, which could be caused by a combination of changes in precipitation and temperature. It is presently not possible to predict rainfall changes at ecologically meaningful scales

with any confidence. (C) 1997 Elsevier Science B.V.

Schortemeyer, M., O.K. Atkin, N. McFarlane, and J.R. Evans. 1999. The impact of elevated atmospheric CO₂ and nitrate supply on growth, biomass allocation, nitrogen partitioning and N₂ fixation of *Acacia melanoxylon*. *Australian Journal of Plant Physiology* 26(8):737-747.

The interactive effects of nitrate supply and atmospheric CO₂ concentration on growth, N₂ fixation, dry matter and nitrogen partitioning in the leguminous tree *Acacia melanoxylon* R. Br. were studied. Seedlings were grown hydroponically in controlled-environment cabinets for 5 weeks at seven N-15- labelled nitrate levels, ranging from 3 to 6400 mmol m⁻³. Plants were exposed to ambient (similar to 350 μ mol mol⁻¹) or elevated (similar to 700 μ mol mol⁻¹) atmospheric CO₂ for 6 weeks. Total plant dry mass increased strongly with nitrate supply. The proportion of nitrogen derived from air decreased with increasing nitrate supply. Plants grown under either ambient or elevated CO₂ fixed the same amount of nitrogen per unit nodule dry mass (16.6 mmol N per g nodule dry mass) regardless of the nitrogen treatment. CO₂ concentration had no effect on the relative contribution of N₂ fixation to the nitrogen yield of plants. Plants grown with greater than or equal to 50 mmol m⁻³ N and elevated CO₂ had approximately twice the dry mass of those grown with ambient CO₂ after 42 days. The rates of net CO₂ assimilation under growth conditions were higher per unit leaf area for plants grown under elevated CO₂. Elevated CO₂ also decreased specific foliage area, due to an increase in foliage thickness and density. Dry matter partitioning between plant organs was affected by ontogeny and nitrogen status of the plants, but not by CO₂ concentration. In contrast, plants grown under elevated CO₂ partitioned more of their nitrogen to roots. This could be attributed to reduced nitrogen concentrations in foliage grown under elevated CO₂.

Schortemeyer, M., U.A. Hartwig, G.R. Hendrey, and M.J. Sadowsky. 1996. Microbial community changes in the rhizospheres of white clover and perennial ryegrass exposed to free air carbon dioxide enrichment (FACE). *Soil Biology and Biochemistry* 28(12):1717-1724.

Increases in the global atmospheric concentration of CO₂ will not only directly affect the growth of plants, but might also alter the living conditions for soil biota. This could lead to shifts in the size and composition of the soil microbial communities. In this study we investigated the response of heterotrophic bacteria, NH₄⁺-oxidising bacteria, and *Rhizobium leguminosarum* by. *trifolii* populations to elevated atmospheric CO₂ concentrations in a model field-scale grassland ecosystem. The Free Air CO₂ Enrichment (FACE) facility in Eschikon, Switzerland, releases CO₂-enriched air into three large circular areas, each of 18 m dia, to a final CO₂ concentration of 600 μ mol mol⁻¹, while three control areas of the same size receive ambient CO₂ concentrations (similar to 350 μ mol mol⁻¹). For this study, white clover (*Trifolium repens* L.) and perennial ryegrass (*Lolium perenne* L.) were grown as replicated monocultures within the FACE rings. Soil samples were taken from 0-10 cm depth in May and November 1994 (the second year of CO₂-enrichment), and rhizosphere soil was obtained from clover and ryegrass roots for enumeration of bacteria. While the total numbers of culturable heterotrophic bacteria (determined by plate counts) in the rhizospheres of both plant species

were little affected by CO₂-enrichment, the populations of *R. leguminosarum* by. *trifolii* (enumerated by MPN) were increased two-fold in the rhizospheres of white clover exposed to elevated atmospheric CO₂. There was no effect of the CO₂ concentration on the populations of *R. leguminosarum* by. *trifolii* in the rhizospheres of perennial ryegrass, indicating that the increase of *Rhizobium* numbers is a host-related response to elevated atmospheric CO₂. The numbers of autotrophic NH₄⁺-oxidizing bacteria in the rhizospheres (enumerated by MPN) were unaffected by the atmospheric CO₂ concentration. There was also no effect of the CO₂ concentration on the amount of microbial biomass C in the bulk, non-rhizosphere soils in white clover or perennial ryegrass plots. These data indicate that under a legume crop, at least in terms of inoculum quality in the rhizosphere soil, symbiotic nitrogen-fixing organisms might be favoured by elevated atmospheric CO₂ concentrations. Schrope, M.K., J.P. Chanton, L.H. Allen, and J.T. Baker. 1999. Effect of CO₂ enrichment and elevated temperature on methane emissions from rice, *Oryza sativa*. *Global Change Biology* 5(5):587-599.

Methane emissions from rice grown within Temperature Gradient Greenhouse Tunnels under doubled CO₂ concentrations were 10-45 times less than emissions from control plants grown under ambient CO₂. For two cultivars of rice (cvs. Lemont and IR-72), methane emissions increased with a temperature increase of 2 degrees, from outdoor ambient temperatures to the first cell of the ambient CO₂ tunnel (ambient temperature + 2 degrees C). Within both tunnels and for both cultivars methane emissions decreased with further temperature increases (from 2 degrees to 5 degrees C above ambient). Carbon dioxide enrichment stimulated both above- and below-ground production. Our original hypothesis was that increased CO₂ would stimulate plant productivity and therefore stimulate methane emission, since direct linkages between these parameters have been observed. We hypothesize that CO₂ enrichment led to the attenuation of methane production due to increased delivery of oxygen to the rhizosphere because of increased root biomass and porosity. The increased root biomass due to elevated CO₂ may have more effectively aerated the soil, suppressing methane production. However, this study may be unique because the low organic content (<1%) of the sandy soils in which the rice was grown created very little oxygen demand.

Schulte, M., C. Herschbach, and H. Rennenberg. 1998. Interactive effects of elevated atmospheric CO₂, mycorrhization and drought on long-distance transport of reduced sulphur in young pedunculate oak trees (*Quercus robur* L.). *Plant, Cell and Environment* 21(9):917-926.

Pedunculate oak (*Quercus robur* L.) was germinated and grown under nutrient non-limiting conditions for a total of 10-15 weeks at ambient CO₂ concentration and 1100 μ mol mol⁻¹ CO₂ either in the presence or the absence of the mycorrhizal fungus *Laccaria laccata*. Half of the oak trees of these treatments were exposed to drought during final growth by suspending the water supply for 21 d. Mycorrhization and elevated atmospheric CO₂ each enhanced total plant biomass per tree. Whereas additional biomass accumulation of trees grown under elevated

CO₂ was mainly attributed to increased growth of lateral roots, mycorrhization promoted shoot growth. Water deficiency reduced biomass accumulation without affecting relative water content, but this effect was more pronounced in mycorrhizal as compared to non-mycorrhizal trees. Elevated CO₂ partially prevented the development of drought stress, as indicated by leaf water potential, but did not counteract the negative effects of water deficiency on growth during the time studied. Enhanced biomass accumulation requires adaption in protein synthesis and, as a consequence, enhanced allocation of reduced sulphur produced in the leaves to growing tissues. Therefore, allocation of reduced sulphur from oak leaves was studied by flap-feeding radiolabelled GSH, the main long-distance transport form of reduced sulphur, to mature oak leaves. Export of radiolabel proceeded almost exclusively in basipetal direction to the roots. The rate of export of radioactivity out of the fed leaves was significantly enhanced under elevated CO₂, irrespective of mycorrhization. A higher proportion of the exported GSH was transported to the roots than to basipetal stem sections under elevated CO₂ as compared to ambient CO₂. Mycorrhization did not affect S-35 export out of the fed leaves, but the distribution of radiolabel between stem and roots was altered in preference of the stem. Trees exposed to drought did not show appreciable export of the S-35 radioactivity fed to the leaves when grown under ambient CO₂. Apparently, drought inhibited basipetal transport of reduced sulphur at the level of phloem loading and/or phloem transport. Elevated CO₂ seemed to counteract this effect of drought stress to some extent, since higher leaf water potentials and improved S-35 export out of the fed leaves was observed in oak trees exposed to drought and elevated CO₂ as compared to trees exposed to drought and ambient CO₂.

Schwanz, P., K.H. Haberle, and A. Polle. 1996. Interactive effects of elevated CO₂, ozone and drought stress on the activities of antioxidative enzymes in needles of Norway spruce trees (*Picea abies*, [L.] Karsten) grown with luxurious N- supply. *Journal of Plant Physiology* 148(3-4):351-355.

The aim of the present study was to address the complex interactions of environmental constraints, ozone and drought stress, with elevated atmospheric CO₂ on the activities of antioxidative enzymes and soluble protein contents in needles of Norway spruce trees (*Picea abies* L.). Five-year-old spruce trees were kept from bud break in June until January of the following year in phytochambers under climatic conditions similar to those of a natural site in the Bavarian forest. The trees were well-supplied with nitrogen and exposed to either elevated CO₂ (ambient + 200 µmol L⁻¹), elevated ozone (80 nL L⁻¹), from June to October) or to a combination of both factors. Controls were grown with 20 nL L⁻¹ O₃ and ambient CO₂ levels. In each chamber, a subset of trees was subjected to episodic drought stress in summer. Needles from controls investigated in October (summer conditions) and January (winter conditions) showed little seasonal variation of superoxide dismutase (SOD), an approximately 2-fold reduction in catalase (CAT), and a 2-fold increase in guaiacol peroxidase (POD) activity. Exposure to elevated CO₂ did not affect the activities of any of these enzymes in October and January, respectively, but caused a significant reduction in soluble protein. Ozone had no significant effect. Drought stress caused memory effects. In January, needles from trees drought-stressed in summer contained higher activities of defence enzymes and soluble protein contents than needles from well-watered trees. Three weeks after the end of a drought episode in summer, needles from spruce trees grown at elevated CO₂ contained increased CAT and POD activities as compared to needles from trees grown at ambient CO₂. This response was increased, if elevated ozone was present as an additional stress

factor. These observations suggest that Norway spruce trees grown under elevated atmospheric CO₂ concentrations might better be able to compensate environmental stresses than trees grown at ambient atmospheric CO₂ concentrations.

Schwanz, P., B.A. Kimball, S.B. Idso, D.L. Hendrix, and A. Polle. 1996. Antioxidants in sun and shade leaves of sour orange trees (*Citrus aurantium*) after long-term acclimation to elevated CO₂. *Journal of Experimental Botany* 47(305):1941-1950.

Antioxidative systems and the contents of pigments, malondialdehyde, soluble protein, and carbohydrate were investigated in sun- and shade-acclimated leaves of sour orange (*Citrus aurantium*) trees that had been grown for 7.5 years under ambient and elevated (+300 µmol mol⁻¹) atmospheric CO₂ concentrations. Sun-acclimated leaves contained higher ascorbate, glutathione and soluble carbohydrate contents and higher catalase activities than shade-acclimated leaves. The activities of superoxide dismutases, which belonged to the family of Cu/Zn-isozymes, were similar in sun- and shade-acclimated leaves and decreased in response to enhanced CO₂. In shade-acclimated leaves, none of the other parameters studied was affected by elevated CO₂. In sun-acclimated leaves elevated CO₂ caused increases in carbohydrate and ascorbate contents. There was no evidence for enhanced lipid peroxidation as assessed from the determination of the malondialdehyde contents under either conditions.

Schwanz, P., C. Picon, P. Vivin, E. Dreyer, J.M. Guehl, and A. Polle. 1996. Responses of antioxidative systems to drought stress in pendunculate oak and maritime pine as modulated by elevated CO₂. *Plant Physiology* 110(2):393-402.

The aim of the present study was to investigate the effects of an enhanced CO₂ concentration alone or in combination with drought stress on antioxidative systems of a deciduous (oak; *Quercus robur*) and an evergreen (pine; *Pinus pinaster*) tree species. The seedlings were grown for one season in a greenhouse in tunnels supplied with 350 or 700 µmol L⁻¹ CO₂. The experiment was repeated in a second year. Antioxidants, protective enzymes, soluble protein, and pigments showed considerable fluctuations in different years. Elevated CO₂ caused significant reductions in the activities of superoxide dismutases in both oak and pine. The activities of ascorbate peroxidase and catalase were also reduced in most cases. The activities of dehydroascorbate reductase, monodehydroascorbate radical reductase, glutathione reductase, and guaiacol peroxidase were affected little or not at all by elevated CO₂. When the trees were subjected to drought stress by withholding water, the activities of antioxidative enzymes decreased in leaves of pine and oak grown at ambient CO₂ and increased in plants grown at elevated CO₂ concentrations. The present results suggest that growth in elevated CO₂ might reduce oxidative stress to which leaf tissues are normally exposed and enhance metabolic flexibility to encounter increased stress by increases in antioxidative capacity.

Schwanz, P., and A. Polle. 1998. Antioxidative systems, pigment and protein contents in leaves of adult Mediterranean oak species (*Quercus pubescens* and *Q. ilex*) with lifetime exposure to elevated CO₂. *New Phytologist* 140(3):411-423.

The aim of the present study was to investigate the effects of elevated CO₂ on the antioxidative systems and the contents of pigments, soluble protein and lipid peroxidation in leaves of adult oaks, *Quercus pubescens* and *Quercus ilex*, grown at naturally enriched CO₂ concentrations. For this purpose, a field study was conducted at two CO₂ springs in Central Italy. Measurements of the pre-dawn water potentials indicated less drought stress in trees close to CO₂ springs than in those grown at ambient CO₂ concentrations. Most leaf constituents investigated showed significant variability between sampling dates, species and sites. The foliar contents of protein and chlorophylls were not affected in trees grown close to the CO₂ vents compared with those in ambient conditions. Increases in glutathione and other soluble thiols were observed, but these responses might have been caused by a low pollution of the vents with sulphurous gases. At CO₂ vents, glutathione reductase was unaffected, and superoxide dismutase activity was significantly diminished, in both species. Generally, the activities of catalase, guaiacol peroxidase and ascorbate peroxidase as well as the sum of dehydroascorbate and ascorbate were decreased in leaves from trees grown in naturally CO₂-enriched environments compared with those grown at ambient CO₂ concentrations. The reduction in protective enzymes did not result in increased lipid peroxidation, but increased monodehydroascorbate radical reductase and dehydroascorbate reductase activities found in leaves of *Q. pubescens* suggest that the smaller pool of ascorbate was subjected to higher turnover rates. These data show that changes in leaf physiology persist, even after lifetime exposure to enhanced atmospheric CO₂. The results suggest that the down-regulation of protective systems, which has also previously been found in young trees or seedlings under controlled exposure to elevated CO₂ concentrations, might reflect a realistic response of antioxidative defences in mature trees in a future high-CO₂ world.

Schwartz, M.W. 1992. Potential effects of global climate change on the biodiversity of plants. *The Forestry Chronicle* 68(4):462-471.

Climatologists have observed a consistent increase in atmospheric CO₂ over the past 30 years. It is predicted that CO₂ levels could double the pre-industrial level of 280 ppm by the year 2100, perhaps much earlier. Climate models of doubled atmospheric CO₂ predict that mean temperatures will increase between 1.5 and 4.5-degrees-C globally; these temperature changes will be greater at high latitudes. Mid-continental regions will experience lower rainfall. Predictions of species northward range shifts in response to climate change vary from 100 km to over 500 km. Historical evidence of species range movements following the Pleistocene indicate that tree species typically migrated at rates of 10 km to 40 km per century. A simulation model that predicts the migration response of trees through modern fragmented landscapes predicts migration rates much lower than Pleistocene observations. Thus migration response is likely to lag far behind rates of climatic change, potentially threatening narrowly distributed species whose predicted future ranges do not overlap with their current range. Insect pests and microbial pathogens should respond to climatic warming faster than long-lived trees. Predicted increased drought frequency may increase plant stress and thereby increase the frequency of insect outbreaks and disease. Predictions of species responses are complicated by direct effects of increased CO₂, such as increased water-use efficiency. However, response to elevated CO₂ varies among species. Thus, shifts

in composition within plant communities are also likely, but are, as yet, unpredictable.

Scurlock, J.M.O., and D.O. Hall. 1998. The global carbon sink: a grassland perspective. *Global Change Biology* 4(2):229-233.

The challenge to identify the biospheric sinks for about half the total carbon emissions from fossil fuels must include a consideration of below-ground ecosystem processes as well as those more easily measured above-ground. Recent studies suggest that tropical grasslands and savannas may contribute more to the 'missing sink' than was previously appreciated, perhaps as much as 0.5 Pg (= 0.5 Gt) carbon per annum. The rapid increase in availability of productivity data facilitated by the Internet will be important for future scaling-up of global change responses, to establish independent lines of evidence about the location and size of carbon sinks.

Seaton, K.A., and D.C. Joyce. 1993. Effects of low-temperature and elevated CO₂ treatments and of heat-treatments for insect disinfestation on some native-australian cut flowers. *Scientia Horticulturae* 56(2):119-133.

For bioassay insects, 14 days storage at 1-degrees-C was required for 100% kill of adult flour beetles (*Tribolium confusum* Koch.), and 10 days at 1-degrees-C killed 100% of Mediterranean fruit fly larvae (*Ceratitis capitata* Wied.). A CO₂ enriched atmosphere of between 45% and 60% (11% and 8% O₂, respectively) reduced the time required to achieve 100% mortality of these bioassay insects to 7 days at 1-degrees-C. Increasing the CO₂ content of the atmosphere to 80% (4% O₂) did not further reduce the time to achieve 100% mortality. Vase life of red kangaroo paw (*Anigozanthos rufus*) was reduced below that of the unstored control after just 3.5 days at 1-degrees-C. Geraldton wax (*Chamaelucium uncinatum*) cultivar 'Newmarracarra' was similarly affected after 14 days, and acorn banksia (*Banksia prionotes*) after 28 days. Vase lives of Geraldton wax cultivar 'Newmarracarra' and of red kangaroo paw were not reduced following 7 days storage at 1-degrees-C in 15% CO₂, compared with controls stored in air. However, Geraldton wax and red kangaroo paw vase lives were shortened and flower colour was altered after storage for 7 days in 30% CO₂ (15% O₂). Geraldton wax and red kangaroo paw had no vase lives following storage in 80% CO₂ (4% O₂) at 1-degrees-C for 3.5 days. Heat treatments of hot water dips (46-degrees-C for 30 min or 56-degrees-C for 10 min) and vapour heat (66-degrees-C for 10 min) killed 100% of adult flour beetles and Mediterranean fruit fly larvae, but damaged and shortened the vase lives of Geraldton wax and banksia.

Seegmuller, S., and H. Rennenberg. 1994. Interactive effects of mycorrhization and elevated carbon-dioxide on growth of young pedunculate oak (*Quercus robur* L.) trees. *Plant and Soil* 167(2):325-329.

Pedunculate oak (*Quercus robur* L.) was germinated and grown at ambient CO₂ level and 650 ppmv CO₂ in the presence and absence of the ectomycorrhizal fungus *Laccaria laccata* for a total of 6 months under

nutrient non-limiting conditions. Mycorrhization and elevated atmospheric CO₂ each supported the growth of the trees. Stem height, stem diameter, and dry matter accumulation of pedunculate oak were increased by mycorrhization. Elevated atmospheric CO₂ enhanced stem height, stem diameter, fresh weight and dry weight, as well as lateral root formation of the trees. In combination, mycorrhization and elevated atmospheric CO₂ had a more than additive, positive effect on tree height and biomass accumulation, and further improved lateral root formation of the trees. From these findings it is suggested that the efficiency of the roots in supporting the growth of the shoot is increased in mycorrhized oak trees at elevated atmospheric CO₂.

Seegmuller, S., M. Schulte, C. Herschbach, and H. Rennenberg. 1996. Interactive effects of mycorrhization and elevated atmospheric CO₂ on sulphur nutrition of young pedunculate oak (*Quercus robur* L.) trees. *Plant, Cell and Environment* 19(4):418-426.

Pedunculate oak (*Quercus robur* L.) was germinated and grown at ambient CO₂ concentration and 650 $\mu\text{mol mol}^{-1}$ CO₂ in the presence and absence of the ectomycorrhizal fungus *Laccaria laccata* for a total of 22 weeks under non-limiting nutrient conditions. Sulphate uptake, xylem loading and exudation were analysed in excised roots. Despite a relatively high affinity for sulphate ($K_M = 1.6 \text{ mmol m}^{-3}$), the rates of sulphate uptake by excised lateral roots of mycorrhizal oak trees were low as compared to herbaceous plants. Rates of sulphate uptake were similar in mycorrhizal and non-mycorrhizal roots and were not affected by growth of the trees at elevated CO₂. However, the total uptake of sulphate per plant was enhanced by elevated CO₂ and further enhanced by elevated CO₂ and mycorrhization. Sulphate uptake seemed to be closely correlated with biomass accumulation under the conditions applied. The percentage of the sulphate taken up by mycorrhizal oak roots that was loaded into the xylem was an order of magnitude lower than previously observed for herbaceous plants. The rate of xylem loading was enhanced by mycorrhization and, in roots of mycorrhizal trees only, by growth at elevated CO₂. On a whole-plant basis this increase in xylem loading could only partially be explained by the increased growth of the trees. Elevated CO₂ and mycorrhization appeared to increase greatly the sulphate supply of the shoot at the level of xylem loading. For all treatments, calculated rates of sulphate exudation were significantly lower than the corresponding rates of xylem loading of sulphate. Radiolabelled sulphate loaded into the xylem therefore seems to be readily diluted by unlabelled sulphate during xylem transport. Allocation of reduced sulphur from oak leaves was studied by flap-feeding radiolabelled GSH to mature oak leaves. The rate of export of radioactivity from the fed leaves was 4.5 times higher in mycorrhizal oak trees grown at elevated CO₂ than in those grown at ambient CO₂. Export of radiolabel proceeded almost exclusively in a basipetal direction to the roots. From these experiments it can be concluded that, in mycorrhizal oak trees grown at elevated CO₂, the transport of sulphate to the shoot is increased at the level of xylem loading to enable increased sulphate reduction in the leaves. Increased sulphate reduction seems to be required for the enhanced allocation of reduced sulphur to the roots which is observed in trees grown at elevated CO₂. These changes in sulphate and reduced sulphur allocation may be a prerequisite for the positive effect of elevated CO₂ on growth of oak trees previously observed.

Segal, M., P. Alpert, U. Stein, M. Mandel, and M.J. Mitchell. 1994. Some assessments of the potential 2 X CO₂ climatic effects on water-balance components in the eastern mediterranean. *Climatic Change* 27(4):351-371.

General circulation model (GCM) coarse evaluations of the climatological impact in the Eastern Mediterranean due to global doubling of the atmospheric CO₂ concentration were used as input for a preliminary estimation of modifications in local processes affecting the water balance in this region. It is suggested that: (i) in the 2 x CO₂ climate the average regional change of precipitation associated with typical mid-winter cyclonic systems is relatively small, however, it is associated with redistribution of the regional rainfall; (ii) in the elevated terrain in the northern part of the region, daytime snowmelt due to warm air advection may be enhanced, as much as 2.8 cm per day; and (iii) transpiration in the coastal area of the Eastern Mediterranean may increase by approximately 13% of its current level in the summer and somewhat more in the winter.

Seginer, I., C. Gary, and M. Tchamitchian. 1994. Optimal temperature regimes for a greenhouse crop with a carbohydrate pool - a modeling study. *Scientia Horticulturae* 60(1-2):55-80.

A simple crop model with two state variables, namely structural biomass and carbohydrate pool, was used to explore the effect of alternative temperature regimes on greenhouse crop production. Assuming a repeated environmental cycle, certain qualitative predictions could be made. (1) The smaller the plants and the higher the light integral and CO₂ enrichment, the higher are the temperatures which lead to maximum production. (2) Day temperatures higher than night temperatures usually lead to higher production. On winter days, however, an inverse temperature regime may result in energy saving without loss of production. (3) Temperature variations may often be tolerated, provided that the mean temperature (temperature integral) is maintained at the level appropriate for maximum production. A limited amount of published experimental data was used to fit the model, leading to a satisfactory agreement.

Sehmer, L., V. Fontaine, F. Antoni, and P. Dizengremel. 1998. Effects of ozone and elevated atmospheric carbon dioxide on carbohydrate metabolism of spruce needles. Catabolic and detoxification pathways. *Physiologia Plantarum* 102(4):605-611.

We have studied the effects of ozone, carbon dioxide and ozone combined with carbon dioxide fumigations on catabolic and detoxification pathways in spruce (*Picea abies* [L.] Karst.) needles. The results obtained showed an increase in the activities of three enzymes involved in the detoxification pathway, superoxide dismutase (SOD, EC 1.15.1.1), ascorbate peroxidase (AsCPD, EC 1.11.1.11) and glutathione reductase (GR, EC 1.6.4.2) when trees were exposed to ozone and to ozone-carbon dioxide treatments. In these two treatments, the fraction of SOD activity due to the chloroplastic isoform was increased (1.5-fold). In the needles of trees exposed to ozone and to ozone-carbon dioxide fumigation, an increase in the activities of glucose-6-phosphate dehydrogenase (G-6-PDH, EC 1.1.1.49) showed that the cell had the capacity to produce more NADPH necessary for the detoxification. Stimulation of other enzymes of catabolic pathways (fumarase [EC 4.2.1.2], phosphofructokinase [PFK, EC 7.1.1] and

phosphoenolpyruvate carboxylase [PEPC, EC 4.1.1.31]), was also observed making it possible for the cell to provide the reducing power necessary for detoxification as well as energy and carbon skeletons involved in the repair processes. When carbon dioxide alone was applied, no effects could be detected on these enzyme activities. However, when carbon dioxide was combined with ozone, the effect of ozone on trees was less than that induced by ozone alone, suggesting that elevated atmospheric carbon dioxide concentrations may to some extent protect plants from ozone injury.

Seko, Y., and M. Nishimura. 1996. Effect of CO₂ and light on survival and growth of rice regenerants grown in vitro on sugar-free medium. *Plant Cell Tissue and Organ Culture* 46(3):257-264.

Rice (*Oryza sativa* L.) plantlets regenerated from callus (rice regenerants) were grown in vitro during the preparation stage either on a 1/4 strength N6 gellan gum (4 g l⁻¹) medium without sucrose (SFM) or with 30 g l⁻¹ sucrose (SCM), and under CO₂ concentrations of 0.4, 2, 10, 50 or 100 mmol mol⁻¹, a photoperiod of 24 h and a photosynthetic photon flux density (PPFD) of 125 μ mol m⁻² s⁻¹. Rice regenerants were also grown in vitro on SFM or SCM under CO₂ concentration of 50 mmol mol⁻¹, a photoperiod of 12 or 24 h and a PPFD of 80 or 125 μ mol m⁻² s⁻¹. All rice regenerants grew successfully on SFM under CO₂ concentrations of 50 or 100 mmol mol⁻¹. Increasing the CO₂ concentration increased the survival percentage, shoot length and shoot and root dry weights of rice regenerants grown on SFM. Increasing CO₂ concentration had no significant effect on the survival or growth of rice regenerants grown on SCM. Survival percentages of rice regenerants grown on SCM were less than 80% for each of the CO₂ concentrations. A photoperiod of 24 h under CO₂ enrichment improved the survival and growth of rice regenerants grown on SFM, and increased the survival percentage and shoot dry weight of rice regenerants grown on SCM.

Seligman, N.G., and T.R. Sinclair. 1995. Global environment change and simulated forage quality of wheat .2. Water and nitrogen stress. *Field Crops Research* 40(1):29-37.

Forage crops are frequently subjected to stress conditions resulting from inadequate supplies of water and N. Because forages grown under these stress conditions constitute an important resource in animal agriculture, this study was undertaken to assess possible changes in the nutritive value and productivity of forage crops as a consequence of global environment change. A relatively simple, mechanistic model of wheat was extended to simulate growth and important determinants of feed quality ([N], leaf:stem, dry matter digestibility) in an annual, temperate climate C-3 forage grass. Weather data for a semiarid region and different levels of applied N were used to examine the response of forage productivity to various levels of water and N availability. Not surprisingly, responses to global environment change were highly dependent on the availability of both water and N. When either resource was available at low levels, production of digestible dry matter was nearly unchanged by elevated [CO₂] or increased temperature. When compared at equivalent development stages, small increases in forage quality were simulated, mainly because higher temperature resulted in achievement of the initiation of grain fill at an earlier date. As N

availability increased, differences in forage characteristics and productivity became more prominent. Elevated ambient [CO₂] increased vegetative mass, digestible dry matter, and concentration of digestible dry matter but decreased leaf:stem and [N]. Increased temperature generally had an effect on forage traits that was opposite to the elevated [CO₂] response. The combined effects of both factors sometimes cancelled each other, but usually one of the factors was dominant. Negative effects of temperature tended to be aggravated by dry conditions. At crop maturity, positive effects of elevated atmospheric [CO₂] on forage productivity and quality were severely decreased by nutrient and physiological constraints. These simulations indicate that when forage crops are grown under irrigation in semiarid regions, there may be substantial and complex changes in productivity and feed quality as a consequence of warmer temperature and elevated atmospheric [CO₂]. Under rainfed conditions, these differences could be quite erratic and virtually unpredictable within the current range of interannual variation in forage productivity and quality.

BOREAS in 1997: Experiment overview, scientific results, and future directions. *Journal of Geophysical Research-Atmospheres* 102(D24):28731-28769.

The goal of the Boreal Ecosystem-Atmosphere Study (BOREAS) is to improve our understanding of the interactions between the boreal forest biome and the atmosphere in order to clarify their roles in global change. This overview paper describes the science background and motivations for BOREAS and the experimental design and operations of the BOREAS 1994 and BOREAS 1996 field years. The findings of the 83 papers in this journal special issue are reviewed. In section 7, important scientific results of the project to date are summarized and future research directions are identified.

Sellers, P., F. Hall, H. Margolis, B. Kelly, D. Baldocchi, G. Denhartog, J. Cihlar, M.G. Ryan, B. Goodison, P. Crill, K.J. Ranson, D. Lettenmaier, and D.E. Wickland. 1995. The boreal ecosystem-atmosphere study (boreas) - an overview and early results from the 1994 field year. *Bulletin of the American Meteorological Society* 76(9):1549-1577.

The Boreal Ecosystem Atmosphere Study (BOREAS) is a large-scale international field experiment that has the goal of improving our understanding of the exchanges of radiative energy, heat, water, CO₂, and trace gases between the boreal forest and the lower atmosphere. An important objective of BOREAS is to collect the data needed to improve computer simulation models of the processes controlling these exchanges so that scientists can anticipate the effects of global change. From August 1993 through September 1994, a continuous set of monitoring measurements-meteorology, hydrology, and satellite remote sensing-were gathered over the 1000 x 1000 km BOREAS study region that covers most of Saskatchewan and Manitoba, Canada. This monitoring program was punctuated by six campaigns that saw the

deployment of some 300 scientists and aircrew into the field, supported by 11 research aircraft. The participants were drawn primarily from U.S. and Canadian agencies and universities, although there were also important contributions from France, the United Kingdom, and Russia. The field campaigns lasted for a total of 123 days and saw the compilation of a comprehensive surface-atmosphere flux dataset supported by ecological, trace gas, hydrological, and remote sensing science observations. The surface-atmosphere fluxes of sensible heat, latent heat, CO₂, and momentum were measured using eddy correlation equipment mounted on a surface network of 10 towers complemented by four flux-measurement aircraft. All in all, over 350 airborne missions (remote sensing and eddy correlation) were flown during the 1994 field year. Preliminary analyses of the data indicate that the area-averaged photosynthetic capacity of the boreal forest is much less than that of the temperate forests to the south. This is reflected in very low photosynthetic and carbon drawdown rates, which in turn are associated with low transpiration rates (less than 2 mm day⁻¹ over the growing season for the coniferous species in the area). The strong sensible fluxes generated as a result of this often lead to the development of a deep dry planetary boundary layer over the forest, particularly during the spring and early summer. The effects of frozen soils and the strong physiological control of evapotranspiration in the biome do not seem to be well represented in most operational general circulation models of the atmosphere. Analyses of the data will continue through 1995 and 1996. Some limited revisits to the field are anticipated.

Seneweera, S.P., A.S. Basra, E.W. Barlow, and J.P. Conroy. 1995. Diurnal regulation of leaf blade elongation in rice by CO₂ - is it related to sucrose-phosphate synthase activity. *Plant Physiology* 108(4):1471-1477.

The relationship between leaf blade elongation rates (LER) and sucrose-phosphate synthase (SPS) activity was investigated at different times during ontogeny of rice (*Oryza sativa* L. cv Jarrah) grown in flooded soil at either 350 or 700 µmol L⁻¹ CO₂. High CO₂ concentrations increased LER of expanding blades and in vivo activity (V-limiting) SPS activity of expanded blades during the early vegetative stage (21 d after planting [DAP]), when tiller number was small and growing blades were strong carbohydrate sinks. Despite a constant light environment, there was a distinct diurnal pattern in LER, V-limiting SPS activity, and concentration of soluble sugars, with an increase in the early part of the light period and a decrease later in the light period. The strong correlation ($r = 0.65$) between LER and V-limiting SPS activity over the diurnal cycle indicated that SPS activity played an important role in controlling blade growth. The higher V-limiting SPS activity at elevated CO₂ at 21 DAP was caused by an increase in the activation state of the enzyme rather than an increase in V-max. Fructose and glucose accumulated to a greater extent than sucrose at high CO₂ and may have been utilized for synthesis of cell-wall components, contributing to higher specific leaf weight. By the mid-tillering stage (42 DAP), CO₂ enrichment enhanced V-limiting and V-max activities of source blades. Nevertheless, LER was depressed by high CO₂, probably because tillers were stronger carbohydrate sinks than growing blades.

Seneweera, S., A. Blakeney, P. Milham, A.S. Basra, E.W.R. Barlow, and J. Conroy. 1996. Influence of rising atmospheric CO₂ and phosphorus nutrition on the grain yield and quality of rice (*Oryza sativa* cv. Jarrah). *Cereal Chemistry* 73(2):239-243.

Raising the atmospheric CO₂ concentration from 350 µmol L⁻¹ of CO₂ per liter to a level expected by the end of the next century (700 µmol L⁻¹) influenced both the grain yield and quality of the short-duration rice (*Oryza sativa*) cultivar, Jarrah. Yield was enhanced by up to 58%, primarily due to an increase in grain number, although grain size was also greater at high CO₂. Varying the supply of phosphorus influenced the magnitude of the CO₂ response with greatest responses occurring at medium rather than luxury or low phosphorus supplies. However, yield enhancement by high CO₂ was observed even when phosphorus supply was severely growth limiting. Chemical (amylose and nutrient concentration) and physical (relative paste viscosity) measurements made on the ground grain indicated that cooked rice grain from plants grown under high levels of CO₂ would be firmer. The nutritive value of grain was also changed at high CO₂ due to a reduction in grain nitrogen and, therefore, protein concentration. However, total nitrogen content per grain was unaffected by high CO₂. In contrast, phosphorus content per grain was greater at high CO₂ and there was a strong correlation between magnesium and phosphorus concentrations. These results indicate that there is a need to plan for the inevitable rise in atmospheric CO₂ concentrations by selecting genotypes that will maintain suitable quality characteristics under global change.

Seneweera, S.P., and J.P. Conroy. 1997. Growth, grain yield and quality of rice (*Oryza sativa* L.) in response to elevated CO₂ and phosphorus nutrition (Reprinted from Plant nutrition for sustainable food production and environment, 1997). *Soil Science and Plant Nutrition* 43:1131-1136.

The influence of rising atmospheric CO₂ concentrations and phosphorus nutrition on growth, grain yield and quality of a early maturing rice cultivar (*Oryza sativa* L. cv. Jarrah) was investigated by growing plants in a range of phosphorus levels at either 350 or 700 µmol L⁻¹ CO₂ in the growth chambers. Total above ground biomass and grain yield were greater at elevated CO₂ concentrations and with increasing phosphorus supply. The CO₂ response was evident at all but the lowest phosphorus treatments but its magnitude was greater at moderate phosphorus supplies. The increase in grain yield at high CO₂ was due mainly to an enhancement of tiller number. The phosphorus concentration in the foliage was unaffected by CO₂ enrichment and the critical concentration of 1.8 g kg⁻¹ dwt was the same as reported for field-grown rice. The concentration of calcium in the foliage was increased by high CO₂ and the nitrogen concentration was reduced. Chemical analysis (amylose and mineral concentration) indicated that cooked rice grain from high-CO₂-grown plants would be firmer and that concentrations of Zn and Fe, which are important in the diet of humans, will be lower. These results indicate that there is a need to plan for the inevitable rise in global CO₂ concentrations by selecting cultivars which will be more productive and yet maintain suitable quality characteristics under elevated CO₂ levels.

Seneweera, S.P., O. Ghannoum, and J. Conroy. 1998. High vapour pressure deficit and low soil water availability enhance shoot growth responses of a C-4 grass (*Panicum coloratum* cv. Bambatsi) to CO₂ enrichment. *Australian Journal of Plant Physiology* 25(3):287-292.

The hypothesis that shoot growth responses of C-4 grasses to elevated CO₂ are dependent on shoot water relations was tested using a C-4 grass, *Panicum coloratum* (NAD-ME subtype). Plants were grown for 35 days at CO₂ concentrations of 350 or 1000 µmol L⁻¹. Shoot water relations were altered by growing plants in soil which was brought daily

to 65, 80 or 100% field capacity (FC) and by maintaining the vapour pressure deficit (VPD) at 0.9 or 2.1 kPa. At 350 $\mu\text{mol L}^{-1}$ CO₂, high VPD and lower soil water content depressed shoot dry mass, which declined in parallel at each VPD with decreasing soil water content. The growth depression at high VPD was associated with increased shoot transpiration, whereas at low soil water, leaf water potential was reduced. Elevated CO₂ ameliorated the impact of both stresses by decreasing transpiration rates and raising leaf water potential. Consequently, high CO₂ approximately doubled shoot mass and leaf length at a VPD of 2.1 kPa and soil water contents of 65 and 80% FC but had no effect on unstressed plants. Water use efficiency was enhanced by elevated CO₂ under conditions of stress but this was primarily due to increases in shoot mass. High CO₂ had a greater effect on leaf growth parameters than on stem mass. Elevated CO₂ increased specific leaf area and leaf area ratio, the latter at high VPD only. We conclude that high CO₂ increases shoot growth of C-4 grasses by ameliorating the effects of stress induced by either high VPD or low soil moisture. Since these factors limit growth of field-grown C-4 grasses, it is likely that their biomass will be enhanced by rising atmospheric CO₂ concentrations.

Seneweera, S., P. Milham, and J. Conroy. 1994. Influence of elevated CO₂ and phosphorus-nutrition on the growth and yield of a short-duration rice (*Oryza-sativa* L. CV Jarrah). *Australian Journal of Plant Physiology* 21(3):281-292.

The growth and development of a short-duration rice cultivar (*Oryza sativa* L. cv. Jarrah), grown in flooded soil with a range of phosphorus (P) levels and exposed to atmospheric CO₂ concentrations of either 350 or 700 $\mu\text{mol L}^{-1}$ was followed for 146 days after planting (DAP). Development (estimated by rate of tiller production and time to flowering) was faster with higher soil P levels and CO₂ enrichment, the effect being more pronounced with CO₂ enrichment. During the early vegetative phase (up to 35 DAP), when rates of tiller production were low, shoot growth and rates of leaf expansion were faster at elevated CO₂ concentrations and high soil P levels. Rates of tiller production were greater with these treatments during the 35-56 DAP period, when tillering was at a maximum. Shoot elongation was reduced at elevated CO₂ levels and at high soil P levels during this period. By 146 DAP leaf weight was greater at high P levels, but CO₂ enrichment accelerated tiller production to such an extent that final leaf weight was lower at high CO₂, probably because there were fewer, and smaller, leaves on each tiller. Despite this, grain yield was increased by up to 58% by CO₂ enrichment, with increases occurring even at low soil P levels. This was due mainly to an increase in grain number per panicle, although panicle number also increased. Higher soil P levels also increased grain number and yield. The P concentration in the foliage was unaffected by the CO₂ treatments and the concentration required to produce maximum yield was 0.18% (dry wt basis) at both CO₂ levels. Greater starch accumulation in the stems of high-CO₂-grown plants may have accounted for the higher number of grains in each panicle.

Senock, R.S., J.M. Ham, T.M. Loughin, B.A. Kimball, D.J. Hunsaker, P.J. Pinter, G.W. Wall, R.L. Garcia, and R.L. LaMorte. 1996. Sap flow in wheat under free-air CO₂ enrichment. *Plant, Cell and Environment* 19(2):147-158.

The effects of elevated carbon dioxide (CO₂) concentration on plant water use are best evaluated on plants grown under field conditions and

with measurement techniques that do not disturb the natural function of the plant, seat balance sap flow gauges were used on individual main stems of wheat (*Triticum aestivum* L. cv Yecora rojo) grown under normal ambient conditions (control) and in a free-air CO₂ enrichment (FACE) system in Arizona with either high (control+high H₂O=CW; FACE+high H₂O=FW) or low (control+low H₂O=CD; FACE+low H₂O=FD) irrigation regimens. Over a 30d period (stem elongation to anthesis), combinations of treatments were monitored with 10-40 gauges per treatment. The effects of increased CO₂ on tiller water use were inconsistent in both the diurnal patterns of sap flow and the statistical analyses of daily sap flow (F-tot). Initial results suggested that the reductions in F-tot from CO₂ enrichment were small (0-10%) in relation to the H₂O treatment effect (20-30%). For a 3d period, F-tot of FW was 19-26% less than that of CW (P=0.10). Examination of the different sources of variation in the study revealed that the location of gauges within the experimental plots influenced the variance of the sap flow measurements. This variation was probably related to positional variation in subsurface drip lines used to irrigate plots. A sampling design was proposed for use of sap flow gauges in FACE systems with subsurface irrigation that takes into account the main treatment effects of CO₂ enrichment and the other sources of variation identified in this study. Despite the small and often statistically non-significant differences in F-tot between the CW and FW treatments, cumulative water use of the FW treatment at the end of the first three test periods ranged from 7 to 23% lower than that of the CW treatment. Differences in sap flow between FW and CW compared well with treatment differences in evapotranspiration. The results of the study, based on the first reported sap flow measurements of wheat, suggest that irrigation requirements for wheat production, in the present climatic regimen of the south-western US, may be predicted to decrease slightly because of increasing atmospheric CO₂.

Serraj, R., L.H. Allen, and T.R. Sinclair. 1999. Soybean leaf growth and gas exchange response to drought under carbon dioxide enrichment. *Global Change Biology* 5(3):283-291.

This study was conducted to determine the response in leaf growth and gas exchange of soybean (*Glycine max*: Merr.) to the combined effects of water deficits and carbon dioxide (CO₂) enrichment. Plants grown in pots were allowed to develop initially in a glasshouse under ambient CO₂ and well-watered conditions. Four-week old plants were transferred into two different glasshouses with either ambient (360 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) CO₂. Following a 2-day acclimation period, the soil of the drought-stressed pots was allowed to dry slowly over a 2-week period. The stressed pots were watered daily so that the soil dried at an equivalent rate under the two CO₂ levels. Elevated [CO₂] decreased water loss rate and increased leaf area development and photosynthetic rate under both well-watered and drought-stressed conditions. There was, however, no significant effect of [CO₂] in the response relative to soil water content of normalized leaf gas exchange and leaf area. The drought response based on soil water content for transpiration, leaf area, and photosynthesis provide an effective method for describing the responses of soybean physiological processes to the available soil water, independent of [CO₂].

Serraj, R., T.R. Sinclair, and L.H. Allen. 1998. Soybean nodulation and N-2 fixation response to drought under carbon dioxide enrichment.

The combined effects of carbon dioxide (CO₂) enrichment and water deficits on nodulation and N-2 fixation were analysed in soybean [*Glycine max* (L.) Merr.]. Two short-term experiments were conducted in greenhouses with plants subjected to soil drying, while exposed to CO₂ atmospheres of either 360 or 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$. Under drought-stressed conditions, elevated [CO₂] resulted in a delay in the decrease in N₂ fixation rates associated with drying of the soil used in these experiments. The elevated [CO₂] also allowed the plants under drought to sustain significant increases in nodule number and mass relative to those under ambient [CO₂]. The total non-structural carbohydrate (TNC) concentration was lower in the shoots of the plants exposed to drought; however, plants under elevated CO₂ had much higher TNC levels than those under ambient CO₂. For both [CO₂] treatments, drought stress induced a substantial accumulation of TNC in the nodules that paralleled N-2 fixation decline, which indicates that nodule activity under drought may not be carbon limited. Under drought stress, ureide concentration increased in all plant tissues. However, exposure to elevated [CO₂] resulted in substantially less drought-induced ureide accumulation in leaf and petiole tissues. A strong negative correlation was found between ureide accumulation and TNC levels in the leaves. This relationship, together with the large effect of elevated [CO₂] on the decrease of ureide accumulation in the leaves, indicated the importance of ureide breakdown in the response of N-2 fixation to drought and of feedback inhibition by ureides on nodule activity. It is concluded that an important effect of CO₂ enrichment on soybean under drought conditions is an enhancement of photoassimilation, an increased partitioning of carbon to nodules and a decrease of leaf ureide levels, which is associated with sustained nodule growth and N-2 rates under soil water deficits. We suggest that future [CO₂] increases are likely to benefit soybean production by increasing the drought tolerance of N-2 fixation.

Sgherri, C.L.M., M.F. Quartacci, M. Menconi, A. Raschi, and F. Navari-Izzo. 1998. Interactions between drought and elevated CO₂ on alfalfa plants. *Journal of Plant Physiology* 152(1):118-124.

Alfalfa (*Medicago sativa* L.) plants were grown in open top chambers at ambient (340 ppm) and high (600 ppm) CO₂ concentrations. Twenty-five days after the first cutting one set of both plants was subjected to water deficit conditions by withholding water for 5 days. A chamber effect on proteolytic activity, monogalactosyl diacylglycerol to digalactosyl diacylglycerol molar ratio, total non-structural carbohydrates and soluble protein contents occurred. In contrast, no change in leaf water potential was observed between plants grown outdoors and inside the chambers. Plants grown at high CO₂ concentration showed a lower decrease in leaf water potential in comparison with plants grown at atmospheric CO₂ when subjected to water stress. Under high CO₂ concentration leaf nitrogen content decreased whereas starch accumulation and a higher proteolytic activity were recorded. Following water depletion, CO₂-enriched plants showed a decrease in total non- structural carbohydrates and soluble proteins. In thylakoid membranes high CO₂ caused an increase in chlorophyll and lipid contents and a degradation of monogalactosyl diacylglycerol. A higher degree of unsaturation in the main thylakoid lipids was also observed. CO₂-enriched plants were less affected by water stress as shown by reduced chlorophyll degradation and a higher membrane stability.

Shafer, S.R., U. Blum, S.J. Horton, and D.L. Hesterberg. 1998. Biomass of tomato seedlings exposed to an allelopathic phenolic acid and enriched atmospheric carbon dioxide. *Water, Air, and Soil Pollution* 106(1-2):123-136.

Increased atmospheric CO₂ can affect plant growth, so competition among plants may be influenced. Allelopathy is one mechanism involved in plant competition. Experiments were conducted in a controlled-environment chamber to determine if the concentration of atmospheric CO₂ altered the dose-response relationship between an allelopathic phenolic acid and tomato seedling biomass. Seeds of *Lycopersicon lycopersicum* were planted in quartz sand in styrofoam cups and allowed to germinate and grow for 15-17 days. During the next 14 days, seedlings were watered twice daily with nutrient solution amended with p-coumaric acid (4-hydroxycinnamic acid, HOC₆H₄CH = CHCO₂H; ranging 0-0.85 mg mL⁻¹); 5 concentrations in each experiment) and exposed 24 hr day⁻¹ in continuous-stirred tank reactors (CSTRs) to ambient air (335-375 ppm CO₂) or ambient air to which 350 ppm CO₂ was added (i.e., approximately twice-ambient CO₂; two CSTRs per CO₂ concentration in each experiment). Dose-response data relating p-coumaric acid concentration and shoot, root, and total biomass were fit to a flexible decay function. In all three experiments, twice- ambient CO₂ significantly increased the y-intercept for the dose-response model for the p-coumaric acid effect on shoot biomass by 25-50% but had negligible effects on other aspects of the models. Results suggest that if CO₂ affects plant competition, mechanisms involving allelopathic phenolic acids may not be involved.

Shainisky, L.J., and S.R. Radosevich. 1992. Mechanisms of competition between douglas-fir and red alder seedlings. *Ecology* 73(1):30-45.

Mechanisms of interactions between Douglas-fir (*Pseudotsuga menziesii*) and red alder (*Alnus rubra*) seedlings were assessed in experimentally manipulated stands. The density of each species was varied systematically, creating a matrix of competitive regimes that consisted of five monoculture densities and 25 mixtures of all possible pairwise combinations of the monoculture densities. Response surfaces for growth rates, leaf area, photon flux density, soil moisture content and depletion, and plant water potential were generated within the matrix. Regression coefficients quantified the effects of species densities on response variables, and correlation analysis yielded insight into interrelationships between variables. Tree performance, leaf area per square metre of ground surface area, resources, and physiological variables were all quantitatively altered by alder density, Douglas-fir density, and the interaction between species densities. Alder was the dominant competitor and overtopped the Douglas-fir. Competition for light was mediated by density effects on the leaf area of each species per square metre of ground surface area. Increasing alder leaf area reduced the light reaching the understory Douglas-fir. In contrast, increasing Douglas-fir leaf areas increased the light penetrating through to the understory conifers, due to Douglas-fir's suppression of alder leaf area per square metre. Soil moisture limitations were also created by increasing the density of both species and resulted in increasingly negative leaf water potentials for both species. Growth rates concurrently declined as plant water stress increased. Response variables were assembled into a conceptual modeling proposing how species density

regulated growth through the interactions between resource limitations and impairment of physiological function.

Sharma, A., and U.K. Sengupta. 1997. Carbon allocation and partitioning in *Vigna radiata* (L.) Wilczek as affected by additional carbon gain. *Photosynthetica* 34(3):419-426.

Carbon allocation to the source leaf export and partitioning to the sink were studied in mungbean supplied by additional carbon from the source leaves subjected to high CO₂ concentrations (600 and 900 cm³ m⁻³) in three metabolic and functional source-sink combinations. The plants were pruned to a source-path-sink system. With CO₂ enrichment there was an appreciable increase in net photosynthetic CO₂ uptake in earlier formed and physiologically younger leaves. Most of the carbon fixed as a result of enrichment was translocated out of the source leaf within one diurnal cycle. The carbon remaining in the source leaf was unchanged. Partitioning of extra carbon into starch or sugar depended upon the amount of extra carbon synthesized. The unloading of the extra carbon into sinks depended on whether it was used for growth or stored. Under increased carbon content, the leaf as a sink was able to reorganize its metabolic reactions more rapidly to maintain the required gradient for unloading than the pod acting as the sink.

Sharma-Natu, P., F.A. Khan, and M.C. Ghildiyal. 1997. Photosynthetic acclimation to elevated CO₂ in wheat cultivars. *Photosynthetica* 34(4):537-543.

Wheat (*T. aestivum*) cvs. Kalyansona and Kundan grown under atmospheric (CA) and elevated CO₂ concentrations (650-150 cm³ m⁻³) - CE in open top chambers were examined for net photosynthetic rate (P-N), stomatal limitation (I(S)) of P-N, ribulose-1,5-bisphosphate carboxylase (RuBPC) activity, and saccharide content of the leaves. The P-N values of both CA- and CE-grown plants compared at the same CO₂ concentration showed a down regulation under CE at the post-anthesis stage. The negative acclimation of P-N appeared to be due to both stomatal and mesophyll components, and the RuBPC activity got also adjusted. There was a decrease in activation state of RuBPC under CE. In connection with this, an increased accumulation of saccharides in wheat leaf under CE was observed. Kalyansona, owing to its larger sink potential in terms of the number of grains, showed a greater enhancement under CE in both post-ear emergence dry matter production and grain yield. Under CE, this cultivar also showed a lower down regulation of P-N than Kundan.

Sheehy, J.E., F. Gastal, P.L. Mitchell, J.L. Durand, G. Lemaire, and F.I. Woodward. 1996. A nitrogen-led model of grass growth. *Annals of Botany* 77(2):165-177.

This model is built by considering the utilization rate of nitrogen as the first step in calculating the rate of growth of the various organs of a grass crop. The amount of carbohydrate determines whether there are sufficient carbon skeletons and sufficient energy available to support synthesis of new material. Growth of roots, tillers/stems and leaves is simulated with leaf divided into photosynthetic and non-photosynthetic structures. The model keeps account of soluble carbohydrate and nitrogen pools in each of the organs and storage pools of carbohydrate in the leaves and roots. The modelled crop has an age structure so that each plant organ has an age profile describing daily changes in growth; when the oldest tissue becomes senescent a fraction of its nitrogen is recycled. Seasonal changes in the percentage nitrogen content of the crop, when large amounts of soil nitrogen are available, are shown to be a consequence of changes in both soluble and stored carbohydrate. The contrast between high and low nitrogen treatments is shown to be a consequence of different allocation priorities for nitrogen. The model demonstrates that considering nitrogen as the primary element of synthesis provides an approach that predicts dry matter production successfully, as well as giving a different perspective of the growth processes, and suggesting that the capacity of the enzymatic processes governing synthesis ultimately limits crop yields. This different perspective may be most useful when trying to understand what controls growth and the relative influence of environmental changes on the physiology and morphology of the crop. Sheppard, M.I., L.L. Ewing, and J.L. Hawkins. 1994. Soil processes and chemical-transport - soil degassing of C-14 dioxide - rates and factors. *Journal of Environmental Quality* 23(3):461-468.

Soil air normally contains elevated levels of CO₂ relative to the atmosphere. The primary source of soil C is plant-root and microbial respiration. The exchange of soil and atmospheric CO₂ is important to many environmental concerns, such as acid rain, global warming and waste management. Proposed disposal of high-level nuclear wastes containing primarily inorganic C-14 may provide a source of (CO₂)-C-14 to the atmosphere. Field and laboratory experiments show that (CO₂)-C-14 Soil degassing rate constants, the flux density (Bq.M².s⁻¹) divided by soil inventory (Bq-m⁻²), range from -10(-7) to -10(-2) S⁻¹, and that the loss of inorganic C-14 is driven primarily by gaseous diffusion. These constants are affected by soil pH and porosity, with smaller influences of soil temperature, moisture and organic matter content. Degassing rate constants derived through mass balance calculations to estimate loss differ only by 20% from direct trapping methods. Frozen soil degassing rate constants were up to 25 times smaller than lab values, indicating that annual C-14 loss rates in northern climates would be lower because of reduced gaseous diffusion during the winter months. Using our field data, we recommend an annual C-14 soil degassing rate constant of -1 x 10(-6) s⁻¹ for acidic soils and a value of -5 x 10(-7) S⁻¹ for calcareous soils. For probabilistic assessment modelling, we recommend a geometric mean degassing constant of -4.3 X 10(-7) S⁻¹ with a geometric standard deviation of 3.26 for three different soils. This indicates the median half-life of C-14

in surface soils is 18 d, with a 99% confidence interval of 13 h and 640 d.

Sheu, B.H., and C.K. Lin. 1999. Photosynthetic response of seedlings of the sub-tropical tree *Schima superba* with exposure to elevated carbon dioxide and temperature. *Environmental and Experimental Botany* 41(1):57-65.

Seedlings of *Schima superba* were exposed to both ambient (375 ppm) and 720 ppm levels of CO₂ in combination with two incubation temperatures (25/20, 30/25 degrees C, day/night) for a six-month period. Net height growth of seedlings was enhanced in the early period of exposure to high levels of CO₂. However, when seedlings were exposed for a longer period of time to this high concentration, net height growth was inhibited. Decreased photosynthetic rate with elevated CO₂ was observed when measured in the ambient CO₂ over a long-term exposure of 6 months. In contrast, a significant increase in photosynthesis was noted for seedlings exposed to higher incubation temperature in either ambient or 720 ppm CO₂ concentrations. The response of CO₂ assimilation to internal C_i was indicated by the lower sensitivity in seedlings grown in elevated CO₂ concentration. Though this response could also be found in a higher sensitivity in seedlings grown at higher temperature, the seedlings grown in normal conditions (ambient CO₂ and temperature) were still more sensitive to CO₂ assimilation response to internal C_i. This experiment suggests that: (1) exposure of seedlings to higher CO₂ levels for longer periods may lead to a decrease in seedling height growth and photosynthetic rate, as well as decreasing sensitivity to changing internal CO₂ concentrations; (2) the optimum temperature for photosynthesis of seedlings grown in an elevated CO₂ concentration was higher than that for seedlings grown in ambient concentration. Shipley, B., M. Lechowicz, S. Dumont, and W.H. Hendershot. 1992. Interacting effects of nutrients, pH-al and elevated co₂ on the growth of red spruce (*picea-rubens sarg*) seedlings. *Water, Air, and Soil Pollution* 64(3-4):585-600.

A 4 mo growth chamber experiment was conducted to evaluate the presence and importance of interactions between nutrient supply, atmospheric CO₂ concentration, and four different combinations of pH - Al concentration on the growth, vitality, and tissue element concentrations of 1-yr-old red spruce seedlings. Solution chemistry was chosen to simulate soil conditions at a red spruce die-back site at Roundtop Mountain (Quebec) that has high acid loadings. CO₂ levels were chosen to simulate ambient levels and those expected in the next century. All three experimental factors affected growth and all factors except CO₂ affected the visual symptoms of die-back. There was an important interaction between nutrient levels and the different pH - Al combinations, indicating that the response of red spruce to various pH and Al concentrations changes with soil fertility. The positive growth response to enriched CO₂ was not sufficient to offset the negative effects of the acid rain induced stresses. A principal component analysis showed that multivariate functions of foliar element concentrations could clearly distinguish plants from different experimental regimes.
