Comparison of Predicted and Derived Measures of Volatile Organic Compounds inside Four Relocatable Classrooms Due to Identified Interior Finish Sources

Alfred T. Hodgson, Derek G. Shendell, William J. Fisk, and Michael G. Apte

June 2003

Abstract - Indoor exposures to toxic and odorous volatile organic compounds (VOCs) are of general concern. Recently, VOCs in portable or relocatable classrooms (RCs) have received particular attention. However, very little was known about indoor environmental quality (IEQ) and the sources, composition, and indoor concentrations of VOCs in RCs.

This project task focused on developing and demonstrating a process for selecting interior finish materials for RCs that have relatively low impacts with respect to their emissions of toxic and odorous VOCs. This task was part of a larger project to demonstrate the potential for simultaneous improvements in IEQ and energy efficiency in four new RCs equipped both with a continuously ventilating advanced heating, ventilating, and air conditioning system (HVAC) and a standard HVAC system. These HVACs were operated on alternate weeks. One RC per pair was constructed with standard interior finish materials, and the other included alternate interior materials identified in our prior laboratory study to have low VOC emissions. The RCs were sited in side-by-side pairs at two elementary schools in distinct northern California climate zones. Classroom VOC emission rates (mg hr^{-1}) and concentrations were predicted based on VOC emission factors ($\mu\text{g m}^{-2} \text{hr}^{-1}$) measured for individual materials in the laboratory, the quantities of installed materials and design ventilation rates. Predicted emission rates were compared to values derived from classroom measurements of VOC concentrations and ventilation rates made at pre-occupancy, eight weeks, and 27 weeks. Predicted concentrations were compared to measured integrated VOC indoor minus outdoor concentrations during school hours in the fall cooling season with the advanced HVAC operated. These measured concentrations also were compared between standard and material-modified RCs.

Our combined laboratory and field process proved effective by correctly predicting that IEQ impacts of material VOC emissions would be minor when RCs were ventilated at or above code-

minimum requirements. Assuming code-minimum ventilation rates are maintained, the benefits attributable to the use of alternate interior finish materials in RC's constructed by the manufacturer associated with this study are small, implying that it is not imperative to use such alternative finishing materials. However, it is essential to avoid materials that can degrade IEQ, and the results of this study demonstrate that laboratory-based material testing combined with modeling and field validation can help to achieve that aim.

Introduction and Background

Indoor exposures to toxic volatile organic compounds (VOCs) are of general concern. In California and elsewhere in the U.S., schools have become a focus of complaints regarding children's potential exposures to biological and toxic, airborne, chemical contaminants including formaldehyde. Odorous VOCs also are of potential concern because they can adversely affect people's acceptance of indoor environments and possibly their performance. A few studies have been conducted to identify and quantify the sources of toxic and odorous VOCs in new manufactured houses (Hodgson *et al.*, 2000 and 2002). Much less is known about the sources, composition, and concentrations of VOCs of concern in schools, particularly new relocatable classrooms (RCs, also termed modular or portable classrooms).

California is rapidly constructing new schools and additional classrooms. The State's public schools for grades K-12 currently enroll approximately six million students, with more than 200,000 staff. The projected rapid population growth of school aged children and class size reduction policies require increased classroom space. Relocatable classrooms provide school districts with a quick, convenient and relatively low cost way to add or replace classrooms. Since 1986, California legislation has mandated 20 percent or more of new classrooms be RCs.

Ensuring new RCs are both energy efficient and provide healthy environments for students and staff is an important goal for the State. The task reported on here was part of a larger project designed to address these twin issues. Specifically, the overall project goals were to engineer and evaluate an improved RC design incorporating an energy efficient heating, ventilation, and air conditioning (HVAC) system, with the potential to consume less energy and provide

improved indoor air and environmental quality (IEQ) as compared to the currently available RC models.

This project task focused on developing and demonstrating a process for selecting interior finish materials for RCs that have relatively low impacts with respect to their emissions of toxic and odorous VOCs, including formaldehyde and acetaldehyde. The task involved the participation of a large northern California manufacturer of conventional RCs and two northern California school districts. It was conducted as a two-stage study with both laboratory- and field-based components. The laboratory study was documented in a previous report (Hodgson *et al.*, 2001) and is further discussed herein. Its objectives were to characterize the emissions of VOCs from standard materials used to finish the interiors of RCs produced by this manufacturer and to identify alternate, non cost-prohibitive, easy to clean and maintain materials to reduce VOC concentrations in new classrooms. The results of the laboratory study were used to develop specifications for four new RCs. Two were designed with standard interior finishes, and two were designed with alternate materials. In the selection of alternate materials, emphasis was placed on reducing the potential concentrations of VOCs that appear on California agency lists of toxic compounds.

The four classrooms were constructed in summer 2001. They were installed in pairs at elementary schools in the two participating school districts for use starting with the fall semester. The classrooms were to be occupied by third and fourth grade children who spend most of their time in their homeroom. The classrooms were each uniquely equipped with two independent HVAC systems, a conventional compressor-based unit and an advanced system that was the subject of the energy efficient ventilation project task. The classrooms were instrumented to measure a number of IEQ and energy use parameters. The impacts of the two HVAC systems on energy consumption and IEQ were investigated over the fall and spring semesters using a case crossover design; each RC served as its own control, as the different HVAC systems were operated on alternate weeks. The study included the weekly measurement of school day integrated indoor and outdoor VOC concentrations.

The objectives of this project task were to determine: 1) if indoor VOC concentrations in the new classrooms were predicted with reasonable accuracy from the results of the laboratory study of material VOC emissions; and 2) if concentrations of VOCs of concern were reduced through

the process we devised for interior material selection. These objectives were addressed in two ways. Experiments were conducted in the classrooms prior to first occupancy and during the fall and spring semesters to derive whole-building VOC emission rates. These values were compared between standard and source-modified classrooms and to classroom emission rates predicted from the laboratory study results. In addition, VOC concentrations measured during occupied hours in the fall semester with the advanced HVAC system operational were similarly compared between classrooms and to predicted concentrations.

Methods

Laboratory Study Methods

The methods employed in the laboratory-based study are summarized here and are described in detail elsewhere (Hodgson *et al.*, 2001).

The RC manufacturer provided samples of most standard classroom interior finish materials. These were either taken from stock or collected from the production facility. Samples of several standard materials were purchased. Material manufacturers provided samples of the alternate materials, which were specified to be newly manufactured. There were 17 material samples in total encompassing floor coverings, tackable wall panels and acoustical ceiling panels. Small-scale test specimens, with typical, exposed, surface area dimensions of 15 cm by 15 cm were prepared for each material sample.

The emissions of VOCs from the test specimens were individually determined following the guidance of ASTM D 5116-97 (ASTM, 1997). Specimens were initially conditioned at typical indoor conditions for ten days prior to emission testing. At the end of the conditioning period, a test specimen was transferred to a 10.5-L stainless steel chamber. The chamber was maintained at $23 \pm 1^\circ \text{C}$ temperature with a $0.059 \pm 0.003 \text{ m}^3 \text{ h}^{-1}$ inlet flow rate of high purity nitrogen preconditioned to 50 ± 5 percent relative humidity. Samples for the analysis of VOCs and aldehydes were collected from the chamber exhaust at 96-h elapsed time. Analytical methods for VOCs and aldehydes were identical to those given below for the classroom study.

The chamber samples were qualitatively analyzed to identify all VOCs emitted by each material. Then, the samples were quantitatively analyzed for odorous chemicals and chemicals of concern listed by any of three California programs regulating and/or assessing health risks of

toxic chemicals (i.e., Chemicals with Established Noncancer Chronic Toxicity Reference Exposure Levels, Substances identified as Toxic Air Contaminants, and Safe Drinking Water and Toxic Enforcement Act of 1986; Table 4, Hodgson *et al.*, 2001).

Material VOC emission rates, emission factors, and predicted classroom concentrations were calculated from the chamber results.

Classroom Study Methods

The methods employed in the classroom-based study are summarized here and are described in detail elsewhere (Shendell *et al.*, 2002a-b).

The field study was conducted at two elementary schools in two separate northern California school districts, designated School Districts (SDs) A and B. Working with the RC manufacturer and the school districts, we developed specifications for four new RCs, which were produced in late summer 2001 and installed at the schools for occupancy by the fall 2001 semester. The two source-modified classrooms were finished with alternate tackable wall panels, ceiling panels, and carpet (one school) as described in Laboratory Study Results. Each classroom was equipped with two separate ventilation systems; a standard 10 SEER Heat Pump Air Conditioner (HPAC) system and an advanced indirect/direct evaporative cooling with hydronic heating (IDEC) system. A standard and a modified classroom were sited adjacent to each other at each of the two schools. These have been designated SDA-A, modified classroom at SD A (formerly designated RC 2 in Hodgson *et al.*, 2001, 2002); SDA-B, standard classroom at SD A (formerly RC 1c); SDB-A, modified classroom at SD B (formerly RC 4); and SDB-B, standard classroom at SD B (formerly RC 3c).

Throughout the course of the field study, each classroom was alternated on a weekly basis between the HPAC and IDEC systems. The changeovers were coordinated, *i.e.*, the two classrooms at each school were always operating on the same system. The classroom teachers had control of the fan and temperature settings for both systems. The study was conducted from August 2001 through March 2002 during eight and nine weeks in the fall cooling and winter heating seasons, respectively.

School-day integrated air samples (~7 hours) were collected for aldehydes and VOCs inside each classroom and outdoors at each school during mid-week. VOC and aldehyde active

sampling systems, located within outdoor enclosures, consisted of timer-controlled peristaltic pumps collecting single or duplicate VOC samples on multisorbent tubes and aldehyde samples on treated silica-gel cartridges. The sampling media were located inside each classroom ~2.25 m above the floor and 0.7 m away from the back wall, and outside facing away from the standard HVAC system air inlet ~1 m from the back wall of a classroom. Flow rates of the sampling systems, ~150 cm³ min⁻¹ for aldehyde sampling and ~5-6 cm³ min⁻¹ for VOC sampling, were measured in the morning within 30 minutes after the start and in the afternoon. Duplicate indoor aldehyde and VOC samples, at least 10% overall for each sample type, were collected. Field blanks, 10% overall for each sample type, also were collected.

Samples were analyzed within two weeks of collection. The chemical analysis method for VOC samples was gas chromatography/mass spectrometry with thermal desorption sample injection. For aldehyde samples, the method was extraction of the analyte derivatives from the cartridges with acetonitrile followed by analysis with high performance liquid chromatography and UV detection. The standard deviations (i.e., precision) for the analyses were calculated by analysis of variance from the sample-pair data. The lower limit of quantitation (LOQ) for each compound was calculated as the 95% confidence interval of the precision. For compounds with measured outdoor concentrations, the LOQs for indoor minus outdoor concentrations were determined by propagation of uncertainties. Values below the LOQ were assigned one-half the LOQ in the data files for statistical analyses. The criteria for selecting target VOCs were the same as those used in the laboratory study.

For complete details of the sampling, sample handling, calibration, analytical, and data handling procedures, refer to Hodgson *et al.* (2001) and Shendell *et al.* (2002a).

Separate studies of VOC emission rates were conducted prior to occupancy and eight and 27 weeks after first occupancy. These studies were performed with the classrooms unoccupied. For the pre-occupancy sampling event, the classrooms were operated with the HPAC systems, which were positioned so the fans were on continuously. The systems had not been adjusted to their final settings at this time. For the subsequent two sampling events, the classrooms were operated with the advanced IDEC systems, which were on continuously. The IDEC systems were run over night. Ventilation rates were measured in the early evening and VOC samples were collected on the following morning prior to class.

Ventilation rates were determined by tracer gas decay. Pure carbon dioxide (CO₂) from a cylinder was injected in front of an air inlet to mix the gas in a classroom in the early evening. The initial target CO₂ concentration was ~3,000 ppm. Concentrations in indoor and outdoor air were measured on a six-minute cycle with the calibrated CO₂ monitors installed in the classroom. The ventilation rate in air changes per hour (h⁻¹) was calculated as the slope of the least squares linear regression of the natural log of indoor minus outdoor CO₂ concentrations versus time. Data within the linear range were retained in the analysis.

Samples for VOCs and aldehydes were simultaneously collected inside and outdoors over an approximate one-hour period using pump systems set to operate at ~50 cm³ min⁻¹ and ~1 L min⁻¹ for VOCs and aldehydes, respectively.

Data Analysis

Emission rates (ERs) of the target compounds in mass per time (mg h⁻¹) were calculated for the chamber study and derived for the classrooms assuming the chamber and the classrooms were ideal continuously-stirred tank reactors (CSTRs) operating at near steady-state conditions (ASTM, 1997). Losses of compounds due to factors other than ventilation (*e.g.*, as the result of sink effects) were ignored; consequently, the calculated values were net rates. The steady-state form of the mass-balance model for CSTRs was used:

$$ER = Q (C - C_0) \quad (1)$$

where Q is the chamber inlet gas flow rate (m³ h⁻¹) or the flow rate of outside air (m³ h⁻¹) into the classrooms; C is the air concentration of the compound in the chamber or classroom (μg m⁻³); and C₀ is the chamber background concentration or the outdoor air concentration (μg m⁻³).

Area-specific emission rates or emission factors (EFs) in mass per area-time (μg m⁻² h⁻¹) were calculated as:

$$EF = \frac{Q (C - C_0)}{A} \quad (2)$$

where A is the material surface area (m²) for the chamber study and the floor area for the classroom study.

Laboratory Study Results and Selection of Materials

The alternate floor coverings, tackable wall panels and acoustic ceiling panels for the source-modified classrooms primarily were selected to have lower emissions of both toxic compounds of concern and odorous compounds than the standard materials typically used by the RC manufacturer. Attainment of reductions in the expected classroom concentrations of formaldehyde was a high priority in this process as formaldehyde is a potent sensory irritant and is considered a probable human carcinogen. Other selection criteria for the alternate materials included performance parameters (*e.g.*, durability, maintenance requirements, and sound properties), appearance, cost, and acceptance by the school districts and the RC manufacturer. The project task covered the incremental material and labor costs associated with upgrading to the alternate materials. Additionally, the student desks in all classrooms were specified to have fully encapsulated tops to eliminate these furnishings as a strong VOC source.

SD A routinely installs an upgraded carpet in their schools and specified this carpet for use in both study classrooms. It is a Nylon-6,6 fiber broadloom carpet bonded to the plywood subfloor with a solvent-free full-spread adhesive. Approximately 12 gallons (45 L) of adhesive were used per classroom. A Nylon-6,6 fiber carpet with an olefin, chlorine free hardback was selected for use in the SD B modified classroom (SDB-A). This was intended to be installed using a dry adhesive mesh system. The mesh, however, did not bond properly to the plywood, and the carpet was installed with a solvent-free full-spread adhesive. In standard classroom SDB-B, an intermediate grade, Nylon-6 fiber broadloom carpet was installed, also with a solvent-free full-spread adhesive.

The same commercial grade, sheet vinyl floor covering used in all classrooms. However, the area of sheet vinyl floor covering was larger in the SD A classrooms than in the SD B classrooms.

The RC manufacturer follows standard industry practice and finishes the four walls of their classrooms with vinyl-covered fiberboard tackable wall panels. The alternate material selected for the modified classrooms was the same fiberboard panel covered with Teflon-coated vinyl. This coated vinyl material is primarily intended for use on surfaces in need of frequent cleaning, and may serve as a diffusion barrier to VOC emissions.

The manufacturer finishes the grid ceilings of their classrooms using a fiberglass panel with a vinyl coating on its exposed surface. A mineral fiber ceiling panel with no detectable emissions of formaldehyde was selected as the alternate material for the two modified classrooms.

The only other interior finish material with a significant surface area was the built-in cabinetry. This cabinetry and the associated countertops were high quality units constructed with surfaces of the composite wood components encapsulated with laminate. This surface treatment substantially reduces the emissions of formaldehyde (Kelly *et al.*, 1999). As our specifications for cabinetry were met and no lower emitting materials at reasonable cost were available, the cabinetry components were not tested for emissions of VOCs.

The standard and alternate materials selected and used to finish the interiors of the four classrooms are listed in Table 1 along with their exposed surface areas.

Emission factors (EFs) for chemicals of concern and odorous compounds emitted by the eight standard and alternate materials are given in Table 2. The compounds in this and subsequent tables are listed by chemical class (*i.e.*, alcohols and glycol ethers, ketones, aldehydes, esters, terpene hydrocarbons and terpenols, aromatic hydrocarbons, chlorinated hydrocarbons, and nitrogen-containing compounds) and then in order of decreasing vapor pressure or volatility within each class. Lower LOQs for the EFs were approximately 3 $\mu\text{g m}^{-2} \text{h}^{-1}$ for formaldehyde and acetaldehyde and 1.5 $\mu\text{g m}^{-2} \text{h}^{-1}$ for the other compounds. Values below these limits were not reported. In total, there were five odorous compounds (α -terpineol, hexanal, nonanal, decanal, and 4-phenylcyclohexene) and 11 toxic compounds of concern emitted by the eight materials. The specification of the carpet used in classroom SDB-B was changed subsequent to completion of the chamber study. Thus, the EFs for the Nylon-6 fiber carpet that was originally tested as an alternate were used as proxies for the installed material's EFs. However, the formaldehyde EF was excluded since this compound likely derived from the plywood used as the substrate for the test assembly.

For each material in the chamber study, the calculated VOC EFs were multiplied by the projected surface area of the material exposed in a classroom to predict the ERs attributable to the material. Then for each compound, the ERs from the various materials in a classroom were summed (Table 3). The predicted formaldehyde ERs were almost entirely attributable to the standard ceiling panel. 1,2,4-Trimethylbenzene, 1-methyl-2-pyrrolidinone, and di(ethylene

glycol)butyl ether were almost entirely attributable to the standard wall panel. The alternate wall panel was predicted to virtually eliminate these compounds and measurably reduce the emissions of vinyl acetate. A tradeoff associated with using the alternate wall panel was the emergence of predicted toluene emissions in the modified classrooms. Carpets were the source of the caprolactam emissions in the SD B classrooms, with the Nylon-6 carpet being the predominant source.

Classroom Study Results

Ventilation Rates

The code minimum ventilation rate for school classrooms is 15 cfm (7 L s^{-1} or $26 \text{ m}^3 \text{ h}^{-1}$) per occupant (ASHRAE, 1989). The numbers of occupants were the obtained classroom enrollments, approximately 30 in SD A and 20 in SD B, plus one teacher. Thus, the design ventilation rates were 465 cfm or $790 \text{ m}^3 \text{ h}^{-1}$ for SD A and 315 cfm or $535 \text{ m}^3 \text{ h}^{-1}$ for SD B.

The ventilation rates measured by CO_2 tracer gas decay in each of the classrooms for the pre-occupancy, fall and spring sampling events are presented in Table 4. Calculated airflow rates are also shown. As previously noted, the standard HPAC systems used for the pre-occupancy measurements were not adjusted until later, and the fall and spring measurements were made with the IDEC systems. The calculated airflow rates were lower during the 27 week sampling event when the IDEC systems were predominantly in the heating mode. The airflow rates were higher than, or approximately equivalent to, the code-minimum ventilation requirements except at 27 weeks in classrooms SDA-A (39% low) and SDB-B (12% low).

VOC Emission Rates

The emission rates (ERs) of 28 VOCs, including formaldehyde and acetaldehyde, derived for the four classrooms immediately prior to first occupancy are presented in Table 5. Lower LOQs for indoor minus outdoor (*i.e.*, adjusted indoor) concentrations were used to estimate lower LOQs for the ERs. The derived ERs of these compounds in the four classrooms eight and 27 weeks after first occupancy are shown in Tables 6 and 7, respectively. Decreases in ERs of selected VOCs with time after installation are illustrated in Figures 1 and 2 for classrooms SDA-B and SDB-B, respectively. For most of these compounds, there was a substantial drop in ERs between the time of installation and eight weeks after first occupancy, when many of the values were

below LOQs. ERs of VOCs generally decreased between eight and 27 weeks; however, some of these changes were difficult to evaluate because the values were below their LOQs. In the final period, the formaldehyde and acetaldehyde ERs for classroom SDB-B were low but still quantifiable due to the corresponding low ventilation rate.

The derived ERs of formaldehyde in classroom SDB-A are notable. Initially, this classroom had the lowest formaldehyde ER of 2.4 mg h^{-1} . At eight weeks, the formaldehyde ER increased more than ten-fold to 27 mg h^{-1} . In the subsequent final sampling event, the formaldehyde ER was below the initial value and consistent with the values derived for the other classrooms. We were unsuccessful in our attempt to identify the transient source of the elevated fall ER. An inspection of the classroom shortly after the fall event revealed the presence of teaching aids. The date of introduction was determined to be prior to the eight-week sampling event. The teaching aids were personal pegboards constructed of hardboard with one exposed surface and personal dry-erase marking boards constructed of particleboard with one exposed surface. Both hardboard and particleboard have been identified as sources of formaldehyde (Kelly *et al.*, 1999; Hodgson *et al.*, 2002). Emissions of formaldehyde from specimens of these products collected from the classroom were measured in small-scale chambers at 96 h without conditioning. The measured EFs for pegboards and marking boards were 86 and $570 \text{ } \mu\text{g m}^{-2} \text{ h}^{-1}$, respectively. Based on the sizes and numbers of teaching aids in the classroom, we predicted they could contribute 0.66 mg h^{-1} to the total derived formaldehyde ER, or only about 2.5 percent of the total. Thus, these materials were unlikely to be the source of the elevated formaldehyde ER. Another potential, but unmeasured, source of formaldehyde observed in the classroom at the time of ER sampling in the fall was a collection of painted paper mache art projects.

Classroom VOC Concentrations

Concentrations of VOCs measured in the classrooms when they were operating with the IDEC systems during the fall semester provide the best available measures of concentrations when the classrooms were new and operating with near code-minimum ventilation rates. We must note, however, the IDEC systems were not continuously operated by the teachers during some of the individual classroom/week sampling events, especially in the fall 2001 cooling season. Thus, the average ventilation rates during some of the measurement periods may have been below the minimum code requirements used to predict concentrations. The average adjusted indoor

concentrations and concentration ranges of 15 VOCs, which were quantified in the chamber study, are presented by classroom in Table 8. One of the compounds from the chamber study, di(ethylene glycol)butyl ether, was not detected in any of the classroom samples. Among the four classrooms, week-to-week variability as shown by the concentration ranges was generally lowest for classroom SDA-A. This was presumably the result of relatively consistent operation of the IDEC system in this classroom. Only formaldehyde had average adjusted indoor concentrations in excess of 5 parts-per-billion (ppb). Among the other compounds, only phenol, acetaldehyde, hexanal, nonanal, and caprolactam had average concentrations in excess of 1 ppb.

Discussion

Comparisons of adjusted indoor VOC concentrations and derived classroom ERs with their corresponding predicted values are indicators of how well VOC sources in classrooms can be estimated based on data generated by the small-scale laboratory studies. Due to the uncertainties involved in this process, the boundary for acceptable agreement has been defined as up to a factor of two divergence between actual and predicted values. The derived classroom ERs, which were determined immediately prior to occupancy and eight weeks after first occupancy for the 15 VOCs quantified in the chamber study, were compared to the predicted ERs of these VOCs. These comparisons are shown for school districts A and B in Tables 9 and 10, respectively. Compounds for which the derived ERs in either the pre-occupancy or the eight-week sampling event agreed within a factor of two of the predicted rates in two or more classrooms were phenol, formaldehyde, acetaldehyde, hexanal, toluene, and caprolactam. The primary sources of these compounds appear in Table 2. The un-coated, vinyl-covered tackable wall panel used in the standard classrooms was predicted to be a relatively large source of vinyl acetate, 1,2,4-trimethylbenzene and 1-methyl-2-pyrrolidinone. The Teflon-coated, vinyl-covered wall panel used in the modified classrooms also was predicted to be a large source of vinyl acetate. From the comparisons of derived and predicted ERs, it is apparent that the wall panels installed in the classrooms were substantially lower sources of these compounds than forecasted by the chamber study. Possible reasons are rapid decay in the emissions of these compounds from the panels and/or real differences between the tested and installed materials.

The average adjusted indoor concentrations of the 15 VOCs measured in the classrooms when they were operating with the IDEC systems during the fall semester are compared in Table

11 to concentrations predicted by dividing the summed VOC ERs by their corresponding design ventilation rates. For more than one-third of the individual comparisons for which there were measurable classroom concentrations, 16 of 42 possible comparisons, the average measured concentrations were within a factor of two of the predicted concentrations.

The adjusted indoor concentrations measured during the fall semester when the classrooms were operating with the IDEC system at near code-minimum ventilation rates comprise the most useful data to evaluate the effectiveness of material selection for reducing potential VOC exposures in classrooms. Thus, adjusted indoor concentrations measured in modified and standard classrooms on weeks two, four, six and eight at each school district were paired by week creating eight pairs of measurements for the combined school districts. The hypothesis which stated there was no significant difference in mean concentrations between modified and standard classrooms when both were operating with the IDEC systems was tested with a paired Student's t test (two-tailed test, seven degrees of freedom, $P = 0.05$). The results for the ten VOCs with sufficient numbers of data points above the LOQs are shown in Table 12. For caprolactam, the test was run with only the four pairs of measurements from SD B since there was no source of caprolactam in either classroom at SD A. Statistically significant differences in mean adjusted indoor VOC concentrations between modified and standard classrooms were observed for phenol, hexanal, nonanal, 1-methyl-2-pyrrolidinone, and caprolactam. In each case, the concentrations were lowest in the modified classrooms. With the exception of caprolactam, the mean concentration differences between modified and standard classrooms were less than 1 ppb.

It is of interest to compare VOC emissions in the classrooms with VOC emissions in other new buildings. A recent study measured VOC concentrations and ventilation rates in new HUD-code manufactured houses and site-built houses and found the same predominant compounds at similar concentrations in both house types (Hodgson *et al.*, 2000). The houses were unoccupied and one to two months old when they were first sampled. The methodologies were similar to those employed in the classroom study. In Table 13, the ranges of derived VOC EFs in the four classrooms eight weeks after first occupancy are compared to the geometric mean EFs and ranges for the four manufactured houses in that study. Also shown in Table 13 are derived VOC EFs calculated from data generated by a detailed study of VOC sources in a single manufactured house (Hodgson *et al.*, 2002). These comparisons were made for 14 compounds quantified in the

classrooms and in one or both of the house studies. The classroom EFs of 2-butanone, hexanal, heptanal, 2-octenal, α -pinene, and d-limonene were below the values derived for the houses, while toluene EFs were higher in the classrooms. Formaldehyde EFs, excluding the uncharacteristically high value in classroom SDB-A, were similar in the two building types.

There are several differences between the interior construction of the classrooms and houses, which suggest that emissions of some VOCs should be lower in the classrooms than in houses. In the manufactured houses, the cabinetry, which had large areas of bare composite wood surfaces, was shown to be a substantial source of formaldehyde, as well as a source of other aldehydes and terpene hydrocarbons such as α -pinene (Hodgson *et al.*, 2002). Substantially less cabinetry was used in the classrooms, and this cabinetry was constructed with all surfaces including the undersides of countertops encapsulated with laminate. Another difference was the carpet system used in the two types of buildings. In the houses, the carpet was installed over a carpet cushion using tack strips. This installation method has little effect on the emissions of higher molecular weight aldehydes and terpene hydrocarbons from the plywood subfloor (Hodgson *et al.*, 2002). In the classrooms, the installation of the carpet directly over the plywood subfloor with full-spread adhesive may have contributed to the low emissions of formaldehyde and other VOCs often associated with plywood.

Conclusions

The study produced encouraging results regarding the emissions of toxic and odorous volatile organic compounds (VOCs) of potential concern from the materials used to construct the interiors of these relocatable classrooms (RCs). The classroom interiors generally were shown to be low sources of specific VOCs including odorous aldehydes. Thus, concentrations as the result of material emissions were anticipated to be relatively low, which was also influenced by the substantially higher ventilation rates required in classrooms than in other settings, e.g., houses, due to higher occupant densities. In fact, when the classrooms were operating during the fall 2001 cooling season with the advanced IDEC systems, only the average adjusted indoor concentrations of formaldehyde exceeded 5 ppb, while the majority of the target compounds had average concentrations less than 1 ppb.

Emission rates (ERs) of most VOCs were shown to decrease substantially with time following installation of the classrooms. As a consequence of these decreases, the derived ERs

of many compounds were below lower limits of quantitation at eight and 27 weeks after first occupancy.

In roughly one third of the compared cases, VOC ERs and concentrations in the classrooms were predicted with reasonable accuracy, *i.e.*, within a factor of two, based on the results of the laboratory study of material emissions. Some of the largest discrepancies occurred because the standard and alternate vinyl-covered wall panels installed in the classrooms were lower sources of VOCs than projected from the laboratory study. An exception was formaldehyde in one classroom, whose ERs and concentrations were elevated over the predicted values. Although the source was not identified, the transient elevation likely was not due to the interior finish materials.

Differences in mean VOC concentrations over the fall 2001 cooling season between modified and standard classrooms were small, *i.e.*, typically less than 1 ppb on average, when the classrooms were operated with the IDEC systems. Nevertheless, for five compounds, these differences were statistically significant. Lower concentrations of phenol in modified classrooms likely were due to the use of Teflon-coated vinyl-covered wall panels and/or the mineral fiber ceiling panels. Lower concentrations of 1-methyl-2-pyrrolidone likely were due to the alternate wall panels. The use of carpets without Nylon-6 fibers resulted in low to non-detectable concentrations of caprolactam.

In general, the emissions of VOCs from the standard materials used by the manufacturer were sufficiently low to achieve acceptable air quality assuming that code-minimum ventilation rates are maintained. Under these conditions, the small magnitude of the beneficial effects attributable to the use of alternate interior finish materials suggests that it is not imperative to use such materials. However, it is probable that there will be periods in many classrooms during which ventilation rates are below code requirements due to teacher preference (e.g., as observed in this study), improper adjustment, or poor maintenance. Thus, it is important that low VOC-impact materials are used to accommodate reduced ventilation rate conditions. The results of this study demonstrated that the process of laboratory-based material testing combined with modeling of expected air pollutant concentrations and field validation was sufficiently accurate to inform the material selection process with the goal of reducing potential occupant exposures to toxic indoor air pollutants.

Abstract published in *Epidemiology*, 13 (4), S143.

Table 1. Projected surface areas of standard and alternate interior finish materials installed in four classrooms

Material Description	Lab. Code	Surface Area (m ²)			
		Sch. Dist. A	Sch. Dist. B	Classrm.	Classrm.
		SDA-A	SDA-B	SDB-A	SDB-B
Floor					
Nylon-6,6 broadloom carpet ^{a,b}	BLC2	72.0	72.0		
Nylon-6 broadloom carpet ^a	BLC3 ^c				81.5
Nylon-6,6 olefin hardback carpet ^{a,b}	HBC			81.5	
Sheet vinyl flooring	SVF	12.8	12.8	3.3	3.3
Walls					
Vinyl-covered fiberboard wall panels	VWP1		92.0		92.0
Teflon-coated vinyl-covered fiberboard wall panels ^b	VWP2	92.0		92.0	
Ceiling					
Fiberglass ceiling panels	FCP		84.8		84.8
Mineral fiber ceiling panels ^b	MCP2	84.8		84.8	

a. Bonded to plywood subfloor with solvent-free, full-spread adhesive.

b. Alternate interior finish material for source-modified classrooms.

c. Installed carpet had similar face fibers as carpet designated BLC3 in laboratory study.

Table 2. Laboratory measured VOC emission factors for standard and alternate interior finish materials installed in four classrooms

Compound	BLC2 ^a	Emission Factor ($\mu\text{g m}^{-2} \text{h}^{-1}$)						
		Floor Coverings		SVF	Wall Panels		Ceiling Panels	
		BLC3 ^b	HBC		VWP1	VWP2	FCP	MCP2
Phenol				240	53	6.1	18.1	
DEGBE ^c	6.0				50			
2-Butanone	3.4							
Formaldehyde			4.0				32	
Acetaldehyde	24	13.0		12.8	46	23		
Hexanal	41	46						
Nonanal		6.6						2.6
Decanal	1.7	2.7			7.5	2.0		
Vinyl acetate					840	290		
α -Terpineol	2.6							
Toluene						20		
1,2,4-TMB ^c				26	100			
Naphthalene	3.4							
4-PCH ^c		2.6						
NMP ^c					158			
Caprolactam		126	8.5					

a. Material identification codes used in laboratory study are defined in Table 1.

b. EFs for Nylon-6 carpet that was originally tested as alternate were used as proxies for installed material's EFs (see text).

c. DEGBE = Di(ethylene glycol)butyl ether; 1,2,4-TMB = 1,2,4-trimethylbenzene; 4-PCH = 4-phenylcyclohexene;
NMP = 1-methyl-2-pyrrolidinone

Table 3. Predicted emission rates of toxic and odorous VOCs in four classrooms

Compound	Predicted Emission Rate (mg h ⁻¹)			
	<u>Sch. Dist. A Classrm.</u>		<u>Sch. Dist. B Classrm.</u>	
	SDA-A	SDA-B	SDB-A	SDB-B

Caprolactam	-4.2 ^a	4	-3.94	0.029

a. Statistically significant difference between modified and standard classrooms.

b. Compound abbreviations defined in Table 2.

Table 13. Range of derived VOC emission factors in four classrooms eight weeks after first occupancy compared to derived emission factors from two studies of new, unoccupied manufactured houses

Compound	Derived Emission Factor ($\mu\text{g m}^{-2} \text{h}^{-1}$)		
	4 Classrooms Range	4 Manuf. Houses ^a GM ^b (Range)	1 Manu. House Value ^c
Phenol	<2.4-3.6	9.6 (2.2-16.6)	--
2-Butanone	<5.4-7.9	22 (8.6-90)	--
Formaldehyde	<23-320	45 (29-68)	62±10
Acetaldehyde	<10.9-16.6	17 (6-46)	26±4.4
Pentanal	<7.0	--	50±8.1
Hexanal	<37	77 (46-137)	181±31
Heptanal	<3.5	7.7 (3.9-12.9)	16.9±2.5
Octanal	<8.8	14.1 (7.4-22)	29±4.4
2-Octenal	<3.4	--	13.1±1.9
Nonanal	<25	14.7 (3.3-23)	28±4.4
α -Pinene	4.1-14.9	105 (41-189)	156±25
d-Limonene	4.5-9.6	18.5 (9.9-36)	28±4.4
Toluene	11.2-34	3.9 (<2.7-9.6)	--
Styrene	1.08-2.2	4.1 (1.8-15.5)	--

a. From Table 5, Hodgson *et al.* (2000).

b. Geometric mean (GM) and range for measurements made in four houses on three occasions over nine months after installation.

c. Calculated from Table 5, Hodgson *et al.* (2002); derived EFs from house measurements $\pm$ one standard deviation.

Figure 1. Derived emission rates of selected VOCs in classroom SDA-B prior to occupancy and at eight and 27 weeks after first occupancy. The "<" symbols indicate values at or below the empirical lower limit of quantitation for the analysis.

Figure 2. Derived emission rates of selected VOCs in classroom SDB-B prior to occupancy and at eight and 27 weeks after first occupancy. The “<” symbols indicate values at or below the empirical lower limit of quantitation for the analysis.
