Abstract

Two large chemical explosions were detonated in the Dead Sea on November 10 and 11, 1999 for the purposes of calibrating seismic travel times to improve regional network location. These explosions were large enough to be observed with good signal-to-noise ratios by seismic stations in northwestern Saudi Arabia (distances < 500 km). In this report, we present a preliminary analysis of the recordings from these shots.
Introduction

The Dead Sea explosions were recorded by stations of the Saudi National Seismic Network (SNSN) in northeastern Saudi Arabia. The SNSN stations consist primarily of broadband (Streckeisen STS-2) and short-period (Ranger 1-Hz) instrumentation and record at a sampling rate of 100/sec. Figure 1 shows the explosion and station locations. The shot location (star) was taken from the Geophysical Institute of Israel (GII http://www.gii.co.il) announcement. The paths range in distance from 180-480 km. At further ranges the signal-to-noise ratio is low. The recorded shot on November 10 had a local magnitude of 3.6 reported by GII. No magnitude information was available for the November 11 shot, but it was recorded with amplitudes roughly a factor of 2 larger than the November 10 shot.

Figures 2 and 3 show the waveforms recorded for the November 10 and 11 shots, respectively. The data were demeaned, tapered and high-pass filtered with a corner frequency of 1 Hz. Inspection of the broadband records revealed no long-period energy (frequencies < 0.2 Hz). Travel times of the main regional phases (Pn, Pg and Sg) were picked from the filtered data. The horizontal components of station DBAS were not working properly at the time of the shots.

Notice the impulsive first arriving P-wave observed at QURS. This is probably the crustal P-wave, Pg. This phase is seen on the more distant records. At station ALWS the first arriving P-wave is probably Pn and is followed by Pg. At further stations the Pn and
Pg arrivals become more separated in time. The crustal S-wave, Sg, is best observed on the horizontal components but is still difficult to pick with high accuracy. The mantle S-wave, Sn, was difficult to observe on all traces and was not picked.

**Travel Times**

Figure 4 shows the travel times versus distance from which apparent velocities may be inferred. The arrivals from both shots are plotted. The travel times were calculated using the announced location and origin time (Table 2). Apparent velocities are shown assuming an intercept time for P- and S-waves of 5 and 10 seconds, respectively. Notice that the Pn, Pg and Sg phases arrive with apparent velocities of 8.0, 6.5 and 3.8 km/s, respectively. These travel times may be used to develop a velocity model for regional network location for the Gulf of Aqaba region.

**SNSN Event Locations**

Figure 1 also shows the automatic locations from the SNSN real-time system. These locations are based on automatically detected P-waves and the iasp91 velocity model. While not in agreement with the ground truth, the automatic locations are reasonably good. The mislocation from the reported ground truth is given in Table 1. The location can be improved by using human analyst travel picks and a better velocity model.
Conclusions

The Saudi National Seismic Network recorded the Dead Sea shots with good signal-to-noise out to ranges of almost 500 km. These recordings provide an excellent data source for the development of a regional velocity model. Future research will focus on velocity model development and magnitude calibration.
