Sicher, R.C. 1997. Irradiance and spectral quality affect chlorosis of barley primary leaves during growth in elevated carbon dioxide. *International Journal of Plant Science* 158(5):602-607.

The development of chlorosis was studied in primary leaves of barley plants (*Hordeum vulgare* L. cv. Brant) grown at ambient and twice-ambient CO₂ partial pressures. Leaf yellowing was observed 17 d after sowing when plants were grown in controlled environment chambers equipped with high-intensity discharge lamps at an irradiance of 800 $\mu\text{mol quanta m}^{-2} \text{s}^{-1}$. The extent of leaf yellowing, measured as changes of total chlorophyll, increased when the CO₂ partial pressure was raised from 37 to 70 Pa. Chlorosis was increased further by increasing the irradiance from 800 to 1100 $\mu\text{mol quanta m}^{-2} \text{s}^{-1}$. Rates of photosynthetic O₂ evolution by primary leaves, measured 17 d after sowing, were 20% lower for elevated compared with ambient CO₂-grown plants. This result agreed with the level of chlorosis. However soluble protein, Rubisco protein (ribulose, 1,5-bisphosphate carboxylase/oxygenase), and initial and total Rubisco activity 17 d after sowing were unaffected by CO₂ enrichment and the extent of chlorosis. Leaf starch, sucrose, and glucose were increased by elevated CO₂ treatment at almost every sampling. However, only glucose was correlated with leaf damage. Leaf yellowing also was observed on primary leaves of plants grown under microwave-powered sulfur lamps at 800 but not at 550 $\mu\text{mol quanta m}^{-2} \text{s}^{-1}$. The extent of leaf yellowing on plants grown under microwave- powered sulfur lamps was unaffected by CO₂ enrichment. It was concluded that leaf yellowing was influenced by irradiance, photoquality, and CO₂ enrichment. Photobleaching of antenna chlorophyll, rather than premature senescence, was the most likely cause of visible leaf injury in barley.

Sicher, R.C. 1998. Yellowing and photosynthetic decline of barley primary leaves in response to atmospheric CO₂ enrichment. *Physiologia Plantarum* 103(2):193-200.

The photosynthetic response of barley (*Hordeum vulgare* L. cv. Brant) primary leaves was studied as a function of chlorosis induced by CO₂ enrichment. Leaf yellowing; measured as changes of chlorophyll a and b, was more extensive in controlled environments at elevated (680 $\pm$ 17

mu l l(-1)) than at ambient (380 +/- 21 mu l l(-1)) CO₂. Stomatal conductance of primary leaves was decreased by growth in elevated CO₂ between 11 and 18 days after sowing (DAS) when measured at both 380 and 680 mu l l(-1) CO₂. Internal leaf CO₂ concentration (C-i) was also lower for elevated- compared to ambient-CO₂-grown primary leaves between 11 and 14 DAS. Results suggest that non-stomatal factors were responsible for the decreased photosynthetic rates of elevated- compared to ambient-CO₂-grown primary leaves 18 DAS. Various photochemical measurements, including quantum absorptance (alpha), minimal (F-0), maximal (F-m), and variable (F-v) chlorophyll fluorescence, as well as the F-v/F-m ratio, were significantly decreased 18 DAS in the elevated- compared to ambient-CO₂ treatment. Photochemical (q(P)) and nonphotochemical (q(N)) chlorophyll fluorescence quenching: coefficients of 18-day-old primary leaves did not differ between CO₂ treatments. Photosynthetic electron transport rates of photosystem II were slightly lower for elevated- compared to ambient-CO₂-grown primary leaves 18 DAS. Concentrations of alpha-amino N (i.e. free amino acids) in barley primary leaves were increased by CO₂ enrichment 10 DAS, but subsequently, alpha-amino N decreased in association with photosynthetic decline. Total acid protease activity was greater in elevated- than in ambient-CO₂-grown leaves 18 DAS. The above findings suggest that photoinhibition and premature senescence were factors in the CO₂-dependent yellowing of barley primary leaves.

Sicher, R.C. 1999. Photosystem-II activity is decreased by yellowing of barley primary leaves during growth in elevated carbon dioxide. *International Journal of Plant Science* 160(5):849-854.

Leaf yellowing was studied in 10-18-d-old barley seedlings (*Hordeum vulgare* L. cv. Brant) grown at ambient (38 Pa) and at elevated (68, 100, and 140 Pa) CO₂ partial pressures in controlled-environment chambers. Maximal total chlorophyll (Chl) concentrations of primary leaves from all four CO₂ growth treatments were 0.36 +/- 0.01 g m(-2), and these concentrations were observed 10-12 d after sowing (DAS). Total Chl levels in primary leaves were 35%, 64%, and 78% below maximal levels in the 38, 68, and 100 Pa CO₂ growth treatments, respectively, when measured 18 DAS. Losses of Chl in 18-d-old primary leaves were similar in the 100 and 140 Pa CO₂ treatments. Decreases of Chl a and Chl b in response to CO₂ enrichment were comparable in isolated chloroplast preparations and in intact 18-d-old barley primary leaves of plants grown at 38 and 68 Pa CO₂. Total thylakoid membrane proteins, the Chl a/b binding protein (LHC-II), and D1 protein levels were also lower in chloroplast preparations from plants grown in the elevated compared to the ambient CO₂ treatment. Both ferricyanide reduction and whole-chain electron-transport rates (H₂O --> methylviologen) were significantly lower for chloroplasts from plants grown at 68 Pa CO₂ compared with those grown at 38 Pa CO₂. However, photosystem-I-dependent chloroplast photoreductions did not differ between CO₂ treatments. The results indicated that the CO₂-dependent yellowing of barley primary leaves adversely affected photosystem-II activity. Growth in elevated CO₂ may have increased the susceptibility of photosystem-II to light damage.

Sicher, R.C., and J.A. Bunce. 1997. Relationship of photosynthetic acclimation to changes of Rubisco activity in field-grown winter wheat

and barley during growth in elevated carbon dioxide. *Photosynthesis Research* 52(1):27-38.

The responses of photosynthesis, Rubisco activity, Rubisco protein, leaf carbohydrates and total soluble protein to three carbon dioxide treatments were studied in winter wheat [*Triticum aestivum* (L.)] and barley [*Hordeum vulgare* (L.)]. Barley and wheat plants were grown in small field plots during 1995 and 1996 in clear, acrylic chambers (1.2-2.4 m(2)) and were provided with continuous carbon dioxide fertilization at concentrations of 350, 525 and 700 mu mol mol(-1). Photosynthetic rates of barley penultimate leaves and wheat flag leaves measured at growth carbon dioxide concentrations decreased with leaf age in all three CO₂ treatments during 1995 and 1996. Photosynthetic acclimation to elevated CO₂ was observed on seven of eight measurement dates for barley and ten of eleven measurement dates for wheat over both years. Initial Rubisco activity, total soluble protein and Rubisco protein in barley penultimate leaves and wheat flag leaves also decreased with leaf age. Total Rubisco activity was not used because of enzyme degradation. There was a significant CO₂ treatment effect on initial Rubisco activity, total soluble protein and Rubisco protein for wheat in 1995 and 1996 and for barley in 1995. Responses of barley penultimate leaf Rubisco activity and leaf protein concentrations to elevated carbon dioxide were nonsignificant in 1996. A significant CO₂ treatment effect also was detected when means of Rubisco activity, soluble protein and Rubisco protein for wheat flag leaves were combined over harvests and years. These three flag leaf parameters were not significantly different in the 350 and 525 mu mol mol(-1) CO₂ treatments but were decreased during growth in 700 mu mol mol(-1) CO₂ relative to the other two CO₂ treatments. Ratios of photosynthesis at 700 and 350 mu mol mol(-1) were compared to ratios of Rubisco activity at 700 and 350 mu mol mol(-1) using wheat flag leaf data from 1995 and 1996. Regression analysis of these data were linear [$y = 0.586 + 1.103x(r^2 = 0.432)$] and were significant at P less than or equal to 0.05. This result indicated that photosynthetic acclimation was positively correlated with changes of initial Rubisco activity in wheat flag leaves in response to CO₂ enrichment. Effects of elevated CO₂ on wheat leaf proteins during 1995 and 1996 and on barley during 1995 were consistent with an acceleration of senescence.

Sicher, R.C., and J.A. Bunce. 1998. Evidence that premature senescence affects photosynthetic decline of wheat flag leaves during growth in elevated carbon dioxide. *International Journal of Plant Science* 159(5):798-804.

Net CO₂ exchange (NCE) rates and various flag leaf constituents were measured in wheat plants (*Triticum aestivum* L.) grown in field chambers at either 350 or 700 mu l l(-1) CO₂. Rates of NCE decreased with leaf age in both CO₂ treatments during 1997. A stimulation of NCE initially occurred in response to CO₂ enrichment, but this was not observed on the final eight of 33 experimental days. Net photosynthetic rates in response to growth at elevated CO₂ were decreased ca. 22% on average for all measurement dates in 1997 and when all NCE rates measured at elevated CO₂ for 1995-1997 were averaged (P less than or equal to 0.0001). Soluble protein, alpha-amino nitrogen, and Chl a + b concentrations were significantly lower (P less than or equal to 0.0001) in elevated compared with ambient CO₂-grown wheat flag leaves in 1997. The treatment by date interactions for these flag leaf constituents were nonsignificant (P greater than or equal to 0.05). Flag leaf storage carbohydrates were measured on 10 dates in 1997, but only starch and sucrose were affected by the elevated CO₂ treatment. An increase of acid proteinase activity was observed on the last two measurement dates of this study. However, changes of acid proteinase activity were unaffected

by CO₂ enrichment (P greater than or equal to 0.05) and only occurred during late stages of senescence. These findings supported the suggestion that premature senescence contributed to the photosynthetic decline observed in wheat flag leaves during growth at elevated CO₂. Changes of alpha-amino nitrogen were correlated with photosynthetic decline, but acid proteinase activity probably was under endogenous control.

Sicher, R.C., and D.F. Kremer. 1994. Responses of nicotiana-tabacum to co₂ enrichment at low-photon flux-density. *Physiologia Plantarum* 92(3):383-388.

Effects of CO₂ enrichment on photosynthesis and on dry matter allocation were examined in two tobacco (*Nicotiana tabacum* L.) genotypes, Samsun and W38. Plants were grown from seed in controlled environment chambers at a photosynthetic photon flux density of 450 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Averaged over the 9 day study, net photosynthesis rates were 14.2 $\pm$ 0.5 and 13.0 $\pm$ 0.4 $\mu\text{mol m}^{-2} \text{s}^{-1}$ in elevated (70 Pa) and in ambient (35 Pa) CO₂ air, respectively, when measured at the irradiance and CO₂ partial pressure employed for plant growth. However, photosynthesis rates of plants grown in elevated CO₂ were 50% less than those of the ambient controls on the last day of treatment, when measured at 70 Pa CO₂ air and an irradiance of 900 $\mu\text{mol m}^{-2} \text{s}^{-1}$. Total plant dry weight and specific leaf weight were greater (P<0.05) in enriched-CO₂-grown than in ambient-CO₂-grown plants. Leaf starch, measured during the first hour of the photoperiod, increased over 7 days of treatment in elevated-CO₂-grown but not in ambient-CO₂-grown plants. Ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) activities of tobacco plants grown at 35 and 70 Pa CO₂ air were 58.5 $\pm$ 4.5 and 48.5 $\pm$ 3.7 $\mu\text{mol m}^{-2} \text{s}^{-1}$, respectively, between days 0 and 9 of the study. Rubisco activation state, Rubisco protein concentration, soluble protein and total chlorophyll were unaffected by CO₂ enrichment. The above findings demonstrated that photosynthesis was down regulated in tobacco plants after 7 to 9 days of CO₂ enrichment at low photosynthetic photon flux density, but less than at moderate irradiances.

Sicher, R.C., and D.F. Kremer. 1996. Rubisco activity is altered in a starchless mutant of *Nicotiana sylvestris* grown in elevated carbon dioxide. *Environmental and Experimental Botany* 36(4):385-391.

Dry matter and net photosynthesis of a wild type and a starchless mutant NS 458 of *Nicotiana sylvestris* (Speg. et Comes) were studied after 25 d of CO₂ enrichment. Plants were grown from seed in controlled environment chambers and treatments of either ambient (35 Pa) or twice ambient (70 Pa) CO₂ were initiated when plants were 3-4 weeks old. Photosynthetic rates measured at 35 and 70 Pa CO₂ and at 900 $\mu\text{mol m}^{-2} \text{s}^{-1}$ were unaffected (P>0.05) by 25 d of CO₂ enrichment. However, a CO₂-by-genotype interaction was observed indicating that photosynthetic rates of the wild type but not the mutant at 35 Pa CO₂ differed in response to CO₂ enrichment. Photosynthetic enhancement was greater (P < 0.001) in the wild type than in the mutant when the measurement CO₂ was doubled. Total biomass and leaf areas of the

mutant and wild type also were unaffected by CO₂ enrichment, although specific leaf weight increased 27% and 13% (P<0.001) for the wild type and mutant lines, respectively. Neither chlorophyll nor soluble leaf protein were affected by CO₂ enrichment. Starch, sucrose, glucose and fructose in wild type and mutant leaf samples were also unaffected by CO₂ enrichment. Rubisco protein levels of the wild type and mutant were about 20% lower in elevated compared to ambient CO₂-grown plants. Initial and total Rubisco activities of wild type and mutant leaf samples were not significantly different (P>0.05) between CO₂ environments. However, initial Rubisco activity was more than 30% lower in mutant than in wild type samples when results from ambient and elevated CO₂-grown plants were combined. Ribulose 1,5-bisphosphate and 3-phosphoglycerate were 280% and 28% greater in the mutant than in the wild type, respectively. These findings suggested that photosynthesis rates of the mutant were limited by Rubisco activity at 35 Pa CO₂ and that end product synthesis rates limited photosynthesis of the mutant at 70 Pa CO₂.

Sicher, R.C., D.F. Kremer, and J.A. Bunce. 1995. Photosynthetic acclimation and photosynthate partitioning in soybean leaves in response to carbon dioxide enrichment. *Photosynthesis Research* 46(3):409-417.

Photosynthetic rates and photosynthate partitioning were studied in three-week-old soybean [*Glycine max* (L.) Merr. cv. Williams] plants exposed to either ambient (35 Pa) or elevated (70 Pa) CO₂ in controlled environment chambers. Ambient CO₂-grown plants also were given a single 24 h treatment with 70 Pa CO₂ 1 d prior to sampling. Photosynthetic rates of ambient CO₂-grown plants initially increased 36% when the measurement CO₂ was doubled from 35 to 70 Pa. Photosynthetic rates of the third trifoliolate leaf, both after 1 and 21 d of elevated CO₂ treatment, were 30 to 45% below those of ambient CO₂-grown plants when measured at 35 Pa CO₂. These reduced photosynthetic rates were not due to increased stomatal resistance and were observed for 2 to 8 h after plants given 1 d of CO₂ enrichment were returned to ambient CO₂. Initial and total ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) activities, percent activation, Rubisco protein, soluble protein and leaf chlorophyll content were similar in all CO₂ treatments. Quantum yields of photosynthesis, determined at limiting irradiances and at 35 Pa CO₂, were 0.049 $\pm$ 0.003 and 0.038 $\pm$ 0.005 mol CO₂ fixed per mol quanta for ambient and elevated CO₂-grown plants, respectively (p < 0.05). Leaf starch and sucrose levels were greater in plants grown at 70 than at 35 Pa CO₂. Starch accumulation rates during the day were greater in ambient CO₂-grown plants than in plants exposed to elevated CO₂ for either 1 or 21 d. However, the percentage of C partitioned to starch relative to total C fixed was unaffected by 1 d of CO₂ enrichment. The above results showed that both photosynthetic and starch accumulation rates of soybean leaflets measured at 35 Pa CO₂ were temporarily reduced after 1 and 21 d of CO₂ enrichment. The biochemical mechanism affecting these responses was not identified.

Sicher, R.C., D.F. Kremer, and S.R. Rodermel. 1993. Role of rubisco during acclimation of transformed tobacco to co₂ enriched atmospheres. *Plant Physiology* 102(1):88.

2208

Sicher, R.C., D.F. Kremer, and S.R. Rodermel. 1994. Photosynthetic acclimation to elevated CO₂ occurs in transformed tobacco with decreased ribulose-1,5-bisphosphate carboxylase/oxygenase content. *Plant Physiology* 104(2):409-415.

Inhibition of net carbon assimilation rates during growth at elevated CO₂ was studied in transgenic tobacco (*Nicotiana tabacum* L.) plants containing zero to two copies of antisense DNA sequences to the small subunit polypeptide (rbcS) gene of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco). High- and low-Rubisco tobacco plants were obtained from the selfed progeny of the original line 3 transformant (S.R. Rodermel, M.S. Abbott, L. Bogorad [1988] *Cell* 55: 673-681). Assimilation rates of high- and low-Rubisco tobacco plants increased 22 and 71%, respectively, when transferred from 35- to 70-Pa CO₂ chamber air at 900 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photon flux density. However, CO₂-dependent increases of net carbon assimilation rates of high- and low-Rubisco plants virtually disappeared after 9 d of growth in elevated CO₂ chamber air. Total above-ground dry matter production of high- and low-Rubisco plants was 28 and 53% greater, respectively, after 9 d of growth at 70 Pa compared with 35 Pa CO₂. Most of this dry weight gain was due to increased specific leaf weight. Rubisco activity, Rubisco protein, and total chlorophyll were lower in both high- and low-Rubisco plants grown in enriched compared with ambient CO₂ chamber air. Soluble leaf protein also decreased in response to CO₂ enrichment in high- but not in low-Rubisco tobacco plants. Decreased Rubisco activities in CO₂-adapted high- and low-Rubisco plants were not attributable to changes in activation state of the enzyme. Carbonic anhydrase activities and subunit levels measured with specific antibodies were similar in high- and low-Rubisco tobacco plants and were unchanged by CO₂ enrichment. Collectively, these findings suggested that photosynthetic acclimation to enriched CO₂ occurred in tobacco plants either with or without transgenically decreased Rubisco levels and also indicated that the down-regulation of Rubisco in CO₂-adapted tobacco plants was related to decreased specific activity of this enzyme.

Siebbe, K., and E. Weis. 1995. Imaging of chlorophyll-a-fluorescence in leaves: Topography of photosynthetic oscillations in leaves of *Glechoma hederacea*. *Photosynthesis Research* 45(3):225-237.

Images of chlorophyll-alpha-fluorescence oscillations were recorded using a camera-based fluorescence imaging system. Oscillations with frequencies around 1 per min were initiated by a transient decrease in light intensity during assimilation at an elevated CO₂-concentration. The oscillation was inhomogeneously distributed over the leaf. In cells adjacent to minor veins, frequency and damping rate was high, if there was any oscillation. In contrast, the amplitude was highest in cells most distant from phloem elements (maximal distance about 300 μm). The appearance of minor veins in oscillation images is explained by a gradient in the metabolic control in the mesophyll between minor veins and by transport of sugar from distant cells to phloem elements. The potential of fluorescence imaging to visualize 'microscopic' source-sink interactions and metabolic domains in the mesophyll is discussed.

Signora, L., N. Galtier, L. Skot, H. Lucas, and C.H. Foyer. 1998. Over-expression of sucrose phosphate synthase in *Arabidopsis thaliana* results in increased foliar sucrose/starch ratios and favours decreased foliar carbohydrate accumulation in plants after prolonged growth with CO₂ enrichment. *Journal of Experimental Botany* 49(321):669-680.

Arabidopsis thaliana ecotype Columbia was transformed with a maize sucrose phosphate synthase (SPS) cDNA under the control of the promoter for the small subunit of ribulose-1,5-bisphosphate carboxylase from tobacco (rbcS). The effects of SPS over-expression were compared in plants of the T-2 and T-3 generations grown either in air or with CO₂ enrichment (700 $\mu\text{mol l}^{-1}$) for either 4 or 10 weeks. Maximal extractable foliar SPS activities were three times those of the untransformed controls in the highest rbcS-SPS expressing line. In untransformed *Arabidopsis* leaves SPS activity was not subject to light/dark regulation, but was modified by incubation with either the inhibitor, orthophosphate, or the activator, mannose. Photosynthesis (A(max)) values were similar in all lines grown in air. After 10 weeks of CO₂ enrichment a decrease in A_{max} in the untransformed controls, but not in the high SPS expressors, was observed. There was a strong correlation between the sucrose-to-starch ratio of the leaves and their SPS activity in both growth conditions. The total foliar carbohydrate contents of 4-week-old plants was similar in all lines whether plants were grown in air or with CO₂ enrichment. After 10 weeks growth the leaves of the high rbcS-SPS expressors accumulated much less total carbohydrate than untransformed control leaves in both growth conditions. It was concluded that SPS overexpression causes increased foliar sucrose/starch ratios in *Arabidopsis* leaves and favours decreased foliar carbohydrate contents when plants are grown for long periods with CO₂ enrichment.

Sild, E., S. Younis, H. Pleijel, and G. Sellden. 1999. Effect of CO₂ enrichment on non-structural carbohydrates in leaves, stems and ears of spring wheat. *Physiologia Plantarum* 107(1):60-67.

Field-grown spring wheat (*Triticum aestivum* L, cv, Dragon) was exposed to ambient and elevated CO₂ concentrations (15 and 2 times ambient) in open-top chambers. Contents of non-structural carbohydrates were analysed enzymatically in leaves, stems and ears six times during the growing season. The impact of elevated CO₂ on wheat carbohydrates was non-significant in most harvests. However, differences in the carbohydrate contents due to elevated CO₂ were found in all plant compartments. Before anthesis, at growth stage (GS) 30 (the stem is 1 cm to the shoot apex), the plants grown in elevated CO₂ contained significantly more water soluble carbohydrates (WSC), fructans, starch and total non-structural carbohydrates (TNC) in the leaves in comparison with the plants grown in ambient CO₂. It is hypothesised that the plants from the treatments with elevated CO₂ were sink-limited at GS30. After anthesis, the leaf WSC and TNC contents of the plants from elevated CO₂ started to decline earlier than those of the plants from ambient CO₂. This may indicate that the leaves of plants grown in the chambers with elevated CO₂ senesced earlier. Elevated CO₂ accelerated grain development: 2 weeks after anthesis, the plants grown in elevated CO₂ contained significantly more starch and significantly less fructans in the ears compared to the plants grown in ambient CO₂. Elevated CO₂ had no effect on ear starch and TNC contents at the final harvest. Increasing the CO₂ concentration from 360 to 520 $\mu\text{mol mol}^{-1}$ had a larger effect on wheat nonstructural carbohydrates than the further increase from 520 to 680 $\mu\text{mol mol}^{-1}$. The results are discussed in relation to the effects of elevated CO₂ on yield and yield components.

Silver, W.L. 1998. The potential effects of elevated CO₂ and climate change on tropical forest soils and biogeochemical cycling. *Climatic Change* 39(2-3):337-361.

Tropical forests are responsible for a large proportion of the global terrestrial C flux annually for natural ecosystems. Increased atmospheric CO₂ and changes in climate are likely to affect the distribution of C pools in the tropics and the rate of cycling through vegetation and soils. In this paper, I review the literature on the pools and fluxes of carbon in tropical forests, and the relationship of these to nutrient cycling and climate. Tropical moist and humid forests have the highest rates of annual net primary productivity and the greatest carbon flux from soil respiration globally. Tropical dry forests have lower rates of carbon circulation, but may have greater soil organic carbon storage, especially at depths below 1 meter. Data from tropical elevation gradients were used to examine the sensitivity of biogeochemical cycling to incremental changes in temperature and rainfall. These data show significant positive correlations of litterfall N concentrations with temperature and decomposition rates. Increased atmospheric CO₂ and changes in climate are expected to alter carbon and nutrient allocation patterns and storage in tropical forest. Modeling and experimental studies suggest that even a small increase in temperature and CO₂ concentrations results in more rapid decomposition rates, and a large initial CO₂ efflux from moist tropical soils. Soil P limitation or reductions in C:N and C:P ratios of litterfall could eventually limit the size of this flux. Increased frequency of fires in dry forest and hurricanes in moist and humid forests are expected to reduce the ecosystem carbon storage capacity over longer time periods.

Silvola, J., and U. Ahlholm. 1993. Effects of CO₂ concentration and nutrient status on growth, growth rhythm and biomass partitioning in a willow, *Salix phylicifolia*. *Oikos* 67(2):227-234.

Cuttings of the willow *Salix phylicifolia* were grown in pots containing moist organic-rich soil for four months in closed chambers at 4 CO₂ concentrations (300, 500, 700, 1000 ppm) and 4 nutrient levels (fertilization of 0, 100, 500, 1000 kg ha⁻¹ monthly). The plants received natural light, but the average temperature was 3-6-degrees-C higher than out of doors. Both CO₂ concentration and fertilization affected biomass production. The average increase caused by CO₂ enhancement being approx. 100%. Nutrient level had a considerable effect on the increased biomass production achieved by CO₂ enhancement, since the increase was minimal at lower nutrient levels. At the same time the effect of fertilization was dependent on the CO₂ concentration, the production increase caused by fertilization being much less at 300 ppm than at the other CO₂ concentrations. CO₂ concentration and fertilization had the opposite effects on biomass partitioning, a higher nutrient level increasing the proportion of the biomass located in the stems and a higher CO₂ concentration that in the roots. Both fertilization and CO₂ concentration affected the growth rhythm, a high CO₂/nutrient ratio leading to a shorter growing season and a low ratio to a longer one.

Silvola, J., and U. Ahlholm. 1995. Combined effects of CO₂ concentration and nutrient status on the biomass production and nutrient-uptake of birch seedlings (*Betula pendula*). *Plant and Soil* 169:547-553.

Birch seedlings (*Betula pendula*) were grown for four months in a greenhouse at three nutrient levels (fertilization of 0, 100 and 500 kg ha⁻¹ monthly) and at four CO₂ concentrations (350, 700, 1050 and 1400 ppm). The effect of CO₂ concentration on the biomass production depended on the nutrient status. When mineralization of the soil material was the only source of nutrients (0 kg ha⁻¹), CO₂ enhancement reduced the biomass production slightly, whereas the highest production increase occurred at a fertilization of 100 kg ha⁻¹, being over 100% between 350 and 700 ppm CO₂. At 500 kg ha⁻¹ the production increase was smaller, and the production decreased beyond a CO₂ concentration of 700 ppm. The CO₂ concentration had a slight effect on the biomass distribution, the leaves accounting for the highest proportion at the lowest CO₂ concentration (350 ppm). An increase in nutrient status led to a longer growth period and increased the nutrient concentrations in the plants, but the CO₂ concentration had no effect on the growth rhythm and higher CO₂ reduced the nutrient concentrations.

Simard, S.W., D.M. Durall, and M.D. Jones. 1997. Carbon allocation and carbon transfer between *Betula papyrifera* and *Pseudotsuga menziesii* seedlings using a C-13 pulse-labeling method. *Plant and Soil* 191(1):41-55.

Here we describe a simple method for pulse-labeling tree seedlings with (CO₂(gas)-C-13), and then apply the method in two related experiments: (i) comparison of carbon allocation patterns between *Betula papyrifera* Marsh. and *Pseudotsuga menziesii* (Mirb.) France, and (ii) measurement of one-way belowground carbon transfer from *B. papyrifera* to *P. menziesii*. Intraspecific carbon allocation patterns and interspecific carbon transfer both influence resource allocation, and consequently development, in mixed communities of *B. papyrifera* and *P. menziesii*. In preparation for the two experiments, we first identified the appropriate (CO₂(gas)-C-13) pulse-chase regime for labeling seedlings: a range of pulse (100-mL and 200-mL 99 atom% (CO₂(gas)-C-13)) and chase (0, 3 and 6 d) treatments were applied to one year-old *B. papyrifera* and *P. menziesii* seedlings. The amount of (CO₂-C-13) fixed immediately after 1.5 h exposure was greatest for both *B. papyrifera* (40.8 mg excess C-13) and *P. menziesii* (22.9 mg excess C-13) with the 200-mL pulse, but higher C-13 loss and high sample variability resulted in little difference in excess C-13 content between pulse treatments after 3 d for either species. The average excess C-13 root/shoot ratio of *B. papyrifera* and *P. menziesii* changed from 0.00 immediately following the pulse to 0.61 and 0.87 three and six days later, which reflected translocation of 75% of fixed isotope out of foliage within 3 d following the pulse and continued enrichment in fine roots over 6 d. Based on these results, the 100-mL CO₂(gas) and 6-d chase were considered appropriate for the carbon allocation and belowground transfer experiments. In the carbon allocation experiment, we found after 6 d that *B. papyrifera* allocated 49% (average 9.5 mg) and *P. menziesii* 41% (average 5.8 mg) of fixed isotope to roots, of which over 55% occurred in fine roots in both species. Species differences in isotope allocation patterns paralleled differences in tissue biomass distribution. The greater pulse labeling

efficiency of *B. papyrifera* compared to *P. menziesii* was associated with its two-fold and 13-fold greater leaf and whole seedling net photosynthetic rates, respectively, 53% greater biomass, and 35% greater root/shoot ratio. For the carbon transfer experiment, *B. papyrifera* and *P. menziesii* were grown together in laboratory rootboxes, with their roots intimately mingled. A pulse of 100 mL (CO₂(gas)-C-13) was applied to paper birch and one-way transfer to neighboring *P. menziesii* was measured after 6 d. Of the excess C-13 fixed by *B. papyrifera*, 4.7% was transferred to neighboring *P. menziesii*, which distributed the isotope evenly between roots and shoots. Of the isotope received by *P. menziesii*, we estimated that 93% was taken up through belowground pathways, and the remaining 7% taken up by foliage as (CO₂(gas)-C-13) respired by *B. papyrifera* shoots. These two experiments indicate that *B. papyrifera* fixes more total carbon and allocates a greater proportion to its root system than does *P. menziesii*, giving it a competitive edge in resource gathering; however, below-ground carbon sharing is of sufficient magnitude that it may help ensure co-existence of the two species in mixed communities.

Simola, L.K., J. Lemmetyinen, and A. Santanen. 1992. Lignin release and photomixotrophism in suspension-cultures of *Picea abies*. *Physiologia Plantarum* 84(3):374-379.

The effect of different concentrations of sucrose (0-4%) and of two growth regulators (0-50- μ M 2,4-D and 0-25- μ M kinetin) was tested on growth and chlorophyll content of suspension cultures of *Picea abies* (L.) Karst. originating from chlorophyllous embryo callus in an elevated CO₂ (2%) atmosphere. A continuous chlorophyllous suspension culture was achieved on a medium containing 2% sucrose and a low level of organic nitrogen (0.25 mM arginine and 0.5 mM glutamine) supplemented with 2,4-D (0.5- μ M) and kinetin (2.5- μ M). The same medium with 4% sucrose gave the best growth response, but a negative correlation between chlorophyll level and growth was observed. The chlorophyllous cultures grew slowly in a medium with low (0.5%) sucrose or without any carbohydrate source, suggesting photomixotrophism. A high concentration of kinetin inhibited both growth and chlorophyll synthesis. Release of lignin into the nutrient medium was observed in several experiments, especially in slow-growing cultures supplemented with sucrose. Only a few successive passages of suspensions that produced lignin could be cultured before cell death. The cultures releasing lignin may be unique for studies on synthesis and biodegradation of this very complex compound.

Simon, J.P. 1996. Molecular forms and kinetic properties of pyruvate, P-i dikinase from two populations of barnyard grass (*Echinochloa crus-galli*) from sites of contrasting climates. *Australian Journal of Plant Physiology* 23(2):191-199.

Plants from two populations of the C-4 barnyard grass (*Echinochloa crus-galli* (L.) Beauv.) from Quebec (QUE) and Mississippi (MISS) were acclimated under controlled conditions to 26/20 and 14/8 degrees C day/night. The apparent energy of activation (E(a)), K-m for pyruvate, V-max/K-m ratios, K-cat (substrate turnover number) and specific activity of pyruvate, P-i dikinase (PPDK, EC 2.7.9.1) were analysed from partially purified Sephadex G-25 extracts of PPDK from leaves and from highly purified PPDK. PPDK from both populations consisted of

one isomorph with the same electrophoretic mobility in polyacrylamide gels and similar molecular weights for the native enzyme (385 kDa) and for the subunit of the tetramer (94.8 kDa). No significant differences were observed for any of the kinetic properties of partially purified or purified PPDK or for the specific activity per mg protein of purified PPDK extracted from plants of the two populations and acclimated to the two thermoperiods. Net photosynthetic rates (Ps) were positively correlated with PPDK activity levels (E) but E/Ps ratios were lower than 1.0, ranging from 0.43 to 0.67. Results indicate that differences in activity levels, thermal properties and in the kinetics of light activation and dark inactivation of PPDK extracted from cold-acclimated MISS and QUE plants, as reported in earlier studies, are due to causes other than kinetic properties or electrophoretic characteristics of PPDK.

Sims, D.A., W.X. Cheng, Y.Q. Luo, and J.R. Seemann. 1999. Photosynthetic acclimation to elevated CO₂ in a sunflower canopy. *Journal of Experimental Botany* 50(334):645-653.

Sunflower canopies were grown in mesocosm gas exchange chambers at ambient and elevated CO₂ concentrations (360 and 700 ppm) and leaf photosynthetic capacities measured at several depths within each canopy. Elevated [CO₂] had little effect on whole-canopy photosynthetic capacity and total leaf area, but had marked effects on the distribution of photosynthetic capacity and leaf area within the canopy. Elevated [CO₂] did not significantly reduce the photosynthetic capacities per unit leaf area of young leaves at the top of the canopy, but it did reduce the photosynthetic capacities of older leaves by as much as 40%. This effect was not dependent on the canopy light environment since elevated [CO₂] also reduced the photosynthetic capacities of older leaves exposed to full sun on the south edge of the canopy. In addition to the effects on leaf photosynthetic capacity, elevated [CO₂] shifted the distribution of leaf area within the canopy so that more leaf area was concentrated near the top of the canopy. This change resulted in as much as a 50% reduction in photon flux density in the upper portions of the elevated [CO₂] canopy relative to the ambient [CO₂] canopy, even though there was no significant difference in the total canopy leaf area. This reduction in PFD appeared to account for leaf carbohydrate contents that were actually lower for many of the shaded leaves in the elevated as opposed to the ambient [CO₂] canopy. Photosynthetic capacities were not significantly correlated with any of the individual leaf carbohydrate contents. However, there was a strong negative correlation between photosynthetic capacity and the ratio of hexose sugars to sucrose, consistent with the hypothesis that sucrose cycling is a component of the biochemical signalling pathway controlling photosynthetic acclimation to elevated [CO₂].

Sims, D.A., Y. Luo, and J.R. Seemann. 1998. Comparison of photosynthetic acclimation to elevated CO₂ and limited nitrogen supply in soybean. *Plant, Cell and Environment* 21(9):945-952.

Plants grown at elevated CO₂ often acclimate such that their photosynthetic capacities are reduced relative to ambient CO₂-grown plants. Reductions in synthesis of photosynthetic enzymes could result

either from reduced photosynthetic gene expression or from reduced availability of nitrogen-containing substrates for enzyme synthesis. Increased carbohydrate concentrations resulting from increased photosynthetic carbon fixation at elevated CO₂ concentrations have been suggested to reduce the expression of photosynthetic genes. However, recent studies have also suggested that nitrogen uptake may be depressed by elevated CO₂, or at least that it is not increased enough to keep pace with increased carbohydrate production. This response could induce a nitrogen limitation in elevated-CO₂ plants that might account for the reduction in photosynthetic enzyme synthesis. If CO₂ acclimation were a response to limited nitrogen uptake, the effects of elevated CO₂ and limiting nitrogen supply on photosynthesis and nitrogen allocation should be similar. To test this hypothesis we grew non-nodulating soybeans at two levels each of nitrogen and CO₂ concentration and measured leaf nitrogen contents, photosynthetic capacities and Rubisco contents. Both low nitrogen and elevated CO₂ reduced nitrogen as a percentage of total leaf dry mass but only low nitrogen supply produced significant decreases in nitrogen as a percentage of leaf structural dry mass. The primary effect of elevated CO₂ was to increase non-structural carbohydrate storage rather than to decrease nitrogen content. Both low nitrogen supply and elevated CO₂ also decreased carboxylation capacity (V_{cmax}) and Rubisco content per unit leaf area. However, when V_{cmax} and Rubisco content were expressed per unit nitrogen, low nitrogen supply generally caused them to increase whereas elevated CO₂ generally caused them to decrease. Finally, elevated CO₂ significantly increased the ratio of RuBP regeneration capacity to V_{cmax} whereas neither nitrogen supply nor plant age had a significant effect on this parameter. We conclude that reductions in photosynthetic enzyme synthesis in elevated CO₂ appear not to result from limited nitrogen supply but instead may result from feedback inhibition by increased carbohydrate contents.

Sims, D.A., Y. Luo, and J.R. Seemann. 1998. Importance of leaf versus whole plant CO₂ environment for photosynthetic acclimation. *Plant, Cell and Environment* 21(11):1189-1196.

The reduction of photosynthetic capacity in many plants grown at elevated CO₂ is thought to result from a feedback effect of leaf carbohydrates on gene expression. Carbohydrate feedback at elevated CO₂ could result from limitations on carbohydrate utilization at many different points, for example export of triose phosphates from the chloroplast, sucrose synthesis and phloem loading, transport in the phloem, unloading of the phloem at the sinks, or utilization for growth of sinks. To determine the relative importance of leaf versus whole plant level limitations on carbohydrate utilization at elevated CO₂, and the possible effects on the regulation of photosynthetic capacity, we constructed a treatment system in which we could expose single, attached, soybean leaflets to CO₂ concentrations different from those experienced by the rest of the plant. The single leaflet treatments had dramatic effects on the carbohydrate contents of the treated leaflets. However, photosynthetic capacity and rubisco content were unaffected by the individual leaflet treatment and instead were related to the whole plant CO₂ environment, despite the fact that the CO₂ environment around the rest of the plant had no significant effect on the total non-structural carbohydrate (TNC) contents of the treated leaflets. These results necessitate a re-evaluation of the response mechanisms to CO₂ as well as some of the methods used to test these responses. We propose mechanisms by which sink strength could influence leaf physiology independently of changes in carbohydrate accumulation.

Sims, D.A., J.R. Seemann, and Y. Luo. 1998. The significance of differences in the mechanisms of photosynthetic acclimation to light, nitrogen and CO₂ for return on investment in leaves. *Functional Ecology* 12(2):185-194.

1. We report changes in photosynthetic capacity of leaves developed in varying photon flux density (PFD), nitrogen supply and CO₂ concentration. We determined the relative effect of these environmental factors on photosynthetic capacity per unit leaf volume as well as the volume of tissue per unit leaf area. We calculated resource-use efficiencies from the photosynthetic capacities and measurements of leaf dry mass, carbohydrates and nitrogen content. 2. There were clear differences between the mechanisms of photosynthetic acclimation to PFD, nitrogen supply and CO₂. PFD primarily affected volume of tissue per unit area whereas nitrogen supply primarily affected photosynthetic capacity per unit volume. CO₂ concentration affected both of these parameters and interacted strongly with the PFD and nitrogen treatments. 3. Photosynthetic capacity per unit carbon invested in leaves increased in the low PFD, high nitrogen and low CO₂ treatments. Photosynthetic capacity per unit nitrogen was significantly affected only by nitrogen supply. 4. The responses to low PFD and low nitrogen appear to function to increase the efficiency of utilization of the limiting resource. However, the responses to elevated CO₂ in the high PFD and high nitrogen treatments suggest that high CO₂ can result in a situation where growth is not limited by either carbon or nitrogen supply. Limitation of growth at elevated CO₂ appears to result from internal plant factors that limit utilization of carbohydrates at sinks and/or transport of carbohydrates to sinks.

Sims, D.A., J.R. Seemann, and Y.Q. Luo. 1998. Elevated CO₂ concentration has independent effects on expansion rates and thickness of soybean leaves across light and nitrogen gradients. *Journal of Experimental Botany* 49(320):583-591.

The rate and extent of leaf thickness and development are important determinants of plant photosynthetic capacity. The interactive effects of photon flux density (PFD), nitrogen supply and CO₂ concentration on leaf expansion rate were measured as well as final leaf size and thickness of soybean. Leaf thickness and final area were not correlated with leaf relative expansion rate (RER) suggesting that these parameters are controlled by different mechanisms and that final leaf dimensions are determined by the duration rather than the rate of leaf expansion. Carbohydrate supply did not explain the variation in leaf RER since RER increased with increasing CO₂ concentration, but decreased with increasing PFD. Leaf thickness and final area were related to resource supply but not in a simple fashion. Both positive and negative correlations between leaf thickness and carbohydrate and nitrogen concentrations were obtained depending on the environmental variable responsible for the variation. In contrast, there was a simple proportional relationship between whole plant relative growth rate and a correlate of leaf thickness (leaf water content per unit area), suggesting that leaf thickness responds to the balanced supply of all resources, in the same fashion as RGR, rather than to any individual resource.

Sinclair, T.R. 1992. Mineral-nutrition and plant-growth response to climate change. *Journal of Experimental Botany* 43(253):1141-1146.

The limiting factor concept has often been used to describe plant growth responses to altered availability of resources. However, even preliminary experiments, where atmospheric CO₂ concentrations and solution mineral concentrations were varied, demonstrated that a more complex concept was required to interpret the potential effects of climate change and mineral availability on plant growth. It is proposed that these resources for plant growth may be better viewed as simultaneously limiting. Further, in considering the limitation in plant growth to mineral nutrition it is important to consider both the solution concentration and the total amount of the individual minerals available to the plant. Sustaining a positive response to increased CO₂ concentration, for example, requires an increase in plant uptake of the total amount of minerals. Consequently, it is very difficult to predict the plant growth response to climate change because of the large uncertainty about mineral availability. On the one hand, increased CO₂ concentrations should stimulate nitrogen fixation by both free-living organisms and symbiotic systems, and improve soil properties for mineral availability as a result of increased organic matter deposition in the soil. On the other hand, increased temperature and altered rainfall patterns may result in increased losses of soil minerals. Even the direction in the net change in available soil minerals is unclear. Realistic evaluations of the effects of climate change on plant growth will be challenged to contend with the large uncertainty and complexities in understanding mineral availability and plant mineral nutrition.

Sinclair, T.R., and N.G. Seligman. 1995. Global environment change and simulated forage quality of wheat .1. Nonstressed conditions. *Field Crops Research* 40(1):19-27.

Projected changes in the global environment may affect both the quantity and quality of grain and forage mass produced and harvested in that environment. Quality is a major factor in determining the value of a forage crop as feed for ruminants. The objective of this study was to make a preliminary assessment of potential changes in the quantity and quality of forage as measured by [N] and leaf:stem of an annual, temperate climate C-3 forage crop grown under nonstressed conditions. Starting with a relatively simple, well-checked mechanistic model of wheat, adaptations were added to estimate changes in forage attributes. Increased temperature influenced both yield and nutritive value, mainly through changes in ontological development rates. Elevated,atmospheric [CO₂] resulted in greater mass accumulation, but with lower leaf:stem and [N]. The combined effect of increased temperature and elevated [CO₂] was to decrease slightly forage yield and to increase the forage nutritive value. These compensating effects of higher temperature and elevated [CO₂] could be modified by interactions between [CO₂] and the chemical composition and cell wall structure of forage plants. Analysis of such subtle interaction requires considerable experimental amplification.

Singer, A., A. Eshel, M. Agami, and S. Beer. 1994. The contribution of aerenchymal co₂ to the photosynthesis of emergent and submerged culms of scirpus-lacustris and cyperus- papyrus. *Aquatic Botany* 49(2-3):107-116.

In this work it was investigated whether sediment-derived aerenchymal CO₂ could be utilized for photosynthesis in the culms of the two emergent aquatic macrophytes *Scirpus lacustris* L. (a C-3 plant) and *Cyperus papyrus* L. (a C-4 plant). Aerenchymal CO₂ concentrations within the submerged parts of the culms were found to be 30 000-50 000, $\mu\text{mol l}^{-1}$, and ca. 800 $\mu\text{mol l}^{-1}$ in the emergent parts of *Scirpus lacustris* and 2000 $\mu\text{mol l}^{-1}$ in *Cyperus papyrus*. These concentrations tended to be lower during the day in *Cyperus*, while no clear diurnal pattern was observed for *Scirpus*. Photosynthetic rates based on fixation of external or internal CO₂ were measured in situ by providing (CO₂)-C-14 either externally or from the aerenchyma (by supplying C-14-labelled CO₂ through test-tubes attached to excised culms). The results showed that the contribution of aerenchymal CO₂ to the total photosynthesis of emergent culms was less than 0.25% in both species. This has a rationale in that photosynthetic rates of both species were saturated at the ambient air CO₂ concentration, but it remains unclear why CO₂ does not diffuse towards the photosynthesizing tissues. By contrast, internal CO₂ appeared to be the only source of inorganic carbon used for photosynthesis of young submerged green culms. It is thus suggested that the aerenchyma, in addition to other functions, is important in providing sediment-derived CO₂ for photosynthesis in young shoots or culms if growing submerged, before they reach the water surface.

Singh, B., and R.B. Stewart. 1991. Potential impacts of a CO₂-induced climate change using the GISS scenario on agriculture in quebec, canada. *Agriculture Ecosystems & Environment* 35(4):327-347.

This study examines the potential impacts of a climate change resulting from an effective doubling of atmospheric CO₂ on the potential and anticipated yields of a variety of agricultural crops including corn, soya, potatoes, wheat, phaseolus beans, sorghum, barley, oats, rapeseed and sunflowers and two horticultural crops namely apples and grapes, for southern Quebec. The GISS climate change scenario is used. Our results show that yields would increase for some crops such as corn, soybeans, potatoes, phaseolus beans and sorghum and would decrease for the cereal and oilseed crops, namely wheat, barley, oats, sunflowers and rapeseed. Production opportunities for apples and grapes are enhanced. Also it would seem that the more northerly regions of Abitibi-Temiscamingue and Lac St-Jean would benefit most, in terms of agriculture, from a CO₂-induced climate change.

Singh, T., and E.E. Wheaton. 1991. Boreal forest sensitivity to global warming - implications for forest management in western interior canada. *The Forestry Chronicle* 67(4):342-348.

Unmitigated global warming due to the enhanced greenhouse effect could have significant impacts on the boreal forest in interior western Canada. Increases in annual temperature of 3 to 7-degrees-C are projected for Alberta under a 2 x CO₂ scenario by 2030-2050 A.D. Such an unprecedented rate of change has many short- and long-term

implications for forest management and for industries. As the boreal forest is highly sensitive to climatic changes, foresters need to develop a set of safe strategies to minimize the negative impacts and maximize the benefits of these changes.

Slafer, G.A. 1995. Wheat development as affected by radiation at two temperatures. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 175(4):249-263.

A wheat cultivar (Condor) was grown in two experiments (thermal regimes 18/13 and 21/16 degrees C) under low (298 $\mu\text{mol m}^{-2} \text{s}^{-1}$) radiation regimes during either an early phase from seedling emergence to terminal spikelet initiation (S-1), a late phase from terminal spikelet initiation to anthesis (S-2), or for the full period from seedling emergence to anthesis (S-12), or high (560 $\mu\text{mol m}^{-2} \text{s}^{-1}$) radiation throughout the growing period (S-0) to determine whether developmental events are affected by radiation. The main developmental events considered in this study were the timing of terminal spikelet initiation and anthesis, the final number of leaf and spikelet primordia initiated in the apex and the rate of leaf appearance. Number of grains per spike and culm height were also measured. The duration of each phenophase was not affected by radiation intensity. Temperature affected the rate of wheat development, but the acceleration of development due to temperature during the seedling emergence-terminal spikelet initiation phase only slightly reduced (from 24.8 to 23.2 days). Differences in time from terminal spikelet initiation to anthesis were greater than in the earlier phases, having been the duration reduced from 24.6 to 20.0 days due to high temperature. Associated with the lack of effect of radiation on phasic development and the negligible effect of temperature on the duration of the early phases of development, final leaf number was practically unchanged in this study by either the radiation level or the growing temperature. Thus, radiation did not affect the rate of leaf initiation. The number of spikelets was affected by neither the treatments nor the thermal environment. The rates of leaf appearance were accelerated by temperature. Radiation, on the other hand, did not significantly alter the rates of leaf appearance in any of the treatments. As expected from many sources in the literature, the number of grains per spike was significantly affected by radiation during the phase from terminal spikelet initiation to anthesis. Due to the lack of significant effects of radiation on the developmental patterns of wheat, the changes in number of grains per spike were due to changes in the number of grains born in each spikelet. The results of the present study were compared with others available in the literature on the effects (or lack of them) of radiation and CO₂ concentration on phasic development, plastochron and phyllochron in wheat to reach the general conclusion that the rate of developmental events in wheat, in contrast to other plants, is almost completely independent of the availability of assimilates, with a possible exception for the Equatorial latitudes.

Slafer, G.A., and H.M. Rawson. 1997. CO₂ effects on phasic development, leaf number and rate of leaf appearance in wheat. *Annals of Botany* 79(1):75-81.

It has been predicted that the concentration of CO₂ in the air could double during the 21st century. Though it is recognized that CO₂-doubling could increase yield through its effects on plant photosynthesis and stomatal behaviour, it is unclear whether CO₂-doubling will change phasic development in wheat. A phytotron study was conducted with

two contrasting cultivars of wheat, Condor (spring) and Cappelle Desprez (winter), to determine whether development is affected by a season-long exposure to 360 and 720 ppmv CO₂. Plants were vernalized for 50 d (8/4 degrees C, 8 h photoperiod) before their exposure to the CO₂ treatments. There were significant differences between cultivars in the duration of different phenophases as well as in the final number of leaves. However, CO₂ concentration had no effect in either cultivar on the duration of the early developmental phase to terminal spikelet initiation, or on the final number of leaves, though CO₂-doubling did slightly increase the later phase from terminal spikelet initiation to heading in Cappelle Desprez. Condor and Cappelle Desprez also differed markedly in the dynamics of leaf appearance. While the former had a constant rate of leaf appearance throughout development, the latter had a fast rate initially (between leaves 1 and 7), similar to that of Condor, which was followed by a slower rate after the appearance of leaf 7. Overall, CO₂-doubling did not significantly affect the rates of leaf appearance nor the shape of the relationship. Phyllochron for the first seven leaves was the same for both CO₂ concentrations. However, the change in phyllochron associated with CO₂-doubling for leaves 7-12 in Cappelle Desprez, although quite small (4%), accounts for part of the slightly increased duration of the phase from terminal spikelet initiation to heading under high CO₂ concentration in that cultivar. We conclude that CO₂ concentration does not influence development in wheat to a degree relevant to agronomy. (C) 1997 Annals of Botany Company

Smart, D.R., N.J. Chatterton, and B. Bugbee. 1994. The influence of elevated CO₂ on nonstructural carbohydrate distribution and fructan accumulation in wheat canopies. *Plant, Cell and Environment* 17(4):435-442.

We grew 2.4 m² wheat canopies in a large growth chamber under high photosynthetic photon flux (1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$) and using two CO₂ concentrations, 360 and 1200 $\mu\text{mol mol}^{-1}$. Photosynthetically active radiation (400-700 nm) was attenuated slightly faster through canopies grown in 360 $\mu\text{mol mol}^{-1}$ than through canopies grown in 1200 $\mu\text{mol mol}^{-1}$, even though high-CO₂ canopies attained larger leaf area indices. Tissue fractions were sampled from each 5-cm layer of the canopies. Leaf tissue sampled from the tops of canopies grown in 1200 $\mu\text{mol mol}^{-1}$ accumulated significantly more total non-structural carbohydrate, starch, fructan, sucrose, and glucose (p less than or equal to 0.05) than for canopies grown in 360 $\mu\text{mol mol}^{-1}$. Non-structural carbohydrate did not significantly increase in the lower canopy layers of the elevated CO₂ treatment. Elevated CO₂ induced fructan synthesis in all leaf tissue fractions, but fructan formation was greatest in the uppermost leaf area. A moderate temperature reduction of 10-degrees-C over 5 d increased starch, fructan and glucose levels in canopies grown in 1200 $\mu\text{mol mol}^{-1}$, but concentrations of sucrose and fructose decreased slightly or remained unchanged. Those results may correspond with the use of fructosyl-residues and release of glucose when sucrose is consumed in fructan synthesis.

Smart, D.R., K. Ritchie, A.J. Bloom, and B.B. Bugbee. 1998. Nitrogen balance for wheat canopies (Triticum aestivum cv. Veery 10) grown under elevated and ambient CO₂ concentrations. *Plant, Cell and Environment* 21(8):753-763.

We examined the hypothesis that elevated CO₂ concentration would increase NO₃⁻ absorption and assimilation using intact wheat canopies (Triticum aestivum cv, Veery 10), Nitrate consumption, the sum of plant absorption and nitrogen loss, was continuously monitored for 23 d following germination under two CO₂ concentrations (360 and 1000 $\mu\text{mol mol}^{-1}$ CO₂) and two root zone NO₃⁻ concentrations (100 and 1000 mmol m^{-3} NO₃⁻). The plants were grown at high density (1780 m^{-2}) in a 28 m³ controlled environment chamber using solution culture techniques. Wheat responded to 1000 $\mu\text{mol mol}^{-1}$ CO₂ by increasing carbon allocation to root biomass production. Elevated CO₂ also increased root zone NO₃⁻ consumption, but most of this increase did not result in higher biomass nitrogen. Rather, nitrogen loss accounted for the greatest part of the difference in NO₃⁻ consumption between the elevated and ambient [CO₂] treatments. The total amount of NO₃⁻-N absorbed by roots or the amount of NO₃⁻-N assimilated per unit area did not significantly differ between elevated and ambient [CO₂] treatments. Instead, specific leaf organic nitrogen content declined, and NO₃⁻ accumulated in canopies growing under 1000 $\mu\text{mol mol}^{-1}$ CO₂. Our results indicated that 1000 $\mu\text{mol mol}^{-1}$ CO₂ diminished NO₃⁻ assimilation. If NO₃⁻ assimilation were impaired by high [CO₂], then this offers an explanation for why organic nitrogen contents are often observed to decline in elevated [CO₂] environments.

Smart, D.R., K. Ritchie, J.M. Stark, and B. Bugbee. 1997. Evidence that elevated CO₂ levels can indirectly increase rhizosphere denitrifier activity. *Applied and Environmental Microbiology* 63(11):4621-4624.

We examined the influence of elevated CO₂ concentration on denitrifier enzyme activity in wheat rhizoplanes by using controlled environments and solution culture techniques. Potential denitrification activity was from 3 to 24 times higher on roots that were grown under an elevated CO₂ concentration of 1,000 μmol of CO₂ mol^{-1} than on roots grown under ambient levels of CO₂. Nitrogen loss, as determined by a nitrogen mass balance, increased with elevated CO₂ levels in the shoot environment and with a high NO₃⁻ concentration in the rooting zone. These results indicated that aerial CO₂ concentration can play a role in rhizosphere denitrifier activity.

Smeekens, S. 1998. Sugar regulation of gene expression in plants. *Current Opinion in Plant Biology* 1(3):230-234.

The molecular details of sugar sensing and sugar-mediated signal transduction pathways are unclear but recent results suggest that hexokinase functions as an important plant sugar sensor in a way that is similar to that found in yeast. The use of mutants in Arabidopsis defective in specific signaling steps is of particular importance because these give access to the genes encoding components in the signaling pathways. In addition, the physiological analysis of such mutants may reveal the interaction of sugar-induced signaling pathways and those induced by other stimuli such as environmental or biotic stress.

Smernoff, D.T., J. Gale, B.A. MacIer, and J. Reuveni. 1993. Inhibition of photosynthesis in duckweed by elevated CO₂ concentration is rapid and is not offset by a temperature- induced increase in metabolic-rate. *Photosynthetica* 28(1):17-28.

The rates of net photosynthesis (P(N)), respiration and growth of Lemna gibba L. were measured as functions of time across ranges of temperature, irradiance and carbon dioxide concentrations. P(N) on an area basis increased with temperature up to 30-degrees-C but decreased dramatically with a few hours of exposure to elevated CO₂, when reported on a dry mass basis. Reductions in the apparent quantum efficiency, photosynthetic capacity and the affinity of ribulose- 1,5-bisphosphate carboxylase/oxygenase for CO₂ were observed for plants grown at elevated CO₂. Starch concentration was not significantly affected by elevated CO₂. Although elevated temperature increased metabolic activity, it only partially alleviated the inhibition of P(N). L. gibba exhibits a characteristic C3-type response to elevated CO₂ and the methodology described is useful for further elucidating the mechanism of photosynthetic acclimation to elevated CO₂.

Smit, B., and Y.L. Cai. 1996. Climate change and agriculture in China. *Global Environmental Change-Human and Policy Dimensions* 6(3):205-214.

The implications of climate change for agriculture and food are global concerns, and they are very important for China. The country depends on an agricultural system which has evolved over thousands of years to intensively exploit environmental conditions. The pressures on the resource base are accentuated by the prospect of climate change. This paper synthesizes information from a variety of studies on Chinese agriculture and climate. Historical studies document the impacts of past climate changes and extremes, and the types of adjustments which have occurred, the vulnerability of Chinese agriculture to climate change. Climate change scenarios are assessed relative to the current distribution of agro-climatic regions and systems. Notwithstanding the enhancing effects of warming and elevated CO₂ levels, expected moisture deficits and uncertain changes in the timing and frequency of critical conditions indicate that there are serious threats to the stability and adaptability of China's food production system. Smith, P.H.D., and T.H. Jones. 1998. Effects of elevated CO₂ on the chrysanthemum leafminer, Chromatomyia syngenesiae: a greenhouse study. *Global Change Biology* 4(3):287-291.

Although feeding behaviour of Chromatomyia syngenesiae on plants grown in elevated CO₂ (ambient + 200ppm) was unaffected, leaf-miner development was slower in elevated compared to ambient CO₂ atmospheres. Pupal weight was lower at high CO₂ and correlated with the area of leaf mined; no such correlation existed in ambient CO₂. There appears to be no compensatory feeding by the leaf-miner for the reduced food quality of plants growing in elevated CO₂. The implications of these findings are discussed.

Smith, R.B. 1992. Controlled-atmosphere storage of redcoat strawberry fruit. *Journal of the American Society for Horticultural Science* 117(2):260-264.

Strawberries (*Fragaria x ananassa* Duch.) cv. Redcoat were stored at several temperatures and for various intervals in controlled atmospheres (CA) containing 0% to 18% CO₂ and 15% to 21% O₂. Bioyield point forces recorded on the CA-stored fresh fruit indicated that the addition of CO₂ to the storage environment enhanced fruit firmness. Fruit kept under 15% CO₂ for 18 hours was 48% firmer than untreated samples were initially. Response to increasing CO₂ concentrations was linear. There was no response to changing O₂ concentrations. Maximum enhancement of firmness was achieved at a fruit temperature of 0°C; there was essentially no enhancement at 21°C. In some instances, there was a moderate firmness enhancement as time in storage increased. Carbon dioxide acted to reduce the quantity of fruit lost due to rot. Fruit that was soft and bruised after harvest became drier and firmer in a CO₂-enriched environment.

Smith, R.B., and L.J. Skog. 1992. Postharvest carbon-dioxide treatment enhances firmness of several cultivars of strawberry. *Hortscience* 27(5):420-421.

Various cultivars of strawberry (*Fragaria x ananassa* Duch.) were stored for 42 h under an atmosphere of 15% CO₂ to determine whether their firmness would be enhanced. Compared to initial samples and stored control samples, enhanced firmness was found in 21 of the 25 cultivars evaluated. The CO₂ had no effect on color, as measured by Hunter 'L', 'a' and 'b', or on soluble solids concentration (SSC) or pH. There were significant differences among cultivars in firmness; Hunter color 'L', 'a', and 'b'; SSC; and pH.

Smith, T.M., W.P. Cramer, R.K. Dixon, R. Leemans, R.P. Neilson, and A.M. Solomon. 1993. The global terrestrial carbon-cycle. *Water, Air, and Soil Pollution* 70(1-4):19-37.

There is great uncertainty with regard to the future role of the terrestrial biosphere in the global carbon cycle. The uncertainty arises from both an inadequate understanding of current pools and fluxes as well as the potential effects of rising atmospheric concentrations of CO₂ on natural ecosystems. Despite these limitations, a number of studies have estimated current and future patterns of terrestrial carbon storage. Future estimates focus on the effects of a climate change associated with a doubled atmospheric concentration of CO₂. Available models for examining the dynamics of terrestrial carbon storage and the potential role of forest management and landuse practices on carbon conservation and sequestration are discussed.

Smith, T.M., R. Leemans, and H.H. Shugart. 1992. Sensitivity of terrestrial carbon storage to CO₂-induced climate change - comparison of 4 scenarios based on general- circulation models. *Climatic Change* 21(4):367-384.

The potential impacts of CO₂-induced climate change on terrestrial carbon storage was estimated using the Holdridge Life-Zone Classification and four climate change scenarios derived from general circulation models. Carbon values were assigned to life-zones and their associated soils from published studies. All four scenarios suggest an increase in area occupied by forests although details of predicted patterns vary among the scenarios. There is a poleward shift of the forested zones, with an increase in the areal extent of tropical forests and a shift of the boreal forest zone into the region currently occupied by tundra. Terrestrial carbon storage increased from 0.4% (8.5 Gt) to 9.5% (180.5 Gt) above estimates for present conditions. These changes represent a potential reduction of 4 to 85 ppm on elevated atmospheric CO₂ levels.

Smith, W.K., and R.A. Donahue. 1991. Simulated influence of altitude on photosynthetic CO₂ uptake potential in plants. *Plant, Cell and Environment* 14(1):133-136.

A simulation of the quantitative influence of altitude on photosynthetic CO₂ uptake capability (A(P)) included the effects of predicted changes (1) in air temperature (lapse rate) and (2) leaf temperature, (3) ambient pressure and CO₂ concentration, and (4) the diffusion coefficient for CO₂ in air. When a dry lapse rate (0.01-degrees-C m⁻¹) in air temperature was simulated, significant declines (up to 14%) in A(P) were predicted from sea level to 4km altitude. A moist lapse rate of 0.003-degrees-C m⁻¹ resulted in less than a 4% decrease in A(P) over the same altitude range. When natural leaf temperatures (predicted from heat balance analyses) were simulated, A(P) was significantly greater (almost-equal-to 20%) than when leaf temperatures were considered equal to air temperature for all lapse conditions. There was virtually no change in A(P) with altitude when predicted leaf temperatures and moist lapse conditions were simulated. There was a significant (almost-equal-to 10%) increase in A(P) with altitude when leaf temperature was held constant at 30-degrees- C (regardless of altitude) under moist lapse conditions. Future studies evaluating the effects of elevation on photosynthesis could benefit from the above considerations of the effects of natural leaf temperature regimes and prevailing lapse conditions on CO₂ uptake potential.

Socias, F.X., H. Medrano, and T.D. Sharkey. 1993. Feedback limitation of photosynthesis of *Phaseolus-vulgaris* L grown in elevated CO₂. *Plant, Cell and Environment* 16(1):81-86.

The capacity for photosynthesis is often affected when plants are grown in air with elevated CO₂ partial pressure. We grew *Phaseolus vulgaris* L. in 35 and 65Pa CO₂ and measured photosynthetic parameters. When assayed at the growth CO₂ level, photosynthesis was equal in the two CO₂ treatments. The maximum rate of ribulose-1,5-bisphosphate (RuBP) consumption was lower in plants grown at 65Pa, but the CO₂ partial pressure at which the maximum occurred was higher in the high-CO₂-grown plants, indicating acclimation to high CO₂. The acclimation of RuBP consumption to CO₂ involved a reduction of the activity of RuBP carboxylase which resulted from reduced carbamylation, not a loss of protein. The rate of RuBP consumption declined with CO₂ when the CO₂ partial pressure was above 50Pa in plants grown under both CO₂ levels. This was caused by feedback inhibition as judged by a lack of response to removing O₂ from the air stream. The rate of photosynthesis at high CO₂ was lower in the high-CO₂-grown plants and this was correlated with reduced activity of sucrose-phosphate synthase. This is only the second report Of O₂-insensitive

photosynthesis under growth conditions for plants grown in high CO₂.

Solarova, J., and J. Pospisilova. 1997. Effect of carbon dioxide enrichment during in vitro cultivation and acclimation to ex vitro conditions. *Biologia Plantarum* 39(1):23-30.

Tobacco and carnation plantlets were grown in vitro on Murashige and Skoog's medium with 2% saccharose. Carnation plantlets were also grown fully photoautotrophically on a medium without saccharose. The ambient CO₂ concentration was increased from 0.6 to 10 or 40 g m⁻³ during the last 3 weeks of in vitro cultivation or during the first 3 weeks of acclimation to ex vitro condition (plantlets transplanted to pots with sand and nutrient solution) or during both growth phases. CO₂ enrichment during in vitro cultivation markedly stimulated growth of tobacco plantlets, and also of carnation plantlets, both with and without saccharose. CO₂ enrichment during the acclimation period promoted plant growth more effectively in plantlets grown in vitro at a CO₂ concentration of 0.6 g m⁻³ than in plantlets grown in either growth phase at higher CO₂ concentrations.

Sombroek, W.G., F.O. Nachtergaele, and A. Hebel. 1993. Amounts, dynamics and sequestering of carbon in tropical and subtropical soils. *Ambio* 22(7):417-426.

The organic carbon pool in the upper 1 m of the world's soils contains 1220 Gt organic carbon, 1.5 times the total for the standing biomass. In the widespread deep soils in the tropics the carbon stored below 1 m may add about 50 Gt C. The contributions of charcoal, roots and soil fauna should be added to these totals. The much less dynamic carbonate-carbon pool amounts to 720 Gt C. Changes in land use, particularly by clearing of forests, reduce organic carbon by 20 to 50% in the upper soil layers, but little in deeper layers. On the other hand, there are indications that a human-induced enrichment of soil organic matter can be maintained over centuries. Research on the causative soil processes should be supported, because an improved understanding of this phenomenon might lead to better management strategies and sound programs to stimulate organic carbon storage and fertility levels in tropical and subtropical soils. Recent research data on the CO₂ fertilization effect and the associated antitranspiration effect due to an increase of CO₂ in the atmosphere indicate that a positive influence on soil organic carbon levels can be expected.

Sommerfeld, R.A., W.J. Massman, R.C. Musselman, and A.R. Mosier. 1996. Diffusional flux of CO₂ through snow: Spatial and temporal variability among alpine-subalpine sites. *Global Biogeochemical Cycles* 10(3):473-482.

Three alpine and three subalpine sites were monitored for up to 4 years to acquire data on the temporal and spatial variability of CO₂ flux through snowpacks. We conclude that the snow formed a passive cap which controlled the concentration of CO₂ at the snow-soil interface,

while the flux of CO₂ into the atmosphere was controlled by CO₂ production in the soil. Seasonal variability in the flux at all sites was characterized by early winter minima followed by a rise in flux that averaged 70% above the minima over about a 1-month period. The seasonal variability was not related to soil temperatures which remained relatively constant. Interannual variability was small, and spatial variability was smaller than previously reported. Spatial variability on a scale of 1 to 10 m was less than 30% of the average fluxes and not significantly greater than estimated error in most cases. Spatial variability on a scale of 10- to 100-m was about a factor of 2 and on a scale of 100 to 1000 m was about a factor of 4. The 100- to 1000-m variability was complicated by the fact that the sites were in different ecosystems, alpine and subalpine, and at different elevations. We attribute the small variability at the 1- to 10- m scale to the deep snow cover, from 1.4 to 5 m. We hypothesize that horizontal diffusion under the snow cover reduced small- scale horizontal gradients, while the insulating effect of the deep snow cover kept the soil temperature and moisture relatively constant. Equivalent annual wintertime flux averaged about 95 g C m⁻² yr⁻¹ in the alpine and about 232 g C m⁻² yr⁻¹ in the subalpine sites. Measurements of CO₂ concentrations at 0.2 and 0.5 m in the soil of one of the subalpine sites indicated that production early in the snow season occurred at or below 0.5 m while production between 0.5 m, and the surface became important after the start of the melt season.

Sonesson, M., T.V. Callaghan, and L.O. Bjorn. 1995. Short-term effects of enhanced UV-B and CO₂ on lichens at different latitudes. *Lichenologist* 27:547-557.

Interaction effects of UV-B and CO₂ on three lichens species, *Cladonia arbuscula*, *Cetraria islandica* and *Stereocaulon paschale*, from two latitudinal sites, 68 degrees N and 56 degrees N, were studied in a laboratory experiment. The response of the plants was recorded by measuring their chlorophyll fluorescence. All species had a similar response to enhanced UV-B depending on the latitude from which the population came and the time of the season when they were sampled. Overall, there was a significant increase in photosystem II yield (as measured by a fluorescence technique) due to UV-B and no separate effect due to enhanced CO₂, although there was a significant interaction between CO₂ and UV-B. The increase due to UV-B was at the low CO₂ level. There were also significant differences in response due to latitude. The results contradict our hypotheses that negative effects of UV-B would be larger in the North than in the South and that a negative response should be especially large during the early season. Sonesson, M., T.V. Callaghan, and B.A. Carlsson. 1996. Effects of enhanced ultraviolet radiation and carbon dioxide concentration on the moss *Hylocomium splendens*. *Global Change Biology* 2(1):67-73.

In a laboratory experiment interaction effects of UV-B and CO₂ on photosynthesis and growth of the moss *Hylocomium splendens* were studied. The plants were exposed to two CO₂ levels (350 ppm and 600 ppm) and three UV-B levels (no UV-B, ambient UV-B and that corresponding to 20% ozone depletion) for 5 months. The effects were recorded by measuring the photosynthetic response and growth of the plants. There was a statistically significant change in photosynthetic

efficiency and maximum photosynthetic rates due to time and to enhanced CO₂ concentration, whereas there was no effect due to UV-B. There was a decreased growth due to both UV-B and CO₂ and an interaction effect on growth (in length). The UV-B dose corresponding to the ambient level had a larger reducing effect on growth than the highest UV-B dose. This was a counter-intuitive result and the following tentative interpretation was made: differences in the measured UV-A/UV-B/PAR ratios between the treatments could explain the result provided there was a non-linear response to UV over the range of irradiance levels used.

Soule, P.T., and P.A. Knapp. 1999. Western juniper expansion on adjacent disturbed and near-relict sites. *Journal of Range Management* 52(5):525-533.

We determined rates of western juniper (*Juniperus occidentalis* spp. *occidentalis* Hook.) density and cover change during the period 1951 to 1994 at 3 adjacent sites with nearly identical elevation, slope, aspect, soils, plant communities, and climate, but different land-use histories. The 3 sites are located in central Oregon at the confluence of the Deschutes and Crooked Rivers. Two of the sites are typical of central Oregon rangelands in that they have a history of anthropogenic disturbance including active fire suppression and domestic livestock grazing. The third site is a relict mesa that is a protected Research Natural Area and has experienced minimal anthropogenic impacts. We used large scale aerial photography to determine cover and density of western juniper in 1951, 1956, 1961, 1972, 1982, and 1994. We found that western juniper density and cover during the last 4 decades increased at all sites, with changes on the relict site similar to those on one of the disturbed sites. We suggest that even though 2 of the traditionally cited causes of western juniper expansion since the late 1800s (altered fire regimes, domestic livestock grazing) may have contributed to expansion on our disturbed sites, these mechanisms can not explain expansion on the near-relict mesa. Further, we examined climatic changes since 1900 in the region and concluded that the data did not fully support a climate-driven mechanism for the expansion. In seeking to explain western juniper expansion on semiarid rangelands, we suggest that all potential causal mechanisms (e.g., fire history, biological inertia, climate, domestic grazing, atmospheric CO₂ enrichment) be considered.

Soussana, J.F., E. Casella, and P. Loiseau. 1996. Long-term effects of CO₂ enrichment and temperature increase on a temperate grass sward .2. Plant nitrogen budgets and root fraction. *Plant and Soil* 182(1):101-114.

Perennial ryegrass swards were grown in large containers on a soil and were exposed during two years to elevated (700 μ mol L⁻¹) or ambient atmospheric CO₂ concentration at outdoor temperature and to a 3 degrees C increase in air temperature in elevated CO₂. The nitrogen nutrition of the grass sward was studied at two sub-optimal (160 and 530 kg N ha⁻¹ y⁻¹) and one non-limiting (1000 kg N ha⁻¹ y⁻¹) N fertilizer supplies. At cutting date, elevated CO₂ reduced by 25 to 33%, on average, the leaf N concentration per unit mass. Due to an increase in the leaf blade weight per unit area in elevated CO₂, this decline did not translate for all cuts in a lower N concentration per unit leaf blade

area. With the non-limiting N fertilizer supply, the leaf N concentration (% N) declined with the shoot dry-matter (DM) according to highly significant power models in ambient (% N=4.9 DM^{-0.38}) and in elevated (% N=5.3 DM^{-0.52}) CO₂. The difference between both regressions was significant and indicated a lower critical leaf N concentration in elevated than in ambient CO₂ for high, but not for low values of shoot biomass. With the sub-optimal N fertilizer supplies, the nitrogen nutrition index of the grass sward, calculated as the ratio of the actual to the critical leaf N concentration, was significantly lowered in elevated CO₂. This indicated a lower inorganic N availability for the grass plants in elevated CO₂, which was also apparent from the significant declines in the annual nitrogen yield of the grass sward and in the nitrate leaching during winter. For most cuts, the harvested fraction of the plant dry-matter decreased in elevated CO₂ due, on average, to a 45-52% increase in the root phytomass. In the same way, a smaller share of the plant total nitrogen was harvested by cutting, due, on average, to a 25-41% increase in the N content of roots. The annual means of the DM and N harvest indices were highly correlated to the annual means of the nitrogen nutrition index. Changes in the harvest index and in the nitrogen nutrition index between ambient and elevated CO₂ were also positively correlated. The possible implication of changes in the soil nitrogen cycle and of a limitation in the shoot growth potential of the grass in elevated CO₂ is discussed.

Soussana, J.F., and U.A. Hartwig. 1996. The effects of elevated CO₂ on symbiotic N-2 fixation: A link between the carbon and nitrogen cycles in grassland ecosystems. *Plant and Soil* 187(2):321-332.

The response of plants to elevated CO₂ is dependent on the availability of nutrients, especially nitrogen. It is generally accepted that an increase in the atmospheric CO₂ concentration increases the C:N ratio of plant residues and exudates. This promotes temporary N-immobilization which might, in turn, reduce the availability of soil nitrogen. In addition, both a CO₂ stimulated increase in plant growth (thus requiring more nitrogen) and an increased N demand for the decomposition of soil residues with a large C:N will result under elevated CO₂ in a larger N-sink of the whole grassland ecosystem. One way to maintain the balance between the C and N cycles in elevated CO₂ would be to increase N-input to the grassland ecosystem through symbiotic N-2 fixation. Whether this might happen in the context of temperate ecosystems is discussed, by assessing the following hypothesis: i) symbiotic N-2 fixation in legumes will be enhanced under elevated CO₂, ii) this enhancement of N-2 fixation will result in a larger N-input to the grassland ecosystem, and iii) a larger N input will allow the sequestration of additional carbon, either above or below-ground, into the ecosystem. Data from long-term experiments with model grassland ecosystems, consisting of monocultures or mixtures of perennial ryegrass and white clover, grown under elevated CO₂ under free-air or field-like conditions, supports the first two hypothesis, since: i) both the percentage and the amount of fixed N increases in white clover grown under elevated CO₂ ii) the contribution of fixed N to the nitrogen nutrition of the mixed grass also increases in elevated CO₂. Concerning the third hypothesis? an increased nitrogen input to the grassland ecosystem from N-2 fixation usually promotes shoot growth (above-ground C storage) in elevated CO₂. However, the consequences of this larger N input under elevated CO₂ on the belowground carbon fluxes are not fully understood. On one hand, the positive effect of elevated CO₂ on the quantity of plant residues might be overwhelming and lead to an increased long-term below-ground C storage; on the other hand, the enhancement of the decomposition process by the N-rich legume material might favour carbon turn-over and, hence, limit the storage of below-ground carbon.

Sozzi, G.O., G.D. Trinchero, and A.A. Frascina. 1999. Controlled-atmosphere storage of tomato fruit: low oxygen or elevated carbon dioxide levels alter galactosidase activity and inhibit exogenous ethylene action. *Journal of the Science of Food and Agriculture* 79(8):1065-1070.

The effects of 3% O₂ and 20% CO₂, both alone and together with 100 µg g⁻¹ C₂H₄, on ethylene production, chlorophyll degradation, carotenoid biosynthesis and alpha- and beta- galactosidase activity in breaker tomato (*Lycopersicon esculentum* Mill) fruit were investigated. The low O₂ and high CO₂ atmospheres prevented the rise in ethylene production, total carotenoid and lycopene biosynthesis and alpha- and beta- galactosidase activity and slowed down chlorophyll degradation and loss of firmness (P<0.05). These suppressive effects were not reversed, or only in part - in the case of chlorophyll breakdown - by addition of 100 µg g⁻¹ C₂H₄ to said controlled atmospheres. After transfer from the various atmospheres to air, flesh firmness decreased and ethylene production, total carotenoids, lycopene and beta-galactosidase II activity increased but these parameters were, in all cases, still significantly different from those of fruit held in air. Keeping tomatoes in controlled atmospheres, even in the presence of ethylene, had marked residual effects. Results suggest an antagonism between elevated CO₂/low O₂ and exogenous ethylene which could determine most of the ripening parameter behaviour under controlled-atmosphere storage, though a direct regulatory mechanism by O₂ and/or CO₂ should not be discarded. Spring, G.M., G.H. Priestman, and J.P. Grime. 1996. A new field technique for elevating carbon dioxide levels in climate change experiments. *Functional Ecology* 10(4):541-545.

1. A compact, low-cost, free-air carbon dioxide enrichment system for use in climate change experiments is described. The system has been used in a small-scale study of the effects of an enriched carbon dioxide atmosphere on the growth and functioning of a natural plant community. 2. The experiment ran for 4 months in summer on a nutrient-poor limestone grassland in Derbyshire. The study examined the separate and combined effects of elevated CO₂, temperature and soil nutrient status on the growth of seedlings of obligate mycorrhizal and non-mycorrhizal plant species native to the site. 3. It was demonstrated that the CO₂ elevation could be controlled within the limits set for 64% of the time. Significant effects of elevated CO₂ on the growth and recruitment of seedlings were found in the presence of added nutrients and elevated temperatures.

Spunda, V., J. Kalina, M. Cajanek, H. Pavlickova, and M.V. Marek. 1998. Long-term exposure of Norway spruce to elevated CO₂ concentration induces changes in photosystem II mimicking an adaptation to increased irradiance. *Journal of Plant Physiology* 152(4-5):413-419.

Fifteen-year-old Norway spruces (*Picea abies* [L.] Karst.) were grown in open top chambers (OTC) at ambient (A) and elevated (i.e. ambient + 350 µmol(CO₂)/mol(-1)) concentrations of CO₂ (E) for four growing seasons (1992-1995). During this time period several examples of the depression of photosynthetic activities were observed for E needles. In order to better characterize the nature of this depression the gas exchange and fluorescence parameters were analyzed on current year needles during the last season (July 1995). The photon flux density response curves of CO₂ uptake (P-N) revealed a significantly reduced stimulation of P-N for E needles as compared with short-term exposure to doubled CO₂. Moreover, the sudden exposure of E shoots to 350 µmol(CO₂)/mol(-1) at saturating irradiance revealed a depression of both P-N_{max} (by 20 %) and quantum yield of PS II (by 32 %) compared with A shoots measured at 350 µmol(CO₂)/mol(-1). The data supporting the diminished light harvesting system of photosystem II (PS II) in E shoots compared with A shoots were obtained from pigment analysis, low temperature fluorescence spectra and Chl a fluorescence induction kinetics. The relative proportion of inactive reaction centres of PS II determined from F-pl of the fluorescence induction was 20 % higher for E needles. These changes found for E needles mimicked an adaptation of PS II to increased irradiance compared with A needles. As the irradiance exposure was the same for the examined needles from both E and A spruces we suggest that these changes reported for E needles resulted from the feed-back limitation of photochemical reactions due to suppressed electron transport through the plastoquinone pool.

Sritharan, R., H. Caspari, and F. Lenz. 1992. Influence of CO₂ enrichment and phosphorus supply on growth, carbohydrates and nitrate utilization of kohlrabi plants. *Gartenbauwissenschaft* 57(5):246-251.

Kohlrabi (*Brassica oleracea* var. *gongylodes* (L.) cv. Express Forcer) plants were grown in sand with adequate nutrient supply. From two weeks after germination until harvest they were treated with two levels of phosphorus supply (1.0 or 0.005 mM P). Four weeks after introducing the P supply regimes the plants were exposed to either a low (300 µL CO₂ L⁻¹) or high (900 µL CO₂ L⁻¹) CO₂ concentration in growth chambers for three weeks. At elevated CO₂ concentration plants with 1.0 mM phosphorus produced a larger leaf area and dry matter than those grown at low CO₂. At reduced P supply CO₂ enrichment promoted leaf senescence and did not increase growth and dry matter. Phosphorus deficiency resulted in increased accumulation of starch in leaves, tuber, and roots and reduced NO₃-N concentrations in all plant parts. The CO₂ enrichment reduced N and NO₃ concentration and increased nitrate utilization efficiency at both P levels. Phosphorus deficiency decreased nitrogen, potassium, calcium, and magnesium concentrations in leaves particularly at high CO₂.

Sritharan, R., and F. Lenz. 1992. Effects of carbon-dioxide enrichment and nitrogen supply on kohlrabi (*brassica-oleracea* var *gongylodes* L.) .1. Water-use, gas-exchange, and carbohydrate partitioning. *Gartenbauwissenschaft* 57(3):138-145.

Six weeks old kohlrabi plants (*Brassica oleracea* var. *gongylodes* [L.] cv.

Express Forcer) were grown in growth chambers for three weeks at two levels of CO₂ concentration (300- μ l CO₂ l⁻¹-low or 900- μ l CO₂ l⁻¹-high) and three levels of N-nutritional regimes (0.1, 1.0 or 6.0 mM nitrate supply). Carbon dioxide enrichment significantly increased total water uptake of plants at all N supply levels. Water use efficiency, photosynthesis and stomatal conductance were increased by high CO₂ only at 1.0 and 6.0 mM supply and reduced at the lowest N level. Photosynthetic efficiency (μ -Mol CO₂ fixed m⁻² s⁻¹ per μ -l intercellular CO₂ l⁻¹) was reduced by both low N supply and CO₂ enrichment. Intercellular CO₂ concentration was not affected by N deficiency at both CO₂ levels. Low NO₃ had a lesser effect on photosynthesis than on leaf area growth; photosynthetic rates of mature leaves at both CO₂ levels were lowered by about 30 % as compared to the respective controls, after seven weeks of reduction in NO₃ supply. In leaves lowest NO₃ treatment increased starch and sucrose and in roots starch glucose, fructose, and sucrose and in tuber starch concentrations. Photosynthetic reduction at low N supply showed a significant correlation with leaf starch concentration at both CO₂ levels indicating that the inhibition is a result of feed back inhibition. Carbohydrate partitioning within the plant organs were predominantly governed by N supply levels than CO₂ treatments.

Staddon, P.L. 1998. Insights into mycorrhizal colonisation at elevated CO₂: a simple carbon partitioning model. *Plant and Soil* 205(2):171-180.

A simulation model was used to investigate the effect of an increased rate of plant photosynthesis at enhanced atmospheric CO₂ concentration on a non-leguminous plant-mycorrhizal fungus association. The model allowed the user to modify carbon allocation patterns at three levels: (1) within the plant (shoot-root), (2) between the plant and the mycorrhizal fungus and (3) within the mycorrhizal fungus (intraradical- extraradical structures). Belowground (root and fungus) carbon losses via respiration (and turnover) could also be manipulated. The specific objectives were to investigate the dynamic nature of the potential effects of elevated CO₂ on mycorrhizal colonisation and to elucidate some of the various mechanisms by which these effects may be negated. Many of the simulations showed that time (i.e. plant age) had a more significant effect on the observed stimulation of mycorrhizal colonisation by elevated CO₂ than changes in carbon allocation patterns or belowground carbon losses. There were two main mechanisms which negated a stimulatory effect of elevated CO₂ on internal mycorrhizal colonisation: an increased mycorrhizal carbon allocation to the external hyphal network and an increased rate of mycorrhizal respiration. The results are discussed in relation to real experiments. The need for studies consisting of multiple harvests is emphasised, as is the use of allometric analysis. Implications at the ecosystem level are discussed and key areas for future research are presented.

Staddon, P.L., and A.H. Fitter. 1998. Does elevated atmospheric carbon dioxide affect arbuscular mycorrhizas? *Trends in Ecology and Evolution* 13(11):455-458.

It is well established that an increase in the concentration of atmospheric CO₂ stimulates plant growth. Recently, many researchers have concluded that elevated CO₂ concentrations also stimulate mycorrhizal colonization. However, new evidence suggests that the observed CO₂

effects on arbuscular mycorrhizal fungi are indirect and are a result of faster plant growth at higher CO₂ concentrations. Potential changes to species assemblages of mycorrhizal fungi could affect soil carbon storage and, consequently, the feedback effects of terrestrial soil-vegetation systems on global environmental change.

Staddon, P.L., A.H. Fitter, and J.D. Graves. 1999. Effect of elevated atmospheric CO₂ on mycorrhizal colonization, external mycorrhizal hyphal production and phosphorus inflow in *Plantago lanceolata* and *Trifolium repens* in association with the arbuscular mycorrhizal fungus *Glomus mosseae*. *Global Change Biology* 5(3):347-358.

Plantago lanceolata and *Trifolium repens* were grown under ambient (400 μ mol mol⁻¹) and elevated (650 μ mol mol⁻¹) atmospheric CO₂ conditions. Plants were inoculated with the arbuscular mycorrhizal fungus *Glomus mosseae* and given a phosphorus supply in the form of bonemeal. Six sequential harvests were taken in order to determine whether the effect of elevated CO₂ on internal mycorrhizal colonization and external hyphal production was independent of the stimulatory effect of elevated CO₂ on plant growth. At a given time, elevated CO₂ increased the percentage of root length colonized (RLC), the total length of colonized root and the external mycorrhizal hyphal (EMH) density and decreased the ratio of EMH to total length of colonized root. When plant size was taken into account, the CO₂ effect on RLC and total length of colonized root was greatly reduced and only apparent for early harvests in *T. repens*) and the effects on the EMH parameters disappeared. Root tissue P concentration was unchanged at elevated CO₂, but there was a decrease in shoot P at the later harvests. There was no direct effect of elevated CO₂ on P inflow for the earlier period (< 50 d) of the experiment. However, over the last period, there was a significant negative effect of elevated CO₂ on P inflow for both species, independent of plant size. It is concluded that elevated CO₂ had no direct effect on mycorrhizal colonization or external hyphal production, and that any observed effects on a time basis were due to faster growing plants at elevated CO₂. However, for older plants, elevated CO₂ had a direct negative effect on P inflow. This decrease in P inflow coincides with the observed decrease in shoot P concentration. This is discussed in terms of downregulation of photosynthesis often seen in elevated CO₂ grown plants, and the potential for mycorrhizas (via external hyphal turnover) to alleviate the phenomenon. The direction for future research is highlighted, especially in relation to carbon flow to and storage in the soil.

Staddon, P.L., A.H. Fitter, and D. Robinson. 1999. Effects of mycorrhizal colonization and elevated atmospheric carbon dioxide on carbon fixation and below-ground carbon partitioning in *Plantago lanceolata*. *Journal of Experimental Botany* 50(335):853-860.

Plantago lanceolata with or without the mycorrhizal fungus *Glomus mosseae* were grown over a 100 d period under ambient (380 $\pm$ 50 μ mol mol⁻¹) and elevated (600 $\pm$ 150 μ mol mol⁻¹) atmospheric CO₂ conditions. To achieve similar growth, non-mycorrhizal plants received phosphorus in solution whereas mycorrhizal plants were supplied with bonemeal. Measures of plant growth, photosynthesis and carbon input to the soil were obtained. Elevated CO₂ stimulated plant growth to the same extent in mycorrhizal and non-mycorrhizal plants,

but had no effect on the partitioning of carbon between shoots and roots or on shoot tissue phosphorus concentration. Mycorrhizal colonization was low, but unaffected by CO₂ treatment. Net photosynthesis was stimulated both by mycorrhizal colonization and elevated CO₂, and there was a more than additive effect of the two treatments on net photosynthesis. Colonization by mycorrhizal fungi inhibited acclimation, in terms of net carbon assimilation, of plants to elevated CO₂. C-13 natural abundance techniques were used to measure carbon input into the soil, although the results were not conclusive. Direct measurements of below-ground root biomass showed that elevated CO₂ did stimulate carbon flow below-ground and this was higher in mycorrhizal than non-mycorrhizal plants. For the four treatment combinations, the observed relative differences in amount of below-ground carbon were compared with those expected from the differences in net photosynthesis. A considerable amount of the extra carbon fixed both as a result of mycorrhizal colonization and growth in elevated CO₂ did not reveal itself as increased plant biomass. As there was no evidence for a substantial increase in soil organic matter, most of this extra carbon must have been respired by the mycorrhizal fungus and the roots or by the plants as dark-respiration. The need for detailed studies in this area is emphasized.

Staddon, P.L., J.D. Graves, and A.H. Fitter. 1998. Effect of enhanced atmospheric CO₂ on mycorrhizal colonization by *Glomus mosseae* in *Plantago lanceolata* and *Trifolium repens*. *New Phytologist* 139(3):571-580.

Plantago lanceolata L. and *Trifolium repens* L. were grown for 16 wk in ambient (360 $\mu\text{mol mol}^{-1}$) and elevated (610 $\mu\text{mol mol}^{-1}$) atmospheric CO₂. Plants were inoculated with the arbuscular mycorrhizal (AM) fungus *Glomus mosseae* (Nicol. & Gerd.) Gerdemann & Trappe and given a phosphorus supply in the form of bonemeal, which would not be immediately available to the plants. Seven sequential harvests were taken to determine whether the effect of elevated CO₂ on mycorrhizal colonization was independent of the effect of CO₂ on plant growth. Plant growth analysis showed that both species grew faster in elevated CO₂ and that *P. lanceolata* had increased carbon allocation towards the roots. Elevated CO₂ did not affect the percentage of root length colonized (RLC); although total colonized root length was greater, when plant size was taken into account this effect disappeared. This finding was also true for root length colonized by arbuscules. No CO₂ effect was found on hyphal density (colonization intensity) in roots. The P content of plants was increased at elevated CO₂, although both shoot and root tissue P concentration were unchanged. This was again as a result of bigger plants at elevated CO₂. Phosphorus inflow was unaffected by CO₂ concentrations. It is concluded that there is no direct permanent effect of elevated CO₂ on mycorrhizal functioning, as internal mycorrhizal development and the mycorrhizal P uptake mechanism are unaffected. The importance of sequential harvests in experiments is discussed. The direction for future research is highlighted, especially in relation to C storage in the soil.

Staddon, P.L., J.D. Graves, and A.H. Fitter. 1999. Effect of enhanced atmospheric CO₂ on mycorrhizal colonization and phosphorus inflow in 10 herbaceous species of contrasting growth strategies. *Functional*

Ecology 13(2):190-199.

1. Ten herbaceous species were grown over a 4-month period under ambient (360 $\mu\text{mol mol}^{-1}$) and elevated (610 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ conditions. Plants were inoculated with the arbuscular mycorrhizal (AM) fungus *Glomus mosseae* and given a phosphorus (P) supply which was not immediately available to the plants. 2. Multiple harvests were taken in order to determine whether the effect of elevated CO₂ on mycorrhizal colonization and phosphorus inflow was independent of its effect on plant growth. 3. All species grew faster under elevated CO₂ and carbon partitioning was altered, generally in favour of the shoots. All species responded similarly to elevated CO₂. 4. Elevated CO₂ did not affect the percentage of root length colonized by AM fungi, but the total amount of colonized root length was increased, because the plants were bigger. 5. Elevated CO₂ increased total P content, but had little or no effect on P concentration. At a given age, P inflow was stimulated by elevated CO₂, but when root length was taken into account the CO₂ effect disappeared. 6. In these host species there is no evidence for a direct effect of elevated CO₂ on mycorrhizal functioning, because both internal mycorrhizal colonization and P inflow are unaffected. 7. Future research should concentrate on the potential for carbon flow to the soil via the external mycelial network.

Stange, G. 1997. Effects of changes in atmospheric carbon dioxide on the location of hosts by the moth, *Cactoblastis cactorum*. *Oecologia* 110(4):539-545.

Sensory organs that detect CO₂ are common in herbivorous moths and butterflies, but their function has been unclear until now. As the CO₂ gradients in the vicinity of a host plant depend on its physiological condition, CO₂ could provide a sensory cue for the suitability of the plant as a larval food source. This study investigated whether changing the atmospheric CO₂ concentration affected oviposition by *Cactoblastis cactorum* on its host, the cactus *Opuntia stricta*. On host plants exposed to rapid fluctuations in CO₂ concentration, the frequency of oviposition was reduced by a factor of 3.2 compared to the control. As the fluctuations mask the much smaller CO₂ signals generated by the plants, this suggests that those signals constitute an important component of the host identification process. On host plants exposed to a constant background of doubled CO₂, oviposition was also reduced, by a factor of 1.8. An increased background reduces host signal detectability, partially as a consequence of a general principle of sensory physiology (Weber-Fechner's law), and partially due to other factors specific to CO₂-receptor neurons.

Stanghellini, C., and J.A. Bunce. 1993. Response of photosynthesis and conductance to light, CO₂, temperature and humidity in tomato plants acclimated to ambient and elevated CO₂. *Photosynthetica* 29(4):487-497.

In tomato (*Lycopersicon esculentum* L.) plants, net carbon dioxide exchange rate (P(N)) response curves to both irradiance (I) and short-term [CO₂] were similar for plants grown at both 350 and 700 $\mu\text{mol CO}_2 \text{ m}^{-3}$. However, water vapor conductance (gH₂O) of plants grown at high [CO₂] was less sensitive to short term [CO₂] variations,

when measured at low vapor pressure difference, and was larger than the conductance of "ambient [CO₂]" plants when both were exposed to high [CO₂]. P(N) and g(H₂O) under high I increased with temperature over the range 18 to 32-degrees-C. P(N) of plants grown in both [CO₂] treatments increased at most about 25 % from 350 to 700 cm³ m⁻³ at 18 and 25-degrees-C, and decreased when exposed to 1000 cm³ m⁻³ at these temperatures. Thus increasing atmospheric [CO₂] might not increase P(N) by as much as expected and water use of crops might not decrease.

Steffen, W.L., W. Cramer, M. Plochl, and H. Bugmann. 1996. Global vegetation models: Incorporating transient changes to structure and composition. *Journal of Vegetation Science* 7(3):321-328.

We describe an approach for developing a Dynamic Global Vegetation Model (DGVM) that accounts for transient changes in vegetation distribution over a decadal time scale. The DGVM structure is based on a linkage between an equilibrium global vegetation model and smaller scale ecosystem dynamics modules that simulate the rate of vegetation change. Vegetation change is classified into four basic types, based largely on the projected change in above-ground biomass of the vegetation. These four types of change are: (1) dieback of forest, shrubland or grassland; (2) successional replacement within forest, shrubland or grassland; (3) invasion of forest, shrubland or grassland; (4) change in tree/grass ratio. We then propose an approach in which the appropriate ecosystem dynamics module for each type of change is applied and the grid cells of the global model updated accordingly. An approach for accounting for fire, as an example of a disturbance which may strongly influence the rate and spatial pattern of forest dieback, is incorporated. We also discuss data needs for the development, calibration and validation of the model.

Steffen, W.L., and J.S.I. Ingram. 1995. Global change and terrestrial ecosystems: An initial integration. *Journal of Biogeography* 22(2-3):165-174.

We present a framework for integrating GCTE's research programme based on three interacting axes-time, space and applicability. We use the contributed papers from the First GCTE Science Conference to undertake an initial integration of GCTE-type research using this three-axis structure. We assess where progress is being made, where progress is likely to be made in the near future, and where critical gaps exist which require a major effort to eliminate. Elevated CO₂ research is one of the most mature areas within GCTE, and provides scope for initial integration along all three axes. Soils, being key to the functioning of all terrestrial ecosystems, provide another excellent opportunity to integrate research along all three axes. A major obstacle to further integration is our lack of understanding of landscape-scale processes, particularly disturbances, and our ability to simulate global change impacts on them. GCTE's Focus 2, Change in Ecosystem Structure, is perhaps best placed to attack many of the gaps that prevent this further integration along space and time scales, and is now entering a rapid development phase; the other Foci also have a major role to play. Integration specifically along the applicability axis is being developed in some areas but requires an enhanced effort to achieve its potential to increase scientific efficiency and effectiveness. The emerging field of global ecology, i.e.

ecology at very large space and time scales, is progressing rapidly on the basis of linkages to more traditional ecological research at smaller scales, but requires further interaction with work along the applicability axis.

Steinger, T., C. Lavigne, A. Birrer, K. Groppe, and B. Schmid. 1997. Genetic variation in response to elevated CO₂ in three grassland perennials - a field experiment with two competition regimes. *Acta Oecologica-International Journal of Ecology* 18(3):263-268.

Intraspecific Variation in the response to increased concentrations of atmospheric CO₂ was investigated in three plant species (*Bromus erectus*, *Prunella vulgaris*, *P. grandiflora*) in a calcareous grass land. Genotypes of each species were grown both in multispecies communities and under reduced competition pressure in tubes buried in the soil. Plant growth was reduced in the artificial communities but no significant effect of CO₂ was observed on any of the measured traits. Significant genotype by-CO₂ interactions were found in two species when plants were grown under reduced competition in the tubes. No genotype-by-CO₂ interactions were found for the same genotypes grown in the multispecies communities indicating that genetic variation was swamped by large environmental variation. Furthermore, no correlations were observed between CO₂ responses of identical genotypes grown individually in tubes and in multispecies communities. This result cautions about the ability to predict CO₂-induced evolutionary changes from data of individually-grown plants.

Stekiel, T.A., W.J. Stekiel, M. Tominaga, A. Stadnicka, Z.J. Bosnjak, and J.P. Kampine. 1996. Effect of halothane and isoflurane on in situ diameter responses of small mesenteric veins to acute graded hypercapnia. *Anesthesia and Analgesia* 82(2):349-357.

The purpose of the present study was to quantify the inhibitory effect of inhaled halothane and isoflurane on acute hypercapnia-induced responses of capacitance-regulating veins and related cardiovascular variables in response to sequential 40-s periods of 5%, 10%, 15%, and 20% inspired CO₂ (FICO₂). Measurements were made in normoxic alpha-chloralose- anesthetized rabbits before, during, and after either 0.75 minimum alveolar anesthetic concentration inhaled halothane or isoflurane. The graded hypercapnia caused graded venoconstriction and bradycardia but minimal pressor responses. Hypercapnia-induced venoconstriction was blocked by prior local superfusion of the exposed veins with 3 x 10⁻⁶ M tetrodotoxin. Both the hypercapnia-induced venoconstriction and bradycardia responses were significantly attenuated by halothane or isoflurane and did not fully recover after removal of the anesthetics from the circulation. Both anesthetics produced a significant baseline (i.e., prehypercapnia) hypotension and a tendency toward a resultant tachycardia. The baseline hypotension did not recover completely after elimination of the anesthetic. Neither anesthetic altered baseline vein diameter. These results agree with previous studies demonstrating that hypercapnic acidosis produces mesenteric venoconstriction by elevating excitatory sympathetic efferent neural input via activation of peripheral and central chemoreceptors and that bradycardia results from activation of compensatory baroreflexes. The neural components of these reflexes are possible primary sites for attenuation of these cardiovascular responses by halothane and isoflurane.

Sternberg, M., V.K. Brown, G.J. Masters, and I.P. Clarke. 1999. Plant community dynamics in a calcareous grassland under climate change manipulations. *Plant Ecology* 143(1):29-37.

This study investigates the effects of field manipulations of local climate to determine the potential impact of climate change on plant community dynamics in a calcareous grassland. The experimental site is located in a grassland at the Wytham estate, Oxfordshire, UK. The one hectare study area is within a 10 ha abandoned arable field on Jurassic corallian limestone. Two climate change scenarios were used: warmer winters with increased summer rainfall and warmer winters with summer drought. Plant cover and species richness were significantly increased in plots receiving supplemented summer rainfall, while the amount of litter was significantly reduced. Litter formation was significantly increased by winter warming and drought. The responses of the plant community to the climate manipulations were related to the life-history attributes of the dominant species. Seedling recruitment was limited by microsite availability, which also varied in the different climate manipulations. The results are discussed in terms of successional dynamics. They suggest that warmer winters may delay succession, as gap formation in the sward will provide sites for colonisation of annuals, thereby enabling their persistence in the sward. Under wetter conditions during summer, perennial grasses tend to close the sward, thereby inhibiting the establishment of later successional species.

Stewart, J.D., and J. Hoddinott. 1993. Photosynthetic acclimation to elevated atmospheric carbon-dioxide and uv irradiation in pinus-banksiana. *Physiologia Plantarum* 88(3):493-500.

Pinus banksiana seedlings were grown for 9 months in enclosures in greenhouses at CO₂ concentrations of 350 or 750 $\mu\text{mol mol}^{-1}$ with either low (0.005 to 0.3 W M⁻²) or high (0.25 to 0.90 W M⁻²) ultraviolet-B (UV-B) irradiances. Total seedling dry weight decreased with high UV treatment but was unaffected by CO₂ enrichment. High UV treatment also shifted biomass partitioning in favor of leaf production. Both CO₂ and UV treatments decreased the dark respiration rate and light compensation point. High UV light inhibited photosynthesis at 350 but not at 750 $\mu\text{mol mol}^{-1}$ CO₂ due to a UV induced increase in ribulose-1,5-bisphosphate carboxylase/oxygenase efficiency and ribulose-1,5-bisphosphate regeneration. Stomatal density was increased by high UV irradiance but was unchanged by CO₂ enrichment.

Stewart, J., and C. Potvin. 1996. Effects of elevated CO₂ on an artificial grassland community: Competition, invasion and neighbourhood growth. *Functional Ecology* 10(2):157-166.

1. We analysed the effect of CO₂ enrichment on plant-plant interactions in an artificial community dominated by *Trifolium repens* and *Poa pratensis*. Plants were enriched either in open-tops or growth chambers. 2. Our main hypotheses were supported, i.e. elevated CO₂ increased the strength and number of plant-plant interactions and *Trifolium* benefited more than *Poa* from a high CO₂ concentration. However, responses

differed depending on whether plants were enriched in open-top or in growth chambers. These differences are discussed regarding possible density dependence. 3. This study emphasizes the importance of invasions in the dynamics of our artificial community. Invasiveness was best predicted by traits pertaining to space acquisition. 4. To provide insights into evolutionary processes, phenotypic plasticity and genetic correlation of individual traits were analysed across environments. Our results suggest that little opportunity had occurred for adaptive plasticity to evolve for most characters.

Stiling, P., A.M. Rossi, B. Hungate, P. Dijkstra, C.R. Hinkle, W.M. Knott, and B. Drake. 1999. Decreased leaf-miner abundance in elevated CO₂: Reduced leaf quality and increased parasitoid attack. *Ecological Applications* 9(1):240-244.

Most studies on the effects of elevated CO₂ have focused on the effects on plant growth and ecosystem processes. Fewer studies have examined the effects of elevated CO₂ on herbivory, and of these, most have examined feeding rates in laboratory conditions. Our study takes advantage of an open-top CO₂ fertilization study in a Florida scrub-oak community to examine the effects of elevated CO₂ on herbivore densities, herbivore feeding rates, and levels of attack of herbivores by natural enemies. Higher atmospheric CO₂ concentration reduced plant foliar nitrogen concentrations, decreased abundance of leaf-mining insect herbivores, increased per capita leaf consumption by leafminers, and increased leaf miner mortality. As suggested by other authors, reduced foliar quality contributed to the increase in herbivore mortality, but only partly. The major factor increasing mortality was higher attack rate by parasitoids. Thus increasing CO₂ concentrations may reduce the survivorship of insect herbivores directly, by reducing plant quality, but also indirectly, by changing herbivore feeding and eliciting greater top-down pressure from natural enemies.

Stirling, C.M., P.A. Davey, T.G. Williams, and S.P. Long. 1997. Acclimation of photosynthesis to elevated CO₂ and temperature in five British native species of contrasting functional type. *Global Change Biology* 3(3):237-246.

Acclimation of photosynthesis to growth at elevated CO₂ concentration varies markedly between species. Species functionally classified as stress-tolerators (S) and ruderals (R), are thought to be incapable, or the least capable, of responding positively in terms of growth to elevated [CO₂]. Is this pattern of response also apparent in leaf photosynthesis of wild S- and R-strategists? Acclimatory loss of a photosynthetic and growth response to elevated [CO₂] is assumed to reflect limitation on capacity to utilize additional photosynthate. The doubling of pre-industrial global [CO₂] is expected to coincide with a 3 degrees C increase in mean temperature which could stimulate growth; will photosynthetic capacity at elevated [CO₂] be greater when the concurrent temperature increase is simulated? Five species from natural grassland of NW Europe and of contrasting ecological strategy were grown in hemispherical greenhouses, environmentally controlled to track the external microclimate. Within a replicated design, plants were grown at (i) current ambient [CO₂] and temperature, (ii) elevated [CO₂] (ambient + 340 $\mu\text{mol mol}^{-1}$) and ambient temperature, (iii) ambient [CO₂] and elevated temperature (ambient + 3 degrees C), or (iv) elevated [CO₂] and elevated temperature. After 75-104 days, the CO₂

response of light-saturated rates of photosynthesis ($A(\text{sat})$) was analysed in controlled-environment cuvettes in a field laboratory. There was no acclimatory loss of photosynthetic capacity with growth in elevated $[\text{CO}_2]$ or elevated temperature over this period in *Poa alpina* (S), *Bellis perennis* (R) or *Plantago lanceolata* (mixed C-S-R strategist), and a significant ($P < 0.05$) increase in capacity in *Helianthemum nummularium* (S) and *Poa annua* (R). Photosynthetic rates of leaves grown and measured in elevated $[\text{CO}_2]$ were therefore significantly higher than rates for leaves grown and measured in ambient $[\text{CO}_2]$, for all species. With the exception of *Poa alpina*, stomatal conductance and stomatal limitation on $A(\text{sat})$ showed no acclimatory response to growth in elevated $[\text{CO}_2]$. Carboxylation efficiency, determined from the initial slope of the response of $A(\text{sat})$ to intercellular CO_2 concentration was significantly increased by elevated $[\text{CO}_2]$ and elevated temperature in *H. nummularium*, implying a possible increase in *in vivo* RubisCO activity. Increased carboxylation efficiency of this species was also reflected by an increase in the CO_2 - and light- saturated rates of photosynthesis, indicating an increased capacity for regeneration of the primary CO_2 acceptor in photosynthesis. The results show that R-strategists and slow- growing S-strategists, are inherently capable of large increases in leaf photosynthetic capacity with growth in elevated $[\text{CO}_2]$ in contrast to expectations from growth studies. With the exception of *P. annua*, where there was a significant negative interaction between CO_2 and temperature, concurrent increase in growth temperature had little effect on this pattern of response.

Stirling, C.M., M. Heddell-Cowie, M.L. Jones, T.W. Ashenden, and T.H. Sparks. 1998. Effects of elevated CO_2 and temperature on growth and allometry of five native fast-growing annual species. *New Phytologist* 140(2):343-354.

Whereas much is known of the short-term growth response to elevated atmospheric CO_2 concentrations, $[\text{CO}_2](\text{elev})$, there is relatively little information on how the response of native species is modified by temperature, despite the fact that an increase in global mean temperature is expected to accompany the rise in $[\text{CO}_2]$. In this study, five functionally related annual native species were exposed to different combinations of ambient and elevated $[\text{CO}_2]$ and temperatures in order to assess their response in terms of growth and allometry. Fast-growing annuals were selected for the study because their growth responses could be assessed over a major portion of the plant's life cycle and in as short a period as 8 wk. Plants were grown in eight hemi-spherical glasshouses, programmed to track outside ambient conditions and provide a replicated experimental design. Treatments comprised (i) current ambient $[\text{CO}_2]$ and temperature, (ii) elevated $[\text{CO}_2]$ (ambient + 34 kPa), and ambient temperature (iii) ambient $[\text{CO}_2]$ and elevated temperature (ambient + 3 degrees C) and (iv) elevated $[\text{CO}_2]$ and elevated temperature (T degrees C-elev). All five species responded positively to $[\text{CO}_2](\text{elev})$, although the response was statistically significant for only one, *Poa annua* L. Averaged over all five species, $[\text{CO}_2](\text{elev})$ increased total plant biomass by 25 % ($P = 0.005$) at 56 d, reflecting a proportionally greater increase in leaf and stem mass relative to root weight. Elevated $[\text{CO}_2]$ had no effect on leaf area, either at the individual species level or overall. Elevated T degrees C, by contrast, had little effect on shoot growth but increased root mass on average by 43 % and leaf area by 22 %. Few interactions between elevated $[\text{CO}_2]$ and T degrees C were observed, with the CO_2 response generally greater at elevated than ambient T degrees C. Both $[\text{CO}_2](\text{elev})$ and T degrees C-elev resulted in a transient increase in relative growth rate, (RGR), during the first 14 d exposure and a 3 degrees C increase in temperature had no effect on the duration of the response. CO_2 stimulation of growth operated through a sustained increase in net assimilation rate. (NAR),

although the potential benefit to RGR was offset by a concurrent decline in leaf area ratio (LAR), as a result of a decrease in leaf area per unit leaf mass (SLA). The response to T degrees C-elev was generally opposite of that to $[\text{CO}_2](\text{elev})$. For example, T degrees C-elev increased LAR through an increase in SLA and this, rather than any effect on NAR, was the major factor responsible for the stimulation of RGR. Allometric analysis of CO_2 effects revealed that changes in allocation observed at individual harvests were due solely to changes associated with plant size. Elevated T degrees C, by contrast, had a direct effect on allocation patterns to leaves, with an increase in leaf area expansion relative to whole plant mass during the initial stages of growth and subsequent increased allocation of biomass away from leaves to other regions of the plant. No change in the allometric relation between roots and shoots were observed at either elevated $[\text{CO}_2]$ or T degrees C. We conclude, therefore, that allocation of biomass and morphological characteristics such as SLA, are relatively insensitive to $[\text{CO}_2]$, at least when analysed at the whole-plant level, and where changes have been observed, these are the product of comparing plants of the same age but different size.

Stitt, M. 1991. Rising CO_2 levels and their potential significance for carbon flow in photosynthetic cells. *Plant, Cell and Environment* 14(8):741-762.

In the first part of this review, I discuss how we can predict the direct short-term effect of enhanced CO_2 on photosynthetic rate in C3 terrestrial plants. To do this, I consider: (1) to what extent enhanced CO_2 will stimulate or relieve demand on partial processes like carboxylation, light harvesting and electron transport, the Calvin cycle, and end-product synthesis; and (2) the extent to which these various processes actually control the rate of photosynthesis. I conclude that control is usually shared between Rubisco (which responds sensitively to CO_2) and other components (which respond less sensitively), and that photosynthesis will be stimulated by 25- 75% when the CO_2 concentration is doubled from 35 to 70 Pa. This is in good agreement with the published responses. In the next part of the review, I discuss the evidence that most plants undergo a gradual inhibition of photosynthesis during acclimation to enhanced CO_2 . I argue that this is related to an inadequate demand for carbohydrate in the remainder of the plant. Differences in the long-term response to CO_2 may be explained by differences in the sink-source status of plants. depending upon the species, the developmental stage, and the developmental conditions. In the third part of the review, I consider the biochemical mechanisms which are involved in 'sink' regulation of photosynthesis. Accumulating carbohydrate could lead to a direct inhibition of photosynthesis, involving mechanical damage by large starch grains or Pi-limitation due to inhibition of sucrose synthesis. I argue that Pi is important in the short-term regulation of partitioning to sucrose and starch, but that its contribution to 'sink' regulation has not yet been conclusively demonstrated. Indirect or 'adaptive' regulation of photosynthesis is probably more important, involving decreases in amounts of key photosynthetic enzymes, including Rubisco. This decreases the rate of photosynthesis, and potentially would allow resources (e.g. amino acids) to be remobilized from the leaves and reinvested in sink growth to readjust the sink-source balance. In the final part of the review, I argue that similar changes of Rubisco and, possibly, other proteins are probably also involved during acclimation to high CO_2 .

Stütt, M., and A. Krapp. 1999. The interaction between elevated carbon dioxide and nitrogen nutrition: the physiological and molecular background. *Plant, Cell and Environment* 22(6):583-621.

This review first summarizes the numerous studies that have described the interaction between the nitrogen supply and the response of photosynthesis, metabolism and growth to elevated [CO₂]. The initial stimulation of photosynthesis in elevated [CO₂] is often followed by a decline of photosynthesis, that is typically accompanied by a decrease of ribulose-1,5- bisphosphate carboxylase/oxygenase (Rubisco), an accumulation of carbohydrate especially starch, and a decrease of the nitrogen concentration in the plant. These changes are particularly marked when the nitrogen supply is low, whereas when the nitrogen supply is adequate there is no acclimation of photosynthesis, no major decrease in the internal concentration of nitrogen or the levels of nitrogen metabolites, and growth is stimulated markedly. Second, emerging evidence is discussed that signals derived from nitrate and nitrogen metabolites such as glutamine act to regulate the expression of genes involved in nitrate and ammonium uptake and assimilation? organic acid synthesis and starch accumulation, to modulate the sugar-mediated repression of the expression of genes involved in photosynthesis, and to modulate whole plant events including shoot-root allocation, root architecture and flowering. Third, increased rates of growth in elevated [CO₂] will require higher rates of inorganic nitrogen uptake and assimilation. Recent evidence is discussed that an increased supply of sugars can increase the rates of nitrate and ammonium uptake and assimilation, the synthesis of organic acid accepters, and the synthesis of amino acids. Fourth, interpretation of experiments in elevated [CO₂] requires that the nitrogen status of the plants is monitored. The suitability of different criteria to assess the plant nitrogen status is critically discussed. Finally the review returns to experiments with elevated [CO₂] and discusses the following topics: is, and if so how, are nitrate and ammonium uptake and metabolism stimulated in elevated [CO₂], and does the result depend on the nitrogen supply? Is acclimation of photosynthesis the result of sugar- mediated repression of gene expression, end-product feedback of photosynthesis, nitrogen-induced senescence, or ontogenetic drift? Is the accumulation of starch a passive response to increased carbohydrate formation, or is it triggered by changes in the nutrient status? How do changes in sugar production and inorganic nitrogen assimilation interact in different conditions and at different stages of the life history to determine the response of whole plant growth and allocation to elevated [CO₂]?

Stütt, M., W.P. Quick, U. Schurr, E.D. Schulze, S.R. Rodermel, and L. Bogorad. 1991. Decreased ribulose-1,5-bisphosphate carboxylase-oxygenase in transgenic tobacco transformed with antisense rbcS .2. Flux- control coefficients for photosynthesis in varying light, CO₂, and air humidity. *Planta* 183(4):555-566.

Transgenic tobacco (*Nicotiana tabacum* L.) plants transformed with 'antisense' rbcS to produce a series of plants with a progressive decrease in the amount of ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) have been used to investigate the contribution of Rubisco to

the control of photosynthesis at different irradiance, CO₂ concentrations and vapour-pressure deficits. Assimilation rates, transpiration, the internal CO₂ concentration and chlorophyll fluorescence were measured in each plant. (i) The flux-control coefficient of Rubisco was estimated from the slope of the plot of Rubisco content versus assimilation rate. The flux-control coefficient had a value of 0.8 or more in high irradiance, (1050 μmol m⁻² s⁻¹), low-vapour pressure deficit (4 mbar) and ambient CO₂ (350-μ-bar). Control was marginal in enhanced CO₂ (450-μ-bar) or low light (310 μmol m⁻² s⁻¹) and was also decreased at high vapour- pressure deficit (17 mbar). No control was exerted in 5% CO₂. (ii) The flux-control coefficients of Rubisco were compared with the fractional demand placed on the calculated available Rubisco capacity. Only a marginal control on photosynthetic flux is exerted by Rubisco until over 50% of the available capacity is being used. Control increases as utilisation rises to 80%, and approaches unity (i.e. strict limitation) when more than 80% of the available capacity is being used. (iii) In low light, plants with reduced Rubisco have very high energy-dependent quenching of chlorophyll fluorescence (qE) and a decreased apparent quantum yield. It is argued that Rubisco still exerts marginal control in these conditions because decreased Rubisco leads to increased thylakoid energisation and high-energy dependent dissipation of light energy, and lower light-harvesting efficiency. (iv) The flux-control coefficient of stomata for photosynthesis was calculated from the flux-control coefficient of Rubisco and the internal CO₂ concentration, by applying the connectivity theorem. Control by the stomata varies between zero and about 0.25. It is increased by increased irradiance, decreased CO₂ or decreased vapour-pressure deficit. (v) Photosynthetic oscillations in saturating irradiance and CO₂ are suppressed in decreased- activity transformants before the steady-state rate of photosynthesis is affected. This provides direct evidence that these oscillations reveal the presence of "excess" Rubisco. (vi) Comparison of the flux-control coefficients of Rubisco with mechanistic models of photosynthesis provides direct support for the reliability of these models in conditions where Rubisco has a flux-control coefficient approach unity (i.e. "limits" photosynthesis), but also indicates that these models are less useful in conditions where control is shared between Rubisco and other components of the photosynthetic apparatus.

Stocker, R., C. Korner, B. Schmid, P.A. Niklaus, and P.W. Leadley. 1999. A field study of the effects of elevated CO₂ and plant species diversity on ecosystem-level gas exchange in a planted calcareous grassland. *Global Change Biology* 5(1):95-105.

The relationship between plant species diversity and ecosystem CO₂ and water vapour fluxes was investigated for planted calcareous grassland communities composed of 5, 12, or 32 species assembled from the native plant species pool. These diversity manipulations were done in factorial combination with a CO₂ enrichment experiment in order to investigate the degree to which ecosystem responses to elevated CO₂ are altered by a loss of plant diversity. Ecosystem CO₂ and H₂O fluxes were measured over several 24-h periods during the 1994 and 1995 growing seasons. Ecosystem CO₂ assimilation on a ground area basis decreased with decreasing plant diversity in the first year and this was related to a decline in above-ground plant biomass. In the second year, however, CO₂ assimilation was not affected by diversity, and this corresponded to the disappearance of a diversity effect on above-ground biomass. Irrespective of diversity treatment, CO₂ assimilation on a ground area basis was linearly related to peak aboveground biomass in both years. Elevated CO₂ significantly increased ecosystem CO₂ assimilation in both years with no interaction between diversity and CO₂ treatment, and no corresponding increase in above-ground biomass. There were no significant effects of diversity on water vapour nux, which was measured only in the second year. There were indications of a small CO₂ effect on

water vapour flux (3-9% lower at elevated CO₂ depending on the light level). Our findings suggest that decreasing plant species diversity may substantially decrease ecosystem CO₂ assimilation during the establishment of such planted calcareous grassland communities, but also suggest that this effect may not persist. In addition, we find no evidence that plant species diversity alters the response of ecosystem CO₂ assimilation to elevated CO₂.

Stocker, R., P.W. Leadley, and C. Korner. 1997. Carbon and water fluxes in a calcareous grassland under elevated CO₂. *Functional Ecology* 11(2):222-230.

1. As part of a long-term study of the effects of elevated CO₂ on biodiversity and ecosystem function in a calcareous grassland, we measured ecosystem carbon dioxide and water- vapour fluxes over 24-h periods during the 1994 and 1995 growing seasons. Data were used to derive CO₂ and H₂O gas- exchange response functions to quantum flux density (QFD). 2. The relative increase in net ecosystem CO₂ flux (NEC) owing to CO₂ enrichment increased as QFD rose. Daytime NEC at high QFD under elevated CO₂ increased by 25% to 60%, with the greatest increases in the spring and after mowing in June when above-ground biomass was lowest. There was much less stimulation of NEC in early June and again in October when the canopy was fully developed. Night-time NEC was not significantly altered under elevated CO₂. 3. Short-term reversal of CO₂ concentrations between treatments after two seasons of CO₂ exposure provided evidence for a 50% downward adjustment of NEC expressed per unit above-ground plant dry weight. However, when expressed on a land area basis, this difference disappeared because of a c. 20% increase in above-ground biomass under elevated CO₂. 4. Ecosystem evapotranspiration (ET) was not significantly altered by elevated CO₂ when averaged over all measurement dates and positions. However, ET was reduced 3-18% at high QFD in plots at the top of the slope at our study site. In summary, CO₂ enrichment resulted in a large stimulation of ecosystem CO₂ capture, especially during periods of a large demand of carbon in relationship to its supply, and resulted in a relatively small and variable effect on ecosystem water consumption.

Stocklin, J., and C. Korner. 1999. Interactive effects of elevated CO₂, P availability and legume presence on calcareous grassland: results of a glasshouse experiment. *Functional Ecology* 13(2):200-209.

1. We investigated the interactive effects of elevated CO₂, supply of phosphorus (P) and legume presence in model communities of calcareous grassland. Half of the communities contained six graminoids and eight non-legume forb species. In the other half, four non-legume forbs were replaced by legumes. 2. Ecosystem responses. Above-ground phytomass (>5 cm) hardly responded to elevated CO₂ alone. However, when P and legumes were combined, the CO₂ effect on above-ground community phytomass in year two was a stimulation of 45% ($P < 0.001$). Below-ground community dry matter was stimulated by elevated CO₂ alone by + 36% ($P < 0.01$), but was only + 20% ($P < 0.05$) when legumes were present and P was added. At the final (late season) harvest the mean effect of elevated CO₂ on total above- and below-ground phytomass was + 23% ($P < 0.001$) and revealed no significant interactions among treatment combinations, because above- and

belowground effects of CO₂ enrichment had opposite directions. 3. Functional group responses. When legumes were absent, graminoids increased their total above- and below-ground phytomass in elevated CO₂ by 60% ($P < 0.001$) but there was no increase when legumes were present. The response of forbs to CO₂ was not significant, irrespective of co-treatment. Legumes, however, were significantly stimulated by P supply and their CO₂ response was much larger when P was added (+ 55%, $P < 0.01$ vs + 25%, NS). 4. Species responses. CO₂ effects on species ranged from highly positive (+ 143%) to moderately negative (- 43%). 5. Our results demonstrate that the effect of CO₂ enrichment in such natural grassland communities will be low on above-ground phytomass and largely below-ground if no additional nutrients are provided. N-2- fixing legumes appear to be crucial for the community response to elevated CO₂ but legume responsiveness is largely controlled by P availability.

Stocklin, J., P.W. Leadley, and C. Korner. 1997. Community and species level responses to elevated CO₂ in designed calcareous grassland communities. *Acta Oecologica-International Journal of Ecology* 18(3):241-248.

We present a synthesis of two independent glasshouse experiments in which we investigated the short term response of model communities of calcareous grassland species to CO₂- enrichment. Communities consisted of six species in the first study and of 14 species in the second study. Communities were grown in containers filled with ca. 20 liters of natural soil. Total aboveground biomass production was increased by 14% (n.s., $p=0.21$) in the first study and by 8.5% ($p=0.03$) in the second study. This community level response was due to a significant stimulation of growth in 2 and 5 species, respectively. In each of the experiments, one species responded negatively to CO₂-enrichment. The remaining species, including all legumes, remained unaffected by CO₂-enrichment. Positive or negative responding species did not belong to specific functional groups, hence responses could not have been predicted from a priori knowledge of individual plant traits. *Bromus erectus*, which is the dominant species in calcareous grasslands of the Jura mountains, did not exhibit a CO₂- response at the species level, but genotype-specific responses in this species varied significantly and included positive as well as negative responses. No such genotypic differentiation of CO₂-response was observed in *Festuca ovina*. In the long term, we expect directional selection of positively responding genotypes and shifts in species composition to alter both population and community structure of calcareous grasslands - a conclusion that may also hold for other diverse plant communities.

Stocklin, J., K. Schweizer, and C. Korner. 1998. Effects of elevated CO₂ and phosphorus addition on productivity and community composition of intact monoliths from calcareous grassland. *Oecologia* 116(1-2):50-56.

We investigated the effects of elevated CO₂ (600 $\mu\text{mol l}^{-1}$ vs 350 $\mu\text{mol l}^{-1}$) and phosphorus supply (1 g P m⁻² year⁻¹ vs unfertilized) on intact monoliths from species-rich calcareous grassland in a greenhouse. Aboveground community dry mass remained almost unaffected by elevated CO₂ in the first year (+ 6%, n.s.), but was significantly stimulated by CO₂ enrichment in year two (+26%, $P < 0.01$). Among

functional groups, only graminoids contributed significantly to this increase. The effect of phosphorus alone on community biomass was small in both years and marginally significant only when analyzed with MANOVA (+6% in year one, +9% in year two, 0.1 greater than or equal to $P > 0.05$). Belowground biomass and stubble after two seasons were not different in elevated CO₂ and when P was added. The small initial increase in aboveground community biomass under elevated CO₂ is explained by the fact that some species, in particular *Carex flacca*, responded very positively right from the beginning, while others, especially the dominant *Bromus erectus*, responded negatively to CO₂ enrichment. Shifts in community composition towards more responsive species explain the much larger CO₂ response in the second year. These shifts, i.e., a decline in xerophytic elements (*B. erectus*) and an increase in mesophytic grasses and legumes occurred independently of treatments in all monoliths but were accelerated significantly by elevated CO₂. The difference in average biomass production at elevated compared to ambient CO₂ was higher when P was supplied (at the community level the CO₂ response was enhanced from 20% to 33% when P was added, in graminoids from 17% to 27%, in legumes from 4% to 60% and in *C. flacca* from 120% to 298% by year two). Based on observations in this and similar studies, we suggest that interactions between CO₂ concentration, species presence, and nutrient availability will govern community responses to elevated CO₂.

Stoffella, P.J., Y.C. Li, R.R. Pelosi, and A.M. Hamner. 1995. Citrus rootstock and carbon-dioxide enriched irrigation influence on seedling emergence, growth, and nutrient content. *Journal of Plant Nutrition* 18(7):1439-1448.

Seeds of Carrizo citrange (*Citrus senensis* (L.) Osb. X *Poncirus trifolliata* (L.), Cleopatra mandarin (*C. reticulata* Bianco), Sour orange (*C. aurantium* L.), and Rough lemon (*C. limon* (Burm f.) were sown in trays, irrigated without or with enriched Carbon dioxide (CO₂) (1,362 mg L⁻¹) and evaluated for seedling emergence, growth, and nutrient contents. Rough lemon had a faster rate and higher percent emergence than the other rootstocks. Carrizo citrange had thicker stem diameters and taller seedlings than other rootstocks. Cleopatra mandarin had the smallest seedling shoot and root weights and larger shoot:root ratios than Rough lemon and Sour orange. Carrizo citrange and Cleopatra mandarin had higher leaf chlorophyll-a and total chlorophyll content than Rough lemon or Sour orange. Carbon dioxide enriched irrigation had no effects on emergence or seedling growth variables except lower root weight. Lower media pH (6.90 versus 5.65), attributed to CO₂ enriched irrigation, may have adversely affected root growth as compared to shoot characteristics. Leaf nutrient contents generally differed between rootstocks but were not affected by CO₂ enriched water except for higher Zn and lower Mn contents. These results indicate that citrus seedling emergence, subsequent growth and leaf nutrient content differed between rootstocks but there are no beneficial effect from CO₂ enriched irrigation.

Storlie, C.A., and J.R. Heckman. 1996. Bell pepper yield response to carbonated irrigation water. *Journal of Plant Nutrition* 19(10-11):1477-1484.

Field studies were conducted to determine the influence of carbonated irrigation water on bell pepper (*Capsicum annuum* L.) yield, plant nutrient status, canopy carbon dioxide (CO₂) concentration, and soil pH. Marketable yield, early yield, marketable fruit size distribution, and

plant nutrient status were unaffected by carbonated irrigation water. Air CO₂ concentration in the lowest portion of the canopy increased during irrigation events, but returned to the ambient CO₂ concentration shortly after irrigation ceased. The effect of carbonated irrigation water on soil pH was marginal and unpredictable.

Strain, B.R., and R.B. Thomas. 1992. Field-measurements of CO₂ enhancement and climate change in natural vegetation. *Water, Air, and Soil Pollution* 64(1-2):45-60.

It is generally assumed that healthy, natural ecosystems have the potential to sequester carbon under favorable environmental conditions. There is also evidence that CO₂ acts as a plant fertilizer. It is of interest to know if these assumptions are valid and how natural systems might respond under future scenarios of CO₂ increase and possible climate changes. Few measurements of the effects of CO₂ and global climate change have been made on "natural" ecosystems under realistic field conditions. Most measurements have been conducted in the synthetic environments of totally controlled greenhouses and growth chambers. Several lines of evidence indicate that controlled environment studies using plants growing in pots induce experimental artifacts that reduce confidence in the use of results for prediction of future global responses. Open top chambers are being used in several autecological field studies in an attempt to obtain more realistic field environments. A few field microcosm studies have been completed and a system for the free air release of CO₂ has been applied in cotton fields. Unfortunately, the requirement of large amounts of CO₂ and financial restrictions have precluded the initiation of larger scale field studies in natural vegetation. This paper lists and summarizes the best field studies available but draws heavily on studies from artificial environments and conditions in an attempt to summarize knowledge of global environmental change on forests and other non-agricultural ecosystems. Finally the paper concludes that there is a need for the development and application of equipment for field measurements in several representative natural ecosystems and makes specific recommendation of the creation of a tropical research center.

Strand, M., D.A. Herms, M.P. Ayres, M.E. Kabiske, M.G. Kaufman, E.D. Walker, K.S. Pregitzer, and R.W. Merritt. 1999. Effects of atmospheric CO₂, light availability and tree species on the quality of leaf detritus as a resource for treehole mosquitoes. *Oikos* 84(2):277-283.

Elevated CO₂ could alter the productivity of heterotrophic aquatic ecosystems through effects on allochthonous litter inputs. The effects of atmospheric CO₂ concentration, light availability to trees and tree species, on leaf detritus quality as a food resource for eastern treehole mosquitoes (*Aedes triseriatus*) were examined. Larvae were reared in laboratory microcosms (simulated treeholes) with naturally- senesced, abscised foliage from seedlings of red oak (*Quercus rubra*) and paper birch (*Betula papyrifera*) grown in ambient and elevated atmospheric CO₂ environments. Elevated CO₂ did not have significant effects on any measure of mosquito performance. In contrast, host species and light availability had dramatic effects on mosquito development time and survival; light availability had additional effects on adult size. Mosquito reproductive potential (+/- SE) averaged 8.4 +/- 1.5 females female(-1)

generation(-1) when litter input was from birch-sun leaves, but was 19.6 +/- 1.8 when the litter was from birch-shade leaves and 13.0 +/- 1.8 when from oak-sun leaves. Mosquito development time was nearly halved when the litter input was from oak-sun leaves versus birch-sun leaves, suggesting a potential for even greater demographic effects (e.g. two generations per year instead of one could yield a 20- fold increase in annual growth rate). Trophic transfer rates (mg insect detritivore g litter(-1) d(-1)) were 3-fold greater on birch-shade leaves than on birch-sun leaves. Changes in insolation and tree species composition can have important consequences for forest ecosystems, because of effects on litter quality that impact microbial saprobes and, ultimately, invertebrate detritivores.

Street-Perrott, F.A., Y.S. Huang, R.A. Perrott, G. Eglinton, P. Barker, L. BenKhelifa, D.D. Harkness, and D.O. Olago. 1997. Impact of lower atmospheric carbon dioxide on tropical mountain ecosystems. *Science* 278(5342):1422-1426.

Carbon-isotope values of bulk organic matter from high-altitude lakes on Mount Kenya and Mount Elgon, East Africa, were 10 to 14 per mil higher during glacial times than they are today. Compound-specific isotope analyses of leaf waxes and algal biomarkers show that organisms possessing CO₂-concentrating mechanisms, including C-4 grasses and freshwater algae, were primarily responsible for this large increase. Carbon limitation due to lower ambient CO₂ partial pressures had a significant impact on the distribution of forest on the tropical mountains, in addition to climate. Hence, tree line elevation should not be used to infer palaeotemperatures.

Stronach, I.M., S.C. Clifford, A.D. Mohamed, P.R. Singletonjones, S.N. Azamali, and N.M.J. Crout. 1994. The effects of elevated carbon-dioxide, temperature and soil- moisture on the water-use of stands of groundnut (*arachis- hypogaea* L). *Journal of Experimental Botany* 45(280):1633-1638.

Stands of groundnut (*Arachis hypogaea* L. cv. Kadiri 3) were grown in controlled environment glasshouses at two mean air temperatures (28 degrees C and 32 degrees C), two atmospheric CO₂ concentrations (375 ppmv and 700 ppmv) and two soil moisture treatments (irrigated weekly to field capacity or allowed to dry from 22 d after sowing). The transpiration equivalent, Omega(W) (g kPa kg(-1))-the product of the accumulated biomass/transpired water ratio and the saturation deficit-was calculated for all the treatments using aboveground harvest, root core and neutron probe measurements. Neither temperature nor soil moisture treatment was found to have an effect on Omega(W). Increased CO₂ concentration raised Omega(W) from 6.21 +/- 0.30 to 7.67 +/- 0.29 g kPa kg(-1), an increase of 24% (P < 0.005). The importance of accounting for root material and pod composition when calculating Omega(W) was highlighted.

Stulen, I., and J. Denhertog. 1993. Root-growth and functioning under atmospheric co2 enrichment. *Vegetatio* 104:99-115.

This paper examines the extent to which atmospheric CO₂ enrichment may influence growth of plant roots and function in terms of uptake of water and nutrients, and carbon allocation towards symbionts. It is concluded that changes in dry matter allocation greatly depend on the experimental conditions during the experiment, the growth phase of the plant, and its morphological characteristics. Under non-limiting conditions of water and nutrients for growth, dry matter partitioning to the root is not changed by CO₂ enrichment. The increase in root/shoot ratio, frequently observed under limiting conditions of water and/or nutrients, enables the plant to explore a greater soil volume, and hence acquire more water and nutrients. However, more data on changes in dry matter allocation within the root due to atmospheric CO₂ are needed. It is concluded that nitrogen fixation is favored by CO₂ enrichment since nodule mass is increased, concomitant with an increase in root length. The papers available so far on the influence of CO₂ enrichment on mycorrhizal functioning suggest that carbon allocation to the roots might be increased, but also here more experiments are needed.

Stutte, G.W., N.C. Yorio, and R.M. Wheeler. 1996. Interacting effects of photoperiod and photosynthetic photon flux on net carbon assimilation and starch accumulation in potato leaves. *Journal of the American Society for Horticultural Science* 121(2):264-268.

The effect of photoperiod (PP) on net carbon assimilation rate (A(net)) and starch accumulation in newly mature canopy leaves of 'Norland' potato (*Solanum tuberosum* L.) was determined under high (412 proportional to mol .(m-)2 . s(-1)) and low (263 proportional to mol . m(-2) . s(-1)) photosynthetic photon flux (PPF) conditions. The A(net) decreased from 13.9 to 11.6 and 9.3 mu mol . m(-2) . s(-1), and leaf starch increased from 70 to 129 and 118 mg . g(-1) drymass (DM) as photoperiod (PP) was increased from 12/12 to 18/6, and 24/0, respectively. Longer PP had a greater effect with high PPF conditions than with low PPF treatments, with high PPF showing greater decline in A(net). Photoperiod did not affect either the CO₂ compensation point (50 mu mol . mol(-1)) or CO₂ saturation point (1100-1200 mu mol . mol(-1)) for A(net). These results show an apparent limit to the amount of starch that can be stored (approximate to 15% DM) in potato leaves. An apparent feedback mechanism exists for regulating A(net) under high PPF, high CO₂ and long PP, but there was no correlation between A(net) and starch concentration in individual leaves. This suggests that maximum A(net) cannot be sustained with elevated CO₂ conditions under long PP (greater than or equal to 12 hours) and high PPF

conditions. If a physiological limit exists for the fixation and transport of carbon, then increasing photoperiod and light intensity under high CO₂ conditions is not the most appropriate means to maximize the yield of potatoes.

Sukumar, R., H.S. Suresh, and R. Ramesh. 1995. Climate change and its impact on tropical montane ecosystems in southern India. *Journal of Biogeography* 22(2-3):533-536.

The montane regions (>2000 m MSL) of the Western Ghats in southern India feature stunted evergreen forests (C3 plant type) interspersed with extensive grasslands (C3 or C4 plant types). We have studied the vegetational history of this ecosystem in relation to climate change during the late Quaternary through stable-carbon isotope analysis of peat deposits as indicators of C3 or C4 plant types. Grasslands (of C4 type) were predominant during the last glacial maximum (20- 18 kyr sp) and again during 6-3.5 kyr sp, while forest and possibly C3 grassland expanded during the deglaciation, attaining their peak distribution at 10 kyr sp. The shift in C3 and C4 plant types seems related to changes in moisture and atmospheric CO₂, with lower moisture and CO₂ levels favouring the latter plant types. The oscillating climate and vegetation has influenced the structure and composition of the montane ecosystem. Plant diversity of the near-pristine montane forests is relatively lower than other comparable sites in the neotropics. The implications of global change on the tropical montane ecosystem, in particular the composition of the angiosperm and vertebrate communities, are discussed. In particular, an expansion of montane forest and replacement of C4 with C3 grassland can be expected. Human impact on the natural vegetation, such as conversion of grasslands to monoculture plantations of wattle and eucalypts may, however, interfere with natural succession caused by global climate change. Endemic mammals such as the Nilgiri tahr would face increased risk of extinction.

Sullivan, J.H. 1997. Effects of increasing UV-B radiation and atmospheric CO₂ on photosynthesis and growth: Implications for terrestrial ecosystems. *Plant Ecology* 128(1-2):194-206.

Increases in UV-B radiation reaching the earth as a result of stratospheric ozone depletion will most likely accompany increases in atmospheric CO₂ concentrations. Many studies have examined the effects of each factor independently, but few have evaluated the combined effects of both UV-B radiation and elevated CO₂. In general the results of such studies have shown independent effects on growth or seed yield. Although interspecific variation is large, high levels of UV-B radiation tends to reduce plant growth in sensitive species, while CO₂ enrichment tends to promote growth in most C-3 species. However, most previous studies have not looked at temporal effects or at the relationship between photosynthetic acclimation to CO₂ and possible photosynthetic limitations imposed by UV-B radiation. Elevated CO₂ may provide some protection against UV-B for some species. In contrast, UV-B radiation may limit the ability to exploit elevated CO₂ in other species. Interactions between the effects of CO₂ enrichment and UV-B radiation exposure have also been shown for biomass allocation. Effects on both biomass allocation and photosynthetic acclimation may be important to ecosystem structure in terms of seedling establishment, competition and reproductive output. Few studies have evaluated ecosystem processes such as decomposition or nutrient cycling. Interactive effects may be subtle and species specific but should not be ignored in the assessment

of the potential impacts of increases in CO₂ and W-B radiation on plants.

Sullivan, J.H., and A.H. Teramura. 1994. The effects of uv-b radiation on loblolly-pine .3. Interaction with co2 enhancement. *Plant, Cell and Environment* 17(3):311-317.

Projected depletions in the stratospheric ozone layer will result in increases in solar ultraviolet-B radiation (290- 320nm) reaching the earth's surface. These increases will likely occur in concert with other environmental changes such as increases in atmospheric carbon dioxide concentrations. Currently very little information is available on the effectiveness of UV-B radiation within a CO₂-enriched atmosphere, and this is especially true for trees. Loblolly pine (*Pinus taeda* L.) seedlings were grown in a factorial experiment at the Duke University Phytotron with either 0, 8.8 or 13.8 kJ m⁻² of biologically effective UV-B radiation (UV- B-BE) The CO₂ concentrations used were 350 and 650 μ mol mol⁻¹. Measurements of chlorophyll fluorescence were made at 5- week intervals and photosynthetic oxygen evolution and leaf pigments were measured after 22 weeks, prior to harvest. The results of this study demonstrated a clear growth response to CO₂ enrichment but neither photosynthetic capacity nor quantum efficiency were altered by CO₂. The higher UV-B irradiance reduced total biomass by about 12% at both CO₂ levels but biomass partitioning was altered by the interaction of CO₂ and UV-B radiation. Dry matter was preferentially allocated to shoot components by UV-B radiation at 350 μ mol mol⁻¹ CO₂ and towards root components at 650 μ mol mol⁻¹ CO₂. These subtle effects on biomass allocation could be important in the future to seedling establishment and competitive interactions in natural as well as agricultural communities.

Sultemeyer, D. 1997. Changes in the CO₂ concentrating mechanism during the cell cycle in *Dunaliella tertiolecta*. *Botanica Acta* 110(1):55-61.

Synchronised cells of *Dunaliella tertiolecta* were used to investigate the expression of the CO₂ concentrating mechanism over the cell cycle during growth in either ambient air (low Ci cells) or air enriched with 5% CO₂ (high Ci cells). The cultures were analysed for extracellular carbonic anhydrase activity, affinity of photosynthesis for inorganic carbon (Ci) and the ability to accumulate Ci. In high Ci cells, carbonic anhydrase activity changed between 2-4 units mg⁻¹ Chl during the light-dark rhythm showing no clear periodicity. Similarly, the apparent affinity for Ci remained rather constant over the cell cycle. This was judged from the Ci concentrations required for half maximum rate of photosynthesis (K_{1/2}(Ci)) of 72-80 μ M. In the same cells the accumulation ratio of internal Ci versus external Ci ranged between 5 and 9.5 without a clear rhythm. In contrast, these parameters showed distinct periodical changes in synchronised low Ci cells. Carbonic anhydrase activity changed from 10 to 350 units mg⁻¹ Chl with maximum and minimum activities occurring in the middle and at the end of the light period, respectively. The K_{1/2}(Ci) values showed similar periodicity ranging between 13-36 μ M. In addition the

accumulation ratio increased up to 30 in the middle of illumination and decreased to its lowest level of 12 at the end of the light period. These results indicate the presence of a common step in regulating the induction of the measured parameters and that light is not an absolute requirement for the induction of the CO₂ concentrating mechanism in synchronous low CO₂ grown cells of *Dunaliella tertiolecta*.

Sultemeyer, D., and K.A. Rinast. 1996. The CO₂ permeability of the plasma membrane of *Chlamydomonas reinhardtii*: Mass-spectrometric O-18-exchange measurements from (CO₂)-C-13-O-18 in suspensions of carbonic anhydrase-loaded plasma-membrane vesicles. *Planta* 200(3):358-368.

The unicellular green alga *Chlamydomonas reinhardtii* possesses a CO₂-concentrating mechanism. In order to measure the CO₂ permeability coefficients of the plasma membranes (PMs), carbonic anhydrase (CA)-loaded vesicles were isolated from *C. reinhardtii* grown either in air enriched with 50 mL CO₂ · L⁻¹ (high-C-i cells) or in ambient air (350 μL CO₂ · L⁻¹; low-C-i cells). Marker-enzyme measurements indicated less than 1% contamination with thylakoid and mitochondrial membranes, and that more than 90% of the PMs from high- and low-C-i cells were orientated right-side-out. The PMs appeared to be sealed as judged from the ability of vesicles to accumulate [C-14]acetate along a proton gradient for at least 10 min. Carbonic anhydrase-loaded PMs from high- and low-C-i cells of *C. reinhardtii* were used to measure the exchange of O-18 between doubly labelled CO₂((CO₂)-C-13-O-18) and H₂O in stirred suspensions by mass spectrometry. Analysis of the kinetics of the O-18 depletion from (CO₂)-C-13-O-18 in the external medium provides a powerful tool to study CO₂ diffusion across the PM to the active site of CA which catalyses O-18 exchange only inside the vesicles but not in the external medium (Silverman et al., 1976, *J Biol Chem* 251: 4428-4435). The activity of CA within loaded PM vesicles was sufficient to speed-up the O-18 loss to H₂O to 45360-128800 times the uncatalysed rate, depending on the efficiency of CA-loading and PM isolation. From the O-18-depletion kinetics performed at pH 7.3 and 7.8, CO₂ permeability coefficients of 0.76 and 1.49 · 10⁻³ cm · s⁻¹, respectively, were calculated for high- C-i cells. The corresponding values for low-C-i cells were 1.21 and 1.8 · 10⁻³ cm · s⁻¹. The implications of the similar and rather high CO₂ permeability coefficients (low CO₂ resistance) in high- and low-C-i cells for the CO₂-concentrating mechanism of *C. reinhardtii* are discussed.

Sulzman, E.W., K.A. Poiani, and T.G.F. Kittel. 1995. Modeling human-induced climatic-change - a summary for environmental managers. *Environmental Management* 19(2):197-224.

The rapid increase in atmospheric concentrations of greenhouse gases has caused concern because of their potential to alter the earth's radiation budget and disrupt current climate patterns. While there are many uncertainties associated with use of general circulation models (GCMs), GCMs are currently the best available technology to project changes in climate associated with elevated gas concentrations. Results indicate increases in global temperature and changes in global precipitation patterns are likely as a result of doubled CO₂. GCMs are not reliable for

use at the regional scale because local scale processes and geography are not taken into account. Comparison of results from five GCMs in three regions of the United States indicate high variability across regions and among models depending on season and climate variable. Statistical methods of scaling model output and nesting finer resolution models in global models are two techniques that may improve projections. Despite the many limitations in GCMs, they are useful tools to explore climate-earth system dynamics when used in conjunction with water resource and ecosystem models. A variety of water resource models showed significant alteration of regional hydrology when run with both GCM-generated and hypothetical climate scenarios, regardless of region or model complexity. Similarly, ecological models demonstrate the sensitivity of ecosystem production, nutrient dynamics, and distribution to changes in climate and CO₂ levels. We recommend the use of GCM-based scenarios in conjunction with water resource and ecosystem models to guide environmental management and policy in a "no-regrets" framework or as part of a precautionary approach to natural resource protection.

Sun, J.D., G.E. Edwards, and T.W. Okita. 1999. Feedback inhibition of photosynthesis in rice measured by O-2 dependent transients. *Photosynthesis Research* 59(2-3):187-200.

The kinetic properties of photosynthesis (both transient and steady-state) were monitored using three non-invasive techniques to evaluate limitations on triose-phosphate (triose- P) conversion to carbohydrate in rice. These included analyzing the O-2 sensitivity of CO₂ fixation and the assimilatory charge (AC) using gas exchange (estimate of the ribulose 1,5- bisphosphate pool) and measuring Photosystem II activity by chlorophyll fluorescence analysis under varying light, temperature and CO₂ partial pressures. Photosynthesis was inhibited transiently upon switching from 20 to 2 kPa O-2 (reversed O-2 sensitivity), the degree of which was correlated with a terminal, steady-state suppression of low O-2 enhancement of photosynthesis. Under current ambient levels of CO₂ and moderate to high light, the transient pattern was more obvious at 18 degrees C than at 26 degrees C while at 34 degrees C no transient response was observed. The transient inhibition at 18 degrees C ranged from 15% to 31% depending on the pre-measurement temperature. This pattern, symptomatic of feedback, was observed with increasing light and CO₂ partial pressures with the degree of feedback decreasing from moderate (18 degrees C) up to high temperature (34 degrees C). Under feedback conditions, the rate of assimilation is shifted from being photorespiration limited to being triose-P utilization limited. Transitory changes in CO₂ assimilation rates (A) under low O-2 indicative of feedback coincided with a transitory drop in assimilatory charge (AC) and inhibition of electron transport. In contrast to previous studies with many C-3 species, our studies indicate that rice shows susceptibility to feedback inhibition under moderate temperatures and current atmospheric levels of CO₂.

Suzuki, K. 1995. Phosphoglycolate phosphatase-deficient mutants of *Chlamydomonas reinhardtii* capable of growth under air. *Plant and Cell Physiology* 36(1):95-100.

Mutants deficient in phosphoglycolate phosphatase (PGPase) require elevated levels of CO₂ for growth in the light and cannot grow when photorespiration occurs. Revertants, namely, double mutants capable of growth under air without restoration of the missing PGPase activity, might be expected to have secondary mutations that reduce or eliminate photorespiration. Nineteen revertants were selected from a culture of a PGPase-deficient mutant of *Chlamydomonas reinhardtii* (pgp-1-18-7F) after a second mutagenesis that involved treatment with 5-fluorodeoxyuridine and ethyl methanesulfonate. There were significant differences in the photosynthetic affinity for CO₂ among revertant cells grown under 5% CO₂. Eight revertants had five times higher photosynthetic affinity for CO₂ than that of wild type 2137 cells grown under 5% CO₂, resembling air-adapted wild-type cells, whereas four revertants had less than half the affinity for CO₂ of the wild type. In all of the revertant cells with higher affinity grown in 5% CO₂, the rates of photosynthesis under levels of CO₂ below those in air were apparently higher than that of the wild type, whereas the rates under CO₂-saturating conditions were lower than that of wild type, indicating that the efficiency of photosynthesis under air was significantly improved in these revertants. In addition, some revertants had a photosynthetic capacity and a growth rate higher than those of the wild type, without any increased photosynthetic affinity for CO₂.

Svedang, M.U. 1992. Carbon-dioxide as a factor regulating the growth dynamics of *Juncus bulbosus*. *Aquatic Botany* 42(3):231-240.

The unusual growth pattern exhibited by *Juncus bulbosus* L. in a slightly acidic Swedish brown-water lake is due to a CO₂ deficit. Decrease in growth rate during the summer can be avoided through CO₂ addition in July when CO₂ availability is low and epiphytes are thriving. Growth of *J. bulbosus* in the laboratory is stimulated by CO₂ addition up to a concentration somewhat higher than in air (500 ppm), while higher CO₂ pressure restrains growth. Root growth reflects the leaf biomass development, but is favoured by elevated CO₂ levels even more than the leaves.

Svensson, B.H., T.R. Christensen, E. Johansson, and M. Oquist. 1999. Interdecadal changes in CO₂ and CH₄ fluxes of a subarctic mire: Stordalen revisited after 20 years. *Oikos* 85(1):22-30.

The first subarctic wetland CO₂ and CH₄ flux measurements were made at Stordalen in the beginning of the 1970s in connection with the IBP study. A return to this area in 1994-95 offered a unique opportunity to study possible interdecadal changes in northern wetland CO₂ and CH₄ emissions. Measurements of CO₂ and CH₄ fluxes were carried out in similar habitats as those investigated in 1974. The mire distribution of wet minerotrophic areas relative to the elevated ombrotrophic areas had changed dramatically over the twenty years. There were no significant differences between the CH₄-flux in 1974, 1994, and 1995. However, the CO₂ fluxes were significantly higher in 1995 than in 1974. Since differences in climatic conditions gave no cause for such a change it suggests a possible increase in decomposition rate to be due to other factors. We suggest changes in vegetation composition, altered mineralization pathways and disintegration of permafrost as causes for the interdecadal increase in decomposition rates.

Swift, M.J., O. Andren, L. Brussaard, M. Briones, M.M. Couteaux, K. Ekschmitt, A. Kjoller, P. Loiseau, and P. Smith. 1998. Global change, soil biodiversity, and nitrogen cycling in terrestrial ecosystems: three case studies. *Global Change Biology* 4(7):729-743.

The relative contribution of different soil organism groups to nutrient cycling has been quantified for a number of ecosystems. Some functions, particularly within the N-cycle, are carried out by very specific organisms. Others, including those of decomposition and nutrient release from organic inputs are, however, mediated by a diverse group of bacteria, protozoa, fungi and invertebrate animals. Many authors have hypothesized that there is a high degree of equivalence and flexibility in function within this decomposer community and thence a substantial extent of redundancy in species richness and resilience in functional capacity. Three case studies are presented to examine the relationship between soil biodiversity and nitrogen cycling under global change in ecosystem types from three latitudes, i.e. tundra, temperate grassland and tropical rainforest. In all three ecosystems evidence exists for the potential impact of global change factors (temperature change, CO₂ enrichment, land-use-change) on the composition and diversity of the soil community as well as on various aspects of the nitrogen and other cycles. There is, however, very little unequivocal evidence of direct causal linkage between species richness and nutrient cycling efficiency. Most of the changes detected are shifts in the influence of major functional groups of the soil biota (e.g. between microflora and fauna in decomposition). There seem to be few data, however, from which to judge the significance of changes in diversity within functional groups. Nonetheless the soil biota are hypothesized to be a sensitive link between plant detritus and the availability of nutrients to plant uptake. Any factors affecting the quantity or quality of plant detritus is likely to change this link. Rigorous experimentation on the relationships between soil species richness and the regulation or resilience of nutrient cycles under global change thus remains a high priority.

Sykes, M.T., I.C. Prentice, and W. Cramer. 1996. A bioclimatic model for the potential distributions of north European tree species under present and future climates. *Journal of Biogeography* 23(2):203-233.

A bioclimatic model based on physiological constraints to plant growth and regeneration is used here in an empirical way to describe the present natural distributions of northern Europe's major trees. Bioclimatic variables were computed from monthly means of temperature, precipitation and sunshine (%) interpolated to a 10' grid taking into account elevation. Minimum values of mean coldest-month temperature (T-c) and 'effective' growing degree days (GDD*) were fitted to species' range limits. GDD* is total annual growing degree days (GDD) minus GDD to budburst (GDD(o)). Each species was assigned to one of the chilling-response categories identified by Murray, Cannell & Smith (1989) to calculate GDD(o). Maximum T-c values were fitted to continental species' mild-winter limits and other deciduous species' warm-winter limits. Minimum values of relative growing-season moisture availability (α^*) were estimated from silvics. Growth indices were calculated based on potential net assimilation (a quadratic in daily temperature) and α^* . Growth can be rapid near a range limit, e.g. *Picea abies* (L.) Karsten in southern Sweden. Climate changes expected for CO₂ doubling were projected on to the grid. Simulated distribution changes reflected interspecific differences in response to changing seasonality. Chilling responses proved important, e.g. the predicted range limit of *Fagus sylvatica* L. contracts in the west while expanding northwards as winters warm more than summers. Transient responses to climate change can be modelled using the same information provided that fundamental and realized niche limitations are distinguished—a caveat that underlines the dearth of experimental information on the climatic requirements for growth, and especially regeneration, of many important trees.

Syvertsen, J., and J.H. Graham. 1997. Carbon budgets of two Citrus sp. in response to elevated CO₂ VA mycorrhizae and phosphorus status. *Plant Physiology* 114(3):111.

2307

Syvertsen, J.P., and J.H. Graham. 1999. Phosphorus supply and arbuscular mycorrhizas increase growth and net gas exchange responses of two Citrus spp. grown at elevated [CO₂]. *Plant and Soil* 208(2):209-219.

We hypothesized that greater photosynthate supply at elevated [CO₂] could compensate for increased below-ground C demands of arbuscular mycorrhizas. Therefore, we investigated plant growth, mineral nutrition, starch, and net gas exchange responses of two Citrus spp. to phosphorus (P) nutrition and mycorrhizas at elevated atmospheric [CO₂]. Half of the seedlings of sour orange (*C. aurantium* L.) and 'Ridge Pineapple' sweet orange (*C. sinensis* L. Osbeck) were inoculated with the arbuscular mycorrhizal (AM) fungus, *Glomus intraradices* Schenck and Smith and half were non-mycorrhizal (NM). Plants were grown at ambient or 2X ambient [CO₂] in unshaded greenhouses for 11 weeks and fertilized daily with nutrient solution either without added P or with 2 mM P in a low-P soil. High P supply reduced AM colonization whereas elevated [CO₂] counteracted the depressive effect of P on intraradical colonization and vesicle development. Seedlings grown at either elevated [CO₂], high P or with *G. intraradices* had greater growth, net assimilation of CO₂ (A(CO₂)) in leaves, leaf water-use efficiency, leaf dry wt/area, leaf starch and carbon/nitrogen (C/N) ratio. Root/whole plant dry wt ratio was decreased by elevated [CO₂], P, and AM

colonization. Mycorrhizal seedlings had higher leaf-P status but lower leaf N and K concentrations than nonmycorrhizal seedlings which was due to growth dilution effects. Starch in fibrous roots was increased by elevated [CO₂] but reduced by *G. intraradices*, especially at low-P supply. In fibrous roots, elevated [CO₂] had no effect on C/N, but AM colonization decreased C/N in both Citrus spp. grown at low-P supply. Overall, there were no species differences in growth or A(CO₂). Mycorrhizas did not increase plant growth at ambient [CO₂]. At elevated [CO₂], however, mycorrhizas stimulated growth at both P levels in sour orange, the more mycorrhiza-dependent species, but only at low-P in sweet orange, the less dependent species. At low-P and elevated [CO₂], colonization by the AM fungus increased A(CO₂) in both species but more so in sour orange than in sweet orange. Leaf P and root N concentrations were increased more and root starch level was decreased less by AM in sour orange than in sweet orange. Thus, the additional [CO₂] availability to mycorrhizal plants increased CO₂ assimilation, growth and nutrient uptake over that of NM plants especially in sour orange under P limitation.

Szente, K., Z. Nagy, and Z. Tuba. 1998. Enhanced water use efficiency in dry loess grassland species grown at elevated air CO₂ concentration. *Photosynthetica* 35(4):637-640.

Net CO₂ assimilation rate (P-N), Stomatal conductance (g(s)), transpiration rate (E), and water use efficiency (WUE) in four perennial C-3 species (grasses: *Dactylis glomerata*, *Festuca rupicola*, dicots: *Filipendula vulgaris*, *Salvia nemorosa*) grown for 231 d in open-top chambers at ambient (CA, 350 $\mu\text{mol mol}^{-1}$) or elevated (CE, 700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations were compared. When measured at CE, PN was significantly higher in CE plants of all four species than in the CA ones. The increase in P-N was less prominent in the two grasses than in the two dicots. The E was significantly higher in the CE-grass *F. rupicola* and CE-dicot *F. vulgaris* than in the CA plants. There was no change in E owing to CE in the other grass and dicot. The g(s) in *F. vulgaris* and *F. rupicola* increased, while there was a decrease in *D. glomerata* and no change in *S. nemorosa*. WUE increased in all species grown in CE: four- to five-fold in the dicots and less than two-fold in the grasses. The increase in WUE was primarily due to an increase in P-N and not to a decrease in E.

Tajiri, T. 1997. Studies on the cultivation and storage quality of bean sprouts .13. Growth and quality of thick bean sprouts cultivated with a CO₂-enriched rotary method. *Journal of the Japanese Society for Food Science and Technology-Nippon Shokuhin Kagaku Kogaku Kaishi* 44(4):332-339.

Thick bean sprouts cultivated using a rotary box (rotary cultivation, RC) have a decreased yield and inferior quality, although the growth of sprouts from the beans is promoted and the nutrient content of the sprouts is improved(1)2)). Because exposure to high levels of carbon dioxide was useful for promoting the growth of the hypocotyl and increasing the quantity of harvested sprouts(3)), we combined the rotary box method with the CO₂-enriched method(1)). Herein the usefulness of this combination method for improving the physical properties and the yield of bean sprouts by controlling hypocotyl growth were

examined.

Takagi, M., K. Gyokusen, and A. Saito. 1998. Increase in the CO₂ exchange rate of leaves of *Ilex rotunda* with elevated atmospheric CO₂ concentration in an urban canyon. *International Journal of Biometeorology* 42(1):16-21.

It was found that the atmospheric carbon dioxide (CO₂) concentration in an urban canyon in Fukuoka city, Japan during August 1997 was about 30 $\mu\text{mol mol}^{-1}$ higher than that in the suburbs. When fully exposed to sunlight, in situ the rate of photosynthesis in single leaves of *Ilex rotunda* planted in the urban canyon was higher when the atmospheric CO₂ concentration was elevated. A biochemically based model was able to predict the in situ rate of photosynthesis well. The model also predicted an increase in the daily CO₂ exchange rate for leaves in the urban canyon with an increase in atmospheric CO₂ concentration. However, in situ such an increase in the daily CO₂ exchange rate may be offset by diminished sunlight, a higher air temperature and a lower relative humidity. Thus, the daily CO₂ exchange rate predicted using the model based solely on the environmental conditions prevailing in the urban canyon was lower than that predicted based only on environmental factors found in the suburbs.

Takle, E.S., D.J. Bramer, W.E. Heilman, and M.R. Thompson. 1994. A synoptic climatology for forest-fires in the ne US and future implications from gcm simulations. *International Journal of Wildland Fire* 4(4):217-224.

We studied surface-pressure patterns corresponding to reduced precipitation, high evaporation potential, and enhanced forest-fire danger for West Virginia, which experienced extensive forest-fire damage in November 1987. From five years of daily weather maps we identified eight weather patterns that describe distinctive flow situations throughout the year. Map patterns labeled extended-high, back-of-high, and pre-high were the most frequently occurring patterns that accompany forest fires in West Virginia and the nearby four-state region. Of these, back-of-high accounted for a disproportionately large amount of fire-related damage. Examination of evaporation acid precipitation data showed that these three patterns and high-to-the-south patterns all led to drying conditions and all other patterns led to moistening conditions. Surface-pressure fields generated by the Canadian Climate Centre global circulation model for simulations of the present (1xCO₂) climate and 2xCO₂ climate were studied to determine whether forest-fire potential would change under increased atmospheric CO₂. The analysis showed a tendency for increased frequency of drying in the NE US, but the results were not statistically significant.

Talbott, L.D., A. Srivastava, and E. Zeiger. 1996. Stomata from growth-chamber-grown *Vicia faba* have an enhanced sensitivity to CO₂. *Plant, Cell and Environment* 19(10):1188-1194.

Abaxial stomata from *Vicia faba* leaves grown in a growth chamber under constant light, temperature and humidity showed an elaborate pattern of aperture changes over the course of a light cycle. These aperture changes, were tightly correlated with changes in chamber CO₂

concentration ($r^2=0.83$). Changes in chamber [CO₂] resulted, in turn, from substantial daily fluctuations in ambient [CO₂], typical of the Los Angeles environment, with a constant offset caused by photosynthesis and respiration of the plants within the chamber. The dominant role of the stomatal response to CO₂ in the control of aperture was confirmed by manipulation of chamber [CO₂]. Fast (15 min) increases and decreases in [CO₂] caused rapid decreases and increases in aperture, while constant [CO₂] resulted in constant aperture. In contrast, aperture changes in comparable plants grown under greenhouse conditions were tightly correlated with changes in incident solar radiation ($r^2=0.80$), and poorly correlated with changes in [CO₂] ($r^2=0.09$). Greenhouse-grown plants transferred to growth chamber conditions showed no apparent response to CO₂. These data indicate that growth-chamber-grown *V. faba* leaves provide an experimental system optimally suited for the study of the stomatal response to CO₂, and suggest that acclimation to environmental conditions alters the sensitivity of stomata to CO₂.

Talkkari, A., S. Kellomaki, and H. Peltola. 1999. Bridging a gap between a gap model and a physiological model for calculating the effect of temperature on forest growth under boreal conditions. *Forest Ecology and Management* 119(1-3):137-150.

The applicability of the parabolic function of the Jabowa gap model for the relationship between tree growth and temperature sum for aggregating short-term temperatures responses was investigated by determining parameter values for the temperature function in a gap model from material generated by means of a physiological model (Kellomaki et al., 1993; Kellomaki and Vaisanen, 1997), in which the growth and development of a tree stand is linked with the climate and soil through photosynthesis, respiration, transpiration and the uptake of water and nitrogen. Predictions of stand volume and total stand production were compared using the following functions for Scots pine (*Pinus sylvestris* L.): (i) the original parabolic function of the Jabowa model with parameter values based on the geographical distribution of trees (TO), (ii) the same parabolic function with parameter values obtained by fitting data generated using the physiological model (T1), and (iii) a fit of a truncated parabolic function to data generated using the physiological model (T2). The differences in volume and total production between the functions were greater at the site in northern Finland than at the sites in southern and central Finland, although absolute timber production was lowest at the northern site. The stand volume and timber production were highest at all three sites with the truncated parabola (T2) under conditions of climate change. Total production following climate change (average of TO, T1, and T2) was an average of 104% of that observed under current climatic conditions at the southern site, 105% at the central site and 121% at the northern site. The gap model was not found to be sensitive to the growing degree-days (gdd) response curve when the model was applied to Finnish conditions, and thus appeared to be satisfactory for aggregating the short-term physiological responses of Scots pine to temperature. The situation would be more problematic, however, if the model were applied under the conditions prevailing near the southern or northern edge of the geographical distribution of Scots pine. Tanaka, M., T. Takamura, H. Watanabe, M. Endo, T. Yanagi, and K. Okamoto. 1998. In vitro growth of Cymbidium plantlets cultured under superbright red and blue light-emitting diodes (LEDs). *Journal of Horticultural Science & Biotechnology* 73(1):39-44.

The effects of light generated by superbright blue and red LEDs on the growth of Cymbidium plantlets cultured in vitro have been studied. Leaf growth, chlorophyll content and shoot and root weights were affected by different LED irradiations. Red light promoted leaf growth but decreased chlorophyll content. This was reversed by blue light. The growth of Cymbidium plantlets in terms of increase in total shoot and root weights was comparable under red plus blue LEDs and the fluorescent systems. Generally, the response to different LED was similar for plantlets grown on sugar-free medium with or without CO₂ enrichment and sugar-containing medium but without CO₂ enrichment. The growth of Cymbidium plantlets was enhanced by CO₂ enrichment. Our study demonstrates the effectiveness of a total irradiation system for Cymbidium plantlets growth in vitro. The significance of our findings in relation to the development of a suitable lighting system for plant tissue culture is discussed.

Tanaka, M., D.C.H. Yap, C.K.Y. Ng, and C.S. Hew. 1999. The physiology of Cymbidium plantlets cultured in vitro under conditions of high carbon dioxide and low photosynthetic photon flux density. *Journal of Horticultural Science & Biotechnology* 74(5):632-638.

Cymbidium plantlets were grown in vitro under conditions of high CO₂ and low photosynthetic photon flux density using the Miracle Pack(R) culture system. Shoots and roots of plantlets showed differential growth characteristics. Shoot growth was not different in plantlets cultured under CO₂-enriched (CDE) and non-enriched (NCDE) conditions. Root growth was promoted in plantlets cultured under CDE in the presence or absence of 2% sucrose (S) with rockwool (R) as the supporting material. Growth was poor in plantlets cultured in 1% agar. Root growth was best in plantlets cultured under CDE R:S. Sucrose is still an important component for root growth under CDE conditions even though CO₂ can be used as an alternative carbon source. Photosynthetic measurements (CO₂ uptake and total Rubisco activity) showed the presence of active and operational photosynthetic machinery in plantlets cultured under CDE and NCDE conditions. The apparent lack of photoautotrophy (as evident from the lack of starch grains in chloroplasts) in plantlets cultured under NCDE conditions is not the result of a lesser potential for photoautotrophy; rather it is a consequence of sub-optimal CO₂ concentrations within the culture vessels.

Tang, K.L., X.H. Feng, and G. Funkhouser. 1999. The delta C-13 of tree rings in full-bark and strip-bark bristlecone pine trees in the White Mountains of California. *Global Change Biology* 5(1):33-40.

Dendrochronological work at Sheep Mountain in the White Mountains, CA has demonstrated that bristlecone pine trees in two forms, full-bark and strip-bark, have experienced different cambial growth rates over the past century or longer. The strip-bark trees showed a greater growth increase than the full-bark ones. A calculation of the plant water-use efficiency (W) in response to anthropogenic CO₂ released into the atmosphere shows that W of trees in both forms has increased for the past 200 years. However, there is no significant difference between the two tree forms in the rate of increase in W. This implies at least two

possibilities with respect to the CO₂ fertilization effect. First, the biomass in both tree forms might have increased, but carbon distribution among different parts of a tree was different. Second, the biomass may increase without causing any corresponding change in the plant water-use efficiency.

Tanigawa, T., Y. Kobayashi, H. Matsui, and Y. Sakai. 1995. Effects of CO₂ enrichment on growth and vase life of cut flowers of dendranthema-grandiflorum (ramat) kitamura. *Journal of the Japanese Society for Horticultural Science* 64(2):417-424.

The effects of CO₂ enrichment of chrysanthemum (Dendranthema grandiflorum) on the subsequent growth and mineral and carbohydrate contents of the plant and on CO₂ and C₂H₄ production and vase life of cut flowers were investigated. By enriching the atmosphere with 1,000 and 2,000 ppm CO₂ for 2-1/2 hours each morning, stem length, fresh weight, and leaf number of cut flowers were increased by 3 to 11%, and vase life was extended 3 days compared with flowers grown in ambient CO₂ concentration of 350 ppm. N, K, Mg, and Na concentrations, especially in the lower leaves were lower, whereas P and Ca concentrations were either the same or higher in the CO₂ treatment than they were in leaves of plants grown in the ambient CO₂. Starch and sugar contents in the leaves and stem were increased under CO₂ enriched condition. CO₂ production in the leaves was significantly reduced by the CO₂ treatments; C₂H₄ production was unaffected. From these data, we propose that the decline of [N+K]/Ca ratio (Funakoshi, 1984) and the increase in starch and sugar contents in the leaves and seem as a result of the CO₂ enriched atmosphere effectively prolonged vase life of the cut flowers.

Tanigawa, T., M. Nagaoka, H. Ikeda, and A. Shimizu. 1993. Effects of CO₂-enrichment on growth, photosynthesis and physiological-activity of roots of dendranthema X grandiflorum (ramat) kitamura. *Journal of the Japanese Society for Horticultural Science* 61(4):873-878.

To assess the effect of CO₂ enrichment on growth of greenhouse chrysanthemum, the plants were cultivated in the phytotron with 300, 600 and 1,200 ppm CO₂. 1. CO₂ enriched plants showed a significant increase in stem length, number of leaves, leaf area, and fresh and dry weights. The greatest rate of increase after 60 days of CO₂ enrichment was observed in the dry weight of roots (39%). Flower bud formation was delayed 3 days under CO₂ enriched condition. 2. No difference in photosynthetic rates of whole plants measured in 400 and 800 ppm CO₂ was observed among those grown under high CO₂ (600 or 1,200 ppm) and those grown in ambient air (300 ppm). After 60 days of exposure to ambient and high CO₂, the photosynthetic rate measured in 800 PPM CO₂ declined markedly compared to the rate at the beginning of the treatment. 3. TTC (2, 3, 5-triphenyl tetrazolium chloride) reductive activity of roots decreased under CO₂ enriched atmosphere, but it increased on a per plant basis because fresh weight of the roots increased. There was a high positive correlation between TTC reduction per plant and the fresh weight of the top (aerial part).

Tanimoto, H., T. Kagi, and S. Morita. 1993. Relationship between the utilization of sugars by cultured petiole segments of *Begonia x hiemalis* and the optimum time for CO₂ enrichment. *Journal of the Japanese Society for Horticultural Science* 62(2):437-441.

By monitoring the utilization of sugars by petiole segments of *Begonia x hiemalis* cultured in medium containing the plant growth regulators, kinetin (1 PPM), NAA (1 ppm), the optimum time for beginning the CO₂ enrichment treatment was established. The total sugar concentration in the medium decreased rapidly after 40 days of culturing. The cessation of sugar depletion by the tissues after 60 days is attributed to the onset of photosynthesis by the plantlets. CO₂ administration at this time promoted leaf development, whereas CO₂ enrichment 10 to 20 days earlier halted the development of adventitious shoots. These observations suggest that the optimum period to begin CO₂ enrichment to promote shoot growth and to enhance photosynthesis is about 60 days after the culturing of the petiole segments.

Tarnawski, M.G., T.G.A. Green, B. Buedel, A. Meyer, H. Zellner, and O.L. Lange. 1994. Diel changes of atmospheric CO₂ concentration within, and above, cryptogam stands in a New Zealand temperate rainforest. *New Zealand Journal of Botany* 32(3):329-336.

Atmospheric CO₂ levels were determined (at 2m height) in the rainforest and in a clearing outside the forest, during spring (November) 1991, Urewera National Park, New Zealand. CO₂ levels within the forest were 30 ppm higher and showed a more variable diel pattern (range up to 70 ppm) than outside the forest. CO₂ levels were generally higher at night than during the day. Detailed measurements were made at several sites at a depth of 25 mm in the phylloplane of three moss species and under, or between, the thalli of four lichen species. Mean levels were 50% (moss phylloplane) and 10% (lichen thalli) higher than the levels in the clearing and, in 80% of sites, also higher than air within the rainforest. The diel pattern of the CO₂ concentration at each of the sites was not predictable from measurements of CO₂ in the bulk air of the forest. High levels of CO₂ may be important in elevating photosynthetic rates of mosses and, to a lesser extent, lichens in the field.

Tate, K.R. 1992. Assessment, based on a climosequence of soils in tussock grasslands, of soil carbon storage and release in response to global warming. *Journal of Soil Science* 43(4):697-707.

A soil climosequence in tussock grasslands in South Island, New Zealand, encompassing climates ranging from cold to warm temperate provided a spatial analogue of climate change for investigating the effects of global warming on soil C contents and turnover. Mean annual temperature (T) and annual precipitation (P) ranged from 2 to 10-degrees-C, and 350 to 5000 mm, respectively. Soil C contents were curvilinearly related to T/P across the sequence ($r = -0.95$, significant at $P < 0.01$), indicating that east of the Southern Alps, increased decomposition of organic matter with global warming would provide a positive feedback to further increase atmospheric CO₂. This decrease in New Zealand's soil C, estimated to be up to 10% of the current content for a global temperature rise of 0.03 K a⁻¹ to 2050, could contribute about 0.5×10^{15} g C to the atmosphere over the next 60 years. These conclusions were generally supported by changes in soil C turnover estimated from 'bomb' C-14 enrichment. The unexpectedly slow turnover found for two soils was explained by a 'memory' effect from the former

southern beech forest that grew on these soils in prehistoric times. Accumulation of Al-humus under the forest may be responsible for the slow C turnover observed.

Tate, K.R., and D.J. Ross. 1997. Elevated CO₂ and moisture effects on soil carbon storage and cycling in temperate grasslands. *Global Change Biology* 3(3):225-235.

In grassland ecosystems, most of the carbon (C) occurs below-ground. Understanding changes in soil fluxes induced by elevated atmospheric CO₂ is critical for balancing the global C budget and for managing grassland ecosystems sustainably. In this review, we use the results of short-term (1-2 years) studies of below-ground processes in grassland communities under elevated CO₂ to assess future prospects for longer-term increases in soil C storage. Results are broadly consistent with those from other plant communities and include: increases in below-ground net primary productivity and an increase in soil C cycling rate, changes in soil faunal community, and generally no increase in soil C storage. Based on other experimental data, future C storage could be favoured in soils of moderate nutrient status, moderate-to-high clay content, and low (or moderately high) soil moisture status. Some support for these suggestions is provided by preliminary results from direct measurements of soil C concentrations near a New Zealand natural CO₂-venting spring, and by simulations of future changes in grassland soils under the combined effects of CO₂ fertilization and regional climate change. Early detection of any increase in soil C storage appears unlikely in complex grassland communities because of (a) the difficulty of separating an elevated CO₂ effect from the effects of soil factors including moisture status, (b) the high spatial variability of soil C and (c) the effects of global warming. Several research imperatives are identified for reducing the uncertainties in the effects of elevated atmospheric CO₂ on soil C.

Tateno, M., and F.S. Chapin. 1997. The logic of carbon and nitrogen interactions in terrestrial ecosystems. *The American Naturalist* 149(4):723-744.

Simple ecosystem models of carbon (C) and nitrogen (N) interactions between plants and soil show that differences in N-use efficiency cause convergence of plant growth in ecosystems with a closed N cycle because rapid growth associated with high N-use efficiency results in litter with a high C:N ratio and a low N mineralization rate, whereas slow growth associated with low N-use efficiency leads to a low C:N ratio and a high N mineralization rate. This plant-induced negative feedback on production contrasts with the positive feedback that had previously been hypothesized. Our model explains the causes and results of several important ecological patterns. First, all ecosystems with a fixed N pool will show a small increase in C storage (especially in soils) in response to elevated CO₂ despite constraints by litter-quality feedbacks to N mineralization rate. Second, the decreased N-use efficiency and plateauing of primary production in forest ecosystems with a high N supply reflect saturation of photosynthetic rate with high plant N pools. Finally, the addition of inorganic N to ecosystems induces a quick increase in productivity and N supply. However, these increases disappear if N additions are not sustained. These findings suggest that

those global changes that alter N input to or output from ecosystems are likely to have larger long-term impact on biomass, productivity, and C storage of ecosystems with a tightly closed N cycle than would changes in plant N-use efficiency.

Taulavuori, E., K. Taulavuori, K. Laine, T. Pakonen, and E. Saari. 1997. Winter hardening and glutathione status in the bilberry (*Vaccinium myrtillus*) in response to trace gases (CO₂, O₃) and nitrogen fertilization. *Physiologia Plantarum* 101(1):192-198.

Bilberry plants (*Vaccinium myrtillus* L.) at a field site in northern Finland (65 degrees N) were subjected to nitrogen fertilization [6.5 mmol m⁻² NH₄NO₃ x Ca(OH)₂] at the beginning of 3 growing seasons in late May and to trace gas fumigation (CO₂ and O₃) for 5 months (May-September) in 1993- 1995 in order to investigate frost resistance and glutathione concentrations during the winter hardening period, and to assess the correlation between these variables. Harvesting was performed twice in the autumn of both 1994 and 1995, and the two-year data for each harvest were pooled. The frost resistance of the bilberry stems increased by about 10 degrees C during the hardening period between the two harvests. Nitrogen fertilization increased the frost resistance towards late autumn. The fumigation treatments had no marked effect on it. The combination of elevated CO₂ and nitrogen fertilization induced a decrease in frost resistance. Increases in total glutathione concentrations and the proportion of reduced glutathione (GSH) in the stems were evident during hardening. Nitrogen fertilization positively affected the total glutathione concentration and the proportion of GSH at the beginning of the hardening period but the effect disappeared during the hardening process. Trace gas fumigation as such had no marked effect on glutathione concentration. Increases in glutathione concentrations during hardening did not correlate with frost resistance, possibly due to different timing of the appearance of the response to fertilization treatment, i.e., glutathione responded in the beginning of hardening while frost resistance at the end. The lack of correlation with frost resistance, and especially the different responses to nitrogen fertilization, may reflect the indirect role of glutathione in the development of winter hardening, as a transport and storage form of reduced nitrogen and sulphur. In conclusion, winter hardening and glutathione status in the bilberry seems to be sensitive to nitrogen fertilization, and not affected by elevated CO₂ and O₃.

Tausz, M., L.J. DeKok, I. Stulen, and D. Grill. 1996. Physiological responses of Norway spruce trees to elevated CO₂ and SO₂. *Journal of Plant Physiology* 148(3-4):362-367.

Young Norway spruce (*Picea abies* (L.) Karst.) trees were exposed to elevated CO₂ (0.8 mL L⁻¹), SO₂ (0.06 µL L⁻¹), and elevated CO₂ and SO₂ (0.8 mL L⁻¹ and 0.06 µL L⁻¹, respectively) for three months. Exposure to elevated CO₂ resulted in an increased biomass production of the needles, while the pigment content was decreased. Exposure to SO₂ hardly affected growth and pigment contents. Chlorophyll/carotenoid- and chlorophyll a/chlorophyll b-ratios were not affected by either CO₂ or SO₂. The epoxidation state of the xanthophyll-cycle was changed upon SO₂-exposure, due to a higher zeaxanthin and a lower violaxanthin content. Chlorophyll fluorescence measurements

showed F-v/F-m-ratios of 0.7 or higher for all needles, which indicated a healthy photosynthetic apparatus. Exposure to SO₂ resulted in increased foliar contents of sulfate, total glutathione (reduced and oxidized form), cyst(e)ine, and a slightly more reduced redox state of glutathione. Exposure to elevated CO₂ resulted in a slight decrease in glutathione contents, but it did not affect sulfate or cyst(e)ine contents of the spruce needles. Neither ascorbic acid content nor its redox state were affected by CO₂ or SO₂. The effects of CO₂ and SO₂ were independent from each other, since significant interactions CO₂xSO₂ were not observed.

Taylor, G., S.D.L. Gardner, C. Bosac, T.J. Flowers, M. Crookshanks, and L. Dolan. 1995. Effects of elevated CO₂ on cellular mechanisms, growth and development of trees with particular reference to hybrid poplar. *Forestry* 68(4):379-390.

Growth is often stimulated when C-3 plants, including trees, are exposed to elevated CO₂, although evidence from the literature suggests that the responsiveness of trees to CO₂ varies, depending on species. This paper explores some of the cellular mechanisms which underlie increased growth, using both the authors' own data and information from the literature. Mechanisms include photosynthetic fixation of CO₂ and the role of Rubisco, the link between carbon fixation and growth, in particular, how increased carbon is thought to influence the process of plant cell expansion and cell production and finally the consequences of cellular effects for the growth and development of whole plants. Data are presented for the growth and development of hybrid poplars in elevated CO₂, following both field (open-top chambers) and laboratory experiments which suggest that this type of tree with indeterminate, rapid growth may be favoured by the CO₂ concentrations of the next century.

Taylor, G., S. Ranasinghe, C. Bosac, S.D.L. Gardner, and R. Ferris. 1994. Elevated CO₂ and plant-growth - cellular mechanisms and responses of whole plants. *Journal of Experimental Botany* 45(280):1761-1774.

Much research has focused on the photosynthetic responses of plants to elevated CO₂, with less attention given to the post- photosynthetic events which may lead to changes in the growth of tissues, organs and whole plants. The aim of this review is to identify how plant growth is altered in elevated CO₂ and to determine which growth processes or cellular mechanisms are sensitive to carbon supply. For leaves, both the expansion of individual leaves and the initiation of leaf primordia are stimulated in elevated CO₂. When lamina growth is promoted, this is usually associated with increased leaf cell expansion rather than increased leaf cell production. Using several clones of hybrid poplar (*Populus euramericana*, *P. interamericana*) two native herbs (*Plantago media*, *Sanguisorba minor*) and bean (*Phaseolus vulgaris*) we have identified the mechanism through which leaf cell expansion is promoted in elevated CO₂. Changes in the water relations, turgor pressure (P) and yield turgor (Y) of growing leaves cannot explain increased cell expansion; this appears to occur because cell wall loosening is promoted, as suggested by three pieces of evidence. (i) The rate of decline of water potential (psi) with time is accelerated when growing leaves are placed in psychrometers and allowed to relax, (ii) Instron-measured cell wall extensibility (WEX), is greater for leaves exposed to elevated CO₂ and

(iii) the activity of the putative wall loosening enzyme, XET is increased for leaves of *P. vulgaris* exposed to elevated CO₂. Species differences do, however, exist; in the herb *Lotus corniculatus* small stimulations of leaf growth in elevated CO₂ are due to increased leaf cell production and decreased cell size in elevated CO₂. These results are discussed in relation to the concept of functional types. There is evidence to suggest that both cell production and cell expansion are promoted in roots of plants exposed to elevated CO₂. For native herbs (*Anthyllis vulneraria*, *Lotus corniculatus*, *P. media* and *S. minor*), increased root growth in elevated CO₂ is due to increased cell elongation. In contrast to leaves, this appears to occur because both root cell turgor pressure (P) and root cell wall extensibility (WEX) are promoted by exposure of shoots to elevated CO₂. In longer-term studies on root growth, the effects of additional carbon on the production of root primordia and root branching are of overriding importance, suggesting that carbon supply may influence some aspect of the cell cycle, when effects on the extension of individual roots may not be apparent.

Taylor, J., and A.S. Ball. 1994. The effect of plant-material grown under elevated CO₂ on soil respiratory activity. *Plant and Soil* 162(2):315-318.

The biodegradability of aerial material from a C₄ plant, sorghum grown under ambient (345 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ concentrations were compared by measuring soil respiratory activity. Initial daily respiratory activity (measured over 10 h per day) increased four fold from 110 to 440 $\mu\text{mol CO}_2 \text{ 100g dry weight soil}^{-1} \text{ h}^{-1}$ in soils amended with sorghum grown under either elevated or ambient CO₂. Although soil respiratory activity decreased over the following 30 days, respiration remained significantly higher (t-test; $p > 0.05$) in soils amended with sorghum grown under elevated CO₂ concentrations. Analysis of the plant material revealed no significant differences in C:N ratios between sorghum grown under elevated or ambient CO₂. The reason for the differences in soil respiratory activity have yet to be elucidated. However if this trend is repeated in natural ecosystems, this may have important implications for C and N cycling.

Taylor, J.A., and J. Lloyd. 1992. Sources and sinks of atmospheric CO₂. *Australian Journal of Botany* 40(4-5):407-418.

The biosphere plays an important role in determining the sources, sinks, levels and rates of change of atmospheric CO₂ concentrations. Significant uncertainties remain in estimates of the fluxes of CO₂ from biomass burning and deforestation, and uptake and storage of CO₂ by the biosphere arising from increased atmospheric CO₂ concentrations. Calculation of probable rates of carbon sequestration for the major ecosystem complexes and global 3-D tracer transport model runs indicate the possibility that a significant net CO₂ uptake ($> 1 \text{ Pg C yr}^{-1}$), a CO₂ 'fertilisation effect', may be occurring in tropical rainforests, effectively accounting for much of the 'missing sink'. This sink may currently balance much of the CO₂ added to the atmosphere from deforestation and biomass burning. Interestingly, CO₂ released from biomass burning may itself be playing an important role in enhanced carbon storage by tropical rainforests. This has important implications for predicting future CO₂ concentrations. If tropical rainforest destruction continues then much of the CO₂ stored as a result of the

CO₂ 'fertilisation effect' will be rereleased to the atmosphere and much of the 'missing sink' will disappear. These effects have not been considered in the IPCC (Intergovernmental Panel on Climate Change) projections of future atmospheric CO₂ concentrations. Predictions which take account of the combined effects of deforestation, the return of carbon previously stored through the CO₂ 'fertilisation effect' and the loss of a large proportion of the 'missing sink' as a result of deforestation, would result in much higher predicted concentrations and rates of increase of atmospheric CO₂ and, as a consequence, accelerated rates of climate change.

Taylor, K., and C. Potvin. 1997. Understanding the long-term effect of CO₂ enrichment on a pasture: the importance of disturbance. *Canadian Journal of Botany-Revue Canadienne De Botanique* 75(10):1621-1627.

This study is part of a research program examining the effects of elevated atmospheric carbon dioxide on a pasture. It was designed to examine (i) the interaction between disturbance and the atmospheric CO₂ concentration at the community level, and (ii) the response of a major weed *Chenopodium album* to CO₂ enrichment in a natural field situation. Although both the total number of species and Simpson's index increased upon disturbance, these traits did not respond to CO₂ fertilization. Counter to our expectation, we found no significant interaction between disturbance and CO₂. The composition of the community that established in the open, disturbed spaces was a function of seed availability and as such independent of the atmospheric CO₂ concentration. Using height of the background vegetation to assess the impact of elevated CO₂, we found some evidence for density dependence in the undisturbed quadrats but not in the disturbed ones. For *C. album*, the disturbance regimes outweigh the CO₂ increase in importance. Neighboring plants have a strong influence on *C. album* growth, this even though the *C. album* photosynthetic mechanisms are potentially responsive to elevated CO₂. The present study highlights the complex feed-back interactions occurring when a community is exposed to elevated CO₂ concentration.

Teese, P. 1995. Intraspecific variation for CO₂ compensation point and differential growth among variants in a C-3-C-4 intermediate plant. *Oecologia* 102(3):371-376.

CO₂ compensation point (Gamma), the concentration of CO₂ at which photosynthesis and respiration are at equilibrium, is a commonly used diagnostic for the C-4 photosynthetic pathway, since it reflects the reduced photorespiration that is a property of C-4 photosynthesis. Geographic variation for Gamma was examined within *Flaveria linearis*, a C-3-C-4 intermediate species. Collections from four widely separated Floridian populations were propagated in a greenhouse and measured for Gamma. Little differentiation among populations was found, but significant within-population variation was present. Temperature is a hypothesized selective agent for the C-4 photosynthetic pathway. To test this hypothesis, plants exhibiting a range of Gamma were cloned and placed in growth chambers at 25 degrees C and 40 degrees C. After 7 weeks, Gamma values were remeasured and plants were harvested and weighed. There was a poor correlation between initial and final measures of Gamma for a given genotype ($r = 0.38$, $P > 0.1$). Broad sense heritability for Gamma was computed to be 0.10. At 25 degrees C, there was no relationship between final size and Gamma. At 40 degrees C,

more C₄-like plants, as indicated by their low Gamma, had grown larger. Differences in relative growth rate were attributable more to differences in net assimilation rate than in leaf area ratio. Taken together, these results demonstrate that although significant plasticity exists in the amount of photorespiration in this C₃-C₄ species, high temperature appears to be an effective selective agent for the reduction of photorespiration and the enhancement of C₄-like traits.

Telewski, F.W., R.T. Swanson, B.R. Strain, and J.M. Burns. 1999. Wood properties and ring width responses to long-term atmospheric CO₂ enrichment in field-grown loblolly pine (*Pinus taeda* L.). *Plant, Cell and Environment* 22(2):213-219.

Loblolly pine (*Pinus taeda* L.) were grown in the field, under non-limiting nutrient conditions, in open-top chambers for 4 years at ambient CO₂ partial pressures (pCO₂) and with a CO₂-enriched atmosphere (+ 30 Pa pCO₂) compared to ambient concentration). A third replicate of trees were grown without chambers at ambient pCO₂. Wood anatomy, wood density and tree ring width were analysed using stem wood samples. No significant differences were observed in the cell wall to cell lumen ratio within the latewood of the third growth ring formed in 1994. No significant differences were observed in the density of resin canals or in the ratio of resin canal cross-sectional area to xylem area within the same growth ring. Ring widths were significantly wider in the CO₂-enrichment treatment for 3 of 4 years compared to the ambient chamber control treatment. Latewood in the 1995 growth ring was significantly wider than that in the ambient control and represented a larger percentage of the total growth-ring width. Carbon dioxide enrichment also significantly increased the total wood specific gravity (determined by displacement). However, when determined as total sample wood density by X-ray densitometry, the density of enriched samples was not significantly higher than that of the ambient chamber controls. Only the 1993 growth ring of enriched trees had a significantly higher maximum latewood density than that of trees grown on non-chambered plots or ambient chambered controls. No significant differences were observed in the minimum earlywood density of individual growth rings between chambered treatments. These results show that the most significant effect of CO₂ enrichment on wood production in loblolly pine is its influence on radial growth, measured as annual tree ring widths. This influence is most pronounced in the first year of growth and decreases with age.

Teramura, A.H., and J.H. Sullivan. 1994. Effects of uv-b radiation on photosynthesis and growth of terrestrial plants. *Photosynthesis Research* 39(3):463-473.

The photosynthetic apparatus of some plant species appears to be well-protected from direct damage from UV-B radiation. Leaf optical properties of these species apparently minimize exposure of sensitive targets to UV-B radiation. However, damage by UV-B radiation to Photosystem II and Rubisco has also been reported. Secondary effects of this damage may include reductions in photosynthetic capacity, RuBP regeneration and quantum yield. Furthermore, UV-B radiation may decrease the penetration of PAR, reduce photosynthetic and accessory pigments, impair stomatal function and alter canopy morphology, and thus indirectly retard photosynthetic carbon assimilation. Subsequently,

UV-B radiation may limit productivity in many plant species. In addition to variability in sensitivity to UV-B radiation, the effects of UV-B radiation are further confounded by other environmental factors such as CO₂, temperature, light and water or nutrient availability. Therefore, we need a better understanding of the mechanisms of tolerance to UV-B radiation and of the interaction between UV-B and other environmental factors in order to adequately assess the probable consequences of a change in solar radiation.

Teskey, R.O. 1995. A field-study of the effects of elevated CO₂ on carbon assimilation, stomatal conductance and leaf and branch growth of pinus-taeda trees. *Plant, Cell and Environment* 18(5):565-573.

A study was conducted in 21-year-old loblolly pine (*Pinus taeda* L.) trees growing in plantation in north central Georgia, USA. The experiment used branch chambers to impose treatments of ambient, ambient+165 and ambient+330 $\mu\text{mol mol}^{-1}$ CO₂. After one growing season there was no indication of acclimation to elevated CO₂. In August and September, carbon assimilation, measured by two different methods, was twice as high at ambient +330 $\mu\text{mol mol}^{-1}$ CO₂ than at ambient. Dark respiration was suppressed by 6% at ambient+165 and by 14% at ambient+330 $\mu\text{mol mol}^{-1}$ CO₂. This suppression was immediate, and not an effect of exposure to elevated CO₂ during growth, since respiration was reduced by the same amount in all treatments when measured at a high CO₂ concentration. Elevated CO₂ increased the growth of foliage and woody tissue. It also increased instantaneous transpiration efficiency, but it had no effect on stomatal conductance. Since the soil at the study site had low to moderate fertility, these results suggest that the growth potential of forests on many sites may be enhanced by global increases in atmospheric CO₂ concentration.

Teskey, R.O. 1997. Combined effects of elevated CO₂ and air temperature on carbon assimilation of *Pinus taeda* trees. *Plant, Cell and Environment* 20(3):373-380.

Branches of 22-year-old loblolly pine (*Pinus taeda* L.) trees growing in a plantation were exposed to ambient CO₂, ambient + 165 $\mu\text{mol mol}^{-1}$ CO₂ or ambient + 330 $\mu\text{mol mol}^{-1}$ CO₂ concentrations in combination with ambient or ambient + 2 degrees C air temperatures for 3 years. Field measurements in the third year indicated that net carbon assimilation was enhanced in the elevated CO₂ treatments in all seasons. On the basis of A/C-i curves, there was no indication of photosynthetic down-regulation. Branch growth and leaf area also increased significantly in the elevated CO₂ treatments. The imposed 2 degrees C increase in air temperature only had slight effects on net assimilation and growth. Compared with the ambient CO₂ treatment, rates of net

assimilation were approximate to 1.6 times greater in the ambient + 165 $\mu\text{mol mol}^{-1}$ CO₂ treatment and 2.2 times greater in the ambient + 330 $\mu\text{mol mol}^{-1}$ CO₂ treatment. These ratios did not change appreciably in measurements made in all four seasons even though mean ambient air temperatures during the measurement periods ranged from 12.6 to 28.2 degrees C. This indicated that the effect of elevated CO₂ concentrations on net assimilation under field conditions was primarily additive. The results also indicated that the effect of elevated CO₂ (+ 165 or + 330 $\mu\text{mol mol}^{-1}$) was much greater than the effect of a 2 degrees C increase in air temperature on net assimilation and growth in this species.

Teughels, H., I. Nijs, P. VanHecke, and I. Impens. 1995. Competition in a global change environment: The importance of different plant traits for competitive success. *Journal of Biogeography* 22(2-3):297-305.

Plant traits of both structural and physiological nature have been reported to play an important role in the outcome of a competitive interaction. In this experiment a survey of the importance of characteristics such as height, leaf area and vertical distribution, leaf inclination, light transmission through a leaf and through the canopy together with leaf photosynthesis rates, was made for two grasses: *Lolium perenne* L. and *Festuca arundinacea* Schreb. Both species were grown in a competitive set-up with minimal belowground interactions under four different global change conditions of CO₂ concentration and air temperature (ambient, elevated CO₂ concentration 700 $\mu\text{mol mol}^{-1}$, increased air temperature +4 degrees C, combined) in naturally sunlit air-conditioned half-open plastic greenhouses. Plants were grown for a whole growing season with regular (every 4 weeks) clippings at 3.5 cm height. Results demonstrate that *Lolium* has a much greater competitive ability when compared to *Festuca* (aggressivity = 0.465). This may be a consequence of the slightly higher leaf photosynthesis rates (+15%) in combination with a larger amount of foliage area, which could result in a higher canopy photosynthesis. The greater leaf area remaining after mowing may lead to an additional advantage for *Lolium*. Height, leaf inclination, optical properties and the vertical distribution of leaf area seem to be of minor importance in this experiment. Global change treatments (elevated CO₂ concentration and increased temperature) influence leaf photosynthesis rates predominantly and have little or no direct effect on structural traits such as height, leaf angles and vertical leaf distribution; nor do they exert an influence on light transmission through a leaf or through the canopy. However, treatment effects on leaf area can add to explain differences in canopy photosynthesis. In this competition experiment, focused on above-ground interactions, both a structural (leaf area) and a physiological feature (leaf photosynthesis) contribute to the competitive success of a species.

Theobald, J.C., R.A.C. Mitchell, M.A.J. Parry, and D.W. Lawlor. 1998. Estimating the excess investment in ribulose-1,5-bisphosphate carboxylase/oxygenase in leaves of spring wheat crown under elevated CO₂. *Plant Physiology* 118(3):945-955.

Wheat (*Triticum aestivum* L.) was grown under CO₂ partial pressures of 36 and 70 Pa with two N-application regimes. Responses of photosynthesis to varying CO₂ partial pressure were fitted to estimate the maximal carboxylation rate and the nonphotorespiratory respiration

rate in flag and preceding leaves. The maximal carboxylation rate was proportional to ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) content, and the light-saturated photosynthetic rate at 70 Pa CO₂ was proportional to the thylakoid ATP-synthase content. Potential photosynthetic rates at 70 Pa CO₂ were calculated and compared with the observed values to estimate excess investment in Rubisco. The excess was greater in leaves grown with high N application than in those grown with low N application and declined as the leaves senesced. The fraction of Rubisco that was estimated to be in excess was strongly dependent on leaf N content, increasing from approximately 5 % in leaves with 1 g N m⁻² to approximately 40 % in leaves with 2 g N m⁻². Growth at elevated CO₂ usually decreased the excess somewhat but only as a consequence of a general reduction in leaf N, since relationships between the amount of components and N content were unaffected by CO₂. We conclude that there is scope for improving the N-use efficiency of C-3 crop species under elevated CO₂ conditions.

Thibaud, M.C., N. Cortez, H. Riviere, and T. Betsche. 1995. Photorespiration and related enzymes in pea (*Pisum-sativum*) grown in high CO₂. *Journal of Plant Physiology* 146(5-6):596-603.

The adaptation of pea (*Pisum sativum* L. cv. Douce Provence) to the low photorespiratory conditions imposed by high CO₂ was investigated at the level of enzymes and gas exchange. Seedlings were CO₂-enriched (1000 and 4800 $\mu\text{mol L CO}_2(\text{L}^{-1})$) during most of the vegetative period, yielding <<acclimated leaves>>. Alternatively, young plants were pre-grown in ambient CO₂ and then CO₂-enriched, yielding <<transferred leaves>>. The level of nutrient supply was high. High CO₂ did not significantly alter the specific activities of the photorespiratory enzymes glycolate oxidase, NADH- and NADPH- hydroxypyruvate reductase and glutamine synthetase in either of the experiments. Moreover, no significant effect of high CO₂ on specific carboxylase activity and relative abundance of ribulose bisphosphate carboxylase-oxygenase (Rubisco) was observed. In contrast, high CO₂ markedly affected the photorespiratory enzymes catalase (Cat) and phosphoglycolate phosphatase, the activity of the latter being increased. Decline of Cat activity was detected 1 day after transfer to high CO₂ and in the course of 7 days, the inhibition reached values of 33% (1000 $\mu\text{mol L CO}_2(\text{L}^{-1})$) and 50% (4800 $\mu\text{mol L CO}_2(\text{L}^{-1})$). The relative abundance of Cat protein also declined, but no change in the isoform pattern was observed. Photorespiratory O₂ uptake, determined with O-18(2), decreased by 54% in an atmosphere containing 1000 $\mu\text{mol L CO}_2(\text{L}^{-1})$. This suggests that Rubisco-oxygenase activity occurred at a substantial rate at threefold that of the current atmospheric CO₂ concentration. CO₂ enrichment to 4000 $\mu\text{mol L CO}_2(\text{L}^{-1})$ further inhibited photorespiratory O₂ uptake. The decline of Cat was thus positively correlated with the inhibition of light O₂ uptake. In <<acclimated leaves>>, Cat inhibition was slight or absent, depending on the level of CO₂ enrichment. This suggests that Cat inhibition in <<transferred leaves>> is a transient response that can be overcome by yet unidentified adaptive mechanisms.

Thom, R.M. 1996. CO₂-enrichment effects on eelgrass (*Zostera marina*

L) and bull kelp (*Nereocystis luetkeana* (Mert) P & R). *Water, Air, and Soil Pollution* 88(3-4):383-391.

I investigated the effect of CO₂-enrichment on productivity of two aquatic plant species [*Zostera marina* L., *Nereocystis luetkeana* (Mert.) P. & R.] that form significant components of coastal ecosystems in the Pacific Northwest. Short-term (i.e., 2-hr) experiments showed that doubling CO₂ resulted in up to a 2.5-fold increase in *Zostera* net apparent productivity (NAP). *Nereocystis* NAP was increased 2.2 - 2.8 fold. In experiments involving seven enrichment treatments, NAP increased with increasing CO₂ between ambient (1.0x) and 2.5x CO₂ in both *Zostera* and *Nereocystis*. *Nereocystis* acid *Zostera* NAP was lowest at highest (i.e., 5x) CO₂ concentrations. In growth experiments, mean growth rate of *Zostera* increased with increasing CO₂ during one of the two trials. I conclude that increasing CO₂ in the surface waters of the coastal ocean would predictably result in increased NAP of these two species. These results supplement limited published data showing that shallow estuarine and marine systems are vulnerable to increased carbon dioxide.

Thomas, R.B., and K.L. Griffin. 1994. Direct and indirect effects of atmospheric carbon-dioxide enrichment on leaf respiration of glycine-max (L) merr. *Plant Physiology* 104(2):355-361.

Long-term and short-term effects of CO₂ enrichment on dark respiration were investigated using soybean (*Glycine max* [L.] Merr.) plants grown at either 35.5 or 71.0 Pa CO₂. Indirect effects, or effects of growth in elevated CO₂, were examined using a functional model that partitioned respiration into growth and maintenance components. Direct effects, or immediate effects of a short-term change in CO₂, were examined by measuring dark respiration, first, at the CO₂ partial pressure at which plants were grown, and second, after equilibration in the reciprocal CO₂ partial pressure. The functional component model indicated that the maintenance coefficient of respiration increased 34% with elevated CO₂, whereas the growth coefficient was not significantly affected. Changes in maintenance respiration were correlated with a 33% increase in leaf total nonstructural carbohydrate concentration, but leaf nitrogen content of soybean leaves was not affected by CO₂ enrichment. Thus, increased maintenance respiration may be a consequence of increased nonstructural carbohydrate accumulation. When whole soybean plants were switched from low CO₂ to high CO₂ for a brief period, leaf respiration was always reduced. However, this direct effect of CO₂ partial pressure was approximately 50% less in plants grown in elevated CO₂. We conclude from this study that there are potentially important effects of CO₂ enrichment on plant respiration but that the effects are different for plants given a short-term increase in CO₂ partial pressure versus plants grown in elevated CO₂.

Thomas, R.B., J.D. Lewis, and B.R. Strain. 1994. Effects of leaf nutrient status on photosynthetic capacity in loblolly-pine (*Pinus taeda* L.) seedlings grown in elevated atmospheric CO₂. *Tree Physiology* 14(7-9):947-960.

We measured needle photosynthesis of loblolly pine seedlings grown in a factorial experiment with two CO₂ partial pressures (35 and 65 Pa) and three nutrient treatments (7 mM NH₄NO₃ + 1 mM PO₄; 7 mM NH₄NO₃ + 0.2 mM PO₄; 1 mM NH₄NO₃ + 1 mM PO₄). The data were

used to parameterize a physiologically based photosynthetic model that included limitations imposed by ribulose-1,5-bisphosphate carboxylase/oxygenase activity, electron transport capacity and inorganic phosphate availability. With nonlimiting nutrients, seedlings grown at 65 Pa CO₂ had significantly higher net photosynthesis and lower stomatal conductance than seedlings grown at 35 Pa CO₂. Nutrient limitations by either N or P significantly reduced photosynthetic capacity. When either N or P was limiting, there was no effect of growth CO₂ partial pressure on photosynthesis, but stomatal conductance was significantly lower for seedlings grown at 65 Pa CO₂. Modeled biochemical parameters suggest that, in all cases, photosynthesis was co-limited by carboxylation, electron transport and phosphate regeneration. Acclimation to growth in elevated CO₂ involved a reduction in leaf N content. In the low-N and low-P treatments, modeled parameters indicated that the biochemical processes of photosynthesis were down regulated to the point that there was no effect of increasing CO₂ partial pressure. The capacity to regenerate phosphate was reduced in both low nutrient treatments, but was only reduced by elevated CO₂ when seedlings were grown under low soil P conditions. Increased photosynthetic water use efficiency and nutrient use efficiency in response to CO₂ enrichment occurred in all three nutrient treatments and have important implications for whole-plant water and nutrient balance. These data support the contention that soil nutrient status in forest ecosystems will be a critical influence on tree seedling response to increasing atmospheric CO₂ partial pressures.

Thomas, R.B., C.D. Reid, R. Ybema, and B.R. Strain. 1993. Growth and maintenance components of leaf respiration of cotton grown in elevated carbon-dioxide partial-pressure. *Plant, Cell and Environment* 16(5):539-546.

Elevated atmospheric carbon dioxide partial pressures have been shown to have variable direct and indirect effects on plant respiration rates. In this study, growth, leaf respiration, and leaf nitrogen and carbohydrate partitioning were measured in *Gossypium hirsutum* L. grown in 35 and 65 Pa CO₂ for 30 d. Growth and maintenance coefficients of leaf respiration were estimated using gas exchange techniques both at night and during the day. Elevated CO₂ stimulated biomass production (107%) and net photosynthetic rates (35-50%). Total day-time respiration (R(d)) was not significantly affected by growth CO₂ partial pressure. However, night respiration (R(n)) of leaves grown in 65 Pa CO₂ was significantly greater than that of plants grown in 35 Pa CO₂. Correlation of R(d) and R(n) with leaf expansion rates indicated that plants in both CO₂ treatments had equivalent growth respiration coefficients but maintenance respiration was significantly greater in elevated CO₂. Increased maintenance coefficients in elevated CO₂ appeared to be related to increased starch accumulation rather than to changes in leaf nitrogen.

Thomas, R.B., D.D. Richter, H. Ye, P.R. Heine, and B.R. Strain. 1991. Nitrogen dynamics and growth of seedlings of an N-fixing tree (*Gliricidia sepium* (Jacq) Walp) exposed to elevated atmospheric carbon-dioxide. *Oecologia* 88(3):415-421.

Seeds of *Gliricidia sepium* (Jacq.) Walp., a tree native to seasonal tropical forests of Central America, were inoculated with N-fixing *Rhizobium* bacteria and grown in growth chambers for 71 days to investigate interactive effects of atmospheric CO₂ and plant N status on early seedling growth, nodulation, and N accretion. Seedlings were

grown with CO₂ partial pressures of 350 and 650- μ bar (current ambient and a predicted partial pressure of the mid-21st century) and with plus N or minus N nutrient solutions to control soil N status. Of particular interest was seedling response to CO₂ when grown without available soil N, a condition in which seedlings initially experienced severe N deficiency because bacterial N-fixation was the sole source of N. Biomass of leaves, stems, and roots increased significantly with CO₂ enrichment (by 32%, 15% and 26%, respectively) provided seedlings were supplied with N fertilizer. Leaf biomass of N-deficient seedlings was increased 50% by CO₂ enrichment but there was little indication that photosynthate translocation from leaves to roots or that plant N (fixed by Rhizobium) was altered by elevated CO₂. In seedlings supplied with soil N, elevated CO₂ increased average nodule weight, total nodule weight per plant, and the amount of leaf nitrogen provided by N-fixation (as indicated by leaf δ -N-15). While CO₂ enrichment reduced the N concentration of some plant tissues, whole plant N accretion increased. Results support the contention that increasing atmospheric CO₂ partial pressures will enhance productivity and N-fixing activity of N-fixing tree seedlings, but that the magnitude of early seedling response to CO₂ will depend greatly on plant and soil nutrient status.

Thomas, R.B., and B.R. Strain. 1991. Root restriction as a factor in photosynthetic acclimation of cotton seedlings grown in elevated carbon-dioxide. *Plant Physiology* 96(2):627-634.

Interactive effects of root restriction and atmospheric CO₂ enrichment on plant growth, photosynthetic capacity, and carbohydrate partitioning were studied in cotton seedlings (*Gossypium hirsutum* L.) grown for 28 days in three atmospheric CO₂ partial pressures (270, 350, and 650 microbars) and two pot sizes (0.38 and 1.75 liters). Some plants were transplanted from small pots into large pots after 20 days. Reduction of root biomass resulting from growth in small pots was accompanied by decreased shoot biomass and leaf area. When root growth was less restricted, plants exposed to higher CO₂ partial pressures produced more shoot and root biomass than plants exposed to lower levels of CO₂. In small pots, whole plant biomass and leaf area of plants grown in 270 and 350 microbars Of CO₂ were not significantly different. Plants grown in small pots in 650 microbars Of CO₂ produced greater total biomass than plants grown in 350 microbars, but the dry weight gain was found to be primarily an accumulation of leaf starch. Reduced photosynthetic capacity of plants grown at elevated levels Of CO₂ was clearly associated with inadequate rooting volume. Reductions in net photosynthesis were not associated with decreased stomatal conductance. Reduced carboxylation efficiency in response to CO₂ enrichment occurred only when root growth was restricted suggesting that ribulose-1,5- biphosphate carboxylase/oxygenase activity may be responsive to plant source-sink balance rather than to CO₂ concentration as a single factor. When root-restricted plants were transplanted into large pots, carboxylation efficiency and ribulose-1, 5-bisphosphate regeneration capacity increased indicating that acclimation of photosynthesis was reversible. Reductions in photosynthetic capacity as root growth was progressively restricted suggest sink-limited feedback inhibition as a possible mechanism for regulating net photosynthesis of plants grown in elevated CO₂.

Thomas, S.C., and F.A. Bazzaz. 1996. Elevated CO₂ and leaf shape:

Are dandelions getting toothier? *American Journal of Botany* 83(1):106-111.

Heteroblastic leaf development in *Taraxacum officinale* is compared between plants grown under ambient (350 ppm) vs. elevated (700 ppm) CO₂ levels. Leaves of elevated CO₂ plants exhibited more deeply incised leaf margins and relatively more slender leaf laminae than leaves of ambient CO₂ plants. These differences were found to be significant in allometric analyses that controlled for differences in leaf size, as well as analyses that controlled for leaf developmental order. The effects of elevated CO₂ on leaf shape were most pronounced when plants were grown individually, but detectable differences were also found in plants grown at high density. Although less dramatic than in *Taraxacum*, significant effects of elevated CO₂ on leaf shape were also found in two other weedy rosette species, *Plantago major* and *Rumex crispus*. These observations support the long-standing hypothesis that leaf carbohydrate level plays an important role in regulating heteroblastic leaf development, though elevated CO₂ may also affect leaf development through direct hormonal interactions or increased leaf water potential. In *Taraxacum*, pronounced modifications of leaf shape were found at CO₂ levels predicted to occur within the next century.

Thomas, S.M., D. Whitehead, J.A. Adams, J.B. Reid, R.R. Sherlock, and A.C. Leckie. 1996. Seasonal root distribution and soil surface carbon fluxes for one-year-old *Pinus radiata* trees growing at ambient and elevated carbon dioxide concentration. *Tree Physiology* 16(11-12):1015-1021.

The increase in number of fine (< 0.5 mm diameter) roots of one-year-old clonal *Pinus radiata* D. Don trees grown in large open-top field chambers at ambient (362 μ mol mol⁻¹) or elevated (654 μ mol mol⁻¹) CO₂ concentration was estimated using minirhizotron tubes placed horizontally at a depth of 0.3 m. The trees were well supplied with water and nutrients. Destructive harvesting of roots along an additional tube showed that there was a linear relationship between root number estimated from the minirhizotron and both root length density, L(v), and root carbon density, C-v, in the surrounding soil. Root distribution decreased with horizontal distance from the tree. At a depth of 0.3 m, 88% of the total C-v was concentrated within a 0.15-m radius from tree stems in the elevated CO₂ treatment, compared with 35% for trees in the ambient CO₂ treatment. Mean C-v along the tubes ranged up to 5 x 10⁻² μ g mm⁻³ and tended to be greater for trees grown at elevated CO₂ concentration, although the differences between CO₂ treatments were not significant. Root growth started in spring and continued until late summer. There was no significant difference in seasonal rates of increase in C-v between treatments, but roots were observed four weeks earlier in the elevated CO₂ treatment. No root turnover occurred at a depth of 0.3 m during the first year after planting. Mean values of carbon dioxide flux density at the soil surface, F, increased from 0.02 to 0.13 g m⁻² h⁻¹ during the year, and F was 30% greater for trees grown at elevated CO₂ concentration than at ambient CO₂. Diurnal changes in F were related to air temperature. The seasonal increase in F continued through the summer and early autumn, well after air temperature had begun to decline, suggesting that the increase was partly caused by increase in C-v as the roots colonized the soil profile.

Thomas, S.M., D. Whitehead, J.B. Reid, F.J. Cook, J.A. Adams, and A.C. Leckie. 1999. Growth, loss, and vertical distribution of *Pinus radiata* fine roots growing at ambient and elevated CO₂ concentration. *Global Change Biology* 5(1):107-121.

Increased below-ground carbon allocation in forest ecosystems is a likely consequence of rising atmospheric CO₂ concentration. If this results in changes to fine root growth, turnover and distribution long-term soil carbon cycling and storage could be altered. Bi-weekly measurements were made to determine the dynamics and distribution of fine roots (<1 mm diameter) for *Pinus radiata* trees growing at ambient (350 $\mu\text{mol mol}^{-1}$) and elevated (650 $\mu\text{mol mol}^{-1}$) CO₂ concentration in large open-top chambers. Measurements were made using minirhizotrons installed horizontally at depths of 0.1, 0.3, 0.5 and 0.9 m. During the first year, at a depth of 0.3 m, the increase in relative growth rate of roots occurred 6 weeks earlier in the elevated CO₂ treatment and the maximum rate was reached 10 weeks earlier than for trees in the ambient treatment. After 2 years, cumulative fine root growth (P-t) was 36% greater for trees growing at elevated CO₂ than at ambient CO₂ concentration, although this difference was not significant. A model of root growth driven by daily soil temperature accounted for between 43 and 99% of root growth variability. Total root loss (L-t) was 9% in the ambient and 14% in the elevated CO₂ treatment, although this difference was not significant. Root loss was greatest at 0.3 m. In the first year, 62% of fine roots grown between mid-summer and late-autumn disappeared within a year in the elevated CO₂ treatment, but only 18% in the ambient CO₂ treatment ($P < 0.01$). An exponential model relating L-t to time accounted for between 74 and 99% of the variability. Root cohort half-lives were 951 d for the ambient and 333 d for the elevated treatment. Root length density decreased exponentially with depth in both treatments, but relatively more fine roots grown in the elevated CO₂ treatment tended to occur deeper in the soil profile.

Thompson, G.B., J.K.M. Brown, and F.I. Woodward. 1993. The effects of host carbon-dioxide, nitrogen and water-supply on the infection of wheat by powdery mildew and aphids. *Plant, Cell and Environment* 16(6):687-694.

In two experiments, winter wheat (*Triticum aestivum* cv. Cerco) was grown in 350 (ambient) and 700 $\mu\text{mol mol}^{-1}$ (elevated) atmospheric CO₂ concentrations. In the first experiment, plants were grown at five levels of nitrogen fertilization, and in the second experiment, plants were grown at three levels of water supply. All plants were infected with powdery mildew, caused by the fungus *Erysiphe graminis*. Plants grown in elevated atmospheric CO₂ concentrations had significantly reduced % shoot nitrogen contents and significantly increased % shoot water contents. At elevated atmospheric CO₂ concentrations, where plant nitrogen content was significantly reduced, the severity of mildew infection was significantly reduced, and where host water content was significantly increased, the severity of mildew infection was significantly increased. In a moderate water supply treatment, the plants grown in elevated atmospheric CO₂ concentrations had significantly reduced nitrogen contents (9.9%) and significantly increased water content (4%), the amount of mildew infection was unchanged. The severity of mildew infection appeared to be more sensitive to host water content than to host nitrogen content.

Thompson, G.B., and B.G. Drake. 1994. Insects and fungi on a C-3 sedge and a C-4 grass exposed to elevated atmospheric CO₂ concentrations in open-top chambers in the field. *Plant, Cell and Environment* 17(10):1161-1167.

The effects of elevated atmospheric CO₂ concentration on plant-fungi and plant-insect interactions were studied in an emergent marsh in the Chesapeake Bay. Stands of the C-3 sedge *Scirpus olneyi* Grey. and the C-4 grass *Spartina patens* (Ait.) Muhl. have been exposed to elevated atmospheric CO₂ concentrations during each growing season since 1987. In August 1991 the severities of fungal infections and insect infestations were quantified. Shoot nitrogen concentration ([N]) and water content (WC) were determined. In elevated concentrations of atmospheric CO₂, 32% fewer *S. olneyi* plants were infested by insects, and there was a 37% reduction in the severity of a pathogenic fungal infection, compared with plants grown in ambient CO₂ concentrations. *S. olneyi* also had reduced [N], which correlated positively with the severities of fungal infections and insect infestations. Conversely, *S. patens* had increased WC but unchanged [N] in elevated concentrations of atmospheric CO₂ and the severity of fungal infection increased. Elevated atmospheric CO₂ concentration increased or decreased the severity of fungal infection depending on at least two interacting factors, [N] and WC; but it did not change the number of plants that were infected with fungi. In contrast, the major results for insects were that the number of plants infected with insects decreased, and that the amount of tissue that each insect ate also decreased.

Thompson, G.B., and F.I. Woodward. 1994. Some influences of CO₂ enrichment, nitrogen nutrition and competition on grain-yield and quality in spring wheat and barley. *Journal of Experimental Botany* 45(276):937-942.

Spring wheat and spring barley were grown in elevated atmospheric CO₂ in controlled environments. Wheat was grown in monoculture and in competition with three weed species. In monoculture, wheat had 30% more grain yield and 28% less grain nitrogen in elevated compared to ambient atmospheric CO₂. In competition, wheat had no significant increase in yield with elevated atmospheric CO₂. In competition, grain nitrogen concentration was reduced in response to CO₂ with the largest reduction occurring with the smallest competitor and the smallest reduction occurring with the largest competitor. Spring barley was grown in monoculture at three nitrogen fertilizer supplies. In elevated atmospheric CO₂ there were significant increases in grain yield and reductions in grain nitrogen concentration at all levels of nitrogen supply. In both species the reductions in grain nitrogen concentration were large enough to affect current bread making processes.

Thornley, J.H.M. 1998. Dynamic model of leaf photosynthesis with acclimation to light and nitrogen. *Annals of Botany* 81(3):421-430.

A simple model of photosynthesis in a mature C-3 leaf is described, based on a non-rectangular hyperbola: the model allows the high-light asymptote of that equation (P-max) to respond dynamically to light and nitrogen. This causes the leaf light response equation to acclimate continuously to the current conditions of light and N nutrition, which

can vary greatly within a crop canopy, and through a growing season, with important consequences for gross production. Predictions are presented for the dynamics of acclimation, acclimated and non-acclimated photosynthetic rates are compared, and the dependence of leaf properties on light and N availability is explored. There is good correspondence of predictions with experimental results at the leaf level. The model also provides a mechanism for a down regulation of photosynthesis in response to increased carbon dioxide concentrations, whose magnitude will depend on conditions, particularly of nitrogen nutrition. Thornley, J.H.M., and M.G.R. Cannell. 1996. Temperate forest responses to carbon dioxide, temperature and nitrogen: A model analysis. *Plant, Cell and Environment* 19(12):1331-1348.

The ITE Edinburgh Forest Model, which describes diurnal and seasonal changes in the pools and fluxes of C, N and water in a fully coupled forest-soil system, was parametrized to simulate a managed conifer plantation in upland Britain. The model was used to examine (i) the transient effects on forest growth of an IS92a scenario of increasing [CO₂] and temperature over two future rotations, and (ii) the equilibrium (sustainable) effects of all combinations of increases in [CO₂] from 350 to 550 and 750 $\mu\text{mol mol}^{-1}$, mean annual temperature from 7.5 to 8.5 and 9.5 degrees C and annual inputs of 20 or 40 kg N ha⁻¹ yr⁻¹. Changes in underlying processes represented in the model were then used to explain the responses. Eight conclusions were supported by the model for this forest type and climate. (1) Increasing temperatures above 3 degrees C alone may cause forest decline owing to water stress. (2) Elevated [CO₂] can protect trees from water stress that they may otherwise suffer in response to increased temperature. (3) In N-limiting conditions, elevated [CO₂] can increase allocation to roots with little increase in leaf area, whereas in N-rich conditions elevated [CO₂] may not increase allocation to roots and generally increases leaf area. (4) Elevated [CO₂] can decrease water use by forests in N-limited conditions and increase water use in N-rich conditions. (5) Elevated [CO₂] can increase forest productivity even in N-limiting conditions owing to increased N acquisition and use efficiency. (6) Rising temperatures (along with rising [CO₂]) may increase or decrease forest productivity depending on the supply of N and changes in water stress. (7) Gaseous losses of N from the soil can increase or decrease in response to elevated [CO₂] and temperature. (8) Projected increases in [CO₂] and temperature (IS92a) are likely to increase net ecosystem productivity and hence C sequestration in temperate forests.

Thornley, J.H.M., and M.G.R. Cannell. 1997. Temperate grassland responses to climate change: An analysis using the Hurley pasture model. *Annals of Botany* 80(2):205-221.

The Hurley Pasture Model is process-based and couples the carbon, nitrogen and water cycles in the soil-grass-animal system. It was used to examine the responses of grasslands in southern, lowland and northern, upland climates in Britain. Short-term response to step-wise increases in CO₂ concentration (350 to 700 $\mu\text{mol mol}^{-1}$) and temperature (5 degrees C) were contrasted with long-term equilibrium (the term 'equilibrium' is equivalent to 'steady state' throughout this paper)

responses and with responses to gradually increasing [CO₂] and temperature. Equilibrium responses to a range of climate variables were also examined. Three conclusions were drawn regarding the interpretation of experiments: (1) initial ecosystem responses to stepwise changes can be different in both magnitude and sign to equilibrium responses, and this can continue for many years; (2) grazing can drastically alter the magnitude and sign of the response of grasslands to climate change, be highly site-specific. It was concluded that experiments should try to lessen uncertainty about processes within models rather than try to predict ecosystem responses directly. Three conclusions were also drawn about the operation of grasslands as carbon sinks: (1) increasing [CO₂] alone will produce a carbon sink, as long as it continues to accelerate photosynthesis and increase net primary productivity; (2) by contrast, increasing temperatures alone are likely to produce a carbon source, because soil respiration is accelerated more than net primary productivity, even when assuming the same temperature function for most soil and plant biochemical processes; and (3) the net effect of projected increases in [CO₂] and temperature is likely to be a carbon sink of 5-15 g C m⁻² yr⁻¹ in humid, temperate grasslands for several decades, which is consistent with the magnitude of the hypothesized current global terrestrial carbon sink. Thron, C., K. Hahn, and C. Lutz. 1997. In situ effects of elevated CO₂ on chlorophyll fluorescence and chloroplast pigments of alpine plants. *Acta Oecologica-International Journal of Ecology* 18(3):193-200.

Alpine vegetation responds to elevated CO₂ with downward adjustment of photosynthesis. The experiments should show if doubling of ambient CO₂ reduces the maximum quantum yield and the chlorophylls thus altering the pigment composition of the thylakoid membranes in typical species of an alpine grassland (*Caricetum curvulae*). The studies were part of a CO₂ enrichment experiment with open-top chambers in the Swiss Central Alps in 2 470 m altitude over a period of four years. The leaves of *Carer curvula* and *Trifolium alpinum* were analysed in situ under ambient (355 $\mu\text{mol l}^{-1}$) or elevated (680 $\mu\text{mol l}^{-1}$) CO₂ and at two different nutrient levels. In each vegetation period both species showed a tendency to lower ratios of variable to maximum fluorescence (F-v/F-m) in plants with elevated CO₂ treatment compared to the ambient variants. These reductions in F-v/F-m were statistically different only for *Carer curvula* in 1993 and 1995. CO₂ enrichment caused reductions of leaf pigment concentrations of 10-30% especially for *Trifolium alpinum* whereas *Carer curvula* was less affected. The lower pigment contents per leaf were probably due to reductions of thylakoid membranes. In most cases, the influences of elevated CO₂ or of nutrient treatments on pigment composition and primary photochemistry were very small. This indicates that the downward regulation begins at early stages in the photosynthetic process. Some changes of the photosynthetic apparatus are species-specific and possibly reflect different strategies of protective acclimation processes of alpine vegetation.

Tian, H., C.A.S. Hall, and Y. Qi. 1998. Modeling primary productivity of the terrestrial biosphere in changing environments: Toward a dynamic biosphere model. *Critical Reviews in Plant Sciences* 17(5):541-557.

There is a widespread perception that the atmosphere and the climate are

beginning to change, and that these changes could have profound impacts on the primary productivity of the terrestrial biosphere. The terrestrial biosphere is a dynamic system that interacts with the atmosphere and climate principally through the exchanges of energy, water, and elements. Due to the limitations of equilibrium terrestrial biosphere models, new generation models - dynamic biosphere models, are critically needed for assessing and predicting the primary production and biogeochemical cycles of the terrestrial biosphere in changing global environment. The goal of dynamic biosphere modeling is to model terrestrial ecosystem dynamics induced by natural and anthropogenic disturbances, as well as the interactions of energy, water, and carbon cycles within the terrestrial biosphere and between the terrestrial biosphere and the atmosphere. The critical gaps in developing such a terrestrial biosphere model are not our inability to construct model code but instead the poorly developed links between empiricism and the concepts we used to construct our models, especially a lack of data that would help to make our models mechanistic, an incomplete fundamental knowledge about how complex terrestrial ecosystems work, a poor understanding of how to scale up what we do know and of how to validate such a model. The interaction among data, model structure, parameter sets, and predictive uncertainty will lead to important progress in the development of dynamic biosphere models.

Ticha, I. 1996. Optimization of photoautotrophic tobacco in vitro culture: Effect of suncaps closures on plantlet growth. *Photosynthetica* 32(3):475-479.

Maintenance of high carbon dioxide concentration during in vitro culture of tobacco plantlets by using suncaps closures (Sigma) and CO₂ enrichment in the cultivation chamber increased dramatically the growth of plantlets measured as total dry matter accumulation and total leaf area production. The effect was enhanced with duration of culture. Photomixotrophically grown plantlets with 3 % saccharose in the Murashige-Skoog medium accumulated more dry matter and developed a larger total leaf area than plantlets grown strictly photoautotrophically without saccharose but the effect of better CO₂ supply (suncaps) was seven (dry matter) to ten (leaf area) times higher in photoautotrophic plantlets as compared with photomixotrophic ones.

Tingey, D.T., M.G. Johnson, D.L. Phillips, D.W. Johnson, and J.T. Ball. 1996. Effects of elevated CO₂ and nitrogen on the synchrony of shoot and root growth in ponderosa pine. *Tree Physiology* 16(11-12):905-914.

We monitored effects of elevated CO₂ and N fertilization on shoot and fine root growth of *Pinus ponderosa* Dougl. ex P. Laws. and C. Laws. grown in native soil in open-top field-exposure chambers at Placerville, CA, over a 2-year period. The experimental design was a replicated 3 x 3 factorial with the center treatment missing; plants were exposed to ambient (similar to 365 $\mu\text{mol mol}^{-1}$) air or ambient air plus either 175 or 350 $\mu\text{mol mol}^{-1}$ CO₂ in combination with one of three rates of N addition (0, 100 or 200 kg ha⁻¹ year⁻¹). All CO₂ by N interactions were nonsignificant. Both the CO₂ and N treatments increased plant height, stem diameter and leaf area index (LAI). Elevated

CO₂ increased fine root area density and the occurrence of mycorrhizae, whereas N fertilization increased coarse root area density but had no effect on fine root area density. Spring flushes of shoot height and diameter growth were initiated concurrently with the increase in new root area density but height and diameter growth reached their maxima before that of fine roots. The temporal patterns of root and shoot growth were not altered by providing additional CO₂ or N. Greatest root loss occurred in the summer, immediately following the period of greatest new fine root growth. Elevated N initially reduced the fine root area density/LAI ratio independently of CO₂ treatment, indicating that the relationship between fine roots and needles was not changed by CO₂ exposure.

Tingey, D.T., M.G. Johnson, D.L. Phillips, and M.J. Storm. 1995. Effects of elevated CO₂ and nitrogen on ponderosa pine fine roots and associated fungal components. *Journal of Biogeography* 22(2-3):281-287.

The effects of CO₂ and nitrogen treatments on ponderosa pine (*Pinus ponderosa* Dougl. ex P. Laws. & C. Laws.) fine roots and associated fungal structures were monitored for a year (October 1992 to October 1993) using a minirhizotron camera system. The trees were grown in native soil in open-top field-exposure chambers at Placerville, CA and exposed to ambient (similar to 350 $\mu\text{mol mol}^{-1}$) air or ambient air plus either 175 or 350 $\mu\text{mol mol}^{-1}$ CO₂ and three levels of nitrogen addition (0, 100 and 200 kg ha⁻¹); however, the 100 kg ha⁻¹ N treatment at ambient plus 175 $\mu\text{mol mol}^{-1}$ CO₂ treatment was omitted from the experimental design. Roots were classified as new, white, brown, decaying or missing and their lengths and diameters measured. The occurrence of mycorrhizae and fungal hyphae was also recorded. The majority (>90%) of roots observed were smaller than 2 mm and the mean diameter decreased during the study. None of the root parameters measured showed a significant response to elevated CO₂. The elevated CO₂ treatments consistently showed an increase in root area density averaging 50% larger compared to ambient CO₂, but this response was not statistically significant due to the high spatial variability of root distribution. Only new root area density showed a significant nitrogen response. The most new roots were initiated between April and June and the highest level of root loss occurred between June and August. The occurrence of mycorrhizae and fungal hyphae increased in response to CO₂ treatment but not the nitrogen. Their highest levels of occurrence were during August and October 93.

Tingey, D.T., B.D. McVeety, R. Waschmann, M.G. Johnson, D.L. Phillips, P.T. Rygielwicz, and D.M. Olszyk. 1996. A versatile sun-lit controlled-environment facility for studying plant and soil processes. *Journal of Environmental Quality* 25(3):614-625.

A new environmental-tracking, sun-lit controlled-environment facility (terracosm) that can control and manipulate climatic and edaphic factors while maintaining natural environmental variability was developed to study the effects of environmental stresses on a model ecosystem (i.e., plant and soil processes). An analysis of terracosm performance data indicates that the terracosms simulated natural seasonal and diurnal changes in atmospheric CO₂, air and soil temperatures, vapor pressure

deficit (VPD), and soil moisture. The terracosc performance data indicate that between 92 and 100% of the hourly CO₂ concentrations are within $\pm 50 \mu\text{mol mol}^{-1}$ of the target concentrations for both ambient and elevated treatments (1 Nov. 1993 through 30 Nov. 1994). Air temperatures are within 2 degrees C of the target temperature between 85 and 100% of the hours for both ambient and elevated temperature treatments. The VPD was approximately the same (0.09 kPa difference between treatments) in the ambient and elevated temperature treatments. Distributed process control was implemented to minimize down- time. Terracosc downtime, periods when terracosc environmental conditions could not be reliably controlled, varied between 2.4 and 2.8% of all hours, and was equally distributed between biological sampling and equipment problems.

Tingey, D.T., D.L. Phillips, M.G. Johnson, M.J. Storm, and J.T. Ball. 1997. Effects of elevated CO₂ and N fertilization on fine root dynamics and fungal growth in seedling *Pinus ponderosa*. *Environmental and Experimental Botany* 37(2-3):73-83.

The effects of elevated CO₂ and N fertilization on fine root growth of *Pinus ponderosa* Dougl. ex P. Laws. C. Laws., grown in native soil in open-top held-exposure chambers at Placerville, CA, were monitored for a 2-year period using minirhizotrons. The experimental design was a replicated 3 x 3 factorial with a treatment missing; plants were exposed to ambient (approximate to 365 $\mu\text{mol mol}^{-1}$) air or ambient air plus either 175 or 350 $\mu\text{mol mol}^{-1}$ CO₂ and three levels of N addition (0, 100 and 200 kg ha⁻¹ year⁻¹). By the second year, elevated CO₂ increased fine root occurrence and root length while N fertilization had no effect. The CO₂ x N interactions were not significant. Neither elevated CO₂ nor N fertilization altered fine root diameter. Fine root mortality was increased by increasing soil N but was reduced in elevated CO₂. Highest fine root mortality occurred during summer and was lowest during winter. Elevated CO₂ increased mycorrhizal and fungal occurrence earlier than N fertilization. (C) 1997 Elsevier Science B.V.

Tischler, C.R., H.W. Polley, H.B. Johnson, and H.S. Mayeux. 1998. Environment and seedling age influence mesquite response to epicotyl removal. *Journal of Range Management* 51(3):361-365.

Herbivory by small mammals is a major factor controlling survival of honey mesquite (*Prosopis glandulosa* Torr. var. *glandulosa*) seedlings. Clipping below the cotyledons is lethal; removal of the epicotyl may not

be lethal but can severely limit seedling growth. Seedlings of other woody species sometimes compensate for epicotyl removal by prolonging the life of cotyledons. Also, projected future increases in atmospheric CO₂ concentration could influence survival and growth after epicotyl removal. Objectives of this study were to determine effects of epicotyl removal at various seedling ages, atmospheric CO₂ concentrations, and soil fertility, on (1) seedling survival, (2) cotyledonary leaf longevity, and (3) shoot and root growth of young seedlings. Mesquite seedlings were grown at 350, 700, and 1,000 $\mu\text{mol L}^{-1}$ atmospheric CO₂ concentration in nutrient poor and nutrient rich soils. All ages of seedlings survived epicotyl removal. Cotyledonary leaf fresh mass and chlorophyll content were higher in plants where epicotyls were clipped. Root and shoot mass of both clipped and unclipped plants generally increased at higher CO₂ concentrations when mineral nutrition was adequate, but responded less to CO₂ when soil fertility was low. Responses to epicotyl clipping in mesquite seedlings are complex, being strongly influenced by soil fertility, atmospheric CO₂ concentration, seedling age at clipping, and interactions between these factors.

Tissue, D.T., K.L. Griffin, and J.T. Ball. 1999. Photosynthetic adjustment in field-grown ponderosa pine trees after six years of exposure to elevated CO₂. *Tree Physiology* 19(4-5):221-228.

Photosynthesis of tree seedlings is generally enhanced during short-term exposure to elevated atmospheric CO₂, but longer-term photosynthetic responses are often more variable because they are affected by morphological, biochemical and physiological feedback mechanisms that regulate carbon assimilation to meet sink demand. To examine biochemical and morphological factors that might regulate the long-term photosynthetic response of field-grown trees to elevated CO₂, we grew ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) trees in open-top chambers for six years in native soil at ambient CO₂ (35 Pa) and elevated CO₂ (70 Pa) at a site near Placerville, CA. Trees were well watered and exposed to natural light and ambient temperature. At the end of the sixth growing season at elevated CO₂, net photosynthesis was enhanced 53%, despite reductions in photosynthetic capacity. The positive net photosynthetic response to elevated CO₂ reflected greater relative increases in Rubisco sensitivity compared with the decreases resulting from biochemical adjustments. Analyses of net photosynthetic rate versus internal CO₂ partial pressure curves indicated that reductions in photosynthetic capacity in response to elevated CO₂ were the result of significant reductions in maximum photosynthetic rate (20%), Rubisco carboxylation capacity (36%), and electron transport capacity (21%). Decreased photosynthetic capacity was accompanied by reductions in various photosynthetic components, including total chlorophyll (24%), Rubisco protein content (38%), and mass-based leaf nitrogen concentration (14%). Net photosynthesis was unaffected by morphological adjustments because there was no change in leaf mass per unit area at elevated CO₂. An apparent positive response of photosynthetic adjustment in the elevated CO₂ treatment was the redistribution of N within the photosynthetic system to balance Rubisco carboxylation and electron transport capacities. We conclude that trees, without apparent limitations to root growth, may exhibit photosynthetic adjustment responses in the field after long-term exposure to elevated CO₂.

Tissue, D.T., K.L. Griffin, R.B. Thomas, and B.R. Strain. 1995. Effects of low and elevated CO₂ on C-3 and C-4 annuals .2. Photosynthesis and leaf biochemistry. *Oecologia* 101(1):21-28.

Abutilon theophrasti (C-3) and *Amaranthus retroflexus* (C-4), were grown from seed at four partial pressures of CO₂: 15 Pa (below Pleistocene minimum), 27 Pa (pre-industrial), 35 Pa (current), and 70 Pa (future) in the Duke Phytotron under high light, high nutrient, and well-watered conditions to evaluate their photosynthetic response to historic and future levels of CO₂. Net photosynthesis at growth CO₂ partial pressures increased with increasing CO₂, for C-3 plants, but not C-4 plants. Net photosynthesis of *Abutilon* at 15 Pa CO₂ was 70% less than that of plants grown at 35 Pa CO₂, due to greater stomatal and biochemical limitations at 15 Pa CO₂. Relative stomatal limitation (RSL) of *Abutilon* at 15 Pa CO₂ was nearly 3 times greater than at 35 Pa CO₂. A photosynthesis model was used to estimate ribulose-1,5-bisphosphate carboxylase (rubisco) activity (V_c(max)), electron transport mediated RuBP regeneration capacity (J(max)), and phosphate regeneration capacity (PiRC) in *Abutilon* from net photosynthesis versus intercellular CO₂ (A-C-i) curves. All three component processes decreased by approximately 25% in *Abutilon* grown at 15 Pa compared with 35 Pa CO₂. *Abutilon* grown at 15 Pa CO₂ had significant reductions in total rubisco activity (25%), rubisco content (30%), activation state (29%), chlorophyll content (39%), N content (32%), and starch content (68%) compared with plants grown at 35 Pa CO₂. Greater allocation to rubisco relative to light reaction components and concomitant decreases in J(max) and PiRC suggest co-regulation of biochemical processes occurred in *Abutilon* grown at 15 Pa CO₂. There were no significant differences in photosynthesis or leaf properties in *Abutilon* grown at 27 Pa CO₂ compared with 35 Pa CO₂, suggesting that the rise in CO₂ since the beginning of the industrial age has had little effect on the photosynthetic performance of *Abutilon*. For *Amaranthus*, limitations of photosynthesis were balanced between stomatal and biochemical factors such that net photosynthesis was similar in all CO₂ treatments. Differences in photosynthetic response to growth over a wide range of CO₂ partial pressures suggest changes in the relative performance of C-3 and C-4 annuals as atmospheric CO₂ has fluctuated over geologic time.

Tissue, D.T., J.P. Megonigal, and R.B. Thomas. 1997. Nitrogenase activity and N-2 fixation are stimulated by elevated CO₂ in a tropical N-2-fixing tree. *Oecologia* 109(1):28-33.

Seeds of *Gliricidia sepium*, a fast-growing woody legume native to seasonal tropical forests of Central America, were inoculated with N-2-fixing Rhizobium bacteria and grown in environmentally controlled glasshouses for 67-71 days under ambient CO₂ (35 Pa) and elevated CO₂ (70 Pa) conditions. Seedlings were watered with an N-free, but otherwise complete, nutrient solution such that bacterial N-2 fixation was the only source of N available to the plant. The primary objective of our study was to quantify the effect of CO₂ enrichment on the kinetics of photosynthate transport to nodules and determine its subsequent effect on N-2 fixation. Photosynthetic rates and carbon storage in leaves were higher in elevated CO₂ plants indicating that more carbon was available for transport to nodules. A (CO₂)-C-14 pulse-chase experiment demonstrated that photosynthetically fixed carbon was supplied by leaves to nodules at a faster rate when plants were grown in elevated CO₂. Greater rates of carbon supply to nodules did not affect nodule mass per plant, but did increase specific nitrogenase activity (SNA) and total nitrogenase activity (TNA) resulting in greater N-2 fixation. In fact,

a 23% increase in the rate of carbon supplied to nodules coincided with a 23% increase in SNA for plants grown in elevated CO₂, suggesting a direct correlation between carbon supply and nitrogenase activity. The improvement in plant N status produced much larger plants when grown in elevated CO₂. These results suggest that *Gliricidia*, and possibly other N-2-fixing trees, may show an early and positive growth response to elevated CO₂, even in severely N- deficient soils, due to increased nitrogenase activity.

Tissue, D.T., R.B. Thomas, and B.R. Strain. 1993. Long-term effects of elevated CO₂ and nutrients on photosynthesis and rubisco in loblolly-pine seedlings. *Plant, Cell and Environment* 16(7):859-865.

The effects of long-term CO₂ enhancement and varying nutrient availability on photosynthesis and ribulose-1,5-bisphosphate carboxylase/oxygenase (rubisco) were studied on loblolly pine (*Pinus taeda* L.) seedlings grown in two atmospheric CO₂ partial pressures (35 and 65 Pa) and three nutrient treatments (low N, low P, and high N and P). Measurements taken in late autumn (November) after 2 years of CO₂ enrichment and nutrient addition showed that photosynthetic rates were higher for plants grown at elevated CO₂ only when they received supplemental N. Total rubisco activity and rubisco content decreased at elevated CO₂, but there was an increase in activation state. At elevated CO₂, proportionately less N was found in rubisco and more N was found in the light reaction components. These results demonstrate acclimation of photosynthetic processes to elevated CO₂ through reallocation of N. Loblolly pine grown in nutrient conditions similar to native soils (low N availability) had lower needle N and chlorophyll content, lower total rubisco activity and content, and lower photosynthetic rates than plants grown at high N and P. This suggests that the magnitude of the photosynthetic response to a future, high-CO₂ environment will be dependent on soil fertility in the system.

Tissue, D.T., R.B. Thomas, and B.R. Strain. 1996. Growth and photosynthesis of loblolly pine (*Pinus taeda* L.) after exposure to elevated CO₂ for 19 months in the field. *Tree Physiology* 16(1-2):49-59.

To detect seasonal and long-term differences in growth and photosynthesis of loblolly pine (*Pinus taeda* L.) exposed to elevated CO₂ under ambient conditions of precipitation, light, temperature and nutrient availability, seedlings were planted in soil representative of an early, abandoned agricultural field and maintained for 19 months in the field either in open-top chambers providing one of three atmospheric CO₂ partial pressures (ambient, ambient +15 Pa, and ambient +30 Pa) or in unchambered control plots. An early and positive response to elevated CO₂ substantially increased total plant biomass. Peak differences in relative biomass enhancement occurred after 11 months of CO₂ treatment when biomass of plants grown at +15 and +30 Pa CO₂ was 111 and 233% greater, respectively, than that of plants grown at ambient CO₂. After 19 months, there was no significant difference in biomass between +15 Pa CO₂-treated plants and ambient CO₂-treated plants, whereas biomass of +30 Pa CO₂-treated plants was 111% greater than that of ambient CO₂-treated plants. Enhanced rates of leaf-level photosynthesis were maintained in plants in the elevated CO₂ treatments throughout the 19-month exposure period despite reductions in both

leafN concentration and ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) activity during the first 11 months of CO₂ exposure. Reductions in Rubisco activity indicated photosynthetic adjustment to elevated CO₂, but Rubisco-mediated control of photosynthesis was small. Seasonal shifts in sink strength affected photosynthetic rates, greatly magnifying the positive effects of elevated CO₂ on photosynthesis during periods of rapid plant growth. Greater carbon assimilation by the whole plant accelerated plant development and thereby stimulated new sinks for carbon through increased plant biomass, secondary branching and new leaf production. We conclude that elevated CO₂ will enhance photosynthesis and biomass accumulation in loblolly pine seedlings under high nutrient conditions; however, reductions over time in the relative biomass response of plants to elevated CO₂ complicate predictions of the eventual magnitude of carbon storage in this species under future CO₂ conditions.

Tissue, D.T., R.B. Thomas, and B.R. Strain. 1997. Atmospheric CO₂ enrichment increases growth and photosynthesis of Pinus taeda: a 4 year experiment in the field. *Plant, Cell and Environment* 20(9):1123-1134.

Forest trees are major components of the terrestrial biome and their response to rising atmospheric CO₂ plays a prominent role in the global carbon cycle. In this study, loblolly pine seedlings were planted in the field in recently disturbed soil of high fertility, and CO₂ partial pressures were maintained at ambient CO₂ (Amb) and elevated CO₂ (Amb + 30 Pa) for 4 years. The objective of the study was to measure seasonal and long- term responses in growth and photosynthesis of loblolly pine exposed to elevated CO₂ under ambient field conditions of precipitation, light, temperature and nutrient availability. Loblolly pine trees grown in elevated CO₂ produced 90% more biomass after four growing seasons than did trees grown in ambient CO₂. This large increase in final biomass was primarily due to a 217% increase in leaf area in the first growing season which resulted in much higher relative growth rates for trees grown in elevated CO₂. Although there was not a sustained effect of elevated CO₂ on relative growth rate after the first growing season, absolute production of biomass continued to increase each year in trees grown in elevated CO₂ as a consequence of the compound interest effect of increased leaf area on the production of more new leaf area and more biomass. Allometric analyses of biomass allocation patterns demonstrated size-dependent shifts in allocation, but no direct effects of elevated CO₂ on partitioning of biomass. Leaf photosynthetic rates were always higher in trees grown in elevated CO₂, but these differences were greater in the summer (60-130% increase) than in the winter (14-44% increase), reflecting strong seasonal effects of temperature on photosynthesis. Our results suggest that seasonal variation in the relative photosynthetic response to elevated CO₂ will occur in natural ecosystems, but total non-structural carbohydrate (TNC) levels in leaves indicate that this variation may not always be related to sink activity. Despite indications of canopy-level adjustments in carbon assimilation, enhanced levels of leaf photosynthesis coupled with increased total leaf area indicate that net carbon assimilation for the whole tree was greater for trees grown under elevated CO₂ compared with ambient CO₂. If the large growth enhancement observed in loblolly pine were maintained after canopy closure, then these trees could be a large sink for fossil carbon emitted to the atmosphere and produce a negative feedback on atmospheric CO₂.

Titus, J.E. 1992. Submersed macrophyte growth at low pH .2. Co₂ X sediment interactions. *Oecologia* 92(3):391-398.

The submersed macrophyte *Vallisneria americana* was grown for seven weeks in a greenhouse to test for differences in the ability of three different sediments to support growth stimulation in response to CO₂ enrichment at low pH. Plants accumulated 21- to 24-fold greater biomass at 10 x ambient CO₂ concentrations than at ambient CO₂ on all sediments. At both CO₂ levels, plants grown on sediment from an acidified lake accumulated ca. 81%, and those grown on oligotrophic lake sediment ca. 47% as much biomass as plants grown on alkaline lake sediment. Despite striking CO₂ and sediment effects on biomass accumulation, there was no significant interaction (using log-transformed data) between CO₂ and sediment effects, indicating that all sediments allowed similar proportionate growth responses to CO₂ enrichment. Plants grown on the less fertile sediments showed greater relative allocation to horizontal versus vertical growth by producing more rosette- bearing stolons in relation to plant height (leaf length) than plants grown on relatively fertile, alkaline lake sediment. Tissue analysis suggested that sediment effects on *Vallisneria* growth could be attributed neither to mineral nutrient (nitrogen and phosphorus) limitation nor to aluminum toxicity in these low pH treatments. In any case, CO₂ availability can be an important regulator of submersed macrophyte growth at low pH on a variety of sediment types, including those from oligotrophic and acidic lakes.

Titus, J.E., and J.H. Andorfer. 1996. Effects of CO₂ enrichment on mineral accumulation and nitrogen relations in a submersed macrophyte. *Freshwater Biology* 36(3):661-671.

1. Six- to eight-week greenhouse experiments with independent control of pH and dissolved CO₂ evaluated the potential for CO₂ enrichment to stimulate the accumulation of Al, Fe, P and N in shoots of *Vallisneria americana*, particularly at pH 5. These minerals were provided only as they occurred in natural lake sediments. 2. The effect of CO₂ enrichment at pH 5 v pH 7.3 on growth and tissue N concentration was also determined. 3. CO₂ enrichment at pH 5 effected 5.5- and 7-fold increases in total shoot accumulation of Al and Fe, respectively. In a two-way factorial experiment, CO₂ enrichment yielded 6- to 11-fold greater total shoot P accumulation in plants grown on less and more fertile sediments, respectively. 4. In a three-way factorial experiment, CO₂ enrichment stimulated *Vallisneria* growth, especially at pH 5, and resulted in a 31-58% reduction in tissue [N] for different pH x sediment combinations. These are greater reductions than previously reported. It also increased total shoot N accumulation up to 6-fold, and there were significant interactions with pH and sediment source: the CO₂ enrichment effect on shoot N accumulation was greater at pH 5 than at pH 7.3, and it was greater with the more fertile sediment at pH 5. 5. Water chemistry (pH and/or [CO₂]) and sediment fertility thus both indirectly influenced the accumulation of sediment-derived minerals in macrophyte shoots within the water column.

Tjoelker, M.G., J. Oleksyn, and P.B. Reich. 1998. Seedlings of five boreal tree species differ in acclimation of net photosynthesis to elevated CO₂ and temperature. *Tree Physiology* 18(11):715-726.

Biochemical models of photosynthesis suggest that rising temperatures will increase rates of net carbon dioxide assimilation and enhance plant responses to increasing atmospheric concentrations of CO₂. We tested this hypothesis by evaluating acclimation and ontogenetic drift in net photosynthesis in seedlings of five boreal tree species grown at 370 and 580 $\mu\text{mol mol}^{-1}$ CO₂ in combination with day/night temperatures of 18/12, 21/15, 24/18, 27/21, and 30/24 degrees C. Leaf-area-based rates of net photosynthesis increased between 13 and 36% among species in plants grown and measured in elevated CO₂ compared to ambient CO₂. These CO₂-induced increases in net photosynthesis were greater for slower-growing *Picea mariana* (Mill.) B.S.P., *Pinus banksiana* Lamb., and *Larix laricina* (Du Roi) K. Koch than for faster-growing *Populus tremuloides* Michx. and *Betula papyrifera* Marsh., paralleling longer-term growth differences between CO₂ treatments. Measures at common CO₂ concentrations revealed that net photosynthesis was down-regulated in plants grown at elevated CO₂. In situ leaf gas exchange rates varied minimally across temperature treatments and, contrary to predictions, increasing growth temperatures did not enhance the response of net photosynthesis to elevated CO₂ in four of the five species. Overall, the species exhibited declines in specific leaf area and leaf nitrogen concentration, and increases in total nonstructural carbohydrates in response to CO₂ enrichment. Consequently, the elevated CO₂ treatment enhanced rates of net photosynthesis much more when expressed on a leaf area basis (25 %) than when expressed on a leaf mass basis (10%). In all species, rates of leaf net CO₂ exchange exhibited modest declines with increasing plant size through ontogeny. Among the conifers, enhancements of photosynthetic rates in elevated CO₂ were sustained through time across a wide range of plant sizes. In contrast, for *Populus tremuloides* and *B. papyrifera*, mass-based photosynthetic rates did not differ between CO₂ treatments. Overall, net photosynthetic rates were highly correlated with relative growth rate as it varied among species and treatment combinations through time. We conclude that interspecific variation may be a more important determinant of photosynthetic response to CO₂ than temperature.

Tjoelker, M.G., J. Oleksyn, and P.B. Reich. 1998. Temperature and ontogeny mediate growth response to elevated CO₂ in seedlings of five boreal tree species. *New Phytologist* 140(2):197-210.

We tested the extent to which growth responses to elevated carbon dioxide (CO₂) are temperature-dependent and change through early seedling ontogeny among boreal tree species of contrasting relative growth rates (RGR). *Populus tremuloides* Michx., *Betula papyrifera* Marsh., *Larix laricina* (Du Roi) K. Koch, *Pinus banksiana* Lamb., and *Picea mariana* (Mill.) B.S.P. were grown from seeds for 3 months in controlled-environment chambers at two CO₂ concentrations (370 and 580 $\mu\text{mol mol}^{-1}$) and five temperature regimes of 18/12, 21/15, 24/18, 27/21 and 30/24 degrees C (light/dark). Growth increases in response to CO₂ enrichment were minimal at the lowest temperature and

maximal at 21/15 OC for the three conifers and at 24/18 degrees C or higher for the two broadleaved species, corresponding with differences in optimal temperatures for growth. In both CO₂ treatments, RGR among species and temperatures correlated positively with leaf area ratio (LAR) (r greater than or equal to 0.90, $P < 0.0001$). However, at a given LAR, RGR was higher in elevated CO₂, owing to enhanced whole-plant net assimilation rate. On average in all species and temperatures at a common plant mass, CO₂ enrichment increased RGR (9 %) through higher whole-plant net assimilation rate (22 %), despite declines in LAR in high CO₂ (11 %). Reductions in LAR are thus an important feedback mechanism reducing positive plant growth responses to CO₂. Proportional allocation of dry mass to roots did not vary between CO₂ treatments. Early in the experiment, proportional increases in plant dry mass in elevated CO₂ were larger in faster-growing *Populus tremuloides* and *B. papyrifera* than in the slower-growing conifers. However, growth increases in response to CO₂ enrichment fell with time for broadleaved species and increased for the conifers. With increasing plant size over time, compensatory adjustments to CO₂ enrichment in the factors that determine RGR, such as LAR, were much larger in broadleaves than in conifers. Thus, the hypothesis that faster-growing species are more responsive to elevated CO₂ was not supported, given contrasting patterns of growth response to CO₂ with increasing plant size and age.

Tjoelker, M.G., J. Oleksyn, and P.B. Reich. 1999. Acclimation of respiration to temperature and CO₂ in seedlings of boreal tree species in relation to plant size and relative growth rate. *Global Change Biology* 5(6):679-691.

The role of acclimation of dark respiration to temperature and CO₂ concentration and its relationship to growth are critical in determining plant response to predicted global change. We explored temperature acclimation of respiration in seedlings of tree species of the North American boreal forest. *Populus tremuloides*, *Betula papyrifera*, *Larix laricina*, *Pinus banksiana*, and *Picea mariana* plants were grown from seed in controlled-environments at current and elevated concentrations of CO₂ (370 and 580 $\mu\text{mol mol}^{-1}$) in combination with three temperature treatments of 18/12, 24/18, and 30/24 degrees C (light/dark period). Specific respiration rates of roots and shoots acclimated to temperature, damping increases in rates across growth-temperature environments compared to short-term temperature responses. Compared at a standard temperature, root and shoot respiration rates were, on average, 40% lower in plants grown at the highest compared to lowest growth temperature. Broad-leaved species had a lower degree of temperature acclimation of respiration than did the conifers. Among species and treatment combinations, rates of respiration were linearly related to size and relative growth rate, and relationships were comparable among growth environments. Specific respiration rates and whole-plant respiratory CO₂ efflux as a proportion of daily net CO₂ uptake increased at higher growth temperatures, but were minimally affected by CO₂ concentration. Whole-plant specific respiration rates were two to three times higher in broad-leaved than coniferous species. However, compared to faster-growing broad-leaved species, slower-growing conifers lost a larger proportion of net daily CO₂ uptake as respiratory CO₂ efflux, especially in roots. Interspecific variation in acclimation responses of dark respiration to temperature is more important than acclimation of respiration to CO₂ enrichment in modifying tree seedling growth responses to projected increases in CO₂ concentration and temperature.

Tjoelker, M.G., P.B. Reich, and J. Oleksyn. 1999. Changes in leaf nitrogen and carbohydrates underlie temperature and CO₂ acclimation of dark respiration in five boreal tree species. *Plant, Cell and Environment* 22(7):767-778.

We tested the hypothesis that acclimation of foliar dark respiration to CO₂ concentration and temperature is associated with adjustments in leaf structure and chemistry. *Populus tremuloides* Michx., *Betula papyrifera* Marsh., *Larix laricina* (Du Roi) K. Koch, *Pinus banksiana* Lamb., and *Picea mariana* (Mill.) B.S.P. were grown from seed in combined CO₂ (370 or 580 $\mu\text{mol mol}^{-1}$) and temperature treatments (18/12, 24/18, or 30/24 degrees C). Temperature and CO₂ effects were predominately independent. Specific respiration rates partially acclimated to warmer thermal environments through downward adjustment in the intercept, but not Q(10) of the temperature-response functions. Temperature acclimation of respiration was larger for conifers than broad-leaved species and was associated with pronounced reductions in leaf nitrogen concentrations in conifers at higher growth temperatures. Shortterm increases in CO₂ concentration did not inhibit respiration. Growth in the elevated CO₂ concentration reduced leaf nitrogen and increased non-structural carbohydrate concentrations. However, for a given nitrogen concentration, respiration was higher in leaves grown in the elevated CO₂ concentration, as rates increased with increasing carbohydrates. Across species and treatments, respiration rates were a function of both leaf nitrogen and carbohydrate concentrations ($R^2 = 0.71$, $P < 0.0001$). Longterm acclimation of foliar dark respiration to temperature and CO₂ concentration is largely associated with changes in nitrogen and carbohydrate concentrations.

Tognetti, R., A. Giovannelli, A. Longobucco, F. Miglietta, and A. Raschi. 1996. Water relations of oak species growing in the natural CO₂ spring of Rapolano (central Italy). *Annales Des Sciences Forestieres* 53(2-3):475-485.

The effect of elevated atmospheric carbon dioxide on water relations was examined on downy oak (*Quercus pubescens*) and helm oak (*Q. ilex*) trees. The study was conducted on trees growing in a naturally enriched CO₂ spring. Sap velocity and sap flow were measured by the heat pulse technique. On the same trees, daily courses of xylem water potential, leaf conductance and transpiration were monitored. Plant water relations were evaluated by pressure-volume analysis method on shoots; on the same branches, relative conductivity of xylem was measured. Both species exhibited increased osmotic potential and decreased symplasmic fraction of water in trees adapted to increased CO₂. Downy oak showed lower stomatal conductance under elevated CO₂, but helm oak did not. Both species displayed higher sap flow in control trees. In both species, increased carbon dioxide did not influence xylem embolism formation.

Tognetti, R., and J.D. Johnson. 1999. The effect of elevated atmospheric CO₂ concentration and nutrient supply on gas exchange, carbohydrates and foliar phenolic concentration in live oak (*Quercus*

virginiana Mill.) seedlings. *Annals of Forest Science* 56(5):379-389.

We determined the direct effects of atmospheric CO₂ concentration ([CO₂]) on leaf gas exchange, phenolic and carbohydrate allocation in live oak seedlings (*Quercus virginiana* Mill.) grown at present (370 $\mu\text{mol mol}^{-1}$) or elevated (520 $\mu\text{mol mol}^{-1}$) [CO₂] for 6 months in open-top chambers. Two soil nitrogen (N) treatments (20 and 90 $\mu\text{mol mol}^{-1}$ total N, low N and high N treatments, respectively) were imposed by watering the plants every 5 d with modified water soluble fertilizer. Enhanced rates of leaf-level photosynthesis were maintained in plants subjected to elevated [CO₂] over the 6-month treatment period in both N treatments. A combination of increased rates of photosynthesis and decreased stomatal conductance was responsible for nearly doubling water use efficiency under elevated [CO₂]. The sustained increase in photosynthetic rate was accompanied by decreased dark respiration in elevated [CO₂]. Elevated [CO₂] led to increased growth rates; while total non-structural carbohydrate (sugars and starch) concentrations were not significantly affected by elevated [CO₂] treatment. The concentration of phenolic compounds increased significantly under elevated [CO₂]. ((C) Inra/Elsevier, Paris.).

Tognetti, R., and J.D. Johnson. 1999. Responses of growth, nitrogen and carbon partitioning to elevated atmospheric CO₂ concentration in live oak (*Quercus virginiana* Mill.) seedlings in relation to nutrient supply. *Annals of Forest Science* 56(2):91-105.

Live oak (*Quercus virginiana* Mill.) seedlings were exposed at two concentrations of atmospheric carbon dioxide ([CO₂], 370 or 520 $\mu\text{mol mol}^{-1}$) in combination with two soil nitrogen (N) treatments (20 and 90 $\mu\text{mol mol}^{-1}$ total N) in open-top chambers for 6 months. Seedlings were harvested at 5-7 weeks interval. CO₂ treatment had a positive effect on seedling growth. Differences in biomass between elevated and ambient CO₂-treated plants increased over the experimental period. Soil N availability did not significantly affect growth. Nevertheless, growth in elevated [CO₂] in combination with high N levels led to a consistently higher accumulation of total biomass by the end of the experiment (30-40 %). Biomass allocation between plant parts was similar for seedlings in all treatments, but was significantly different between harvests. The N regimes did not result in different relative growth rate (RGR) and net assimilation rate (NAR), while CO₂ treatment had an overall significant effect. Across all [CO₂] and N levels, there was a positive relationship between plant mass and subsequent RGR, and this relationship did not differ between treatments. Overall, specific leaf area (SLA) decreased in CO₂-enriched air. Fine root-leaf mass ratio was increased by elevated [CO₂] and decreased by high N. High CO₂- and high N- treated plants had the greatest height and basal stem diameter. The allometric relationships between shoot and root dry weight and between height and basal stem diameter were not significantly affected by elevated [CO₂]. Leaf N concentrations were reduced by low soil N. Plant N concentrations decreased with time. Elevated [CO₂] increased the C/N ratio of all plant compartments, as a result of decreasing N concentrations. High CO₂-grown plants reduced N concentrations relative to ambient CO₂-grown plants when compared at a common time, but similar when compared at a common size. ((C) Inra/Elsevier, Paris.).

Tognetti, R., and J.D. Johnson. 1999. Responses to elevated atmospheric CO₂ concentration and nitrogen supply of *Quercus ilex* L-seedlings from a coppice stand growing at a natural CO₂ spring. *Annals of Forest Science* 56(7):549-561.

Quercus ilex acorns were collected from a population of trees with a lifetime exposure to elevated atmospheric CO₂ concentration (CO₂), and after germination seedlings were exposed at two [CO₂] (370 or 520 μmol mol⁻¹) in combination with two soil N treatments (20 and 90 μmol mol⁻¹ total N) in open-top chambers for 6 months. Increasing [CO₂] stimulated photosynthesis and leaf dark respiration regardless of N treatment. The increase in photosynthesis and leaf dark respiration was associated with a moderate reduction in stomatal conductance, resulting in enhanced instantaneous transpiration efficiency in leaves of seedlings in CO₂-enriched air. Elevated [CO₂] increased biomass production only in the high-N treatment. Fine root/leaf mass ratio decreased with high-N treatment and increased with CO₂ enrichment. There was evidence of a preferential shift of biomass to below-ground tissue at a low level of nutrient addition. Specific leaf area (SLA) and leaf area ratio (LAR) decreased significantly in leaves of seedlings grown in elevated [CO₂] irrespective of N treatment. Leaf N concentration decreased significantly in elevated [CO₂] irrespective of N treatment. As a result of patterns of N and carbon concentrations, C/N ratio generally increased with elevated [CO₂] treatment and decreased with high nutrient supply. Afternoon starch concentrations in leaves did not increase significantly with increasing [CO₂], as was the case for morning starch concentrations at low-N supply. Starch concentrations in leaves, stem and roots increased with elevated [CO₂] and decreased with nutrient addition. The concentration of sugars was not significantly affected by either CO₂ or N treatments. Total foliar phenolic concentrations decreased in seedlings grown in elevated [CO₂] irrespective of N treatment, while nutrient supply had less of an effect. We conclude that available soil N will be a major controlling resource for the establishment and growth of *Q. ilex* in rising [CO₂] conditions. Tognetti, R., J.D. Johnson, M. Michelozzi, and A. Raschi. 1998. Response of foliar metabolism in mature trees of *Quercus pubescens* and *Quercus ilex* to long-term elevated CO₂. *Environmental and Experimental Botany* 39(3):233-245.

Long-term effects on and adaptations of the carbon physiology of long-lived trees exposed to increasing atmospheric levels of CO₂ are unknown. We compared two indigenous *Quercus* species, *Q. ilex* and *Q. pubescens*, growing in a natural CO₂ spring located in central Italy and at a nearby control site. In May, 1995 photosynthetic rate at least doubled when measured with supplemental CO₂ in both species and sites. Dark respiration was much higher at the CO₂ spring site in both species. Foliar sugar and starch concentrations in *Q. ilex* exhibited significant site and diurnal differences (May and September). In July, 1995 there was little difference in the water potential values of the measured trees at the different sites over the diurnal period. Photosynthetic rate was higher for both species in the CO₂ spring, particularly in the early morning and late afternoon. Mid-day stomatal closure reduced photosynthesis to similar levels. In the morning leaf conductance and transpiration were generally lower in the CO₂ spring trees, contributing to higher instantaneous water use efficiency for both species. Isoprene emission rates were higher in *Q. pubescens* trees growing in the CO₂ spring. The maximum difference between control

and CO₂ spring trees occurred in late afternoon. In contrast, *Q. ilex* exhibited isoprene emission near background level. Foliage and branch carbon and nitrogen status showed increased concentrations of starch and tannins in *Q. ilex* and of soluble sugars in *Q. pubescens* in the elevated CO₂ environment, while nitrogen concentration decreased in both species. Wood gravity increased 6 and 3% in *Q. ilex* and *Q. pubescens*, respectively, growing in the CO₂ spring. *Q. ilex* exhibited afternoon recovery of water potential compared to *Q. pubescens* which had better night-time recovery. *Q. ilex* and *Q. pubescens* exposed to elevated CO₂ for prolonged periods exhibit different mechanisms for dealing with additional reduced carbon and do maintain an altered carbon physiology, even in midst of the region's characteristic summer drought. Tognetti, R., A. Longobucco, F. Miglietta, and A. Raschi. 1998. Transpiration and stomatal behaviour of *Quercus ilex* plants during the summer in a Mediterranean carbon dioxide spring. *Plant, Cell and Environment* 21(6):613-622.

Variations in the water relations and stomatal response of *Quercus ilex* were analysed under field conditions by comparing trees at two locations in a Mediterranean environment during two consecutive summers (1993 and 1994). We used the heat-pulse velocity technique to estimate transpirational water use of trees during a 5 month period from June to November 1994. At the end of sap flow measurements, the trees were harvested, and the foliage and sapwood area measured. A distinct environmental gradient exists between the two sites with higher atmospheric CO₂ concentrations in the proximity of a natural CO₂ spring. Trees at the spring site have been growing for generations in elevated atmospheric CO₂ concentrations. At both sites, maximum leaf conductance was related to predawn shoot water potential. The effects of water deficits on water relations and whole-plant transpiration during the summer drought were severe. Leaf conductance and water potential recovered after major rainfall in September to predrought values. Sap flow leaf conductance and predawn water potential decreased in parallel with increases in hydraulic resistance, reaching a minimum in mid-summer. These relationships are in agreement with the hypothesis of the stomatal control of transpiration to prevent desiccation damage but also to avoid 'runaway embolism'. Trees at the CO₂ spring underwent less reduction in hydraulic resistance for a given value of predawn water potential. The decrease in leaf conductance caused by elevated CO₂ was limited and tended to be less at high than at low atmospheric vapour pressure deficit. Mean land diurnal sap flux were consistently higher in the control site trees than in the CO₂ spring trees. The degree of reduction in water use between the two sites varied among the summer periods. The control site trees had consistently higher sap flow at corresponding values of either sapwood cross-sectional area or foliage area. Larger trees displayed smaller differences than smaller trees, between the control and the CO₂ spring trees. A strong association between foliage area and sapwood cross-sectional area was found in both the control and the CO₂ spring trees, the latter supporting a smaller foliage area at the corresponding sapwood stem cross-sectional area. The specific leaf area (SLA) of the foliage was not influenced by site. The results are discussed in terms of the effects of elevated CO₂ on plant water use at the organ and whole-tree scale.

Tognetti, R., A. Longobucco, F. Miglietta, and A. Raschi. 1999. Water relations, stomatal response and transpiration of *Quercus pubescens* trees during summer in a Mediterranean carbon dioxide spring. *Tree Physiology* 19(4-5):261-270.

Variations in water relations and stomatal response of *Quercus pubescens* Willd. were analyzed under Mediterranean field conditions during two consecutive summers (1993 and 1994) at two locations characterized by different atmospheric CO₂ concentrations because of the presence at one of them of a CO₂ spring. Trees at the CO₂ spring site have been growing for generations in elevated atmospheric CO₂ concentrations. The heat-pulse velocity technique was used to estimate water use of trees during a 5-month period from June to November 1994. At the end of the sap flow measurements, the trees were harvested and foliage and sapwood area measured. At both sites, maximum leaf conductance was related to predawn shoot water potential. Effects of summer drought on plant water relations, including whole-plant transpiration, were severe, but leaf conductance and water potential recovered to predrought values after major rainfall in September. Leaf conductance, predawn water potential, and sometimes sap flow, decreased in parallel with increases in hydraulic resistance, reaching a minimum in midsummer. Hydraulic resistance was higher in trees at the control site than in trees at the CO₂ spring site. The effect of elevated CO₂ concentration on leaf conductance was less at high leaf-to-air water vapor pressure difference than at low leaf-to-air water vapor pressure difference. Mean and diurnal sap fluxes were consistently higher in trees at the control site than in trees at the CO₂ spring site. During the summer period, plant water use varied between the two sites. Trees at the control site had consistently higher sap flow at corresponding values of sapwood cross-sectional area than trees at the CO₂ spring site. Because trees at the CO₂ spring site supported a smaller foliage area for a corresponding sapwood cross-sectional area than trees at the control site, the overall mean sap flux/foliage area ratio did not differ between sites. The results are discussed in terms of effects of elevated CO₂ concentration on plant water use at the organ and whole-tree scale.

Tognetti, R., A. Longobucco, and A. Raschi. 1999. Seasonal embolism and xylem vulnerability in deciduous and evergreen Mediterranean trees influenced by proximity to a carbon dioxide spring. *Tree Physiology* 19(4-5):271-277.

We investigated how proximity to natural CO₂ springs affected the seasonal patterns of xylem embolism in *Quercus ilex* L., *Quercus pubescens* Willd., *Fraxinus ornus* L., *Populus tremula* L. and *Arbutus unedo* L., which differ in leaf phenology and wood anatomy. Xylem embolism was evaluated in both artificially dehydrated branches and in hydrated apical branches collected at monthly intervals during a 20-month sampling period. Initial specific hydraulic conductivity was also evaluated. We found species-dependent differences in xylem hydraulic properties in response to elevated CO₂ concentration. *Populus tremula* was the most embolized and *A. unedo* was the least embolized of the species examined. Effects of elevated CO₂ were significant in *Q. pubescens*, *P. tremula* and *A. unedo*, whereas the overall response to elevated CO₂ was less evident in *F. ornus* and *Q. ilex*. Specific hydraulic conductivity differed among species but not between sites, although the interaction between species and site was significant. Differences in xylem vulnerability between trees growing near to the CO₂ spring and those growing in control areas were small. Although differences in hydraulic properties in response to elevated CO₂ concentration were small, they may be of great importance in determining future community

composition in Mediterranean-type forest ecosystems. The possible causes and ecological significance of such differences are discussed in relation to elevated CO₂ concentration and other environmental conditions.

Tognetti, R., A. Longobucco, A. Raschi, F. Miglietta, and I. Fumagalli. 1999. Responses of two *Populus* clones to elevated atmospheric CO₂ concentration in the field. *Annals of Forest Science* 56(6):493-500.

Two poplar clones, hybrid *Populus deltoides* Bartr. Ex Marsh x *Populus nigra* L. (*Populus x euramericana*), clone I-214, and *Populus deltoides*, clone Lux, were grown from clonal hardwood cuttings for one growing season in either ambient (360 $\mu\text{mol mol}^{-1}$) or elevated (560 $\mu\text{mol mol}^{-1}$) [CO₂] in FACE-system rings at Rapolano Terme (Siena, Italy). Both clones I-214 and Lux exhibited a higher above-ground biomass, photosynthesis at light saturation and instantaneous transpiration efficiency (ITE) in CO₂-enriched air. The elevated [CO₂]-induced responses of clone I-214 included increased investment in branch and leaf biomass, and enhanced stem volume. The elevated [CO₂]-induced responses of clone Lux included an increase in the number of branches and leaf area (which might result in a higher leaf area index, LAI). Photosynthetic acclimation under elevated [CO₂] was found only during the early morning and only in clone I-214. Stomatal conductance and transpiration (on a leaf area basis) decreased under elevated [CO₂] particularly in clone Lux and at the end of the experiment. The effects of elevated [CO₂] on leaf osmotic potential were limited, at least in conditions of non-limiting water availability. Clonal differences in response to elevated [CO₂] should be taken in account when planning future poplar plantations in the forecast warmer and drier Mediterranean sites. ((C) Inra/Elsevier, Paris.).

Tomlinson, P.T., and P.D. Anderson. 1998. Ontogeny affects response of northern red oak seedlings to elevated CO₂ and water stress - II. Recent photosynthate distribution and growth. *New Phytologist* 140(3):493-504.

Northern red oak in the western Lake States area of the USA exists on the most xeric edge of its distribution range. Future climate-change scenarios for this area predict decreased water availability along with increased atmospheric CO₂. We examined recent photosynthate distribution and growth in seedlings as a function of CO₂ mole fraction (400, 530 and 700 $\mu\text{mol mol}^{-1}$ CO₂), water regime (well watered and water-stressed), and ontogenic stage. Water stress effects on growth were largely offset by elevated CO₂. Water stress increased root mass ratio without concurrently increasing allocation of recent photosynthate to the roots. However, apparent sink strength of water-stressed seedlings at the completion of the third growth stage tended to be greater than that

of well watered seedlings, as shown by continued high export, which may contribute carbon reserves to support preferential root growth under water- stressed conditions. Elevated CO₂ decreased apparent shoot sink strength associated with the rapid expansion of the third flush. Carbon resources for the observed enhanced growth under elevated CO₂ could be provided by enhanced photosynthetic rate over an increased leaf area (Anderson & Tomlinson, 1998, this volume). Increased sink strength of LG seedlings under water- stressed conditions, together with decreased apparent shoot sink strength associated with growth in elevated CO₂ provide mechanisms for offsetting water stress effects by growth in elevated CO₂. Careful control of ontogeny was necessary to discern these changes and provides further evidence of the need for such careful control in mechanistic studies.

Topp, C.F.E., and C.J. Doyle. 1996. Simulating the impact of global warming on milk and forage production in Scotland .2. The effects on milk yields and grazing management of dairy herds. *Agricultural Systems* 52(2-3):243-270.

The potential impact of global warming and the enhanced atmospheric CO₂ concentration on grassland management on dairy farms within the UK requires assessment. This has led to the development of a mathematical model of the grazing dairy cow. The model, that embraces grass and grass-white clover swards, has been used to assess the effects that the projected increases in temperature and rainfall under global warming and the increased levels of CO₂ might have on milk production and on silage conservation for a typical dairy farm. The results suggest that the impact on milk production for grass-based systems will vary depending on the locality. On the other hand, for herds grazed on grass-white clover swards milk output might increase regardless of site, when the concentration of CO₂ is enhanced. As regards silage production from grass-white clover swards, under global warming and at current levels of CO₂ there is an apparent tendency to increase the percentage of total silage yield obtained from the first cut, although this does not occur for grass swards. At the same time, there are also indications that global warming will increase the percentage of clover in the herbage cut for conservation. Copyright (C) 1996 Published by Elsevier Science Ltd

Torbert, H.A., S.A. Prior, and H.H. Rogers. 1995. Elevated atmospheric carbon-dioxide effects on cotton plant residue decomposition. *Soil Science Society of America Journal* 59(5):1321-1328.

Assessing the impact of elevated atmospheric CO₂ concentration on the global environment is hampered due to a lack of understanding of global C cycling. Carbon fixed within plant biomass ultimately enters the soil via plant residues, but the effects of elevated-CO₂-grown plant material on decomposition rates and long-term soil C storage are unknown. The objective of this study was to determine the decomposition rate of plant residues grown under an elevated CO₂ environment as affected by soil type. Cotton (*Gossypium hirsutum* L. 'Delta Pine 77') samples were collected from a free-air CO₂ enrichment (550 μ L L⁻¹) experiment. The plant residues were incubated under ambient CO₂ conditions to determine decomposition rates of leaves, stems, and roots and potential N and P mineralization- immobilization in three soil series: a Blanton

loamy sand (loamy siliceous, thermic Grossarenic Paleudult), a Decatur silt loam (clayey, kaolinitic, thermic Rhodic Paleudult), and a Houston clay loam (very fine, montmorillonitic Typic Chromudert). No significant difference was observed between plant residue grown under CO₂ enrichment vs. ambient CO₂ conditions for soil respiration or P mineralization- immobilization. Significantly greater net N immobilization was observed during the incubation in all soil types for plant residue grown at elevated CO₂. These results indicate that while decomposition of plant residue may not be reduced by CO₂ enrichment, N dynamics may be markedly changed.

Torbert, H.A., S.A. Prior, H.H. Rogers, and G.B. Runion. 1998. Crop residue decomposition as affected by growth under elevated atmospheric CO₂. *Soil Science* 163(5):412-419.

Increasing atmospheric CO₂ level has led to concerns about process changes in the biosphere. Elevated atmospheric CO₂ concentration has been shown to increase plant biomass, resulting in greater amounts of residue returned to soil. However, the effects on long-term storage of C in soil are highly debated. Changes in both quantity and quality of plant residue, as well as residue management, may alter soil C and N dynamics that will, in turn, affect the ability of soil to store C. Plant residues were collected from an experiment using open top chambers to increase CO₂ levels under field conditions. A soil incubation study was conducted with a Blanton loamy sand (loamy siliceous, thermic, Grossarenic Paleudults) to examine the effect of residue additions to two crop species (soybean, *Glycine max* (L.) Merr. and grain sorghum, *Sorghum bicolor* (L.) Moench), grown at two CO₂ concentrations (ambient and twice ambient), and two incorporation treatments (incorporated or surface placement) on potential C and N mineralization. The difference in biomass inputs between plants grown in ambient and elevated atmospheric CO₂ was also considered. Simulated residue incorporation reduced inorganic N concentration but had no effect on C mineralization. Both inorganic N content and C mineralization were higher with soybean than with grain sorghum. Although changes to both plant residue quality and quantity caused by elevated CO₂ concentration affected C cycling in soil, residue quality may be more important for determining C storage. Nitrogen cycling in soil may be a controlling factor for C storage in terrestrial ecosystems.

Torbert, H.A., S.A. Prior, H.H. Rogers, W.H. Schlesinger, G.L. Mullins, and G.B. Runion. 1996. Elevated atmospheric carbon dioxide in agroecosystems affects groundwater quality. *Journal of Environmental Quality* 25(4):720-726.

Increasing atmospheric carbon dioxide (CO₂) concentration has led to concerns about global changes to the environment. One area of global change that has not been addressed is the effect of elevated atmospheric CO₂ on ground water quality below agroecosystems. Elevated CO₂ concentration alterations of plant growth and C/N ratios may modify C and N cycling in soil and affect nitrate (NO₃⁻) leaching to groundwater. This study was conducted to examine the effects of a legume soybean [*Glycine max* (L.) Merr.] and a nonlegume grain sorghum [*Sorghum bicolor* (L.) Moench] CO₂-enriched agroecosystems on NO₃⁻ movement below the root zone in a Blanton loamy sand (loamy siliceous, thermic, Grossarenic Paleudults). The study was a split-plot design replicated three times with plant species (soybean and grain sorghum) as the main plots and CO₂ concentration (approximate to 360 and similar to 720 μ L L⁻¹ CO₂) as subplots using open-top held chambers. Fertilizer

application was made with N-15-depleted NH_4NO_3 to act as a fertilizer tracer. Soil solution samples were collected weekly at 90-cm depth for a 2-yr period and monitored for $\text{NO}_3\text{-N}$ concentrations. Isotope analysis of soil solution indicated that the decomposition of organic matter was the primary source of $\text{NO}_3\text{-N}$ in soil solution below the root zone through most of the monitoring period. Significant differences were observed for $\text{NO}_3\text{-N}$ concentrations between soybean and grain sorghum, with soybean having the higher $\text{NO}_3\text{-N}$ concentrations. Elevated CO_2 increased total dry weight, total N content, and C/N ratio of residue returned to soil in both years. Elevated CO_2 significantly decreased $\text{NO}_3\text{-N}$ concentrations below the root zone in both soybean and grain sorghum. The results of this study indicate that retention of N in organic pools because of elevated atmospheric CO_2 could reduce the nitrate concentration in groundwater beneath agroecosystems as indicated by $\text{NO}_3\text{-N}$ movement.

Torbert, H.A., H.H. Rogers, S.A. Prior, W.H. Schlesinger, and G.B. Runion. 1997. Effects of elevated atmospheric CO_2 in agro-ecosystems on soil carbon storage. *Global Change Biology* 3(6):513-521.

Increasing global atmospheric CO_2 concentration has led to concerns regarding its potential effects on the terrestrial environment. Attempts to balance the atmospheric carbon (C) budget have met with a large shortfall in C accounting (approximate to 1.4×10^{15} g C y^{-1}) and this has led to the hypothesis that C is being stored in the soil of terrestrial ecosystems. This study examined the effects of CO_2 enrichment on soil C storage in C3 soybean (*Glycine max* L.) Merr. and C4 grain sorghum (*Sorghum bicolor* L.) Moench. agroecosystems established on a Blanton loamy sand (loamy siliceous, thermic, Grossarenic Paleudults). The study was a split-plot design replicated three times with two crop species (soybean and grain sorghum) as the main plots and two CO_2 concentration (ambient and twice ambient) as subplots using open top field chambers. Carbon isotopic techniques using $\delta^{13}\text{C}$ were used to track the input of new C into the soil system. At the end of two years, shifts in $\delta^{13}\text{C}$ content of soil organic matter carbon were observed to a depth of 30 cm. Calculated new C in soil organic matter with grain sorghum was greater for elevated CO_2 vs. ambient CO_2 (162 and 29 g m^{-2} , respectively), but with soybean the new C in soil organic matter was less for elevated CO_2 vs. ambient CO_2 (120 and 291 g m^{-2} , respectively). A significant increase in mineral associated organic C was observed in 1993 which may result in increased soil C storage over the long-term, however, little change in total soil organic C was observed under either plant species. These data indicate that elevated atmospheric CO_2 resulted in changes in soil C dynamics in agro-ecosystems that are crop species dependent.

Townend, J. 1993. Effects of elevated carbon-dioxide and drought on the growth and physiology of clonal Sitka spruce plants (*Picea sitchensis* (Bong.) Carr.). *Tree Physiology* 13(4):389-399.

Two-year-old Sitka spruce (*Picea sitchensis* (Bong.) Carr.) plants from four clones were grown in naturally lit growth chambers for 6 months at either ambient (350 ppm) or ambient + 250 ppm (600 ppm) CO_2 concentration. Plants were grown in large boxes filled with peat, in a system that allowed the roots of individual plants to be harvested easily at the end of the growing season. Half of the boxes were kept well watered and half were allowed to dry out slowly over the summer. Plants growing in elevated CO_2 showed a 6.9% increase in mean relative growth rate compared to controls in the drought treatment and a 9.8% increase compared to controls in the well-watered treatment, though there was considerable variation in response among the different clones and water treatments. Rates of net CO_2 assimilation were higher and stomatal conductances were lower in plants grown in elevated CO_2 than in ambient CO_2 in both the well-watered and drought treatments. Both of these factors contributed to the doubling of instantaneous water use efficiency. The partitioning of biomass to roots was unaffected by elevated CO_2 , but the ratio of needle mass/stems + branches mass decreased. Together with reduced stomatal conductance, this probably caused the observed increases in xylem pressure potentials with elevated CO_2 .

2396

Townend, J. 1995. Effects of elevated CO_2 , water and nutrients on *Picea sitchensis* (Bong.) Carr. seedlings. *New Phytologist* 130(2):193-206.

Sitka spruce (*Picea sitchensis* (Bong.) Carr.) seedlings were grown from seed for one year in naturally lit growth chambers with either ambient or ambient + 250 ppm concentrations of CO_2 . In the following year the plants were grown in the same CO_2 treatments for the whole growing season at two concentrations of nutrients and were either well-watered or subjected to a long-term, gradually increasing drought. Elevated CO_2 increased significantly growth in all treatments except the well-watered, unfertilized treatment. The relative increases in end-of-year biomass in the elevated CO_2 treatment compared with the ambient treatment were: well-watered, fertilized + 52%, well-watered, unfertilized + 19%, droughted, fertilized + 44%, and droughted, unfertilized + 49%. Growth analysis revealed that treatment effects on both unit leaf rates and leaf area duration were important in determining the final masses of the plants. Plants growing in elevated CO_2 had increased relative growth rates in the first half of the growing season but only slightly increased or even slightly decreased relative growth rates in the later part of the growing season in all water x nutrient treatments. Overall there was a significant CO_2 x water x nutrient interaction on end-of-year biomass. A combination of small nutrient concentration and adequate water supply led to the smallest growth response to elevated CO_2 .

Townend, J., and A.L. Dickinson. 1995. A comparison of rooting environments in containers of different sizes. *Plant and Soil* 175(1):139-146.

Experiments on plants are often carried out in growth chambers or greenhouses which necessitate the use of an artificial rooting environment, though this is seldom characterized in detail. Measurements were made to compare the rooting environment in large boxes (0.25 m^3) with that in small pots (0.19, 0.55 and 1.90 dm^3) in naturally lit chambers. Diurnal temperature fluctuations of 14.6, 11.6 and 7.7 degrees C occurred in the pots compared with only 1.9 degrees

C in the boxes. Soil drying to a matric potential of -50 kPa was approximately 25 times faster in the pots. The mean heights of 2 year old Sitka spruce (*Picea sitchensis* (Bong.) Carr.) seedlings grown throughout their second growing season in the three sizes of pots were 38, 62 and 92% of the mean height of those grown in the boxes. Soil solution nutrient concentrations in the boxes were considerably increased by soil drying, an aspect which seems to have received little attention in experiments involving artificially imposed drought. An alternative system of constraining the roots of individual plants within nylon fabric bags, embedded in larger volumes of soil, to facilitate harvesting of complete root systems is described. The importance of the rooting environment in determining the outcome of physiological experiments is also briefly discussed.

Traw, M.B., R.L. Lindroth, and F.A. Bazzaz. 1996. Decline in gypsy moth (*Lymantria dispar*) performance in an elevated CO₂ atmosphere depends upon host plant species. *Oecologia* 108(1):113-120.

Plant species differ broadly in their responses to an elevated CO₂ atmosphere, particularly in the extent of nitrogen dilution of leaf tissue. Insect herbivores are often limited by the availability of nutrients, such as nitrogen, in their host plant tissue and may therefore respond differentially on different plant species grown in CO₂-enriched environments. We reared gypsy moth larvae (*Lymantria dispar*) in situ on seedlings of yellow birch (*Betula allegheniensis*) and gray birch (*B. populifolia*) grown in an ambient (350 ppm) or elevated (700 ppm) CO₂ atmosphere to test whether larval responses in the elevated CO₂ atmosphere were species-dependent. We report that female gypsy moths (*Lymantria dispar*) reared on gray birch (*Betula populifolia*) achieved similar pupal masses on plants grown at an ambient or an elevated CO₂ concentration. However, on yellow birch (*B. allegheniensis*), female pupal mass was 38% smaller on plants in the elevated-CO₂ atmosphere. Larval mortality was significantly higher on yellow birch than gray birch, but did not differ between the CO₂ treatments. Relative growth rate declined more in the elevated CO₂ atmosphere for larvae on yellow birch than for those on gray birch. In preference tests, larvae preferred ambient over elevated CO₂-grown leaves of yellow birch, but showed no preference between gray birch leaves from the two CO₂ atmospheres. This differential response of gypsy moths to their host species corresponded to a greater decline in leaf nutritional quality in the elevated CO₂ atmosphere in yellow birch than in gray birch. Leaf nitrogen content of yellow birch dropped from 2.68% to 1.99% while that of gray birch leaves only declined from 3.23% to 2.63%. Meanwhile, leaf condensed tannin concentration increased from 8.92% to 11.45% in yellow birch leaves while gray birch leaves only increased from 10.72% to 12.34%. Thus the declines in larval performance in a future atmosphere may be substantial and host-species-specific.

Tremblin, G., P. Jolivet, and A. Coudret. 1993. Light quality effects on subsequent dark 14C-fixation in *Fucus serratus*. *Hydrobiologia* 261:471-475.

The intensity and fate of (CO₂)-C-14-fixation in the dark are studied on *Fucus serratus* apices previously maintained under low illumination conditions using white, blue, red or yellow isoquantic lights. In the case

of a 180 s pulse, light quality affected dark carbon-fixation, with a higher level of incorporation into ethanol-soluble organic matter in the case of yellow light cultivated apices. After a 30 s pulse C-14 was mainly fixed into glycerate and aspartate-malate pools whatever the pre-treatment light conditions, with a higher level into glycerate when apices were pre-illuminated with blue or yellow light. After a 180 s pulse, C-14 was mainly transferred into amino acids (glutamate and alanine) at the expense of aspartate and malate in red and yellow pre-illumination conditions, as found in the white light reference experiment, and only at the expense of glycerate in blue light pre-illumination conditions. The metabolic pathway of glycerate formation, principally enhanced by blue light preillumination, remains unexplained under these non-photosynthetic conditions. Results are discussed with reference to CO₂-fixation via phosphoenolpyruvate carboxykinase and light quality effects on its in vitro activity.

Tremmel, D.C., and D.T. Patterson. 1993. Responses of soybean and 5 weeds to CO₂ enrichment under 2 temperature regimes. *Canadian Journal of Plant Science* 73(4):1249-1260.

Rising atmospheric CO₂ levels could affect plant growth both directly, through effects on physiology, and indirectly, through the effects of possible CO₂-induced temperature increases. In this study we examined the interacting effects of CO₂ enrichment and temperature on the growth and allocation of soybean and five weeds. Individual plants of soybean [*Glycine max* (L.) Merr. 'Braxton'], johnsongrass [*Sorghum halepense* (L.) Pers.], quackgrass [*Elytrigia repens* (L.) Nevski], redroot pigweed [*Amaranthus retroflexus* L.], sicklepod (*Cassia obtusifolia* L.), and velvetleaf (*Abutilon theophrasti* Medic.) were grown in growth chambers in all combinations of two temperatures (avg. day/night of 26/19-degrees-C and 30/23-degrees-C) and two CO₂ concentrations (350 and 700 ppm) for 35 d. Leaf area and plant biomass were greater at higher temperatures, regardless of CO₂ level, in all species except quackgrass. Quackgrass (C3) produced its greatest leaf area and biomass at elevated CO₂, whereas johnsongrass (C4) showed little response. Redroot pigweed (C4) and the C3 dicotyledonous species (soybean, sicklepod, velvetleaf) produced their greatest biomass at high CO₂, though effects on leaf area were less consistent or absent. In general, when significant CO₂ by temperature interactions were found, CO₂ responses were smallest at higher temperatures. These differential responses to elevated CO₂ concentrations may cause changes in the relative importance of competitive pressure from these weeds.

Tremmel, D.C., and D.T. Patterson. 1994. Effects of elevated CO₂ and temperature on development in soybean and 5 weeds. *Canadian Journal of Plant Science* 74(1):43-50.

Developmental rates of soybean [*Glycine max* (L.) Merr. 'Braxton'], johnsongrass [*Sorghum halepense* (L.) Pers.], quackgrass [*Elytrigia repens* (L.) Nevski], redroot pigweed [*Amaranthus retroflexus* L.], sicklepod (*Cassia obtusifolia* L.), and velvetleaf (*Abutilon theophrasti* Medic.) were compared among plants grown in all combinations of two temperature levels (avg. day/night of 26/19 degrees C and 30/23 degrees C) and two CO₂ levels (350 and 700 ppm). Neither temperature nor CO₂ affected johnsongrass tillering rate, but plants began tillering earlier at higher temperatures. Adverse effects of higher temperatures on quackgrass development were alleviated by elevated

CO₂ conditions. Plastochron rate was higher at higher temperatures in all dicot species (soybean, redroot pigweed, sicklepod, and velvetleaf), and was higher at elevated CO₂ in all dicots except velvetleaf. Calculating plastochron rates on a degree day basis removed differences between temperature treatments, but did not affect responses to CO₂. Responses of dicot branch and branch leaf production to treatments varied among species. Branch production per day increased with higher temperatures in redroot pigweed, decreased with higher temperatures in sicklepod, and was unaffected by temperature in soybean. The relationship between main axis and branch developmental rates was altered by temperature in soybean, and by both temperature and CO₂ in sicklepod, but was unaffected by either treatment in redroot pigweed. These results indicate that developmental responses to temperature and CO₂ depend on both the species and the aspect of development being considered.

Trenberth, K.E. 1999. Conceptual framework for changes of extremes of the hydrological cycle with climate change. *Climatic Change* 42(1):327-339.

A physically based conceptual framework is put forward that explains why an increase in heavy precipitation events should be a primary manifestation of the climate change that accompanies increases in greenhouse gases in the atmosphere. Increased concentrations of greenhouse gases in the atmosphere increase downwelling infrared radiation, and this global heating at the surface not only acts to increase temperatures but also increases evaporation which enhances the atmospheric moisture content. Consequently all weather systems, ranging from individual clouds and thunderstorms to extratropical cyclones, which feed on the available moisture through storm-scale moisture convergence, are likely to produce correspondingly enhanced precipitation rates. Increases in heavy rainfall at the expense of more moderate rainfall are the consequence along with increased runoff and risk of flooding. However, because of constraints in the surface energy budget, there are also implications for the frequency and/or efficiency of precipitation. It follows that increased attention should be given to trends in atmospheric moisture content, and datasets on hourly precipitation rates and frequency need to be developed and analyzed as well as total accumulation.

Treonis, A.M., and J.F. Lussenhop. 1997. Rapid response of soil protozoa to elevated CO₂. *Biology and Fertility of Soils* 25(1):60-62.

Short-term changes in bacterial and protozoan populations from the soil of plants grown under elevated atmospheric CO₂ were quantified. We grew *Brassica nigra* at either ambient or twice-ambient CO₂ levels within open-top chambers in the field for 4 weeks. Plant biomass, above- and belowground, was unaffected by elevated CO₂. Direct count bacterial density was unchanged under elevated CO₂. Flagellate density tended to increase, whereas amoebal density significantly declined under elevated CO₂. This change in protozoan community structure suggests trophic transfer of the elevated CO₂ fertilization effect through the soil food chain.

Tripp, K.E., W.K. Kroen, M.M. Peet, and D.H. Willits. 1992. Fewer whiteflies found on CO₂-enriched greenhouse tomatoes with high C:N ratios. *Hortscience* 27(10):1079-1080.

Eight tomato (*Lycopersicon esculentum*) cultivars were grown for 16 weeks in greenhouses enriched for an average of 8.1 hours daily to 1000 µl CO₂/liter of air or in greenhouses maintained at ambient CO₂. Carbon dioxide enrichment significantly decreased the mean number of greenhouse whiteflies [*Trialeurodes vaporariorum* (Westward), Homoptera: Aleyrodidae] as measured by counts from commercial yellow sticky traps. The number of whiteflies present was negatively correlated with both seasonal foliar C:N ratio and percent C but positively correlated with percent N in the foliage. Thus, CO₂ enrichment apparently alters plant composition in such a way as to reduce significantly the population growth of greenhouse whiteflies.

Tripp, K.E., M.M. Peet, D.M. Pharr, D.H. Willits, and P.V. Nelson. 1991. CO₂-enhanced yield and foliar deformation among tomato genotypes in elevated CO₂ environments. *Plant Physiology* 96(3):713-719.

Yield increases observed among eight genotypes of tomato (*Lycopersicon esculentum* Mill.) grown at ambient CO₂ (about 350) or 1000 microliters per liter CO₂ were not due to carbon exchange rate increases. Yield varied among genotypes while carbon exchange rate did not. Yield increases were due to a change in partitioning from root to fruit. Tomatoes grown with CO₂ enrichment exhibited nonepinastic foliar deformation similar to nutrient deficiency symptoms. Foliar deformation varied among genotypes, increased throughout the season, and became most severe at elevated CO₂. Foliar deformation was positively related to fruit yield. Foliage from the lower canopy was sampled throughout the growing season and analysed for starch, K, P, Ca, Mg, Fe, and Mn concentrations. Foliar K and Mn concentrations were the only elements correlated with deformation severity. Foliar K decreased while deformation increased. In another study, foliage of half the plants of one genotype received foliar applications of 7 millimolar KH₂PO₄. Untreated foliage showed significantly greater deformation than treated foliage. Reduced foliar K concentration may cause CO₂-enhanced foliar deformation. Reduced K may occur following decreased nutrient uptake resulting from reduced root mass due to the change in partitioning from root to fruit.

Tripp, K.E., M.M. Peet, D.H. Willits, and D.M. Pharr. 1991. CO₂-enhanced foliar deformation of tomato-relationship to foliar starch concentration. *Journal of the American Society for Horticultural Science* 116(5):876-880.

Two cultivars of greenhouse tomato (*Lycopersicon esculentum* Mill.) were grown with ambient or 1000-µl CO₂/liter during Jan.-June 1987 and 1988. In both years, CO₂-enrichment increased foliar deformation and foliar starch, but during the season, foliar starch levels decreased while deformation increased. 'Laura' had more deformation, while 'Michigan-Ohio' had higher foliar starch concentration. During an entire season, there was no significant relationship between foliar starch concentration and deformation severity. Foliar C exchange rates in the

lower canopy were not affected by severity of deformation. Data from these experiments do not support the hypothesis that excess foliar starch is responsible for foliar deformation at elevated CO₂.

Tschaplinski, T.J., R.J. Norby, and S.D. Wullschlegel. 1993. Responses of loblolly-pine seedlings to elevated CO₂ and fluctuating water-supply. *Tree Physiology* 13(3):283-296.

Osmotic adjustment of loblolly pine (*Pinus taeda* L.) seedlings to fluctuating water supply in elevated CO₂ was investigated. Seedlings were grown in controlled-environment chambers in either 350 or 700 μ mol l⁻¹ CO₂ with weekly watering for four months, after which they were either watered weekly (well- watered treatment) or every two weeks (water-stress treatment) for 59 days. Osmotic adjustment was assessed by pressure-volume analysis of shoots and by analysis of soluble carbohydrates and free amino acids in roots during the last drying cycle. In well-watered seedlings, elevated CO₂ increased the concentration of soluble sugars in roots by 68%. Water stress reduced the soluble sugar concentration in roots of seedling growing in ambient CO₂ to 26% of that in roots of well-watered seedlings. Elevated CO₂ mitigated the water stress-induced decrease in the concentration of soluble sugars in roots. However, this was probably due, in part, to carbohydrate loading during the first four months when all seedlings were grown in the presence of a high water supply, rather than to osmotic adjustment to water stress. Water stress caused a doubling in the concentration of free primary amino acids in roots, whereas elevated CO₂ reduced primary amino acid and nitrogen concentrations to 32 and 74%, respectively, of those in roots of seedlings grown in ambient CO₂. There was no indication of large-scale osmotic adjustment to water stress or that elevated CO₂ enhanced osmotic adjustment in loblolly pine.

Tschaplinski, T.J., D.B. Stewart, P.J. Hanson, and R.J. Norby. 1995. Interactions between drought and elevated CO₂ on growth and gas-exchange of seedlings of 3 deciduous tree species. *New Phytologist* 129(1):63-71.

Interactions between elevated atmospheric CO₂ and drought on growth and gas exchange of American sycamore (*Platanus occidentalis* L.), sweetgum (*Liquidambar styraciflua* L.) and sugar maple (*Acer saccharum* Marsh.) were investigated using 1- yr-old seedlings, planted in 81 pots and grown in four open-top chambers, containing either ambient air or ambient air enriched with 300 μ mol mol⁻¹ CO₂. Two soil moisture regimes were included within each chamber: a 'well-watered' treatment with plants watered daily and a 'drought' treatment in which plants were subjected to a series of drought cycles. Duration and depth of the drought cycles were determined by soil matric potential. Mean soil water potential at rewetting for the water-stressed seedlings under ambient CO₂ for sugar maple, sweetgum and sycamore was -0.5, -0.7 and -1.8 MPa, respectively, compared with > -0.1 MPa for all well-watered plants. Elevated CO₂ increased relative growth rate of well-watered sugar maple by 181%, resulting in a 4.3-fold increase in total plant dry weight after 81 d, compared with 1.4 and 1.6-fold increases for sweetgum and sycamore, respectively, after 69 d. Although elevated CO₂ increased net CO₂ assimilation rate of sugar maple by 115 %, there was a 10-fold increase in leaf area which contributed to the growth response. Although drought did not eliminate a growth response of sugar maple to elevated CO₂, it greatly reduced the elevated CO₂- induced enhancement of relative growth rate. In contrast, relative growth rates of sweetgum and sycamore were not significantly increased by elevated CO₂. Drought, under elevated CO₂, reduced leaf area of all three species

to a greater extent than it reduced net CO₂ assimilation rate. The response ranged from no effect in sugar maple to a 40 % reduction in sycamore, with sweetgum exhibiting an intermediate response. Results indicate that drought may alter the growth response, gas exchange and water relations of tree species growing in an elevated CO₂ atmosphere. Under high nutrient and water availability, sugar maple may benefit the most (of the three species studied) from a CO₂-enriched atmosphere, but productivity gains will be limited if frequent drought is prevalent.

Tschaplinski, T.J., D.B. Stewart, and R.J. Norby. 1995. Interactions between drought and elevated CO₂ on osmotic adjustment and solute concentrations of tree seedlings. *New Phytologist* 131(2):169-177.

Although drought tolerance of tree species is a critical determinant of forest composition, how elevated CO₂ affects drought tolerance is uncertain. Interactions between elevated CO₂ and drought on osmotic potential and osmotic adjustment of American sycamore (*Platanus occidentalis* L.), sweetgum (*Liquidambar styraciflua* L.), and sugar maple (*Acer saccharum* Marsh.) were investigated using 1-yr-old seedlings, planted in 81 pots and grown in four open-top chambers, containing either ambient air or ambient air enriched with 300 μ mol mol⁻¹ CO₂. A well-watered treatment with plants watered daily and a droughted treatment in which plants were subjected to a series of drought cycles were included within each chamber. Sugar maple and sweetgum seedlings completed a total of seven drying cycles, whereas sycamore seedlings, because of their greater leaf area and plant size, completed 11 cycles. The mean soil water potential at re-watering for droughted seedlings in ambient CO₂ was -0.5, -0.7, and -1.8 MPa for sugar maple, sweetgum and sycamore, respectively, compared with -0.2, -0.7, and -1.2 MPa, respectively, under elevated CO₂. By contrast, all well-watered plants were maintained at soil water potential >-0.1 MPa. Drought under ambient CO₂ reduced osmotic potential at saturation for leaves of sycamore and sweetgum by 0.30 MPa and 0.61 MPa, respectively, but leaves of sugar maple did not display osmotic adjustment to drought. Elevated CO₂ increased osmotic potential at turgor loss for leaves of sugar maple by 0.33 MPa under well-watered conditions, and 0.48 MPa under drought. This response was not evident in the other species and might be related to the rapid growth of sugar maple causing a depletion of solutes. Whereas drought reduced the total solute concentration in roots of sugar maple, primarily the result of a reduction in K, elevated CO₂ did not alter the concentration of total solutes in roots of any of the three species. Elevated CO₂ has differing effects on drought tolerance among tree species, and thus might alter the competitive relations between species.

Tsygankov, A.A., L.T. Serebryakova, K.K. Rao, and D.O. Hall. 1998. Acetylene reduction and hydrogen photoproduction by wild-type and mutant strains of *Anabaena* at different CO₂ and O₂ concentrations. *Fems Microbiology Letters* 167(1):13-17.

Hydrogen photoproduction by growing cultures of *Anabaena variabilis* and *A. azollae* did not occur under air+CO₂ or argon+CO₂ atmospheres at saturating light but did take place under argon alone. It was shown that CO₂ inhibited photoproduction of H₂ as a result of the

photosynthetic production of O₂ whereas photoreduction of C₂H₂ by these cyanobacteria was not inhibited by O₂ concentrations up to 20% in the assay gas phase. In contrast to the wild type of *A. variabilis* and of *A. azollae*, H₂ photoproduction by the hydrogenase-impaired mutant *A. variabilis* PK84 showed only a slight dependence on O₂ concentration. Thus, in the wild-type *Anabaena* the decrease in the observed rate of H₂ evolution at elevated O₂ concentrations could be the result of an increase in hydrogenase-mediated uptake of H₂ via an oxyhydrogen reaction. Tuba, Z., Z. Csintalan, K. Szente, Z. Nagy, and J. Grace. 1998. Carbon gains by desiccation-tolerant plants at elevated CO₂. *Functional Ecology* 12(1):39-44.

1. There have been no reports of the long-term responses of the desiccation-tolerant (DT) plants to elevated CO₂. Xerophyta scabrada is a DT woody shrub, which loses chlorophylls and thylakoids during desiccation: a so-called poikilochlorophyllous desiccation-tolerant species (PDT). When the leaves of *X. scabrada* are allowed to desiccate, the species shows many of the normal features of (P)DT plants. 2. However, the duration of: photosynthesis in *X. scabrada* is prolonged by 300% when the measurements are: made at 700 as opposed to 350 p.p.m. CO₂. The implication is that the carboxylating enzymes must still have been active at this time to enable appreciable photosynthetic activity. This response could have far-reaching implications for the success of such species in a future climate. 3. Lichens and mosses, representing the homoiochlorophyllous DTs (HDT), retain their chlorophyll content and photosynthetic apparatus during desiccation. We show the desiccation responses of two common HDT species (*Cladonia convoluta* and *Tortula ruralis*) to elevated CO₂ for comparison. Both HDT species showed increased net CO₂ uptake in the material grown at high CO₂ by more than 30% in moss and by more than 50% in lichen. It is concluded that desiccation-tolerant plants will be among the main beneficiaries of a high CO₂ future.

This article summarises present knowledge of the ecophysiological responses to elevated atmospheric CO₂ of desiccation tolerant (DT) plants. It deals primarily with lichens and bryophytes, as the most prominent groups of DT photosynthetic organisms, but includes some

comment on algae and vascular DT plants. Results of research on DT plants are compared with those on desiccation sensitive vascular Cg plants, the most widely investigated group in the field of global change. Both DT and non-DT plants show an immediate positive response of photosynthesis to elevated CO₂, but in both groups the longer term effect is generally reduced (or even reversed) by down-regulation or feedback inhibition of photosynthesis, or other limitations on production and growth. In bryophytes and lichens, enhanced short-term photosynthesis may or may not be reflected in increased production; bryophytes have limited source-sink differentiation, and lichens invest excess photosynthate in secondary metabolites. DT plants may gain some advantage from elevated CO₂ at both low and excessive water contents. Neither theoretical considerations nor experimental results suggest that elevated atmospheric CO₂ will lead to any substantial shift in the balance of advantage between DT and non-DT plants.

Tuba, Z., K. Szente, and J. Koch. 1994. Response of photosynthesis, stomatal conductance, water-use efficiency and production to long-term elevated CO₂ in winter-wheat. *Journal of Plant Physiology* 144(6):661-668.

Responses of photosynthesis, stomatal conductance, water use efficiency (at the beginning of flowering) and production allocation (at full ear/grain ripening) to long-term elevated CO₂ were assessed in winter wheat (*Triticum aestivum* L. cv. MV16). Plants were grown in open top chambers under a temperate-continental climate from germination at ambient (350 $\mu\text{mol mol}^{-1}$) and elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. High CO₂ plants displayed a decreased initial slope of the A/C_i response curve, with the assimilation rate (A) continuing to increase above 400 $\mu\text{mol mol}^{-1}$ internal CO₂ concentration (C_i). A in the ambient plants showed P regeneration limitation while RuBP regeneration appeared to be limiting A in the high CO₂ treatment. Variable fluorescence ratios (R_{fd} 690) were lower in the high CO₂ plants indicating a lower potential photochemical activity. The increase in the values for the chlorophyll fluorescence ratio F₆₉₀/F₇₃₅ in the high CO₂ plants was in agreement with the lower chlorophyll a+b concentrations. The high CO₂ plants had higher concentrations of starch in their leaves and roots than the ambient plants. Stomatal conductance (g(s)) was lower in the high CO₂ plants at every CO₂ concentration (C_a) and C_i and the C_i-dependent g(s) response had a large influence on the A/g(s) function. The higher water use efficiency (WUE) values (at C_a's > 350 $\mu\text{mol mol}^{-1}$) in the high CO₂ wheat plants were the result of a larger decrease in transpiration rate (E) in the high CO₂ plants than in the ambient plants, and of a simultaneous larger increase in A in the range of C_a above 350 $\mu\text{mol mol}^{-1}$ COP. The integrated and combined effect of the photosynthetic and stomatal acclimation to elevated CO₂ produced a higher C_i-assimilation in high CO₂ plants at elevated CO₂ than in the ambient plants, however, this was not followed by an acclimation in C_i-allocation. These were reflected in a slightly increased (6.7%) overall dry matter production and lower reproductive allocation (RA).

Tuba, Z., K. Szente, Z. Nagy, Z. Csintalan, and J. Koch. 1996. Responses of CO₂ assimilation, transpiration and water use efficiency to long-term elevated CO₂ in perennial C-3 xeric loess steppe species.

CO₂ assimilation (A), transpiration (E), water use efficiency (WUE), leaf-nitrogen and carbohydrate responses to 11 months elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ exposure in four perennial C-3 species (*Festuca rupicola*, *Dactylis glomerata*, *Filipendula vulgaris*, *Salvia nemorosa*) from a xeric temperate loess steppe are reported. The responses in the species varied greatly owing to their differing acclimation. The acclimation of photosynthesis was somewhat downward in *F. rupicola*, fully downward in *D. glomerata*, and upward in *S. nemorosa* and *F. vulgaris*. The reduction in the initial slope of the A/c(i) response curve in *E. rupicola* and *D. glomerata* suggested a decrease in Rubisco capacity. Net CO₂ assimilation at 700 $\mu\text{mol mol}^{-1}$ CO₂ c(a) in the high CO₂ *F. rupicola* was higher than in those grown at present (350 $\mu\text{mol mol}^{-1}$) CO₂; there was no difference in *D. glomerata*. The initial slope of the A/c(i) curve indicated an increased Rubisco capacity in high CO₂ *F. vulgaris* and *S. nemorosa*. Their net CO₂ assimilation was higher in the plants grown in the high CO₂ treatment at c(i)'s over 200 $\mu\text{mol mol}^{-1}$ than that in the plants grown at present CO₂. The A/c(i) response curves, which were saturated in all species grown at present CO₂, did not reach saturation in the plants grown at elevated CO₂, reflecting that the Pi limitation of CO₂ assimilation was alleviated in the plants grown at high CO₂. Transpiration decreased with an increase in c(i) in both the present and elevated CO₂ *F. rupicola* and *D. glomerata*. In *F. vulgaris*, an increase in ci caused a reduction in transpiration in the plants grown at high CO₂ only. Transpiration rate in both the present and elevated CO₂ *S. nemorosa* was not affected by any change in c(i). It is suggested then that long-term exposure to high CO₂ causes a similar acclimation of stomatal regulation and transpiration to that of photosynthesis. High CO₂ caused a significant decrease in protein-nitrogen content only in *D. glomerata*. Starch increased in *F. rupicola* and *D. glomerata* and soluble sugar content was higher in all species grown at high CO₂ than at ambient. Instantaneous WUE significantly increased in all species grown at elevated CO₂.

Tubiello, F.N., G. Lin, J.W. Druitt, and B.D.V. Marino. 1999. Ecosystem-level evapotranspiration and water-use efficiency in the desert biome of Biosphere 2. *Ecological Engineering* 13(1-4):263-271.

We estimate whole-system water and carbon fluxes for the desert biome of Biosphere 2 under two different daily-mean CO₂ concentrations: 450 ppmv and 850 ppmv. The desert mesocosm occupies an area of approximately 1500 m², has a total atmospheric Volume of about 25000 m³ and contains a heterogeneous distribution of plants and soils. Atmospheric water content and CO₂ concentrations were measured continuously using a variety of sensors, including a Li-cor 6262 for CO₂ deployed within the experimental area. Daily carbon and water budgets were calculated in the desert biome, isolated from the rest of Biosphere 2 by deploying isolation curtains for 24-h periods. Data collected for six closure periods suggest that elevated CO₂ concentration increased whole-system carbon uptake, while evapotranspiration remained constant. As a result, whole-system water-use efficiency (WUE, defined as net ecosystem carbon uptake per unit water transpired) in the Biosphere 2 desert increased by more than 40%. Our measurements investigate soil-plant processes at a medium scale, ideally bridging the gap between traditional controlled-environment growth chambers and open-held studies. Tubiello, F.N., T. Mahato, T. Morton, J.W. Druitt, T. Volk, and B.D.V. Marino. 1999. Growing wheat in Biosphere 2 under elevated CO₂: Observations and modeling. *Ecological Engineering* 13(1-4):273-286.

Spring wheat (*Triticum aestivum* L., cv. Yecora Rojo) was grown in the intensive agricultural biome (IAB) of Biosphere 2 during the 1995-1996 winter/spring season. Environmental conditions were characterized by a day/night temperature regime of 27/17 degrees C, relative humidity (RH) levels around 45%, mean atmospheric CO₂ concentration of 450 ppmv, and natural light conditions with mean intensities about half of outside levels. Weekly samples of above-ground plant matter were collected throughout the growing season and phenological events recorded. A computer model, CERES-Wheat, previously tested under both field and controlled conditions, was used to simulate the observed crop growth and to help in data analysis. We found that CERES-Wheat simulated the data collected at Biosphere 2 to within 10% of observed, thus suggesting that wheat growth inside the IAB was comparable to that documented in other environments. The model predicts phenological stages and final dry matter (DM) production within 10% of the observed data. Measured DM production rates, normalized for light absorbed by the crop, suggested photosynthetic efficiencies intermediate between those observed under optimal field conditions and those recorded in NASA-Controlled Ecological Life-Support Systems (CELSS). We suggest that such a difference can be explained primarily in terms of low light levels inside the IAB, with additional effects due to elevated CO₂ concentrations and diffuse light fractions. Tubiello, F.N., C. Rosenzweig, B.A. Kimball, P.J. Pinter, G.W. Wall, D.J. Hunsaker, R.L. LaMorte, and R.L. Garcia. 1999. Testing CERES-wheat with free-air carbon dioxide enrichment (FACE) experiment data: CO₂ and water interactions. *Agronomy Journal* 91(2):247-255.

Dynamic crop-growth models are used to project the effects of rising atmospheric CO₂ concentration and associated climate change on crop yields. Such model predictions are largely untested in the field, for lack of experimental data. We tested the CERES-Wheat model, modified to include leaf-level photosynthesis response to elevated CO₂, using field data from 2 yr of Free-Air Carbon Dioxide Enrichment (FACE) experiments with spring wheat (*Triticum aestivum* L. cv. Yecora Rojo) in Maricopa, AZ. Two irrigation treatments (well-watered, WW; water-deficit stressed, WS) and two atmospheric CO₂ concentrations (ambient, 350 $\mu\text{mol mol}^{-1}$; elevated, 550 $\mu\text{mol mol}^{-1}$) were simulated. The model was evaluated using measurements of crop phenology, aboveground dry matter (DM) production, grain yield, and evapotranspiration (ET). Model calculations of crop phenology were within 2 to 3 d of observed values under WW, ambient CO₂ conditions in both years. The model did not simulate the accelerated crop phenology (5-8 d at physiological maturity) observed in the WW and elevated CO₂ treatments, indicating the need to include effects of increased stomatal resistance on canopy temperature. Simulations of DM and grain yield were within 10% of measured values, except for a tendency to overcalculate DM response to CO₂ by 10 to 15% in Year 1 for WS treatments. The model undercalculated cumulative ET under WW conditions by 15%; model sensitivity analyses suggest that simulation of potential evapotranspiration (PET) was too low for this arid site. The model reproduced measured dynamics of CO₂-water interactions. Simulated reductions in water loss due to elevated CO₂ were about 4%, in agreement with measurements. The model simulated

larger increases in DM production and yield due to elevated CO₂ under WS than under WW conditions. In Year 1, simulated crop response to CO₂ was 2% larger (measured: 3%) under WS than under WW conditions; in Year 2, it was 11% larger (measured: 9%). The ability to simulate CO₂-water interactions, though it needs to be further evaluated with additional experimental datasets, is an important attribute of models used to project crop yields under elevated CO₂ and climate change.

Tubiello, F.N., C. Rosenzweig, and T. Volk. 1995. Interactions of CO₂, temperature and management-practices - simulations with a modified version of CERES-wheat. *Agricultural Systems* 49(2):135-152.

A new growth subroutine was developed for CERES-Wheat, a computer model of wheat (*Triticum aestivum*) growth and development. The new subroutine simulates canopy photosynthetic response to CO₂ concentrations and light levels, and includes the effects of temperature on canopy light-use efficiency. Its performance was compared to the original CERES-Wheat V-2.10 in 30 different cases. Biomass and yield predictions of the two models were well correlated (correlation coefficient $r > 0.95$). As an application, summer growth of spring wheat was simulated at one site. Modeled crop responses to higher mean temperatures, different amounts of minimum and maximum warming, and doubled CO₂ concentrations were compared to observations. The importance of irrigation and nitrogen fertilization in modulating the wheat crop climatic responses were also analyzed. Specifically, in agreement with observations, rainfed crops were found to be more sensitive to CO₂ increases than irrigated ones. On the other hand, low nitrogen applications depressed the ability of the wheat crop to respond positively to CO₂ increases. In general, the positive effects of high CO₂ grain yield were found to be almost completely counterbalanced by the negative effects of high temperatures. Depending on how temperature minima and maxima were increased, yield changes averaged across management practices ranged from -4% to 8%.

Turnbull, M.H., D.T. Tissue, K.L. Griffin, G.N.D. Rogers, and D. Whitehead. 1998. Photosynthetic acclimation to long-term exposure to elevated CO₂ concentration in *Pinus radiata* D. Don. is related to age of needles. *Plant, Cell and Environment* 21(10):1019-1028.

The effects of CO₂ enrichment on photosynthesis and ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) in current year and 1-year-old needles on the same branch were studied on *Pinus radiata* D. Don. trees growing for 4 years in large, open-top chambers at ambient (36 Pa) and elevated (65 Pa) CO₂ partial pressures. At this age trees were 3.5-4 m tall. Measurements made late in the growing cycle (March) showed that photosynthetic rates at the growth CO₂ concentration [(pCO₂)(a)] were lower in 1-year-old needles of trees grown at elevated CO₂ concentrations than in those of trees grown at ambient (pCO₂)(a). At elevated CO₂ concentrations V_{cmax} (maximum carboxylation rate) was reduced by 13% and J(max) (RuBP regeneration capacity mediated by maximum electron transport rate) by 17%. This corresponded with photosynthetic rates at the growth (pCO₂)(a) of 4.68 ± 0.41 μmol m⁻² s⁻¹ and 6.15 ± 0.46 μmol m⁻² s⁻¹ at 36 and 65 Pa, respectively (an enhancement of 31%). In current year needles photosynthetic rates at the growth (pCO₂)(a) were 6.2 ± 0.72 μmol m⁻² s⁻¹ at 36 Pa and 10.15 ± 0.64 μmol m⁻² s⁻¹ at 65 Pa (an

enhancement of 63%). The smaller enhancement of photosynthesis in 1-year-old needles at 65 Pa was accompanied by a reduction in Rubisco activity (39%) and content (40%) compared with that at 36 Pa. Starch and sugar concentrations in 1-year-old needles were not significantly different in the CO₂ treatments. There was no evidence in biochemical parameters for down-regulation at elevated (pCO₂)(a) in fully expanded needles of the current year cohort. These data show that enhancement of photosynthesis continues to occur in needles after 4 years' exposure to elevated CO₂ concentrations. Photosynthetic acclimation reduces the degree of this enhancement, but only in needles after 1 year of growth. Thus, responses to elevated CO₂ concentration change during the lifetime of needles, and acclimation may not be apparent in current year needles. This transitory effect is most probably attributable to the effects of developmental stage and proximity to actively growing shoots on sink strength for carbohydrates. The implications of such age-dependent responses are that older trees, in which the contribution of older needles to the photosynthetic biomass is greater than in younger trees, may become progressively more acclimated to elevated CO₂ concentration.

Tyree, M.T., and J.D. Alexander. 1993. Plant water relations and the effects of elevated CO₂ - a review and suggestions for future-research. *Vegetatio* 104:47-62.

Increased ambient carbon dioxide (CO₂) has been found to ameliorate water stress in the majority of species studied. The results of many studies indicate that lower evaporative flux density is associated with high CO₂-induced stomatal closure. As a result of decreases in evaporative flux density and increases in net photosynthesis, also found to occur in high CO₂ environments, plants have often been shown to maintain higher water use efficiencies when grown at high CO₂ than when grown in normal, ambient air. Plants grown at high CO₂ have also been found to maintain higher total water potentials, to increase biomass production, have larger root-to-shoot ratios, and to be generally more drought resistant (through avoidance mechanisms) than those grown at ambient CO₂ levels. High CO₂-induced changes in plant structure (i.e., vessel or tracheid anatomy, leaf specific conductivity) may be associated with changes in vulnerability to xylem cavitation or in environmental conditions in which runaway embolism is likely to occur. Further study is needed to resolve these important issues. Methodology and other CO₂ effects on plant water relations are discussed.

Ueda, Y., and J.H. Bai. 1993. Effect of short-term exposure of elevated CO₂ on flesh firmness and ester production of strawberry. *Journal of the Japanese Society for Horticultural Science* 62(2):457-464.

Strawberry fruits (*Fragaria X ananassa* cv. Hokowase) were treated with 20% CO₂ for 12 to 48 hr at 1-degrees-C and then stored at the same temperature for an additional 24 to 48 hr; subsequently they were transferred to 20-degrees-C and held for 8 hours. 1. Berries exposed to CO₂, including those stored for 8 hr at 20-degrees-C were firmer than the control berries exposed to air. 2. The CO₂ treatment had a little

effect on the evolution of methyl acetate and methyl butyrate, the predominant volatiles. However, the evolution of ethyl acetate and ethyl butyrate, the minor volatiles, was increased sharply by the CO₂ treatment. These changes in the concentration of volatiles gave the berries an unnatural aroma. 3. In berries given the same CO₂ treatment for 24 hr but stored longer period at 1-degrees-C, the abnormal aroma formation persisted for at least 5 days.

Upreti, D.C. 1998. Carbon dioxide enrichment technology: Open top chambers a new tool for global climate research. *Journal of Scientific & Industrial Research* 57(5):266-270.

There are many technical difficulties in conducting crop response studies for elevated carbon dioxide. Available facilities include green house, leaf cuvettes, phytotron, and air exclusion systems. The environmental control on these systems induces uncertainty in the extrapolation of results to the variable natural environments. However, open top chamber technology does not modify the micro-climate and induces realistic natural conditions. Open top chambers are cylindrical, aluminium frames with clear flexible covering and frustum to reduce the incursion of external air. CO₂ enriched air is introduced into the chamber through a perforated spurt with the help of a blower to distribute CO₂ uniformly. A relatively simpler design and construction of open top chambers make them the most likely method to be used in the near future for long-term elevated CO₂ exposures of crops and other ecosystems.

Upreti, D.C., N. Dwivedi, and R. Mohan. 1998. Characterization of CO₂ responsiveness in a Brassica oycamp interspecific hybrid. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 180(1):7-13.

A study of the characterization of CO₂ responsiveness in Brassica oycamp and its parents Brassica oxyrrhina and Brassica campestris was done using open top chamber technology. The response of the X. B. oycamp (hybrid) to elevated CO₂ was significantly positive in respect of photosynthesis and growth and similar to that of its parent B. campestris is. X B. oycamp and B. campestris with greater sink potential responded significantly, whereas B. oxyrrhina with a poor sink did not respond to CO₂ enrichment. Photosynthetic changes at elevated CO₂ levels in the hybrid and parents are partially attributed to the CO₂ effects on stomatal conductance and chlorophyll fluorescence.

Upreti, D.C., R.S. Mishra, and Y.P. Abrol. 1995. Effect of elevated CO₂ on the photosynthesis, growth and water relation of Brassica species under moisture stress. *Journal of Agronomy and Crop Science-Zeitschrift Fur Acker Und Pflanzenbau* 175(4):231-237.

An attempt has been made to study the interactive effect of elevated CO₂ and moisture stress on photosynthesis, growth and water relations of Brassica species using open top chambers. It was observed that plants responded to elevated CO₂ significantly under moisture stress condition mitigating the adverse effects on photosynthesis and growth of Brassica species. Relatively drought susceptible species, viz. B. campestris and B. nigra, responded to elevated CO₂ markedly as compared to less sensitive B. carinata and B. juncea plants. The water status of plants significantly improved under elevated CO₂ concentration possibly by

increasing stomatal resistance and/or by increased root growth.

Upreti, D.C., and B.K. Rabha. 1999. Effect of elevated CO₂ and moisture stress on the carbon and nitrogen contents in Brassica juncea. *Biologia Plantarum* 42(1):133-136.

The responses of Brassica juncea cv, Pusa Bold to elevated CO₂ was studied under water stress. Carbon accumulation in leaves, stem and roots was significantly higher at elevated CO₂ concentration. The water stress decreased the carbon content in these plant parts and this adverse effect was reduced by CO₂ enrichment. On the contrary nitrogen content of leaves, stem and roots was significantly reduced at elevated CO₂. Water stress caused reduction in nitrogen content in these plant parts, similar at ambient as well as elevated CO₂ concentration.

Uselman, S.M., R.G. Qualls, and R.B. Thomas. 1999. A test of a potential short cut in the nitrogen cycle: The role of exudation of symbiotically fixed nitrogen from the roots of a N-fixing tree and the effects of increased atmospheric CO₂ and temperature. *Plant and Soil* 210(1):21-32.

N-fixing trees facilitate the growth of neighboring trees of other species. These neighboring species benefit from the simple presence of the N fixation symbiosis in their surroundings. Because of this phenomenon, it has been hypothesized that a change in atmospheric CO₂ concentration may alter the role of N-fixing trees in their environment. It is thought that the role of N-fixing trees in ecosystems of the future may be more important since they may help sustain growth increases due to increased CO₂ concentration in nitrogen limited forests. We examined: (1) whether symbiotically fixed N was exuded from roots, (2) whether a doubled atmospheric CO₂ concentration would result in increased organic N exudation from roots, and (3) whether increased temperature or N availability affected N exudation from roots. This study analyzed exudation of dissolved organic N from the roots of seedlings of the N-fixing tree Robinia pseudoacacia L. in a full factorial design with 2 CO₂ (35.0 and 70.0 Pa) x 2 temperature (26 or 30 degrees C during the day) x 2 N fertilizer (0 and 10.0 mM N concentration) levels. Trees with no other source of N except N fixation exuded about 1% to 2% of the fixed N through their roots as dissolved organic N. Increased atmospheric CO₂ concentrations did not, however, increase N exudation rates on a per gram belowground biomass basis. A 4 degrees C increase in temperature and N fertilization did, however, significantly increase N exudation rates. These results suggest that exudation of dissolved organic N from roots or nodules of N-fixing trees could be a significant, but minor, pathway of transferring N to neighboring plants in a much more rapid and direct way than cycling through death, decomposition and mineralization of plant residues. And, while exudation rates of dissolved organic N from roots were not significantly affected by atmospheric CO₂ concentration, the previously observed 'CO₂ fertilization effect' on N-fixing trees suggests that N exudation from roots could play a significant but minor role in sustaining increases in forest growth, and thus C storage, in a CO₂ enriched atmosphere.

Usuda, H., and K. Shimogawara. 1998. The effects of increased atmospheric carbon dioxide on growth, carbohydrates, and photosynthesis in radish, *Raphanus sativus*. *Plant and Cell Physiology* 39(1):1-7.

The effects of sink capacity on the regulation of the acclimation of photosynthetic capacity to elevated levels of carbon dioxide are important from a global perspective. We investigated the effects of elevated (750 $\mu\text{mol mol}^{-1}$) and ambient (350 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ on growth, carbohydrate levels, and photosynthesis in radish seedlings from 15 to 46 d after planting. In radish, a major sink is the storage root, and its thickening is initiated early. Elevated CO₂ increased the accumulation of dry matter by 111% but had no effect on the acclimation of the rate of photosynthesis or on the levels of carbohydrates in leaves at dawn. Elevated CO₂ increased the dry weight in storage roots by 105% by 46 d after planting, apparently enhancing the sink capacity. This enhanced capacity seemed to be responsible for absorption of elevated levels of photosynthate and to result in the absence of any over-accumulation of carbohydrates in source leaves and the absence of negative acclimation of photosynthetic capacity at the elevated level of CO₂.

Utriainen, J., and T. Holopainen. 1998. Ultrastructural and growth responses of young Scots pine seedlings (*Pinus sylvestris*) to increasing carbon dioxide and ozone concentrations. *Chemosphere* 36(4-5):795-800.

Three-year-old Scots pine seedlings were exposed to ambient or elevated (2 x ambient) O₃ and CO₂ levels, singly and in combination, during one growth period in open-top field chambers. Growth measurements showed increased shoot length and needle width in response to CO₂ enrichment, whereas O₃ exposure resulted in visible injury (chlorotic mottling and increased yellowing of previous year needles). At the ultrastructural level, O₃ caused increased electron density of chloroplast stroma and increased number of cytoplasmic ribosomes at both CO₂ levels. CO₂ enrichment also resulted in an increase in the size of starch grains in chloroplasts. In general, simultaneous exposure to elevated O₃ reduced the impact of elevated CO₂. Vadstrup, M., and T.V. Madsen. 1995. Growth limitation of submerged aquatic macrophytes by inorganic carbon. *Freshwater Biology* 34(3):411-419.

1. This study determined the effects of CO₂ and HCO₃⁻ enrichment on in situ growth of two submerged macrophytes, *Elodea canadensis* and *Callitriche cophocarpa*, in two Danish lakes: Lake Hampen and Lake Vaeng. Lake Hampen is an oligotrophic low-alkaline lake (0.4 meg 1(-1)) and Lake Vaeng is mesotrophic with an alkalinity of 1.1 meg 1(-1). In Lake Hampen experiments were carried out throughout the growth season, whereas experiments in Lake Vaeng were restricted to late summer. The CO₂ and HCO₃⁻ enrichment procedures used increased the concentration of free-CO₂ by 500-1000 μM and the concentration of HCO₃⁻ by about 80 μM . 2. The concentration of free-CO₂ in Lake Hampen was about five times atmospheric equilibrium concentration (55 μM) in early summer declining to virtually zero at the end of summer.

3. Under ambient conditions *Callitriche*, which is restricted to CO₂ use, was unable to grow and survive in both lakes. In contrast, *Elodea*, which has the potential to use HCO₃⁻ in photosynthesis, grew at rates varying from 0.046 to 0.080 day(-1) over the season. 4. Under CO₂ enrichment the growth rate of *Callitriche* varied from 0.089 to 0.124 day(-1) and for *Elodea* from 0.076 to 0.117 day(-1) over the season. Enrichment with HCO₃⁻ affected *Elodea* only and only to a limited extent. This may be a result of insufficient increase in [HCO₃⁻] upon enrichment or to a limited capacity of the plants to take up HCO₃⁻. 5. The substantial stimulation of in situ growth of *Elodea* and *Callitriche* by enhanced concentrations of free-CO₂ shows that inorganic carbon is an important determinant of growth of submerged macrophytes and that inorganic carbon limitation of in situ growth may be a common phenomenon in nature, even in lakes with an alkalinity as high as 1 meg 1(-1). Inorganic carbon, however, is only one of many parameters important for growth, and the growth rates of *Elodea* at both ambient and high free-CO₂ were closely coupled to day length and photon irradiance, indicating that light had an ultimate control on growth.

Vaisanen, H., H. Standman, and S. Kellomaki. 1994. A model for simulating the effects of changing climate on the functioning and structure of the boreal forest ecosystem - an approach based on object-oriented design. *Tree Physiology* 14(7-9):1081-1095.

We have developed a forest ecosystem model to assess the effects of climate change on the functioning and structure of boreal coniferous forests assuming that temperature and precipitation are the major variables of the niche occupied by a tree species. We specified weather patterns to a level representing the time constant of different physiological and ecological processes relevant to the survival, growth and death of trees. We thereby coupled the long-term dynamics of the forest ecosystem with climate through physiological mechanisms such as photosynthesis and respiration in terms of energy flow through the ecosystem. The hydrological and nutrient cycles couple the dynamics of the forest ecosystem with climate change through soil processes, which represent the thermal and hydraulic properties of the soil, and the decomposition of litter and humus with mineralization of nutrients. Simulations for southern Finland (62-degrees-N) indicated that an increase in temperature of 5-degrees-C over one hundred years could reduce soil water in Scots pine-dominated forest ecosystems. At the same time, the temperature increase could enhance photosynthesis up to 6-8% under current CO₂ concentrations (330 ppm) and up to 8-10% under elevated CO₂ concentrations (660 ppm). Because the elevated temperature and CO₂ concentration caused an increase in respiration (12-14% more than under the current climate), total stem production increased only up to 4% with a 5-degrees-C increase in temperature and up to 6% when temperature and atmospheric CO₂ concentration were increased simultaneously. Because transpiration only increased up to 5% in response to elevated temperature and CO₂ concentration, the water use efficiency of Scots-pine dominated forest ecosystems increased up to 3%, particularly during the late rotation.

van Breemen, N., A. Jenkins, R.F. Wright, D.J. Beerling, W.J. Arp, F. Berendse, C. Beier, R. Collins, D. van Dam, L. Rasmussen, P.S.J. Verburg, and M.A. Wills. 1998. Impacts of elevated carbon dioxide and temperature on a boreal forest ecosystem (CLIMEX project). *Ecosystems* 1(4):345-351.

To evaluate the effects of climate change on boreal forest ecosystems,

both atmospheric CO₂ (to 560 ppmv) and air temperature (by 3 degrees-5 degrees C above ambient) were increased at a forested headwater catchment in southern Norway. The entire catchment (860 m²) is enclosed within a transparent greenhouse, and the upper 20% of the catchment area is partitioned such that it receives no climate treatment and serves as an untreated control. Both the control and treatment areas inside the greenhouse receive deacidified rain. Within 3 years, soil nitrogen (N) mineralization has increased and the growing season has been prolonged relative to the control area. This has helped to sustain an increase in plant growth relative to the control and has also promoted increased N export in stream water. Photosynthetic capacity and carbon-nitrogen ratio of new leaves of most plant species did not change. While the ecosystem now loses N, the long-term fate of soil N is a key uncertainty in predicting the future response of boreal ecosystems to climate change.

Vandasselaar, A.V., and E.A. Lantinga. 1995. Modeling the carbon-cycle of grassland in the Netherlands under various management strategies and environmental-conditions. *Netherlands Journal of Agricultural Science* 43(2):183-194.

A simulation model of the carbon cycle of grassland (CCGRASS) was developed to evaluate the long-term effects of different management strategies and various environmental conditions on carbon sequestration in the soil. The results presented here refer to permanent grassland on a young sedimentary loam soil in the Netherlands. The model predicted that the rate of increase in the amount of soil organic carbon will be highest at low to moderate application rates of nitrogen (100 - 250 kg N ha⁻¹ yr⁻¹). This is due to the fact that the annual gross photosynthetic uptake of CO₂ in permanent grassland is hardly influenced by the level of N supply. Since N shortage stimulates the growth of the unharvested plant parts (roots and stubble) the carbon supply to the soil is highest at low to moderate N application rates. The rate of increase in the amount of soil organic carbon will be higher under grazing than under mowing as a result of a greater amount of carbon added to the soil. Increase of atmospheric CO₂ concentration may induce an increase in decomposition rate of soil organic matter due to simultaneously increased temperatures. At the same time: plant productivity and thus carbon supply to the soil will be stimulated due to the CO₂-fertilization effect. Under the assumption of a temperature increase of 3 degrees C if the present atmospheric CO₂ concentration doubles, the model predicted that the combined effect of elevated CO₂ and temperature will slightly reduce the rate of increase in the amount of organic carbon in grassland soils compared to that under unchanged environmental conditions. There was 2% less carbon sequestration by grassland at the end of a period of 100 years as a result of these changes in environmental conditions. The separate effects of increased temperature or elevated CO₂ were 10% less and 10% more carbon storage at the end of a period of 100 years, respectively.

Vandegeijn, S.C., J. Vos, J. Groenwold, J. Goudriaan, and P.A. Leffelaar. 1994. The wageningen rhizolab - a facility to study soil-root-shoot-atmosphere interactions in crops .1. Description of main functions. *Plant and Soil* 161(2):275-287.

A research facility is described for the integrated study of soil-root-shoot-atmosphere relationships in crops. The Wageningen Rhizolab has

been in use since 1990, and consists of two rows, each with eight below-ground compartments aligned along a corridor. A rain shelter automatically covers the experimental area at the start of rainfall. Compartments are 125 cm x 125 cm and 200 cm deep. Each compartment has a separate drip irrigation system. Crop canopy photosynthesis, respiration, and transpiration can be measured simultaneously and continuously on four out of eight compartments at a time. Each compartment can be filled with a selected soil material (repacked soil) and is accessible from the corridor over its full depth. Multiple sensors for measuring soil moisture status, electrical conductivity, temperature, soil respiration, trace gases and oxygen are installed in spatial patterns in accordance with the requirements of the experiments. Sensors are connected to control and data-acquisition devices. Likewise, provisions have been made to sample manually the soil solution and soil atmosphere. Root observation tubes (minirhizotrons) are installed horizontally at depth intervals ranging from 5 cm (upper soil layers) to 25 cm (below 1 m). The facility is at present in use to study growth and development of vegetation (crops) in relation to drought, nutrient status, soil-borne diseases, and underground root competition. One important application is the study of elevated CO₂ concentration and climate change and the way they affect crops and their carbon economy. Growth and development of field grown vegetables and winter cover crops are also evaluated. The common aspect of those studies is to gain a better understanding of crop growth under varying environmental conditions, and to collect datasets that may help to improve mechanistic crop growth simulation models that can address suboptimal growth conditions.

VanderKooij, T.A.W., and L.J. DeKok. 1996. Impact of elevated CO₂ on growth and development of *Arabidopsis thaliana* L. *Phyton-Annales Rei Botanicae* 36(2):173-184.

After germination, *Arabidopsis thaliana* L. (cv. Landsberg) was grown at 350 µl l⁻¹ (control) or 700 µl l⁻¹ (elevated) CO₂. Total shoot biomass at the end of the vegetative growth period was increased by 56% due to a short transient stimulation of the relative growth rate by elevated CO₂ at the onset of the exposure. Thereafter the relative growth rate was comparable for both CO₂ levels during the remaining vegetative part of the life cycle (0.42 g g⁻¹ day⁻¹). Flowering architecture was not affected by elevated CO₂, but seed production was 51% higher. Starch content of the shoot was substantially increased upon exposure to elevated CO₂, while the soluble sugar content remained unaffected. Total nitrogen content, on a dry mass basis, was decreased at elevated CO₂ mainly as a result of the increased starch content. Photosynthesis was stimulated at elevated CO₂ and no acclimation of the photosynthesis at elevated CO₂ was observed. Even though the stimulation of relative growth rate was only temporary, elevated CO₂ resulted in an increased fitness of *Arabidopsis thaliana* by an increased reproductive output.

Van der Kooij, T.A.W., L.J. De Kok, and I. Stulen. 1999. Biomass production and carbohydrate content of *Arabidopsis thaliana* at atmospheric CO₂ concentrations from 390 to 1680 µl l⁻¹. *Plant Biology* 1(4):482-486.

The concentration dependency of the impact of elevated atmospheric CO₂ concentrations on *Arabidopsis thaliana* L. was studied. Plants were exposed to nearly ambient (390), 560, 810, 1240 and 1680 µl l⁻¹

CO₂ during the vegetative growth phase for 8 days. Shoot biomass production and dry matter content were increased upon exposure to elevated CO₂. Maximal increase in shoot fresh and dry weight was obtained at 560 $\mu\text{mol l}^{-1}$ CO₂, which was due to a transient stimulation of the relative growth rate for up to 3 days. The shoot starch content increased with increasing CO₂ concentrations up to two-fold at 1680 $\mu\text{mol l}^{-1}$ CO₂, whereas the contents of soluble sugars and phenolic compounds were hardly affected by elevated CO₂. The chlorophyll and carotenoid contents were not substantially affected at elevated CO₂ and the chlorophyll a/b ratio remained unaltered. There was no acclimation of photosynthesis at elevated CO₂; the photosynthetic capacity of leaves, which had completely developed at elevated CO₂ was similar to that of leaves developed in ambient air. The possible consequences of an elevated atmospheric CO₂ concentration to *Arabidopsis thaliana* in its natural habitat is discussed.

van der Westhuizen, M.M., and M.D. Cramer. 1998. The influence of elevated rhizosphere dissolved inorganic carbon concentrations on respiratory O₂ and CO₂ flux in tomato roots. *Journal of Experimental Botany* 49(329):1977-1985.

Respiratory CO₂ and O₂ flux were measured in hydroponically grown *Lycopersicon esculentum* (L.) Mill. cv. F144 plants at either low (0 $\mu\text{mol mol}^{-1}$) or elevated CO₂ concentrations (>2000 $\mu\text{mol mol}^{-1}$) supplied to the roots. In NO₃⁻-fed plants the consumption of O₂ and the engagement of the alternative pathway were increased by elevated dissolved inorganic carbon (DIC=CO₂+ HCO₃⁻) concentrations. This was ascribed to the influence of organic acids on the ICA cycle and electron transport pathways. Inhibition of O₂ consumption by elevated DIC in NH₄⁺-fed plants may be due to the reduction requirements of anaplerotic carbon entering the TCA cycle or the removal of carbon from the TCA cycle for amino acid synthesis. In both NO₃⁻ and NH₄⁺-fed plants elevated DIC inhibited root CO₂ release due to high rates of DIC incorporation by phosphoenolpyruvate carboxylase (PEPc) activity. Transient net CO₂ consumption due to the inhibition of respiration by salicylhydroxamic acid and KCN, together with high respiratory quotients after the addition of inhibitors of carbonic anhydrase (CA) activity, were also ascribed to high rates of DIC incorporation at elevated DIC concentrations. Ethoxzolamide, an inhibitor of CA activity, inhibited both DIC-14 incorporation into organic products and NO₃⁻ uptake by 81% and 40%, respectively. This, together with a 32% increase in (DIC)-C-14 accumulation and inhibition of NO₃⁻ uptake upon inhibition of anion transport by diisothiocyanato-stilbene-2,2'-disulphonic acid (DIDS) may indicate the exchange of HCO₃⁻ for NO₃⁻ across the root plasmalemma. It was concluded that dark incorporation of HCO₃⁻ by PEPc increased at elevated rhizosphere DIC concentrations and that the products of DIC incorporation may stimulate respiratory electron transport. Additional reducing energy and carbon skeletons from the tricarboxylic acid (TCA) cycle would therefore be available for respiration and the reduction and incorporation of NO₃⁻ into amino acids.

vandeStaaaij, J.W.M., E. Bolink, J. Rozema, and W.H.O. Ernst. 1997. The impact of elevated UV-B (280-320 nm) radiation levels on the reproduction biology of a highland and a lowland population of *Silene vulgaris*. *Plant Ecology* 128(1-2):172-179.

A highland (altitude 1600 m) and a lowland (altitude -2 m) population of the perennial herb *Silene vulgaris* were tested on the effects of elevated levels of UV-B radiation on their reproductivity. Highland populations receive higher natural UV-B doses than lowland populations. Therefore adaptation to high UV-B levels of the highland population is to be expected. The lowland population showed a decrease in the number of seed producing flowers and the number of seeds produced per plant under elevated UV-B levels. The highland population increased the number of seeds per plant under elevated UV-B levels. In both populations individual seed mass as well as seed germination percentages were unaffected by the UV-B flux received by the parental plant. Possible effects of UV-B induced alterations in reproductivity on the geographical distribution of the different populations are discussed.

Vandestaaij, J.W.M., R. Huijsmans, W.H.O. Ernst, and J. Rozema. 1995. The effect of elevated uv-b (280-320 nm) radiation-levels on *Silene vulgaris* - a comparison between a highland and a lowland population. *Environmental Pollution* 90(3):357-362.

Highland (altitude 1600 m above sea level) and lowland (altitude -2 m below sea level) populations of the perennial herb *Silene vulgaris* (Moench) Garcke, were tested on their response to elevated levels of UV-B radiation. Highland populations typically receive high natural UV-B fluxes, whereas lowland populations receive a lower natural UV-B dose. Adaptation to high UV-B levels of the highland population is to be expected. Experimental comparison of growth rates, gas exchange rates, transpiration and biochemical parameters using adult plants as well as seedlings did not show a difference in the response to elevated UV-B levels between the two populations. Individuals of both populations were relatively insensitive to elevated UV-B radiation. The response of alpine and lowland populations of *Silene vulgaris* is discussed in relation to the dispersal of this species after the last ice age.

Vandestaaij, J.W.M., G.M. Lenssen, M. Stroetenga, and J. Rozema. 1993. The combined effects of elevated CO₂ levels and uv-b radiation on growth-characteristics of *Elymus athericus* (= *E. pycnanthus*). *Vegetatio* 104:433-439.

Elymus athericus (Link) Kerguelen, a C₃ grass, was grown in a greenhouse experiment to determine the effect of enhanced atmospheric CO₂ and elevated UV-B radiation levels on plant growth. Plants were subjected to the following treatments: a) ambient CO₂-Control UV-B, b) ambient CO₂-elevated UV-B, c) double CO₂-control UV-B, d) double CO₂-elevated UV-B. Elevated CO₂ concentrations stimulated plant growth, biomass production was 67% higher than at ambient CO₂. Elevated UV-B radiation had a negative effect on growth, biomass production was depressed by 31%. Enhanced CO₂ combined with elevated UV-B levels caused a biomass depression of 8% when compared with the control plants. UV-B induced growth depression can be modified by a growth stimulus caused by high CO₂ concentrations. Growth analysis has been performed and possible physiological mechanisms behind changing growth parameters are discussed.

Vangarding, P.R., J. Grace, D.D. Harkness, F. Miglietta, and A. Raschi. 1995. Carbon-dioxide emissions at an Italian mineral spring - measurements of average CO₂ concentration and air-temperature. *Agricultural and Forest Meteorology* 73(1-2):17-27.

Emissions of carbon dioxide from vents at the Bossoleto mineral spring in Central Italy have been calculated to exceed 12 t day⁻¹. This emission leads to enhanced atmospheric concentrations of CO₂ over an area of more than 3000 m². The vent gas is over 99% pure CO₂, with a characteristic isotopic signature that is totally depleted in C-14. At night, concentrations at the bottom of the bowl-like depression can increase to levels approaching 75%. In the morning, this high concentration of CO₂ is associated with a rapid temperature increase of over 10 degrees C before the CO₂ disperses. This site is being used in a number of studies of the response of plant communities to long-term enhanced CO₂ concentrations. The problem of defining CO₂ concentrations in these studies was approached by comparing estimates determined by gas analysis measurements and isotopic analysis of leaf material. The isotopic method used C-14 as a tracer, integrating effective concentration over the life of a leaf by calculating from the ratio of C-14 measurements of plant material growing near the spring and at a control site. The estimates obtained using isotopic analysis of leaf material were similar to gas analysis measurements obtained during the day. This suggests that plants at this site are responding to the concentrations during the day, rather than the much higher night-time concentrations, making the system useful for biological research.

van Ginkel, J.H., and A. Gorissen. 1998. In situ decomposition of grass roots as affected by elevated atmospheric carbon dioxide. *Soil Science Society of America Journal* 62(4):951-958.

The effects of elevated CO₂ on belowground C input, on decomposition of roots in situ vs. decomposition of disturbed roots, and on soil microbial biomass were investigated in a perennial grass species. Forty ryegrass (*Lolium perenne* L.) plants were homogeneously C-14-labeled in two controlled environments for 115 d in a continuous (CO₂)-C-14 atmosphere at 350 and 700 µmol L⁻¹ and two soil N levels (low, LN, and high, HN). Thereafter, some of the plants were destructively harvested. Undisturbed root systems of the remaining plants were incubated in situ (IRS) for comparison with a disturbed incubation of the dried and ground roots (DRS) in their original soils. At the start of the incubation, elevated CO₂ had increased total C-14-labeled soil C input by 44 and 27% at LN and HN, respectively, compared with input at ambient CO₂. After incubation for 230 d, 40% of C-14 soil content was mineralized to (CO₂)-C-14 in the disturbed system and 52% in the intact system. Native soil organic matter (SOM) decomposition of the DRS was lower than the SOM decomposition of the IRS. The formation of C-14-labeled soil microbial biomass (C-14-SMB) in the soil with DRS was 130% higher than in the soil with the IRS. Elevated CO₂ decreased the decomposition of roots and root-derived products by 10% and increased the size of the C-14-SMB by 28% for both IRS and DRS, whereas the decomposition of SOM was not affected by CO₂ at either LN or HN. After plant growth and in situ incubation, the C-14-labeled C in the soil solution showed a highly positive correlation with the amount of C-14-SMB. The ratio between C-14-labeled microorganisms and total (CO₂)-C-14 evolved was not affected by elevated CO₂. It seems that microorganisms adapt to changing soil C input under elevated CO₂ and there is no effect on their turnover and behavior.

van Ginkel, J.H., A. Gorissen, and J.A. van Veen. 1996. Long-term decomposition of grass roots as affected by elevated atmospheric carbon dioxide. *Journal of Environmental Quality* 25(5):1122-1128.

Carbon input into the soil and decomposition processes under elevated CO₂ are highly relevant for C sequestering in the soil. Plant growth and decomposition of root material under ambient and elevated atmospheric CO₂ concentrations were monitored in wind tunnels. Grass roots (*Lolium perenne* L.) were homogeneously C-14-labeled at 350 and 700 µmol L⁻¹ CO₂ and at two N levels to obtain roots of different qualities. This root material was mixed with fresh loamy sand and transferred to four wind tunnels to observe its decomposition in bare soil and as affected by plant growth (*L. perenne*) at ambient CO₂ and elevated CO₂ for two growing seasons. After the second growing season, elevated CO₂ had stimulated shoot and root growth by 13 and 92%, respectively. The CO₂ and N concentrations at which the grass roots had been grown affected the decomposition rate. After the first growing season, the overall decomposition of 700 roots was 19% lower than that of 350 roots. The C-14-labeled microbial biomass in the soil with 700 roots was higher (44%) compared with 350 roots. After the second growing season, the decomposition of 700 low N roots was 14% lower than that of 350 low N roots, whereas the decomposition of the high N roots was unaffected. The C-14-labeled microbial biomass in the soil with 700 roots was still higher (30%) than with 350 roots. The combination of higher root yields at elevated CO₂ combined with a decrease in root decomposition will lead to a longer residence time of C in the soil and probably to a higher C storage.

van Ginkel, J.H., A. Gorissen, and J.A. van Veen. 1997. Carbon and nitrogen allocation in *Lolium perenne* in response to elevated atmospheric CO₂ with emphasis on soil carbon dynamics. *Plant and Soil* 188(2):299-308.

The effect of elevated CO₂ on the carbon and nitrogen distribution within perennial ryegrass (*L. perenne* L.) and its influence on belowground processes were investigated. Plants were homogeneously C-14-labeled in two ESPAS growth chambers in a continuous C-14-CO₂ atmosphere of 350 and 700 µmol L⁻¹ CO₂ and at two soil nitrogen regimes, in order to follow the carbon flow through all plant and soil compartments. After 79 days, elevated CO₂ increased the total carbon uptake by 41 and 21% at low (LN) and high nitrogen (HN) fertilisation, respectively. Shoot growth remained unaffected, whereas CO₂ enrichment stimulated root growth by 46% and the root/soil respiration by 111%, irrespective of the nitrogen concentration. The total C-14-soil content increased by 101 and 28% at LN and HN, respectively. The decomposition of the native soil organic matter was not affected either by CO₂ or by the nitrogen treatment. Elevated CO₂ did not change the total nitrogen uptake of the plant either at LN or at HN. Both at LN and HN elevated CO₂ significantly increased the total amount of nitrogen taken up by the roots and decreased the absolute and relative amounts translocated to the shoots. The amount of soil nitrogen immobilised by micro-organisms and the size of the soil microbial biomass were not affected by elevated CO₂, whereas both were significantly increased at the higher soil N content. Most striking was the 88% increase in net carbon input into the soil expressed as: C-14-roots plus total C-14-soil content minus the C-12-carbon released by decomposition of native soil organic matter. The net carbon input into the soil at ambient CO₂ corresponded with 841 and 1662 kg ha⁻¹ at LN and HN, respectively. Elevated CO₂ increased these amounts with an extra carbon input of 950 and 1056 kg ha⁻¹. Combined with a reduced decomposition rate of

plant material grown at elevated CO₂ this will probably lead to carbon storage in grassland soils resulting in a negative feed back an the increasing CO₂ concentration of the atmosphere.

van Ginkel, J.H., A.P. Whitmore, and A. Gorissen. 1999. Lolium perenne grasslands may function as a sink for atmospheric carbon dioxide. *Journal of Environmental Quality* 28(5):1580-1584.

Model calculations and scenario studies suggest the existence of a considerable positive feedback between temperature and CO₂ levels in the atmosphere. Rising temperatures are supposed to increase decomposition of soil organic C leading to increased production of CO₂ and this extra CO₂ induces a positive feedback by raising the temperature still further. Evidence was found that negative feedback mechanisms also exist: more primary production is allocated to roots as atmospheric CO₂ rises and these roots decompose more slowly than roots grown at ambient CO₂ levels. Experimental data partly obtained with C-14-techniques were applied in a grassland C model. The model results show that at an atmospheric CO₂ concentration of 700 $\mu\text{mol L}^{-1}$ increased belowground C storage will be more than sufficient to balance the increased decomposition of soil organic C in a ryegrass (*Lolium perenne* L.) grassland soil. Once a doubling of the present atmospheric CO₂ concentration has been reached, C equivalent to 55% of the annual CO₂ increase above 1 ha ryegrass can be withdrawn from the atmosphere. This indicates that grassland soils represent a significant sink for rising atmospheric CO₂.

VanHenten, E.J., J. Bontsema, and G. VanStraten. 1997. Improving the efficiency of greenhouse climate control: an optimal control approach. *Netherlands Journal of Agricultural Science* 45(1):109-125.

In this paper a method to improve the efficiency of greenhouse climate control is described. This method is based on the framework of optimal control theory. By exploiting a dynamic model of the greenhouse crop production process, information of the auction price, the operating costs of the climate conditioning equipment and the outdoor climate conditions, the optimal greenhouse climate control scheme balances on a purely objective basis costs against revenues of operating the climate conditioning equipment. Though optimal control of greenhouse climate has received considerable attention in the literature, until now little evidence supported by experimental work has been reported as to the possible improvement in efficiency which can be realised using this approach during a whole growing period. This paper reports a first exploration of this matter for a lettuce crop. In a greenhouse experiment the behaviour of conventional greenhouse climate control supervised by the grower was measured. Then, in simulation experiments, optimal control strategies were calculated for the same conditions (outdoor climate, auction price, energy price). The results obtained support the conclusion that a considerable improvement in the efficiency of greenhouse climate management is possible. This improvement may well exceed 15%.

Vanhinsberg, N., and R.F. Horton. 1992. Ethylene metabolism in pulvini of *Phaseolus vulgaris* L. *Biochimie Und Physiologie Der Pflanzen* 188(1):51-55.

The ability of leaf blade, pulvinar and petiolar tissue from primary leaves of *Phaseolus vulgaris* to release ethylene when incubated in a 1 mM solution of the ethylene-biosynthesis precursor, 1-aminocyclopropane-1-carboxylic acid, was determined over a 6h period. Ethylene release was measured under CO₂-enriched and CO₂-depleted conditions in the light and dark. In contrast to blade and petiolar tissue, the pulvini released more ethylene in the light than in the dark when held in sealed flasks. The amount of the gas released is largely independent of external levels of carbon dioxide.

Van Labeke, M.C., and P. Dambre. 1998. Effect of supplementary lighting and CO₂ enrichment on yield and flower stem quality of *Alstroemeria* cultivars. *Scientia Horticulturae* 74(4):269-278.

The effects of CO₂ enrichment and supplementary lighting on the production and flower stem quality of five *Alstroemeria* cultivars ('Barbara', 'Fiona', 'Helios', 'Mona Lisa' and 'Tiara') were studied. CO₂ enrichment up to 900 $\mu\text{mol L}^{-1}$ alone was beneficial for an increase in the number of flower stems and flower stem quality regardless of the use of supplementary lighting. Supplementary lighting alone enhanced flower stem production and quality to a lower extent than CO₂ enrichment. The combination of both supplementary lighting and CO₂ enrichment resulted in superior flower stem production for *Alstroemeria* 'Fiona', 'Helios' and 'Mona Lisa', and flower stem quality for *Alstroemeria* 'Barbara', 'Fiona' and 'Mona Lisa'. vanMinnen, J.G., K.K. Goldewijk, and R. Leemans. 1995. The importance of feedback processes and vegetation transition in the terrestrial carbon cycle. *Journal of Biogeography* 22(4-5):805-814.

The Integrated Model to Assess the Greenhouse Effect (IMAGE 2) is developed to simulate dynamically the global society-biosphere-climate system. The terrestrial C cycle model is an important component of this model. It is implemented on a grid, runs on an annual time step and simulates the major C fluxes between the atmosphere and the biosphere and controls the storage capacity of C in different compartments. The C fluxes are influenced by the direct and indirect response of ecosystems to changing atmospheric CO₂ concentrations and climates. Each ecosystem is characterized by its NPP, which depends on environmental conditions. Incorporation of grid cell specific feedback processes is an innovation in this model. Implemented feedback processes are CO₂ fertilization, effects of climate change on photosynthesis, plant respiration and decomposition and shifts in vegetation patterns due to climate change and changes in water use efficiency. This paper presents an evaluation of the importance of feedback processes on global and regional scales. Temperature feedback on plant growth is the most important feedback process at the global scale, while CO₂ fertilization is of lesser importance. However, CO₂ fertilization is the most significant feedback in low latitudes, while temperature change most strongly influences the C cycle in the high latitudes. The C dynamics of land cover change, including feedbacks, depend on characteristics of the

former and actual land cover type. The shifts in land cover are parameterized so that they mimic succession. The course and duration of the transitional phase strongly affect the C fluxes. We applied both an equilibrium approach with instantaneous transitions and dynamic approaches with gradual type-dependent transitions. Transitions in natural vegetation between 1990 and 2050 involve about one-third of all grid cells, especially in the higher latitudes. The impact of vegetation transitions on C fluxes differs depending on the instantaneous or gradual transition strategy. The latter results in higher and delayed NEP fluxes, resulting in significantly different atmospheric CO₂ concentrations. The dynamic approach is more realistic and should be included in integrated assessment models that project future atmospheric CO₂ levels.

van Noordwijk, M., P. Martikainen, P. Bottner, E. Cuevas, C. Rouland, and S.S. Dhillon. 1998. Global change and root function. *Global Change Biology* 4(7):759-772.

Global change includes land-use change, elevated CO₂ concentrations, increased temperature and increased rainfall variability. All four aspects by themselves and in combination will influence the role of roots in linking below- and above- ground ecosystem function via organic and inorganic resource flows. Root-mediated ecosystem functions which may be modified by global change include below-ground resource (water, nutrients) capture, creation and exploitation of spatial heterogeneity, buffering of temporal variations in above-ground factors, supply and storage of C and nutrients to the belowground ecosystem, mobilization of nutrients and C from stored soil reserves, and gas exchange between soil and atmosphere including the emission from soil of greenhouse gases. The theory of a functional equilibrium between root and shoot allocation is used to explore predicted responses to elevated CO₂ in relation to water or nutrient supply as limiting root function. The theory predicts no change in root:shoot allocation where water uptake is the limiting root function, but substantial shifts where nutrient uptake is (or becomes) the limiting function. Root turnover will not likely be influenced by elevated CO₂, but by changes in regularity of water supply. A number of possible mechanisms for root-mediated N mineralization is discussed in the light of climate change factors. Rhizovory (root consumption) may increase under global change as the balance between plant chemical defense and adapted root consuming organisms may be modified during biome shifts in response to climate change. Root-mediated gas exchange allows oxygen to penetrate into soils and methane (CH₄) to escape from wetland soils of tundra ecosystems as well as tropical rice production systems. The effect on net greenhouse gas emissions of biome shifts (fens replacing bogs) as well as of agricultural land management will depend partly on aerenchyma in roots.

van Oene, H., F. Berendse, and C.G.F. de Kovel. 1999. Model analysis of the effects of historic CO₂ levels and nitrogen inputs on vegetation succession. *Ecological Applications* 9(3):920-935.

(S)imulation models are useful to analyze and predict the effects of changes in atmospheric CO₂ concentration and N deposition on terrestrial ecosystems. The effects of such abiotic changes on ecosystem variables such as nitrogen mineralization and carbon accumulation can

affect plant species composition, which in turn may affect various ecosystem processes. However, these interacting effects of plant species composition on ecosystem processes and vice versa are often not included in simulation models. In this paper, a model is developed that includes both plant competition and the flows of nutrients, carbon, and water through the ecosystem. Direct effects of changing atmospheric CO₂ on biomass, plant nitrogen concentrations, and litter quantity and quality are simulated together with indirect effects through changes in plant species composition. This model is validated against data from a primary succession chronosequence sere of Dutch inland dunes. For this validation, historical N deposition and atmospheric CO₂ concentration records are used. Simulated plant species biomass, organic matter C and N, and total C and N accumulation were found to correspond to measured data. The model simulated plant species replacement well at the different sites of the chronosequence even though the historic conditions differed much between the sites. Additional analyses of the effect of N deposition (preindustrial to present-day) and elevated CO₂ (preindustrial to present-day) in this ecosystem showed that N deposition had a strong effect both on vegetation development and on C and N accumulation. Compared to this, the stimulating effects of elevated CO₂ on vegetation development were relatively small. Elevated CO₂ affected early vegetation development, but the long-term response of vegetation development is dependent on N availability. In old mature forest, N deposition had only small effects while elevated CO₂ delayed forest aging. Indirect effects of CO₂ on C and N accumulation through changing plant competitive relations may ultimately be larger than direct CO₂ effects.

van Oijen, M., and F. Ewert. 1999. The effects of climatic variation in Europe on the yield response of spring wheat cv. Minaret to elevated CO₂ and O-3: an analysis of open-top chamber experiments by means of two crop growth simulation models. *European Journal of Agronomy* 10(3-4):249-264.

In the ESPACE-Wheat programme, 25 open-top chamber experiments were carried out in 1994, 1995 and 1996, on nine locations, divided over eight European countries. In most experiments, spring wheat cv. Minaret was subjected to two levels of atmospheric CO₂ and two levels of ozone. Grain yields in the control treatments (ambient levels of CO₂ and O-3) varied strongly between sites. Also, yield response to elevated CO₂ and O-3 showed great variation. The present study was conducted to determine whether climatic differences between sites could account for the observed variation. Two simulation models were used for the analysis: AFRCWHEAT2-O3 and LINTULCC. AFRCWHEAT2-O3 simulates phenology, canopy development and photosynthesis in greater detail than LINTULCC. Both models account for the effects of radiation and temperature on crop growth. New algorithms were developed to simulate the effects of CO₂ and O-3. Weather data that were measured in the experiments were used as input, and simulated growth responses to CO₂ and O-3 were compared with measurements. No attempt was made to merge the two models. Thus two independent tools for analysis of data related to climate change were developed and applied. The average measured grain yield in the control treatment, across all 25 experiments, was 5.9 tons per hectare (t ha⁻¹), with a standard deviation (SD) of 1.9 t ha⁻¹. The models predicted similar average yields (5.5 and 5.8 t ha⁻¹ for AFRCWHEAT2-O3 and LINTULCC, respectively), but smaller variation (SD for both models: 1.2 t ha⁻¹). Average measured yield increase due to CO₂-doubling was 30% (SD 22%). AFRCWHEAT2-O3 expected a slightly lower value (24%, SD 9%), whereas LINTULCC overestimated the response (42%, SD 11%). The average measured yield decrease due to nearly-doubled O-3 levels was 9% (SD 11%). Both models showed similar results, albeit at lower

variation (7% yield decrease at SDs of 6 and 4%). Simulations accounted well for the observation that, at elevated CO₂, the percentage yield loss due to O-3 was lower than at ambient CO₂. The models predicted lower variation among sites and years than was measured. Yield response to CO₂ and O-3 was predicted to depend on the climate, with a predominant effect of temperature on the response to CO₂. In the measurements, these climatic effects were indeed observed, but a greater part of the variation was not related to light intensity, temperature, CO₂, or O-3. This unexplained variability in the measured dataset was probably caused by factors not accounted for in the models, possibly related to soil characteristics. We therefore conclude that even perfect information on the climate variables examined in ESPACE-Wheat, i.e. light intensity and temperature, by itself would be insufficient for accurate prediction of the response of spring wheat to future elevated levels of CO₂ and O-3. Van Oijen, M., A.H.C.M. Schapendonk, M.J.H. Jansen, C.S. Pot, and R. Maciorowski. 1999. Do open-top chambers overestimate the effects of rising CO₂ on plants? An analysis using spring wheat. *Global Change Biology* 5(4):411-421.

The microclimate in facilities for studying effects of elevated CO₂ on crops differs from ambient conditions. Open-top chambers (OTCs) increase temperature by 1-3 degrees C. If temperature and CO₂ interact in their effect on crops, this would limit the value of OTC experiments. Furthermore, interaction of CO₂ and temperature deserves study because increases in atmospheric CO₂ concentration are expected to cause global warming. This paper describes two experiments in which a recently developed cooling system for OTCs was used to analyse the effects of temperature on photosynthesis, growth and yield of spring wheat (*Triticum aestivum* L., cv. Minaret). Two levels of CO₂ were used (350 and 700 ppm), and two levels of temperature, with cooled OTCs being 1.6-2.4 degrees C colder than noncooled OTCs. Photosynthetic rates were increased by elevated CO₂, but no effect of temperature was found. Cross-switching CO₂ concentrations as well as determination of A-Ci curves showed that plant photosynthetic capacity after anthesis acclimated to elevated CO₂. The acclimation may be related to the effects of CO₂ on tissue composition: elevated CO₂ decreased leaf nitrogen concentrations and increased sugar content. Calculations of the seasonal mean crop light-use efficiency (LUE) were consistent with the photosynthesis data in that CO₂ increased LUE by 20% on average whereas temperature had no effect. Both elevating CO₂ and cooling increased grain yield, by an average of 11% and 23%, respectively. CO₂ and temperature stimulated yield via different mechanisms: CO₂ increased photosynthetic rate, but decreased crop light interception capacity (LAI), whereas cooling increased grain yield by increasing LAI and extending the growing season with 10 days. The effects of CO₂ and temperature were not additive: the CO₂ effect was about doubled in the noncooled open-top chambers. In most cases, effects on yield were mediated through increased grain density rather than increased individual grain weights. The higher growth response to elevated CO₂ in noncooled vs. cooled OTCs shows that a cooling system may remove a bias towards overestimating crop growth response to CO₂ in open-top chambers.

van Oijen, M., A.H.C.M. Schapendonk, M.J.H. Jansen, C.S. Pot, J. van Kleef, and J. Goudriaan. 1998. Effects of elevated CO₂ on

development and morphology of spring wheat grown in cooled and non-cooled open-top chambers. *Australian Journal of Plant Physiology* 25(5):617-626.

Facilities for studying effects of elevated CO₂ on crops affect the microclimate in the crop. Open-top chambers may increase temperature by 1-3 degrees C compared to ambient conditions. This paper describes a newly developed cooling system for open-top chambers. In 1995 and 1996, experiments were carried out to test the system and analyse the effects of temperature on crop phenological and morphological response to elevated CO₂. Spring wheat (*Triticum aestivum* L. cv. Minaret) was subjected to ambient and doubled CO₂ concentration in both cooled and non-cooled chambers. The cooling system reduced temperature by 1.6-2.4 degrees C, and this delayed maturity by 10 days. In contrast, elevated CO₂ did not affect phenological development. Elevated CO₂ reduced tiller density, green leaf number per tiller and specific leaf area, thereby reducing the capacity for light interception of the crop. Crop height growth before anthesis mainly responded to temperature, but after anthesis it was only affected by CO₂, indicating a shift from sink- to source-limited growth. For none of the parameters studied, a significant statistical interaction of CO₂ and temperature was found. The cooling system proved effective. A temperature difference of about 2 degrees C affected crop development and morphology more strongly than CO₂ doubling. However, the absence of CO₂-temperature interaction suggests that CO₂ effects may validly be investigated even without a cooling system.

Vanoosten, J.J., D. Afif, and P. Dizengremel. 1992. Long-term effects of a CO₂ enriched atmosphere on enzymes of the primary carbon metabolism of spruce trees. *Plant Physiology and Biochemistry* 30(5):541-547.

The long-term effects of an enriched CO₂ atmosphere on the primary carbon metabolism of 4-year-old spruce trees (*Picea abies* L. Karst) were examined. Eight key enzymes were studied in 1-year-old needles of trees submitted for two years in open-top chambers to three CO₂ levels (350, 480 and 570 ppm V). The specific activity and quantity of ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO, EC 4.1.1.39), and the specific activities of photorespiratory enzymes, glycolate oxidase (EC 1.1.3.15) and hydroxypyruvate reductase (HPR, EC 1.1.1.29) showed a significant decrease in the CO₂-enriched atmospheres. By contrast, a net increase was found for the specific activities of the mitochondrial enzymes, NAD-malic enzyme (NAD-ME, EC 1.1.1.39) and especially fumarase (EC 4.2.1.2). The specific activity of phosphofructophosphotransferase (PFK, EC 2.7.1.90), a glycolytic enzyme, did not change while a slight decrease of the activity of glucose 6-phosphate dehydrogenase (G6PDH, EC 1.1.1.49), a pentose phosphate pathway enzyme, was observed. The carboxylating enzyme, phosphoenolpyruvate carboxylase (PEPC, EC 4.1.1.31) showed a marked decrease in activity. These results clearly demonstrate both increases in enzyme activities linked to the respiratory process and decreases in activities of CO₂-fixing enzymes as a result of long-term exposure to less than twice the ambient level of CO₂.

Vanoosten, J.J., and R.T. Besford. 1994. Sugar feeding mimics effect of acclimation to high CO₂-rapid down-regulation of rubisco small-subunit transcripts but not of the large subunit transcripts. *Journal of Plant Physiology* 143(3):306-312.

The abundance of rbcS transcripts, derived from the nuclear gene-family coding for the small subunit of RuBisCO, was dramatically reduced in tomato plants exposed to high CO₂ for 4 days or more whereas the decline in the rbcL RNA transcripts, from the chloroplast gene coding for the large subunit of RuBisCO, was less pronounced. The rate of decline in the abundance of the rbcS transcripts was enhanced when leaves were detached and supplied with water so as to deprive them of any major sink and simultaneously exposed to high CO₂. The reduction in the abundance of rbcS mRNA, but not rbcL, was mimicked when sucrose or glucose was supplied to leaf tissue, whereas acetate or sorbitol had no effect. Based on these and other published data a molecular model involving the repression of transcription of nuclear-encoded genes for chloroplast proteins by photosynthetic end-products is proposed to account for photosynthetic acclimation to high CO₂ in tomato and other species.

Vanoosten, J.J., and R.T. Besford. 1995. Some relationships between the gas-exchange, biochemistry and molecular-biology of photosynthesis during leaf development of tomato plants after transfer to different carbon-dioxide concentrations. *Plant, Cell and Environment* 18(11):1253-1266.

Tomato plants were exposed to four concentrations of CO₂ (350, 700, 1050 or 1400 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) for 31 d. The light-saturated rate of photosynthesis (A) of the unshaded fifth leaf was measured at either an ambient CO₂ concentration of 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ [A (350)] or at the level of CO₂ at which the plants were grown. The chloroplast protein composition and the level of transcripts of nuclear or plastid photosynthesis-associated genes (PAGs), as well as the main carbohydrate content of the fifth leaf maintained horizontal and unshaded, were also measured during leaf development. At 60 and 95 % leaf expansion, the A of high CO₂-grown plants measured at growth CO₂ was higher than the A (350) of the plants grown at ambient CO₂. However, in the fully mature leaves, A (growth CO₂) declined linearly as growth CO₂ concentration increased. The A (350) of plants exposed to elevated CO₂ up to 60% leaf expansion had not acclimated to high CO₂. At 95% leaf expansion, A (350) was lower in plants grown at high CO₂. A versus CO₂ (C-i) for mature leaves showed that A of the plants grown at high CO₂ was lower over the entire range than that for plants grown at present ambient CO₂ concentration. Lines fitted to the linear part of the A/C-1 curves were concurrent at a C-i of 49 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ and A=-1.21 $\mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$. This C-i value is close to Γ_{min} (46 $\mu\text{mol CO}_2 \text{ mol}^{-1}$), the compensation point at 27 degrees C calculated from the equation described in Brooks & Farquhar (1985, *Planta* 165, 397-406). This A is an estimate of respiration in the light (R(1)) and was not affected by acclimation to elevated CO₂. Thylakoid proteins (photosystem I core protein, D-1 and D-2 of the photosystem II core complex, cytochrome f) were all reduced by elevated CO₂ only in the fully mature leaves (310 exposure), whereas the large and small subunits of Rubisco and Rubisco activase proteins had already declined after 22 d exposure. Transcript levels of the plastid-encoded FAG (rbcL, psbA, psaA-B) were reduced in the mature leaves by elevated CO₂ when expressed on a total RNA basis, but they were not sensitive to elevated CO₂ when expressed on a chloroplast 16S rRNA basis. However, rbcS, rca and cab mRNA transcripts were lower in the

plants grown at high CO₂ than in control plants after 22 d exposure when expressed on a nuclear rRNA basis. The loss of these nuclear PAGs was correlated with an accumulation of soluble sugars and starch.

VanOosten, J.J., and R.T. Besford. 1996. Acclimation of photosynthesis to elevated CO₂ through feedback regulation of gene expression: Climate of opinion. *Photosynthesis Research* 48(3):353-365.

Although down-regulation of photosynthesis in higher C-3 plants exposed to long-term elevated CO₂ has been recognized in plants with low sink activity or poor nutrient status, the underlying molecular mechanisms remain unclear. This review covers aspects of rising CO₂ on plant productivity in general, and then focuses on photosynthesis, biochemistry (stroma and thylakoid proteins, Rubisco activities and metabolites), and gene expression in tomato plants grown under ambient or elevated CO₂. Taking into account these data and the recent discovery that glucose triggers repression of photosynthetic gene transcription, a molecular mechanism is proposed for feedback regulation of photosynthesis under high CO₂. Different living organisms such as bacteria, yeast, and mammals have been investigated for the sensing mechanisms of the carbohydrate status of their cells, and this information is used together with some recent data obtained for plants to propose how hexose levels might be sensed in higher plant cells.

Vanoosten, J.J., D. Wilkins, and R.T. Besford. 1994. Regulation of the expression of photosynthetic nuclear genes by CO₂ is mimicked by regulation by carbohydrates - a mechanism for the acclimation of photosynthesis to high CO₂. *Plant, Cell and Environment* 17(8):913-923.

The abundance of transcripts of cab-7 and cab-3C, which code for the chlorophyll a/b binding proteins of the light-harvesting complexes I and II, respectively, and the abundance of transcripts of Rca, which encodes Rubisco activase, were reduced in tomato plants exposed to high CO₂ for up to 9d, whereas the abundance of mRNA from psa A-psa B and psb A, which encode the proteins of the core complex of PSI and the D1 protein of PSII, respectively, and the abundance of glycolate oxidase, which is involved in photorespiration, were not affected. However, the abundance of the transcript for the B subunit of ADP-glucose pyrophosphorylase was increased after 1 d at elevated CO₂. The chlorophyll a/b ratio decreased significantly over 9 d of exposure to elevated CO₂. The responses of the nuclear genes to high CO₂ were enhanced when leaves were detached so as to deprive them of any major sink. The responses of these transcripts to high CO₂ were mimicked when sucrose or glucose was supplied to the leaf tissue, whereas acetate or sorbitol had no effect. Carbohydrate analyses of leaves grown in high CO₂ or supplied with sucrose revealed that major increases occurred in the amount of glucose and fructose. Based on these and other published data, a molecular model involving the repression or activation of the transcription of nuclear genes coding for chloroplast proteins by photosynthetic end-products is proposed to account for photosynthetic acclimation to high CO₂ in tomato plants and other species.

Vanoosten, J.J., D. Wilkins, and R.T. Besford. 1995. Acclimation of tomato to different carbon-dioxide concentrations - relationships between biochemistry and gas-exchange during leaf development. *New Phytologist* 130(3):357-367.

Tomato plants were transferred to different CO₂ mole fractions (350, 700, 1050 and 1400 $\mu\text{mol CO}_2 \text{ mol}^{-1}$) 31 d after sowing (2% of full expansion) and the light saturated rate of photosynthesis (P-max) of the unshaded 5th leaf was measured at either an ambient CO₂ mole fraction, C-a of 350 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ [P-max (350)] or at the mole fraction of CO₂ at which the plants were grown. At 60% and 95% leaf expansion, P-max of high CO₂ grown plants measured at growth CO₂, was greater than the P-max (350) of the ambient CO₂ grown plants. However, by leaf maturity, P-max (growth CO₂) declined linearly as growth CO₂ concentration increased. P-max (350) of plants exposed to elevated CO₂ up to 60% leaf expansion had not acclimated to high CO₂. At 95% leaf expansion, P-max (350) was smaller in the high CO₂ grown plants. P-max (350) was predicted from Rubisco in vitro carboxylation capacity using tomato Rubisco kinetic constants. By 95% leaf expansion, high CO₂ grown plants showed similarities to the response of plants to low nitrogen supply, in terms of Rubisco and chlorophyll content. The observed and theoretical relationships between the initial slopes of the P-max/C-i responses and Rubisco activity were statistically equivalent. Both short-term and long-term effects of elevated CO₂ on dark respiration (R(n)) were also investigated at two stages of leaf development (50 and 100% expansion). R(a) (growth CO₂) was smaller for the high CO₂ grown plants compared with the control plants, whereas R(n) (350) was either equal or greater for the plants grown in high CO₂.

Vantelgen, H.J., A. Vanmil, and B. Kunneman. 1992. Effect of propagation and rooting conditions on acclimatization of micropropagated plants. *Acta Botanica Neerlandica* 41(4):453-459.

Plantlets of *Calathea ornata* rooted at frequencies varying between 75 and 100% irrespective of the presence of 6-benzylaminopurine (BAP) or indolebutyric acid (IBA). After transfer to soil all plants grew rapidly with the exception of BAP-rooted plants, probably because these plants lacked lateral roots. Plantlets of *Malus* showed slightly improved rooting and considerably improved survival at increasing sucrose concentration from 20 to 30 g l⁻¹ during multiplication. Their survival and performance after planting in soil depended upon the number of roots formed in rooting medium. Elevated CO₂-levels (800 $\mu\text{mol m}^{-3}$) during acclimatization increased survival rate and plant height of rooted and non-rooted plantlets.

Vanveen, J.A., E. Liljeroth, L.J.A. Lekkerkerk, and S.C. Vandegeijn. 1991. Carbon fluxes in plant-soil systems at elevated atmospheric CO₂ levels. *Ecological Applications* 1(2):175-181.

The flow of carbon from photosynthesizing tissues of higher plants, through the roots and into the soil is one of the key processes in terrestrial ecosystems. An increased level of CO₂ in the atmosphere will likely result in an increased input of organic carbon into the soil due to the expected increase in primary production. Whether this will lead to accumulation of greater amounts of organic carbon in soil depends on the flow of carbon through the plant into the soil and its subsequent transformation in the soil by microorganisms. In this paper the major controls of carbon translocation via roots into the soil as well as the subsequent microbial turnover of root-derived carbon are reviewed. We discuss possible consequences of an increased CO₂ level in the atmosphere on these processes.

VanVuuren, M.M.I., D. Robinson, A.H. Fitter, S.D. Chaselow, L. Williamson, and J.A. Raven. 1997. Effects of elevated atmospheric CO₂ and soil water availability on root biomass, root length, and N, P and K uptake by wheat. *New Phytologist* 135(3):455-465.

We investigated interactions between the effects of elevated atmospheric carbon dioxide concentrations ([CO₂]) and soil water availability on root biomass, root length and nutrient uptake by spring wheat (*Triticum aestivum* cv. Tonic). We grew plants at 350 and 700 $\mu\text{mol mol}^{-1}$ CO₂ and with frequent and infrequent watering ('wet' and 'dry' treatments, respectively). Water use per plant was 1.25 times greater at 350 than at 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$, and 1.4 times greater in the 'wet' than in the 'dry' treatment. Root biomass increased with [CO₂] and with watering frequency. Elevated [CO₂] changed the vertical distribution of the roots, with a greater stimulation of root growth in the top layers of the soil. These data were confirmed by the video data of root lengths in the 'dry' treatment, which showed a delayed root development at depth under elevated [CO₂]. The apparent amount of N mineralized appeared to be equal for all treatments. Nutrient uptake was affected by [CO₂] and by watering frequency, and there were interactions between these treatments. These interactions were different for N, K and P, which appeared to be related to differences in nutrient availability and mobility in the soil. Moreover, these interactions changed with time as the root system became larger with [CO₂] and with watering frequency, and as fluctuations in soil moisture contents increased. Elevated [CO₂] affected nutrient uptake in contrasting ways. Potassium uptake appeared to be reduced by the smaller mass flow of water reaching the root surface. However, this might be countered with time by the greater root biomass at elevated [CO₂], by the greater soil moisture contents at elevated [CO₂], enabling faster diffusion, or both. Phosphorus uptake appeared to be increased by the greater root biomass at elevated [CO₂]. We conclude that plant nutrient uptake at elevated [CO₂] is affected by interactions with water availability, though differences between nutrients preclude generalizations of the response.

VargasSuarez, M., A. RinconGuzman, C. MujicaJimenez, R.A. MunozClares, and E.S. deJimenez. 1996. Influence of carbon source and CO₂-enrichment on biochemical parameters associated with photomixotrophy in maize callus cultures. *Journal of Plant Physiology* 149(5):585-591.

To learn about the biochemical processes underlying the induction of

photomixotrophia in maize cell culture, maize calli were cultured in medium containing either glucose or starch as the carbon source. The effect of a CO₂-enriched atmosphere on different parameters was tested. Levels of chlorophyll and CO₂ fixing enzymes were measured to assess the greening process concomitant to histological observations of chloroplast development. Both starch and glucose promoted higher chlorophyll accumulation in callus cultured under light than sucrose. Histological analysis of green callus grown on glucose-containing medium revealed the formation of poorly developed chloroplasts containing starch grains, whereas in starch medium a large number of elongated chloroplasts containing thylakoids were observed. Exposure of these calli to a CO₂-enriched atmosphere enhanced the plastid differentiation process up to mature chloroplasts with grana and intergranal thylakoids. Western-blot analysis demonstrated the presence of CO₂-fixing enzymes, Rubisco (EC 4.1.1.39) and PEP carboxylase (EC 4.1.1.31), as well as Rubisco activase in greening callus. Rubisco and PEP carboxylase activities showed large values when starch was the carbon source in the medium. Results of histological analysis and a/b chlorophyll ratios indicated that the chloroplasts formed were of the C-3-type. PEP carboxylase kinetic properties were also consistent with a C-3-type enzyme involved in anaplerotic functions. It is concluded that under the experimental conditions tested, starch plus CO₂-enriched atmosphere are the best carbon source for inducing and supporting photomixotrophia in maize cultures, as indicated by several biochemical parameters.

Varoquaux, P., J. Mazollier, and G. Albagnac. 1996. The influence of raw material characteristics on the storage life of fresh-cut butterhead lettuce. *Postharvest Biology and Technology* 9(2):127-139.

The physiological characteristics of 5 butterhead lettuce cultivars (*Lactuca sativa* L.) were investigated using etiolated leaves. Their storage life under modified and controlled atmospheres was assessed. When prepacked butterhead lettuce was maintained under a low oxygen atmosphere to prevent enzymatic browning, high CO₂ content was the main factor increasing the rate of decay. Shelf life was negatively correlated with respiration rate and susceptibility to CO₂. Potassium leakage was a good indicator of physiological disorders. High oxygen and low CO₂ enhanced enzymatic browning, while low oxygen and, more significantly, high carbon dioxide enhanced CO₂ injury (brown stain). Maintaining CO₂ concentration within the packs below 5% resulted in an improved preservation of the lettuce leaves. Practical means for obtaining modified atmospheres which were in equilibrium yet were low in both O₂ and CO₂ are discussed.

Vasseur, L., and C. Potvin. 1998. Natural pasture community response to enriched carbon dioxide atmosphere. *Plant Ecology* 135(1):31-41.

We examined the response of a pasture community in southern Quebec (Canada) to long-term exposure of enriched atmospheric CO₂ conditions. The study was conducted using open-top growth chambers directly placed on top of the natural pasture community. To investigate the change in the overall species composition in time and space, we used canonical correspondence analysis, a direct ordination method. Over the three years, the overall community responded significantly to enriched CO₂. The analyses show that, after three years, CO₂ was the most important environmental variable affecting the species composition.

Initially the presence of the wall of the chambers influenced the composition but CO₂ became more important by the third year. Soil and air temperatures only slightly influenced the community composition. The first two axes of the canonical correspondence analysis explained a large proportion of the variation in the three years and these trends appeared to increase with time. Species such as *Agropyron repens* appeared to be positively influenced by the presence of the wall (slightly warmer conditions). However, the analyses suggest that *Phleum pratense* and *Trifolium repens*, for example, were favored by the increase in atmospheric CO₂. The variation in species composition in enriched versus ambient CO₂ chambers suggests that the effect of the environmental factors, particularly CO₂, were important in affecting the rate and pattern of succession. Furthermore, the temporal increase in importance of the variable CO₂ in the present analyses indicates that there might be a time-lag in response to atmospheric enrichment.

Veisz, O., N. Harnos, L. Szunics, and T. Tischner. 1996. Overwintering of winter cereals in Hungary in the case of global warming. *Euphytica* 92(1-2):249-253.

Under phytotronic conditions investigations were made on the effect of important environmental factors, such as temperature, water and an increasing concentration of atmospheric CO₂, on the hardening of young cereal plants. In all the varieties derived from the major wheat growing regions of the world the hardening process was favourably influenced by a doubling of atmospheric CO₂ content, so that a significantly larger number of plants survived the frost test than for plants of the same variety raised under normal conditions. A reduction in freezing temperature and an increase in soil moisture content caused a slight reduction in survival % for varieties with excellent frost resistance and a great reduction for those with medium or poor frost resistance. Predictions suggest that in Central Europe, as the result of global climatic changes, there will be a reduction in the quantity of winter precipitation, a considerable rise in winter temperatures and an increase in atmospheric CO₂ concentration. Judging by the experimental results, these changes could improve the overwintering of winter cereals; at the same time, however, a number of factors (mainly the reduction of precipitation) leading to yield losses must be expected during the vegetation period.

Velikova, V., T. Tsonev, and I. Yordanov. 1999. Light and CO₂ responses of photosynthesis and chlorophyll fluorescence characteristics in bean plants after simulated acid rain. *Physiologia Plantarum* 107(1):77-83.

The effects of simulated acid rain on some chlorophyll fluorescence characteristics and photosynthetic gas exchange at different light intensities and CO₂ concentrations of bean plants were investigated. Measurements were carried out 3, 5 and 24 h after spraying. The results showed that a single acid rain (pH 1.8) treatment of bean plants reduced gas exchange, the maximal carboxylating efficiency and photochemical quenching. This treatment led also to increased CO₂ compensation point and non-photochemical quenching and changed the shape of CO₂ and light curves of photosynthesis. Both stomatal and non-stomatal factors contributed to the decreased photosynthetic rate, but their proportion changed with time of recovery of the photosynthetic apparatus. Three hours after the treatment, the stomatal factors predominated in

photosynthesis reduction, while during the next experimental period (5-24 h), mainly non-stomatal factors determined the decreased photosynthetic rate. It is suggested that the effects observed in consequence of acid rain treatment could be due to an increased intracellular accumulation of H⁺ and harmful ions contained in the cocktail. This probably led to impaired membrane permeability, enhancement of stroma acidity, uncoupled electron transport and insufficient accumulation of ATP and NADPH, which affected carbon metabolism.

Ver, L.M.B., F.T. Mackenzie, and A. Lerman. 1999. Biogeochemical responses of the carbon cycle to natural and human perturbations: Past, present, and future. *American Journal of Science* 299(7-9):762-801.

In the past three centuries, human perturbations of the environment have affected the biogeochemical behavior of the global carbon cycle and that of the other three nutrient elements closely coupled to carbon: nitrogen, phosphorus, and sulfur. The partitioning of anthropogenic CO₂ among its various sinks in the past, for the present, and for projections into the near future is controlled by the interactions of these four elemental cycles within the major environmental domains of the land, atmosphere, coastal oceanic zone, and open ocean. We analyze the past, present, and future behavior of the global carbon cycle using the Terrestrial-Ocean-Atmosphere Ecosystem Model (TOTEM), a unique process-based model of the four global coupled biogeochemical cycles of carbon, nitrogen, phosphorus, and sulfur. We find that during the past 300 yrs, anthropogenic CO₂ was mainly stored in the atmosphere and in the open ocean. Human activities on land caused an enhanced loss of mass from the terrestrial organic matter reservoirs (phytomass and humus) mainly through deforestation and consequently increased humus remineralization, erosion, and transport to the coastal margins by rivers and runoff. Photosynthetic uptake by the terrestrial phytomass was enhanced owing to fertilization by increasing atmospheric CO₂ concentrations and supported by nutrients remineralized from organic matter. TOTEM results indicate that through most of the past 300 yrs, the loss of C from deforestation and other land-use activities was greater than the gain from the enhanced photosynthetic uptake. During the decade of the 1980s, the terrestrial organic reservoirs were in rough carbon balance. Organic and carbonate carbon accumulating in coastal marine sediments is a small but significant sink for anthropogenic CO₂. Increasing inputs of terrestrial organic matter and its subsequent oxidation in the coastal margin (increasing heterotrophy) were significant sources of CO₂ in coastal waters in the 20th century. However, the coastal ocean did not evolve into a greater net source of CO₂ to the atmosphere during this period because of the opposing pressure from rising atmospheric CO₂. Since pre-industrial time (since 1700), the net flux of CO₂ from the coastal waters has decreased by 40 percent, from 0.20 Gt C/yr to 0.12 Gt C/yr. TOTEM analyses of atmospheric CO₂ concentrations for the 21st century were based on the fossil-fuel emission projections of IPCC ("business as usual" scenario) and of the more restrictive UN 1997 Kyoto Protocol. By the mid-21st century, the projected atmospheric CO₂ concentrations range from about 550 ppmv (TOTEM, based on IPCC projected emissions) to 510 ppmv (IPCC projection) and to 460 ppmv (TOTEM, based on the Kyoto Protocol reduced emissions). The difference of about 40 ppmv between the IPCC and TOTEM estimates by the year 2050 reflects the different mechanisms within the C-N-P-S cycles on land that are built into our model. The effects of the reduced emissions prescribed by the Kyoto Protocol begin to show in the atmospheric CO₂ concentrations by the mid-21st century, when our model projects a rise to 460 (year 2050) and 490 ppmv (2075), relative to about 360 ppmv in 1995. However, these projected increases assume no major changes in the present

biogeochemical feedback mechanisms within the system of the coupled C-N-P-S cycles, no global changes in the kind and distribution of ecosystems in response to the rising CO₂ and possibly temperature, and no changes in the mechanisms of CO₂ exchange between the atmosphere and the ocean, such as could be induced by changes in the intensity of oceanic thermohaline circulation.

Verburg, P.S.J., A. Gorissen, and W.J. Arp. 1998. Carbon allocation and decomposition of root-derived organic matter in a plant-soil system of *Calluna vulgaris* as affected by elevated CO₂. *Soil Biology and Biochemistry* 30(10-11):1251-1258.

The effect of elevated CO₂ on C allocation in plant and soil was assessed using soil cores planted with 1-y-old heather (*Calluna vulgaris* (L.) Hull). Plants were pulse-labeled with (CO₂)-C-14 at ambient and elevated CO₂ and two nitrogen regimes (low and high). After harvesting the plants, the soil was incubated to monitor total respiration and decomposition of C-14-labeled rhizodeposits. Total and shoot biomass increased at high N but were not affected by CO₂. Root biomass was not affected by either N or CO₂ treatments. Total C-14 uptake and shoot-C-14 increased upon adding N and elevating CO₂ but the N effect was strongest. Total C-14 uptake per unit shoot mass decreased with N, but increased with CO₂. Root-C-14 content was not significantly affected by the N or CO₂ treatment. Total soil-C-14 slightly increased at elevated CO₂ whereas microbial C-14 increased due to high N. C allocation to shoots increased at the expense of roots, soil and respiration at high N but was not affected by the CO₂ treatment. Variation in C-14 distribution within each treatment was small compared to variation in total C-14 amounts in each plant-soil compartment. Initially, C-14 respiration from rhizodeposits correlated well with root-C-14, total soil-C-14, soil solution-C-14 and microbial C-14, at harvest time and was increased by elevated CO₂. By the end of the incubation, however, decomposition of labeled organic matter was not affected by the treatments whereas total (=C-12+C-14) respiration was lowest for the elevated-CO₂ soils. We speculate that initially, respiration is dominated by decomposition of fresh root exudates whereas in the longer term, respiration originates from decomposition of more recalcitrant root material that had been formed during the entire experiment. The increased net C-14 uptake and unchanged distribution pattern, combined with an increased decomposition of easily-decomposable compounds and a decreased decomposition of more recalcitrant root-derived material indicated a small sink function of a *Calluna* plant-soil system under elevated CO₂. Verburg, P.S.J., W.K.P. Van Loon, and A. Lukewille. 1999. The CLIMEX soil-heating experiment: soil response after 2 years of treatment. *Biology and Fertility of Soils* 28(3):271-276.

Most model predictions concerning the response of boreal forest ecosystems to climate change are inferred from small-scale experiments on artificial, simplified systems. Whole-ecosystem experiments designed to validate these models are scarce. We experimentally manipulated a small forested catchment in southern Norway by increasing soil temperature (+3 degrees C in summer to +5 degrees C in winter) using

heating cables installed at 1 cm depth in the litter layer. Especially nitrification in the 0 to 10-cm soil layer increased as a result of the climate manipulation. Betula litter, produced after exposing trees for 2 years to ambient and elevated CO₂ in greenhouses, was incubated for 1 year in the manipulated catchment. Exposure to elevated CO₂ did not affect the C/N ratio or decomposition of the Betula litter, but lignin content decreased by 10%. We found no effect of elevated temperature on litter decomposition, probably due to desiccation of the litter. The heating cables caused a permanent increase in soil temperature in this soil layer, but when soils were dry, the temperature difference between control and heated plots decreased with increasing distance from the cables. When soils were wet, no gradients in temperature increase occurred.

Vervuren, P.J.A., S.M.J.H. Beurskens, and C.W.P.M. Blom. 1999. Light acclimation, CO₂ response and long-term capacity of underwater photosynthesis in three terrestrial plant species. *Plant, Cell and Environment* 22(8):959-968.

To characterize underwater photosynthetic performance in some terrestrial plants, we determined (i) underwater light acclimation (ii) underwater photosynthetic response to dissolved CO₂, and (iii) underwater photosynthetic capacity during prolonged submergence in three species that differ in submergence tolerance: *Phalaris arundinacea*, *Rumex crispus* (both submergence-tolerant) and *Arrhenatherum elatius* (submergence-intolerant). None of the species had adjusted to low irradiance after 1 week of submergence. Under non-submerged (control) conditions, only *R. crispus* displayed shade acclimation. Submergence increased the apparent quantum yield in this species, presumably because of the enhanced CO₂ affinity of the elongated leaves. In control plants of the grass species *P. arundinacea* and *A. elatius*, CO₂ affinities were higher than for *R. crispus*. The underwater photosynthetic capacity of *R. crispus* increased during 1 month of submergence. In *P. arundinacea* photosynthesis remained constant during 1 month of submergence at normal irradiance; at low irradiance a reduction in photosynthetic capacity was observed after 2 weeks, although there was no tissue degeneration. In contrast, underwater photosynthesis of the submergence-intolerant species *A. elatius* collapsed rapidly under both irradiances, and this was accompanied by leaf decay. To describe photosynthesis versus irradiance curves, four models were evaluated. The hyperbolic tangent produced the best goodness-of-fit, whereas the rectangular hyperbola (Michaelis-Menten model) gave relatively poor results.

Vidal, R., A. Gerbaud, and D. Vidal. 1996. Short-term effects of high light intensities on soybean nodule activity and photosynthesis. *Environmental and Experimental Botany* 36(3):349-357.

There is little information available on the effects of highlight intensity (HLI) on nitrogenase activity in legume nodules. Inhibitory as well as stimulatory effects have been described. The hypothesis that an increase in carbohydrate production is involved in these effects was tested by comparing the effects of high light, high CO₂, or low O₂ exposure of the shoot. The HLI treatment consisted of tripling the light intensity to 1200 $\mu\text{E m}^{-2} \text{s}^{-1}$, compared with the growth intensity of 400 $\mu\text{E m}^{-2} \text{s}^{-1}$.

Acetylene reduction activity (ARA) measuring nitrogenase activity was studied in relation to shoot CO₂ exchange. HLI stimulated ARA. The stimulation was progressive and reached 17% after 10 hr of treatment. Photosynthesis (P) was initially doubled, but photoinhibition appeared after about 8 hr of HLI. Under HLI, P became limited by N fixation. Other treatments increasing photosynthesis were compared with HLI: elevating the ambient CO₂ concentration around the shoot to 900 ppm, or lowering the O₂ concentration to 2%, increased photosynthesis, respectively, by 55% and 70% without effect on ARA. It is concluded that ARA was not regulated by the availability of carbon assimilates and that specific factors promoting or inhibiting ARA are produced by leaves under HLI.

Viiil, J., and T. Parnik. 1992. Fast regulation of ribulose-1,5-bisphosphate carboxylase oxygenase activity during light dark light transitions. *Soviet Plant Physiology* 39(4):483-487.

On the basis of estimates of rubisco activity in leaves of barley (*Hordeum vulgare* L.), we established that it declined by 30-50% in 3-4 sec following disconnection of light in the presence of CO₂. In a medium without CO₂, rubisco activity did not change in this time. Keeping leaves at elevated CO₂ concentration lowered rubisco activity. This effect had a lasting aftereffect. With a sharp change of CO₂ concentration, the rate of assimilation in the first second was proportional to the increase of CO₂ concentration up to at least 1000 $\mu\text{mol liter}^{-1}$. It is recorded that CO₂ binds directly with the enol form of ribulose-1,5-bisphosphate (RuBP) without preliminary binding with the enzyme molecule.

Visser, A.J., M. Tosserams, M.W. Groen, G. Kalis, R. Kwant, G.W.H. Magendans, and J. Rozema. 1997. The combined effects of CO₂ concentration and enhanced UV-B radiation on faba bean. 3. Leaf optical properties, pigments, stomatal index and epidermal cell density. *Plant Ecology* 128(1-2):208-222.

Seedlings of *Vicia faba* L. (cv. Minica) were grown in a factorial experiment in a greenhouse. The purpose of the study was to determine whether CO₂ enrichment and supplemental UV-B radiation affect leaf optical properties and whether the combined effects differ from single factor effects. Seedlings were grown at either 380 $\mu\text{mol mol}^{-1}$ 750 $\mu\text{mol mol}^{-1}$ CO₂ and at four levels of W-B radiation. After 20 and 40 days of treatment, absorbance, transmittance and reflectance of photosynthetically active radiation (PAR) were measured on the youngest fully developed leaf. On the same leaf, the specific leaf area on a fresh weight basis (SLA(fw)), chlorophyll content, UV-B absorbance, transmittance of UV light and stomatal index were measured. W-B radiation significantly increased PAR absorbance and decreased PAR transmittance. The increased PAR absorbance can be explained by an increased chlorophyll content in response to W-B radiation. Leaf transmittance of UV radiation decreased with increasing UV-B levels mainly caused by increased absorbance of UV absorbing compounds. UV-B radiation decreased both the stomatal density and epidermal cell density of the abaxial leaf surface, leaving the stomatal index unchanged. Effects of CO₂ enrichment were less pronounced than those of W-B radiation. The most important CO₂ effect was an increase in stomatal density and epidermal cell density of the adaxial leaf surface.

The stomatal index was not affected. No interaction between CO₂ and UV-B radiation was found. The results are discussed in relation to the internal light environment of the leaf.

Visser, A.J., M. Tosserams, M.W. Groen, G.W.H. Magendans, and J. Rozema. 1997. The combined effects of CO₂ concentration and solar UV-B radiation on faba bean grown in open-top chambers. *Plant, Cell and Environment* 20(2):189-199.

The response of faba bean seedlings to the combined effects of increased atmospheric CO₂ concentrations ([CO₂]) and solar UV-B irradiance was studied using open-top chambers transparent to W-B radiation. The purpose of the study was to determine whether effects of increased [CO₂] on growth and physiology are modified by the present solar UV-B fluence rate in the Netherlands. Seedlings were exposed to 350 or 700 $\mu\text{mol}(-1)\text{CO}_2$. At both [CO₂], solar UV-B irradiance was either present or reduced using polyester foil opaque to UV-B radiation. To obtain information on the time dependence of increased [CO₂] and UV-B radiation effects, three harvests were performed during the experiment. CO₂ enrichment resulted in increased biomass production at all harvests. At the final harvest, UV-B radiation did not affect biomass production but a significant decrease was observed after 14 d of treatment. A reduction of the UV-B fluence increased shoot length at both [CO₂] throughout the experiment, UV-B radiation slightly altered biomass allocation. Plants grown at reduced levels of UV-B radiation invested less biomass in flowers and more in stem material compared to plants grown at ambient UV-B levels. CO₂ enrichment resulted in a stimulation of net photosynthesis after 26 and 38 d of treatment. UV-B reduction did not alter this response. After 26 d of treatment, photosynthetic acclimation to CO₂ enrichment was observed, which was probably the result of accumulation of carbohydrates in the leaves. After 38 d, photosynthetic acclimation was no longer present. The UV absorbance of methanolic leaf extracts was increased by CO₂ enrichment only. Both CO₂ enrichment and solar UV-B reduced the transmittance of radiation through intact attached leaves. Interaction between [CO₂] and UV-B radiation was limited to UV-A transmittance of leaves. Under prevalent experimental conditions, UV-B radiation did not affect the measured physiological parameters. Most open-top chambers used for climate change research are constructed of materials which do not transmit UV-B radiation. Our results indicate that part of the 'chamber effects' on plant height often described in the literature might be explained by the absence of solar UV-B radiation in these chambers.

Vitousek, P.M. 1994. Beyond global warming - ecology and global change. *Ecology* 75(7):1861-1876.

While ecologists involved in management or policy often are advised to learn to deal with uncertainty, there are a number of components of global environmental change of which we are certain-certain that they are going on, and certain that they are human-caused. Some of these are largely ecological changes, and all have important ecological consequences. Three of the well-documented global changes are: increasing concentrations of carbon dioxide in the atmosphere;

alterations in the biogeochemistry of the global nitrogen cycle; and ongoing land use/land cover change. Human activity-now primarily fossil fuel combustion-has increased carbon dioxide concentrations from similar to 280 to 355 $\mu\text{mol L}^{-1}$ since 1800; the increase is unique, at least in the past 160 000 yr, and several lines of evidence demonstrate unequivocally that it is human-caused. This increase is likely to have climatic consequences-and certainly it has direct effects on biota in all Earth's terrestrial ecosystems. The global nitrogen cycle has been altered by human activity to such an extent that more nitrogen is fixed annually by humanity (primarily for nitrogen fertilizer, also by legume crops and as a byproduct of fossil fuel combustion) than by all natural pathways combined. This added nitrogen alters the chemistry of the atmosphere and of aquatic ecosystems, contributes to eutrophication of the biosphere, and has effects on biological diversity in the most affected areas. Finally, human land use/land cover change has transformed one-third to one-half of Earth's ice-free surface. This in and of itself probably represents the most important component of global change now and will for some decades to come; it has profound effects on biological diversity on land and on ecosystems downwind and downstream of affected areas. Overall, any clear dichotomy between pristine ecosystems and human-altered areas that may have existed in the past has vanished, and ecological research should account for this reality. These three and other equally certain components of global environmental change are the primary causes of anticipated changes in climate, and of ongoing losses of biological diversity. They are caused in turn by the extraordinary growth in size and resource use of the human population. On a broad scale, there is little uncertainty about any of these components of change or their causes. However, much of the public believes the causes-even the existence-of global change to be uncertain and contentious topics. By speaking out effectively, we can help to shift the focus of public discussion towards what can and should be done about global environmental change.

Vitousek, P.M., and C.B. Field. 1999. Ecosystem constraints to symbiotic nitrogen fixers: a simple model and its implications. *Biogeochemistry* 46(1):179-202.

The widespread occurrence of N limitation to net primary production (NPP) and other ecosystem processes, despite the ubiquitous occurrence of N-fixing symbioses, remains a significant puzzle in terrestrial ecology. We describe a simple simulation model for an ecosystem containing a generic nonfixer and a symbiotic N fixer, based on: (1) a higher cost for N acquisition by N fixers than nonfixers; (2) growth of fixers and fixation of N only when low N availability limits the growth of nonfixers, and other resources are available; and (3) losses of fixed N from the system only when the quantity of available N exceeds plant and microbial demands. Despite the disadvantages faced by the N fixer under these conditions, N fixation and loss adjust N availability close to the availability of other resources, and biomass and NPP in this simple model can be substantially but only transiently N limited. We then modify the model by adding: (1) losses of N in forms other than excess available N (e.g., dissolved organic N, trace gases produced by nitrification); and (2) constraints to the growth and activity of N fixers imposed by differential effects of shading, P limitation, and grazing. The combination of these processes is sufficient to describe an open system, with input from both precipitation and N fixation, that is nevertheless strongly N-limited at equilibrium. This model is useful for exploring causes and consequences of constraints to N fixation, and hence of N limitation, and we believe it will also be useful for evaluating how N fixation and limitation interact with elevated CO₂ and other components

of global environmental change.

Vivin, P., P. Gross, G. Aussenac, and J.M. Guehl. 1995. Whole-plant CO₂ exchange, carbon partitioning and growth in *Quercus robur* seedlings exposed to elevated CO₂. *Plant Physiology and Biochemistry* 33(2):201-211.

Pedunculate oak acorns (*Quercus robur* L.) were germinated and grown under nonlimiting nutritional and water conditions in controlled-environment greenhouses with ambient (350 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) CO₂ concentrations. A semiclosed gas exchange measurements, and (CO₂)-C-13 labelling, system (1.5% (CO₂)-C-13) was used to simultaneously assess (a) the CO₂ exchange of both aerial and below-ground (roots plus soil) compartments of the soil-plant system and (b) the partitioning of the recently photo-assimilated carbon. Measurements were made during the fast aerial growth phase (July 30) and at the end of the growing season (October 15). On July 30, whole-plant dry mass had been increased by 44% since the beginning of the growing season in the elevated CO₂ treatment, whereas at the end of the growing season the enhancing effect was only 17%. Elevated CO₂ stimulated net CO₂ assimilation rate per unit leaf area (A) in July (+40%), whereas in October this stimulation had disappeared. The respiratory CO₂ evolution of the root-soil compartment (individual plant basis) was stimulated by 35% under the elevated CO₂ conditions on July 30, but not on October 15. In July, relative specific allocation (RSA), a parameter expressing the sink strength, was higher in all compartments under 700 $\mu\text{mol mol}^{-1}$ compared to 350 $\mu\text{mol mol}^{-1}$. Moreover in root tips, the RSA values determined 4 h after the labelling were particularly high (7.8%) with elevated CO₂, whereas under ambient CO₂ RSA values were close to zero.

Vivin, P., and J.M. Guehl. 1997. Changes in carbon uptake and allocation patterns in *Quercus robur* seedlings in response to elevated CO₂ and water stress: an evaluation with C-13 labelling. *Annales Des Sciences Forestieres* 54(7):597-610.

A semi-closed (CO₂)-C-13 labelling system (1.5% C-13) was used to assess both carbon uptake and allocation within pedunculate oak seedlings (*Quercus robur* L.) grown under ambient (350 vpm) and elevated (700 vpm) atmospheric CO₂ concentration ([CO₂]) and in either well-watered or droughted conditions. Pulse-chase C-13 labelling data highlighted the direct positive effect of elevated CO₂ on photosynthetic carbon acquisition. Consequently, in well-watered conditions, CO₂-enriched plants produced 1.52 times more biomass (dry mass at harvest) and 1.33 times more dry root matter (coarse plus fine roots) over the 22-week growing period than plants grown under ambient [CO₂]. The root/shoot biomass ratio was decreased both by drought and [CO₂], despite lower N concentrations in CO₂-enriched plants. However, both long-term and short-term C allocation to fine roots were not altered by CO₂, and relative specific allocation (RSA), a parameter expressing sink strength, was higher in all plant organs under 700 vpm compared to 350 vpm. Results showed that C availability for growth and metabolic processes was greater in fine roots of oaks grown under an elevated CO₂ atmosphere irrespective of soil water availability.

Vivin, P., J.M. Guehl, A.M. Clement, and G. Aussenac. 1996. The effects of elevated CO₂ and water stress on whole plant CO₂ exchange, carbon allocation and osmoregulation in oak seedlings. *Annales Des Sciences Forestieres* 53(2-3):447-459.

Seedlings of *Quercus robur* L. grown under present (350 $\mu\text{mol mol}^{-1}$) or twice the present (700 $\mu\text{mol mol}^{-1}$) atmospheric CO₂ concentrations, were either maintained well-watered or subjected to a drought constraint late in the growing season (25 August 1993). Despite an initial stimulation of biomass growth (+44%) by elevated CO₂, there was no significant difference in plant dry weight at the end of the growing season (15 October 1993) between the two CO₂ treatments, irrespective of watering regime. Under drought conditions, although there was no growth increase in response to elevated CO₂ concentration, there was a stimulation in net photosynthesis. In addition, the respiration rate of the root + soil system (root dry matter basis) was slightly lower in the elevated than in the ambient CO₂ concentration. These results, together with the results from short-term C-13 labelling, suggest enhanced plant carbon losses through processes not assessed here (aerial respiration, root exudation, etc) under elevated CO₂ concentration. In the droughted conditions, new carbon relative specific allocation values (RSA) were greater under elevated CO₂ than under ambient CO₂ concentration in both leaf and root compartments. Osmotic potentials at full turgor ($\pi(o)$) were lowered in response to water stress in leaves by 0.4 MPa for the elevated CO₂ treatment only. In roots, osmotic adjustment (0.3 MPa) occurred in both the CO₂ treatments.

Vivin, P., F. Martin, and J.M. Guehl. 1996. Acquisition and within-plant allocation of C-13 and N-15 in CO₂-enriched *Quercus robur* plants. *Physiologia Plantarum* 98(1):89-96.

We assessed the effects of doubling atmospheric CO₂ concentration, [CO₂], on C and N allocation within pedunculate oak plants (*Quercus robur* L.) grown in containers under optimal water supply. A short-term dual (CO₂)-C-13 and (NO₃-)-N-15 labelling experiment was carried out when the plants had formed their third growing flush. The 22-week exposure to 700 $\mu\text{mol l}^{-1}$ [CO₂] stimulated plant growth and biomass accumulation (+53% as compared with the 350 $\mu\text{mol l}^{-1}$ [CO₂] treatment) but decreased the root/shoot biomass ratio (-23%) and specific leaf area (-18%). Moreover, there was an increase in net CO₂ assimilation rate (+37% on a leaf dry weight basis; +71% on a leaf area basis), and a decrease in both above- and below-ground CO₂ respiration rates (-32 and -26%, respectively, on a dry mass basis) under elevated [CO₂]. C-13 acquisition, expressed on a plant mass basis or on a plant leaf area basis, was also markedly stimulated under elevated [CO₂] both after the 12-h (CO₂)-C-13 pulse phase and after the 60-h chase phase. Plant N content was increased under elevated CO₂ (+36%), but not enough to compensate for the increase in plant C content (+53%). Thus, the plant C/N ratio was increased (+13%) and plant N concentration was decreased (-11%). There was no effect of elevated [CO₂] on fine root-specific N-15 uptake (amount of recently assimilated N-15 per unit fine root dry mass), suggesting that modifications of plant N pools were merely linked to root size and not to root function. N concentration was decreased in the leaves of the first and second growing flushes and in the coarse roots, whereas it was unaffected by [CO₂] in the stem and in the

actively growing organs (fine roots and leaves of the third growth flush). Furthermore, leaf N content per unit area was unaffected by [CO₂]. These results are consistent with the short-term optimization of N distribution within the plants with respect to growth and photosynthesis. Such an optimization might be achieved at the expense of the N pools in storage compartments (coarse roots, leaves of the first and second growth flushes). After the 60-h C-13 chase phase, leaves of the first and second growth flushes were almost completely depleted in recent C-13 under ambient [CO₂], whereas these leaves retained important amounts of recently assimilated C-13 (carbohydrate reserves?) under elevated [CO₂].

Vloedbeld, M., and R. Leemans. 1993. Quantifying feedback processes in the response of the terrestrial carbon-cycle to global change - the modeling approach of image-2. *Water, Air, and Soil Pollution* 70(1-4):615-628.

The terrestrial biosphere component of the Integrated Model to Assess the Greenhouse Effect (IMAGE 2) uses changes in land cover to compute dynamically the C fluxes between the terrestrial biosphere and the atmosphere. The model explores the potential impact of feedback processes incorporated in the model, which are the enhancement of plant growth (CO₂ fertilization) and a more efficient use of water under increased CO₂ concentrations in the atmosphere; the temperature response of photosynthesis and respiration of plants; the temperature and soil water response of decomposition processes; and the climate-induced changes in vegetation and agricultural patterns with the consequent changes in land cover. In this paper we discuss the implementation and operation of the different feedback processes in the IMAGE 2 model. Results are shown for each process separately as well as the combined processes. The aim of this paper is to quantify the importance of these feedback processes geographically. The main results are that vegetation shifts due to climatic change and increased water use efficiency, CO₂ fertilization decreases net C emissions, while changed decomposition rates strongly increase C emissions to the atmosphere. Changes in the global balance between photosynthesis and respiration make little net difference. With the IPPC business-as-usual scenario the terrestrial biosphere continues to emit C into the atmosphere. This behavior is governed by changes in land-use, caused by a multitude of anthropogenic processes.

Voesenek, L.A.C.J., W.H. Vriezen, M.J.E. Smekens, F.H.M. Huitink, G.M. Bogemann, and C.W.P.M. Blom. 1997. Ethylene sensitivity and response sensor expression in petioles of Rumex species at low O-2 and high CO₂ concentrations. *Plant Physiology* 114(4):1501-1509.

Rumex palustris, a flooding-tolerant plant, elongates its petioles in response to complete submergence. This response can be partly mimicked by enhanced ethylene levels and low O-2 concentrations. High levels of CO₂ do not markedly affect petiole elongation in *R. palustris*. Experiments with ethylene synthesis and action inhibitors demonstrate that treatment with low O-2 concentrations enhances petiole extension by shifting sensitivity to ethylene without changing the rate of ethylene production. The expression level of the *R. palustris* gene coding for the putative ethylene receptor (RP-ERS1) is up-regulated by 3% O-2 and

increases after 20 min of exposure to a low concentration of O-2, thus preceding the first significant increase in elongation observable after 40 to 50 min. In the flooding-sensitive species *Rumex acetosa*, submergence results in a different response pattern: petiole growth of the submerged plants is the same as for control plants. Exposure of *R. acetosa* to enhanced ethylene levels strongly inhibits petiole growth. This inhibitory effect of ethylene on *R. acetosa* can be reduced by both low levels of O-2 and/or high concentrations of CO₂.

Vogel, C.S., and P.S. Curtis. 1995. Leaf gas-exchange and nitrogen dynamics of n-2-fixing field-grown *Alnus glutinosa* under elevated atmospheric CO₂. *Global Change Biology* 1(1):55-61.

Few studies have investigated the effects of elevated CO₂ on the physiology of symbiotic N-2-fixing trees. Tree species grown in low N soils at elevated CO₂ generally show a decline in photosynthetic capacity over time relative to ambient CO₂ controls. This negative adjustment may be due to a reallocation of leaf N away from the photosynthetic apparatus, allowing for more efficient use of limiting N. We investigated the effect of twice ambient CO₂ on net CO₂ assimilation (A), photosynthetic capacity, leaf dark respiration, and leaf N content of N-2-fixing *Alnus glutinosa* (black alder) grown in field open top chambers in a low N soil for 160 d. At growth CO₂, A was always greater in elevated compared to ambient CO₂ plants. Late season A vs. internal leaf p(CO₂) response curves indicated no negative adjustment of photosynthesis in elevated CO₂ plants. Rather, elevated CO₂ plants had 16% greater maximum rate of CO₂ fixation by Rubisco. Leaf dark respiration was greater at elevated CO₂ on an area basis, but unaffected by CO₂ on a mass or N basis. In elevated CO₂ plants, leaf N content (μg N cm⁻²) increased 50% between Julian Date 208 and 264. Leaf N content showed little seasonal change in ambient CO₂ plants. A single point acetylene reduction assay of detached, nodulated root segments indicated a 46% increase in specific nitrogenase activity in elevated compared to ambient CO₂ plants. Our results suggest that N-2-fixing trees will be able to maintain high A with minimal negative adjustment of photosynthetic capacity following prolonged exposure to elevated CO₂ on N-poor soils.

Vogel, C.S., P.S. Curtis, and R.B. Thomas. 1997. Growth and nitrogen accretion of dinitrogen-fixing *Alnus glutinosa* (L.) Gaertn under elevated carbon dioxide. *Plant Ecology* 130(1):63-70.

Short-term studies of tree growth at elevated CO₂ suggest that forest productivity may increase as atmospheric CO₂ concentrations rise, although low soil N availability may limit the magnitude of this response. There have been few studies of growth and N-2 fixation by symbiotic N-2-fixing woody species under elevated CO₂ and the N inputs these plants could provide to forest ecosystems in the future. We investigated the effect of twice ambient CO₂ on growth, tissue N accretion, and N-2 fixation of nodulated *Alnus glutinosa* (L.) Gaertn. grown under low soil N conditions for 160 d. Root, nodule, stem, and leaf dry weight (DW) and N accretion increased significantly in response to elevated CO₂. Whole-plant biomass and N accretion increased 54% and 40%, respectively. Delta-N-15 analysis of leaf tissue indicated that

plants from both treatments derived similar proportions of their total N from symbiotic fixation suggesting that elevated CO₂ grown plants fixed approximately 40% more N than did ambient CO₂ grown plants. Leaves from both CO₂ treatments showed similar relative declines in leaf N content prior to autumnal leaf abscission, but total N in leaf litter increased 24% in elevated compared to ambient CO₂ grown plants. These results suggest that with rising atmospheric CO₂ N₂-fixing woody species will accumulate greater amounts of biomass N through N₂ fixation and may enhance soil N levels by increased litter N inputs.

Volin, J.C., and P.B. Reich. 1996. Interaction of elevated CO₂ and O-3 on growth, photosynthesis and respiration of three perennial species grown in low and high nitrogen. *Physiologia Plantarum* 97(4):674-684.

Seedlings of three species native to central North America, a C-3 tree, *Populus tremuloides* Michx., a C-3 grass, *Agropyron smithii* Rybd., and a C-4 grass, *Bouteloua curtipendula* Michx., were grown in all eight combinations of two levels each of CO₂, O-3 and nitrogen (N) for 58 days in a controlled environment. Treatment levels consisted of 360 or 674 $\mu\text{mol mol}^{-1}$ CO₂, 3 or 92 nmol mol^{-1} O-3, and 0.5 or 6.0 mM N. In situ photosynthesis and relative growth rate (RGR) and its determinants were obtained at each of three sequential harvests, and leaf dark respiration was measured at the second and third harvests. In all three species, plants grown in high N had significantly greater whole-plant mass, RGR and photosynthesis than plants grown in low N. Within a N treatment, elevated CO₂ did not significantly enhance any of these parameters nor did it affect leaf respiration. However, plants of all three species grown in elevated CO₂ had lower stomatal conductance compared to ambient CO₂-exposed plants. Seedlings of *P. tremuloides* (in both N treatments) and *B. curtipendula* (in high N) had significant ozone-induced reductions in whole-plant mass and RGR in ambient but not under elevated CO₂. This negative O-3 impact on RGR in ambient CO₂ was related to increased leaf dark respiration, decreased photosynthesis and/or decreased leaf area ratio, none of which were noted in high O-3 treatments in the elevated CO₂ environment. In contrast, *A. smithii* was marginally negatively affected by high O-3.

Volin, J.C., P.B. Reich, and T.J. Givnish. 1998. Elevated carbon dioxide ameliorates the effects of ozone on photosynthesis and growth: species respond similarly regardless of photosynthetic pathway or plant functional group. *New Phytologist* 138(2):315-325.

Due to their different physiological effects, elevated carbon dioxide and elevated ozone might have interactive impacts on plants, and differentially so on plants differing in photosynthetic pathway and growth rate. To test several hypotheses related to these issues, we examined the physiological, morphological and growth responses of six perennial species grown at various atmospheric concentrations of carbon dioxide and ozone. The species involved (two C-3 trees: *Populus tremuloides* Michx., *Quercus rubra* L.; two C-3 grasses: *Agropyron smithii* Rybd., *Koeleria cristata* L.; two C-4 grasses: *Bouteloua curtipendula* Michx., *Schizachyrium scoparium* Michx.) differed in growth form, stomatal conductance and photosynthetic pathway. In situ photosynthesis, relative growth rate (RGR) and its determinants (leaf area ratio, specific leaf area, leaf weight ratio and root weight ratio) were

determined via sequential harvests of seedlings that were grown in all combinations of 366 or 672 $\mu\text{mol mol}^{-1}$ CO₂ and 3 or 95 nmol mol^{-1} O-3 over a 101-d period. Elevated CO₂ had minimal effect on either photosynthesis or RGR. By contrast, RGR for all six species was lower in high O-3 concentrations at ambient CO₂, significantly so in *A. smithii* and *P. tremuloides*. Five of the six species also exhibited reductions in in situ photosynthesis at ambient CO₂ in high-O-3-grown compared with low-O-3-grown plants. For all species, these O-3-induced reductions in RGR and photosynthesis were absent in the elevated CO₂ environment. Root weight ratio was significantly reduced by elevated O-3 in *A. smithii* and *P. tremuloides* in ambient but not elevated CO₂. Species with high stomatal conductance were the most susceptible to oxidant injury, while those with low stomatal conductance, such as the C-4 species and *Q. rubra*, were not as detrimentally affected by O-3. Elevated levels of CO₂ will reduce stomatal conductance and O-3 uptake, and might therefore reduce the potential for oxidant damage. However, there was a stronger relationship of the percent reduction in whole-plant mass due to O-3, related to the ratio of photosynthesis to stomatal conductance. In general, results of this study of six functionally diverse plant species suggest that O-3 pollution effects on carbon balance and growth are likely to be ameliorated by elevated concentrations of atmospheric CO₂.

Volin, J.C., M.G. Tjoelker, J. Oleksyn, and P.B. Reich. 1993. Light environment alters response to ozone stress in seedlings of acer-saccharum marsh and hybrid populus L. 2. Diagnostic gas-exchange and leaf chemistry. *New Phytologist* 124(4):637-646.

Diagnostic gas exchange measurements and foliar chemical assays were conducted on hybrid poplar (*Populus tristis* Fisch. x *P. balsamifera* L. cv. *Tristis*) and sugar maple (*Acer saccharum* Marsh.) seedlings grown under contrasting light and ozone treatments. Seedlings were grown in low irradiance (c. 2.5 $\text{mol m}^{-2} \text{d}^{-1}$) and six-fold greater irradiance (c. 16.6 $\text{mol m}^{-2} \text{d}^{-1}$) in combination with low (< 10 nl l^{-1}) and elevated (99-115 nl l^{-1}) ozone. Analysis of light response curves showed ozone-induced reductions in photosynthetic capacity and quantum yield for unshaded poplar and shaded sugar maple, but not the contrasting light treatments. Photosynthesis at saturating CO₂ concentrations was decreased in the elevated ozone treatment in both the unshaded and shaded poplar and in shaded sugar maple. Poplar had significant reductions in chlorophyll concentration due to ozone exposure in both unshaded and shaded treatments. Older leaves of unshaded poplar plants had significantly greater reductions in chlorophyll levels due to ozone than older leaves of shaded plants. In maple, only shade-grown leaves had significant decreases in chlorophyll concentration due to ozone exposure. The diagnostic gas exchange measurements in conjunction with chlorophyll measurements indicate that in hybrid poplar, unshaded leaves may be more sensitive to ozone than shade leaves, while in sugar maple, shade leaves are more sensitive to ozone. For hybrid poplar a decrease in photosynthetic capacity, quantum yield and chlorophyll concentration in the unshaded, moderately high light environment due to elevated ozone is consistent with prior studies. The results indicating that sugar maple seedlings may be more detrimentally affected by elevated ozone in the lower light environment may have serious implications for this and other shade-adapted species with respect to their performance in an understory environment.

von Tiedemann, A., and K.H. Firsching. 1998. Combined whole-season effects of elevated ozone and carbon dioxide concentrations on a simulated wheat leaf rust (*Puccinia recondita* f. sp. *tritici*) epidemic. *Zeitschrift Fur Pflanzenkrankheiten Und Pflanzenschutz-Journal of Plant Diseases and Protection* 105(6):555-566.

A complete growth season with the physical climate and ozone pollution from 1 April to 31 July as recorded at a field site in Northern Germany, averaged over several years, was simulated in climate chambers and combined either with a current (370-400 $\mu\text{L}(-1)$) or enriched (620-650 $\mu\text{L}(-1)$) CO_2 atmosphere. Wheat, grown from seedling emergence to maturity under the different physico-chemical climates, was inoculated with leaf rust (*Puccinia recondita* f. sp. *tritici*) at tillering stage and a rust epidemic was induced by repeated re-inoculations with the newly Formed inoculum. Ozone significantly reduced disease severity, uredospore production and increased the latent period of leaf rust on young plants, consequently inhibiting the epidemic spread on upper leaves of mature plants. Inhibiting effects of ozone on leaf rust development were not reflected by the early infection stages such as spore germination, germ tube growth, formation of infection hyphae, haustorial mother cells and haustoria, which remained largely unaffected by the ozone treatments. However, ozone induced a significantly higher extent of hypersensitive responses of the infected leaf tissue. Additionally, plants exposed to elevated ozone turned senescent much earlier than plants without this stress which prematurely degraded the growth conditions for the fungal pathogen. Enrichment with CO_2 increased the total carbohydrate content in leaves but this had only minor effects on the disease. Thus, elevated CO_2 only poorly compensated for the disease-inhibiting effects of ozone. The compensation of ozone effects on wheat leaf rust by elevated CO_2 is much smaller than known compensatory effects of both gases on plant productivity.

Vose, J.M., K.J. Elliott, D.W. Johnson, D.T. Tingey, and M.G. Johnson. 1997. Soil respiration response to three years of elevated CO_2 and N fertilization in ponderosa pine (*Pinus ponderosa* Dong Ex Laws). *Plant and Soil* 190(1):19-28.

We measured growing season soil CO_2 evolution under elevated atmospheric $[\text{CO}_2]$ and soil nitrogen (N) additions. Our objectives were to determine treatment effects, quantify seasonal variation, and compare two measurement techniques. Elevated $[\text{CO}_2]$ treatments were applied in open-top chambers containing ponderosa pine (*Pinus ponderosa* L.) seedlings. N applications were made annually in early spring. The experimental design was a replicated factorial combination of CO_2 (ambient, +175, and +350 $\mu\text{L}(-1)$ CO_2) and N (0, 10, and 20 g $\text{m}(-2)$ N as ammonium sulphate). Soils were irrigated to maintain soil moisture at > 25 percent. Soil CO_2 evolution was measured over diurnal periods (20-22 hours) in October 1992, and April, June, and October 1993 and 1994 using a flow-through, infrared gas analyzer measurement system and corresponding pCO_2 measurements were made with gas wells. Significantly higher soil CO_2 evolution was observed in the elevated CO_2 treatments; N effects were not significant. Averaged across all measurement periods, fluxes, were 4.8, 8.0, and 6.5 for ambient + 175 CO_2 , and +350 CO_2 respectively). Treatment variation was linearly related to fungal occurrence as observed in minirhizotron tubes. Seasonal variation in soil CO_2 evolution was non-linearly related to soil temperature; i.e., fluxes increased up to approximately soil temperature (10cm soil depth) and decreased dramatically at temperatures > 18 degrees C. These patterns indicate exceeding optimal temperatures for biological activity. The dynamic, flow-through measurement system was weakly correlated ($r = 0.57$; $p < 0.0001$; $n = 56$) with the pCO_2

measurement method.

Vose, J.M., K.J. Elliott, D.W. Johnson, R.F. Walker, M.G. Johnson, and D.T. Tingey. 1995. Effects of elevated CO_2 and N fertilization on soil respiration from ponderosa pine (*Pinus ponderosa*) in open-top chambers. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 25(8):1243-1251.

We measured growing season soil CO_2 evolution under elevated atmospheric CO_2 and soil nitrogen (N) additions. Our objectives were to determine treatment effects, quantify seasonal variation, and determine regulating mechanisms. Elevated CO_2 treatments were applied in open-top chambers containing 3-year-old ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) seedlings. Nitrogen applications were made annually in early spring. The experimental design was a replicated factorial combination of CO_2 (ambient, +175, and +350 $\mu\text{L}(-1)$ CO_2) and N (0, 10, and 20 g $\text{m}(-2)$ N as ammonium sulfate). Soils were irrigated to maintain soil moisture at >25%. Soil CO_2 evolution was measured over diurnal periods (20-22 h) in April, June, and October 1993 using a flow-through, infrared gas analyzer measurement system. To examine regulating mechanisms, we linked our results with other studies measuring root biomass with destructive sampling and root studies using minirhizotron techniques. Significantly higher soil CO_2 evolution was observed in the elevated CO_2 treatments in April and October; N effects were not significant. In October, integrated daily values for CO_2 evolution ranged from 3.73 to 15.68 g $\text{CO}_2 \cdot \text{m}(-2)\text{day}(-1)$ for the ambient CO_2 + 0 N and 525 $\mu\text{L}(-1)$ CO_2 + 20 g $\text{m}(-2)$ N, respectively. Soil CO_2 flux among treatments was correlated with coarse root biomass ($r^2 = 0.40$; $p > F = 0.0380$), indicating that at least some of the variation observed among treatments was related to variation in root respiration. Across all sample periods and treatments, there was a significant correlation ($r^2 = 0.63$; $p > F = 0.0001$) between soil CO_2 evolution and percent fungal hyphae observed in minirhizotron tubes. Hence, some of the seasonal and treatment variation was also related to differences in heterotrophic activity.

Vourlitis, G.L., W.C. Oechel, S.J. Hastings, and M.A. Jenkins. 1993. A system for measuring insitu CO_2 and CH_4 flux in unmanaged ecosystems - an arctic example. *Functional Ecology* 7(3):369-379.

1. A passive, rapid response, closed system was developed to measure in situ ecosystem CO_2 and CH_4 flux in 0.5-m² plots over diurnal, seasonal, and annual time scales in arctic tundra ecosystems. The system consists of a chamber measuring 0.75 m on a side, 0.3 m in height, with acrylic sides, a mylar top, and 6-10 cm radial fans to ensure thorough mixing of the chamber environment. 2. CO_2 concentration and flux rates were measured using a Li-Cor 6200 Portable Photosynthesis System, which is capable of measuring 0.1 p.p.m. s⁻¹ changes in CO_2 concentration. CH_4 flux rates were measured by sequential sampling of the CH_4 concentration in the chamber over the duration of a 15-20-min incubation period. 3. Performance analyses indicate that light attenuation was less-than-or-equal-to 10% of ambient light. The rate of temperature increase within the chamber over the duration of the measurement period was approximately 1-5-degrees-C and 0.2-degrees-

C for the majority of the sampling days at tussuck tundra and wet coastal tundra sites, respectively. The maximum increase in thaw depth due to the bases was approximately 10%, and was a function of the site water balance and the amount of time that the bases were in place. Generally, thaw depth in plots with bases was greater when the bases were in place for a longer period of time (greater-than-or-equal-to 1 year), while the bases that were installed during the current growing season had a small effect on plot thaw depths. 4. The system had a minimal effect on ecosystem CO₂ flux, compared to plots that lacked bases in a wet coastal tundra and southern California turf ecosystem. 5. The system was successfully used to measure the effect of light intensity, soil temperature, and water balance on ecosystem CO₂ flux. 6. Due to the rapid response of the system, high sensitivity to low flux rates, high portability, low cost, potential for use in field experiments, and non-invasive sampling design, the system allows for the reliable measurement of CO₂, CH₄, and other trace gas flux rates in a variety of ecosystem types.

Vu, J.C.V., L.H. Allen, K.J. Boote, and G. Bowes. 1997. Effects of elevated CO₂ and temperature on photosynthesis and Rubisco in rice and soybean. *Plant, Cell and Environment* 20(1):68-76.

Rice (*Oryza sativa* L. cv. IR-72) and soybean (*Glycine max* L. Merr. cv. Bragg), which have been reported to differ in acclimation to elevated CO₂, were grown for a season in sunlight at ambient and twice-ambient [CO₂], and under daytime temperature regimes ranging from 28 to 40 degrees C. The objectives of the study were to test whether CO₂ enrichment could compensate for adverse effects of high growth temperatures on photosynthesis, and whether these two C-3 species differed in this regard. Leaf photosynthetic assimilation rates (A) of both species, when measured at the growth [CO₂], were increased by CO₂ enrichment, but decreased by supraoptimal temperatures. However, CO₂ enrichment more than compensated for the temperature-induced decline in A. For soybean, this CO₂ enhancement of A increased in a linear manner by 32-95% with increasing growth temperatures from 28 to 40 degrees C, whereas with rice the degree of enhancement was relatively constant at about 60%, from 32 to 38 degrees C. Both elevated CO₂ and temperature exerted coarse control on the Rubisco protein content, but the two species differed in the degree of responsiveness. CO₂ enrichment and high growth temperatures reduced the Rubisco content of rice by 22 and 23%, respectively, but only by 8 and 17% for soybean. The maximum degree of Rubisco down-regulation appeared to be limited, as in rice the substantial individual effects of these two variables, when combined, were less than additive. Fine control of Rubisco activation was also influenced by both elevated [CO₂] and temperature. In rice, total activity and activation were reduced, but in soybean only activation was lowered. The apparent catalytic turnover rate (K-cat) of rice Rubisco was unaffected by these variables, but in soybean elevated [CO₂] and temperature increased the apparent K-cat by 8 and 22%, respectively. Post-sunset declines in Rubisco activities were accelerated by elevated [CO₂] in rice, but by high temperature in soybean, suggesting that [CO₂] and growth temperature influenced the metabolism of 2-carboxyarabinitol-1-phosphate, and that the effects might be species-specific. The greater capacity of soybean for CO₂ enhancement of A at supraoptimal temperatures was probably not due to changes in stomatal conductance, but may be partially attributed to less down-regulation of Rubisco by elevated [CO₂] in soybean than in rice. However, unidentified species differences in the temperature optimum for photosynthesis also appeared to be important. The responses of photosynthesis and Rubisco in rice and soybean suggest that among C-3 plants species-specific differences will be encountered as a result of future increases in global [CO₂] and air temperatures.

Vu, J.C.V., J.T. Baker, A.H. Pennanen, L.H. Allen, G. Bowes, and K.J. Boote. 1998. Elevated CO₂ and water deficit effects on photosynthesis, ribulose biphosphate carboxylase-oxygenase, and carbohydrate metabolism in rice. *Physiologia Plantarum* 103(3):327-339.

Rice (*Oryza sativa* [L.] cv. IR-72) was grown for a season in sunlit, controlled-environment chambers at 350 or 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ under continuously flooded (unstressed) or drought-imposed periods at panicle initiation (stressed). The midday canopy photosynthetic rates (P_n), measured at the CO₂ concentration ([CO₂]) used for growth, were enhanced by high [CO₂] but reduced by drought. High [CO₂] increased P_n by 18 to 34% for the unstressed plants, and 6 to 12% for the stressed plants. In the unstressed plants, CO₂ enrichment increased water-use efficiency (WUE) by 26%, and reduced evapotranspiration (ET) by 8 to 14%. Both high [CO₂] and severe drought decreased the activity and content of ribulose biphosphate carboxylase-oxygenase (Rubisco). High-CO₂-unstressed plants had 6 to 22% smaller content and 5 to 25% lower activity of Rubisco than ambient-CO₂-unstressed plants. Under severe drought, reductions of Rubisco were 53 and 27% in activity and 40 and 12% in content, respectively, for ambient- and high-CO₂ treatments. The apparent catalytic turnover rate (K-cat) of midday fully activated Rubisco was not altered by high [CO₂], but severe drought reduced K-cat by 17 to 23%. Chloroplasts of the high-CO₂ leaves contained more, and larger starch grains than those of the ambient-CO₂ leaves. High [CO₂] did not affect the leaf sucrose content of unstressed plants. In contrast, severe drought reduced the leaf starch and increased the sucrose content in both CO₂ treatments. The activity of leaf sucrose phosphate synthase of unstressed plants was not affected by high [CO₂], whereas that of ambient-CO₂-grown plants was reduced 45% by severe drought. Reduction in ET and enhancements in both P_n and WUE for rice grown under high [CO₂] helped to delay the adverse effects of severe drought and allowed the stressed plants to assimilate CO₂ for an extra day. Thus, rice grown in the next century may utilize less water, use water more efficiently, and be able to tolerate drought better under some situations.

Vu, J.C.V., R.W. Gesch, L.H. Allen, K.J. Boote, and G. Bowes. 1999. CO₂ enrichment delays a rapid, drought-induced decrease in Rubisco small subunit transcript abundance. *Journal of Plant Physiology* 155(1):139-142.

Rice (*Oryza sativa* L. cv. IR-72) was grown in sunlit chambers at 350 and 700 $\mu\text{mol CO}_2 \text{ mol}^{-1}$ under conditions of continuous flooding (control) or drought which was imposed at panicle initiation, to evaluate the effects of CO₂ enrichment and soil water deficit on photosynthesis and Rubisco gene expression. Leaf and canopy photosynthetic rates were enhanced by high [CO₂] but reduced by drought. High [CO₂] and severe drought both reduced rbcS transcript abundance, along with the

activity, activation and protein content of Rubisco, but the K_m (CO₂) was not affected. The transition from moderate to severe drought caused a rapid decline, within 24 h, in the *rbcS* transcript abundance. High [CO₂], however, delayed the adverse effects of severe drought on *rbcS* transcript abundance and activities of Rubisco, and permitted photosynthesis to continue for an extra day during the drought-stress cycle.

Vugts, H.F. 1993. The need for micrometeorological research of the response of the energy-balance of vegetated surfaces to CO₂ enrichment. *Vegetatio* 104:321-328.

A Penman-Monteith equation has been used to evaluate a change in canopy resistance on the evapotranspiration of a savannah and agricultural area in Botswana. After a short introduction, some problems concerning the K-theory or 'first order closure' are indicated when one uses it for transport modelling within and above a canopy. The Penman-Monteith equation was used to calculate the canopy resistance for a savannah vegetation and sorghum under the same environmental conditions. After that, by changing the stomatal resistance due to an increase of the CO₂ content, the change in the evapotranspiration was estimated. Finally some recommendations for future research are given and an outline of a proposed FACE experiment is presented.

Vuorinen, A.H., and W.M. Kaiser. 1997. Dark CO₂ fixation by roots of willow and barley in media with a high level of inorganic carbon. *Journal of Plant Physiology* 151(4):405-408.

Willow (*Salix* cv. *Aquatica gigantea*) and barley (*Hordeum vulgare* L.) plants were grown in a nutrient solution (pH 7) enriched with HCO₃⁻ or gaseous CO₂. The initial and potential *in vivo* rates of dark CO₂ fixation in the roots were measured using 0.015 mmol/L and 0.74 mmol/L (HCO₃⁻)-C-14 as substrates of phosphoenolpyruvate carboxylase (PEPC). Enrichment of the nutrient solution with HCO₃⁻ or CO₂ increased the initial rate of dark CO₂ fixation in roots of both willow and barley compared with the corresponding control roots. In plants grown with NO₃⁻ the initial activity of PEPC was 38 and 89% higher than in control willow and barley, respectively, after the addition of HCO₃⁻. When the nutrient solutions were enriched with CO₂ the initial activity of PEPC increased 52% in willows and 58% in barley, compared with the controls. The supply of HCO₃⁻ into NH₄⁺ media increased the initial activity of PEPC in the roots of willows and barley by 50% and 17%, respectively. The amount of soluble protein in the roots was also higher in plants grown with inorganic carbon than in the control plants.

Measurements from the winter of 1994-95 indicating removal of total reactive nitrogen from the Arctic stratosphere by particle sedimentation

were used to constrain a microphysical model. The model suggests that denitrification is caused predominantly by nitric acid trihydrate particles in small number densities. The denitrification is shown to increase Arctic ozone loss substantially. Sensitivity studies indicate that the Arctic stratosphere is currently at a threshold of denitrification. This implies that future stratospheric cooling, induced by an increase in the anthropogenic carbon dioxide burden, is likely to enhance denitrification and to delay until late in the next century the return of Arctic stratospheric ozone to preindustrial values.

Wait, D.A., C.G. Jones, J. Wynn, and F.I. Woodward. 1999. The fraction of expanding to expanded leaves determines the biomass response of *Populus* to elevated CO₂. *Oecologia* 121(2):193-200.

We examined whether the effects of elevated CO₂ on growth of 1-year old *Populus deltoides* saplings was a function of the assimilation responses of particular leaf developmental stages. Saplings were grown for 100 days at ambient (approximately 350 ppm) and elevated (ambient + 200 ppm) CO₂ in forced-air greenhouses. Biomass, biomass distribution, growth rates, and leaf initiation and expansion rates were unaffected by elevated CO₂. Leaf nitrogen (N), the leaf C:N ratio, and leaf lignin concentrations were also unaffected. Carbon gain was significantly greater in expanding leaves of saplings grown at elevated compared to ambient CO₂. The Rubisco content in expanding leaves was not affected by CO₂ concentration. Carbon gain and Rubisco content were significantly lower in fully expanded leaves of saplings grown at elevated compared to ambient CO₂, indicating CO₂-induced down-regulation in fully expanded leaves. Elevated CO₂ likely had no overall effect on biomass accumulation due to the more rapid decline in carbon gain as leaves matured in saplings grown at elevated compared to ambient CO₂. This decline in carbon gain has been documented in other species and shown to be related to a balance between sink/source balance and acclimation. Our data suggest that variation in growth responses to elevated CO₂ can result from differences in leaf assimilation responses in expanding versus expanded leaves as they develop under elevated CO₂.

Walker, R.F., D.R. Geisinger, D.W. Johnson, and J.T. Ball. 1995. Enriched atmospheric CO₂ and soil P effects on growth and ectomycorrhizal colonization of juvenile ponderosa pine. *Forest Ecology and Management* 78(1-3):207-215.

Interactive effects of atmospheric CO₂ enrichment and soil P fertility on above- and below-ground development of juvenile ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) were examined. Seedlings were reared from seed in atmospheres with 700 μ l(-1), 525 μ l(-1), or ambient CO₂ concentrations, and in a potting mix with 68, 43, or 18 mg g(-1) soil P, and all were inoculated with the mycobiont *Pisolithus tinctorius* (Pers.) Coker and Couch shortly after emergence. At 4-month intervals over the 1-year duration of the study, three whole seedlings of each combination of CO₂ and P treatments were harvested to permit detailed assessment of shoot and root growth and ectomycorrhizal colonization. After 4 months, shoot volume, root dry weight, and total root length of seedlings grown in 700 μ l(-1) CO₂ were greater than those of seedlings grown in the other atmospheres regardless of P

treatment, and shoot/root ratios decreased as the CO₂ concentration increased within each P treatment as well. After 8 months, the smallest shoot volumes and root weights and lengths within each P treatment were those of seedlings grown in ambient CO₂. Root weight and total length increased as the CO₂ concentration increased in high soil P, but the greatest root weights and lengths within the medium and low P treatments were those of seedlings reared in the 525 µmol l⁻¹ CO₂ atmosphere. Nevertheless, shoot/root ratios decreased with increasing CO₂ in both high and medium soil P at the second harvest, and the highest shoot/root ratio in low P was that of seedlings grown in ambient CO₂. After 1 year, the largest shoot and root volumes within the high and medium P treatments were those of seedlings grown in intermediate CO₂, while the reverse was true in low P. The effects of CO₂ concentration on dry weights, total root length, and shoot/root ratio at the final harvest were nonsignificant. As proved true with seedling growth, CO₂ effects on ectomycorrhizal colonization varied temporally, as mycorrhizal development was not affected by the atmospheric treatments after 4 months, while seedlings grown in ambient CO₂ exhibited the highest percent infections within each P treatment at the second harvest but those grown in 700 µmol l⁻¹ CO₂ had the highest percentages after 1 year. These results suggest that elevated CO₂ exerts stimulatory effects on shoot and root development of juvenile ponderosa pine which may be dependent on P availability to some degree, but these effects are somewhat transient and vary in magnitude over time.

Walker, R.F., D.R. Geisinger, D.W. Johnson, and J.T. Ball. 1995. Interactive effects of atmospheric CO₂ enrichment and soil N on growth and ectomycorrhizal colonization of ponderosa pine seedlings. *Forest Science* 41(3):491-500.

Interactive effects of elevated atmospheric CO₂ and soil N fertility on above- and belowground development of juvenile ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) were examined. Seedlings were grown from seed in atmospheres containing 700 µmol l⁻¹, 525 µmol l⁻¹, or ambient CO₂. Medium and high soil N treatments were created by adding sufficient (NH₄)₂SO₄ to the potting mix to increase total N by 100 µg g⁻¹ and 200 µg g⁻¹, respectively, while unamended mix, which had a total N concentration of approximately 300 µg g⁻¹, served as the low N treatment. Three whole-seedling harvests at 4-month intervals permitted assessment of shoot and root growth and ectomycorrhizal formation resulting from inoculation with *Pisolithus tinctorius* (Pers.) Coker and Couch. After 4 months, CO₂ enrichment increased shoot volume and dry weight of seedlings grown in high soil N, but this result was not evident in the other N treatments and did not persist to the second harvest. Root weight, however, increased, and shoot/root ratio decreased as the CO₂ concentration increased within all three N treatments at the first harvest. At the second harvest, root weights within the high and intermediate N treatments were lowest in seedlings grown in ambient CO₂ and shoot/root ratios decreased as CO₂ increased in these two N treatments as well. Although the ectomycorrhizal infection percentage of seedlings grown in 700 µmol l⁻¹ CO₂ was highest among the seedlings grown in high N after 4 months, mycorrhizal colonization was variable overall at the first and second harvests. After 1 yr, the 525 µmol l⁻¹ CO₂ concentration stimulated above- and belowground growth more than the high CO₂ atmosphere in both high and medium soil N. These seedlings also had relatively extensive ectomycorrhizal formation, but colonization was again variable. Results presented here suggest the response of juvenile ponderosa pine to CO₂ enrichment is ephemeral, with the effects on roots more pronounced and persistent overall than those on shoots, and that the response is dependent on N availability.

Walker, R.F., D.R. Geisinger, D.W. Johnson, and J.T. Ball. 1997. Elevated atmospheric CO₂ and soil N fertility effects on growth, mycorrhizal colonization, and xylem water potential of juvenile ponderosa pine in a field soil. *Plant and Soil* 195(1):25-36.

Interactive effects of atmospheric CO₂ enrichment and soil N fertility on above- and below-ground development and water relations of juvenile ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) were examined. Open-top field chambers permitted creation of atmospheres with 700 µmol l⁻¹, 525 µmol l⁻¹, or ambient CO₂ concentrations. Seedlings were reared from seed in field soil with a total N concentration of approximately 900 µg g⁻¹ or in soil amended with sufficient (NH₄)₂SO₄ to increase total N by 100 µg g⁻¹ or 200 µg g⁻¹. The 525 µmol l⁻¹ CO₂ treatment within the intermediate N treatment was excluded from the study. Following each of three consecutive growing seasons, whole seedlings of each combination of CO₂ and N treatment were harvested to permit assessment of shoot and root growth and ectomycorrhizal colonization. In the second and third growing seasons, drought cycles were imposed by withholding irrigation during which predawn and midday xylem water potential and soil water potential were measured. The first harvest revealed that shoot weight and coarse and fine root weights were increased by growth in elevated CO₂. Shoot and root volume and weights were increased by CO₂ enrichment at the second harvest, but growth stimulation by the 525 µmol l⁻¹ CO₂ concentration exceeded that in 700 µmol l⁻¹ CO₂ during the first two growing seasons. At the third harvest, above- and below-ground growth increases were largely confined to the 700 µmol l⁻¹ CO₂ treatment, an effect accentuated by high soil N but evident in all N treatments. Ectomycorrhizal formation was reduced by elevated CO₂ after one growing season, but thereafter was not significantly affected by CO₂ and was unaffected by soil N throughout the study. Results of the xylem water potential measurements were variable, as water potentials in seedlings grown in elevated CO₂ were intermittently higher on some measurement days but lower on others than that of seedlings grown in the ambient atmosphere. These results suggest that elevated CO₂ exerts stimulatory effects on shoot and root growth of juvenile ponderosa pine under held conditions which are somewhat dependent on N availability, but that temporal variation may periodically result in a greater response to a moderate rise in atmospheric CO₂ than to a doubling of the current ambient concentration.

Walker, R.F., D.R. Geisinger, D.W. Johnson, and J.T. Ball. 1998. Atmospheric CO₂ enrichment and soil N fertility effects on juvenile ponderosa pine: Growth, ectomycorrhizal development, and xylem water potential. *Forest Ecology and Management* 102(1):33-44.

Interactive effects of elevated atmospheric CO₂ and soil N fertility on above- and below-ground growth, mycorrhizal colonization, and water relations of juvenile ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) were investigated. One-year-old seedlings were planted in undisturbed field soil within open-top chambers which permitted creation of atmospheres with 700 µmol l⁻¹, 525 µmol l⁻¹, or ambient CO₂ concentrations. High and medium soil N treatments were imposed by incorporating sufficient (NH₄)₂SO₄ to increase total N by 200 µg g⁻¹ and 100 µg g⁻¹, respectively, while unamended soil, which had

a total N concentration of approximately 900 $\mu\text{g g}^{-1}$, constituted the low N treatment. Following each of two consecutive field growing seasons, whole seedlings of every combination of CO₂ and N treatment were harvest-ed to permit assessment of shoot and root growth and quantification of ectomycorrhizal development. Late in the second growing season, a simulated drought episode was imposed by withholding irrigation during which predawn and midday xylem water potential and soil water potential were measured. The initial harvest revealed that coarse and fine root weights were increased by CO₂ enrichment during the first growing season. This result was most apparent in the 525 $\mu\text{mol l}^{-1}$ CO₂ treatment and high soil N, which produced the greatest root volume as well. Shoot/root ratio decreased with increasing CO₂ at the first harvest. After two growing seasons, elevated CO₂ increased seedling diameter, shoot and root volume, and shoot and coarse root weight, again most prominently in high N. Unlike the initial results, however, stimulation of seedling growth by the 700 $\mu\text{mol l}^{-1}$ CO₂ atmosphere exceeded that in 525 $\mu\text{mol l}^{-1}$ CO₂ after two growing seasons, and shoot/root ratio was unaffected by either CO₂ or N. At both harvests, seedlings grown in the enriched atmospheres generally had higher mycorrhizal counts and greater percentages of colonized root length, but differences among treatments in ectomycorrhizal development were nonsignificant regardless of quantification method. During the imposed drought episode, xylem water potential of seedlings grown in elevated CO₂ descended below that of seedlings grown in the ambient atmosphere as soil water potential decreased, most notably in the predawn measurements. These results suggest that CO₂ enrichment stimulates shoot and root growth of juvenile ponderosa pine under field conditions, a response somewhat dependent on soil N availability. However, below-ground growth is not increased proportionally more than that above ground, which may predispose this species to greater stress when soil water is limited. Walker, R.F., D.W. Johnson, D.R. Geisinger, and J.T. Ball. 1998. Growth and ectomycorrhizal colonization of ponderosa pine seedlings supplied different levels of atmospheric CO₂ and soil N and P. *Forest Ecology and Management* 109(1-3):9-20.

Individual and interactive effects of atmospheric CO₂ enrichment and soil N and P fertility on above- and below- ground growth and mycorrhizal colonization of juvenile ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) were examined. Seedlings were grown from seed in atmospheres with 700 $\mu\text{mol l}^{-1}$, 525 $\mu\text{mol l}^{-1}$, or ambient CO₂ concentrations. High and low soil N treatments were created by adding sufficient (NH₄)₂SO₄ to an infertile soil mixture to establish total N concentrations of 500 $\mu\text{g g}^{-1}$ and 400 $\mu\text{g g}^{-1}$ respectively, while high and low P treatments consisted of 68 $\mu\text{g g}^{-1}$ and 43 $\mu\text{g g}^{-1}$ concentrations, respectively, of extractable P created by additions of CaHPO₄. All seedlings were inoculated with the mycobiont *Pisolithus tinctorius* (Pers.) Coker and Couch shortly after emergence. Three whole- seedling harvests at four month intervals permitted assessment of treatment effects on shoot and root growth and ectomycorrhizal development. Initially, 525 $\mu\text{mol l}^{-1}$ CO₂ and high N and P were all influential factors in aboveground growth, with each of these treatments increasing shoot weight while the latter increased height, diameter and volume. Stimulation of root growth was evident in dry weight and length measurements at the first harvest, with N and P main treatment effects again evident, but the response to elevated CO₂ was most pronounced in the 700 $\mu\text{mol l}^{-1}$ atmosphere. After eight months, soil P was of little consequence above- or below- ground, but high N increased shoot dimensions, volume, and weight and root weight and length.

Furthermore, the 525 $\mu\text{mol l}^{-1}$ CO₂ treatment emerged as the dominant stimulatory atmosphere both above- and belowground, as seedlings grown in intermediate CO₂ exhibited the largest shoot diameters, greatest shoot and root weights, and the longest root systems at the second harvest. At the final harvest, interactive effects of 525 $\mu\text{mol l}^{-1}$ CO₂ and high N were prominent, as this treatment combination produced the largest shoot dimensions, volume and weight, and the greatest root volume and coarse and fine root weights. Intermediate CO₂ also produced the longest root systems after 12 months. Shoot/root ratios were lowered by growth in 700 $\mu\text{mol l}^{-1}$ CO₂ after four months and by both enriched atmospheres after eight months, but this effect was no longer evident at the final harvest. Greater numbers of mycorrhizae were formed by seedlings grown in 700 $\mu\text{mol l}^{-1}$ CO₂ after four months and by those grown in 525 $\mu\text{mol l}^{-1}$ CO₂ after eight months. Both enriched atmospheres increased mycorrhizal counts after 12 months, and seedlings grown in high CO₂ and low N exhibited the highest percentage of total root system length colonized at the final harvest as well. Overall, these results indicate that CO₂ enrichment stimulates shoot and root growth of juvenile ponderosa pine, a response dependent on soil N rather than P availability, and that the magnitude of the growth increase is greater in 1.5 x ambient than in 2 x ambient CO₂. (C) 1998 Elsevier Science B.V.

Walklate, P.J., Z.G. Xu, and A.R. McLeod. 1996. A new gas injection method to enhance spatial utilization within a free-air CO₂ enrichment (FACE) system. *Global Change Biology* 2(1):75-78.

Visual observations of smoke dispersion in a wind tunnel and a computational fluid dynamics (CFD) model were used to evaluate methods of improving the performance of Free-Air CO₂ Enrichment (FACE) Systems for field studies of the effects of elevated CO₂ on vegetation. A special baffle, named an Enhanced Local Mixing (ELM) system, was observed to increase the turbulence and consequent dilution of fumigant gas in the atmosphere. Modelling results suggest that the ELM design reduces the spatial variation of fumigant gas concentration in small experimental plots. The potential reduction in CO₂ use and costs warrants further evaluation under field conditions.

Wall, G.W., J.S. Amthor, and B.A. Kimball. 1994. Cotco2 - a cotton growth simulation-model for global change. *Agricultural and Forest Meteorology* 70(1-4):289-342.

In conjunction with the Free-Air-CO₂-Enrichment (FACE) project, a new, physiologically based, mechanistic, modular simulation model of cotton (*Gossypium hirsutum* L.) physiology, growth, development, yield and water use has been constructed. It is named COTCO₂ for cotton response to atmospheric CO₂ concentration. The model is capable of predicting cotton crop responses to elevated atmospheric CO₂ concentrations and potential concomitant changing climate variables. The major plant processes known to be influenced by CO₂ are simulated explicitly, i.e. photosynthesis, photorespiration, and stomatal conductance, and its role in leaf energy balance. The model explicitly simulates the impact of atmospheric CO₂ concentration on C₃ photosynthesis and photorespiration at the level of carboxylation and oxygenation. Growth is simulated for individual organs, i.e. leaf blade, stem segment, taproot and lateral roots, and fruit which includes squares and bolls. Potential growth is calculated and the carbohydrate and nitrogen required to meet this potential are calculated. Actual growth is

based on substrate availability, the potential growth, and water stress. Our intent here is to describe the overall structure of the model, its present status, and future development plans. Further development, documentation, calibration, and validation of the model is in progress. The long range goal of the project is to provide quantitative estimates of global cotton production in a future higher-CO₂ world.

Wand, S.J.E., G.F. Midgley, M.H. Jones, and P.S. Curtis. 1999. Responses of wild C4 and C3 grass (Poaceae) species to elevated atmospheric CO₂ concentration: a meta-analytic test of current theories and perceptions. *Global Change Biology* 5(6):723-741.

C4 plants contribute approximate to 20% of global gross primary productivity, and uncertainties regarding their responses to rising atmospheric CO₂ concentrations may limit predictions of future global change impacts on C4-dominated ecosystems. These uncertainties have not yet been considered rigorously due to expectations of C4 low responsiveness based on photosynthetic theory and early experiments. We carried out a literature review (1980-97) and meta-analysis in order to identify emerging patterns of C4 grass responses to elevated CO₂, as compared with those of C3 grasses. The focus was on nondomesticated Poaceae alone, to the exclusion of C4 dicotyledonous and C4 crop species. This provides a clear test, controlled for genotypic variability at family level, of differences between the CO₂-responsiveness of these functional types. Eleven responses were considered, ranging from physiological behaviour at the leaf level to carbon allocation patterns at the whole plant level. Results were also assessed in the context of environmental stress conditions (light, temperature, water and nutrient stress), and experimental growing conditions (pot size, experimental duration and fumigation method). Both C4 and C3 species increased total biomass significantly in elevated CO₂, by 33% and 44%, respectively. Differing tendencies between types in shoot structural response were revealed: C3 species showed a greater increase in tillering, whereas C4 species showed a greater increase in leaf area in elevated CO₂. At the leaf level, significant stomatal closure and increased leaf water use efficiency were confirmed in both types, and higher carbon assimilation rates were found in both C3 and C4 species (33% and 25%, respectively). Environmental stress did not alter the C4 CO₂-response, except for the loss of a significant positive CO₂-response for above-ground biomass and leaf area under water stress. In C3 species, stimulation of carbon assimilation rate was reduced by stress (overall), and nutrient stress tended to reduce the mean biomass response to elevated CO₂. Leaf carbohydrate status increased and leaf nitrogen concentration decreased significantly in elevated CO₂ only in C3 species. We conclude that the relative responses of the C4 and C3 photosynthetic types to elevated CO₂ concur only to some extent with expectations based on photosynthetic theory. The significant positive responses of C4 grass species at both the leaf and the whole plant level demand a re-evaluation of the assumption of low responsiveness in C4 plants at both levels, and not only with regard to water relations. The combined shoot structural and water use efficiency responses of these functional types will have consequential implications for the water balance of important catchments and range lands throughout the world, especially in semiarid subtropical and temperate regions. It may be premature to predict that C4 grass species will lose their competitive

advantage over C3 grass species in elevated CO₂.

Wand, S.J.E., G.F. Midgley, and C.F. Musil. 1996. Growth, phenology and reproduction of an arid-environment winter ephemeral *Dimorphotheca pluvialis* in response to combined increases in CO₂ and UV-B radiation. *Environmental Pollution* 94(3):247-254.

The winter ephemeral *Dimorphotheca pluvialis* was grown in open-top chambers in ambient or elevated CO₂ (350 or 650 $\mu\text{mol mol}^{-1}$), combined with ambient (2.39 to 7.59 $\text{kJ m}^{-2} \text{d}^{-1}$) or increased (4.94 to 11.13 $\text{kJ m}^{-2} \text{d}^{-1}$) UV-B radiation. Net CO₂ assimilation rate and leaf water use efficiency increased in elevated CO₂, but increased UV-B did not affect gas exchange. Leaf biomass was greater under increased UV-B, but vegetative biomass was unaffected in elevated CO₂. Initiation of reproduction was delayed, and proportional investment in reproductive biomass at harvest was reduced in elevated CO₂. Increased UV-B stimulated reproduction, particularly in ambient CO₂, but also in elevated CO₂ at a later stage. Changes in reproductive phenology and prolonged development in elevated CO₂ during the stressful late season could indirectly be detrimental to reproductive success of *D. pluvialis*, but stimulation of reproduction by enhanced UV-B may to some extent mitigate this. Wand, S.J.E., G.F. Midgley, and C.F. Musil. 1996. Physiological and growth responses of two African species, *Acacia karroo* and *Themeda triandra*, to combined increases in CO₂ and UV-B radiation. *Physiologia Plantarum* 98(4):882-890.

The interactive effects of increased carbon dioxide (CO₂) concentration and ultraviolet-B (UV-B, 280-320 nm) radiation on *Acacia karroo* Hayne, a C-3 tree, and *Themeda triandra* Forsk., a C-4 grass, were investigated. We tested the hypothesis that *A. karroo* would show greater CO₂-induced growth stimulation than *T. triandra*, which would partially explain current encroachment of *A. karroo* into C-4 grasslands, but that increased UV-B could mitigate this advantage. Seedlings were grown in open-top chambers in a greenhouse in ambient (360 $\mu\text{mol mol}^{-1}$) and elevated (650 $\mu\text{mol mol}^{-1}$) CO₂, combined with ambient (1.56 to 8.66 $\text{kJ m}^{-2} \text{day}^{-1}$) or increased (2.22 to 11.93 $\text{kJ m}^{-2} \text{day}^{-1}$) biologically effective (weighted) UV-B irradiances. After 30 weeks, elevated CO₂ had no effect on biomass of *A. karroo*, despite increased net CO₂ assimilation rates. Interaction between UV-B and CO₂ on stomatal conductance was found, with conductances decreasing only where elevated CO₂ and UV-B were supplied separately. Increases in water use efficiencies, foliar starch concentrations, root nodule numbers and total nodule mass were measured in elevated CO₂. Elevated UV-B caused only an increase in foliar carbon concentrations. In *T. triandra*, net CO₂ assimilation rates were unaffected in elevated CO₂, but stomatal conductances and foliar nitrogen concentrations decreased, and water use efficiencies increased. Biomass of all vegetative fractions, particularly leaf sheaths, was increased in elevated CO₂, and was accompanied by increased leaf blade lengths and individual leaf and leaf sheath masses. However, tiller numbers were reduced in elevated CO₂. Significantly moderating effects of elevated UV-B were apparent only in individual masses of leaf blades and sheaths, and in total sheath and

shoot biomass. The direct CO₂-induced growth responses of the species therefore do not support the hypothesis of CO₂-driven woody encroachment of C-4 grasslands. Rather, differential changes in resource use efficiency between grass and woody species, or morphological responses of grass species, could alter the competitive balance. Increased UV-B radiation is unlikely to substantially alter the CO₂ response of these species.

Wang, B., and K. Adachi. 1999. Methane production in a flooded soil in response to elevated atmospheric carbon dioxide concentrations. *Biology and Fertility of Soils* 29(2):218-220.

CH₄ production in a flooded soil as affected by elevated atmospheric CO₂ was quantified in a laboratory incubation study. CH₄ production in the flooded soil increased by 19.6%, 28.2%, and 33.4% after a 2-week incubation and by 38.2%, 62.4%, and 43.0% after a 3-week incubation under atmospheres of 498, 820, and 1050 $\mu\text{mol l}^{-1}$ CO₂, respectively, over that in soil under the ambient CO₂ concentration. CH₄ production in slurry under 690, 920, and 1150 $\mu\text{mol l}^{-1}$ CO₂ increased by 2.7%, 5.5%, and 5.0%, respectively, after a 3-day incubation, and by 6.7%, 12.8%, and 5.4%, respectively, after a 6-day incubation over that in slurry under the ambient CO₂ concentration. The increase in CH₄ production in the soil slurry under elevated CO₂ concentrations in a N-2 atmosphere was more pronounced than that under elevated CO₂ concentrations in air. These data suggested that elevated atmospheric CO₂ concentrations could promote methanogenic activity in flooded soil.

Wang, D.L. 1999. Effect of elevated CO₂ on CH₄ emission. *Chinese Science Bulletin* 44(13):1153-1157.

Global CH₄ emission may increase under CO₂ enrichment condition, which is projected for the future. CO₂ enrichment could affect CH₄ emission in two ways: (i) Photosynthesis of plants that also include plants in rice paddies and natural wetlands will be stimulated under CO₂ enrichment condition. CH₄ emission rate may be increased due to the accumulation of more plant biomass, root exudes and soil organic matters. (ii) Combined with other global warming forces, CO₂ enrichment may bring a change of atmospheric temperature and precipitation around the world. CH₄ emission will also be changed with the variation of the area and distribution of rice paddies and natural wetlands.

Wang, K.Y. 1996. Apparent quantum yield in Scots pine after four years of exposure to elevated temperature and CO₂. *Photosynthetica* 32(3):339-353.

The carbon-dioxide and temperature responses of the apparent quantum yield, $\alpha(A)$, were measured in a uniform, diffuse radiation field for two shoot age classes of Scots pine (*Pinus sylvestris* L.) that had been exposed to elevated CO₂ and temperature for four years (1991-4) in open-top chambers. The treatments were (I) ambient temperature and

CO₂ concentration (ACT), (2) elevated temperature (ET), (3) elevated CO₂ concentration (EC), and (4) elevated CO₂ concentration and temperature (ECT). ET and ECT increased $\alpha(A)$ in the one-year-old shoots, but did not affect $\alpha(A)$ in the current-year shoots. When measured at the same partial pressure of CO₂ and a leaf temperature of 20 degrees C, EC had no significant effect on $\alpha(A)$ in two shoot age classes. However, when the comparison was made between shoots grown in and measured in 35 Pa CO₂ and those grown in and measured in 70 Pa CO₂, EC and ECT led to a significant increase in $\alpha(A)$, by 22.4 and 24.5 %, respectively, for the current-year shoots and by 21.6 and 27.5 %, respectively, for one-year-old shoots. Furthermore, in the one-year-old shoots, ET and ECT led to relatively higher $\alpha(A)$ values at higher temperatures, but EC alone led to relatively lower values of $\alpha(A)$. In contrast, this effect was not significant in the current-year shoots. The differences in $\alpha(A)$ between different treatments and between the shoot age classes could be attributed separately to changes in the efficiency of radiant energy capture. The Kok effect was observed at all partial pressures of CO₂ during measurements. However, with an increase in the partial pressure of CO₂, a parallel decrease was observed in both the measured rate of dark respiration, $R(D)$, and the regressed rate of dark respiration, $R(r)$. This decrease occurred regardless of growth treatment and age class. Consequently, the ratio of $R(r)/R(D)$ was nearly identical in all treatments and age classes having a mean of 0.69.

Wang, K.Y. 1996. Canopy CO₂ exchange of Scots pine and its seasonal variation after four-year exposure to elevated CO₂ and temperature. *Agricultural and Forest Meteorology* 82(1-4):1-27.

Single Scots pines (*Pinus sylvestris* L.), aged 20-25 years, have been grown in open-topped chambers with elevated temperature (during winter and summer, the mean temperature was 5-20 degrees C and 2 degrees C above the outside ambient temperature, respectively), elevated CO₂ (550-600 $\mu\text{mol mol}^{-1}$) from 15 April to 15 September) and a combination of elevated temperature and CO₂ for four years. The vertical and seasonal variations of key physiological parameters concerning photosynthesis and stomatal conductance were measured. The annual canopy photosynthesis and respiration were predicted by using a multilayer model in which the profile of the canopy properties and the microclimate data through a whole year (1994) were used as inputs to the model. The results indicate that during the main growing season (day number 121 to 243), the elevated CO₂ increased the maximum apparent quantum yield by 24% and the mean light-saturated rate of assimilation by 41%, and decreased the mean light-saturated stomatal conductance by 13%. However, elevated temperature had no significant effect on these parameters. During early spring and late autumn, elevated temperature increased significantly the apparent quantum yield, the light-saturated rate of assimilation and stomatal conductance. The predicted annual net photosynthesis increased by 40% for elevated CO₂ alone, by 58% for elevated CO₂ and temperature, and by 10% for elevated temperature alone. The annual sum of respiration increased by 39% for elevated temperature alone and by 29% for elevated CO₂ and temperature. Elevated CO₂ alone caused a depression of 7% in the annual respiration. Seasonal variations of the CO₂-exchange rate between treatments were evident, and they can be largely attributed to changes in the apparent quantum yield, the light-saturated rate of assimilation, leaf area index, and the ability to adapt to environmental stress conditions.

Wang, K.Y., and S. Kellomaki. 1997. Effects of elevated CO₂ and soil-nitrogen supply on chlorophyll fluorescence and gas exchange in Scots pine, based on a branch- in-bag experiment. *New Phytologist* 136(2):277-286.

Applying the branch-in-bag method, naturally seeded Scots pine (*Pinus sylvestris* L.) trees, 25-30 yr old, were subjected to two CO₂ concentrations (350 and 700 $\mu\text{mol mol}^{-1}$) and two soil-nitrogen-supply regimes for three growing seasons (1994- 96). Gas exchange and chlorophyll a fluorescence in detached shoots were measured simultaneously in a diffuse radiation field. Elevated CO₂ did not lead to a significant 'downward regulation' in the light-saturated rate of net photosynthesis (P-n.max), the maximum apparent quantum yield (alpha(A.max)) or the maximum photochemical efficiency (F-v/F-m) of photosystem II (PS II). However, the elevated CO₂ significantly decreased the light-saturated stomatal conductance and increased the sensitivity of stomatal conductance to change in low photon- flux densities. The high soil-nitrogen supply significantly increased photosynthetic capacity, as manifested by increases in P-n.max, alpha(A.max), F-v/F-m, and the effective photochemical efficiency (Delta F/F(m)) at low photon-flux densities, did not, on the other hand, enhance the magnitude of photosynthetic response to elevated CO₂ concentration. In addition, the treatment-induced modifications in fluorescence parameters are discussed in detail.

Wang, K.Y., and S. Kellomaki. 1997. Stomatal conductance and transpiration in shoots of Scots pine after 4-year exposure to elevated CO₂ and temperature. *Canadian Journal of Botany-Revue Canadienne De Botanique* 75(4):552-561.

Single Scots pines (*Pinus sylvestris* L.) trees were subjected to elevated temperature (year-round elevation), elevated CO₂ (elevation from April 15 to September 15), and a combination of elevated temperature and CO₂ for 4 years in open-topped chambers. Measurements and modelling were performed to determine if long-term growth at elevated CO₂ concentration and temperature altered water use efficiency (W-e) and the responses of stomatal conductance (g(s)) to photon flux density (Q(p)), the leaf-to-air vapour pressure difference (D-v), leaf temperature (T-l), and intercellular concentration of CO₂ (C- i). Long-term elevation of CO₂ led to a significant decline in the absolute value of g(s) at almost all levels of Q(p), D-v, C-i and T-l. Elevated temperature treatment increased the absolute value of g(s) only at higher D-v and T-l. The effect of the combination of elevated CO₂ and temperature did not appear as a mean of the effects of the two single factors, while there was an interaction between the two factors. The modifications in the sensitivity of stomata, resulting from different treatments, did not have the same pattern as the change in g(s), but depended on levels of Q(p), D-v, and T-l. Compared with the control treatment, elevated concentration of CO₂ or a combination of elevated CO₂ and temperature led, on average, to 50 and 30% increases in W-E, respectively, which can be attributed mainly to an increase in the rate of net assimilation. In contrast, elevated temperature alone did not significantly change W-E, although transpiration rate was increased.

Wang, K.Y., S. Kellomaki, and K. Laitinen. 1995. Effects of needle age, long-term temperature and co₂ treatments on the photosynthesis of Scots pine. *Tree Physiology* 15(4):211-218.

Naturally regenerated 20-25-year-old Scots pine (*Pinus sylvestris* L.) trees were grown in open-top chambers in the presence of an elevated temperature or CO₂ concentration, or both. The elevated temperature treatment was administered year- round for 3 years. The CO₂ treatment was applied between April 15 and September 15 for 2 years. The photosynthetic responses of 1- and 2-year-old needles to varying photon flux densities (0-1500 $\mu\text{mol m}^{-2} \text{s}^{-1}$) and CO₂ concentrations (350, 700 and 1400 $\mu\text{mol mol}^{-1}$) during measurement were determined. The CO₂ treatment alone increased maximum photosynthetic rate and light-use efficiency, but decreased dark respiration rate, light compensation and light saturation regardless of needle age. In contrast, the temperature treatment decreased maximum photosynthetic rate and photosynthetic efficiency, but increased dark respiration rate, light compensation and light saturation. The aging of needles affected the photosynthetic performance of the shoots; values of all parameters except photosynthetic efficiency were less in 2- than in 1-year-old needles. The CO₂ treatment decreased and the temperature treatment enhanced the reduction in maximum photosynthesis due to needle aging.

Wang, K.Y., S. Kellomaki, and K. Laitinen. 1996. Acclimation of photosynthetic parameters in Scots pine after three years exposure to elevated temperature and CO₂. *Agricultural and Forest Meteorology* 82(1-4):195-217.

Single Scots pine (*Pinus sylvestris* L.) was subjected to elevated temperature (year-round elevation), elevated CO₂ (elevation from April 15 to September 15) and a combination of elevated temperature and CO₂ for three years in open-topped chambers. Using the data obtained from field measurements of gas exchange, Farquhar and von Caemmerer's basic equations for photosynthesis of C-3 plants were parameterized. The values of the estimated parameters at five ranges of leaf-temperature for trees growing in four different environments are presented and discussed. The estimates of the parameters show that Scots pine grown at elevated CO₂ or elevated temperature, compared to those grown in the ambient conditions, did not show significant decreases in the maximum RuP2 (ribulose-1,5-bisphosphate) saturated rate of carboxylation, V-cmax, the maximum rate of electron transport, J(max) and the 'day respiration rate', R(d), within a given range of measuring temperatures (5-25 degrees C). But at high measuring temperature (> 30 degrees C), the elevated CO₂ treatment significantly decreased V(cmax) and J(max) whereas the elevated temperature or the combination of CO₂ and temperature significantly increased V-cmax and J(max). Furthermore, elevated CO₂ led to a slight leftward drift of the whole temperature-response curves for V-cmax and J(max); while elevated temperature or the combination of CO₂ and temperature led a slight rightward drift of the curves. The model computations show that given a constant intercellular CO₂ concentration, C-i (230 or 540 $\mu\text{mol mol}^{-1}$), there are no significant differences in the maximum rates of assimilation among treatments; when C-i was doubled, the maximum rate of assimilation increased by 28%-34% with no significant differences among treatments.

Wang, N., and P.S. Nobel. 1996. Doubling the CO₂ concentration enhanced the activity of carbohydrate-metabolism enzymes, source carbohydrate production, photoassimilate transport, and sink strength for *Opuntia ficus-indica*. *Plant Physiology* 110(3):893-902.

After exposure to a doubled CO₂ concentration of 750 $\mu\text{mol mol}^{-1}$ air for about 3 months, glucose and starch in the chlorenchyma of basal cladodes of *Opuntia ficus-indica* increased 175 and 57%, respectively, compared with the current CO₂ concentration of 370 $\mu\text{mol mol}^{-1}$, but sucrose content was virtually unaffected. Doubling the CO₂ concentration increased the nocturnal malate production in basal cladodes by 75%, inorganic phosphate (Pi) by 32%, soluble starch synthase activity by 30%, and sucrose-Pi synthase activity by 146%, but did not affect the activity of hexokinase. Doubling CO₂ accelerated phloem transport of sucrose out of the basal cladodes, resulting in a 73% higher dry weight for the daughter cladodes. Doubling CO₂ increased the glucose content in 14-d-old daughter cladodes by 167%, increased nocturnal malate production by 22%, decreased total amino acid content by 61%, and increased soluble starch synthase activity by 30% and sucrose synthase activity by 62%. No downward acclimation of photosynthesis during long-term exposure to elevated CO₂ concentrations occurs for *O. ficus-indica* (M. Cui, P.M. Miller, P.S. Nobel [1993] *Plant Physiol* 103: 519-524; P.S. Nobel, A.A. Israel [1994] *J Exp Bot* 45: 295-303), consistent with its higher source capacity and sink strength than under current CO₂. These changes apparently do not result in Pi limitation of photosynthesis or suppression of genes governing photosynthesis for this perennial Crassulacean acid metabolism species, as occur for some annual crops.

Wang, X.F., S.Y. Li, K.Z. Bai, and T.Y. Kuang. 1998. Influence of doubled CO₂ on plant growth and soil microbial biomass C and N. *Acta Botanica Sinica* 40(12):1169-1172.

Salix babylonica L. *Triticum aestivum* L. *Chenopodium album* L. and *Amaranthus cruentus* L. were grown in the N-deficient soil in open-top chambers blown with ambient or doubled ambient CO₂ air, and their growth was measured. Soil samples were collected to assess the influence of doubled CO₂ on the soil microbial biomass C (C-mic) and N (N-mic). Results showed that the biomass of shoot and root was increased by doubled CO₂ in the four species of plants. Doubled CO₂ increased C-mic in *S. babylonica* and decreased C-mic in *T. aestivum* and *C. album*. On the other hand, N-mic in three species except *T. aestivum* was stimulated by doubled CO₂. Doubled CO₂ had no significant effect on C-mic in *A. cruentus* and N-mic in *T. aestivum*. However, the ratios of C-mic- to -N-mic of all four species were consistently declined under doubled CO₂ treatment. It implies that CO₂ enrichment may have positive influence on the quality of organic matter of N-low soil in global change.

Wang, Y.P., A. Rey, and P.G. Jarvis. 1998. Carbon balance of young

birch trees grown in ambient and elevated atmospheric CO₂ concentrations. *Global Change Biology* 4(8):797-807.

We constructed a carbon budget for young birch trees grown in ambient and elevated CO₂ concentrations over their fourth year of growth. The annual total of net leaf photosynthesis was 110% more in elevated CO₂ than in ambient CO₂. However, the trees in elevated CO₂ grew only 59% more biomass than the trees in ambient CO₂ over the year. Modelling studies showed that larger loss of carbon from fine-root production and growth of the root-associated mycorrhiza by the trees in elevated CO₂ probably accounted for all the remaining difference in net photosynthesis between the two treatments. Our modelling also showed that the fraction of net photosynthate consumed by respiration of nonleaf tissue was similar in the two CO₂ treatments, and was 26% and 24% for trees in ambient and elevated CO₂, respectively. Trees in elevated CO₂ had 43% more leaves, and produced 110% more net photosynthate than trees in ambient CO₂, even though the maximum rate of carboxylation per unit leaf nitrogen decreased by 21%. Sensitivity studies showed that down-regulation reduced the annual net photosynthetic production of the trees in elevated CO₂ by only 6%. Direct effects of higher CO₂ on photosynthesis and greater leaf area of the trees in elevated CO₂ increased the net photosynthesis of the trees by 68% and 60%, respectively; and together accounted for most of the difference in net photosynthesis between the two treatments.

Wang, Y.Q., H.J. Zhang, D. Yang, K.Z. Bai, and T.Y. Kuang. 1998. Fractal analysis for root growth of plant seedlings under doubled CO₂ concentration. *Chinese Science Bulletin* 43(22):1891-1893.

Fractal geometry was applied and box dimension was used as an indicator to analyze the effects of doubled CO₂ concentration on the root growth of plant seedlings. Results showed that doubled CO₂ concentration displayed different effects on root branching characteristics of C-3 and C-4 plants. There was an obvious increase of root branches in spring wheat while there were no significant effects on roots of sweet sorghum. In different soil layers, root branching of spring wheat was stimulated and this promotion was most significant in the second layer (10-20 cm), which denoted that elevated CO₂ altered the root branching pattern. That means higher CO₂ concentration influences not only root growth but also its differentiation and development.

Wang, Y.X., and G.M. Shpeyzer. 1997. Genesis of thermal groundwaters from Siping'an district, China. *Applied Geochemistry* 12(4):437-445.

Thermal groundwaters (40-52 degrees C, pH = 7.4-7.8, Eh = 210- 245 mV) from Siping'an district, Shanxi Province, northwestern China, are hydrogeochemically unique. Their occurrence is controlled by faulted structures in Precambrian host rocks. Their hydrochemical type (5 springs and 2 wells) is mainly Cl- SO₄-Na, with TDS values around 1.0 g/l. Some minor elements such as Si, Pr, Sr, and Li, as well as neutral and acid bituminous substances are so enriched that the thermal waters can also be regarded as mineral waters. Their origin is meteoric, as indicated by 3 lines of geochemical evidence: (1) their delta D and delta(18)O compositions are very close to the Craig meteoric line; (2) their dissolved gas compositions are N₂-dominated, with less O₂ and CO₂; and (3) the He-3/He-4 ratios are low (0.028). Geochemical processes responsible for the genesis of the hydrochemical features of the waters include dissolution, mixing, and oxidation. The most

important water-rock interaction is dissolution or hydrolysis of aluminosilicate minerals in the magmatic and metamorphic host rocks, since the waters are still undersaturated with respect to albite, anorthite, K-spar, and chlorite, as shown by saturation indices. The tritium contents of some thermal waters (46–53 TU), higher than the tritium concentration of local meteoric water, result from the mixing of thermal waters with cold, shallow-lying groundwaters that are from the 1960s. The predominant species of Fe in the thermal waters is Fe(OH)(3), as a result of oxidation processes under aerobic conditions of the aquifers. (C) 1997 Elsevier Science Ltd.

Wang, Z.M., M.J. Lechowicz, and C. Potvin. 1994. Early selection of black spruce seedlings and global change - which genotypes should we favor. *Ecological Applications* 4(3):604-616.

We investigated the effects of both soil fertility and predicted changes in climate on the performance of different families of black spruce, *Picea mariana* (Mill.) B.S.P., during the first growing season. The results were used to examine whether reforestation programs should consider changing their preferred family lines in anticipation of altered performance given global climate change. We grew seedlings of 16 open-pollinated maternal families of black spruce under phytotron conditions simulating present and mid-21 st century climatic conditions during the growing season. The realistic, simulated future climate included both elevated CO₂ levels and seasonally appropriate increases in mean daily temperature. To explore the dependence of climatic responses on site quality, seedlings were irrigated with solutions having either 5 or 100 mg/L of nitrogen. The lower nitrogen level represents a poor site for black spruce growth and survival, but the higher level provides ample nitrogen. We also recorded seed size for each seedling to evaluate the degree to which maternal investments might buffer responses to future climate and fertility during the first year on the seedbed. Seedling survival and growth increased both under the future climate regime and with nitrogen fertilization. The two factors interacted synergistically, with nitrogen enrichment significantly enhancing the positive effects of the future climate regime. Nitrogen-poor conditions, however, did not preclude a positive seedling response to the future climate. Our results indicate that seedling survival and height growth are highly dependent upon initial seed mass: larger seeds produced more vigorous 1 st-yr seedlings. The families differed in seed mass, seed germination, and seedling survival and growth, but their relative performances did not vary significantly among the treatments. These results suggest that black spruce families selected for rapid growth under present conditions will also do well in the future, at least in terms of early establishment and performance on sites regenerated by seeding.

Wang, Z.M., M.J. Lechowicz, and C. Potvin. 1995. Responses of black spruce seedlings to simulated present versus future seedbed environments. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 25(4):545-554.

We investigated the effects of nitrogen availability and present versus future atmospheric environments (i.e., climate) on the seedling performance of 16 open-pollinated maternal families of *Picea mariana* (Mill.) B.S.P. over two simulated growing seasons. Diurnal and seasonal patterns of temperature, relative humidity, photoperiod, and light intensity were simulated. The simulated future climate included both elevated CO₂ and seasonally appropriate increases in mean monthly

temperatures. Compared with the present, the future climate increased seedling survival, total and root dry mass, rate of winter bud development, net photosynthetic rate, and water and nitrogen use efficiencies; decreased needle nitrogen content; and altered biomass allocation patterns. Greater nitrogen availability greatly improved seedling performance and changed biomass allocation patterns. Climate and nitrogen level interacted synergistically to promote seedling growth (branch number and root dry mass), survival, and bud development. The future climate increased seedling survival, rate of bud development, and nitrogen use efficiency much more in the low than in the high nitrogen regime. Seedling performance in the second season was dependent on initial seed mass, but less than in the 1st year. Some of the differences among the families and in their interactions with the climate and (or) nitrogen fertilization suggest that families selected for rapid growth under present conditions may not do well in the future, at least in terms of early establishment. Forest managers and tree breeders should take this possibility into consideration in their tree improvement and reforestation programs.

Wang, Z., Q. Pan, and B. Quebedeaux. 1999. Carbon partitioning into sorbitol, sucrose, and starch in source and sink apple leaves as affected by elevated CO₂. *Environmental and Experimental Botany* 41(1):39-46.

Experiments were conducted in controlled growth chambers to evaluate how increases in CO₂ concentration ([CO₂]) affected carbon metabolism and partitioning into sorbitol, sucrose, and starch in various ages of apple leaves. Apple plants (*Mals domestica*), 1 year old, were exposed to [CO₂] of 200, 360, 700, 1000, and 1600 µmol l⁻¹ up to 8 days. Six groups of leaves (counted from the shoot apex): leaves 1-5 (sink), 6-7 (sink to source transition), 8-9 (sink to source transition), 10-11 (nearly-matured source), 21-22 (mid-age source), and 30-32 (aged source), were sampled at 1, 2, 4, and 8 days after [CO₂] treatments for carbohydrate analysis. Increases in [CO₂] from a sub-ambient (200 µmol l⁻¹) to an ambient level (360 µmol l⁻¹) significantly increased the concentrations of sorbitol, sucrose, glucose, and fructose tested in all ages of leaves. Continuous increase in [CO₂] from ambient to super-ambient levels up to 1600 µmol l⁻¹ also increased sorbitol concentration by approximate to 50% in source leaves, but not in sink and sink to source transition leaves. Increases in [CO₂] from 360 to 1600 µmol l⁻¹, however, had little effect on sucrose content in all ages of leaves. Starch concentrations increased in all ages of leaves as [CO₂] increased. Rapid starch increases (e.g. 5-, 6-, 20-, and 50-fold increases for leaf groups 1-5, 6-7, 10-11, and 21-22, respectively) occurred from 700 to 1600 µmol l⁻¹ [CO₂] during which increases in sorbitol concentration either ceased or slowed down. Our results indicate that changes in carbohydrates were much more responsive to CO₂ enrichment in source leaves than in sink and sink to source transition leaves. Carbon partitioning was favored into starch and sorbitol over sucrose in all ages of leaves when [CO₂] was increased from 200 to 700 µmol l⁻¹, and was favored into starch over sorbitol from 700 to 1600 µmol l⁻¹ [CO₂]. Wangwacharakul, V., and R. Bowonwivat. 1995. Economic evaluation of CO₂ response options in the forestry sector: The case of Thailand. *Biomass & Bioenergy* 8(5):293-307.

Using the benefit-cost analysis approach, this paper attempts to evaluate

the potential of the forestry sector in Thailand to reduce carbon emissions of the country. Protecting conserved forests can avoid a substantial amount of carbon emission from deforestation, although certain costs are attached. Reforestation also enhances carbon sequestration and, in most cases, incurs no cost to society. Under the present government's commitment to fully protect the conserved forests and reforest the deforested areas in the country, Thailand could reduce the growth of carbon emission by as much as 260 million tons over the next two decades. The costs to society, if any, would be small given other, non-quantifiable, benefits of the forests.

Ward, J.K., and B.R. Strain. 1997. Effects of low and elevated CO₂ partial pressure on growth and reproduction of *Arabidopsis thaliana* from different elevations. *Plant, Cell and Environment* 20(2):254-260.

Atmospheric CO₂ partial pressure may have been as low as 18 Pa during the Pleistocene and is expected to increase from 35 to 70 Pa before the end of the next century. Low CO₂ reduces the growth and reproduction of C-3 plants, whereas elevated CO₂ often increases growth and reproduction. Plants at high elevation are exposed to reduced CO₂ partial pressure and may be better adapted to the low CO₂ of the Pleistocene, we examined genotypes of *Arabidopsis thaliana* from different elevations for variation in growth and reproduction at the CO₂ levels of the Pleistocene, the present and the future. Genotypes exhibited limited genetic variation in the response of the production of biomass to changes in CO₂, but showed significant variation in reproductive characters. We found evidence that plants from high elevations may be better adapted to low CO₂ when considering seed number, which is an important component of fitness. Genotypes showed greater variation in the response of seed number between 35 and 20 Pa CO₂ compared to 35 and 70 Pa CO₂. We conclude that present-day C-3 annuals may have greater potential for evolution in response to the low CO₂ of the Pleistocene relative to the elevated CO₂ predicted for the future.

Ward, J.K., and B.R. Strain. 1999. Elevated CO₂ studies: past, present and future. *Tree Physiology* 19(4-5):211-220.

Increasing concentrations of atmospheric CO₂ are predicted to impact both current and future ecosystems. Elevated CO₂ is also predicted to affect biological processes at many levels of organization. In this overview, we summarize the responses of plants to elevated CO₂ including primary physiological and molecular responses, growth and reproductive responses, effects on plant-plant competition and interactions with other organisms, evolutionary responses, and effects at the ecosystem level. The objectives of this paper are to: (a) overview studies in this issue that were presented at a 1997 meeting entitled "Critical Assessment of the Response of Forest Ecosystems to Elevated Atmospheric Carbon Dioxide," which was sponsored by the Global Change and Terrestrial Ecosystems (GCTE) group of the International Geosphere Biosphere Program (IGBP), (b) review areas of recent progress in CO₂ research, (c) generalize patterns arising from past research, and (d) list critical areas of research for the future.

Wardle, D.A., K.I. Bonner, G.M. Barker, G.W. Yeates, K.S. Nicholson, R.D. Bardgett, R.N. Watson, and A. Ghani. 1999. Plant removals in perennial grassland: Vegetation dynamics, decomposers, soil biodiversity, and ecosystem properties. *Ecological Monographs* 69(4):535-568.

The consequences of permanent loss of species or species groups from plant communities are poorly understood, although there is increasing evidence that individual species effects are important in modifying ecosystem properties. We conducted a field experiment in a New Zealand perennial grassland ecosystem, creating artificial vegetation gaps and imposing manipulation treatments on the reestablishing vegetation. Treatments consisted of continual removal of different subsets or "functional groups" of the flora. We monitored vegetation and soil biotic and chemical properties over a 3-yr period. Plant competitive effects were clear: removal of the C-3 grass *Lolium perenne* L. enhanced vegetative cover, biomass, and species richness of both the C-4 grass and dicotyledonous weed functional groups and had either positive or negative effects on the legume *Trifolium repens* L., depending on season. Treatments significantly affected total plant cover and biomass; in particular, C-4 grass removal reduced total plant biomass in summer, because no other species had appropriate phenology. Removal of C-4 grasses reduced total root biomass and drastically enhanced overall shoot-to-root biomass ratios. Aboveground net primary productivity (NPP) was not strongly affected by any treatment, indicating strong compensatory effects between different functional components of the flora. Removing all plants often negatively affected three further trophic levels of the decomposer functional food web: microflora, microbe-feeding nematodes, and predaceous nematodes. However, as long as plants were present, we did not find strong effects of removal treatments, NPP, or plant biomass on these trophic groupings, which instead were most closely related to spatial variation in soil chemical properties across all trophic levels, soil N in particular. Larger decomposer organisms, i.e., Collembola and earthworms, were unresponsive to any factor other than removal of all plants, which reduced their populations. We also considered five functional components of the soil biota at finer taxonomic levels: three decomposer components (microflora, microbe-feeding nematodes, predaceous nematodes) and two herbivore groups (nematodes and arthropods). Taxa within these five groups responded to removal treatments, indicating that plant community composition has multitrophic effects at higher levels of taxonomic resolution. The principal ordination axes summarizing community-level data for different trophic groups in the soil food web were related to each other in several instances, but the plant ordination axes were only significantly related to those of the soil microfloral community. There were time lag effects, with ordination axes of soil-associated herbivorous arthropods and microbial-feeding nematodes being related to ordination axes representing plant community structure at earlier measurement dates. Taxonomic diversity of some soil organism groups was linked to plant removals or to plant diversity. For herbivorous arthropods, removal of C-4 grasses enhanced diversity; there were negative correlations between plant and arthropod diversity, presumably because of negative influences of C-4 species in the most diverse treatments. There was evidence of lag relationships between diversity of plants and that of the three decomposer groups, indicating multitrophic effects of altering plant diversity. Relatively small effects of plant removal on the decomposer food web were also apparent in soil processes regulated by this food web. Decomposition rates of substrates added to soils showed no relationship with treatment, and rates of CO₂ evolution from the soil were only adversely affected when all plants were removed. Few plant functional-group effects on soil nutrient dynamics were identified. Although some treatments affected temporal variability (and thus stability) of soil biotic properties (particularly CO₂ release) throughout the experiment, there was no evidence of destabilizing effects of plant removals. Our data provide evidence that permanent exclusion of plant species from the species pool can have important consequences for overall vegetation composition in addition to the direct effects of

vegetation removal, and various potential effects on both the above- and belowground subsystems. The nature of many of these effects is driven by which plant species are lost from the system, which depends on the various attributes or traits of these species.

Wardle, D.A., H.A. Verhoef, and M. Clarholm. 1998. Trophic relationships in the soil microfood-web: predicting the responses to a changing global environment. *Global Change Biology* 4(7):713-727.

In this article, we evaluate how global environmental change may affect microfood-webs and trophic interactions in the soil, and the implications of this at the ecosystem level. First we outline how bottom-up (resource control) and top-down (predation-control) forces regulate food-web components. Food- web components can respond either positively or negatively to shifts in NPP resulting from global change, thus creating difficulties in developing general principles about the response of soil biota to global change phenomena. We also demonstrate that top-down effects can be important in soil food-webs, creating negative feed-backs which may partially counter bottom-up effects. Secondly we determine how soil food- webs and the processes they regulate respond to various global change phenomena. Enhanced atmospheric CO₂ levels can have two main effects on plants which are relevant for the soil food- web, i.e. enhanced NPP (often positive) and diminished organic matter quality (with negative effects, at least in the short term). Climate change effects resulting from elevated CO₂ levels may be mainly secondary through alteration of vegetation, as shown by examples. Intensification of land management is usually associated with greater disturbance, which alters soil food-web composition and key processes; this is particularly apparent in comparisons of conventionally tilled and nontilled agroecosystems. Global change involves shifts in plant species composition and diversity, possibly affecting soil food-webs; we interpret this in terms of theories relating biodiversity to ecosystem function. We conclude that a more detailed understanding of interactions between NPP, soil organic matter and components of the soil food-web, as well as their regulation of biogeochemical processes and ultimately ecosystem-level properties, is essential in better understanding longterm aspects of global change phenomena.

Warwick, K.R., G. Taylor, and H. Blum. 1998. Biomass and compositional changes occur in chalk grassland turves exposed to elevated CO₂ for two seasons in FACE. *Global Change Biology* 4(4):375-385.

Artificial turves composed of 7 chalk grassland species (*Festuca ovina* L.; *Briza media* L.; *Bromopsis erecta* (Hudson) Fourr.; *Plantago media* L.; *Sanguisorba minor* Scop.; *Anthyllis vulneraria* L. and *Lotus corniculatus* L.) were grown from seed and exposed to two seasons of elevated (600 $\mu\text{mol mol}^{-1}$) and ambient (340 $\mu\text{mol mol}^{-1}$) CO₂ concentrations in free air CO₂ enrichment (ETH-FACE, Zurich). The turves were clipped regularly to a height of 5 cm and assessed for above ground biomass production and relative abundance based on accumulated clipped dry biomass as well as by point quadrat recording. Below ground biomass production was assessed with root in- growth

bags during the second season of growth. Increases in total biomass (> 30%) were noted in elevated CO₂, but the differences did not become significant until the second season of growth. Individual species' biomass varied in response to elevated CO₂, with significant increases in biomass in elevated CO₂ turves for both legume species, and no significant CO₂ effect on *S. minor* or *P. media*. An initial positive CO₂ effect on biomass of combined grass species was reversed by the end of the experiment with less biomass and a significantly smaller proportion of total biomass present in elevated CO₂, which was attributed primarily to changes in proportion of *F. ovina*. Species relative abundance was significantly affected by elevated CO₂ in the final 4 of the 6 clip events, with the legume species increasing in proportion at the expense of the other species, particularly the grasses. Root length and dry weight were both significantly increased in elevated CO₂ (77% and 89%, respectively), and these increases were greater than increases in shoot biomass (36%) from the same period. Species responses to elevated CO₂, within the model community, were not consistent with predictions made from data on individual species, leading to the conclusion that responses to elevated CO₂, at the community level, and species within the community level, are the result of direct physiological effects and indirect competitive effects. These conclusions are discussed with respect to the ecological responses of natural communities, and the chalk grassland community in particular, to elevated CO₂.

Watada, A.E., N.P. Ko, and D.A. Minott. 1996. Factors affecting quality of fresh-cut horticultural products. *Postharvest Biology and Technology* 9(2):115-125.

Fresh-cut products, also known as lightly or minimally processed products, are highly perishable because a large proportion of their surface area is without epidermis, the outer protective layer of tissue. Temperature, atmosphere, relative humidity and sanitation must be regulated to maintain quality of fresh-cuts. In the 0-10 degrees C range, Q(10) of respiration rates ranged from 2.0 to 8.6 among various fresh-cut fruits and vegetables. Low O₂ and elevated CO₂ atmosphere reduced the respiration rate; however, the respiratory quotient approached 3.0 with some fresh-cuts. Film bags or coatings are necessary to maintain high relative humidity. Microorganisms were present in chlorine-washed spinach, and populations increased during storage. Stress from the physical action of processing and low O₂ atmosphere affects physiology and biochemistry of the fresh-cuts, which can affect quality and shelf-life. Research in all of these areas is needed to ensure that wholesome, high-quality fresh-cut products are marketed to consumers.

Watling, J.R., and M.C. Press. 1997. How does elevated CO₂ affect the relationship between the C-3 root hemiparasite *Striga hermonthica* and the C-4 host *Sorghum bicolor*? *Plant Physiology* 114(3):46.

2538

Watling, J.R., and M.C. Press. 1997. How is the relationship between the C-4 cereal *Sorghum bicolor* and the C-3 root hemi-parasites *Striga hermonthica* and *Striga asiatica* affected by elevated CO₂? *Plant, Cell and Environment* 20(10):1292-1300.

The C-4 cereal *Sorghum bicolor* was grown under either ambient (350 $\mu\text{mol mol}^{-1}$) or elevated (700 $\mu\text{mol mol}^{-1}$) [CO₂] in either the presence or absence of the C-3 obligate root hemi-parasites *Striga hermonthica* or *S. asiatica*. Both uninfected and infected sorghum plants were taller and had greater biomass, photosynthetic rates, water-use efficiencies and leaf areas under elevated compared with ambient [CO₂]. There was no evidence of any downregulation of photosynthesis in sorghum grown at elevated [CO₂]. Biomass of infected sorghum was lower under both ambient and elevated [CO₂], and although infected plants were larger under elevated [CO₂] the relative impact of infection on host biomass was either the same (*S. asiatica*) or only slightly less (*S. hermonthica*) than under ambient [CO₂]. In contrast, biomass of *S. hermonthica* and *S. asiatica* per host was lower under elevated than ambient [CO₂], although rates of photosynthesis were higher at elevated [CO₂] and parasite stomatal conductance was not responsive to [CO₂]. Parasites emerged above-ground and flowered earlier under ambient compared with elevated [CO₂]. It appears that the mechanism(s) by which the parasites affect host growth is (are) relatively insensitive to increased atmospheric [CO₂] although the parasites themselves were adversely affected by growth at elevated [CO₂].

Wayne, P.M., and F.A. Bazzaz. 1995. Seedling density modifies the growth-responses of yellow birch maternal families to elevated carbon-dioxide. *Global Change Biology* 1(5):315-324.

We studied seedling growth responses to ambient and elevated CO₂ (350 and 700 $\mu\text{mol L}^{-1}$) of three maternal families of yellow birch (*Betula alleghaniensis*), raised both individually and in high-density stands. Seedlings in competitive, dense stands exhibited markedly lower average CO₂-induced growth enhancements than individually grown plants (16% vs. 49%). Maternal families differed in their growth responses to elevated CO₂. However, differences among families were contingent upon density; families which exhibited the greatest CO₂-induced growth at low density exhibited the least CO₂-responsiveness at high density. These data are discussed in two separate contexts; the

reliability of estimates of the CO₂ fertilization potential of forest species based solely on individually grown plants, and the potential evolutionary consequences of rising CO₂ on regenerating forest tree populations.

Wayne, P.M., and F.A. Bazzaz. 1997. Light acquisition and growth by competing individuals in CO₂-enriched atmospheres: Consequences for size structure in regenerating birch stands. *Journal of Ecology* 85(1):29-42.

1 To investigate how CO₂-enriched atmospheres may influence plant competition and stand size structure in regenerating forests, experimental populations comprised of three maternal families of yellow birch (*Betula alleghaniensis* Britt.) were grown in both ambient (350 $\mu\text{mol L}^{-1}$) and elevated (700 $\mu\text{mol L}^{-1}$) CO₂ concentrations in a controlled environment facility. Individual seedling growth, light acquisition, and stand size structure were monitored throughout the first year of growth. 2 Elevated CO₂ increased average seedling biomass in stands by 14%, a value much lower than the average enhancement reported elsewhere for individually grown yellow birch seedlings. Maternal families within stands differed significantly in their growth responsiveness to elevated CO₂, ranging from +51% to -16%. As a result, CO₂ altered the genetic identity of dominants in regenerating stands. 3 Seedling size inequalities were generally lower in CO₂-enriched environments, a result that contrasts with other studies that have reported increased size inequality with increased productivity in resource-rich environments. Distribution modifying functions relating initial seedling size and subsequent growth suggest that there was a relatively smaller advantage to being larger in elevated vs. ambient CO₂ environments. Together, these results suggest that competition in CO₂-enriched environments was less size-asymmetric. 4 Differences in stand size structure between CO₂ treatments were related to competition for light. Empirical measures of seedling light acquisition per unit biomass suggest competition for light was less size-asymmetric in CO₂-enriched environments. Decreased size-asymmetric competition for light was attributable both to differences in the CO₂-use efficiency of high-light canopy dominants vs. low-light canopy subordinates, and to CO₂-induced differences in plant allometry. 5 This study highlights the importance of stand-level competition studies in global change research, and more generally, the value of studies that combine phenomenological descriptions of stand development with physiological mechanisms of competition.

Wayne, P.M., A.L. Carnelli, J. Connolly, and F.A. Bazzaz. 1999. The density dependence of plant responses to elevated CO₂. *Journal of Ecology* 87(2):183-192.

1 Stands of the annual *Brassica kaber* were grown at a range of six densities in both ambient and elevated CO₂ environments, and measurements of shoot growth were made from seedling emergence through to reproduction. 2 Early in stand development (21 days following emergence), CO₂ enhancement (beta) for above-ground biomass was highly density-dependent, ranging from 1.41 at the lowest density (20 plants m^{-2}) to 0.59 at the highest density (652 plants m^{-2}). 3 As stands matured and total biomass exceeded a relatively low threshold level (< 10.0 g m^{-2} ; c. 20% of final yield), the density-

dependence of beta disappeared. Above this shoot biomass threshold, beta-values remained remarkably stable ($\beta = 0.34$) across a broad range of stand biomass, independent of a stand's initial density or age. 4 Average stand-level reproductive beta-values at a final harvest were very similar to biomass values ($\beta = 0.38$) and, as with biomass values at later stages, showed no apparent density-dependence. 5 These results highlight the importance of considering density and the time-course of stand development simultaneously when assessing the potential for CO₂-induced growth enhancements in plants.

Wayne, P.M., E.G. Reekie, and F.A. Bazzaz. 1998. Elevated CO₂ ameliorates birch response to high temperature and frost stress: implications for modeling climate-induced geographic range shifts. *Oecologia* 114(3):335-342.

Despite predictions that both atmospheric CO₂ concentrations and air temperature will rise together, very limited data are currently available to assess the possible interactive effects of these two global change factors on temperate forest tree species. Using yellow birch (*Betula alleghaniensis*) as a model species, we studied how elevated CO₂ (800 vs. 400 $\mu\text{mol l}^{-1}$) influences seedling growth and physiological responses to a 5 degrees C increase in summer air temperatures (31/26 vs. 26/21 degrees C day/night), and how both elevated CO₂ and air temperature during the growing season influence seedling ability to survive freezing stress during the winter dormant season. Our results show that while increased temperature decreases seedling growth, temperature-induced growth reductions are significantly lower at elevated CO₂ concentrations (43% vs. 73%). The amelioration of high-temperature stress was related to CO₂-induced reductions in both whole-shoot dark respiration and transpiration. Our results also show that increased summer air temperature, and to a lesser degree CO₂ concentration, make dormant winter buds less susceptible to freezing stress. We show the relevance of these results to models used to predict how climate change will influence future forest species distribution and productivity, without considering the direct or interactive effects of CO₂.

Webb, A.A.R., M.R. McAinsh, T.A. Mansfield, and A.M. Hetherington. 1996. Carbon dioxide induces increases in guard cell cytosolic free calcium. *Plant Journal* 9(3):297-304.

The hypothesis that increases in cytosolic free calcium ($[\text{Ca}^{2+}]_i$) are a component of the COP signal transduction pathway in stomatal guard cells of *Commelina communis* has been investigated. This hypothesis was tested using fura-2 fluorescence ratio photometry to measure changes in guard cell $[\text{Ca}^{2+}]_i$ in response to challenge with 700 $\mu\text{mol l}^{-1}$ CO₂. Elevated CO₂ induced increases in guard cell $[\text{Ca}^{2+}]_i$ which were similar to those previously reported in response to abscisic acid. $[\text{Ca}^{2+}]_i$ returned to resting values following removal of the CO₂ and further application of CO₂ resulted in a second increase in $[\text{Ca}^{2+}]_i$. This demonstrated that the CO₂-induced increases in $[\text{Ca}^{2+}]_i$ were stimulus dependent. Removal of extracellular calcium both prevented the CO₂-induced increase in $[\text{Ca}^{2+}]_i$ and inhibited the associated reduction in stomatal aperture. These data suggest that Ca²⁺ acts as a second messenger in the CO₂ signal transduction pathway and that an increase in $[\text{Ca}^{2+}]_i$ may be a requirement for the stomatal

response to CO₂.

Webber, A.N., G.Y. Nie, and S.P. Long. 1994. Acclimation of photosynthetic proteins to rising atmospheric CO₂. *Photosynthesis Research* 39(3):413-425.

In this review we discuss how the photosynthetic apparatus, particularly Rubisco, acclimates to rising atmospheric CO₂ concentrations (c_a). Elevated c_a alters the control exerted by different enzymes of the Calvin cycle on the overall rate of photosynthetic CO₂ assimilation, so altering the requirement for different functional proteins. A decreased flux of carbon through the photorespiratory pathway will decrease requirements for these enzymes. From modeling of the response of CO₂ uptake (A) to intracellular CO₂ concentration (c_i) it is shown that the requirement for Rubisco is decreased at elevated c_a , whilst that for proteins limiting ribulose 1,5 bisphosphate regeneration may be increased. This balance may be altered by other interactions, in particular plasticity of sinks for photoassimilate and nitrogen supply; hypotheses on these interactions are presented. It is speculated that increased accumulation of carbohydrate in leaves developed at elevated c_a may signal the 'down regulation' of Rubisco. The molecular basis of this 'down regulation' is discussed in terms of the repression of photosynthetic gene expression by the elevated carbohydrate concentrations. This molecular model is then used to predict patterns of acclimation of perennials to long term growth in elevated c_a .

Wechsung, G., F. Wechsung, G.W. Wall, F.J. Adamsen, B.A. Kimball, R.L. Garcia, P.J. Pinter, and T. Kartschall. 1995. Biomass and growth rate of a spring wheat root system grown in free-air CO₂ enrichment (FACE) and ample soil moisture. *Journal of Biogeography* 22(4-5):623-634.

The response of a wheat crop root system to full-season CO₂-enrichment was investigated using a free-air CO₂ enrichment (FACE) apparatus. A spring wheat (*Triticum aestivum* L. cv. Yecora Rojo) crop was growing at 0.25 m row spacing and 130 plants m^{-2} on a Trix clay loam (hyperthermic Typic Torrifluvent) under two atmospheric CO₂ concentrations (FACE: similar to 550 $\mu\text{mol mol}^{-1}$; control: similar to 370 $\mu\text{mol mol}^{-1}$) and ample soil moisture (100% replacement of potential evapotranspiration). Irrigation was applied with a subsurface drip irrigation system. Root cores were collected at five growth stages (three-leaf, tillering, stem elongation, anthesis, dough development and final harvest, which corresponded with day of year (DOY) 16, 36, 63, 92, 113 and 159, respectively), using a soil core device (86 mm i). Two cores were taken in-row and one in the inter-row space position to examine the horizontal and vertical distribution of roots to a 1-m depth. Root biomass was summed over the entire root profile across all positions to obtain a total. Total root mass was higher in FACE compared to control for all growth stages (i.e. 34% at three-leaf, 21% at tillering, 23% at stem elongation, 28% at dough development and 19% at harvest). Root growth rate was significantly higher in FACE compared to control for both in-row and inter-row positions. Root senescence rate were similar between FACE and control grown plants,

but the absolute difference in root mass during the senescence phase was greater in FACE compared to control grown plants. Roots from FACE grown plants explored a greater proportion of the soil profile earlier in the season than roots from control grown plants. However, there was no evidence that plants grown in FACE had a deeper root system than plants grown in control.

Wechsung, G., F. Wechsung, G.W. Wall, F.J. Adamsen, B.A. Kimball, P.J. Pinter, R.L. Lamorte, R.L. Garcia, and T. Kartschall. 1999. The effects of free-air CO₂ enrichment and soil water availability on spatial and seasonal patterns of wheat root growth. *Global Change Biology* 5(5):519-529.

Spring wheat [*Triticum aestivum* (L.) cv. Yecora Rojo] was grown from December 1992 to May 1993 under two atmospheric CO₂ concentrations, 550 $\mu\text{mol mol}^{-1}$ for high-CO₂ plots, and 370 $\mu\text{mol mol}^{-1}$ for control plots, using a Free-Air CO₂ Enrichment (FACE) apparatus. In addition to the two levels of atmospheric CO₂, there were ample and limiting levels of water supply through a subsurface trip irrigation system in a strip, split-plot design. In order to examine the temporal and spatial root distribution, root cores were extracted at six growth stages during the season at in-row and inter-row positions using a soil core device (86 mm ID, 1.0 m length). Such information would help determine whether and to what extent root morphology is changed by alteration of two important factors, atmospheric CO₂ and soil water, in this agricultural ecosystem. Wheat root growth increased under elevated CO₂ conditions during all observed developmental stages. A maximum of 37% increase in total root dry mass in the FACE vs. Control plots was observed during the period of stem elongation. Greater root growth rates were calculated due to CO₂ enhancement until anthesis. During the early vegetative growth, root dry mass of the inter-row space was significantly higher for FACE than for Control treatments suggesting that elevated CO₂ promoted the production of first-order lateral roots per main axis. Then, during the reproductive period of growth, more branching of lateral roots in the FACE treatment occurred due to water stress. Significant higher root dry mass was measured in the inter-row space of the FACE plots where soil water supply was limiting. These sequential responses in root growth and morphology to elevated CO₂ and reduced soil water supports the hypothesis that plants grown in a high-CO₂ environment may better compensate soil-water-stress conditions.

Weerakoon, W.M., D.M. Olszyk, and D.N. Moss. 1999. Effects of nitrogen nutrition on responses of rice seedlings to carbon dioxide. *Agriculture Ecosystems & Environment* 72(1):1-8.

Global atmospheric CO₂ concentration is increasing, likely increasing the productivity of crops as higher CO₂ enhances plant photosynthesis. Responsiveness to nitrogen supply is an essential trait of modern rice cultivars, and may play a role in the response of rice cultivars to CO₂. To determine the relationship between these two important production variables on young rice plants, seedlings of *Oryza sativa* L. 'IR72' and 'KDML 105' were exposed for 28 days after sowing to CO₂ levels of 373, 545, 723 and 895 $\mu\text{mol mol}^{-1}$, and 3 levels of nitrogen fertility. There were large increases in leaf CO₂ assimilation and biomass production whereas leaf nitrogen concentration dropped sharply as CO₂

increased from 373 to 545 $\mu\text{mol mol}^{-1}$, with little additional effect from higher levels of CO₂. Root and shoot biomass, and tiller number per plant increased with increasing nitrogen supply and with increasing atmospheric CO₂ concentration. The biomass response to CO₂ was slight at low N supply, but became dramatically greater as the N supply increased. Mean root/shoot ratio increased slightly as atmospheric CO₂ concentration increased, but decreased sharply as nitrogen fertility rate increased. These results suggest that careful attention to nitrogen fertilization will be necessary for rice farming to get the full benefit of any future increases in atmospheric CO₂. Weigel, H.J., and U. Dammgen. 1999. The Braunschweig carbon project - atmospheric flux monitoring and free air carbon dioxide enrichment. *Berichte Uber Landwirtschaft* 77(1):49-58.

With respect to the predicted climate change it has become evident that the role of terrestrial ecosystems in the global carbon turnover is not yet fully understood. This is also true for carbon fluxes in agricultural ecosystems. As increasing atmospheric CO₂ concentrations will directly affect plant photosynthesis, plant biomass production and plant water relations, it is of particular importance to predict the dynamics of carbon fluxes between the atmosphere and agricultural canopies and the related consequences for agroecosystems under future atmospheric CO₂ conditions. There are hardly any experimental approaches under real field conditions in crop rotation systems to simulate future CO₂ scenarios. The Braunschweig carbon project is a combination of micrometeorological flux measurements of atmospheric trace gases and other air constituents and of a large scale free air carbon dioxide enrichment (FACE) experiment. The project is particularly designed to meet the data requirement of process and landscape models. The data will also contribute to the improvement and validation of models to predict the consequences of climate changes for agricultural ecosystems. The present contribution is a description of the structure of the experiments and the involvement of modelling approaches.

Weigel, H.J., R. Manderscheid, H.J. Jager, and G.J. Mejer. 1994. Effects of season-long CO₂ enrichment on cereals. I. Growth-performance and yield. *Agriculture Ecosystems & Environment* 48(3):231-240.

Two cultivars each of spring wheat (*Triticum aestivum* L., cultivars 'Star' and 'Turbo') and spring barley (*Hordeum vulgare* L., cultivars 'Alexis' and 'Arena') were exposed throughout the growing season to ambient (384 p.p.m.) and above ambient CO₂ concentrations (471, 551, 624, 718 p.p.m.) in open-top chambers. Plant samples were taken four times during plant development and biomass partitioning into stem, leaves and ear was measured. Total above-ground biomass increased mainly in the CO₂ concentration range between 400-550 p.p.m. for wheat, and between 400-700 p.p.m. for barley. Stimulation of biomass was largely due to an increase in tillering rate. At the tiller level CO₂ enrichment revealed a decrease in leaf dry weight at anthesis stage, which was due to a reduction in leaf size (barley) and in leaf number (wheat). Specific leaf weight of the mature flag leaf was unaffected by CO₂. Stem biomass per tiller was temporarily ('Star', 'Alexis') or during the whole growth period ('Turbo', 'Arena') increased by CO₂ exposure, while ear dry weight was increased (barley) or even decreased ('Star'). Except for the barley cultivar 'Arena', which showed a 84% increase in the number of grains per ear, the number of ears was almost entirely responsible for the

increased grain yield among the CO₂ treatments. At the highest CO₂ concentration yield increase amounted to 19% and 27% for the two wheat cultivars, and 5.2% and 8.9% for the two barley cultivars in comparison with the ambient CO₂ level. Among all cultivars there was an inverse relationship between the total shoot biomass produced at ambient CO₂ conditions and the plant's response to the CO₂ enrichment. This indicates that the genetic potential of wheat unlike barley is highly adapted to present atmospheric CO₂ conditions and thus responsible for the small CO₂ effect on wheat.

Weishampel, J.F., R.G. Knox, and E.R. Levine. 1999. Soil saturation effects on forest dynamics: scaling across a southern boreal/northern hardwood landscape. *Landscape Ecology* 14(2):121-135.

Patch modeling can be used to scale-up processes to portray landscape-level dynamics. Via direct extrapolation, a heterogeneous landscape is divided into its constituent patches; dynamics are simulated on each representative patch and are weighted and aggregated to formulate the higher level response. Further extrapolation may be attained by coarsening the resolution of or lumping environmental data (e.g., climatic, edaphic, hydrologic, topographic) used to delimit a patch. Forest patterns at the southern boreal/northern hardwood transition zone are often defined by soil heterogeneity, determined primarily by the extent and duration of soil saturation. To determine how landscape-level dynamics predicted from direct extrapolation compare when coarsening soil parameters, we simulated forest dynamics for soil series representing a range of drainage classes from east-central Maine. Responses were aggregated according to the distribution of soil associations comprising a 600 ha area based on local- (1:12,000), county- (1:120,000) and state- (1:250,000) scale soil maps. At the patch level, simulated aboveground biomass accumulated more slowly in poorer draining soils. Different soil series yielded different communities comprised of species with various tolerances for soil saturation. When aggregated, removal of waterlogging caused a 20-60% increase in biomass accumulation during the first 50 years of simulation. However, this early successional increase and the maximum level of biomass accumulation over a 200 year period varied by as much as 40% depending on the geospatial data. This marked discrepancy suggests caution when extrapolating with forest patch models by coarsening parameters and demonstrates how rules used to rescale environmental data need to be evaluated for consistency.

Welker, J.M., and D.D. Briske. 1992. Clonal biology of the temperate, caespitose, graminoid *Schizachyrium scoparium* - a synthesis with reference to climate change. *Oikos* 63(3):357-365.

Caespitose graminoids are characterized by the compact spatial arrangement of ramets within clones and the absence of rhizomes or stolons. Resource allocation is principally acropetal with established ramets supporting juvenile ramets during early development. However, after juvenile ramet maturation a responsive resource transfer system is maintained by a low level of continuous resource allocation between parental and juvenile ramets. Isotopic and severing experiments demonstrated that physiological integration in the caespitose graminoid *Schizachyrium scoparium* is restricted to individual ramet sequences

consisting of three connected ramet generations as opposed to all ramets within the clone. This number of ramet generations comprising the physiological individual is determined by demographic variables influencing the recruitment and longevity of individual ramets. Restricted resource allocation among ramet sequences within clones is primarily caused by the disintegration of vascular connections among ramet sequences following death of the seminal ramet. The survival value conferred by a clonal architecture composed of an assemblage of autonomous physiological individuals growing within close proximity requires further evaluation but may center on intra-plant competitive interactions. The response of this large sub-group of clonal plants to climate change will significantly impact community structure and function because of their diversity and dominance in numerous biomes. The impact of climate change on the caespitose graminoid growth form is difficult to anticipate because: 1) caespitose graminoids consist of both C₃ and C₄ species which will complicate the response of the growth form, 2) our understanding about the clonal biology and population ecology of this growth form is still evolving and 3) the modular construction of this growth form may result in variable responses at the ramet, clone and population levels of organization.

Wellburn, A.R. 1998. Atmospheric nitrogenous compounds and ozone - is NO_x fixation by plants a possible solution? *New Phytologist* 139(1):5-9.

Air quality thresholds for O₃ for the protection of human health and vegetation set by the European Union (EU) have been exceeded in Europe regularly in the 1990s. Because target reductions for oxides of nitrogen (NO_x) set for the year 2000 are unlikely to be achieved, these O₃ exceedances are likely to continue into the next millennium. Improvements of plant tolerance towards O₃ are being investigated but very little work has been done to explore NO_x tolerance and plant acclimation to NO₂ and NO. However, it is clear that within the populations of some plant species there is wide variation, and some individuals can fix NO_x, and use the nitrogen directly from the atmosphere, rather than rely upon, for example, root uptake of nitrate. It is possible that individuals capable of fixing NO_x could be selected for a range of species, and genotypes with high rates of uptake could be of value as crops or for forestation in polluted areas (e.g. landscaping in the vicinity of motorways) to reduce tropospheric concentrations of NO_x significantly and also to decrease the potential for O₃ production.

Welsh, D.T., S. Bourgues, R. deWit, and I. Aubry. 1997. Effect of plant photosynthesis, carbon sources and ammonium availability on nitrogen fixation rates in the rhizosphere of *Zostera noltii*. *Aquatic Microbial Ecology* 12(3):285-290.

Rates of nitrogen fixation (measured as acetylene reduction) in the rhizosphere of the seagrass *Zostera noltii* were highly dependent upon plant photosynthetic activity being significantly stimulated at elevated CO₂ concentrations and by light, both in the short-term and over diurnal cycles. Stimulation by light became insignificant when 5 mM sucrose was added to the sediment porewater, indicating that in the absence of added carbon sources, light stimulation was due to direct inputs of plant photosynthate to the rhizosphere. Addition of a range of carbon sources to the rhizosphere sediment stimulated rates of acetylene reduction, with this stimulation being significant for sucrose and lactate. Surprisingly,

whilst low additions of ammonium to the sediment porewater (10 to 50 μM) inhibited 50% of acetylene reduction activity, approximately 30% of this activity persisted in the presence of 1 mM ammonium chloride; this indicating that in at least a proportion of the N-fixing community, nitrogenase activity was not regulated in the short term by the availability of alternative nitrogen sources.

Weltzin, J.F., S. Archer, and R.K. Heitschmidt. 1997. Small-mammal regulation of vegetation structure in a temperate Savanna. *Ecology* 78(3):751-763.

Explanations for documented increases in woody plant dominance in grasslands and savannas of North America include atmospheric CO₂ enrichment and changes in climate, livestock grazing, and fire regimes. However, tree/shrub encroachment has also coincided with the eradication of a once widespread native herbivore, the black-tailed prairie dog (*Cynomys ludovicianus*). We used field experiments and repeat aerial photography to demonstrate that prairie dogs, and the herbivores and granivores associated with their colonies, probably maintained grassland and savanna by preventing woody species such as *Prosopis glandulosa* (honey mesquite) from establishing or attaining dominance. *Prosopis* seed and pod disappearance was 3- 99 times greater within prairie dog colonies. Ants were the primary agent of seed removal, whereas prairie dogs and associated vertebrates were the primary agents of pod removal. Survival of *Prosopis* seedlings protected from vertebrate herbivory was similar on and off prairie dog colonies (approximate to 60%), whereas survival of unprotected seedlings was 3 times greater off- than on-colony. On-colony, prairie dogs and associated herbivores girdled and destroyed all *Prosopis* saplings within 2 d of planting; survival of 1-yr-old seedlings was reduced by 50% after 3 mo of exposure to on- colony herbivores. Despite high levels of woody plant seed disappearance and seedling herbivory, on-colony "seedling" reserves were substantial (950 plants/ha). Thus, prairie dogs and the fauna that occur on their colonies suppressed rather than eliminated *Prosopis* from the colony site. Removal of prairie dogs led to rapid development of *Prosopis* stands. Repeat aerial photography showed that *Prosopis* canopy cover on a colony eradicated in 1950 (27%) increased to a level (61%) comparable to that of off-colony *Prosopis* stands (65%) within 23 yr. These data illustrate how transitions from grassland to woodland vegetation can be mediated by a rodent herbivore. They further demonstrate how purposeful or inadvertent removal of native herbivores can have unforeseen effects on plant species composition and landscape physiognomy. Investigations of environmental constraints on vegetation distribution and abundance should take into account the historical role of herbivores in shaping the present system. Inconsistencies among historic accounts of woody plant distribution and abundance in semiarid western North America may be resolved by considering population dynamics of prairie dogs. Widespread eradication of this formerly abundant rodent has eliminated a significant constraint to woody plant establishment on many semiarid grassland and savanna landscapes and has thereby facilitated transitions to shrubland and woodland states. Past land management designed to remove one perceived impediment to livestock production appears to have contributed significantly to development of another management problem that is now a major detriment to sustainable livestock production.

West, D.C., T.W. Doyle, M.L. Tharp, J.J. Beauchamp, W.J. Platt, and D.J. Downing. 1993. Recent growth increases in old-growth longleaf pine. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 23(5):846-853.

Longleaf pine (*Pinus palustris* Mill.) tree-ring data were obtained from an old-growth stand located in Thomas County, Georgia. The tree-ring chronology from the pine stand is composed of a collection of cores extracted from 26 trees ranging in age from approximately 100 to 400 years. These cores were prepared, dated, and measured, and the resulting data were examined with dendrochronological and statistical techniques. Beginning in approximately 1950 and continuing to the present, annual increments of all age classes examined in this study have increased, resulting in an average annual ring increment approximately 40% greater in 1987 than in 1950. When compared with expected annual increment, the increase for 100- to 150- year-old trees is approximately 45%, while the increase for 200- to 400-year-old trees is approximately 35%. In terms of stand-level aboveground biomass accumulation, the increased growth has resulted in approximately 5% more biomass than expected. The increased growth cannot be explained by disturbance; stand history; or trends in precipitation, temperature, or Palmer drought severity index over the last 57 years. Increased atmospheric CO₂ is a possible explanation for initiation of the observed trend, while SO(x) and NO(x) may be augmenting continuation of this phenomenon.

Wheeler, R.M., K.A. Corey, J.C. Sager, and W.M. Knott. 1993. Gas-exchange characteristics of wheat stands grown in a closed, controlled environment. *Crop Science* 33(1):161-168.

Information on gas exchange of crop stands grown in controlled environments is limited, but is vital for assessing the use of crops for human life-support in closed habitats envisioned for space. Two studies were conducted to measure gas exchange of wheat stands (*Triticum aestivum* L. cv. Yecora Rojo) grown from planting to maturity in a large (20 m² canopy area), closed growth chamber. Daily rates of dark-period respiration and net photosynthesis of the stand were calculated from rates of CO₂ build-up during dark cycles and subsequent CO₂ drawdown in the light (i.e., a closed-system approach). Lighting was provided as a 20-h photoperiod by high-pressure sodium lamps, with canopy-level photosynthetic photon flux density (PPFD) ranging from 500 to 800 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ as canopy height increased. Net photosynthesis rates peaked near 27 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ at 25 d after planting, which corresponded closely with stand closure, and then declined slowly with age. Similarly, dark-period respiration rates peaked near 14 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ at 25 d and then gradually declined with age. Responses to short-term changes in irradiance after canopy closure indicated the stand light compensation point for photosynthesis to be near 200 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ PPFD. Tests in which CO₂ concentration was raised to almost-equal-to 2000 $\mu\text{mol mol}^{-1}$ and then allowed to draw down to a compensation point showed that net photosynthesis was nearly saturated at > 1000 $\mu\text{mol mol}^{-1}$; below almost-equal-to 500 $\mu\text{mol mol}^{-1}$, net photosynthesis rates dropped sharply with decreasing CO₂. The CO₂ compensation point for photosynthesis occurred near 50 $\mu\text{mol mol}^{-1}$. Short-term (24 h) temperature tests showed net photosynthesis at 20-degrees-C greater-than- or-equal-to 16-degrees-C > 24-degrees-C, while dark-period respiration at 24-degrees-C > 20-degrees-C > 16-degrees-C. Rates of stand evapotranspiration peaked near Day 25 and remained relatively constant until about Day 75, after which rates declined slowly. Results from these tests will be used to model the use of plants for CO₂ removal, O₂ production, and water evaporation for controlled ecological life support systems proposed for

extraterrestrial environments.

Wheeler, R.M., C.L. Mackowiak, J.C. Sager, and W.M. Knott. 1994. Growth of soybean and potato at high CO₂ partial pressures. *Life Sciences and Space Research XXV (3) 14(11):251-255.*

Soybean and potato plants were grown in controlled environments at carbon dioxide (CO₂) partial pressures ranging from 0.05 to 1.00 kPa. The highest yields of edible biomass occurred at 0.10 kPa for both species, with higher CO₂ levels being supraoptimal, but not injurious to the plants. Stomatal conductance rates of upper canopy leaves were lowest at 0.10 kPa CO₂, while conductance rates at 0.50 and 1.00 kPa were significantly greater than 0.10 kPa. Total water use by the plants was greatest at the highest CO₂ pressures (i.e. 0.50 and 1.00 kPa); consequently, water use efficiencies (biomass produced / water used) were low at the highest CO₂ pressures. Based on previous CO₂ studies in the literature, the increased conductance and water use at the highest CO₂ pressures were surprising and pose interesting challenges for managing plants in a CELSS, where CO₂ pressures may exceed optimal levels.

Wheeler, R.M., C.L. Mackowiak, L.M. Siegfried, and J.C. Sager. 1993. Supraoptimal carbon-dioxide effects on growth of soybean [glycine-max (L) merr]. *Journal of Plant Physiology 142(2):173-178.*

In tightly closed environments used for human life support in space, carbon dioxide (CO₂) partial pressures can reach 500 to 1000 Pa, which may be supraoptimal or toxic to plants used for life support. To study this, soybeans [Glycine max (L.) Merr. cvs. McCall and Pixie] were grown for 90 days at 50, 100, 200, and 500 Pa partial pressure CO₂ (500, 1000, 2000, and 5000 ppm). Plants were grown using recirculating nutrient film technique with a 12-h photoperiod, a 26-degrees-C/20-degrees-C thermoperiod, and approximately 300 μmol m⁻² s⁻¹ photosynthetic photon flux (PPF). Seed yield and total biomass were greatest at 100 Pa for cv. McCall, suggesting that higher CO₂ levels were supraoptimal. Seed yield and total biomass for cv. Pixie showed little difference between CO₂ treatments. Average stomatal conductance of upper canopy leaves at 50 Pa CO₂ almost-equal-to 500 Pa > 200 Pa > 100 Pa. Total water use over 90 d for both cultivars (combined on one recirculating system) equalled 822 kg water for 100 Pa CO₂, 845 kg for 50 Pa, 879 kg for 200 Pa, and 1194kg for 500 Pa. Water use efficiencies for both cultivars combined equalled 3.03 (g biomass kg⁻¹ water) for 100 Pa CO₂, 2.54 g kg⁻¹ for 200 Pa, 2.42 g kg⁻¹ for 50 Pa, and 1.91 g kg⁻¹ for 500 Pa. The increased stomatal conductance and stand water use at the highest CO₂ level (500 Pa) were unexpected and pose interesting considerations for managing plants in a tightly closed system where CO₂ concentrations may reach high levels.

Wheeler, R.M., C.L. Mackowiak, G.W. Stutte, N.C. Yorio, and W.L. Berry. UNKNOWN YEAR. Effect of elevated carbon dioxide on nutritional quality of tomato. *Life Sciences: Life Support Systems Studies-I :1975-1978.*

Tomato (*Lycopersicon esculentum* Mill.) cvs. Red Robin (RR) and Reimann Philipp (RP) were grown hydroponically for 105 d with a 12 h photoperiod, 26 degrees C /22 degrees C thermoperiod, and 500 μmol.m⁻².s⁻¹ PPF at either 400, 1200, 5000, or 10,000 μmol.mol⁻¹ (0.04, 0.12, 0.50, 1.00 kPa) CO₂. Harvested fruits were analyzed for proximate composition, total dietary fiber, nitrate, and elemental composition. No trends were apparent with regard to CO₂ effects on proximate composition, with fruit from all treatments and both cultivars averaging 18.9% protein, 3.6% fat, 10.2% ash, and 67.2% carbohydrate. In comparison, average values for field-grown fruit are 16.6% protein, 3.8% fat, 8.1% ash, and 71.5% carbohydrate (Duke and Atchely, 1986). Total dietary fiber was highest at 10,000 μmol.mol⁻¹ (28.4% and 22.6% for RR and RP) and lowest at 1000 μmol.mol⁻¹ (18.2% and 15.9% for RR and RP), but showed no overall trend in response to CO₂. Nitrate values ranged from 0.19% to 0.35% and showed no trend with regard to CO₂. K, Mg, and P concentrations showed no trend in response to CO₂ but Ca levels increased from 198 and 956 ppm in RR and RP at 400 μmol.mol⁻¹, to 2537 and 2825 ppm at 10,000 μmol.mol⁻¹. This increase in Ca caused an increase in fruit Ca/P ratios from 0.07 and 0.37 for RR and RP at 400 μmol.mol⁻¹, to 0.99 and 1.23 for RR and RP at 10,000 μmol.mol⁻¹, suggesting that more dietary Ca should be available from high CO₂-grown fruit. Wheeler, R.M., C.L. Mackowiak, N.C. Yorio, and J.C. Sager. 1999. Effects of CO₂ on stomatal conductance: Do stomata open at very high CO₂ concentrations? *Annals of Botany 83(3):243-251.*

Potato and wheat plants were grown for 50 d at 400, 1000 and 10 000 μmol mol⁻¹ carbon dioxide (CO₂), and sweetpotato and soybean were grown at 1000 μmol mol⁻¹ CO₂ in controlled environment chambers to study stomatal conductance and plant water use. Lighting was provided with fluorescent lamps as a 12 h photoperiod with 300 μmol m⁻² s⁻¹ PAR. Mid-day stomatal conductances for potato were greatest at 400 and 10 000 μmol mol⁻¹ and least at 1000 μmol mol⁻¹ CO₂. Mid-day conductances for wheat were greatest at 400 μmol mol⁻¹ and least at 1000 and 10 000 μmol mol⁻¹ CO₂. Mid-dark period conductances for potato were significantly greater at 10 000 μmol mol⁻¹ than at 400 or 1000 μmol mol⁻¹, whereas dark conductance for wheat was similar in all CO₂ treatments. Temporarily changing the CO₂ concentration from the native 1000 μmol mol⁻¹ to 400 μmol mol⁻¹ increased mid-day conductance for all species, while temporarily changing from 1000 to 10 000 μmol mol⁻¹ also increased conductance for potato and sweetpotato. Temporarily changing the dark period CO₂ from 1000 to 10 000 μmol mol⁻¹ increased conductance for potato, soybean and sweetpotato. In all cases, the stomatal responses were reversible, i.e. conductances returned to original rates following temporary changes in CO₂ concentration. Canopy water use for potato was greatest at 10 000, intermediate at 400, and least at 1000 μmol mol⁻¹ CO₂, whereas canopy water use for wheat was greatest at 400 and similar at 1000 and 10 000 μmol mol⁻¹ CO₂. Elevated CO₂ treatments (i.e. 1000 and 10 000 μmol mol⁻¹) resulted in increased plant biomass for both wheat and potato relative to 400 μmol mol⁻¹, and no injurious effects were apparent from the 10 000 μmol mol⁻¹ treatment. Results indicate that super-elevated CO₂ (i.e. 10 000 μmol mol⁻¹) can increase stomatal conductance in some species, particularly during the dark period, resulting in increased water use and decreased water use efficiency. Wheeler, R.M., and T.W. Tibbitts. 1997. Influence of changes in daylength and carbon dioxide on the growth of potato. *Annals of Botany* 79(5):529-533.

Potatoes (*Solanum tuberosum* L.) are highly productive in mid- to high-latitude areas where photoperiods change significantly throughout the growing season. To study the effects of changes in photoperiod on growth and tuber development of potato cv. Denali, plants were grown for 112 d with 400 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photosynthetic photon flux (PPF) under a 12-h photoperiod (short days, SD), a 24-h photoperiod (long days, LD), and combinations where plants were moved between the two photoperiods 28, 56, or 84 d after planting. Plants given LD throughout growth received the greatest total daily PPF and produced the greatest tuber yields. At similar levels of total PPF, plants given SD followed by LD yielded greater tuber dry mass (DM) than plants given LD followed by SD. Stem DM per plant, leaf DM, and total plant DM all increased with an increasing proportion of LD and increasing daily PPF, regardless of the daylength sequence. When studies were repeated, but at an enriched (1000 $\mu\text{mol mol}^{-1}$) CO_2 concentration, overall growth trends were similar, with high CO_2 resulting in greater stem length, stem DM, leaf DM, and total plant DM; but high CO_2 did not increase tuber DM. Wheeler, R.M., T.W. Tibbitts, and A.H. Fitzpatrick. 1991. Carbon-dioxide effects on potato growth under different photoperiods and irradiance. *Crop Science* 31(5):1209-1213.

Carbon dioxide concentration can exert a strong influence on plant growth, but this influence can vary depending on irradiance. To study this, potato plants (*Solanum tuberosum* L.) cultivars 'Norland', 'Russet Burbank', and 'Denali' were grown in controlled-environment rooms at different levels of CO_2 and irradiance. Carbon dioxide levels were maintained either at 350 or 100- $\mu\text{mol mol}^{-1}$ and applied in combination with 12- or 24-h photoperiods at 400 or 800- $\mu\text{mol m}^{-2} \text{s}^{-1}$ photosynthetic photon flux. Air temperatures and relative humidity were held constant at 16-degrees-C and 70%, respectively, and plants were harvested 90 d after planting. When averaged across all cultivars, CO_2 enrichment increased tuber yield and total plant dry weight by 39 and 34%, respectively, under a 12-h photoperiod at 400- $\mu\text{mol m}^{-2} \text{s}^{-1}$; 27 and 19% under 12 h at 800- $\mu\text{mol m}^{-2} \text{s}^{-1}$; 9 and 9% under 24 h at 400- $\mu\text{mol m}^{-2} \text{s}^{-1}$. It decreased dry weights by 9 and 9% under 24 h at 800- $\mu\text{mol m}^{-2} \text{s}^{-1}$. Tuber yield of Denali showed the greatest increase (21%) in response to increased CO_2 across all irradiance treatments, while tuber yields of Russet Burbank and Norland were increased 18 and 9%, respectively. The results show a pattern of greater plant growth from CO_2 enrichment under lower PPF and a short photoperiod.

Wheeler, T.R., G.R. Batts, R.H. Ellis, P. Hadley, and J.I.L. Morison. 1996. Growth and yield of winter wheat (*Triticum aestivum*) crops in response to CO_2 and temperature. *Journal of Agricultural Science* 127:37-48.

Crops of winter wheat (*Triticum aestivum* L. cv. Hereward) were grown

within temperature gradient tunnels at a range of temperatures at either c. 350 or 700 $\mu\text{mol mol}^{-1}$ CO_2 in 1991/92 and 1992/93 at Reading, UK. At terminal spikelet stage, leaf area was 45% greater at elevated CO_2 in the first year due to more tillers, and was 30% greater in the second year due to larger leaf areas on the primary tillers. At harvest maturity, total crop biomass was negatively related to mean seasonal temperature within each year and CO_2 treatment, due principally to shorter crop durations at the warmer temperatures. Biomass was 6-31% greater at elevated compared with normal CO_2 and was also affected by a positive interaction between temperature and CO_2 in the first year only. Seed yield per unit area was greater at cooler temperatures and at elevated CO_2 concentrations. A 7-44% greater seed dry weight at elevated CO_2 in the first year was due to more ears per unit area and heavier grains. In the following year, mean seed dry weight was increased by > 72% at elevated CO_2 , because grain numbers per ear did not decline with an increase in temperature at elevated CO_2 . Grain numbers were reduced by temperatures > 31 degrees C immediately before anthesis at normal atmospheric CO_2 in 1992/93, and at both CO_2 concentrations in 1991/92. To quantify the impact of future climates of elevated CO_2 concentrations and warmer temperatures on wheat yields, consideration of both interactions between CO_2 and mean seasonal temperature, and possible effects of instantaneous temperatures on yield components at different CO_2 concentrations are required. Nevertheless, the results obtained suggest that the benefits to winter wheat grain yield from CO_2 doubling are offset by an increase in mean seasonal temperature of only 1.0 degrees C to 1.8 degrees C in the UK.

Wheeler, T.R., R.H. Ellis, P. Hadley, and J.I.L. Morison. 1995. Effects of CO_2 , temperature and their interaction on the growth, development and yield of cauliflower (*Brassica oleracea* L botrytis). *Scientia Horticulturae* 60(3-4):181-197.

Stands of summer cauliflower were grown within polyethylene-covered tunnels along which a temperature gradient was imposed. Two tunnels were maintained at either normal or elevated CO_2 concentrations. At the last harvest (88 days from transplanting) no interaction between CO_2 and temperature on total biomass was detected. The total dry weight of plants grown at 531 $\mu\text{mol mol}^{-1}$ CO_2 was 34% greater than those grown at 328 $\mu\text{mol mol}^{-1}$ CO_2 , whereas a 1 degrees C rise reduced dry weight by 6%. From serial harvests the radiation conversion coefficient was 2.01 g MJ⁻¹ and 1.42 g MJ⁻¹ at 531 $\mu\text{mol mol}^{-1}$ CO_2 and 328 $\mu\text{mol mol}^{-1}$ CO_2 , respectively, but was not greatly affected by differences in temperature. No effect of either CO_2 or temperature on the canopy light extinction coefficient was detected. The rate of progress towards curd initiation increased to a maximum at 15.5 degrees C, and declined thereafter. Provided the effect of temperature was accounted for, CO_2 enrichment did not affect the time of curd initiation. From serial harvests after curd initiation, the logarithm of curd weight or diameter were negative linear functions of mean temperature from initiation. Increases in curd weight and diameter at 531 compared with 328 $\mu\text{mol mol}^{-1}$ CO_2 were greater at warmer temperatures (27% at 13 degrees C compared with 47% at 15 degrees C, 57 days after initiation). Effects of CO_2 on curd diameter were less than those on curd dry weight because the curd dry matter content was greater at 531 compared with 328 $\mu\text{mol mol}^{-1}$ CO_2 . Thus, the effects of elevated CO_2 concentrations on fresh weight based yield parameters of cauliflower were less than the increase in total dry matter production.

Wheeler, T.R., T.D. Hong, R.H. Ellis, G.R. Batts, J.I.L. Morison, and P. Hadley. 1996. The duration and rate of grain growth, and harvest index, of wheat (*Triticum aestivum* L.) in response to temperature and CO₂. *Journal of Experimental Botany* 47(298):623-630.

Winter wheat (*Triticum aestivum* L. cv. Hereward) was grown in the field inside polyethylene-covered tunnels at a range of temperatures at either 380 or 684 $\mu\text{mol mol}^{-1}$ CO₂. Serial harvests were taken from anthesis until harvest maturity. Grain yield was reduced by warmer temperatures, but increased by CO₂ enrichment at all temperatures. During grain-filling, individual grain dry weight was a linear function of time from anthesis until mass maturity (attainment of maximum grain dry weight) within each plot. The rate of progress to mass maturity (the reciprocal of time to mass maturity) was a positive linear function of mean temperature, but was not affected by CO₂ concentration. The rate of increase in grain dry weight per ear was 2.0 mg d⁻¹ greater per 1 degrees C rise, and was 8.0 mg d⁻¹ greater at 684 compared with 380 $\mu\text{mol mol}^{-1}$ CO₂ at a given temperature. The rate of increase in harvest index was 1.0% d⁻¹ in most plots at 380 $\mu\text{mol mol}^{-1}$ CO₂ and in open field plots, compared with 1.18% d⁻¹ in all plots at 684 $\mu\text{mol mol}^{-1}$ CO₂. Thus, the increased rate of grain growth observed at an elevated CO₂ concentration could be attributed partly to a change in the partitioning of assimilates to the grain. In contrast, the primary effect of warmer temperatures was to shorten the duration of grain-filling. The rate of grain growth at a given temperature and the rate of increase in harvest index were only independent of the number of grains per ear above a critical grain number of 23-24 grains per ear (similar to 20 000 grains m⁻²).

Wheeler, T.R., J.I.L. Morison, R.H. Ellis, and P. Hadley. 1994. The effects of CO₂, temperature and their interaction on the growth and yield of carrot (*Daucus carota* L.). *Plant, Cell and Environment* 17(12):1275-1284.

Stands of carrot (*Daucus carota* L.) were grown in the field within polyethylene-covered tunnels at a range of soil temperatures (from a mean of 7.5 degrees C to 10.9 degrees C) at either 348 (SE = 4.7) or 551 (SE = 7.7) $\mu\text{mol mol}^{-1}$ CO₂. The effect of increased atmospheric CO₂ concentration on root yield was greater than that on total biomass. At the last harvest (137 d from sowing), total biomass was 16% (95% CI=6%, 27%) greater at 551 than at 348 $\mu\text{mol mol}^{-1}$ CO₂, and 37% (95% CI=30%, 44%) greater as a result of a 1 degrees C rise in soil temperature. Enrichment with CO₂, or a 1 degrees C rise in soil temperature increased root yield by 31% (95% CI=19%, 45%) and 34% (95% CI=27%, 42%), respectively, at this harvest. No effect on total biomass or root yield of an interaction between temperature and atmospheric CO₂ concentration at 137 DAS was detected. When compared at a given leaf number (seven leaves), CO₂ enrichment increased total biomass by 25% and root yields by 80%, but no effect of differences in temperature on plant weights was found. Thus, increases in total biomass and root yield observed in the warmer crops were a result of the effects of temperature on the timing of crop growth and development. Partitioning to the storage roots during early root expansion was greater at 551 than at 348 $\mu\text{mol mol}^{-1}$ CO₂. The root to total weight ratio was unaffected by differences in temperature at 551 $\mu\text{mol mol}^{-1}$ CO₂, but was reduced by cooler temperatures at 348 $\mu\text{mol mol}^{-1}$ CO₂. At a given thermal time from sowing, CO₂ enrichment increased the leaf area per plant, particularly during early root growth, primarily as a result of an increase in the rate of leaf area expansion, and not an increase in leaf number.

Whetton, P.H., A.M. Fowler, M.R. Haylock, and A.B. Pittock. 1993. Implications of climate-change due to the enhanced greenhouse- effect on floods and droughts in Australia. *Climatic Change* 25(3-4):289-317.

Potential impacts of climate change on heavy rainfall events and flooding in the Australian region are explored using the results of a general circulation model (GCM) run in an equilibrium enhanced greenhouse experiment. In the doubled CO₂ simulation, the model simulates an increase in the frequency of high-rainfall events and a decrease in the frequency of low-rainfall events. This result applies over most of Australia, is statistically more significant than simulated changes in total rainfall, and is supported by theoretical considerations. We show that this result implies decreased return periods for heavy rainfall events. The further implication is that flooding could increase, although we discuss here the many difficulties associated with assessing in quantitative terms the significance of the modelling results for the real world. The second part of the paper assesses the implications of climate change for drought occurrence in Australia. This is undertaken using an off-line soil water balance model driven by observed time series of rainfall and potential evaporation to determine the sensitivity of the soil water regime to changes in rainfall and temperature, and hence potential evaporation. Potential impacts are assessed at nine sites, representing a range of climate regimes and possible climate futures, by linking this sensitivity analysis with scenarios of regional climate change, derived from analysis of enhanced greenhouse experiment results from five GCMs. Results indicate that significant drying may be limited to the south of Australia. However, because the direction of change in terms of the soil water regime is uncertain at all sites and for all seasons, there is no basis for statements about how drought potential may change.

Whiley, A.W., C. Searle, B. Schaffer, and B.N. Wolstenholme. 1999. Cool orchard temperatures or growing trees in containers can inhibit leaf gas exchange of avocado and mango. *Journal of the American Society for Horticultural Science* 124(1):46-51.

Leaf gas exchange of avocado (*Persea americana* Mill.) and mango (*Mangifera indica* L.) trees in containers and in an orchard (field-grown trees) was measured over a range of photosynthetic photon fluxes (PPF) and ambient CO₂ concentrations (C-a). Net CO₂ assimilation (A) and intercellular partial pressure of CO₂ (C_i) were determined for all trees in early autumn (noncold-stressed leaves) when minimum daily temperatures were greater than or equal to 14 degrees C, and for field-grown trees in winter (cold-stressed leaves) when minimum daily temperatures were less than or equal to 10 degrees C. Cold-stressed trees of both species had lower maximum CO₂ assimilation rates (A(max)), light saturation points (Q(A)), CO₂ saturation points (C-aSAT) and quantum yields than leaves of noncold-stressed, field-grown trees. The ratio of variable to maximum fluorescence (F-v/F-m) was approximate to 50% lower for leaves of cold-stressed, field-grown trees than for leaves of nonstressed, field-grown trees, indicating chill-induced photoinhibition of leaves had occurred in winter. The data indicate that chill-induced photoinhibition of A and/or sink limitations caused by root restriction in container-grown trees can limit carbon assimilation in avocado and mango trees.

White, A., M.G.R. Cannell, and A.D. Friend. 1999. Climate change impacts on ecosystems and the terrestrial carbon sink: a new assessment. *Global Environmental Change-Human and Policy Dimensions* 9:S21-S30.

Climate output from the UK Hadley Centre's HadCM2 and HadCM3 experiments for the period 1860 to 2100, with IS92a greenhouse gas forcing, together with predicted patterns of N deposition and increasing CO₂, were input (offline) to the dynamic vegetation model, Hybrid v4.1 (Friend et al., 1997; Friend and White, 1999). This model represents biogeochemical, biophysical and biogeographical processes, coupling the carbon, nitrogen and water cycles on a sub-daily timestep, simulating potential vegetation and transient changes in annual growth and competition between eight generalized plant types in response to climate. Global vegetation carbon was predicted to rise from about 600 to 800 PgC (or to 650 PgC for HadCM3) while the soil carbon pool of about 1100 PgC decreased by about 8%. By the 2080s, climate change caused a partial loss of Amazonian rainforest, C-4 grasslands and temperate forest in areas of southern Europe and eastern USA, but an expansion in the boreal forest area. These changes were accompanied by a decrease in net primary productivity (NPP) of vegetation in many tropical areas, southern Europe and eastern USA in response to warming and a decrease in rainfall, but an increase in NPP of boreal forests. Global NPP increased from 45 to 50 PgC y⁻¹ in the 1990s to about 65 PgC y⁻¹ in the 2080s (about 58 PgC y⁻¹ for HadCM3). Global net ecosystem productivity (NEP) increased from about 1.3 PgC y⁻¹ in the 1990s to about 3.6 PgC y⁻¹ in the 2030s and then declined to zero by 2100 owing to a loss of carbon from declining forests in the tropics and at warm temperate latitudes - despite strengthening of the carbon sink at northern high latitudes. HadCM3 gave a more erratic temporal evolution of NEP than HadCM2, with a dramatic collapse in NEP in the 2050s. (C) 1999 Elsevier Science Ltd. All rights reserved.

White, N.D.G., D.S. Jayas, and W.E. Muir. 1995. Toxicity of carbon-dioxide at biologically producible levels to stored-product beetles. *Environmental Entomology* 24(3):640-647.

The effect of concentrations of carbon dioxide (CO₂) that can be produced by biological respiration (7.5-19.2%) on oviposition of adult *Tribolium castaneum* (Herbst), *Cryptolestes pusillus* (Schonherr), or *C. ferrugineus* (Stephens) was determined. Relative to controls, *T. castaneum*, *C. pusillus*, and *C. ferrugineus*, exposed to 7.5% CO₂ for 1 wk, had numbers of offspring reduced by 43, 94, and 50%, respectively, and the total population at 6 wk was reduced 53, 84, and 19%, respectively. With levels of greater than or equal to 17.1% CO₂ for 1 wk, no offspring were produced and exposed adults had high mortality. Eggs and subsequent immatures of *Tribolium confusum* J. du Val, *T. castaneum*, or *C. ferrugineus* were exposed for 3 wk to elevated levels of CO₂ at 22 degrees C. Insect development was similar at 7.5 and 8.6% CO₂ with mean mortality 43, 62, and 30% greater than controls for *T. confusum*, *T. castaneum*, and *C. ferrugineus*, respectively. Also, mean levels of 5.8-8.3% CO₂ for 7 wk reduced, on all sampling dates, populations of *T. confusum* by 85%, *T. castaneum* by 99%, *C. pusillus* by 68%, and *C. ferrugineus* by 54%. Although *T. castaneum* had a greater oviposition rate than *C. pusillus* at 7.5% CO₂, immature mortality was greater for *T. castaneum*. Based on long-term exposure to levels of CO₂ which can be produced by biological activity that affects oviposition and immature development, species in increasing order of

sensitivity to CO₂ are *C. ferrugineus*, *C. pusillus*, *T. confusum*, and *T. castaneum*.

Whitehead, D., K.P. Hogan, G.N.D. Rogers, J.N. Byers, J.E. Hunt, T.M. McSeveny, D.Y. Hollinger, R.J. Dungan, W.B. Earl, and M.P. Bourke. 1995. Performance of large open-top chambers for long-term field investigations of tree response to elevated carbon dioxide concentration. *Journal of Biogeography* 22(2-3):307-313.

In preparation for an investigation of the effects of elevated carbon dioxide (CO₂) concentration on the two tree species *Pinus radiata* D. Don and *Nothofagus fusca* (Hook. f.) Oerst, the environmental conditions inside sixteen open-top chambers, of the design described by Heagle et al. (1989), were measured and compared with those outside. During a period in late summer, both air temperature and air saturation deficit were greater inside the chambers, with mean increases of 0.3 degrees C and 0.1 kPa, respectively. The increases were closely related to solar irradiance, reaching maximum differences for temperature and air saturation deficit of 4.3 degrees C and 0.8 kPa, respectively, when solar irradiance was greater than 1600 $\mu\text{mol m}^{-2}\text{s}^{-1}$. The mean ($\pm$ standard deviation) CO₂ concentrations for the ambient and elevated treatments were 362 $\pm$ 37 and 654 $\pm$ 69 $\mu\text{mol mol}^{-1}$, respectively. However, the CO₂ concentration in the elevated treatment decreased as windspeed increased, owing to incursions of ambient air into the chambers. Transmittance of visible solar irradiance (400- 700 nm) through the plastic wall material decreased by 7% after 1 year of exposure at the site. In cloudy conditions the mean transmittance of solar irradiance into the chambers was 81% and on clear days this decreased from 80% to 74% with increasing solar zenith angle. The ratio of diffuse to total solar irradiance in the chambers was 13% and 21% greater than that outside for cloudy and clear conditions, respectively. The implications of these differences on water use efficiency for the trees growing inside and outside the chamber are discussed. A cost effective system, built to separate the CO₂ required for the experiment from waste biogas, is described. This project is contributing to the Global Change and Terrestrial Ecosystems (GCTE) Core Research Programme by providing data on the long-term effects of elevated CO₂ concentration on the above and below-ground carbon balance for the two tree species.

Whitehead, S.J., S.J.M. Caporn, and M.C. Press. 1997. Effects of elevated CO₂, nitrogen and phosphorus on the growth and photosynthesis of two upland perennials: *Calluna vulgaris* and *Pteridium aquilinum*. *New Phytologist* 135(2):201-211.

Bracken (*Pteridium aquilinum* (L.) Kuhn) and heather (*Calluna vulgaris* (L.) Hull) are important upland species which often grow in close proximity in the UK. The effects of factorial treatments of elevated atmospheric CO₂ (539 $\mu\text{mol mol}^{-1}$) as opposed to ambient atmospheric CO₂ concentrations of 355 $\mu\text{mol mol}^{-1}$), added N (50 kg N ha⁻¹ as NH₄NO₃) and added P (20 kg P ha⁻¹ as NaH₂PO₄) on the performance of these two species were studied under controlled environmental conditions using container-grown plants. Plants grown and measured at high CO₂ had higher rates of net photosynthesis than those grown and measured in ambient CO₂. This increase was greater in heather than in bracken and resulted in a large stimulation of growth in the former. In bracken there was no significant change in plant size or phenology. The increase in biomass of heather in high CO₂ was greatest in the absence of added nutrients and lowest when both N and P were supplied. The growth and photosynthesis of both plants responded

positively to the supply of P alone or P with N (in both CO₂ atmospheres), but there was little response to N alone. The implications of these findings for bracken and heather growing in the held under conditions of an elevated CO₂ atmosphere and greater nutrient availability are discussed.

Whiting, D.C., J. Vandenheuvel, and S.P. Foster. 1992. Potential of low oxygen moderate carbon-dioxide atmospheres for postharvest disinfestation of new-zealand apples. *New Zealand Journal of Crop and Horticultural Science* 20(2):217-222.

Work on the mortality responses of four lepidopteran pests of apples in New Zealand-Epiphyas postvittana (Walker), Cydia pomonella (L.), Planotortrix octo Dugdale, and Ctenopseustis obliquana (Walker)-to low O₂/moderate CO₂ atmospheres is reviewed and additional data are presented. For both E. postvittana and C. pomonella, reducing the O₂ concentration and elevating the treatment temperature enhanced controlled atmosphere (CA) efficacy more than did increasing the CO₂ concentration. Thus at 20-degrees-C, a 0.4% O₂/5.0% CO₂ CA gave the most rapid kill of the mixtures tested. The order of lifestage tolerance to this CA was similar for E. postvittana, C. pomonella, P. octo, and C. obliquana i.e., fifth instar > third instar > 3-day eggs > first instar. The four species exhibited a trend of tolerance of C. pomonella > E. postvittana = P. octo = C. obliquana. An increase in the temperature to 30- degrees-C decreased the time for high mortality for all four species. However, this decrease was much greater for P. octo and C. obliquana than for C. pomonella and E. postvittana. The potential of these CA treatments for disinfestation of New Zealand apples for the Japanese and United States markets is discussed.

Whiting, G.J., and J.P. Chanton. 1993. Primary production control of methane emission from wetlands. *Nature* 364(6440):794-795.

WETLANDS, both natural and agricultural, contribute an estimated 40 to 50% of the total methane emitted to the atmosphere each year. Recent efforts in atmospheric modelling¹ and attempts to constrain CH₄ source strengths² have indicated the need to delineate the processes responsible for the large variations in emission rates found within and across wetland types. Numerous biogeochemical factors are known to affect the activity of methanogenic bacteria^{3,4} and although there has been some success in relating water level⁵⁻⁷ and temperature^{8,9} to CH₄ emissions within particular systems, these variables are insufficient for predicting emissions across a variety of wetlands^{2,10}. From simultaneous measurements of CO₂ and CH₄ exchange in wetlands extending from subarctic peatlands to subtropical marshes, we report here a positive correlation between CH₄ emission and net ecosystem production and suggest that net ecosystem production is a master variable, integrating many factors which control CH₄ emission in vegetated wetlands. We find that about 3 per cent of the daily net ecosystem production is emitted back to the atmosphere as CH₄. With projected stimulation of primary production and soil microbial activity in wetlands associated with elevated atmospheric CO₂ concentrations¹¹, we envisage the potential for increasing CH₄ emissions from inundated wetlands, further enhancing the greenhouse effect.

Whitney, S.M., S. von Caemmerer, G.S. Hudson, and T.J. Andrews. 1999. Directed mutation of the Rubisco large subunit of tobacco influences photorespiration and growth. *Plant Physiology* 121(2):579-588.

The gene for the large subunit of Rubisco was specifically mutated by transforming the chloroplast genome of tobacco (*Nicotiana tabacum*). Codon 335 was altered to encode valine instead of leucine. The resulting mutant plants could not grow without atmospheric CO₂ enrichment. In 0.3% (v/v) CO₂, the mutant and wildtype plants produced similar amounts of Rubisco but the extent of carbamylation was nearly twice as great in the mutants. The mutant enzyme's substrate-saturated CO₂-fixing rate and its ability to distinguish between CO₂ and O-2 as substrates were both reduced to 25% of the wild type's values. Estimates of these parameters obtained from kinetic assays with the purified mutant enzyme were the same as those inferred from measurements of photosynthetic gas exchange with leaves of mutant plants. The Michaelis constants for CO₂, O-2, and ribulose-1,5-bisphosphate were reduced and the mutation enhanced oxygenase activity at limiting O-2 concentrations. Consistent with the reduced CO₂ fixation rate at saturating CO₂, the mutant plants grew slower than the wild type but they eventually flowered and reproduced apparently normally. The mutation and its associated phenotype were inherited maternally. The chloroplast-transformation strategy surmounts previous obstacles to mutagenesis of higher-plant Rubisco and allows the consequences for leaf photosynthesis to be assessed.

Whittaker, J.B. 1999. Impacts and responses at population level of herbivorous insects to elevated CO₂. *European Journal of Entomology* 96(2):149-156.

Most studies of responses of insects to elevated carbon dioxide have been made using short-term exposures to treated food plants and have involved measurements of responses in growth, reproduction, food consumption and efficiencies of conversion at specific stages in the life cycle. These will be reviewed in the light of longer-term studies recently published where whole generations have been reared in chambers with simultaneous treatment of plants and where insects have been free to select their food and microenvironment. Factors such as seasonal change in plants, choice of food plant, mode of feeding, timing of exposure, temperature, the role of natural enemies are considered and the whole placed in the context of other aspects of climate change. It is concluded that in studies to date, the only feeding guild in which some species have shown increases in population density in elevated carbon dioxide are the phloem feeders. Chewing insects (both free-living, and mining) generally have shown no change or reduction in abundance, though relative abundance may be greatly affected. Compensatory feeding is common in these groups.

Wiemken, V., L. Kossatz, and K. Ineichen. 1996. Frost hardiness of Norway spruce grown under elevated atmospheric CO₂ and increased nitrogen fertilizing. *Journal of Plant Physiology* 149(3-4):433-438.

Frost hardiness was tested on needles from 6-years-old Norway spruces that had been cultivated for 2 years in artificial ecosystems at an atmospheric CO₂ concentration of 280, 420 or 560 ppm and a nitrogen fertilization corresponding to 0, 30, and 90 kg N ha⁻¹ yr⁻¹ (NH₄NO₃) as well as combinations of these treatments. Samples of previous year's needles were taken after completion of frost hardening in autumn, and at three dates during the dehardening process in spring when potentially harmful late frost events naturally occur. The needles were exposed to freezing temperatures down to -35 degrees C. Samples were taken at 5 degrees C intervals and frost injury was estimated by the electrolyte leakage technique. After autumnal hardening, needles were injured only below -25 degrees C (LT50 < -30 degrees C), while after dehardening in spring the critical frost temperature (LT50) was around -10 degrees C. Frost hardiness was not influenced by the different CO₂ and nitrogen treatments of the trees neither in autumn nor during the dehardening phase in spring.

Wilkins, D., J.J. Vanoosten, and R.T. Besford. 1994. Effects of elevated CO₂ on growth and chloroplast proteins in *Prunus avium*. *Tree Physiology* 14(7-9):769-779.

To predict the future carbon sequestering capacity of trees, we need information about the possible acclimatory mechanisms of plant growth and photosynthesis in rising atmospheric CO₂ under a variety of environmental conditions. We have, therefore, studied the growth response of a tree species (*Prunus avium* L. Stella (wild cherry)) to elevated CO₂ and characterized the associated changes in photosynthetic machinery of the leaf tissue. Self-pollinated seedlings and mature cuttings (clones) from the same parent plant of *P. avium* were grown for two consecutive growing seasons (about 60 days each) in ambient CO₂ (350 μmol mol⁻¹ CO₂) or elevated CO₂ (700 μmol mol⁻¹ CO₂) with a high or low nutrient supply. The degree of acclimation of leaf biochemistry and growth response to elevated CO₂ was dependent on the plant material (seedling or mature cutting) and nutrient supply. There was little or no growth response to elevated CO₂ in seedlings or cuttings in the low nutrient supply treatments, whereas, in both seasons, there was a strongly positive growth response to elevated CO₂ in seedlings and cuttings in the high nutrient supply regimes, resulting in increases in the root/shoot ratio and in carbon allocation to the roots. In contrast, the protein content and activity of ribulose-1,5-bisphosphate carboxylase-oxygenase (Rubisco, EC 4.1.1.39) were down regulated in elevated CO₂. The loss of Rubisco on an area basis in plants in the elevated CO₂ treatments was compensated for at the canopy level by increased leaf area. The loss of Rubisco protein was accompanied by decreases in the contents of chlorophyll and the thylakoid membrane proteins D1, D2 and cytochrome f, which are involved in light harvesting and photo-electron transport. We conclude that, in the medium- to long-term, the initial stimulation of biomass production by elevated CO₂ may be increasingly offset by a lower photosynthetic capacity per unit leaf area in perennial plants.

Wilks, D.S., D.W. Wolfe, and S.J. Riha. 1995. Simple carbon assimilation response functions from atmospheric CO₂, and daily temperature and shortwave radiation. *Global Change Biology* 1(5):337-346.

A global 'CO₂ fertilizer effect' multiplier is often used in crop or ecosystem models because of its simplicity. However, this approach does not take into account the interaction between CO₂, temperature and light on assimilation. This omission can lead to significant under- or overestimation of the magnitude of beneficial effects from elevated CO₂, depending on environmental conditions. We use a mechanistic model of the biochemistry of photosynthesis to represent the response of net assimilation to different levels of CO₂, temperature and radiation, on the daily time scale. Instantaneous assimilation rates for an idealized canopy model are integrated through diurnal cycles of environmental variables derived from historical climate data at three locations in North America. The calculated CO₂ fertilizer effect is greatest at high light and warm temperatures. The results are summarized by assimilation response surfaces specified by the CO₂ concentration, the canopy leaf area index, and by daily values of temperature and radiation available from climatic records. These summary functions are suitable for incorporation into crop or ecosystem models for predicting carbon assimilation or biomass production on a daily time step. An example application of the function reveals that for a relatively cool, high latitude location, the beneficial effects from a CO₂ doubling would be negligible during the early spring, even assuming a + 4 degrees C global warming scenario. In contrast, the beneficial effects from increasing CO₂ at a relatively warm, lower latitude location are greatest in the spring, but decline in late summer because of excessively warm temperatures with a + 4 degrees C global warming.

Will, R.E., and R. Ceulemans. 1997. Effects of elevated CO₂ concentration on photosynthesis, respiration and carbohydrate status of coppice *Populus* hybrids. *Physiologia Plantarum* 100(4):933-939.

To determine how increased atmospheric CO₂ will affect the physiology of coppiced plants, sprouts originating from two hybrid poplar clones (*Populus trichocarpa* x *P. deltoides* - Beaupre and *P. deltoides* x *P. nigra* - Robusta) were grown in open-top chambers containing ambient or elevated (ambient + 360 μmol mol⁻¹) CO₂ concentration. The effects of elevated CO₂ concentration on leaf photosynthesis, stomatal conductance, dark respiration, carbohydrate concentration and nitrogen concentration were measured. Furthermore, dark respiration of leaves was partitioned into growth and maintenance components by regressing specific respiration rate vs specific growth rate. Sprouts of both clones exposed to CO₂ enrichment showed no indication of photosynthetic down-regulation. During reciprocal gas exchange measurements, CO₂ enrichment significantly increased photosynthesis of all sprouts by approximately 60% (P < 0.01) on both an early and late season sampling date, decreased stomatal conductance of all sprouts by 10% (P < 0.04) on the early sampling date and nonsignificantly decreased dark respiration by an average of 11%. Growth under elevated CO₂ had no consistent effect on foliar sugar concentration but significantly increased foliar starch by 80%. Respiration rate was highly correlated with both specific growth rate and percent nitrogen. Long-term CO₂ enrichment did not significantly affect the maintenance respiration coefficient or the growth respiration coefficient. Carbon dioxide enrichment affected the physiology of the sprouts the same way it affected these plants before they were coppiced.

Will, R.E., and R.O. Teskey. 1997. Effect of elevated carbon dioxide concentration and root restriction on net photosynthesis, water relations and foliar carbohydrate status of loblolly pine seedlings. *Tree Physiology* 17(10):655-661.

To determine the effects of CO₂-enriched air and root restriction on photosynthetic capacity, we measured net photosynthetic rates of 1-year-old loblolly pine seedlings grown in 0.6-, 3.8- or 18.9-liter pots in ambient (360 $\mu\text{mol mol}^{-1}$) or 2x ambient CO₂ (720 $\mu\text{mol mol}^{-1}$) concentration for 23 weeks. We also measured needle carbohydrate concentration and water relations to determine whether feedback inhibition or water stress was responsible for any decreases in net photosynthesis. Across all treatments, carbon dioxide enrichment increased net photosynthesis by approximately 60 to 70%. Net photosynthetic rates of seedlings in the smallest pots decreased over time with the reduction occurring first in the ambient CO₂ treatment and then in the 2x ambient CO₂ treatment. Needle starch concentrations of seedlings grown in the smallest pots were two to three times greater in the 2x ambient CO₂ treatment than in the ambient CO₂ treatment, but decreased net photosynthesis was not associated with increased starch or sugar concentrations. The reduction in net photosynthesis of seedlings in small pots was correlated with decreased needle water potentials, indicating that seedlings in the small pots had restricted root systems and were unable to supply sufficient water to the shoots. We conclude that the decrease in net photosynthesis of seedlings in small pots was not the result of CO₂ enrichment or an accumulation of carbohydrates causing feedback inhibition, but was caused by water stress.

Will, R.E., and R.O. Teskey. 1997. Effect of irradiance and vapour pressure deficit on stomatal response to CO₂ enrichment of four tree species. *Journal of Experimental Botany* 48(317):2095-2102.

The stomatal response of seedlings grown in 360 or 720 $\mu\text{mol mol}^{-1}$ to irradiance and leaf-to-air vapour pressure deficit (VPD) at both 360 and 720 $\mu\text{mol mol}^{-1}$ CO₂, was measured to determine how environmental factors interact with CO₂ enrichment to affect stomatal conductance. Seedlings of four species with different conductances and life histories, *Cercis canadensis* (L.), *Quercus rubra* (L.), *Populus deltoides* (Bartr. ex Marsh.) x *P. nigra* (L.), and *Pinus taeda* (L.), were measured in hopes of identifying general responses. Conductance of seedlings grown at 360 and 720 $\mu\text{mol mol}^{-1}$ CO₂ were similar and responded in the same manner to measurement CO₂ concentration, irradiance and VPD. Conductance was lower for all species where measured at 720 than when measured at 360 $\mu\text{mol mol}^{-1}$ CO₂ at both VPDs (similar to 1.5 and similar to 2.5 kPa) and all measured irradiances greater than zero (100, 300, 600, > 1600 $\mu\text{mol m}^{-2} \text{s}^{-1}$). The average decrease in conductance due to measurement in elevated CO₂ concentration was 32% for *Cercis*, 29% for *Quercus*, 26% for *Populus*, and 11% for *Pinus*. For all species, the absolute decrease in conductance due to measurement in CO₂ enrichment decreased as irradiance decreased or VPD increased. The proportional decrease due to measurement in CO₂ enrichment decreased in three of eight cases: from 0.46 to 0.10 in *Populus* and from 0.18 to 0.07 in *Pinus* as irradiance decreased from > 1600 to 100 $\mu\text{mol m}^{-2} \text{s}^{-1}$ and from 0.35 to 0.24 in *Cercis* as VPD increased from 1.3 to 2.6 kPa.

Willekens, H., S. Chamnongpol, M. Davey, M. Schraudner, C. Langebartels, M. VanMontagu, D. Inze, and W. VanCamp. 1997. Catalase is a sink for H₂O₂ and is indispensable for stress defence in C-3 plants. *Embo Journal* 16(16):4806-4816.

Hydrogen peroxide (H₂O₂) has been implicated in many stress conditions. Control of H₂O₂ levels is complex and dissection of mechanisms generating and relieving H₂O₂ stress is difficult, particularly in intact plants. We have used transgenic tobacco with similar to 10% wild-type catalase activity to study the role of catalase and effects of H₂O₂ stress in plants. Catalase-deficient plants showed no visible disorders at low light, but in elevated light rapidly developed white necrotic lesions on the leaves. Lesion formation required photorespiratory activity since damage was prevented under elevated CO₂. Accumulation of H₂O₂ was not detected during leaf necrosis. Alternative H₂O₂-scavenging mechanisms may have compensated for reduced catalase activity, as shown by increased ascorbate peroxidase and glutathione peroxidase levels. Leaf necrosis correlated with accumulation of oxidized glutathione and a 4-fold decrease in ascorbate, indicating that catalase is critical for maintaining the redox balance during oxidative stress. Such control may not be limited to peroxisomal H₂O₂ production. Catalase functions as a cellular sink for H₂O₂, as evidenced by complementation of catalase deficiency by exogenous catalase, and comparison of catalase-deficient and control leaf discs in removing external H₂O₂. Stress analysis revealed increased susceptibility-of catalase-deficient plants to paraquat, salt and ozone, but not to chilling.

Williams, D.W., and A.M. Liebhold. 1995. Herbivorous insects and global change: Potential changes in the spatial distribution of forest defoliator outbreaks. *Journal of Biogeography* 22(4-5):665-671.

The geographical ranges and the spatial extent of outbreaks of herbivorous species are likely to shift with climatic change. We investigated potential changes in spatial distribution of outbreaks of the western spruce budworm, *Choristoneura occidentalis* Freeman, in Oregon, U.S.A. and the gypsy moth, *Lymantria dispar* (L.), in Pennsylvania, U.S.A. using maps of historical defoliation, climate and forest composition in a geographic information system. Maps of defoliation frequency were assembled using historical aerial reconnaissance data. Maps of monthly means of daily temperature maxima and minima and of monthly precipitation averaged over 30 years were developed using an interpolation technique. All maps were at a spatial resolution of 2 x 2 km. Relationships between defoliation status and the environmental variables were modelled using a linear discriminant function. Five climatic change scenarios were investigated: an increase of 2 degrees C, a 2 degrees increase with an increase of 0.5 mm per day in precipitation, a 2 degrees C increase with an equivalent decrease in precipitation, and equilibrium projections of temperature and precipitation by two general circulation models (GCMs) at doubled CO₂. With an increase in temperature alone, the projected defoliated area decreased relative to ambient conditions for the budworm and increased slightly for the gypsy moth. With an increase in temperature and precipitation the defoliated area increased for both species.

Conversely, the defoliated area decreased for both when temperature increased and precipitation decreased. Results for the GCM scenarios contrasted sharply. For the Geophysical Fluids Dynamics Laboratory model, defoliation by budworm was projected to cover Oregon completely, whereas no defoliation was projected by gypsy moth in Pennsylvania. For the Goddard Institute for Space Studies model, defoliation disappeared completely for the budworm and slightly exceeded that under ambient conditions for the gypsy moth. The results are discussed in terms of potential changes in forest species composition.

Williams, M., and J.L. Harwood. 1997. Effects of carbon dioxide concentration and temperature on lipid synthesis by young wheat leaves. *Phytochemistry* 45(2):243-250.

The effects of incubation temperature and CO₂ concentration on lipid synthesis in leaves from 7-day-old wheat plants were studied. Plants were cultivated at 350 $\mu\text{mol mol}^{-1}$ (approximately ambient CO₂) and 20 degrees so that, irrespective of the subsequent incubation conditions, the samples were all derived from plants at the same phenological stage of development. Leaf tissue was incubated with [1-C-14]acetate at 350 $\mu\text{mol mol}^{-1}$ or 700 $\mu\text{mol mol}^{-1}$ CO₂ concentration and at 20 degrees or 24 degrees. Doubling the CO₂ concentration had little or no effect on lipid metabolism. In contrast, a 4 degrees rise in incubation temperature not only increased the rate of radiolabelling but also altered lipid synthesis qualitatively. Most noticeable of these changes was a marked increase in phosphatidylcholine labelling evidently at the expense of that of diacylglycerol. The increase in carbon flux to this extrachloroplastic lipid appeared to be restricted to the distal portions of the leaf tissue, thus indicating that the stage of tissue development was critical. Surprisingly, an increase of polyunsaturated fatty acid labelling was found at the higher incubation temperature. This increase was accompanied by a decrease in labelling of oleate in the main radiolabelled membrane lipids. In phosphatidylcholine the decrease in oleate labelling was compensated by a rise in that of linoleate while in monogalactosyldiacylglycerol, both linoleate and α -linolenate were better labelled at 24 degrees. A molecular basis for these alterations in lipid synthesis and acyl desaturation is suggested. (C) 1997 Elsevier Science Ltd.

Williams, M., E.B. Rastetter, D.N. Fernandes, M.L. Goulden, S.C. Wofsy, G.R. Shaver, J.M. Melillo, J.W. Munger, S.M. Fan, and K.J. Nadelhoffer. 1996. Modelling the soil-plant-atmosphere continuum in a Quercus-Acer stand at Harvard forest: The regulation of stomatal conductance by light, nitrogen and soil/plant hydraulic properties. *Plant, Cell and Environment* 19(8):911-927.

Our objective is to describe a multi-layer model of C-3-canopy processes that effectively simulates hourly CO₂ and latent energy (LE) fluxes in a mixed deciduous Quercus-Acer (oak-maple) stand in central Massachusetts, USA. The key hypothesis governing the biological component of the model is that stomatal conductance ($g(s)$) is varied so that daily carbon uptake per unit of foliar nitrogen is maximized within the limitations of canopy water availability. The hydraulic system is modelled as an analogue to simple electrical circuits in parallel, including a separate soil hydraulic resistance, plant resistance and plant

capacitance for each canopy layer. Stomatal opening is initially controlled to conserve plant water stores and delay the onset of water stress. Stomatal closure at a threshold minimum leaf water potential prevents xylem cavitation and controls the maximum rate of water flux through the hydraulic system. We show a strong correlation between predicted hourly CO₂ exchange rate ($r(2) = 0.86$) and LE ($r(2) = 0.87$) with independent whole-forest measurements made by the eddy correlation method during the summer of 1992. Our theoretical derivation shows that observed relationships between CO₂ assimilation and LE flux can be explained on the basis of stomatal behaviour optimizing carbon gain, and provides an explicit link between canopy structure, soil properties, atmospheric conditions and stomatal conductance.

Williams, M., E.J. Robertson, R.M. Leech, and J.L. Harwood. 1998. The effects of elevated atmospheric CO₂ on lipid metabolism in leaves from mature wheat (*Triticum aestivum* cv Hereward) plants. *Plant, Cell and Environment* 21(9):927-936.

Winter wheat (*Triticum aestivum* L. cv, Hereward) plants were grown for 35 d either at 350 $\mu\text{mol mol}^{-1}$ CO₂ or at 650 $\mu\text{mol mol}^{-1}$ CO₂. Lipid synthesis was studied in these plants by incubating the 5th leaf on the main stem with [1-C-14]acetate. Increased CO₂ concentrations did not significantly affect the total incorporation of radiolabel into lipids of whole leaf tissue, but altered the distribution for individual lipid classes. Most noticeable amongst acyl lipids was the reduction in labelling of diacylglycerol and a corresponding increase in the proportion of phosphatidylcholine labelling. In the basal regions, there were similar changes and, in addition, phosphatidylglycerol labelling was particularly increased following growth in an enriched CO₂ atmosphere. The stimulation of labelling of the mitochondrial-specific lipid, diphosphatidylglycerol, prompted an examination of the mitochondrial population in wheat plants. Mitochondria were localized in intact wheat sections by immunolabelling for the mitochondrial-specific chaperonin probe. Growth in elevated CO₂ doubled the number of mitochondria compared to growth in ambient CO₂. Fatty acid labelling was also significantly influenced following growth at elevated CO₂ concentrations. Most noticeable were the changes in 16C:18C ratios for the membrane lipids, phosphatidylcholine, phosphatidylglycerol and monogalactosyldiacylglycerol. These data imply a change in the apportioning of newly synthesized fatty acids between the 'eukaryotic' and 'prokaryotic' pathways of metabolism under elevated CO₂.

Williams, M., E.J. Robertson, R.M. Leech, and J.L. Harwood. 1998. Lipid metabolism in leaves from young wheat (*Triticum aestivum* cv. Hereward) plants grown at two carbon dioxide levels. *Journal of Experimental Botany* 49(320):511-520.

Lipid synthesis was studied in primary leaves from 7-d-old wheat plants which had been grown at either ambient CO₂ concentration (350 $\mu\text{mol mol}^{-1}$) or elevated CO₂ (650 $\mu\text{mol mol}^{-1}$) by incubating tissue samples with [1-C-14]acetate. Growth at different CO₂ concentrations did not affect the total incorporation of radiolabel into lipids but it did influence the relative labelling of individual lipid classes, such as

diacylglycerol. The leaf basal segment was also studied separately and growth in an enriched CO₂ atmosphere was associated with a dramatic increase (over 6-fold) in diphosphatidylglycerol (cardiolipin) labelling, indicating an increased rate of mitochondrial membrane biogenesis. Immunocytological observations correlated with this metabolic result. Both leaf samples showed significant decreases in pigment and surface wax labelling caused by growth at elevated CO₂. Growth at different CO₂ concentrations also influenced fatty acid labelling patterns, particularly those of the major labelled membrane lipids of the primary leaf whereby there were changes in their ratios of radiolabelled 16 carbon to 18 carbon fatty acids. Phosphatidylglycerol was characterized, for instance, by increased palmitate labelling after wheat was grown in elevated CO₂ concentrations. In contrast, phosphatidylcholine was marked by a dramatic decrease in palmitate labelling but a corresponding increase in labelling of its 18 carbon unsaturated fatty acids. The diacylglycerol fraction showed increased unsaturation of its C18 fatty acids. In addition, changes to the fatty acid moieties from the basal segment lipids were also associated with changes in the amount of labelling of the polyenoic fatty acids of monogalactosyldiacylglycerol. Possible reasons for these changes in lipid labelling are discussed. The data show that growth in elevated atmospheric CO₂ concentrations causes significant changes in the metabolism of leaf lipids as well as increasing mitochondrial biogenesis.

Williams, M., P.R. Shewry, and J.L. Harwood. 1994. The influence of the greenhouse-effect on wheat (*triticum- aestivum* L) grain lipids. *Journal of Experimental Botany* 45(279):1379-1385.

There have been few studies conducted with the objective of investigating comprehensively the 'greenhouse effect' on wheat growth using field-grown crops and even less on the effects on the lipid composition of harvested grains. Therefore, the aim of this study was to define any changes in wheat grain acyl lipids which could result from alterations in environmental growth conditions predicted to mimic the 'greenhouse effect'. Quantitative changes were recorded for both the non-starch and starch lipids. When supplied with low concentrations of nitrogen fertilizer, plants showed increased amounts of total grain lipids when grown under an elevated (700 μ l l⁻¹) carbon dioxide atmosphere. Increasing the ambient temperature by 4 degrees C, however, reduced the total lipid content of grains. Wheat plants treated with high concentrations of nitrogen fertilizer accumulated less lipid compared to low nitrogen controls. Qualitative changes were also observed in the proportions of non-starch and starch lipid classes. However, changes in total acyl composition were limited to starch grain acyl lipids, as a result of changes in atmospheric carbon dioxide, growth temperature and nitrogen fertilizer application. The alterations in wheat lipids observed are likely to affect the properties of the flour produced from the grains.

Williams, M., P.R. Shewry, D.W. Lawlor, and J.L. Harwood. 1995. The effects of elevated-temperature and atmospheric carbon- dioxide concentration on the quality of grain lipids in wheat (*triticum-aestivum* L) grown at 2 levels of nitrogen application. *Plant, Cell and Environment* 18(9):999-1009.

Wheat plants were cultivated under growth regimes combining two temperatures (ambient and 4 degrees C above ambient temperature) with two concentrations of carbon dioxide (350 and 700 μ mol mol⁻¹) and two nitrogen fertilizer applications (high and low). The aim of this study was to define any changes in the acyl lipid composition of wheat grains which could result from alterations in the growth conditions. Qualitative and quantitative changes were observed in both non-starch and starch lipid fractions. Temperature was by far the most influential growth factor, although interactions between all three growth conditions occurred, as confirmed by analysis of variance. Growth at elevated temperatures had the general effect of reducing the amounts of accumulated lipids, particularly non-polar lipids (132mg fatty acids per 100g fresh weight at ambient temperatures as opposed to 77mg fatty acids per 100 g fresh weight at 4 degrees C above ambient temperatures). There were changes in the proportions of the major non-starch as well as the starch lipids. In the former category, non-polar lipids (principally triacylglycerols), the membrane glycosylglycerides and phosphatidylcholine were the main constituents, whereas in the starch lipids, lysophosphatidylcholine and lysophosphatidylethanolamine represented over 70% of the total. Depending on the growth conditions, the percentages of lipids such as monogalactosyldiacylglycerol, digalactosyldiacylglycerol and phosphatidylcholine (non-starch) or the starch lysophosphatidylethanolamine varied 2-fold or more. Significant changes in the acyl composition of individual lipids were also observed, most often in the proportions of palmitate, oleate and linoleate. The observed alterations in wheat lipids are likely to affect the properties of any flours derived from grain grown under climate change conditions.

Williams, M.W., P.D. Brooks, and T. Seastedt. 1998. Nitrogen and carbon soil dynamics in response to climate change in a high-elevation ecosystem in the Rocky Mountains, USA. *Arctic and Alpine Research* 30(1):26-30.

We have implemented a long-term snow-fence experiment at the Niwot Ridge Long-Term Ecological Research (NWT) site in the Colorado Front Range of the Rocky Mountains, U.S.A., to assess the effects of climate change on alpine ecology and biogeochemical cycles. The responses of carbon (C) and nitrogen (N) dynamics in high-elevation mountains to changes in climate are investigated by manipulating the length and duration of snow cover with the 2.6 X 60 m snow fence, providing a proxy for climate change. Results from the first year of operation in 1994 showed that the period of continuous snow cover was increased by 90 d. The deeper and earlier snowpack behind the fence insulated soils from winter air temperatures, resulting in a 9 degrees C increase in annual minimum temperature at the soil surface. The extended period of snow cover resulted in subnival microbial activity playing a major role in annual C and N cycling. The amount of C mineralized under the snow as measured by CO₂ production was 22 g m⁻² in 1993 and 35 g m⁻² in 1994, accounting for 20% of annual net primary aboveground production before construction of the snow fence in 1993 and 31% after the snow fence was constructed in 1994. In a similar fashion, maximum subnival N₂O flux increased 3-fold behind the snow fence, from 75 μ g N m⁻² d⁻¹ in 1993 to 250 μ g N m⁻² d⁻¹ in 1994. The amount of N lost from denitrification was greater than the annual atmospheric input of N in snowfall. Surface litter decomposition studies show that there was a significant increase in the litter mass loss under deep and early snow, with no significant change under medium and little snow conditions. Changes in climate that result in differences in snow duration, depth, and extent may therefore produce large changes in the C and N soil dynamics of alpine ecosystems.

Williams, R.S., D.E. Lincoln, and R.J. Norby. 1998. Leaf age effects of elevated CO₂-grown white oak leaves on spring-feeding lepidopterans. *Global Change Biology* 4(3):235-246.

Folivorous insect responses to elevated CO₂-grown tree species may be complicated by phytochemical changes as leaves age. For example, young expanding leaves in tree species may be less affected by enriched CO₂-alterations in leaf phytochemistry than older mature leaves due to shorter exposure times to elevated CO₂ atmospheres. This, in turn, could result in different effects on early vs. late instar larvae of herbivorous insects. To address this, seedlings of white oak (*Quercus alba* L.), grown in open-top chambers under ambient and elevated CO₂, were fed to two important early spring feeding herbivores; gypsy moth (*Lymantria dispar* L.), and forest tent caterpillar (*Malacosoma disstria* Hubner). Young, expanding leaves were presented to early instar larvae, and older fully expanded or mature leaves to late instar larvae. Young leaves had significantly lower leaf nitrogen content and significantly higher total nonstructural carbohydrate:nitrogen ratio as plant CO₂ concentration rose, while nonstructural carbohydrates and total carbon-based phenolics were unaffected by plant CO₂ treatment. These phytochemical changes contributed to a significant reduction in the growth rate of early instar gypsy moth larvae, while growth rates of forest tent caterpillar were unaffected. The differences in insect responses were attributed to an increase in the nitrogen utilization efficiency (NUE) of early instar forest tent caterpillar larvae feeding on elevated CO₂-grown leaves, while early instar gypsy moth larval NUE remained unchanged among the treatments. Later instar larvae of both insect species experienced larger reductions in foliage quality on elevated CO₂-grown leaves than earlier instars, as the carbohydrate:nitrogen ratio of leaves substantially increased. Despite this, neither insect species exhibited changes in growth or consumption rates between CO₂ treatments in the later instar. An increase in NUE was apparently responsible for offsetting reduced foliar nitrogen for the late instar larvae of both species.

Williams, R.S., D.E. Lincoln, and R.B. Thomas. 1994. Loblolly-pine grown under elevated CO₂ affects early instar pine sawfly performance. *Oecologia* 98(1):64-71.

Seedlings of loblolly pine *Pinus taeda* (L.), were grown in open-topped field chambers under three CO₂ regimes: ambient, 150 µmol l⁻¹ CO₂ above ambient, and 300 µmol l⁻¹ CO₂ above ambient. A fourth, non-chambered ambient treatment was included to assess chamber effects. Needles were used in 96 h feeding trials to determine the performance of young, second instar larvae of loblolly pine's principal leaf herbivore, red-headed pine sawfly, *Neodiprion lecontei* (Fitch). The relative consumption rate of larvae significantly increased on plants grown under elevated CO₂, and needles grown in the highest CO₂ regime were consumed 21% more rapidly than needles grown in ambient CO₂. Both the significant decline in leaf nitrogen content and the substantial increase in leaf starch content contributed to a significant increase in the starch:nitrogen ratio in plants grown in elevated CO₂. Insect consumption rate was negatively related to leaf nitrogen content and positively related to the starch:nitrogen ratio. Of the four volatile leaf monoterpenes measured, only beta-pinene exhibited a significant CO₂ effect and declined in plants grown in elevated CO₂. Although consumption changed, the relative growth rates of larvae were not

different among CO₂ treatments. Despite lower nitrogen consumption rates by larvae feeding on the plants grown in elevated CO₂, nitrogen accumulation rates were the same for all treatments due to a significant increase in nitrogen utilization efficiency. The ability of this insect to respond at an early, potentially susceptible larval stage to poorer food quality and declining levels of a leaf monoterpene suggest that changes in needle quality within pines in future elevated-CO₂ atmospheres may not especially affect young insects and that tree-feeding sawflies may respond in a manner similar to herb-feeding lepidopterans.

Williams, R.S., D.E. Lincoln, and R.B. Thomas. 1997. Effects of elevated CO₂-grown loblolly pine needles on the growth, consumption, development, and pupal weight of red-headed pine sawfly larvae reared within open-topped chambers. *Global Change Biology* 3(6):501-511.

Seedlings of loblolly pine, *Pinus taeda*, were grown in open-topped chambers under four levels of CO₂: two ambient and two elevated. Larvae of the red-headed pine sawfly, *Neodiprion lecontei*, were reared from early instar to pupation, primarily on branches within chambers. Larval growth and mortality were assessed and leaf phytochemistry samples of immature and mature leaves collected weekly. Mature leaves grown under elevated CO₂ had significant reductions in leaf nitrogen and increases in non-structural carbohydrate contents, resulting in foliage being a poorer food source for larvae, i.e. higher carbohydrate:nitrogen ratio. Nutritional constituents of immature needles were unaffected by seedling CO₂ treatment. Volatile mono- and sesquiterpenes were unrelated to plant CO₂ treatments for either leaf age class. Larval consumption of immature needles significantly increased on seedlings grown under CO₂ enrichment, while mature needle consumption was not different between the treatments. The average weight gain per larva significantly declined in late instar larvae consuming elevated CO₂-grown needles. In spite of this reduced growth, neither the days to pupation nor pupal weights were different among the CO₂ treatments. This study suggests that enriched CO₂-induced alterations in pine needle phytochemistry can affect red-headed pine sawfly performance. However, compensatory measures by larvae, such as choosing to consume more nutritious immature needles, apparently helps offset enriched CO₂-induced reductions in the leaf quality of mature needles.

Williams, R.S., R.B. Thomas, B.R. Strain, and D.E. Lincoln. 1997. Effects of elevated CO₂, soil nutrient levels, and foliage age on the performance of two generations of *Neodiprion lecontei* (Hymenoptera: Diprionidae) feeding on loblolly pine. *Environmental Entomology* 26(6):1312-1322.

We investigated how changes in loblolly pine needle phytochemistry caused by elevated CO₂, leaf age, and soil nutrient levels affected the performance of 2 individual generations of the multivoltine folivorous insect pest *Neodiprion lecontei* (Fitch). In 2 feeding trials, mature needles produced in the previous (spring) and current (fall) year from seedlings grown in open-topped chambers under 4 CO₂ and 2 soil

nutrient levels were fed to 2 separate generations of redheaded pine sawfly larvae. Strong seasonal differences (i.e., spring versus fall) in leaf nutritional and defensive constituents resulted in significant between-generation differences in the growth, consumption, and growth efficiency of sawfly larvae. Enriched CO₂-grown needles had higher levels of starch and starch/nitrogen ratios in older, overwintering spring needles, which were lower in leaf nitrogen and monoterpenes than younger, current year needles (fall). Overall, larval growth was higher and consumption lower on the fall needles, presumably because of higher levels of leaf nitrogen compared with the spring needles. The plant CO₂ concentration significantly contributed to the larval consumption responses between seasons (significant CO₂ X season interaction), demonstrating that the 2 sawfly generations were affected differently by CO₂-induced phytochemical alterations in spring versus fall needles. The data presented here suggests that when investigating multivoltine folivorous insect responses to elevated CO₂-grown tree seedlings in which multiple leaf flushes within a growing season expose insects to an array of leaf phytochemical changes, >1 insect generation should be investigated.

Williams, T.G., and B. Colman. 1993. Identification of distinct internal and external isozymes of carbonic-anhydrase in chlorella-saccharophila. *Plant Physiology* 103(3):943-948.

External carbonic anhydrase (CA) was detected in whole cells of alkaline-grown *Chlorella saccharophila* but was suppressed by growth at acid pH or growth on elevated levels of CO₂. Internal CA activity was measured potentiometrically as an increase in activity in cell extracts over that of intact cells. Cells grown under all conditions had equal levels of internal CA activity. Two isozymes were identified after electrophoretic separation of soluble proteins on cellulose acetate plates. The fast isozyme was found in cells grown under all conditions, whereas the slow isozyme was found only in cells grown at alkaline pH. Western blot analysis following sodium dodecyl sulfate-polyacrylamide gel electrophoresis using antibodies produced against the periplasmic form of CA from *Chlamydomonas reinhardtii* revealed a single band at 39 kD, which did not change in intensity between growth conditions and was associated only with proteins eluted from the fast band. The slow isozyme was inactivated by incubation of cell extract at 30 degrees C and by incubation in 10 mM dithiothreitol, whereas the internal form was unaffected. These results indicate that external and internal forms of CA differ in structure and their activities respond differently to environmental conditions.

Williams, T.G., and B. Colman. 1995. Quantification of the contribution of co₂, hco₃⁻, and external carbonic-anhydrase to photosynthesis at low dissolved inorganic carbon in chlorella-saccharophila. *Plant Physiology* 107(1):245-251.

An equation has been developed incorporating whole-cell rate constants for CO₂ and HCO₃⁻ that describes accurately photosynthesis (Phs) in suspensions of unicellular algae at low dissolved inorganic carbon. At pH 8.0 the concentration of CO₂ available to the algal cells depends on the rate of supply from, and the loss to, HCO₃⁻ and the rate of use by the cells. At elevated cell densities (>30 mg chlorophyll [Chl] L⁻¹), at

which CO₂ use by the cells is high, the slope of a graph of absolute Phs versus Chl concentration approaches the rate of Phs on a milligram of Chl basis because of HCO₃⁻ use alone. The slope of a graph of Phs versus HCO₃⁻ will be the rate constant for HCO₃⁻ and for *Chlorella saccharophila* it was 0.16 L mg⁻¹ Chl h⁻¹. The difference between the constants for dissolved inorganic carbon (measured in cells with external carbonic anhydrase) and HCO₃⁻ is the constant for CO₂, which was 26 L mg⁻¹ Chl h⁻¹. This difference causes the half-saturation constant for Phs to increase 5- to 6-fold at high cell densities. The increase in CO₂ use as a result of external carbonic anhydrase is described mathematically as a function of cell density.

Wilsey, B.J. 1996. Plant responses to elevated atmospheric CO₂ among terrestrial biomes. *Oikos* 76(1):201-206.

Although many researchers have stressed the importance of among-species variation in plant response to elevated CO₂, none have quantitatively tested whether variation exists among biomes. I compiled data from the literature and found that, although C-3 plants did respond more than C-4 plants (as predicted), biome origin was a better predictor (accounted for more of the variation) of plant response to elevated CO₂ than mode of photosynthesis. Variation in plant response among biomes was found both between and within latitudinal zones, with plant species from tropical and temperate biomes responding more than plant species from a polar biome. Within the temperate zone, species from forested biomes responded more than species from a grassland biome, and this provides further evidence that forests are acting as major sinks for increasing levels of atmospheric CO₂. A more than 4-fold difference was found among ecosystems in coefficients of variation (calculated across mean species response within each ecosystem). Based on this difference, I suggest that ecosystems may vary in the amount of change in species composition in response to elevated CO₂.

Wilsey, B.J. 1996. Urea additions and defoliation affect plant responses to elevated CO₂ in a C-3 grass from Yellowstone National Park. *Oecologia* 108(2):321-327.

A common grass from Yellowstone National Park, *Stipa occidentalis*, was grown in a factorial experiment to determine if its response to the direct effects of elevated CO₂ would be affected by defoliation, and urea additions simulating the N in a urine hit. Plants were grown in tall pots (to mimic rooting depth in the field) in growth chambers under elevated (700 ppm) and ambient (370 ppm) CO₂, were defoliated or left undefoliated, and given N-supply rates based on field mineralization rates (untreated) or with an additional 40 g N/m². Growth increases in response to elevated CO₂ were largest when plants remained unclipped and received urea additions, and were found primarily in crowns and roots (storage organs). Aboveground biomass, which is the part of the plant consumed by grazing mammals, was not affected by elevated CO₂. The elevated CO₂ treatment caused a reduction in leaf percent N. However, there was a significant interaction between the CO₂ and urea treatments, resulting in a larger difference in leaf percent N between urea-treated and control plants under elevated than under ambient CO₂. Hence, elevations in atmospheric CO₂ may cause an increase in the amount of urine-hit-induced spatial variability in temperate grasslands.

Since food quantity remained largely unchanged in response to elevated CO₂, and forage N content went down, grazing mammals may be negatively affected by increases in atmospheric CO₂.

Wilsey, B.J., J.S. Coleman, and S.J. McNaughton. 1997. Effects of elevated CO₂ and defoliation on grasses: A comparative ecosystem approach. *Ecological Applications* 7(3):844-853.

Three plant species from each of three grassland ecosystems were grown under elevated (700 mL/m³) and ambient (350 mL/m³) CO₂ and were defoliated or left undefoliated to test whether species response to elevated CO₂ and grazing is related to evolutionary grazing history or to mode of photosynthesis. The three ecosystems represented a tropical grassland dominated by C-4 species (the Serengeti of Africa), a temperate grassland dominated by a mixture of C-3 and C-4 species (Flooding Pampa of South America), and a northern temperate grassland dominated by C-3 species (Yellowstone National Park of North America). Plants were grown in growth chambers under common conditions to compare relative responses to grazing and elevated CO₂. Elevated CO₂ caused an increase in total biomass and total productivity (biomass + clippings) only in Yellowstone species, and increases in growth occurred primarily in crowns and roots (storage organs). There were no significant CO₂ effects on biomass or productivity in Serengeti or Flooding Pampa species, and no CO₂ effects on aboveground biomass or productivity (aboveground biomass + clippings) in species from any of the three ecosystems. Since aboveground plant parts are the portions that are available to grazing mammals, this suggests that increased atmospheric CO₂ may not affect food quantity in these three grasslands. There was no interaction between CO₂ and defoliation for any species; thus, it appears that herbivores will not affect how grasses respond to elevated CO₂ (at least under average nutrient conditions). Elevated CO₂ caused a reduction in leaf percentage of N in species from Yellowstone and Flooding Pampa (especially the C-3 species, *Briza subaristata*), but not in Serengeti species. Because the quantity of food was unaffected by the CO₂ treatments and forage N was reduced, grazing mammals in Yellowstone (elk, *Cervus elaphus*, and bison, *Bison bison*) and the Flooding Pampa (cattle) may be negatively affected. Responses to defoliation were fairly consistent among ecosystems in aboveground productivity, which did not differ between defoliated and undefoliated plants, and in leaf water potentials and percentage of N, both of which increased in response to defoliation. However, differences among ecosystems were found for crown and root biomass in response to defoliation: Serengeti species, on average, had higher crown and similar root biomasses after defoliation, whereas defoliated species from the other two ecosystems had reduced crown and root biomass. We suggest that the lower intensity and increased temporal variance in grazing pressure in Yellowstone vs. the Serengeti, selected for plants that shift allocation away from roots and crowns in order to compensate for aboveground herbivory.

Wilsey, B.J., S.J. McNaughton, and J.S. Coleman. 1994. Will increases in atmospheric CO₂ affect regrowth following grazing in C-4 grasses from tropical grasslands - a test with *sporobolus-kentrophyllus*. *Oecologia* 99(1-2):141-144.

We grew a C-4 grass from the Serengeti ecosystem under ambient (370 ppm) and elevated (700 ppm) CO₂, and under clipped and unclipped conditions to test whether regrowth following grazing would be affected by elevated CO₂. Above-ground productivity was slightly decreased under elevated CO₂, and was similar between clipped and unclipped plants. Regrowth (clipping offtake) following clipping was similar in the two CO₂ treatments, and there was no CO₂ by clipping interaction on biomass, productivity, or leaf nutrient concentrations. Based on this evidence, we suggest that C-4 grasses from the Serengeti will show little direct response to future increases in atmospheric CO₂.

Wilson, J.W., D.W. Hand, and M.A. Hannah. 1992. Light interception and photosynthetic efficiency in some glasshouse crops. *Journal of Experimental Botany* 43(248):363-373.

Productivity of glasshouse crops is strongly limited by light receipt, and efficient interception and use of light in photosynthesis is correspondingly important. Mature row crop canopies of cucumber and tomato intercepted about 76% of the light incident on their upper surfaces; about 18% was lost through gaps between the rows. Light transmitted through the entire depth of the canopy was reflected back by white plastic on the ground, so that the lower surface of the canopy received approximately 13% of the light incident on the upper surface. The light flux incident on the sides of these canopies (c. 2 m tall and 6 m x 16 m in area) amounted to some 20-30% of that incident on the upper surface. About 32% of daylight falling on the glasshouse (c. 9 m x 18 m in area) was intercepted by the glasshouse structure and glazing; of the 68% entering the house, some fell on headlands occupying 35% of the glasshouse area. The loss of light to headlands, and the gain from canopy side-lighting, would be relatively smaller for larger glasshouses. At near-ambient CO₂ concentrations, net photosynthetic rates of the cucumber canopy were comparable to those of closed canopies of other glasshouse and field crops which have maximum light conversion efficiencies of 5-8-mu-g CO₂ J⁻¹ at 50-200 W m⁻² incident light flux density. Efficiency decreases only slightly with stronger light. Glasshouse crops with CO₂ enrichment to 1200 vpm achieve conversion efficiencies of 7-10-mu-g CO₂ J⁻¹. Efficiencies of utilization of intercepted light, on an energy basis, reach 6-10% in various field and glasshouse crops with near-ambient CO₂, and reached an exceptional 11% for the cucumber canopy. Glasshouse crops with CO₂ enrichment achieve maximum efficiency of light energy utilization between 12% and 13%.

Wilson, K.B., and J.A. Bunce. 1997. Effects of carbon dioxide concentration on the interactive effects of temperature and water vapour on stomatal conductance in soybean. *Plant, Cell and Environment* 20(2):230-238.

Soybeans were grown at three CO₂ concentrations in outdoor growth chambers and at two concentrations in controlled- environment growth chambers to investigate the interactive effects of CO₂, temperature and leaf-to-air vapour pressure difference (LAVPD) on stomatal conductance. The decline in stomatal conductance with CO₂ was a function of both leaf temperature and LAVPD. In the field measurements, stomatal conductance was more sensitive to LAVPD at low CO₂ at 30 degrees C but not at 35 degrees C. There was also a direct increase in conductance with temperature, which was greater at the two

elevated carbon dioxide concentrations, Environmental growth chamber results showed that the relative stomatal sensitivity to LAVPD decreased with both leaf temperature and CO₂. Measurements in the environmental growth chamber were also performed at the opposing CO₂, and these experiments indicate that the stomatal sensitivity to LAVPD was determined more by growth CO₂ than by measurement CO₂. Two models that describe stomatal responses to LAVPD were compared with the outdoor data to evaluate whether these models described adequately the interactive effects of CO₂, LAVPD and temperature.

Winder, T.L., J.C. Anderson, and M.H. Spalding. 1992. Translational regulation of the large and small subunits of ribulose biphosphate carboxylase oxygenase during induction of the CO₂-concentrating mechanism in *Chlamydomonas reinhardtii*. *Plant Physiology* 98(4):1409-1414.

In conditions of limiting external inorganic carbon, the unicellular alga *Chlamydomonas reinhardtii* induces a mechanism to actively transport and accumulate inorganic carbon within the cell. A high internal inorganic carbon concentration enables the cell to photosynthesize efficiently with little oxygen inhibition, even in conditions of limiting external inorganic carbon. A correlation between limiting inorganic carbon-induced induction of the CO₂-concentrating mechanism and decreased synthesis of the large and small subunits of ribulose 1,5-bisphosphate carboxylase/oxygenase has been observed. Cells that had been transferred from elevated CO₂ to limiting CO₂ exhibit transient declines of label incorporation into both subunit polypeptides. We have found that this decrease in synthesis of large and small subunits results from specific and coordinated down-regulation of translation of both subunits possibly resulting, at least in part, from modification of large and small subunit transcripts.

Winder, T.L., J.D. Sun, T.W. Okita, and G.E. Edwards. 1998. Evidence for the occurrence of feedback inhibition of photosynthesis in rice. *Plant and Cell Physiology* 39(8):813-820.

The response of photosynthesis in the flag leaf of rice (*Oryza sativa*) to elevated CO₂ or reduced O₂ was investigated relative to other environmental factors using steady-state gas exchange techniques. We found under moderate conditions of temperature and photosynthetic flux density (PFD) (26 degrees C and 700 μ mol quanta m⁻²s⁻¹), similar to growth conditions) photosynthesis in the flag leaf of rice during heading and grain filling saturated at near ambient levels of CO₂, with a concomitant loss of O₂ sensitivity, when a high stomatal conductance was maintained by high humidity (low vapor pressure deficit). Under 18 degrees C there was near complete loss of O₂ sensitivity of photosynthesis at normal ambient levels of CO₂. This is in contrast to the large enhancement of photosynthesis by supra-atmospheric levels of CO₂ and sub-atmospheric levels of O₂ by suppression of photorespiration when there is no limitation on utilizing the initial product of CO₂ assimilation (triose-beta) as predicted from Ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) kinetic properties. Thus, loss of sensitivity to CO₂ and O₂ has been previously explained as a limitation on utilization of triose-beta to synthesize carbohydrates. Under high PFD at 25 degrees C, the rate of photosynthesis in rice

declined over a period of hours around midday, while the intercellular levels of CO₂ remained constant suggesting a limitation on utilization of photosynthate. Short-term fluctuations in climatic factors including temperature, light and humidity could result in a feedback limitation on photosynthesis in rice which may be exacerbated by rising CO₂.

Winjum, J.K., R.K. Dixon, and P.E. Schroeder. 1992. Estimating the global potential of forest and agroforest management-practices to sequester carbon. *Water, Air, and Soil Pollution* 64(1-2):213-227.

Forests play a prominent role in the global C cycle. Occupying one-third of the earth's land area, forest vegetation and soils contain about 60% of the total terrestrial C. Forest biomass productivity can be enhanced by management practices, which suggests that, by this means, forests could store more C globally and thereby slow the increase in atmospheric CO₂. The question is how much C can be sequestered by forest and agroforest management practices. To address the question, a global database of information was compiled to assess quantitatively the potential of forestry practices to sequester C. The database presently has information for 94 forested nations that represent the boreal, temperate and tropical latitudes. Results indicate that the most promising management practices are reforestation in the temperate and tropical latitudes, afforestation in the temperate regions, and agroforestry and natural reforestation in the tropics. Across all practices, the median of the mean C storage values for the boreal latitudes is 16 tCha-1 (n=46) while in the temperate and tropical latitudes the median values are 71 tCha-1 (n=401) and 66 tCha-1 (n=170), respectively. Preliminary projections are that if these practices were implemented on 0.6 to 1.2 x 10⁹ ha of available land over a 50-yr period, approximately 50 to 100 GtC could be sequestered.

Winnett, S.M. 1998. Potential effects of climate change on US forests: a review. *Climate Research* 11(1):39-49.

Human-induced changes in climate are likely to affect U.S. domestic forests and the economic systems which rely on them. This paper reviews current knowledge of how changes in temperature and precipitation could affect tree species, forest ecosystems, and the forest products sector of the economy. The various types of models used to predict change and the results they calculate are examined. Models currently project both increases and decreases in the range of various species and ecosystems, and similar results for changes in the productivity, biomass and growth of forests in response to changes in climate. Results vary with the models used, the species or ecosystem studied, and the specific condition of the forest in question. The science of forests and global change is reviewed with regard to plant responses to enhanced CO₂ environments and forests' response to other bioclimatic and indirect factors, such as insect predation, fire, climatic variation and ozone. Three studies of the economic effects of climate change on forests, which project a range of losses and benefits to the economy, are compared. Economic results vary directly with the results of the forest growth and productivity models which were employed as inputs. No one model can provide a complete answer, and current knowledge and models are limited in various ways which point to areas where further research could provide benefits.

Winter, K., and B. Engelbrecht. 1994. Short-term CO₂ responses of light and dark CO₂ fixation in the crassulacean acid metabolism plant *Kalanchoe pinnata*. *Journal of Plant Physiology* 144(4-5):462-467.

Short-term responses of net CO₂ assimilation rate (A), in the light and dark, to ambient CO₂ partial pressure (between about 30 and 1000 μ bar) were studied in leaves of the crassulacean acid metabolism (CAM) plant, *Kalanchoe pinnata*. The results show that it is possible to extrapolate from instantaneous measurements of net CO₂ exchange to diurnal and nocturnal CO₂ balances at different CO₂ partial pressures. Instantaneous CO₂ response curves were obtained by altering CO₂ levels at 10-min intervals during the middle of the 12-h dark period (phase I of CAM) and during the last third of the 12-h light period (phase IV of CAM). CO₂ partial pressures were also altered at longer, 12- to 24-h intervals and maximum rates of net CO₂ uptake (A(max)) during light and dark periods were analysed in response to intercellular CO₂ partial pressures (p(i)) occurring at the time of A(max). A(max)-p(i) relationships were identical to A-p(i)-curves from rapidly performed determinations during phases I and IV. Corresponding to previous findings with non-CAM species, A(max) and integrated net carbon gain during light and dark periods, respectively, showed a linear relationship. Nocturnal CO₂ uptake in normal air was barely affected when light-period carbon gain was manipulated by alterations in CO₂ partial pressure. Carbon gain during light periods, measured in normal air, was also independent of CO₂-related changes in nocturnal carbon gain. Only after 12 h of darkness at the lowest CO₂ concentration used (about 30 μ bar), was carbon gain increased under lighted conditions.

Winter, K., and C.E. Lovelock. 1999. Growth responses of seedlings of early and late successional tropical forest trees to elevated atmospheric CO₂. *Flora* 194(2):221-227.

Seedlings of nine tropical forest tree species were grown outdoors in open-top chambers at ambient and elevated (two times ambient) CO₂ concentrations at the Smithsonian Tropical Research Institute, Republic of Panama. Plants were kept individually in large pots and received non-limiting supplies of water and mineral nutrients. The enhancement of biomass accumulation at elevated CO₂ increased with increasing relative growth rates (RGR) of species at ambient CO₂. Early successional pioneer trees (*Cecropia longipes*, *Ficus insipida*, *Castilla elastica*, *Antirrhoea trichantha*, *Luehea seemannii*, *Pseudobombax septenatum*) grew rapidly, and, at the end of 25 to 39 day treatments, dry matter accumulation was 74 $\pm$ 26% higher at elevated than at ambient CO₂ (mean increase $\pm$ SD, n = 6). By contrast, seedlings of three late successional tree species (*Calophyllum longifolium*, *Tetragastris panamensis*, *Virola surinamensis*) grew slowly and, over an 84 day period, elevated CO₂ led to either no (*C. longifolium*, *T. panamensis*) or only small enhancement in dry matter accumulation (*V. surinamensis*). These different responses to CO₂ enrichment are a result of differences in growth kinetics between early and late successional species at ambient CO₂ rather than a result of intrinsic physiological differences in CO₂ responsiveness between plants from these two functional groups.

Winter, K., A. Richter, B. Engelbrecht, J. Posada, A. Virgo, and M. Popp. 1997. Effect of elevated CO₂ on growth and crassulacean-acid-

metabolism activity of *Kalanchoe pinnata* under tropical conditions. *Planta* 201(4):389-396.

Kalanchoe pinnata (Lam.) Pers. (Crassulaceae), a succulent-leaved crassulacean-acid-metabolism plant, was grown in open-top chambers at ambient and elevated (two times ambient) CO₂ concentrations under natural conditions at the Smithsonian Tropical Research Institute, Republic of Panama. Nocturnal increase in titratable acidity and nocturnal carbon gain were linearly related, increased with leaf age, and were unaffected by CO₂ treatments. However, under elevated CO₂, dry matter accumulation increased by 42-51%. Thus, the increased growth at elevated CO₂ was attributable entirely to increased net CO₂ uptake during daytime in the light. Malic acid was the major organic acid accumulated overnight. Nocturnal malate accumulation exceeded nocturnal citrate accumulation by six- to eightfold at both CO₂ concentrations. Basal (predawn) starch levels were higher in leaves of plants grown at elevated CO₂ but diurnal fluctuations of starch were of similar magnitude under both ambient and elevated CO₂. In both treatments, nocturnal starch degradation accounted for between 78 and 89% of the nocturnal accumulation of malate and citrate. Glucose, fructose, and sucrose were not found to exhibit marked day-night fluctuations.

Winter, K., and A. Virgo. 1998. Elevated CO₂ enhances growth in the rain forest understory plant, *Piper cordatum*, at extremely low light intensities. *Flora* 193(3):323-326.

Seedlings of the rain forest understory shrub *Piper cordatum* were grown for several months at ambient and elevated concentrations of atmospheric CO₂. Photon flux density (PFD) during 12-h photoperiods was maintained at extremely low levels (< 10 μ mol m⁻² s⁻¹). Despite these low PFDs, dry matter accumulation and leaf area production were increased in air containing elevated (approximately twice-ambient) CO₂ concentrations compared to ambient air. In leaves that had developed in deep shade and at ambient CO₂, rates of net CO₂ uptake, measured at 6 μ mol photons m⁻² s⁻¹, were 30% higher at elevated than at ambient CO₂. Rates of net CO₂ loss in the dark were 10% lower at elevated than at ambient CO₂.

Wise, R.R., A. Ortizlopez, and D.R. Ort. 1992. Spatial-distribution of photosynthesis during drought in field-grown and acclimated and nonacclimated growth chamber-grown cotton. *Plant Physiology* 100(1):26-32.

Inhomogeneous photosynthetic activity has been reported to occur in drought-stressed leaves. In addition, it has been suggested that these water stress-induced nonuniformities in photosynthesis are caused by "patchy" stomatal closure and that the phenomenon may have created the illusion of a nonstomatal component to the inhibition of photosynthesis. Because these earlier studies were performed with nonacclimated growth chamber-grown plants, we sought to determine whether such "patches" existed in drought-treated, field-grown plants or in chamber-grown plants that had been acclimated to low leaf water potentials (ψ (leaf)). Cotton (*Gossypium hirsutum* L.) was grown in the field and subjected to drought by withholding irrigation and rain from 24 d after planting. The distribution of photosynthesis, which may

reflect the stomatal aperture distribution in a heterobaric species such as cotton, was assayed by autoradiography after briefly exposing attached leaves of field-grown plants to (CO₂)-C-14. A homogeneous distribution of radioactive photosynthate was evident even at the lowest psi(leaf) of -1.34 MPa. "Patchiness" could, however, be induced by uprooting the plant and allowing the shoot to air dry for 6 to 8 min. In parallel studies, growth chamber-grown plants were acclimated to drought by withholding irrigation for three 5-d drought cycles interspersed with irrigation. This drought acclimation lowered the psi(leaf) value at which control rates of photosynthesis could be sustained by approximately 0.7 MPa and was accompanied by a similar decline in the psi(leaf) at which patchiness first appeared. Photosynthetic inhomogeneities in chamber-grown plants that were visible during moderate water stress and ambient levels of CO₂ could be largely removed with elevated CO₂ levels (3000 µL L⁻¹), suggesting that they were stomatal in nature. However, advanced dehydration (less than approximately 2.0 MPa) resulted in "patches" that could not be so removed and were probably caused by nonstomatal factors. The demonstration that patches do not exist in drought-treated, field-grown cotton and that the presence of patches in chamber-grown plants can be altered by treatments that cause an acclimation of photosynthesis leads us to conclude that spatial heterogeneities in photosynthesis probably do not occur frequently under natural drought conditions.

Witjaksono Schaffer, B.A., A.M. Colls, R.E. Litz, and P.A. Moon. 1999. Avocado shoot culture, plantlet development and net CO₂ assimilation in an ambient and CO₂ enhanced environment. *In Vitro Cellular & Developmental Biology-Plant* 35(3):238-244.

The proliferation and survival of avocado nodal cultures of juvenile origin were affected by the form anti concentration of nitrogen. Optimum growth was achieved on modified Murashige and Skoog medium containing 67% KNO₃ and 33% NH₄NO₃ with total N of 40 mM supplemented with 100 mg l⁻¹ (1) myo-inositol, 1 mg l⁻¹ (-1) thiamine HCl, 30 g l⁻¹ (1) sucrose, and 4.44 µM BA with a 16-h photoperiod (120-150 µmol m⁻² s⁻¹). Proliferating shoots and plantlets, were photosynthetically active. Better shoot growth and accumulation of higher biomass occurred in a CO₂-enriched environment than under ambient CO₂ conditions. CO₂ assimilation efficiency, however, was higher under the latter conditions than in a CO₂-enhanced environment, e.g., 31 ± 7 and 17 ± 2 µmol CO₂ m⁻² s⁻¹, respectively. The net CO₂ assimilation rates of in vitro grown plantlets were comparable to those of seedlings ex vitro.

Wolf, J. 1996. Effects of nutrient (NPK) supply on faba bean response to elevated atmospheric CO₂. *Netherlands Journal of Agricultural*

Science 44(3):163-178.

The effects of increased atmospheric CO₂ on crop growth and dry matter allocation may change if nutrient supply becomes insufficient for maximal growth. Increased atmospheric CO₂ may also cause changes in maximum dilution of nutrients in plant tissue and hence, in the minimum nutrient concentration levels and the maximum yield-nutrient uptake ratios of crops. To study these effects for faba bean, pot experiments have been carried out in two glass houses at ambient and doubled CO₂ concentration. Bean plants were grown at different supplies of N, P or K. Doubling of atmospheric CO₂ resulted in a strong increase (+100%) in total yield. This CO₂ effect disappeared rapidly with increasing nitrogen, phosphorus or potassium shortage. Doubling of atmospheric CO₂ resulted in no change in minimum nitrogen concentration and a nil to slight decrease in minimum phosphorus concentration in crop residues. Nutrient requirements to attain a certain yield level might change with a future increase in atmospheric CO₂. However, such conclusions cannot yet be drawn because nutrient concentrations in seeds were not available.

Wolf, J. 1996. Effects of nutrient supply (NPK) on spring wheat response to elevated atmospheric CO₂. *Plant and Soil* 185(1):113-123.

The effects of increased atmospheric CO₂ on crop growth and dry matter allocation may change if nutrient supply becomes insufficient for maximal growth. Increased atmospheric CO₂ may also cause changes in minimum nutrient concentration in plant tissue and hence in the nutrient use efficiency or yield-nutrient uptake ratios of crops. To study these effects for spring wheat, pot experiments have been carried out in two glass houses at ambient and doubled CO₂ concentration. Wheat plants were grown at different supplies of N, P or K. Doubling of ambient CO₂ resulted in a large increase in total biomass (+70%) and grain yield when the nutrient supply was optimum. With strong N and K limitation this CO₂ effect was about halved and with strong P limitation it became almost nil. Doubling of ambient CO₂ resulted in a 10% lower minimum N concentration in plant tissue and in no change in the minimum P concentration.

Wolf, J. 1998. Effects of nutrient (NPK) supply on sugar beet response to elevated atmospheric CO₂. *Netherlands Journal of Agricultural Science* 46(2):157-170.

The effects of increased atmospheric CO₂ on crop growth and dry matter allocation may change if nutrient supply becomes insufficient. Increased atmospheric CO₂ may also cause changes in maximum dilution of nutrients in plant tissue and hence, in the minimum nutrient concentration levels and the maximum yield-nutrient uptake ratios of crops. To study these effects of increased CO₂ for sugar beet (*Beta vulgaris* L.), pot experiments have been carried out at ambient and doubled CO₂ concentration. Beet plants were grown for four months at different supplies of N, P or K. Doubling of ambient CO₂ resulted in a moderate increase in total yield (+24%) and beet yield (+34%), however this CO₂ effect disappeared with increasing nutrient shortage (in particular nitrogen). CO₂ doubling did not result in significant changes in the minimum nutrient concentrations in leaves and beets.

Wolfe, D.W., R.M. Gifford, D. Hilbert, and Y.Q. Luo. 1998. Integration of photosynthetic acclimation to CO₂ at the whole-plant level. *Global Change Biology* 4(8):879-893.

Primary events in photosynthetic (PS) acclimation to elevated CO₂ concentration ([CO₂]) occur at the molecular level in leaf mesophyll cells, but final growth response to [CO₂] involves acclimation responses associated with photosynthate partitioning among plant organs in relation to resources limiting growth. Source-sink interactions, particularly with regard to carbon (C) and nitrogen (N), are key determinants of PS acclimation to elevated [CO₂] at the whole-plant level. In the long term, PS and growth response to [CO₂] are dependent on genotypic and environmental factors affecting the plant's ability to develop new sinks for C, and acquire adequate N and other resources to support an enhanced growth potential. Growth at elevated [CO₂] usually increases N use efficiency because PS rates can be maintained at levels comparable to those observed at ambient [CO₂] with less N investment in PS enzymes. A frequent acclimation response, particularly under N-limited conditions, is for the accumulation of leaf carbohydrates at elevated [CO₂] to lead to repression of genes associated with the production of PS enzymes. The hypothesis that this is an adaptive response, leading to a diversion of N to plant organs where it is of greatest benefit in terms of competitive ability and reproductive fitness, needs to be more rigorously tested. The biological control mechanisms which plants have evolved to acclimate to shifts in source-sink balance caused by elevated [CO₂] are complex, and will only be fully elucidated by probing at all scales along the hierarchy from molecular to ecosystem. Use of environmental manipulations and genotypic comparisons will facilitate the testing of specific hypotheses. Improving our ability to predict PS acclimation to [CO₂] will require the integration of results from laboratory studies using simple model systems with results from whole-plant studies that include measurements of processes operating at several scales.

Wolfenden, J., and P.J. Diggle. 1995. Canopy gas-exchange and growth of upland pasture swards in elevated CO₂. *New Phytologist* 130(3):369-380.

Vegetation monoliths (450 x 450 mm) from two contrasting upland grassland communities were grown in Solardomes in either ambient air or ambient air enriched with 250 ppm CO₂. During the first two growing seasons measurements of canopy gas exchange showed that rates of photosynthesis of limestone swards were enhanced by growth in elevated CO₂, by approx. 50% during spring and early summer. Although canopy respiration was also greater in elevated CO₂, the overall effect was an average increase of 33% in net CO₂ assimilation. Enhanced respiration rates persisted into the autumn, whereas the effect on photosynthesis diminished through the growing season, so that in September swards growing in high CO₂ had net photosynthesis rates similar to, or even lower than those in ambient air. This response varied between swards of differing species composition. In acidic grassland no significant effects of CO₂ on respiration or net CO₂ uptake rates were detected at any time.

The above ground productivity of limestone grassland was measured in several harvests throughout both seasons, and was not affected by CO₂ concentration at any time. Similarly, the acidic grassland, harvested at the end of the second season, showed no significant effect of CO₂ on above-ground biomass. The results suggest that increasing atmospheric CO₂ concentration is unlikely to cause large changes in net primary productivity in these grasslands.

Wong, S.C. 1993. Interaction between elevated atmospheric concentration of CO₂ and humidity on plant-growth - comparison between cotton and radish. *Vegetatio* 104:211-221.

Cotton plants (*Gossypium hirsutum* L. var Deltapine 90) and radish plants (*Raphanus sativus* L var Round Red) were grown under full sunlight using a factorial combination of atmospheric CO₂ concentrations (350 μmol mol⁻¹ and 700 μmol mol⁻¹) and humidities (35% and 90% RH at 32-degrees-C during the day). Cotton plants showed large responses to increased humidity and to doubled CO₂. In cotton plants, the enhanced dry matter yield due to doubled CO₂ concentration was 1.6-fold greater at low humidity than at high humidity. Apart from the direct effect of elevated CO₂ level on photosynthesis, the greater effect of doubled CO₂ concentration on dry matter yield at low humidity was probably due to: (1) increased leaf water potential caused by reduction of transpiration resulting from the negative CO₂ response of stomata to increased CO₂ concentration the consequence being greater leaf area expansion. (2) reduction of CO₂ assimilation rate at low humidity and normal CO₂ concentration as a result of humidity response of stomata causing reduction of intercellular CO₂ concentration. In contrast, apart from the very early stage of development, radish plants do not respond to increased humidity but had a relatively large response to doubled CO₂ concentration. Furthermore, due to the determinate growth pattern as well as having a prominent storage root, the extra photoassimilate derived at doubled CO₂ level is allocated to the storage root.

Wong, S.C., P.E. Kriedemann, and G.D. Farquhar. 1992. CO₂ X nitrogen interaction on seedling growth of 4 species of eucalypt. *Australian Journal of Botany* 40(4-5):457-472.

Four eucalypt species were selected to represent two ecologically disparate groups which would be expected to contrast in seedling vigour and in the nature of growth responses to CO₂ X nitrogen supply. *Eucalyptus camaldulensis* and *E. cypellocarpa* were taken as examples of fast-growing species with a wide distribution, that develop into large trees. By contrast, *E. pauciflora* and *E. pulverulenta* become smaller trees, and show a more limited distribution. Seedlings were established in pots (5 L) of a loamy soil and supplied with nutrient solution containing either 1.2 or 6.0 mM NO₃⁻ in both ambient (33 Pa) and CO₂-enriched (66 Pa) greenhouses. Analysis of growth response to treatments

(2 X 2 factorial) was based on destructive harvest of plants sampled on four occasions over 84 days for *E. camaldulensis* and *E. cytellocarpa*, and 100 days for *E. pulverulenta* and *E. pauciflora*. A positive CO₂ X N interaction on plant dry mass and leaf area was expressed in all species throughout the study period. In *E. camaldulensis* and *E. cytellocarpa*, plant mass was doubled by high N at 33 Pa CO₂, compared with a three to four- fold increase at 66 Pa to reach 34 g by final harvest. In *E. pulverulenta* and *E. pauciflora*, slower growth resulted in about 50% less mass at a given age, but relative increases due to CO₂ and N were of a similar order. A distinction can be made between N and CO₂ effects on growth processes as follows. When trees were grown on low N, elevated CO₂ increased nitrogen-use efficiency (NUE) at both leaf and whole plant levels. On high N, leaf NUE was increased in *E. camaldulensis* and *E. cytellocarpa*, but decreased in *E. pulverulenta* and *E. pauciflora*. Whole plant NUE showed no consistent response to elevated CO₂ when plants were supplied high N. Net assimilation rate (NAR) was increased by elevated CO₂ in all species on either N treatment. Moreover, high N increased NAR under either CO₂ treatment in all species. There was a positive N X CO₂ interaction on NAR in *E. camaldulensis* and *E. cytellocarpa*, but not in *E. pulverulenta* and *E. pauciflora*. Growth indices for *E. camaldulensis* and *E. cytellocarpa* species, and especially *E. camaldulensis*, generally exceeded those for *E. pulverulenta* and *E. pauciflora* in terms of NAR, leaf NUE, N-enhancement of CO₂ effects on leaf area and biomass, and non-structural carbohydrate content of foliage.

Wong, S.C., and C.B. Osmond. 1991. Elevated atmospheric partial-pressure of CO₂ and plant-growth .3. Interactions between *Triticum aestivum* (C3) and *Echinochloa frumentacea* (C4) during growth in mixed culture under different CO₂, N-nutrition and irradiance treatments, with emphasis on belowground responses estimated using the delta-C-13 value of root biomass. *Australian Journal of Plant Physiology* 18(2):137-152.

Wheat (*Triticum aestivum* L.), a C3 species, and Japanese millet (*Echinochloa frumentacea* Link), a C4 species, were grown in pots in monoculture and mixed culture (2 C3:1 C4 and 1 C3:2 C4) at two ambient partial pressures of CO₂ (320 and 640-mu-bar), two photosynthetic photon flux densities (PPFDs) (daily maximum 2000 and 500-mu-mol m⁻² s⁻¹) and two levels of nitrogen nutrition (12 mM and 2 mM NO₃BAR). Growth of shoots of both components in mixed culture was measured by physical separation, and the proportions of root biomass due to each component were calculated from delta-C-13 value of total root biomass. In air (320-mu-bar CO₂) at high PPFD and with high root zone-N, the shoot biomass of C3 and C4 components at the first harvest (28 days) was in proportion to the sowing ratio. However, by the second harvest (36 days) the C4 component predominated in both mixtures. Under the same conditions, but with low PPFD, C3 plants predominated at the first harvest but C4 plants had overtaken them by the time of the second harvest. Elevated atmospheric CO₂ (640-mu-bar) stimulated shoot growth of *Triticum* in 15 of 16 treatment combinations and the stimulation was greatest in plants provided with low NO₃BAR. Root growth of the C3 plants was generally stimulated by elevated CO₂, but was only occasionally sensitive to the presence of C4 plants in mixed culture. However, growth of the C4 plants was often sensitive to the presence of C3 plants in mixed culture. In mixed cultures, elevated CO₂ plants stimulated growth of C4 plants at high PPFD, high-N and in all low-N treatments but this was insufficient to offset a marked decline in shoot growth with increasing proportion of C3 plants in mixed cultures. The unexpected stimulation of growth of C4 plants by elevated CO₂ was correlated with more negative delta- C-13 values of C4 root biomass, suggesting a partial failure of the CO₂ concentrating mechanism of C4

photosynthesis in *Echinochloa* under low-N. These experiments show that for these species nitrogen was more important than light or elevated pCO₂ in determining the extent of competitive interactions in mixed culture.

Wood, C.W., H.A. Torbert, H.H. Rogers, G.B. Runion, and S.A. Prior. 1994. Free-air co₂ enrichment effects on soil carbon and nitrogen. *Agricultural and Forest Meteorology* 70(1-4):103-116.

Since the onset of the industrial revolution, atmospheric CO₂ concentration has increased exponentially to the current 370 mumol mol⁻¹ level, and continued increases are expected. Previous research has demonstrated that elevated atmospheric CO₂ results in larger plants returning greater amounts of C to the soil. However, the effects of elevated CO₂ on C and N cycling and long-term storage of C in soil have not been examined. Soil samples (in 0-50, 50-100, and 100-200 mm depth increments) were collected after 3 years of cotton (*Gossypium hirsutum* L.) production under free-air CO₂ enrichment (FACE, at 550 mumol CO₂ mol⁻¹), in combination with 2 years of different soil moisture regimes (wet, 100% of evapotranspiration replaced, or dry, 75% and 67% of evapotranspiration replaced in 1990 and 1991, respectively) on a Trix clay loam (fine, loamy, mixed (calcareous), hyperthermic Typic Torrifluent) at Maricopa, Arizona. Ambient plots (370 mumol CO₂ mol⁻¹ (control)), in combination with the wet and dry soil moisture regimes, were also included in the study. Soil organic C and N concentrations, potential C and N mineralization, and C turnover were measured. Increased input of cotton plant residues under FACE resulted in treatment differences and trends toward increased organic C in all three soil depths. During the first 30 days of laboratory incubation, available N apparently limited potential C mineralization and C turnover in all treatments. Between 30 and 60 days of incubation, soils from FACE plots had greater potential C mineralization with both water regimes, but C turnover increased in soils from the dry treatment and decreased in soils where cotton was not water stressed. These data indicate that in high-CO₂ environments without water stress, increased C storage in soil is likely, but it is less likely where water stress is a factor. More research is needed before the ability of soil to store additional C in a high-CO₂ world can be determined.

Woodbury, P.B., J.E. Smith, D.A. Weinstein, and J.A. Laurence. 1998. Assessing potential climate change effects on loblolly pine growth: A probabilistic regional modeling approach. *Forest Ecology and Management* 107(1-3):99-116.

Most models of the potential effects of climate change on forest growth have produced deterministic predictions. However, there are large uncertainties in data on regional forest condition, estimates of future climate, and quantitative relationships between environmental conditions and forest growth rate. We constructed a new model to analyze these uncertainties along with available experimental results to make probabilistic estimates of climate change effects on the growth of loblolly pine (*Pinus taeda* L.) throughout its range in the USA. Complete regional data sets were created by means of spatial interpolation, and uncertainties in these data were estimated. A geographic information system (GIS) was created to integrate current and predicted climate data with regional data including forest distribution, growth rate, and stand characteristics derived from USDA Forest Service data. A probabilistic

climate change scenario was derived from the results of four different general circulation models (GCM). Probabilistic estimates of forest growth were produced by linking the GIS to a Latin Hypercube carbon (C) budget model of forest growth. The model estimated a greater than 50% chance of a decrease in loblolly pine growth throughout most of its range. The model also estimated a 10% chance that the total regional basal area growth will decrease by more than $24 \times 10(6) \text{ m}(2) \text{ yr}(-1)$ (a 92% decrease), and a 10% chance that basal area growth will increase by more than $62 \times 10(6) \text{ m}(2) \text{ yr}(-1)$ (a 142% increase above current rates). The most influential factor at all locations was the relative change in C assimilation. Of climatic factors, CO₂ concentration was found to be the most influential factor at all locations. Substantial regional variation in estimated growth was observed, and probably was due primarily to variation in historical growth rates and to the importance of historical growth in the model structure. Woodin, S., B. Graham, A. Killick, U. Skiba, and M. Cresser. 1992. Nutrient limitation of the long-term response of heather [calluna-vulgaris (L) hull] to CO₂ enrichment. *New Phytologist* 122(4):635-642.

In a 27-month CO₂-enrichment experiment, Calluna vulgaris plants were grown on peat obtained from an upland heath in NE Scotland and given a nutrient supply which mimicked that in precipitation in the area. Three CO₂ concentrations were used; ambient, + 100 ppm and + 200 ppm. Calluna showed a negative growth response to increased CO₂ over the first year of treatment and a positive response by the end of the experiment. Final above-ground biomass was greatest in the enriched CO₂ treatments, showing an increase of 30 % in + 100 ppm CO₂. Determination of tissue nutrient concentration, and calculation of total nutrient uptake, demonstrated that nutrient uptake did not increase with increased growth, resulting in significant dilution of elements in leaf tissue. This suggests that, in its typical, nutrient poor habitats, the growth response of Calluna to CO₂ will be limited by nutrient deficiency, and will reach a maximum with a relatively small increase in CO₂ concentration. Flowering was advanced and extremely prolific in + 100 ppm CO₂ grown plants, but the ecological significance of this is uncertain. The results highlight the need for long term studies of native species on their natural soils, using lower CO₂ concentrations than the usual 'double CO₂'.

Woodrow, I.E. 1994. Control of steady-state photosynthesis in sunflowers growing in enhanced CO₂. *Plant, Cell and Environment* 17(3):277-286.

Control coefficients were used to describe the degree to which ribulose biphosphate carboxylase/oxygenase (Rubisco) limits the steady-state rate of CO₂ assimilation in sunflower leaves from plants grown at high (800 $\mu\text{mol mol}(-1)$) and low (350 $\mu\text{mol mol}(-1)$) CO₂. The magnitude of a control coefficient is approximately the percentage change in the flux that would result from a 1% rise in enzyme active site concentration. In plants grown at low CO₂, leaves of different ages varied considerably in their photosynthetic capacities. In a saturating light flux and an ambient CO₂ concentration of 350 $\mu\text{mol mol}(-1)$, the Rubisco control coefficient was about 0.7 in all leaves, indicating that Rubisco activity largely limited the assimilation flux. The Rubisco control coefficient for leaves grown at 350 $\mu\text{mol mol}(-1)$ CO₂ dropped to about zero when the ambient CO₂ concentration was raised to 800 $\mu\text{mol mol}(-1)$. In relatively young, fully expanded leaves of plants grown

at high CO₂, the Rubisco control coefficient was also about 0.7 at a saturating light flux and at the CO₂ concentration at which the plants were grown (800 $\mu\text{mol mol}(-1)$). This apparently resulted from a decrease in the concentration of Rubisco active sites. In older leaves, however, the control coefficient was about 0.2. Because, on the whole, Rubisco activity still largely limits the assimilation flux in plants grown at high CO₂, the kinetics of this enzyme can still be used to model photosynthesis under these conditions. The relatively high Rubisco control coefficient under enhanced CO₂ indicates that the young sunflower leaves have the capacity to acclimate their photosynthetic biochemistry in a way consistent with an optimal use of protein resources.

Woodrow, I.E. 1994. Optimal acclimation of the C-3 photosynthetic system under enhanced CO₂. *Photosynthesis Research* 39(3):401-412.

A range of studies of C-3 plants have shown that there is a change in both the carbon flux and the pattern of nitrogen allocation when plants are grown under enhanced CO₂. This paper examines evidence that allocation of nitrogen both to and within the photosynthetic system is optimised with respect to the carbon flux. A model is developed which predicts the optimal relative allocation of nitrogen to key enzymes of the photosynthetic system as a function of CO₂ concentration. It is shown that evidence from flux control analysis is broadly consistent with this model, although at high nitrogen and under certain conditions at low nitrogen experimental data are not consistent with the model. Acclimation to enhanced CO₂ is also assessed in terms of resource allocation between photosynthate sources and sinks. A means of assessing the optimisation of this source-sink allocation is proposed, and several studies are examined within this framework. It is concluded that C-3 plants probably possess the genetic feedback mechanisms required to efficiently 'smooth out' any imbalance within the photosynthetic system caused by a rise in atmospheric CO₂.

Woodrow, L., and B. Grodzinski. 1993. Ethylene exchange in lycopersicon-esculentum mill - leaves during short-term and long-term exposures to CO₂. *Journal of Experimental Botany* 44(259):471-480.

The effects of long-term and transient exposure to elevated CO₂ concentrations on photosynthetic gas exchange and ethylene release by tomato leaves were investigated. The net CO₂ assimilation rate was enhanced when leaf tissue grown at ambient (35 Pa CO₂) levels was assayed at 100 Pa CO₂. Leaf tissue grown at high (130 Pa) CO₂ exhibited a lower net CO₂ assimilation rate at high CO₂ levels than leaf tissue grown at ambient (35 Pa) CO₂. This decrease in CO₂ exchange rate in response to growth at high CO₂ is typical of C₃ species. Rates of endogenous and 1-aminocyclopropane-1-carboxylic acid (ACC)-stimulated ethylene release from leaf tissue were enhanced by exposure to elevated CO₂ levels whether the leaf tissue had been grown at ambient or enriched CO₂ levels. The data demonstrate that CO₂ enhanced C₂H₄ release from leaf tissue in response to both short-term perturbations in CO₂ concentration and long-term growth and development under high CO₂. Prolonged growth at elevated CO₂ concentrations induced a higher endogenous rate of C₂H₄ release

relative to that of leaf tissue grown at lower CO₂ levels. Leaf tissue from all leaf positions of plants grown at high CO₂ consistently evolved more C₂H₄ than corresponding tissue from ambient-grown plants when assayed under standardized conditions. Endogenous (ACC) tissue contents and rates of ACC-stimulated ethylene release were also higher at all leaf positions in CO₂-enriched tissue. Thus the higher rates appeared to be due to both higher endogenous precursor (ACC) levels in the tissue and greater ACC to C₂H₄ conversion capacity. Growth at elevated CO₂ levels resulted in a persistent increase in the rate of endogenous C₂H₄ release in leaf tissue. The capacity for increased ethylene release in response to CO₂ did not decline after prolonged growth at high CO₂.

Woods, J., and W. Barkmann. 1993. The plankton multiplier - positive feedback in the greenhouse. *Journal of Plankton Research* 15(9):1053-1074.

The plankton multiplier is a positive feedback mechanism linking the greenhouse effect and biological pump (Woods, J.D., Royal Commission on Environmental Pollution, 1990). As pollution increases the atmospheric concentration of carbon dioxide, the enhanced greenhouse effect induces radiative forcing of the ocean, which diminishes the depth of winter convection, reducing the annual resupply of nutrients to the euphotic zone and therefore the annual primary production. That weakens the biological pump, which contributes to oceanic uptake of CO₂. As the ocean takes up less CO₂, more remains in the atmosphere, accelerating the rise in radiative forcing. We have used a mathematical model of the upper ocean ecosystem, based on the Lagrangian Ensemble method, to estimate the sensitivity of the biological pump to radiative forcing, which lies at the heart of the plankton multiplier. We conclude that increasing radiative forcing by 5 W m⁻² (equivalent to doubling atmospheric CO₂) reduces the deep flux of particulate carbon by 10%. That sensitivity is sufficient to produce significant positive feedback in the greenhouse. It means that the plankton multiplier will increase the rate of climate change in the 21st century. It also suggests that the plankton multiplier is the mechanism linking the Milankovich effect to the enhanced greenhouse effect that produces global warming at the end of ice ages.

Woodward, A. 1998. Relationships among environmental variables and distribution of tree species at high elevation in the Olympic mountains. *Northwest Science* 72(1):10-22.

Relationships among environmental variables and occurrence of tree species were investigated at Hurricane Ridge in Olympic National Park, Washington, USA. A transect consisting of three plots was established down one north- and one south-facing slope in stands representing the typical elevational sequence of tree species. Tree species included subalpine fir (*Abies lasiocarpa*), Douglas-fir (*Pseudotsuga menziesii*), mountain hemlock (*Tsuga mertensiana*), and Pacific silver fir (*Abies amabilis*). Air and soil temperature, precipitation, and soil moisture were measured during three growing seasons. Snowmelt patterns, soil carbon and moisture release curves were also determined. The plots represented a wide range in soil water potential, a major determinant of tree species distribution (range of minimum values = -1.1 to -8.0 MPa for Pacific

silver fir and Douglas-fir plots, respectively). Precipitation intercepted at plots depended on topographic location, storm direction and storm type. Differences in soil moisture among plots was related to soil properties, while annual differences at each plot were most often related to early season precipitation. Changes in climate due to a doubling of atmospheric CO₂ will likely shift tree species distributions within, but not among aspects. Change will be buffered by innate tolerance of adult trees and the inertia of soil properties.

Woodward, F.I. 1992. Predicting plant-responses to global environmental-change. *New Phytologist* 122(2):239-251.

Predicting the future responses of plants and ecosystems to further changes in the CO₂ concentration of the atmosphere and to the possibility of global warming are important current concerns. Predictions have been most frequently attempted using short-term, single-factor experiments in controlled environments. However, these experiments have failed to indicate the outcome of field experiments at larger spatial and temporal scales. Some of this failure is due to ignorance of environmental conditions and interactions while some is due to the use of inappropriate short-cuts, such as the addition of fertilizers for simulating enhanced mineralization, and some is due to ignorance of the processes involved in scaling-up from individual plants to populations. Long-term observations on plants in ecosystems nevertheless indicate that community-scale experiments may provide a useful but imperfect capacity to predict ecosystem responses. Although difficult to implement in practice, it is concluded that catchment-scale experiments offer the best opportunity to predict plant, community and ecosystem responses to environmental change.

Woodward, F.I. 1993. The lowland-to-upland transition modeling plant-responses to environmental-change. *Ecological Applications* 3(3):404-408.

A published correlative model has predicted that the distributional limits of plants and vegetation zones on mountains will increase in altitude with global warming. I test this hypothesis using results from published experimental studies. Investigations and models of the responses of leaf growth to temperature are in accord with the prediction. However, the individualistic responses of species to CO₂ enrichment indicate that the prediction is unlikely to be true for all species: growth is stimulated by CO₂ enrichment for some species but not for others. Wind speed generally increases with altitude on mountains, and plants from high altitude tend to be more wind resistant than species from the lowland. Therefore it is expected that, particularly on wind-swept mountains, global warming will not necessarily be followed by the spread of lowland species into the uplands.

Woodward, F.I., and C.K. Kelly. 1995. The influence of CO₂ concentration on stomatal density. *New Phytologist* 131(3):311-327.

A survey of 100 species and 122 observations has shown an average reduction in stomatal density of 14.3% (SE $\pm$ 2.2%) with CO₂ enrichment, with 74% of the cases exhibiting a reduction in stomatal density. A sign test demonstrated that stomatal density decreases, in response to CO₂, significantly more often than expected by chance. Repeated observations on the same species indicated a significant repeatability in the direction of the stomatal response. Analyses which removed the potential effect of taxonomy on this data set showed no significant patterns in the dependency of the degree of stomatal change on growth form (woodiness vs. non-woodiness; trees vs. shrubs), habitat (cool vs. warm) or stomatal distribution on the leaf (amphistomatous vs. hypostomatous). Forty-three of the observations had been made in controlled environments and under a typical range in CO₂ enrichment of 350-700 μ mol mol⁻¹. For these cases the average stomatal density declined by 9% (SE $\pm$ 3.3%) and 60% of the cases showed reductions in stomatal density. When analyses were restricted to these 43 observations, amphistomatous samples more frequently had greater changes in stomatal density than did hypostomatous samples. The degree of reduction in stomatal density with increasing CO₂ increases with initial stomatal density, after the influence of taxonomy is removed using analyses of independent contrasts. When the data were examined for patterns that might be due explicitly to the effects of relatedness, the subclasses of the Hamamelidaceae and the Rosidae showed highly significant reductions in stomatal density with CO₂ (87% of the species studied in the Hamamelidaceae and 80% of the species in the Rosidae showed reduction with CO₂ enrichment) and correlations between initial stomatal density and degree of reduction in stomatal density. The species sampled in the Hamamelidaceae were dominantly trees, whereas herbs dominated the species in the Rosidae. There were insufficient species studied at lower taxonomic levels to warrant further statistical analyses. This problem results from experimental and observational data being most often restricted to one species per taxonomic level, typically up to the level of order, a feature which can severely limit the extraction of taxonomically-related and ecologically-related plant responses.

Woodward, F.I., T.M. Smith, and W.R. Emanuel. 1995. A global land primary productivity and phytogeography model. *Global Biogeochemical Cycles* 9(4):471-490.

A global primary productivity and phytogeography model is described. The model represents the biochemical processes of photosynthesis and the dependence of gas exchange on stomatal conductance, which in turn depends on temperature and soil moisture. Canopy conductance controls soil water loss by evapotranspiration. The assignment of nitrogen uptake to leaf layers is proportional to irradiance, and respiration and maximum assimilation rates depend on nitrogen uptake and temperature. Total nitrogen uptake is derived from soil carbon and nitrogen and depends on temperature. The long-term average annual carbon and hydrological budgets dictate canopy leaf area. Although observations constrain soil carbon and nitrogen, the distribution of vegetation types is not specified by an underlying map. Variables simulated by the model are compared to experimental results. These comparisons extend from biochemical processes to the whole canopy, and the comparisons are favorable for both current and elevated CO₂ atmospheres. The model is used to simulate the global distributions of leaf area index and annual net primary productivity. These distributions are sufficiently realistic to demonstrate that the model is useful for analyzing vegetation responses to global environmental change.

Woolgrove, C.E., and S.J. Woodin. 1996. Ecophysiology of a snow-bed bryophyte *Kiaeria starkei* during snowmelt and uptake of nitrate from meltwater. *Canadian Journal of Botany-Revue Canadienne De Botanique* 74(7):1095-1103.

Snow is a very efficient scavenger of atmospheric pollutants and because of the dynamics of snowmelt, much of the pollutant load of a snowpack is released at very high concentrations in episodes known as the acid flush. The ecological effects of this are largely unknown, but any effects on the bryophyte-dominated vegetation of snow beds will depend in part on the physical environment and physiological state of plants under and just out of snow cover. These factors were investigated at a snow bed in the Cairngorm Mountains, Scotland. The subnivean environment is characterized by slightly elevated CO₂ concentrations (up to 70 μ mol L⁻¹ above ambient), temperatures at and just above 0 degrees C, and very low light intensity, with no light penetrating through more than 50 cm depth of snow. Despite overwinter storage in these conditions, the bryophyte *Kiaeria starkei* is shown to be capable of photosynthetic activity immediately after removal of snow cover, and tissue chlorophyll and carbohydrate concentrations increase by 250 and 60%, respectively, during the 2 weeks thereafter. Comparison of photosynthetic light responses at 5 and 18 degrees C in plants collected from under and out of snow cover demonstrates acclimatization to seasonal environmental change that must enable maximization of growth during the short growing season available. *Kiaeria starkei* is also shown to be capable of nitrate reductase activity even at 2 degrees C and to assimilate more than 90% of the pollutant nitrate coming into contact with it in snowmelt. As nitrate is known to be damaging to bryophytes in excess, this demonstrates a real threat of pollutant deposition to rare snow-bed communities in Scotland today and is an important warning for other regions where snow-bed vegetation is important.

Wright, R.F. 1998. Effect of increased carbon dioxide and temperature on runoff chemistry at a forested catchment in southern Norway (CLIMEX project). *Ecosystems* 1(2):216-225.

CLIMEX (Climate Change Experiment) is an integrated, whole-ecosystem research project that focuses on the response of forest ecosystems at the catchment scale to increased CO₂ and temperature. I(IM catchment (860 m²) is completely enclosed by a transparent greenhouse, receives deacidified "clean" rain, and has elevated CO₂ (560 ppmv) and elevated air temperature (3 degrees-5 degrees C above ambient). The uppermost 20% of the catchment is partitioned off, is not subject to changed CO₂ or temperature, and serves as an untreated control. Fluxes of nitrate and ammonium in runoff from I(IM catchment

increased from 2 mmol m⁻² y⁻¹ each in the 3 years before treatment to 6 and 3 mmol m⁻² y⁻¹, respectively, in the 3 years after treatment (May 1994–April 1997), despite a 15 mmol m⁻² y⁻¹ decrease in N dry deposition due to the sealing of the walls to the enclosure. N flux in runoff from three reference catchments and the control section did not change. The net loss of inorganic N was thus about 20 mmol m⁻² treated soil y⁻¹. There were no changes in organic N or total organic carbon in runoff. The ecosystem switched from a net sink to a net source of inorganic nitrogen (N). The increased loss of N may be due to accelerated decomposition of soil organic matter induced by higher temperature. Due to many decades of N deposition from long-range transported pollutants, the ecosystem prior to treatment was N saturated. If global change induces persistent losses of inorganic N on a regional scale, the result may be a significant increase in nitrate concentrations in fresh waters and N loading to coastal marine ecosystems. In regions with acid sensitive waters, such as southern Norway, the increased nitrate release caused by global change may offset improvements achieved by reduced sulfur and hi deposition.

Wu, W.H., J.Y. Lu, A.R. Jones, D.G. Mortley, P.A. Loretan, C.K. Bonsi, and W.A. Hill. 1997. Proximate composition, amino acid profile, fatty acid composition, and mineral content of peanut seeds hydroponically grown at elevated CO₂ levels. *Journal of Agricultural and Food Chemistry* 45(10):3863-3866.

Peanut plants (*Arachis hypogaea* L. cv. Georgia Red) were grown hydroponically using a recirculating nutrient film technique. The effect of CO₂ enrichment on nutritive composition of hydroponic peanut seeds was examined at two elevated CO₂ levels (700 and 1400 ppm) that simulate potential conditions in National Aeronautics and Space Administration (NASA) Controlled Ecological Life-Support Systems (CELSS) and compared to ambient CO₂ condition in hydroponics (the control). Plants were harvested at 97 days after planting, and the seeds were air-dried and analyzed for composition. Percentages of crude protein, crude fat, ash, and carbohydrate of hydroponic peanut seeds were around 30%, 30%, 3%, and 30%, respectively. The major amino acids were aspartic acid, glutamic acid, and arginine. The limiting amino acid of peanut, methionine, was 1.2%. Linoleic acid was the major fatty acid, followed by oleic and palmitic acids. The major mineral elements were K, P, Mg, and Ca. The results showed that certain peanut varieties can be grown hydroponically. The composition of the hydroponically grown peanuts is generally similar to reported peanut composition. The nutrient composition was not affected at the elevated CO₂ concentrations investigated.

Wullschleger, S.D., J.P. Lynch, and G.M. Berntson. 1994. Modeling the belowground response of plants and soil biota to edaphic and climatic-change - what can we expect to gain. *Plant and Soil* 165(1):149-160.

As atmospheric CO₂ concentrations continue to increase, so too will the emphasis placed on understanding the belowground response of plants to edaphic and climatic change. Controlled-exposure studies that address the significance of an increased supply of carbon to roots and soil biota, and the consequences of this to nutrient cycling will play a prominent role in this process. Models will also contribute to understanding the response of plants and ecosystems to changes in the earth's climate by incorporating experimental results into conceptual or quantitative frameworks from which potential feedbacks within the plant-soil system can be identified. Here we present five examples of

how models can be used in this analysis and how they can contribute to the development of new hypotheses in the areas of root biology, soil biota, and ecosystem processes. Two examples illustrate the role of coarse and fine roots in nitrogen and phosphorus uptake from soils, the respiratory costs associated with this acquisition of nutrients, and the significance of root architecture in these relationships. Another example focuses on a conceptual model that has helped raise new ideas about the effects of elevated CO₂ on root and microbial biomass, and on nutrient dynamics in the rhizosphere. Difficulties associated with modeling the contribution of mycorrhizal fungi to whole-plant growth are also discussed. Finally several broad-scale models are used to illustrate the importance of root turnover, litter decomposition, and nitrogen mineralization in determining an ecosystem's response to atmospheric CO₂ enrichment. We conclude that models are appropriate tools for use both in guiding existing studies and in identifying new hypotheses for future research. Development of models that address the complexities of belowground processes and their role in determining plant and ecosystem function within the context of rising CO₂ concentrations and associated climate change should be encouraged.

Wullschleger, S.D., and R.J. Norby. 1992. Respiratory cost of leaf growth and maintenance in white oak saplings exposed to atmospheric CO₂ enrichment. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 22(11):1717-1721.

Atmospheric CO₂ enrichment reportedly reduces respiration of mature leaves in a number of woody and herbaceous perennials. It has yet to be determined, however, whether these reductions reflect changes in maintenance respiration alone or whether CO₂ might affect growth respiration as well. This possibility was examined in white oak (*Quercus alba* L.) seedlings that had been planted directly into the ground within open-top chambers and exposed to ambient, ambient + 150 µL.L⁻¹, and ambient + 300 µL.L⁻¹ CO₂ concentrations over a 3-year period. In the spring of 1992, respiration rates were measured repeatedly during leaf expansion, and the growth and maintenance coefficients were determined using a two-component model. Specific respiration rates (mg CO₂.g⁻¹.h⁻¹) were consistently lower for leaves of CO₂ enriched saplings than for leaves of ambient-grown saplings. Partitioning these reductions in leaf respiration to either the growth or maintenance coefficients indicated a strong effect of CO₂ on both components. The growth coefficient for leaves exposed to the ambient CO₂ treatment was 964 Mg CO₂.g⁻¹ compared with 849 and 664 mg CO₂.g⁻¹ for leaves from the two elevated CO₂ concentrations, respectively. The maintenance coefficient was similarly reduced from a control rate of 114 mg CO₂.g⁻¹ d⁻¹ to below 65 mg CO₂.g⁻¹.d⁻¹ for leaves exposed to CO₂ enrichment. Our results quantitatively describe the magnitude by which growth and maintenance respiration are affected by CO₂ enrichment and as such should provide useful information for the future modeling of this phenomenon.

Wullschleger, S.D., R.J. Norby, and C.A. Gunderson. 1992. Growth and maintenance respiration in leaves of lirioidendron- tulipifera L exposed to long-term carbon-dioxide enrichment in the field. *New Phytologist* 121(4):515-523.

Specific respiration rate (SRR) was mathematically partitioned into its growth and maintenance components for leaves of yellow-poplar

(*Liriodendron tulipifera* L.) after 3 yr of CO₂ enrichment in open-top field chambers. Despite the absence of a CO₂ effect on individual leaf expansion or specific growth rate (SGR), increasing the CO₂ concentration to ambient + 150 or + 300 cm³ m⁻³ decreased SRR by 28 to 45 % compared with ambient-grown controls. These lower leaf respiration rates were correlated with reduced leaf nitrogen concentrations. As described by the two-component model of growth and maintenance respiration, SRR was a linear function of SGR. Ambient-grown leaves had a growth respiration coefficient of 704 mg CO₂ g⁻¹ dry mass compared with 572 and 570 mg CO₂ g⁻¹ for leaves grown at the two higher CO₂ concentrations. Leaves from the elevated CO₂ treatments had an average maintenance respiration coefficient of 88 mg CO₂ g⁻¹ dry mass d⁻¹ compared with 135 mg CO₂ g⁻¹ d⁻¹ for leaves from the ambient treatment. Incorporating these growth and maintenance coefficients into a leaf growth simulation model indicated that total respiration would be reduced by 21 to 26 % for a leaf exposed to + 150 or + 300 cm³ m⁻³ CO₂ throughout its 50-d lifespan compared with one grown at ambient CO₂ conditions. Reductions in total respiration were dominated by a lower rate of maintenance respiration, while the contribution of a lower specific rate of growth respiration was largely offset by a greater dry mass for leaves grown at elevated CO₂ concentrations. Although reductions in the respiratory loss of carbon could be beneficial, respiration is unlikely to decrease without a concomitant decrease in other metabolic processes. Whether these reductions are beneficial or detrimental to the long-term growth of plants exposed to elevated CO₂ remains unresolved.

Wullschlegel, S.D., R.J. Norby, and P.J. Hanson. 1995. Growth and maintenance respiration in stems of quercus-alba after 4 years of CO₂ enrichment. *Physiologia Plantarum* 93(1):47-54.

Atmospheric CO₂ enrichment is increasingly being reported to inhibit leaf and whole-plant respiration. It is not known, however, whether this response is unique to foliage or whether woody-tissue respiration might be affected as well. This was examined for mid-canopy stem segments of white oak (*Quercus alba* L.) trees that had been grown in open-top field chambers and exposed to either ambient or ambient + 300 µmol mol⁻¹ CO₂ over a 4-year period. Stem respiration measurements were made throughout 1992 by using an infrared gas analyzer and a specially designed in situ cuvette. Rates of woody-tissue respiration were similar between CO₂ treatments prior to leaf initiation and after leaf senescence, but were several fold greater for saplings grown at elevated concentrations of CO₂ during much of the growing season. These effects were most evident on 7 July when stem respiration rates for trees exposed to elevated CO₂ concentrations were 7.25 compared to 3.44 µmol CO₂ m⁻² s⁻¹ for ambient-grown saplings. While other explanations must be explored, greater rates of stem respiration for saplings grown at elevated CO₂ concentrations were consistent with greater rates of stem growth and more stem-wood volume present at the time of measurement. When rates of stem growth were at their maximum (7 July to 3 August), growth respiration accounted for about 80 to 85% of the total respiratory costs of stems at both CO₂ treatments, while 15 to 20% supported the costs of stem-wood maintenance. Integrating growth and maintenance respiration throughout the season, taking into account treatment differences in stem growth and volume, indicated that there were no significant effects of elevated CO₂ concentration on either respiratory process. Quantitative estimates that could be used in modeling the costs of woody-tissue growth and maintenance respiration are provided.

Wullschlegel, S.D., R.J. Norby, and D.L. Hendrix. 1992. Carbon exchange-rates, chlorophyll content, and carbohydrate status of 2 forest tree species exposed to carbon-dioxide enrichment. *Tree Physiology* 10(1):21-31.

Seedlings of yellow-poplar (*Liriodendron tulipifera* L.) and white oak (*Quercus alba* L.) were exposed continuously to one of three CO₂ concentrations in open-top chambers under field conditions and evaluated after 24 weeks with respect to carbon exchange rates (CER), chlorophyll (Chl) content, and diurnal carbohydrate status. Increasing the CO₂ concentration from ambient to +150 or +300 µmol l⁻¹ stimulated CER of yellow-poplar and white oak seedlings by 60 and over 35%, respectively, compared to ambient-grown seedlings. The increases in CER were not associated with a significant change in stomatal conductance and occurred despite a reduction in the amounts of Chl and accessory pigments in the leaves of plants grown in CO₂-enriched air. Total Chl contents of yellow-poplar and white oak seedlings grown at +300 µmol l⁻¹ were reduced by 27 and over 55%, respectively, compared with ambient-grown seedlings. Yellow-poplar and white oak seedlings grown at +300 µmol l⁻¹ contained 72 and 67% more morning starch, respectively, than did ambient-grown plants. In contrast, yellow-poplar and white oak seedlings grown at +300 µmol l⁻¹ contained 17 and 27% less evening sucrose, respectively, than did plants grown at ambient CO₂ concentration. Diurnal starch accumulation and the subsequent depletion of sucrose contributed to a pronounced increase in the starch/sucrose ratio of plants grown in CO₂-enriched air. All seedlings exhibited a substantial reduction in dark respiration as CO₂ concentration increased, but the significance of this increase to the carbohydrate status and carbon economy of plants grown in CO₂-enriched air remains unclear.

Wullschlegel, S.D., R.J. Norby, J.C. Love, and C. Runck. 1997. Energetic costs of tissue construction in yellow-poplar and white oak trees exposed to long-term CO₂ enrichment. *Annals of Botany* 80(3):289-297.

Two methods were used to estimate construction costs for leaves, stems, branches and woody roots of yellow-poplar (*Liriodendron tulipifera* L.) trees grown at ambient (35 Pa) and elevated (65 Pa) CO₂ for 2.7 years and trees of white oak (*Quercus alba* L.) grown at these same CO₂ partial pressures for 4 years. Sample combustion in a bomb calorimeter combined with measurements of ash and nitrogen content provided the primary method of estimating tissue construction costs (W-G; g glucose g⁻¹ dry mass). These values were compared with a second, simpler method in which cost estimates were derived from tissue ash, carbon and nitrogen content (V-G). Estimates of W-G were lower for leaves, branches and roots of yellow-poplar and for leaves of white oak grown at elevated compared with ambient CO₂ partial pressures. These CO₂-induced differences in W-G ranged from 3.7% in yellow-poplar roots to 2.1% in white oak leaves. Only in the case of yellow-poplar leaves, however were differences in V-G observed between CO₂ treatments. Leaf V-G was 1.46 g glucose g⁻¹ dry mass in ambient-grown trees compared with 1.41 g glucose g⁻¹ dry mass for CO₂-enriched trees. Although paired-estimates of W-G and V-G clustered about a 1:1 line for leaves and branches, estimates of V-G were consistently lower than W-G for stems and roots. Construction costs per unit leaf area were 95 g glucose m⁻² for yellow-poplar trees grown at ambient CO₂ and 106 g glucose m⁻² for trees grown at elevated CO₂ partial pressures. No differences in area-based construction costs were observed for white oak. Whole-plant energy content was 1220 g glucose per tree in ambient-grown white oak compared with 2840 g glucose per tree for those grown at elevated CO₂ partial pressures. These differences were driven largely by CO₂-induced changes in total biomass. We conclude that while

construction costs were lower at elevated CO₂ partial pressures, the magnitude of this response argues against an increased efficiency of carbon use in the growth processes of trees exposed to CO₂ enrichment. (C) 1997 Annals of Botany Company.

Wullschlegel, S.D., L.H. Ziska, and J.A. Bunce. 1994. Respiratory responses of higher-plants to atmospheric CO₂ enrichment. *Physiologia Plantarum* 90(1):221-229.

Although the respiratory response of native and agricultural plants to atmospheric CO₂ enrichment has been reported over the past 75 years, only recently have these effects emerged as prominent measures of plant and ecosystem response to the earth's changing climate. In this review we discuss this rapidly expanding field of study and propose that both increasing and decreasing rates of leaf and whole-plant respiration are likely to occur in response to rising CO₂ concentrations. While the stimulatory effects of CO₂ on respiration are consistent with our knowledge of leaf carbohydrate status and plant metabolism, we wish to emphasize the rather surprising short-term inhibition of leaf respiration by elevated CO₂ and the reported effects of long-term CO₂ exposure on growth and maintenance respiration. As is being found in many studies, it is easier to document the respiratory response of higher plants to elevated CO₂ than it is to assign a mechanistic basis for the observed effects. Despite this gap in our understanding of how respiration is affected by CO₂ enrichment, data are sufficient to suggest that changes in leaf and whole-plant respiration may be important considerations in the carbon dynamics of terrestrial ecosystems as global CO₂ continues to rise. Suggestions for future research that would enable these and other effects of CO₂ on respiration to be unravelled are presented.

Wurr, D.C.E., D.W. Hand, R.N. Edmondson, J.R. Fellows, M.A. Hannah, and D.M. Cribb. 1998. Climate change: a response surface study of the effects of CO₂ and temperature on the growth of beetroot, carrots and onions. *Journal of Agricultural Science* 131:125-133.

Ten daylit, controlled-environment cabinets were used to investigate the possible impacts of global rises in atmospheric CO₂ concentration and temperature on beetroot (*Beta vulgaris* L.), carrot (*Daucus carota* L.) and bulb onion (*Allium cepa* L.) plants. Their responses to CO₂ concentrations of 350, 450, 550, 650 and 750 ppm and temperatures of 12, 13.5, 15, 16.5 and 18 degrees C were examined by using a fractional factorial design for the two treatment factors. Use of the daylit cabinets allowed the plants to be grown in natural light, common atmospheric humidities (vpd 0.7 kPa) and nonlimiting supplies of water and mineral nutrients. Polynomial models were used to summarize the whole plant dry weight and fresh weight yield responses and to indicate the potential impact of climate change. Additionally, the models were used to generate predictions of the percentage change in whole plant dry weight and plant fresh weight yield for the years 2025 and 2050 relative to 1992. Baseline values of 350 ppm for CO₂ and a mean temperature of 13.5 degrees C for 1992 together with forecast CO₂ values of 407 and 442 ppm and temperature increases of 0.7 and 1.1 C for 2025 and 2050 respectively were used. For 2025, fresh weight yield changes of + 19%, +9% and +13% were obtained for beetroot, carrot and onion crops

respectively, while for 2050 the respective changes were + 32 %, + 13 % and +21 %. Measurements of the ratio of the maximum diameter of the bulb to the minimum diameter of the neck for onions showed that there was little or no influence of CO₂, whereas the effect of temperature was substantial. Bulbing was accelerated by high temperature and was greatly delayed at low temperature. At temperatures < 15 degrees C, the delays to bulbing resulted in the development of undesirable, thick-necked onions which tended to remain green with erect leaves. These results suggest, therefore, that a warmer climate will be advantageous for the commercial production of bulb onions in Britain.

Wurth, M.K.R., K. Winter, and C. Korner. 1998. In situ responses to elevated CO₂ in tropical forest understorey plants. *Functional Ecology* 12(6):886-895.

1. Plants growing in deep shade and high temperature, such as in the understorey of humid tropical forests, have been predicted to be particularly sensitive to rising atmospheric CO₂. We tested this hypothesis in five species whose microhabitat quantum flux density (QFD) was documented as a covariable. After 7 (tree seedlings of *Tachigalia versicolor* and *Beilschmiedia pendula*) and 18 months (shrubs *Piper cordulatum* and *Psychotria limonensis*, and grass *Pharus latifolius*) of elevated CO₂ treatment (c. 700 $\mu\text{mol l}^{-1}\text{s}^{-1}$) under mean QFD of less than 11 $\mu\text{mol m}^{-2}\text{s}^{-1}$, all species produced more biomass (25-76%) under elevated CO₂. 2. Total plant biomass tended to increase with microhabitat QFD (daytime means varying from 5 to 11 $\mu\text{mol m}^{-2}\text{s}^{-1}$) but the relative stimulation by elevated CO₂ was higher at low QFD except in *Pharus*. 3. Non-structural carbohydrate concentrations in leaves increased significantly in *Pharus* (+ 27%) and *Tachigalia* (+ 40%). 4. The data support the hypothesis that tropical plants growing near the photosynthetic light compensation point are responsive to elevated CO₂. An improved plant carbon balance in deep shade is likely to influence understorey plant recruitment and competition as atmospheric CO₂ continues to rise.

Wurth, M.K.R., K. Winter, and C. Korner. 1998. Leaf carbohydrate responses to CO₂ enrichment at the top of a tropical forest. *Oecologia* 116(1-2):18-25.

The accumulation of non-structural leaf carbohydrates is one of the most consistent plant responses to elevated CO₂. It has been found in both fast- and slow-growing plants and is largely independent of the duration of exposure. Changes in leaf quality are thus to be expected, irrespective of other plant responses to atmospheric CO₂ enrichment. However, there is no experimental evidence from tropical forests, the biome with the largest biomass carbon pool. Here we report in situ mesophyll responses of mature tropical trees to a doubling of CO₂. Individually CO₂-enriched leaves on 25 to 35-m-tall forest trees living at 26-35 degrees C can be assumed to experience little sink limitation, and so, may be expected to exhibit no or very little carbohydrate accumulation. We tested this hypothesis using the leaf cup method on leaves accessible via the canopy crane of the Smithsonian Tropical Research Institute in a semi-deciduous tropical forest in Panama. We also investigated the influence of the leaf-specific light regime, another possible environmental determinant of leaf carbon gain and mobile leaf carbohydrates. Total non-structural carbohydrates (TNC) reached a new steady state concentration after less than 4 days of exposure to twice ambient CO₂ concentration. Against expectation, all four tree species

investigated (*Anacardium excelsum*, *Cecropia longipes*, *C. peltata*, *Ficus insipida*) accumulated significant amounts of TNC (+41 to +61%) under elevated CO₂. The effect was stronger at the end of the daylight period (except for *Ficus*), but was still significant in all four species at the end of the dark period. In contrast, neither artificial nor natural shading affected leaf TNC. Taken together, these observations suggest that TNC accumulation reflects a mesophyll-bound tissue response specific to elevated CO₂, presumably unrelated to sink limitations. Thus, leaves of tropical forests seem not to be an exception, and will most likely contain more non-structural carbohydrates in a CO₂-rich world.

Xiao, X., D.S. Ojima, W.J. Parton, Z. Chen, and D. Chen. 1995. Sensitivity of Inner Mongolia grasslands to climate change. *Journal of Biogeography* 22(4-5):643-648.

We investigated the effects of global climate change and doubled atmospheric CO₂ concentration to plant primary production and soil organic matter of typical steppe (*Leymus chinense* steppe and *Stipa grandis* steppe) and meadow steppe (*Filifolium sibiricum* steppe, *S. baicalensis* steppe and *L. chinense* steppe) at individual sites in Inner Mongolia, using the CENTURY ecosystem model. In the simulation of climate change, loss of soil organic C ranges from 783 gC.m⁻² in meadow steppe to 1485 gC.m⁻² in typical steppe, and annual above-ground net primary production (ANPP) decreases by 17.6 gC.m⁻² in meadow steppe to 29.5 gC.m⁻² in typical steppe under CCC (Canadian Climate Center). While under GFDL (Geophysical Fluid Dynamics Laboratory), loss of soil organic C varies from 584 gC.m⁻² in typical steppe to 1164 gC.m⁻² in meadow steppe, and ANPP decreases in the range of 18.3 gC.m⁻² in typical steppe to 32.1 gC.m⁻² in meadow steppe. In the simulations of climate change plus elevated CO₂ (from 350 p.p.m. to 700 p.p.m.), ANPP decreases by 5.4 gC.m⁻² in meadow steppe to 11.3 gC.m⁻² in typical steppe under CCC + CO₂, while ANPP varies from an increase of 1.8 gC.m⁻² in *S. grmdis* steppe to a decrease of 20.6 gC.m⁻² in meadow steppe under GFDL + CO₂. Losses of soil organic C are slightly lower (in the range of 42 gC.m⁻² to 248 gC.m⁻²) than losses of soil organic C under climate change only. These five steppe ecosystems are very sensitive to climate change, dependent upon projected change in temperature and precipitation by GCMs of CCC and GFDL.

Xu, D.Q., R.M. Gifford, and W.S. Chow. 1994. Photosynthetic acclimation in pea and soybean to high atmospheric CO₂ partial-pressure. *Plant Physiology* 106(2):661-671.

Nonnodulated pea (*Pisum sativum* L. cv Frosty) and soybean (*Glycine max* [L.] Merr. cv Wye) plants were grown under artificial lights from germination with ample nutrients, 600 μmol photons m⁻² s⁻¹, and either 34 to 36 (control) or 64 to 68 Pa (enriched) CO₂. For soybean, pod removal and whole-plant shading treatments were used to alter the source-sink balance and carbohydrate status of the plants. Growth of both species was substantially increased by CO₂ enrichment despite some down-regulation of photosynthesis rate per unit leaf area ("acclimation"). Acclimation was observed in young pea leaves but not old and in old soybean leaves but not young. Acclimation was neither evident in quantum yield nor was it related to triose phosphate limitation of net photosynthesis. A correlation between levels of starch and sugars in the leaf and the amount of acclimation was apparent but was loose and only weakly related to the source-sink balance of the plant. A consistent feature of acclimation was reduced ribulose biphosphate

carboxylase (RuBPCase) content, although in vivo RuBPCase activity was not necessarily diminished by elevated growth CO₂ owing to increased percentage of activation of the enzyme. A proposal is discussed that the complexity of photosynthetic acclimation responses to elevated CO₂ is as an expression of re-optimization of deployment of within-plant resources at three levels of competition.

Xue, X.P., D.A. Gauthier, D.H. Turpin, and H.G. Weger. 1996. Interactions between photosynthesis and respiration in the green alga *Chlamydomonas reinhardtii* - Characterization of light-enhanced dark respiration. *Plant Physiology* 112(3):1005-1014.

The rate of respiratory O₂ consumption by *Chlamydomonas reinhardtii* cell suspensions was greater after a period of photosynthesis than in the preceding dark period. This "light-enhanced dark respiration" (LEDR) was a function of both the duration of illumination and the photon fluence rate. Mass spectrometric measurements of gas exchange indicated that the rate of gross respiratory O₂ consumption increased during photosynthesis, whereas gross respiratory CO₂ production decreased in a photon fluence rate-dependent manner. The rate of postillumination O₂ consumption provided a good measure of the O₂ consumption rate in the light. LEDR was substantially decreased by the presence of 3-(3,4-dichlorophenyl)-1,1-dimethylurea or glycolaldehyde, suggesting that LEDR was photosynthesis-dependent. The onset of photosynthesis resulted in an increase in the cellular levels of phosphoglycerate, malate, and phosphoenolpyruvate and a decrease in whole-cell ATP and citrate levels; all of these changes were rapidly reversed upon darkening. These results are consistent with a decrease in the rate of respiratory carbon flow during photosynthesis, whereas the increase in respiratory O₂ consumption during photosynthesis may be mediated by the export of photogenerated reductant from the chloroplast. We suggest that photosynthesis interacts with respiration at more than one level, simultaneously decreasing the rate of respiratory carbon flow while increasing the rate of respiratory O₂ consumption.

Yakimchuk, R., and J. Hoddinott. 1994. The influence of ultraviolet-B light and carbon-dioxide enrichment on the growth and physiology of seedlings of 3 conifer species. *Canadian Journal of Forest Research-Revue Canadienne De Recherche Forestiere* 24(1):1-8.

Anthropogenic production of CO₂ and stratospheric ozone depleting chemicals is altering the plant growth environment. Numerous studies have examined the influence of increasing CO₂ and UV-B levels on plant physiology, but few studies examine their interaction. Jack pine (*Pinus banksiana* Lamb.), black spruce (*Picea mariana* (Mill.) B.S.P.), and white spruce (*Picea glauca* (Moench) Voss) were raised in growth rooms from seed for 16 weeks in air with either 350 or 700 μmol.mol⁻¹ of CO₂ in the presence or absence of supplemental UV-B irradiation. Classical and functional growth analyses were performed to identify treatment effects. Biomass production in all three species was increased by high CO₂ levels while UV-B light reduced it. Shade-intolerant jack pine showed a greater production of UV-B absorbing pigments in UV-B light than did shade-tolerant spruce species. Overall, white spruce was the most sensitive species to both treatment factors. The relative

magnitude of the effects in the three species caused by enhanced CO₂ and UV-B levels indicate that future conifer seedling growth and competitive ability will be altered by the changing environment.

Yamashita, I., K. Dan, and M. Shimomura. 1999. Active modified atmosphere packaging storage of cabbage plug seedlings. *Journal of the Japanese Society for Horticultural Science* 68(5):1015-1021.

When cabbage plug seedlings were stored under a modified atmosphere packaging (MAP) at 15 degrees C in the dark for 2 weeks, a passive MAP did not create an environment to inhibit stem elongation of seedling in the 0.1mm thick polyethylene (PE) film pouch. An active MAP by adjusting N-2 rich air with 2% O-2 did not successfully retard elongation either. In the active MAP where the internal atmosphere was replaced with N-2 enriched air (2.5% O-2) with elevated CO₂, the elongation was delayed as CO₂ concentration increased. When 16% CO₂ was introduced to the 0.08mm thick nylon/PE film pouch, the inhibit of stem elongation was most successful. Analysis of plant weight, total number of leaves, green color intensity, ascorbic acid content in the leaf blade and head weight of harvested cabbage revealed that the elevated CO₂ active MAP is a favorable storage condition for cabbage plug seedlings. The elevated CO₂ active MAP, however, caused CO₂ injury when CO₂ concentration exceeded 24%.

Yamauchi, N., and A.E. Watada. 1998. Chlorophyll and xanthophyll changes in broccoli florets stored under elevated CO₂ or ethylene-containing atmosphere. *Hortscience* 33(1):114-117.

Chlorophylls and xanthophylls were monitored in broccoli (*Brassica oleracea* L. var. *italica* Plen.) florets stored in air, air + 10 ppm ethylene, or 10% CO₂ + 1% O-2 controlled atmosphere (CA) at 15 degrees C. Chlorophylls a and b, as measured with high-performance liquid chromatography, decreased in florets held in air. The decrease was accelerated by ethylene treatment and suppressed in CA. Chlorophyllide a and pheophorbide a were present in fresh broccoli florets, but the levels decreased significantly in all treatments during storage. The oxidized product of chlorophyll a, 13(2)-hydroxychlorophyll a, did not accumulate. Xanthophylls decreased, but new pigments, suggested to be esterified xanthophylls, formed with yellowing in stored florets. The chlorophyll degradative pathway in broccoli florets was not altered by ethylene or CA and differed from that reported for parsley (*Petroselinum crispum* Nym.) and spinach (*Spinacia oleracea* L.) leaves.

Yavitt, J.B., R.K. Wieder, and G.E. Lang. 1993. CO₂ and CH₄ dynamics of a sphagnum-dominated peatland in west-virginia. *Global Biogeochemical Cycles* 7(2):259-274.

Climatic change could bring about net release of carbon dioxide (CO₂) and/or methane (CH₄) from the deep peat deposits in northern peatlands into the atmosphere. To provide insight into this hypothesis, we studied net flux of CO₂ and CH₄ in Big Run Bog, West Virginia, which has a temperate climate, making it an analog to evaluate climatic change imposed on more northern counterparts. Net CO₂ flux ranged from -564 to 300 mg C m⁻² hr⁻¹. Measurements made during the nighttime showed that net CO₂ flux increased exponentially with increasing air

temperature, whereas CO₂ sequestration increased with increasing air temperature for daytime measurements. Net CH₄ flux ranged from -2.3 to 70 mg C m⁻² hr⁻¹, showing no consistent relationship to temperature or water table level. Net efflux for both CO₂ and CH₄ was tenfold higher from peat cores incubated in a greenhouse compared to field measurements. Even cores drained and allowed to dry for 8 days showed moderately high flux for both CO₂ and CH₄. The enhanced efflux seemed to be due to altered hydrology rather than increased rates of bacterial production (measured in anoxic, in vitro incubations) which could account for only 50% of the whole-core flux. Presumably the remainder was CO₂ and CH₄ stored in the peat cores at the time of collection. Overall, the results suggest that a temperate climate imposed on northern peatlands could mobilize stored carbon and increase CO₂ and CH₄ efflux into the troposphere. Studies involving peat cores must insure that CO₂ and CH₄ dynamics measured in vitro mimic those in situ.

Yearsley, C.W., N.H. Banks, and S. Ganesh. 1997. Effect of carbon dioxide on the internal lower oxygen limits of apple fruit. *Postharvest Biology and Technology* 12(1):1-13.

The effect of elevated CO₂ between 0 and 8 kPa on steady-state lower O-2 limits based on internal atmospheres (LOLi) was estimated for postclimacteric 'Cox's Orange Pippin' and 'Braeburn' apples at 0 and 20 degrees C. Two types of LOLi were estimated: the anaerobic compensation point (ACP(i)), and the internal fermentation threshold based either on the respiratory quotient (FTRQi) or ethanol (EtOH) accumulation (FTEtOH_i). ACP(i), for both cultivars and temperatures, remained constant at 0.5 kPa O-2 for 'Cox's Orange Pippin' and 0.8-1.0 O-2 for 'Braeburn' apples for levels of CO₂ external to the fruit between 0 and 8 kPa. However, for FTRQi and FTEtOH_i no consistent trend with level of CO₂ was evident at 20 degrees C for either cultivar. In contrast, at 0 degrees C FTRQi and FTEtOH_i were 0.2-0.8 kPa O-2 higher at 8 kPa CO₂ than at 0 kPa CO₂ (with the exception of FTRQi for 'Cox's Orange Pippin'). A small decrease in O-2 uptake (estimated from the difference in external and internal O-2 atmospheres) was observed between 2 and 8 kPa CO₂ at 20 degrees C. Elevated CO₂ slightly lowered the respiratory quotient (RQ_i), estimated from the ratio of differences between external and internal atmosphere partial pressures of CO₂ and O-2 of 'Cox's Orange Pippin' in 8 kPa CO₂ and 'Braeburn' in 2 to 8 kPa CO₂ at 20 degrees C, and more markedly in 8 kPa CO₂ at 0 degrees C. The RQ_i of 'Cox's Orange Pippin' and 'Braeburn' apples was slightly and markedly higher respectively at 0 degrees C compared to 20 degrees C. The lower RQ_i of 'Braeburn' at 20 degrees C compared to 'Cox's Orange Pippin' apples indicated 'Braeburn' had a higher permeance to CO₂ relative to O-2 compared to 'Cox's Orange Pippin'. This study indicates the tolerance of 'Cox's Orange Pippin' and 'Braeburn' apples to low O-2 levels may be affected by levels of CO₂. (C) 1997 Elsevier Science B.V.

Yeates, G.W., P.C.D. Newton, and D.J. Ross. 1999. Response of soil nematode fauna to naturally elevated CO₂ levels influenced by soil pattern. *Nematology* 1:285-293.

As experimental elevation of CO₂ in short-term experiments may produce organic matter with decomposition characteristics different from those produced under long-term equilibrated conditions, we

sampled the soil nematode fauna near a natural CO₂ vent in Northland, New Zealand. Various indices of the nematode fauna showed significant effects, with all being significantly correlated with soil pH, microbial carbon and atmospheric CO₂ across the 33 sampling points. There was a general decrease in nematode abundance and diversity, but an increase in dominance and proportion of bacterial-feeding nematodes with increasing atmospheric CO₂ concentration. However, when the nematode data from gley and organic soils present at the site were differentiated most of the significant correlations were with soil microbial carbon; they were positive in the organic soil but negative in the gley soil. That these responses can be related to soil carbon and to microbial carbon demonstrates that any general response to long-term CO₂ enrichment represents an integration of specific responses by the soil biota in the various soils present.

Yeates, G.W., K.R. Tate, and P.C.D. Newton. 1997. Response of the fauna of a grassland soil to doubling of atmospheric carbon dioxide concentration. *Biology and Fertility of Soils* 25(3):307-315.

The effects of elevated CO₂ on rhizosphere processes, including the response of soil faunal populations and community structure, have so far received little attention. We report on significant responses in the soil fauna of ryegrass/white clover swards to both increasing CO₂ from 350 to 750 $\mu\text{mol l}^{-1}$ and, to a period of 60 days when some of the turves were subject to drought, in a controlled climate growth room experiment. The nematodes which increased were predominantly Enoplia, including dorylaimids, alaimids and trichodorids. This accords with both the doubling of Alaimus under elevated CO₂ conditions reported in a similar experiment and with the common association of Enoplia with less disturbed habitats. The most marked decrease was in the bacterial-feeding Rhabditis (Secernentea). The increase in omnivorous and predacious nematodes may have been responsible for the decrease in populations of bacterial-feeding nematodes. However, in contrast to their standing crops, the turnover rate of bacterial-feeding nematodes and soil microbial biomass probably increased as a result of increased grazing by these omnivorous and predacious nematodes. Increases in earthworm and enchytraeid populations were related to increased below-ground productivity reported for the same trial.

Yeo, A. 1999. Predicting the interaction between the effects of salinity and climate change on crop plants. *Scientia Horticulturae* 78(1-4):159-174.

The human population is expected to double so there will be at least a doubled demand for food production. This will increase the demand for irrigation because irrigation gives a higher potential yield per unit area than non-irrigated agriculture, together with more yield stability. The demand for irrigation will be especially focused in semi-arid regions supporting a large population, such as the Mediterranean basin and the Indo-Gangetic plain of northern India and Pakistan. The 'hot/warm

semi-arid' agro-climatic zone is the one projected most to expand in relative proportion as a consequence of climate change brought about by the increase in atmospheric carbon dioxide concentration. Irrigation in semi-arid climates is a major cause of secondary salinisation (that due to human activity) which already affects 1 ha in five of the irrigated lands. Increased demand for irrigation in semi-arid climates, as a result of both population increase and climate change, will tend to increase the extent of secondary salinisation. Any increase in the extent of secondary salinisation could be offset by positive effects of elevated atmospheric CO₂ on crop yield per unit area and per unit input of water. In protected environments, or where CO₂ is the only experimental variable, elevated CO₂ usually enhances plant growth and water-use-efficiency in the short-term and can also do so in the longer term. However, far crop production in the field world-wide, elevated CO₂ per se is not a factor that can be viewed separately from the climate change that it will bring about. Neither the anticipated 'CO₂-fertilisation' nor the 'water-use-efficiency' benefits to the plant of elevated CO₂ is certain to outweigh the climatic effects of elevated CO₂ on temperature, water availability and evaporative demand. Climate change is expected to cause a net increase in the proportion of land classed as semi-arid. Raised temperatures may benefit some crops in some places but disadvantage others through increased evapotranspiration and thermal damage. Increased water-use-efficiency may not reduce leaf salt concentration in a saline environment. Buffering and feedback effects in both agricultural and ecological systems conspire to moderate or even to confound the anticipated gains in net assimilation and water-use-efficiency found in experimental systems. Elevated CO₂ may not, therefore, provide the anticipated decrease in water-use, decrease in leaf salt concentration, and increase in fixed carbon available for re-allocation: factors that might enhance crop performance under salinity stress. If these benefits are not realised then elevated atmospheric CO₂ will exacerbate rather than moderate the problems of secondary salinity in agriculture. (C) 1999 Elsevier Science B.V. Yokota, T., and A. Hagihara. 1998. Changes in the relationship between tree size and aboveground respiration in field-grown hinoki cypress (*Chamaecyparis obtusa*) trees over three years. *Tree Physiology* 18(1):37-43.

Respiration measurements of aerial parts of 18-year-old hinoki cypress (*Chamaecyparis obtusa* (Sieb. et Zucc.) Endl.) trees were made under field conditions over three years to study changing relationships with tree age between respiration and phytomass, phytomass increment, and leaf mass. The relationship between annual respiration ($r(a)$) and phytomass ($w(T)$) was approximated by a proportional function ($r(a) = aw(T)$), where the proportional constant (a) decreased year by year. The effect of time on the relationship between annual respiration and phytomass of each sample tree was fitted by a power function. Respiration of the tree suppressed by the canopy decreased year by year, but respiration of the other trees increased slightly with age. The relationship between annual respiration and leaf mass was also approximated by a generalized power function. Excluding the suppressed tree, the relationship between annual respiration ($r(a)$) and the annual increment of aboveground phytomass ($\Delta w(T)$) was described by a proportional function ($r(a) = 2.27 \Delta w(T)$), where the proportional constant, 2.27, was independent of sample tree and year, indicating that about 2.3 times of the annual aboveground phytomass increment equivalent was respired annually. For any tree, the time constant relationships between annual respiration and leaf mass and phytomass increment for different-sized trees were similar to the corresponding time continuum relationships. In contrast, the time continuum relationship between annual respiration and phytomass

differed from the time constant relationship, indicating that respiration of less active woody tissue contributed significantly to aboveground respiration. Based on the relationship between tree size and annual respiration, annual aboveground stand respiration was estimated to be 25.0, 26.9, and 25.8 Mg-dm ha⁻¹ year⁻¹ for the three consecutive years, respectively, and the corresponding above-ground stand biomass was 60.0, 69.0, and 76.8 Mg-dm ha⁻¹.

Yoo, K.S., C.R. Andersen, and L.M. Pike. 1997. Internal CO₂ concentrations in onion bulbs at different storage temperatures and in response to sealing of the neck and base. *Postharvest Biology and Technology* 12(2):157-163.

Internal CO₂ concentrations were measured in onion (*Allium cepa* L. cv. TG 1015Y) bulbs stored at 1, 7, 13, 20, 27, or 34 degrees C for 12 weeks and their relationships with shoot growth and respiration rates were investigated. Maximum shoot growth was observed at 13 and 20 degrees C. Respiration rates were greatest at 13 and 20 degrees C for 8 weeks, then linearly increased with storage temperatures after 12 weeks. Internal CO₂ concentrations ranging from 2 to 5% increased with increasing storage temperatures, while internal gas volume decreased. Bicarbonate concentrations in outer scales ranged from 130 to 190 μ M and increased with increasing storage temperatures. The centre scale tissues contained 11-17% CO₂, which paralleled respiration rates. Sealing the neck area of onion bulbs stored at 1 or 27 degrees C significantly increased internal CO₂ concentrations, but had no effect on inhibiting shoot growth. Internal CO₂ concentrations appeared to be regulated by gas exchange rates through the neck area and/or elevated HCO₃⁻ concentrations in outer scales. Elevated internal CO₂ concentrations or high levels in centre scale tissues did not appear to be a primary reason for inhibited shoot growth at high storage temperatures. There seems to be thermo-dormancy controlling shoot growth and respiration in onion bulbs. (C) 1997 Elsevier Science B.V.

Yoshioka, T., S. Satoh, and Y. Yamasue. 1998. Effect of increased concentration of soil CO₂ on intermittent flushes of seed germination in *Echinochloa crus-galli* var. *crus-galli*. *Plant, Cell and Environment* 21(12):1301-1306.

Soil-buried seeds of barnyardgrass (*Echinochloa crus-galli* var. *crus-galli*) germinated from April to June in three intermittent flushes. The later two flushes of germination occurred after heavy rainfall. Carbon dioxide concentration in soil air transiently increased to 30 dm³ m⁻³ after the rainfall, probably due to the increase in soil temperature and water potential. Germination of exhumed seeds was stimulated by exposure to CO₂ at 30 dm³ m⁻³. Fluctuating temperature, light, water, ethylene, and nitrate are known to promote seed germination in many species. However, of these environmental factors, within ranges found in the field, only CO₂ was effective in enhancing the germination of barnyardgrass seeds. We conclude that soil CO₂ is responsible for causing intermittent flushes of germination. Detection of vegetation gaps may be explained by the responsiveness of buried seeds to CO₂.

Young, I.M., E. Blanchart, C. Chenu, M. Dangerfield, C. Fragos, M. Grimaldi, J. Ingram, and L.J. Monrozier. 1998. The interaction of soil biota and soil structure under global change. *Global Change*

Biology 4(7):703-712.

The structural framework of soil mediates all soil processes, at all relevant scales. The spatio-temporal heterogeneity prevalent in most soils underpins the majority of biological diversity in soil, providing refuge sites for prey against predator, flow paths for biota to move, or be moved, and localized pools of substrate for biota to multiply. Just as importantly, soil biota play a crucial role in mediating soil structure: bacteria and fungi aggregate and stabilize structure at small scales (μ m-m) and earthworms and termites stabilize and create larger-scale structures (mm-m). The stability of this two-way interaction of structure and biota relations is crucial to the sustainability of the ecosystem. Soil is constantly reacting to changes in microclimates, and many of the soil-plant-microbe processes rely on the functioning of subtle chemical and physical gradients. The effect of global change on soil structure-biota interactions may be significant, through alterations in precipitation, temperature events, or land-use. Nonetheless, because of the complexity and the ubiquitous heterogeneity of these interactions, it is difficult to extrapolate from general qualitative predictions of the effects of perturbations to specific reactions. This paper reviews some of the main soil structure-biota interactions, particularly focusing on soil stability, and the role of biota mediating soil structures. The effect of alterations in climate and land-use on these interactions is investigated. Several case studies of the effect of land-use change are presented.

Yu, M., Q. Gao, and J.P. Guo. 1998. Sensitivity analysis of individual responses of plants to global change. *Acta Botanica Sinica* 40(12):1143-1151.

Today research on global change is becoming one of the three vital topics in ecology. Within this field, simulating an individual plant's physiological responses to global change, especially the combined effects of CO₂ enrichment and the climatic change it caused, is a useful model in predicting the changes of either natural vegetation or agricultural crops, in that the physiological basis of the responses are mostly understood and the results of simulation can be checked with experiments at any level or step when needed. Since the scenarios of the global changes often differ with different GCM's, and will change as the GCM's are being improved, even though, the simulation programs can still be used to for new predictions. In this study, based on the physiological mechanisms, a systematic dynamic model of plant individual growth was established, which included a weather generator and a growth module. The combined effects of enriched CO₂ and climatic change on the main physiological processes, such as photosynthesis, respiration, etc., and seasonal dynamics of biomass were considered in the model. The data sets of the long-term weather records of Beijing Meteorological Station and the observed values of many ecophysiological quantities, obtained in a CO₂ enrichment experiment of soybean, were used to parameterize and to validate the model. The results showed that data obtained from the simulation were quite compatible with those from the observation. When the CO₂ concentration was doubled, the peak values of the total biomass and green biomass were increased approximately by 70% and 56% respectively. Furthermore, the responses of the total net assimilation and the average specific dark respiration rate within the growth season explained the internal mechanism of the biomass responses. The result indicated that the total net assimilation increased, while the average specific dark respiration rate decreased. Thus, it can be deduced that the increase of biomass has brought about not only by the increase of the net assimilation, but also by the decrease of the specific dark respiration rate. Sensitivity analysis was used to the soybean individual responses

to global change. The seasonal dynamics of the total biomass to the combined effects of different levels of CO₂, temperature and precipitation were simulated. CO₂ concentration and precipitation have positive, while temperature has negative effect on total biomass. The positive effect of precipitation became weaker with increasing temperatures, while the negative effect of temperature was strengthened by the increased precipitation. The positive effect of CO₂ concentration became stronger with the increasing temperatures, but weaker under enhancing precipitations. The positive effect of precipitation and the negative effect of temperature were weakened by doubling the CO₂ concentration. These are partly due to the enhanced water use efficiency caused by CO₂ enrichment, which in turn renders the plant individual more resistant and adaptable to the environmental change.

Zadrazil, F., and A.K. Puniya. 1994. Influence of carbon-dioxide on lignin degradation and digestibility of lignocellulosics treated with pleurotus-sajor- caju. *International Biodeterioration & Biodegradation* 33(3):237-244.

This study investigates the effect of different CO₂ concentrations on lignin degradation and in vitro digestibility of wheat straw used as growth substrate for *Pleurotus sajor- caju*. The degradation of wheat straw lignin by *P. sajor-caju* increased under the influence of CO₂ (0-20%) in the atmosphere and then started declining at higher levels. The maximum loss of lignin (39.7%) was found in cultures grown with passive air exchange through cotton plugs while digestibility was higher in cultures actively aerated with 0-30% CO₂. Aside from gases, the period of incubation, i.e. 40 days rather than 20 days, seems to be the most important variable for improving the digestibility of the product. Generally, the process efficiency for change in digestibility per gram loss of organic matter enhanced from 0 to 30% CO₂ at a fixed level of O₂ (20%) in the gaseous phase.

Zak, D.R., K.S. Pregitzer, P.S. Curtis, J.A. Teeri, R. Fogel, and D.L. Randlett. 1993. Elevated atmospheric CO₂ and feedback between carbon and nitrogen cycles. *Plant and Soil* 151(1):105-117.

We tested a conceptual model describing the influence of elevated atmospheric CO₂ on plant production, soil microorganisms, and the cycling of C and N in the plant-soil system. Our model is based on the observation that in nutrient- poor soils, plants (C3) grown in an elevated CO₂ atmosphere often increase production and allocation to belowground structures. We predicted that greater belowground C inputs at elevated CO₂ should elicit an increase in soil microbial biomass and increased rates of organic matter turnover and nitrogen availability. We measured photosynthesis, biomass production, and C allocation of *Populus grandidentata* Michx. grown in nutrient-poor soil for one field season at ambient and twice-ambient (i.e., elevated) atmospheric CO₂ concentrations. Plants were grown in a sandy subsurface soil i) at ambient CO₂ with no open top chamber, ii) at ambient CO₂ in an open top chamber, and iii) at twice-ambient CO₂ in an open top chamber. Plants were fertilized with 4.5 g N m⁻² over a 47 d period midway through the growing season. Following 152 d of growth, we quantified microbial biomass and the availabilities of C and N in rhizosphere and bulk soil. We tested for a significant CO₂ effect on plant growth and soil C and N dynamics by comparing the means of the chambered ambient and chambered elevated CO₂ treatments. Rates of photosynthesis in plants grown at elevated CO₂ were significantly greater than those

measured under ambient conditions. The number of roots, root length, and root length increment were also substantially greater at elevated CO₂. Total and belowground biomass were significantly greater at elevated CO₂. Under N-limited conditions, plants allocated 50-70% of their biomass to roots. Labile C in the rhizosphere of elevated-grown plants was significantly greater than that measured in the ambient treatments; there were no significant differences between labile C pools in the bulk soil of ambient and elevated-grown plants. Microbial biomass C was significantly greater in the rhizosphere and bulk soil of plants grown at elevated CO₂ compared to that in the ambient treatment. Moreover, a short-term laboratory assay of N mineralization indicated that N availability was significantly greater in the bulk soil of the elevated-grown plants. Our results suggest that elevated atmospheric CO₂ concentrations can have a positive feedback effect on soil C and N dynamics producing greater N availability. Experiments conducted for longer periods of time will be necessary to test the potential for negative feedback due to altered leaf litter chemistry.

Zak, D.R., D.B. Ringelberg, K.S. Pregitzer, D.L. Randlett, D.C. White, and P.S. Curtis. 1996. Soil microbial communities beneath *Populus grandidentata* crown under elevated atmospheric CO₂. *Ecological Applications* 6(1):257-262.

In most terrestrial ecosystems, the amount of substrate entering the soil from plant litter production is only sufficient to meet the maintenance requirements of soil microorganisms, allowing for no net annual growth. However, the rising atmospheric CO₂ concentration has the potential to alter such a balance by increasing plant litter production, and hence the amount of substrate available for heterotrophic metabolism in soil. In a recent experiment, we observed that greater belowground plant litter production at elevated atmospheric CO₂ significantly increased the biomass of soil microorganisms in both rhizosphere and non-rhizosphere soil. Because soil microorganisms differ in their ability to convert substrate into biomass, we hypothesized that greater plant litter production at elevated CO₂ should shift community composition as fungal populations increase in response to greater substrate availability. We used a molecular technique, phospholipid fatty acid (PLFA) analysis, to gain insight into the composition of soil microbial communities beneath *Populus grandidentata* growing at ambient and twice-ambient atmospheric CO₂. PLFAs extracted from rhizosphere and non-rhizosphere soil were derivatized and identified using gas chromatography and mass spectrometry. After one growing season the proportions of bacterial, actinomycetal, and fungal PLFAs were not significantly influenced by elevated atmospheric CO₂ in either rhizosphere or non-rhizosphere soil. However, clear differences were present between microbial communities in rhizosphere and non-rhizosphere soil. Although enhanced belowground plant litter production under elevated atmospheric CO₂ increased the biomass of soil microorganisms, we have no evidence to suggest that such an increase occurred through a shift in community composition, at least in the short term.

Zaller, J.G., and J.A. Arnone. 1997. Activity of surface-casting earthworms in a calcareous grassland under elevated atmospheric CO₂. *Oecologia* 111(2):249-254.

Earthworms make up the dominant fraction of the biomass of soil animals in most temperate grasslands and have important effects on the structure and function of these ecosystems. We hypothesized that the effects of elevated atmospheric CO₂ on soil moisture and plant biomass production would increase earthworm activity, expressed as surface cast production. Using a screen-aided CO₂ control facility (open top and open bottom rings), eight 1.2-m(2) grassland plots in Switzerland have been maintained since March 1994 at ambient CO₂ concentrations (350 µmol CO₂ L⁻¹) and eight at elevated CO₂ (610 µmol CO₂ L⁻¹). Cumulative earthworm surface cast production measured 40 times over 1 year (April 1995–April 1996) in plots treated with elevated CO₂ (2206 g dry mass m⁻² year⁻¹) was 35% greater ($P < 0.05$) than that measured in plant communities maintained at ambient CO₂ (1633 g dry mass m⁻² year⁻¹). At these rates of surface cast production, worms would require about 100 years to ingest the equivalent of the amount of soil now found in the Ah horizon (top 15 cm) under current ambient CO₂ concentrations, and 75 years under elevated CO₂. Elevated atmospheric CO₂ had no influence on the seasonality of earthworm activity. Cumulative surface cast production measured over the 7-week period immediately following the 6-week summer dry period in 1995 (no surface casting) was positively correlated ($P < 0.05$) with the mean soil water content calculated over this dry and subsequent wetter period, when viewed across all treatments. However, no correlations were observed with soil temperature or with annual aboveground plant biomass productivity. No CO₂-related differences were observed in total nitrogen (N_{tot}) and organic carbon (C_{org}) concentration of surface casts, although concentrations of both elements varied seasonally. The CO₂-induced increase in earthworm surface casting activity corresponded to a 30% increase of the amount of N_{tot} (8.9 mg N m⁻² vs. 6.9 mg N m⁻²) and C_{org} (126 mg C m⁻² vs. 94 mg C m⁻²) egested by the worms in one year. Thus, our results demonstrate an important indirect stimulatory effect of elevated atmospheric CO₂ on earthworm activity which may have profound effects on ecosystem function and plant community structure in the long term.

Zaller, J.G., and J.A. Arnone. 1999. Earthworm responses to plant species' loss and elevated CO₂ in calcareous grassland. *Plant and Soil* 208(1):1-8.

The objectives of this study were: (1) to quantify the effects of plant species' loss from designed calcareous grassland communities at a field site in northwestern Switzerland on the size and composition of earthworm communities, and (2) to evaluate how exposure of plant communities to elevated atmospheric CO₂ might alter the effects of plant species' loss on earthworm communities. We non-destructively censused earthworm communities in each of 24 1.2 m(2) experimental plots in autumn 1996 when soils were wet and earthworms were active. Each plot contained an experimental plant community with 31, 12 or 5 native plant species (eight plots each). Half of the plots in each species treatment were exposed to ambient CO₂ concentrations (350 µmol CO₂ L⁻¹) and half to elevated CO₂ (600 µmol CO₂ L⁻¹) using screen-aided CO₂ control. The study was conducted in the fourth year after community establishment and the third year of CO₂ treatment as part of a long-term study on the interactive effects of plant species' loss and elevated CO₂ on grassland communities. The size (density and biomass) of earthworm communities declined linearly when the number of plant species in the community was reduced from 31 to 5 species (e.g. 32 ± 1 g m⁻² to 23 ± 2 g m⁻²) due mainly to a decline in the endogeic worm species *Allolobophora rosea* which was the most abundant of nine earthworm species observed (nearly half of all worms in each plot). However, no changes in the relative contribution of individual species

or the three main earthworm ecological groups (anecics, endogeics, epigeics) to the entire earthworm community were observed with declining number of plant species. The responses of earthworm communities to plant species' loss appear to reflect changes in community fine root biomass in the topsoil (e.g. declining worm biomass with declining fine root biomass) observed in parallel studies conducted at this site. Further the results of this study demonstrate that a loss of plant species' from these calcareous grassland communities may also alter the age structure of earthworm communities, but not significantly influence their diversity or composition. Our data also indicate that rising atmospheric CO₂ may not greatly impact the size and composition of worm communities or alter the effects of plant species' loss on earthworm communities. Therefore, the disappearance of plant species from these native grasslands, as a result of ever increasing human activities, may be expected to lead to reductions in the size of earthworm communities and the ecosystem services they provide.

Zaller, J.G., and J.A. Arnone. 1999. Interactions between plant species and earthworm casts in a calcareous grassland under elevated CO₂. *Ecology* 80(3):873-881.

We tested the hypothesis that the spatial proximity of a plant species to nutrient-rich earthworm casts (e.g., 100% more ammonium and 30% more phosphate than in adjacent soil) is an important determinant of a plant's responsiveness to elevated atmospheric CO₂. In 1995 we mapped the location of both earthworm surface casts and plants in each of 16 1.2-m(2) plots in a species-rich calcareous grassland in northwestern Switzerland. Eight plots have been maintained under current ambient CO₂ concentrations (350 µmol CO₂ L⁻¹), and eight have been maintained at elevated CO₂ (600 µmol CO₂ L⁻¹) since March 1994. In addition, total ramet production of each species, as a measure of performance, and cumulative cast production at each location (cell) were recorded at peak community biomass in 1995. Plant species within functional groups (graminoids, non-legume forbs, and legumes) differed markedly in their degree of association with casts; however, after two growing seasons elevated CO₂ had no effect on plant species or functional group associations with casts. No statistically significant relationship could be demonstrated between plant-species response (i.e., ramet production) to elevated CO₂ and the degree of association with casts within any of the functional groups. However, a positive relationship was observed between the mean response of graminoid species to elevated CO₂ (measured as the percentage change in mean total ramet production of graminoid species, relative to mean total ramet production at ambient CO₂) and their mean degree of association (%) with surface casts at ambient CO₂. Thus, graminoid species more frequently associated with casts (e.g., *Anthoxanthum odoratum* and *Carex caryophyllaea*) produced more ramets per square meter at elevated CO₂ than those less frequently associated with casts (e.g., *Agrostis tenuis* and *Danthonia decumbens*). These results, along with the strong and significant positive correlations observed between ramet production and associated cumulative cast mass across CO₂ treatments for most plant species in all functional groups demonstrate: (1) that plant species differ significantly in their degree of association with nutrient-rich earthworm surface casts, regardless of the relative abundance of plant species in the community; (2) that graminoid species that are more highly associated with casts may respond more strongly to rising CO₂ than those less highly associated with casts; and (3) that nutrient-rich earthworm casts stimulate the growth (ramet production) of most plant species in these grassland communities, even at current levels of atmospheric CO₂. The data further suggest that these species-specific relationships between plants and casts have helped define the current structure of these highly diverse grassland communities and will likely influence their future structure as global CO₂ levels continue to rise.

Zamolodchikov, D.G., D.V. Karelin, and A.I. Ivaschenko. 1997. Carbon balance of tundra landscape in Central Siberia: Observations, simulation and GIS-modelling. *Zhurnal Obshchei Biologii* 58(2):15-34.

Comprehensive statistical analysis of field measurements of CO₂ fluxes in ecosystems of typical subarctic tundra in Taymir Peninsula (Central Siberia, Russia) was performed. Simulation models allowing to compute integrate seasonal values of basic components of carbon balance in the most characteristic plant communities of typical tundra were built. To access the landscape pattern of tundra carbon balance we applied GIS-approach based on the original computer map of ecosystem borders. In 1994 the seasonal (from the beginning of snow melting till the end of total soil freezing) carbon balance of typical tundra landscape was estimated as -4 g C . m⁻² . year⁻¹ (carbon sink), the ecosystem total respiration as +145 g C . m⁻² . year⁻¹, and gross primary production as -149 g C . m⁻² year⁻¹. Such a poorly expressed carbon sink conceptually should be considered as landscape equilibrium. Nevertheless the subsequent computer simulation of climate changes confirmed the hypothesis of positive feedback between global warming and change of carbon balance pattern in tundra ecosystems from sink to source. From the other side we found that regional peculiarities of ecological and climatic conditions can strongly effect the climate global change appearance.

Zamorano, J.P., R. Alique, and W. Canet. 1999. Mechanical parameters to assess quality changes in cherimoya fruit. *Zeitschrift Fur Lebensmittel-Untersuchung Und-Forschung A-Food Research and Technology* 208(2):125-129.

Several mechanical parameters obtained by means of compression and penetration tests, and changes in cherimoya (*Annona cherimola* Mill.) fruit quality during storage in air and two controlled atmospheres (CA), (3% O₂ + 0% CO₂ and 3% O₂ + 3% CO₂) were analysed. A gradient of softening was found among the equatorial and the apical areas of the flesh during CA storage, as assessed by localized penetration tests. The combination of low O₂/elevated CO₂ (3% O₂ + 3% CO₂) increased this gradient and had a greater inhibiting effect on skin softening than low O₂. It appeared that the prevention of softening by CA was stronger in the less mature tissues (equatorial and outer areas) than in the more mature tissues (apical and inner areas around the longitudinal axis). CA delayed or inhibited changes in fruit quality observed during air storage: increases in total soluble solids (TSS), titratable acidity (TA), and yellowness of the flesh (b), and diminution in flesh lightness of colour (L). A good relationship between an objective quality index (QI, where QI = TSS + TA + L/b) and the compression slope (CS) was found during storage under all the conditions tested. It is suggested that the relationship, QI = 29.25 + 0.04 x CS - 0.0023 x CS² could be useful when assessing stages of cherimoya fruit quality during storage under different conditions by performing a nondestructive, compression test.

Zanetti, S., and U.A. Hartwig. 1997. Symbiotic N₂ fixation increases under elevated atmospheric pCO₂ in the field. *Acta Oecologica-*

International Journal of Ecology 18(3):285-290.

Plant growth is stimulated by elevated atmospheric pCO₂, and hence demand for nutrients increases. In this context, nitrogen is a very prominent element; it can either be supplied from the limited available soil N or through biological (e.g. symbiotic) nitrogen fixation. In this study, the effect of elevated pCO₂ (60 Pa) on symbiotic N₂ fixation (N-15-isotope dilution method) was investigated using Free-Air-CO₂-Enrichment (FACE) technology over a period of two growing seasons. *Trifolium repens* L. was cultivated either alone or in mixed swards together with *Lolium perenne* L. (non-fixing reference crop). In T. repens, percentage of plant N derived from symbiotic N₂ fixation (%N_{sym}) increased from 59 to 66% under elevated pCO₂. The major part of the additionally assimilated N was derived from symbiotic N₂ fixation. In the mixed swards, increased N yield was entirely due to increased symbiotic N₂ fixation. It is suggested that increased N₂ fixation is an important factor in the satisfaction of increased N demand in both clover and the associated grass under elevated pCO₂.

Zanetti, S., U.A. Hartwig, A. Luscher, T. Hebeisen, M. Frehner, B.U. Fischer, G.R. Hendrey, H. Blum, and J. Nosberger. 1996. Stimulation of symbiotic N₂ fixation in *Trifolium repens* L under elevated atmospheric pCO₂ in a grassland ecosystem. *Plant Physiology* 112(2):575-583.

Symbiotic N₂ fixation is one of the main processes that introduces N into terrestrial ecosystems. As such, it may be crucial for the sequestration of the extra C available in a world of continuously increasing atmospheric CO₂ partial pressure (pCO₂). The effect of elevated pCO₂ (60 Pa) on symbiotic N₂ fixation (N-15-isotope dilution method) was investigated using Free-Air-CO₂-Enrichment technology over a period of 3 years. *Trifolium repens* was cultivated either alone or together with *Lolium perenne* (a nonfixing reference crop) in mixed swards. Two different N fertilization levels and defoliation frequencies were applied. The total N yield increased consistently and the percentage of plant N derived from symbiotic N₂ fixation increased significantly in T. repens under elevated pCO₂. All additionally assimilated N was derived from symbiotic N₂ fixation, not from the soil. In the mixtures exposed to elevated pCO₂, an increased amount of symbiotically fixed N (+7.8, 8.2, and 6.2 g m⁻² a⁻¹) in 1993, 1994, and 1995, respectively) was introduced into the system. Increased N₂ fixation is a competitive advantage for T. repens in mixed swards with pasture grasses and may be a crucial factor in maintaining the C:N ratio in the ecosystem as a whole.

Zanetti, S., U.A. Hartwig, and J. Nosberger. 1998. Elevated atmospheric CO₂ does not affect per se the preference for symbiotic nitrogen as opposed to mineral nitrogen of *Trifolium repens* L. *Plant, Cell and Environment* 21(6):623-630.

The objective of this investigation was to examine the effect of an elevated atmospheric CO₂ partial pressure (pCO₂) on the N-sink strength and performance of symbiotic N₂ fixation in *Trifolium repens* L. cv. Milkanova. After initial growth under ambient pCO₂ in a nitrogen-free nutrient solution, T. repens in the exponential growth stage was exposed to ambient and elevated pCO₂ (35 and 60 Pa) and two

levels of mineral N (N-free and 7.5 mol m⁻³ N) for 36 d in single pots filled with silica sand in growth chambers. Elevated pCO₂ evoked a significant increase in biomass production from day 12 after the start of CO₂ enrichment. For plants supplied with 7.5 mol m⁻³ N, the relative contribution of symbiotically fixed N (%N-sym) as opposed to N assimilated from mineral sources (N-15-isotope-dilution method), dropped to 40%. However, in the presence of this high level of mineral N, %N-sym was unaffected by atmospheric pCO₂ over the entire experimental period. In plants fully dependent on N₂ fixation, the increase in N yield reflects a stimulation of symbiotic N₂ fixation that was the result of the formation of more nodules rather than of higher specific N₂ fixation. These results are discussed with regard to physiological processes governing symbiotic N₂ fixation and to the response of symbiotic N₂ fixation to elevated pCO₂ in field-grown *T. repens*.

Zanetti, S., U.A. Hartwig, C. van Kessel, A. Luscher, T. Hebeisen, M. Frehner, B.U. Fischer, G.R. Hendrey, H. Blum, and J. Nosberger. 1997. Does nitrogen nutrition restrict the CO₂ response of fertile grassland lacking legumes? *Oecologia* 112(1):17-25.

The extent of the response of plant growth to atmospheric CO₂ enrichment depends on the availability of resources other than CO₂. An important growth-limiting resource under field conditions is nitrogen (N). N may, therefore, influence the CO₂ response of plants. The effect of elevated CO₂ (60 Pa) partial pressure (pCO₂) on the N nutrition of field-grown *Lolium perenne* swards, cultivated alone or in association with *Trifolium repens*, was investigated using free air carbon dioxide enrichment (FACE) technology over 3 years. The established grassland ecosystems were treated with two N fertilization levels and were defoliated at two frequencies. Under elevated pCO₂, the above-ground plant material of the *L. perenne* monoculture showed a consistent and significant decline in N concentration which, in general, led to a lower total annual N yield. Despite the decline in the critical N concentration (minimum N concentration required for non-N-limited biomass production) under elevated pCO₂, the index of N nutrition (ratio of actual N concentration and critical N concentration) was lower under elevated pCO₂ than under ambient pCO₂ in frequently defoliated *L. perenne* monocultures. Thus, we suggest that reduced N yield under elevated pCO₂ was evoked indirectly by a reduction of plant-available N. For *L. perenne* grown in association with *T. repens* and exposed to elevated pCO₂ there was an increase in the contribution of symbiotically fixed N to the total N yield of the grass. This can be explained by an increased apparent transfer of N from the associated N₂-fixing legume species to the non-fixing grass. The total annual N yield of the mixed grass/legume swards increased under elevated pCO₂. All the additional N yielded was due to symbiotically fixed N. Through the presence of an N₂-fixing plant species more symbiotically fixed N was introduced into the system and consequently helped to overcome N limitation under elevated pCO₂.

Zebian, K.J., and E.G. Reekie. 1998. The interactive effects of atmospheric carbon dioxide and light on stem elongation in seedlings of four species. *Annals of Botany* 81(2):185-193.

Four species, *Sinapis alba* L., *Medicago sativa* L., *Gypsophila paniculata* L., and *Picea abies* (L.) Karsten, were grown in three light regimes: darkness, low light (25 μmol m⁻² s⁻¹ for 10 min d⁻¹) and high light (120 μmol m⁻² s⁻¹ for 12 h d⁻¹) and four levels of carbon dioxide: 0, 350, 700 and 1400 ± 50 μmol l⁻¹. Germination was not affected by any of the treatments. The effects of carbon dioxide on stem elongation were identical in low and high light: stem length increased at a decreasing rate with level of carbon dioxide in all species. Level of carbon dioxide also affected stem elongation in complete darkness, but the pattern was more complex and varied among species. Total weight did not vary with level of carbon dioxide to any significant extent in either darkness or low light, but increased with level of carbon dioxide at high light in all four species. Due to the absence of any effect of carbon dioxide on growth in darkness and low light, we suggest the effects of carbon dioxide on stem elongation are independent of effects on growth and may be due to a direct interaction with developmental processes. In contrast, level of carbon dioxide had little effect on allocation patterns in the dark and low light experiments, but had marked effects in high light. Therefore, the effect of carbon dioxide on allocation was probably due to the effects of carbon dioxide on growth rather than to any direct interaction between carbon dioxide and development. An understanding of the mechanisms by which carbon dioxide affects development may help us understand the often variable effects of carbon dioxide upon plants. (C) 1998 Annals of Botany Company.

Zeng, W., and J.L. Heilman. 1997. Sensitivity of evapotranspiration of cotton and sorghum in west Texas to changes in climate and CO₂. *Theoretical and Applied Climatology* 57(3-4):245-254.

In regions such as west Texas where water is scarce, changes in the water balance may have a significant impact on agricultural production and management of water resources. We used the mechanistic soil-plant-atmosphere simulation model ENWATBAL to evaluate changes in soil water evaporation (E) and transpiration (T) in cotton and grain sorghum that may occur due to climate change and elevated CO₂ in west Texas. Climatic and plant factors were varied individually, and in combination, to determine their impact on E and T. Of the climatic factors, E was most sensitive to changes in vapor pressure, and T to changes in irradiance. Simulations suggest that if warming is accompanied by higher humidity, the impact of climate change may be minimal. However, if the climate becomes warmer and less humid, ET may increase substantially. Simulations also suggest that enhanced growth due to elevated CO₂ may have a greater impact on ET than climatic change.

Zhang, H.H., and P.S. Nobel. 1996. Photosynthesis and carbohydrate partitioning for the C-3 desert shrub *Encelia farinosa* under current and doubled CO₂ concentrations. *Plant Physiology* 110(4):1361-1366.

Changes in photosynthesis (A) and carbohydrate partitioning were studied for *Encelia farinosa*, a common C-3 desert shrub in the southwestern United States, after a 3-month exposure to the current or a doubled CO₂ concentration (750 μmol l⁻¹). A remained unchanged under the current CO₂ concentration but decreased during the day under the doubled CO₂ concentration, resulting in a 46% enhancement in the

early morning, 26% at midday, and 15% in the late afternoon by the elevated CO₂. The decrease during the day under the doubled CO₂ concentration may represent end-product inhibition, because the sucrose and the starch contents increased during the day proportionally more than under the current CO₂ concentration. The (CO₂)-C-14 activity in sink leaves was maximal 3 h after labeling under the doubled and at 5 h under the current CO₂ concentration, indicating faster movement of photosynthate out of source leaves and into sink tissues under the doubled CO₂ concentration, which may have been responsible for the sustained enhancement in A under the doubled CO₂ concentration.

Zhang, J., and M.J. Lechowicz. 1995. Responses to CO₂ enrichment by 2 genotypes of *Arabidopsis thaliana* differing in their sensitivity to nutrient availability. *Annals of Botany* 75(5):491-499.

The responses of two genotypes of *Arabidopsis thaliana*, which differ in their sensitivities to nutrients to present and predicted future CO₂ concentration were determined under rich vs. poor nutrient regimes on the basis of both single traits and the whole plant. Based on individual traits, the two genotypes responded similarly to CO₂ enrichment for all the traits measured except for rate of increase in crown diameter, for which a decrease was observed in the less nutrient-sensitive genotype grown at increased CO₂. Based on the overall response of the whole plant, by analysing groups of plant traits using multivariate analysis, the two genotypes differed substantially from one another and both responded more strongly to nutrient availability than to CO₂ concentration, especially for traits measured at harvest that related to reproductive fitness. The less nutrient-sensitive genotype also showed a weaker overall response to CO₂, and the pattern of the overall response was strikingly similar at different nutrient supply. In contrast, the more nutrient-sensitive genotype responded more strongly to CO₂ than the less nutrient-sensitive genotype, and responded differently to CO₂ at low vs. high nutrient availability.

Zhang, Y.Q., and J.M. Welker. 1996. Tibetan alpine tundra responses to simulated changes in climate: Aboveground biomass and community responses. *Arctic and Alpine Research* 28(2):203-209.

High-elevation ecosystems are predicted to be some of the terrestrial habitats most sensitive to changing climates. The ecological consequences of changes in alpine tundra environmental conditions are still unclear especially for habitats in Asia. In this study we report findings from a field experiment where an alpine tundra grassland on the Tibetan plateau (37 degrees N, 101 degrees E) was exposed to experimental warming, irradiance was lowered, and wind speed reduced to simulate a suite of potential changes in environmental conditions. Our warming treatment increased air temperatures by 5 degrees C on average and soil temperatures were elevated by 3 degrees C at 5 cm depth. Aboveground biomass of grasses responded rapidly to the warmer conditions whereby biomass was 25% greater than that of controls after only 5 wk of experimental warming. This increase was accompanied by a simultaneous decrease in forb biomass, resulting in almost no net change in community biomass after 5 wk. Lower irradiance reduced grass biomass during the same period. Under ambient conditions total aboveground community biomass increased seasonally from 161 g m⁻² in July to a maximum of 351 g m⁻² in September, declining to 285 g

m⁻² in October. However, under warmed conditions, peak community biomass was extended into October due in part to continued growth of grasses and the postponement of senescence. Our findings indicate that while alpine grasses respond favorably to altered conditions, others may not. And, while peak community biomass may actually change very little under warmer summers, the duration of peak biomass may be extended having feedback effects on net ecosystem CO₂ balances, nutrient cycling, and forage availability.

Zhu, J., D.P. Bartholomew, and G. Goldstein. 1997. Effect of elevated carbon dioxide on the growth and physiological responses of pineapple, a species with Crassulacean acid metabolism. *Journal of the American Society for Horticultural Science* 122(2):233-237.

Despite the potential impact of rising global CO₂ levels, only a limited number of studies have been conducted on the effects of ambient and elevated CO₂ on plants having Crassulacean acid metabolism (CAM). To our knowledge, there are no studies for pineapple [*Ananas comosus* (L.) Merr.], the most commercially important CAM plant. Pineapple plants were grown at CO₂ levels of approximate to 330 (ambient) and approximate to 730 (elevated) $\mu\text{mol} \cdot \text{mol}^{-1}$ in open-top chambers for 4 months. The mean air temperature in the chambers was approximate to 39 degrees C day/24 degrees C night. Average plant dry mass at harvest was 180 g per plant at elevated CO₂ and 146 g per plant at ambient CO₂. More biomass was partitioned to stem and root but less to leaf for plants grown at elevated CO₂; leaf thickness was 11% greater at elevated than at ambient CO₂. The diurnal difference in leaf titratable acidity (H⁺) at elevated CO₂ reached 347 mmol $\cdot \text{m}^{-2}$, which was up to 42% greater than levels in plants grown in ambient CO₂. Carbon isotopic discrimination (Δ) of plants was 3.75% at ambient CO₂ and 3.17% at elevated CO₂, indicating that CO₂ uptake via the CAM pathway was enhanced more by elevated CO₂ than uptake via the C-3 pathway. The nonphotochemical quenching coefficient (q(N)) of leaves was approximate to 45% lower in the early morning for plants grown at elevated than at ambient CO₂, while afternoon values were comparable. The q(N) data suggested that the fixation of external CO₂ was enhanced by elevated CO₂ in the morning but not in the afternoon when leaf temperature was greater than or equal to 40 degrees C. We found no effect of CO₂ levels on leaf N or chlorophyll content. Pineapple dry matter gain was enhanced by elevated CO₂, mainly due to increased CO₂ dark fixation in environments with day temperatures high enough to suppress C-3 photosynthesis.

Zhu, J., G. Goldstein, and D.P. Bartholomew. 1999. Gas exchange and carbon isotope composition of *Ananas comosus* in response to elevated CO₂ and temperature. *Plant, Cell and Environment* 22(8):999-1007.

Ananas comosus L. (Merr.) (pineapple) was grown at three day/night temperatures and 350 (ambient) and 700 (elevated) $\mu\text{mol} \cdot \text{mol}^{-1}$ CO₂ to examine the interactive effects of these factors on leaf gas exchange and stable carbon isotope discrimination (Δ , parts per thousand). All data were collected on the youngest mature leaf for 24 h every 6 weeks. CO₂ uptake (mmol m⁻² d⁻¹) at ambient and elevated CO₂, respectively, were 306 and 352 at 30/20 degrees C, 175 and 346 at 30/25

degrees C and 187 and 343 at 35/25 degrees C, CO₂ enrichment enhanced CO₂ uptake substantially in the day in all environments. Uptake at night at elevated CO₂, relative to that at ambient CO₂, was unchanged at 30/20 degrees C, but was 80% higher at 30/25 degrees C and 44% higher at 35/25 degrees C suggesting that phosphoenolpyruvate carboxylase was not CO₂-saturated at ambient CO₂ levels and a 25 degrees C night temperature. Photosynthetic water use efficiency (WUE) was higher at elevated than at ambient CO₂. Leaf Delta-values were higher at elevated than at ambient CO₂ due to relatively higher assimilation in the light, Leaf Delta was significantly and linearly related to the fraction of total CO₂ assimilated at night. The data suggest that a simultaneous increase in CO₂ level and temperature associated with global warming would enhance carbon assimilation, increase WUE, and reduce the temperature dependence of CO₂ uptake by *A. cosmos*.

Zimmerman, R.C., D.G. Kohrs, D.L. Steller, and R.S. Alberte. 1997. Impacts of CO₂ enrichment on productivity and light requirements of eelgrass. *Plant Physiology* 115(2):599-607.

Seagrasses, although well adapted for submerged existence, are CO₂-limited and photosynthetically inefficient in seawater. This leads to high light requirements for growth and survival and makes seagrasses vulnerable to light limitation. We explored the long-term impact of increased CO₂ availability on light requirements, productivity, and C allocation in eelgrass (*Zostera marina* L.). Enrichment of seawater CO₂ increased photosynthesis 3-fold, but had no long-term impact on respiration. By tripling the rate of light-saturated photosynthesis, CO₂ enrichment reduced the daily period of irradiance-saturated photosynthesis (H-sat) that is required for the maintenance of positive whole-plant C balance from 7 to 2.7 h, allowing plants maintained under 4 h of H-sat to perform like plants growing in unenriched seawater with 12 h of H-sat. Eelgrass grown under 4 h of H-sat without added CO₂ consumed internal C reserves as photosynthesis rates and chlorophyll levels dropped. Growth ceased after 30 d. Leaf photosynthesis, respiration, chlorophyll, and sucrose-phosphate synthase activity of CO₂-enriched plants showed no acclimation to prolonged enrichment. Thus, the CO₂-stimulated improvement in photosynthesis reduced light requirements in the long term, suggesting that globally increasing CO₂ may enhance seagrass survival in eutrophic coastal waters, where populations have been devastated by algal proliferation and reduced water-column light transparency.

Ziska, L.H. 1998. The influence of root zone temperature on photosynthetic acclimation to elevated carbon dioxide concentrations. *Annals of Botany* 81(6):717-721.

Soybean (*Glycine max* 'Clark') was grown from germination to 21 d after sowing (DAS) at ambient (similar to 360 $\mu\text{mol mol}^{-1}$) or elevated (similar to 720 $\mu\text{mol mol}^{-1}$) carbon dioxide (CO₂) at either one of two soil temperatures, 25 or 30 degrees C to determine the influence of root zone temperature on root growth and photosynthetic stimulation at ambient and elevated concentrations of carbon dioxide. Although the photosynthetic rate became less stimulate over time, a significant stimulation of whole plant photosynthesis and plant dry weight was observed at the elevated CO₂ concentration during the experimental period irrespective of soil temperature. At neither carbon dioxide

concentration did the warmer soil temperature (30 degrees C) stimulate whole plant growth compared to a soil temperature of 25 degrees C, but it did increase root growth relative to shoot (top) growth with a subsequent increase in root/shoot ratio. Increasing soil temperature at either carbon dioxide concentration also significantly stimulated whole plant photosynthetic rate. However, the degree of stimulation was reduced with time irrespective of carbon dioxide concentration so that at 21 DAS no difference in photosynthesis between ambient and elevated soil temperatures was observed. Data from this experiment indicate that for soybean, a higher soil temperature stimulates root/shoot ratio and enhances photosynthetic response to elevated carbon dioxide in the short-term (i.e. days), but increasing root/shoot ratios does not provide a satisfactory explanation of long-term stimulation of photosynthesis at elevated levels of carbon dioxide. Ziska, L.H., and J.A. Bunce. 1993. The influence of elevated CO₂ and temperature on seed-germination and emergence from soil. *Field Crops Research* 34(2):147-157.

Seed of six crop species, alfalfa, *Medicago sativa* L. cv. 'Arc', soybean, *Glycine max* L. (Merrill) cv. 'Williams', maize, *Zea mays* L. cv. SS 885, pea, *Pisum sativum* L. cv. 'Maestro', sunflower, *Helianthus annuus* L. cv. 'Mammoth', and pumpkin *Cucurbita pepo* L. cv. 'Big Max' and four weedy species, *Amaranthus hypochondriacus* L., *Amaranthus hybridus* L., *Chenopodium album* L. and *Abutilon theophrasti*, were grown at two different CO₂ concentrations of 350 $\mu\text{mol l}^{-1}$ (ambient) and 700 $\mu\text{mol l}^{-1}$ (elevated) in controlled-environment chambers to determine the effect of elevated CO₂ on germination and emergence. Doubling the CO₂ concentration resulted in an increase in the rate and final percentage of germination, for *M. sativa*, *A. hybridus* and *C. album*. In a separate field experiment (silt-loam soil), elevated CO₂ resulted in a significant increase in the total number of weed seedlings present 3 weeks after tilling. In a second set of experiments using controlled-environment chambers, the interaction between increased temperature and CO₂ was examined in seven of the species used previously. No significant interaction was observed between CO₂ and temperature on the germination response. Overall, this investigation suggests that as CO₂ increases, differential changes in germination and/or emergence between crops and weeds could occur.

Ziska, L.H., and J.A. Bunce. 1993. Inhibition of whole-plant respiration by elevated CO₂ as modified by growth temperature. *Physiologia Plantarum* 87(4):459-466.

Plants of alfalfa (*Medicago sativa*) and orchard grass (*Dactylus glomerata*) were grown in controlled environment chambers at two CO₂ concentrations (350 and 700 $\mu\text{mol mol}^{-1}$) and 4 constant day/night growth temperatures of 15, 20, 25 and 30-degrees-C for 50-90 days to determine changes in growth and whole plant CO₂ efflux (dark respiration). To facilitate comparisons with other studies, respiration data were expressed on the basis of leaf area, dry weight and protein. Growth at elevated CO₂ increased total plant biomass at all temperatures relative to ambient CO₂, but the relative enhancement declined (P less-than-or-equal-to 0.05) as temperature increased. Whole plant respiration ($R(d)$) at elevated CO₂ declined at 15 and 20-degrees-C in *D. glomerata* on an area, weight or protein basis and in *M. sativa* on a weight or protein basis when compared to ambient CO₂. Separation of $R(d)$ into respiration required for growth ($R(g)$) and maintenance ($R(m)$) showed

a significant effect of elevated CO₂ on both components. R(m) was reduced in both species but only at lower temperatures (15-degrees-C in *M. sativa* and 15 and 20-degrees-C in *D. glomerata*). The effect on R(m) could not be accounted for by protein content in either species. R(g) was also reduced with elevated CO₂; however no particular effect of temperature was observed, i.e. R(g) was reduced at 20, 25 and 30-degrees-C in *M. sativa* and at 15 and 25-degrees-C in *D. glomerata*. For the two perennial species used in the present study, the data suggest that both R(g) and R(m) can be reduced by anticipated increases in atmospheric CO₂; however, CO₂ inhibition of total plant respiration may decline as a function of increasing temperature.

Ziska, L.H., and J.A. Bunce. 1994. Direct and indirect inhibition of single leaf respiration by elevated CO₂ concentrations - interaction with temperature. *Physiologia Plantarum* 90(1):130-138.

Two herbaceous perennials, alfalfa (*Medicago sativa* L. cv. Arc) and orchard grass (*Dactylus glomerata* L. cv. Potomac), were grown at ambient (367 $\mu\text{mol mol}^{-1}$) and elevated (729 $\mu\text{mol mol}^{-1}$) CO₂ concentrations at constant temperatures of 15, 20, 25 and 30-degrees-C in order to examine direct and indirect changes in nighttime CO₂ efflux rate (respiration) of single leaves. Direct (biochemical) effects of CO₂ on nighttime respiration were determined for each growth condition by brief (<30 min) exposure to each CO₂ concentration. If no direct inhibition of respiration was observed, then long-term reductions in CO₂ efflux between CO₂ treatments were presumed to be due to indirect inhibition, probably related to long-term changes in leaf composition. By this criterion, indirect effects of CO₂ on leaf respiration were observed at 15 and 20-degrees-C for *M. sativa* on a weight basis, but not on a leaf area or protein basis. Direct effects however, were observed at 15, 20 and 25-degrees-C in *D. glomerata*; therefore the observed reductions in respiration for leaves grown and measured at elevated relative to ambient CO₂ concentrations could not be distinguished as indirect inhibition. No inhibition of respiration at elevated CO₂ was observed at the highest growth temperature (30-degrees-C) in either species. CO₂ efflux increased with measurement and growth temperature for *M. sativa* at both CO₂ concentrations; however, CO₂ efflux in *D. glomerata* showed complete acclimation to growth temperature. Stimulation of leaf area and weight by elevated CO₂ levels declined with growth temperature in both species. Data from the present study suggest that both direct and indirect inhibition of respiration are possible with future increases in atmospheric CO₂, and that the degree of each type of respiratory inhibition is a function of growth temperature.

Ziska, L.H., and J.A. Bunce. 1994. Increasing growth temperature reduces the stimulatory effect of elevated CO₂ on photosynthesis or biomass in 2 perennial species. *Physiologia Plantarum* 91(2):183-190.

We examined how anticipated changes in CO₂ concentration and temperature interacted to alter plant growth, harvest characteristics and photosynthesis in two cold-adapted herbaceous perennials, alfalfa (*Medicago sativa* L. cv. Arc) and orchard grass (*Dactylis glomerata* L. cv. Potomac). Plants were grown at two CO₂ concentrations (362 [ambient] and 717 [elevated] $\mu\text{mol mol}^{-1}$ CO₂) and four constant day/night temperatures of 15, 20, 25 and 30 degrees C in controlled environmental chambers. Elevated CO₂ significantly increased total plant biomass and protein over a wide range of temperatures in both

species. Stimulation of photosynthesis rare, however, was eliminated at the highest growth temperature in *M. sativa* and relative stimulation of plant biomass and protein at high CO₂ declined as temperature increased in both species. Lack of a synergistic effect between temperature and CO₂ was unexpected since elevated CO₂ reduces the amount of carbon lost via photorespiration and photorespiration increases with temperature. Differences between anticipated stimulatory effects of CO₂ and temperature and whole plant single and leaf measurements are discussed. Data from this study suggest that stimulatory effects of atmospheric CO₂ on growth and photosynthesis may decline with anticipated increases in global temperature, limiting the degree of carbon storage in these two perennial species.

Ziska, L.H., and J.A. Bunce. 1995. Growth and photosynthetic response of 3 soybean cultivars to simultaneous increases in growth temperature and CO₂. *Physiologia Plantarum* 94(4):575-584.

Three soybean (*Glycine max* L. Merr.) cultivars (Maple Glen, Clark and CNS) were exposed to three CO₂ concentrations (370, 555 and 740 $\mu\text{mol mol}^{-1}$) and three growth temperatures (20/15 degrees, 25/20 degrees and 31/26 degrees C, day/night) to determine intraspecific differences in single leaf/whole plant photosynthesis, growth and partitioning, phenology and final biomass. Based on known carboxylation kinetics, a synergistic effect between temperature and CO₂ on growth and photosynthesis was predicted since elevated CO₂ increases photosynthesis by reducing photorespiration and photorespiration increases with temperature. Increasing CO₂ concentrations resulted in a stimulation of single leaf photosynthesis for 40-60 days after emergence (DAE) at 20/15 degrees C in all cultivars and for Maple Glen and CNS at all temperatures. For Clark, however, the onset of flowering at warmer temperatures coincided with the loss of stimulation in single leaf photosynthesis at elevated CO₂ concentrations. Despite the season-long stimulation of single leaf photosynthesis, elevated CO₂ concentrations did not increase whole plant photosynthesis except at the highest growth temperature in Maple Glen and CNS, and there was no synergistic effect on final biomass. Instead, the stimulatory effect of CO₂ on growth was delayed by higher temperatures. Data from this experiment suggest that: (1) intraspecific variation could be used to select for optimum soybean cultivars with future climate change; and (2) the relationship between temperature and CO₂ concentration may be expressed differently at the leaf and whole plant levels and may not solely reflect known changes in carboxylation kinetics.

Ziska, L.H., and J.A. Bunce. 1997. Influence of increasing carbon dioxide concentration on the photosynthetic and growth stimulation of selected C-4 crops and weeds. *Photosynthesis Research* 54(3):199-208.

Plants of six weedy species (*Amaranthus retroflexus*, *Echinochloa crus-galli*, *Panicum dichotomiflorum*, *Setaria faberi*, *Setaria viridis*, *Sorghum halapense*) and 4 crop species (*Amaranthus hypochondriacus*, *Saccharum officinarum*, *Sorghum bicolor* and *Zea mays*) possessing the C-4 type of photosynthesis were grown at ambient (38 Pa) and elevated (69 Pa) carbon dioxide during early development (i.e. up to 60 days after sowing) to determine: (a) if plants possessing the C-4 photosynthetic pathway could respond photosynthetically or in biomass production to future increases in global carbon dioxide and (b) whether differences

exist between weeds and crops in the degree of response. Based on observations in the response of photosynthesis (measured as A, CO₂ assimilation rate) to the growth CO₂ condition as well as to a range of internal CO₂ (C- i) concentrations, eight of ten C-4 species showed a significant increase in photosynthesis. The largest and smallest increases observed were for *A. retroflexus* (+30%) and *Z. mays* (+5%), respectively. Weed species (+19%) showed approximately twice the degree of photosynthetic stimulation as that of crop species (+10%) at the higher CO₂ concentration. Elevated carbon dioxide also resulted in significant increases in whole plant biomass for four C-4 weeds (*A. retroflexus*, *E. crus-galli*, *P. dichotomiflorum*, *S. viridis*) relative to the ambient CO₂ condition. Leaf water potentials for three selected species (*A. retroflexus*, *A. hypochondriacus*, *Z. mays*) indicated that differences in photosynthetic stimulation were not due solely to improved leaf water status. Data from this study indicate that C-4 plants may respond directly to increasing CO₂ concentration, and in the case of some C-4 weeds (e.g. *A. retroflexus*) may show photosynthetic increases similar to those published for C-3 species.

Ziska, L.H., and J.A. Bunce. 1997. The role of temperature in determining the stimulation of CO₂ assimilation at elevated carbon dioxide concentration in soybean seedlings. *Physiologia Plantarum* 100(1):126-132.

Soybean (*Glycine max* cv. Clark) was grown at both ambient (ca 350 $\mu\text{mol mol}^{-1}$) and elevated (ca 700 $\mu\text{mol mol}^{-1}$) CO₂ concentration at 5 growth temperatures (constant day/night temperatures of 20, 25, 30, 35 and 40 degrees C) for 17-22 days after sowing to determine the interaction between temperature and CO₂ concentration on photosynthesis (measured as A, the rate of CO₂ assimilation per unit leaf area) at both the single leaf and whole plant level. Single leaves of soybean demonstrated increasingly greater stimulation of A at elevated CO₂ as temperature increased from 25 to 35 degrees C (i.e. optimal growth rates). At 40 degrees C, primary leaves failed to develop and plants eventually died. In contrast, for both whole plant A and total biomass production, increasing temperature resulted in less stimulation by elevated CO₂ concentration. For whole plants, increased CO₂ stimulated leaf area more as growth temperature increased. Differences between the response of A to elevated CO₂ for single leaves and whole plants may be related to increased self-shading experienced by whole plants at elevated CO₂ as temperature increased. Results from the present study suggest that self-shading could limit the response of CO₂ assimilation rate and the growth response of soybean plants if temperature and CO₂ increase concurrently, and illustrate that light may be an important consideration in predicting the relative stimulation of photosynthesis by elevated CO₂ at the whole plant level.

Ziska, L.H., and J.A. Bunce. 1998. The influence of increasing growth temperature and CO₂ concentration on the ratio of respiration to photosynthesis in soybean seedlings. *Global Change Biology* 4(6):637-643.

Using controlled environmental growth chambers, whole plants of soybean, cv. 'Clark', were examined during early development (7-20 days after sowing) at both ambient (approximate to 350 $\mu\text{mol L}^{-1}$) and elevated (approximate to 700 $\mu\text{mol L}^{-1}$) carbon dioxide and a range of air temperatures (20, 25, 30, and 35 degrees C) to determine if future

climatic change (temperature or CO₂ concentration) could alter the ratio of carbon lost by dark respiration to that gained via photosynthesis. Although whole-plant respiration increased with short-term increases in the measurement temperature, respiration acclimated to increasing growth temperature. Respiration, on a dry weight basis, was either unchanged or lower for the elevated CO₂ grown plants, relative to ambient CO₂ concentration, over the range of growth temperatures. Levels of both starch and sucrose increased with elevated CO₂ concentration, but no interaction between CO₂ and growth temperature was observed. Relative growth rate increased with elevated CO₂ concentration up to a growth temperature of 35 degrees C. The ratio of respiration to photosynthesis rate over a 24-h period during early development was not altered over the growth temperatures (20-35 degrees C) and was consistently less at the elevated relative to the ambient CO₂ concentration. The current experiment does not support the proposition that global increases in carbon dioxide and temperature will increase the ratio of respiration to photosynthesis; rather, the data suggest that some plant species may continue to act as a sink for carbon even if carbon dioxide and temperature increase simultaneously.

Ziska, L.H., and J.A. Bunce. 1999. Effect of elevated carbon dioxide concentration at night on the growth and gas exchange of selected C-4 species. *Australian Journal of Plant Physiology* 26(1):71-77.

Biomass of certain C-4 species is increased when plants are grown at elevated CO₂ concentrations. Experiments using four C-4 species (*Amaranthus retroflexus* L., *Amaranthus hypochondriacus* L., *Sorghum bicolor* (L.) Moench and *Zea mays* L.) exposed both day and night from sowing to carbon dioxide concentrations of 370 (ambient) or 700 $\mu\text{mol mol}^{-1}$ (elevated) or to 370 $\mu\text{mol mol}^{-1}$ during the day and 700 $\mu\text{mol mol}^{-1}$ at night, determined whether any biomass increase at elevated CO₂ concentrations was related to a reduction in the night-time rate of CO₂ efflux at high night-time CO₂ concentrations. Of the four species tested, only *A. retroflexus* significantly increased both CO₂ assimilation (+13%) and plant biomass (+21%) at continuous elevated relative to continuous ambient concentrations of CO₂. This increase was not associated with improvement in leaf water potential during dark or light periods. In contrast, high CO₂ only during the night significantly reduced plant biomass compared to the 24 h ambient CO₂ treatment for both *A. retroflexus* and *Z. mays*. This indicates that the observed increase in biomass at elevated CO₂ for *A. retroflexus* was not caused by a reduction of carbon loss at night (i.e. increased carbon conservation), but rather a direct stimulation of daytime CO₂ assimilation, independent of any improvement in leaf water potential.

Ziska, L.H., J.A. Bunce, and F. Caulfield. 1998. Intraspecific variation in seed yield of soybean (*Glycine max*) in response to increased atmospheric carbon dioxide. *Australian Journal of Plant Physiology* 25(7):801-807.

The growth characteristics of six and the reproductive development of five soybean [*Glycine max* (L.) Merr.] cultivars were examined at 39 Pa (ambient) and 70 Pa (elevated) CO₂ partial pressures in temperature-controlled glasshouses. Significant intraspecific variation for both

growth and seed yield in response to elevated CO₂ was observed among the cultivars. At elevated CO₂, total biomass increased an average of 42% at the end of the vegetative stage, while average seed yield increased by only 28%. No changes in % protein or % oil were observed for any cultivar at elevated CO₂, relative to ambient CO₂. The relative enhancement of either vegetative or reproductive growth at elevated CO₂ was not correlated with changes in the absolute or relative increase in single leaf photosynthetic rate among cultivars at elevated CO₂. For soybean, the greatest response of seed yield to elevated CO₂ was associated with increased production of lateral branches, increased pod production or increased seed weight, suggesting different strategies of carbon partitioning in a high CO₂ environment. Data from this experiment indicates that differences in carbon partitioning among soybean cultivars may influence reproductive capacity and fecundity as atmospheric CO₂ increases, with subsequent consequences for future agricultural breeding strategies.

Ziska, L.H., K.P. Hogan, A.P. Smith, and B.G. Drake. 1991. Growth and photosynthetic response of 9 tropical species with long-term exposure to elevated carbon-dioxide. *Oecologia* 86(3):383-389.

Seedlings of nine tropical species varying in growth and carbon metabolism were exposed to twice the current atmospheric level of CO₂ for a 3 month period on Barro Colorado Island, Panama. A doubling of the CO₂ concentration resulted in increases in photosynthesis and greater water use efficiency (WUE) for all species possessing C₃ metabolism, when compared to the ambient condition. No desensitization of photosynthesis to increased CO₂ was observed during the 3 month period. Significant increases in total plant dry weight were also noted for 4 out of the 5 C₃ species tested and in one CAM species, *Aechmea magdalenae* at high CO₂. In contrast, no significant increases in either photosynthesis or total plant dry weight were noted for the C₄ grass, *Paspallum conjugatum*. Increases in the apparent quantum efficiency (AQE) for all C₃ species suggest that elevated CO₂ may increase photosynthetic rate relative to ambient CO₂ over a wide range of light conditions. The response of CO₂ assimilation to internal C(i) suggested a reduction in either the RuBP and/or Pi regeneration limitation with long term exposure to elevated CO₂. This experiment suggests that: (1) a global rise in CO₂ may have significant effects on photosynthesis and productivity in a wide variety of tropical species, and (2) increases in productivity and photosynthesis may be related to physiological adaptation(s) to increased CO₂.

Ziska, L.H., P.A. Manalo, and R.A. Ordonez. 1996. Intraspecific variation in the response of rice (*Oryza sativa* L.) to increased CO₂ and temperature: Growth and yield response of 17 cultivars. *Journal of Experimental Botany* 47(302):1353-1359.

Seventeen rice (*Oryza sativa* L.) cultivars of contrasting ecosystems and origins were exposed to two CO₂ concentrations (373 [ambient] and 664 μ l l⁻¹ CO₂ [elevated]) at two different day/night temperatures (29/21

degrees C and 37/29 degrees C) in glasshouses at the International Rice Research Institute phytotron during the dry seasons of 1994 and 1995. Growth at elevated CO₂ (as determined by total plant biomass at maturity) increased by an average of 70% and 22%, respectively, for all cultivars for growth temperatures of 29/21 degrees C and 37/29 degrees C relative to the ambient CO₂ treatment. At the 29/21 degrees C optimal growth temperature, grain yield increased on average c. 50% with enriched CO₂. In contrast, at the higher growth temperature (37/29 degrees C), grain yield was almost zero, presumably due, in part, to temperature-induced infertility (i.e. the percentage of filled spikelets was < 1%). Among cultivars, IAC 165, a tropical japonica from Brazil, showed the largest relative increase in both biomass and grain yield. While the range of responses to increased CO₂ and/or temperature were quite large (e.g. 10-250%) and may not be applicable to field conditions, data indicate that lines are available which could maximize productivity as CO₂ concentration increases. Additional work, however, would be needed to identify cultivars which would maintain maximum yields in a high CO₂, high temperature environment.

Ziska, L.H., T.B. Moya, R. Wassmann, O.S. Namuco, R.S. Lantin, J.B. Aduna, E. Abao, K.F. Bronson, H.U. Neue, and D. Olszyk. 1998. Long-term growth at elevated carbon dioxide stimulates methane emission in tropical paddy rice. *Global Change Biology* 4(6):657-665.

Recent anthropogenic emissions of key atmospheric trace gases (e.g. CO₂ and CH₄) which absorb infra-red radiation may lead to an increase in mean surface temperatures and potential changes in climate. Although sources of each gas have been evaluated independently, little attention has focused on potential interactions between gases which could influence emission rates. In the current experiment, the effect of enhanced CO₂ (300 μ l l⁻¹ above ambient) and/or air temperature (4 degrees C above ambient) on methane generation and emission were determined for the irrigated tropical paddy rice system over 3 consecutive field seasons (1995 wet and dry seasons 1996 dry season). For all three seasons, elevated CO₂ concentration resulted in a significant increase in dissolved soil methane relative to the ambient control. Consistent with the observed increases in soil methane, measurements of methane flux per unit surface area during the 1995 wet and 1996 dry seasons also showed a significant increase at elevated carbon dioxide concentration relative to the ambient CO₂ condition (+49 and 60% for each season, respectively). Growth of rice at both increasing CO₂ concentration and air temperature did not result in additional stimulation of either dissolved or emitted methane compared to growth at elevated CO₂ alone. The observed increase in methane emissions were associated with a large, consistent, CO₂-induced stimulation of root growth. Results from this experiment suggest that as atmospheric CO₂ concentration increases, methane emissions from tropical paddy rice could increase above current projections.

Ziska, L.H., O. Namuco, T. Moya, and J. Quilang. 1997. Growth and yield response of field-grown tropical rice to increasing carbon dioxide and air temperature. *Agronomy Journal* 89(1):45-53.

Although the response of rice (*Oryza sativa* L.) to increasing atmospheric CO₂ concentration and air temperature has been examined at the greenhouse or growth chamber level, no field studies have been conducted under the tropical, irrigated conditions where the bulk of the world's rice is grown. At the International Rice Research Institute, rice

(cv. IR 72) was grown from germination until maturity for the 1994 wet and 1995 dry seasons at three different CO₂ concentrations (ambient, ambient + 200, and ambient + 300 $\mu\text{mol L}^{-1}$ CO₂) and two different air temperatures (ambient and ambient + 4 degrees C) using open-top field chambers. Averaged for both seasons, increases in CO₂ concentration alone (+ 200, + 300 $\mu\text{mol L}^{-1}$) resulted in a significant increase in total plant biomass (+ 31%, + 40%) and crop yield (+ 15%, + 27%) compared with the ambient control. The increase in crop yield was associated with an increase in the number of panicles per square meter and a greater percentage of filled spikelets. Simultaneous increases in CO₂ and air temperature did not alter the biomass at maturity (relative to elevated CO₂ alone), but plant development was accelerated at the higher growth temperature regardless of CO₂ concentration. Grain yield, however, became insensitive to CO₂ concentration at the higher growth temperature. Increasing both CO₂ and air temperature also reduced grain quality (e.g., protein content). The combination of CO₂ and temperature effects suggests that, in warmer regions (i.e., > 34 degrees C) where rice is grown, quantitative and qualitative changes in rice supply are possible if both CO₂ and air temperature continue to increase.

Ziska, L.H., R.C. Sicher, and J.A. Bunce. 1999. The impact of elevated carbon dioxide on the growth and gas exchange of three C-4 species differing in CO₂ leak rates. *Physiologia Plantarum* 105(1):74-80.

Recent work has suggested that the photosynthetic rate of certain C-4 species can be stimulated by increasing CO₂ concentration, [CO₂], even under optimal water and nutrients. To determine the basis for the observed photosynthetic stimulation, we tested the hypothesis that the CO₂ leak rate from the bundle sheath would be directly related to any observed stimulation in single leaf photosynthesis at double the current [CO₂]. Three C-4 species that differed in the reported degree of bundle sheath leakiness to CO₂, *Flaveria trinervia*, *Panicum miliaceum*, and *Panicum maximum*, were grown for 31-38 days after sowing at a [CO₂] of 350 $\mu\text{mol l}^{-1}$ (ambient) or 700 $\mu\text{mol l}^{-1}$ (elevated). Assimilation as a function of increasing [CO₂] at high photosynthetic photon flux density (PPFD, 1 600 $\mu\text{mol m}^{-2} \text{s}^{-1}$) indicated that leaf photosynthesis was not saturated under current ambient [CO₂] for any of the three C-4 species. Assimilation as a function of increasing PPFD also indicated that the response of leaf photosynthesis to elevated [CO₂] was light dependent for all three C-4 species. The stimulation of leaf photosynthesis at elevated [CO₂] was not associated with previously published values of CO₂ leak rates from the bundle sheath, changes in the ratio of activities of PEP-carboxylase to RuBP carboxylase/oxygenase, or any improvement in day time leaf water potential for the species tested in this experiment. In spite of the stimulation of leaf photosynthesis, a significant increase in growth at elevated [CO₂] was only observed for one species, *F. trinervia*. Results from this study indicate that leaf photosynthetic rates of certain C-4 species can respond directly to increased [CO₂] under optimal growth conditions, but that the stimulation of whole plant growth at elevated carbon dioxide cannot be predicted solely on the response of individual leaves.

Ziska, L.H., R.C. Sicher, and D.F. Kremer. 1995. Reversibility of photosynthetic acclimation of Swiss chard and sugarbeet grown at elevated concentrations of CO₂. *Physiologia Plantarum* 95(3):355-364.

Although leaf photosynthesis and plant growth are initially stimulated by elevated CO₂ concentrations, increasing insensitivity to CO₂ (acclimation) is a frequent occurrence. In order to examine the acclimation process, we studied photosynthesis and whole plant development in swiss chard (*Beta vulgaris* L. Koch ssp. *ciela*) and sugarbeet (*Beta vulgaris* L. ssp. *vulgaris*) grown at either ambient or twice ambient concentrations of CO₂. In an initial controlled environment study, photosynthetic acclimation to elevated CO₂ levels was observed in both subspecies 24 days after sowing (DAS) but was not observed at 42 and 49 DAS for sugarbeet or at 49 DAS for swiss chard. Although sugarbeet and swiss chard differed in root size and morphology, this was not a factor in the onset of photosynthetic acclimation. The reversal of photosynthetic acclimation that was observed in older plants grown at elevated CO₂ concentrations was associated with a rapid increase in root development (i.e. increased root: shoot [R/S] ratio), increased sucrose levels in sinks (roots) and no differences in total soluble leaf protein of either subspecies relative to the ambient CO₂ condition. In a second set of experiments, swiss chard and sugarbeet were grown in outdoor Plexiglass chambers at different times of the year (i.e. summer and early fall). Average 24-h temperature was 30.7 and 19.4 degrees C for the summer and fall plantings, respectively. In agreement with the controlled environment study, lack of photosynthetic acclimation, determined from the response of photosynthetic rate to internal CO₂ concentration, was correlated with increased root biomass and sucrose concentration relative to the ambient condition. However, photosynthetic acclimation was observed depending on the season, i.e. summer (swiss chard) or fall (sugarbeet), suggesting that acclimation was affected by environmental factors, such as temperature. Data from both experiments suggest that continued long-term photosynthetic stimulation may be dependent upon the ability of increased CO₂ to stimulate new sink development which would allow full utilization of the additional carbon made available in a high CO₂ environment.

Ziska, L.H., J.R. Teasdale, and J.A. Bunce. 1999. Future atmospheric carbon dioxide may increase tolerance to glyphosate. *Weed Science* 47(5):608-615.

We tested whether the efficacy of chemical weed control might change as atmospheric CO₂ concentration [CO₂] increases by determining if tolerance to a widely used, phloem mobile, postemergence herbicide, glyphosate, was altered by a doubling of [CO₂]. Tolerance was determined by following the growth of *Amaranthus retroflexus* L. (redroot, pigweed), a C-4 species, and *Chenopodium album* L. (common lambsquarters), a C-3 species, grown at near ambient (360 $\mu\text{mol mol}^{-1}$) and twice ambient (720 $\mu\text{mol mol}^{-1}$) [CO₂] for 14 d following glyphosate application at rates of 0.00 (control), 0.112 kg ai ha⁻¹ (0.1 x the commercial rate), and 1.12 kg ai ha⁻¹ (1.0 x the commercial rate) in four separate trials. Irrespective of [CO₂], growth of the C-4 species, *A. retroflexus*, was significantly reduced and was eliminated altogether at glyphosate application rates of 0.112 and 1.12 kg ai ha⁻¹, respectively. However, in contrast to the ambient [CO₂] treatment, an application rate of 0.112 kg ai ha⁻¹ had no effect on growth, and a 1.12 kg ai ha⁻¹ rate reduced but did not eliminate growth in elevated [CO₂]-grown *C. album*. Although glyphosate tolerance does increase with plant size at the time of application, differences in glyphosate tolerance between CO₂ treatments in *C. album* cannot be explained by size alone. These data indicate that rising atmospheric [CO₂] could increase glyphosate tolerance in a C-3 weedy species. Changes in herbicide tolerance at elevated [CO₂] could limit chemical weed control efficacy and increase weed-crop competition.

Ziska, L.H., and A.H. Teramura. 1992. CO₂ enhancement of growth and photosynthesis in rice (*Oryza sativa*) - modification by increased ultraviolet-B radiation. *Plant Physiology* 99(2):473-481.

Two cultivars of rice (*Oryza sativa* L.) IR-36 and Fujiyama-5 were grown at ambient (360 microbars) and elevated CO₂ (660 microbars) from germination through reproduction in unshaded greenhouses at the Duke University Phytotron. Growth at elevated CO₂ resulted in significant decreases in nighttime respiration and increases in photosynthesis, total biomass, and yield for both cultivars. However, in plants exposed to simultaneous increases in CO₂ and ultraviolet-B (UV-B) radiation, CO₂ enhancement effects on respiration, photosynthesis, and biomass were eliminated in IR-36 and significantly reduced in Fujiyama-5. UV-B radiation simulated a 25% depletion in stratospheric ozone at Durham, North Carolina. Analysis of the response of CO₂ uptake to internal CO₂ concentration at light saturation suggested that, for IR-36, the predominant limitation to photosynthesis with increased UV-B radiation was the capacity for regeneration of ribulose biphosphate (RuBP), whereas for Fujiyama-5 the primary photosynthetic decrease appeared to be related to a decline in apparent carboxylation efficiency. Changes in the RuBP regeneration limitation in IR-36 were consistent with damage to the photochemical efficiency of photosystem II as estimated from the ratio of variable to maximum chlorophyll fluorescence. Little change in RuBP regeneration and photochemistry was evident in cultivar Fujiyama-5, however. The degree of sensitivity of photochemical reactions with increased UV-B radiation appeared to be related to leaf production of UV-B-absorbing compounds. Fujiyama-5 had a higher concentration of these compounds than IR-36 in all environments, and the production of these compounds in Fujiyama-5 was stimulated by UV-B fluence. Results from this study suggest that in rice alterations in growth or photosynthesis as a result of enhanced CO₂ may be eliminated or reduced if UV-B radiation continues to increase.

Ziska, L.H., and A.H. Teramura. 1992. Intraspecific variation in the response of rice (*Oryza sativa*) to increased CO₂ - photosynthetic, biomass and reproductive characteristics. *Physiologia Plantarum* 84(2):269-276.

Two rice (*Oryza sativa* L.) cultivars of contrasting morphologies, IR-36 and Fujiyama-5, were exposed to ambient (360-μmol L⁻¹) and ambient plus 300-μmol L⁻¹ CO₂ from time of emergence until ca 50% grain fill at the Duke University Phytotron, Durham, North Carolina. Exposure to increased CO₂ resulted in about a 50% increase in the photosynthetic rate for both cultivars and photosynthetic enhancement was still evident after 3 months of exposure to a high CO₂ environment. The photosynthetic response at 5% CO₂ and the response of CO₂ assimilation (A) to internal CO₂ (C_i) suggest a reallocation of biochemical resources from RuBP carboxylation to RuBP regeneration. Increases in total plant biomass at elevated CO₂ were approximately the same in both cultivars, although differences in allocation patterns were noted in root/shoot ratio. Differences in reproductive characteristics were also observed between cultivars at an elevated CO₂ environment with a significant increase in harvest index for IR-36 but not for Fujiyama-5. Changes in carbon allocation in reproduction between these two cultivars suggest that lines of rice could be identified that would maximize reproductive output in a future high CO₂ environment.

Ziska, L.H., W. Weerakoon, O.S. Namuco, and R. Pamplona. 1996. Influence of nitrogen on the elevated CO₂ response in field-grown rice. *Australian Journal of Plant Physiology* 23(1):45-52.

Rice (*Oryza sativa* L. cv. IR72) was grown in the tropics at ambient (345 μmol L⁻¹) or twice ambient (elevated, 700 μmol L⁻¹) CO₂ concentration at three levels of supplemental nitrogen (N) (no additional N (N-0), 90 kg ha⁻¹ (N-1) and 200 kg ha⁻¹ (N-2)) in open-top chambers under irrigated field conditions from seeding until flowering. The primary objective of the study was to determine if N supply alters the sensitivity of growth and photosynthesis of field-grown rice to enriched CO₂. A second objective was to determine the influence of elevated CO₂ on N uptake and tissue concentrations. Although photosynthesis was initially stimulated at the leaf and canopy level with elevated CO₂ regardless of supplemental N supply, with time the photosynthetic response became highly dependent on the level of supplemental N, increasing proportionally as N availability increased. Similarly, a synergistic effect was noted between CO₂ and N with respect to above-ground biomass with no effect of elevated CO₂ observed for the N-0 treatment. Most of the increase in above-ground biomass with increasing CO₂ and N was associated with increased tiller and, to a lesser extent, root production. The concentration of above-ground N decreased at elevated CO₂ regardless of N treatment; however, total above-ground N did not change for the N-1 and N-2 treatments because of the greater amount of biomass associated with elevated CO₂. For rice, the photosynthetic and growth response to elevated CO₂ may be highly dependent on the supply of N. If additional CO₂ is given and N is not available, lack of sinks for excess carbon (e.g. tillers) may limit the photosynthetic and growth response.

Zobayed, S.M.A., F. Afreen-Zobayed, C. Kubota, and T. Kozai. 1999. Stomatal characteristics and leaf anatomy of potato plantlets cultured in vitro under photoautotrophic and photomixotrophic conditions. *In Vitro Cellular & Developmental Biology-Plant* 35(3):183-188.

Potato plantlets (*Solanum tuberosum* L. cv. Benimaru) were cultured under photoautotrophic (without an) sucrose in the nutrient medium and with enriched CO₂ and high photosynthetic photon flux and photomixotrophic conditions (20 g L⁻¹ sucrose in the medium). Leaf anatomy and stomatal characteristics of the leaves were studied in relation to stomatal size and density. Leaf diffusive resistance, transpiration rate and water content of the leaves were also investigated. In the photoautotrophic treatment, stomata behaved normally (closing in the dark and opening in the light). The stomatal density increased twofold compared to that of the photomixotrophic treatment. Relatively thick leaves and an organized palisade layer were observed and the epicuticular wax content was remarkably higher in this treatment, i.e., seven times greater than that of photomixotrophic treatment. In general,

higher diffusive resistance of the leaves was observed than under photomixotrophic conditions; also the resistance increased in darkness and decreased in the light. All these characteristics led the plantlets to have a normal and controlled transpiration rate which was exceptionally high in the photomixotrophic treatment throughout the light and the dark period.
