Abstract

Auger recombination in *p*-type GaSb, InAs and their alloys is enhanced due to the proximity of the bandgap energy and the energy separation to the spin split-off valence band. This can affect the device performance even at moderate doping concentration. We report electron lifetime measurements in a *p*-type 0.54-eV GaInAsSb alloy, commonly used in a variety of infrared devices. We have studied a series of double-capped heterostructures with varied thicknesses and doping levels, grown by organometallic vapor phase epitaxy on GaSb substrates. The Auger coefficient value of $2.3 \times 10^{-28} \text{ cm}^6/\text{s}$ is determined by analyzing the photoluminescence decay constants with a systematic separation of different recombination mechanisms.

The GaInAsSb quaternary alloy lattice matched to GaSb is an attractive material for mid-infrared (IR) optoelectronic devices, and is considered to be one of the primary materials for thermophotovoltaic (TPV) energy conversion systems that operate with thermal sources heated to approximately 1000 °C.¹⁻³ To maximize overall TPV system efficiency, the band-gap energy E_g of the absorber (emitter layer) should match the peak emission wavelength of the infrared radiator. Thus, GaInAsSb alloy compositions corresponding to $E_g = 0.5 - 0.6$ eV are of particular interest. TPV devices utilize a *p*-type emitter to take advantage of higher minority electron mobility and therefore longer diffusion length. 0.52 - 0.55-eV GaInAsSb TPV cells fabricated by organometallic vapor phase epitaxy (OMVPE) demonstrate high performance. The internal quantum efficiency of *p*-on-*n* devices with a 4- μ m-thick emitter doped to 2×10^{17} cm⁻³ was reported to approach the theoretical limit of 100 %.³ However, the open circuit voltage V_{oc} was only 330 meV, which is about 60 % of the material E_g . This indicated the need for further improvement.

Optimization of the GaInAsSb emitter doping level is a critical issue for TPV cell design. On the one hand, higher dopant concentration boosts the diode built-in potential, which is beneficial for increasing the open-circuit voltage. On the other hand, conversion efficiency degrades with higher doping due to radiative and Auger recombination losses. The effect of radiative recombination on the device performance is alleviated by reabsorption of the emitted photons, known as the photon recycling effect. Therefore in TPV diodes with higher emitter doping levels, Auger recombination can be regarded as a major mechanism limiting device performance. In this paper, recombination processes in

GaInAsSb were studied for p-doping concentration up to $2 \times 10^{17} \text{ cm}^{-3}$, which is a typical level for TPV devices^{2,3}.

In III-V compound materials, such as GaSb, InAs and a number of their alloys, the magnitude of E_g is similar in value to the spin-orbit splitting energy.⁴⁻⁵ In this case, the Auger process that generates holes in the split-off valence band (CHHS) occurs with small momentum transfer and, therefore, low activation energy. This leads to an enhanced rate of Auger recombination, as was first suggested by Takeshima⁶ and experimentally shown in the pioneering work by Benz and Conradt.⁷

Auger recombination has been extensively studied in bulk and epitaxial GaSb, InAs and some GaSb-based ternary alloys.⁸⁻⁹ In contrast, there have been only a few reported measurements of Auger lifetimes in epitaxial GaInAsSb. Interpolation of the limited data reported in the literature for III-V compounds yields spreading of Auger coefficient for 0.54-eV materials within two orders of magnitude.¹ Auger lifetimes in $\text{Ga}_{0.84}\text{In}_{0.16}\text{As}_{0.14}\text{Sb}_{0.86}$ layers grown by liquid phase epitaxy were determined by Riech et al.¹⁰ The authors applied a photo-acoustic (PA) technique, which allowed monitoring the heat generated in the sample. Lifetime values were indirectly obtained by fitting the experimentally measured PA phase signal, a procedure that required prior knowledge of a number of thermal and recombination parameters of the material.

In this letter, we report the lifetime in *p*-type 0.54-eV GaInAsSb determined by a direct method from the transient photoluminescence (PL). Time-resolved PL is an alternative to radio-frequency photoconductive decay method used in the mid-IR wavelength range for lifetimes greater than 10-20 ns.¹¹⁻¹² The setup we developed allows measurement of the luminescence decay in the mid-IR range by a HgCdTe mesa

photodiode. The overall time resolution of the detection system is better than 5 ns. Details of the setup were described earlier.¹⁶

Three sets of GaSb/p-Ga_{0.85}In_{0.15}As_{0.14}Sb_{0.86}/GaSb double heterostructures (DHs) with active layers Zn-doped to 1×10^{16} , 1×10^{17} , and 2×10^{17} cm⁻³ were grown by OMVPE on (100) n-GaSb substrates misoriented 6° toward (111)B. The GaInAsSb layer thickness (W) was varied from 1.2 to 5 μm. GaSb confinement layers (caps) were 50-nm-thick and nominally undoped but known to be lightly p -type, with $p = 1 \times 10^{16}$ cm⁻³. The 4-K PL spectra exhibited a full width at half maximum of 5 to 12 meV, with the smallest values being measured for the most lightly doped samples. Absorption in the front GaSb cap layer was estimated to be 12 % of the incident excitation power. The 300-K PL spectra demonstrated a single peak at 2.3 μm exhibiting no evidence of luminescence from the cap.

Figure 1 shows the typical PL decay for DHs with different thicknesses. The transient response was measured under low excitation conditions. Under these conditions, the decay time τ_{PL} is a characteristic of the structure, and independent of the concentration of photogenerated electrons. Non-equilibrium electron-hole pairs are generated in the active region near the interface. Quasi-equilibrium electron distribution across the active layer is established by diffusion within the time $\tau \sim W^2/D$, where D is the diffusion coefficient. For the thickest samples with $W = 5$ μm and minority electron mobility of 5×10^3 cm²/s¹³, the diffusion time τ is about 2 ns.

Under conditions of low excitation $\Delta n \ll p$ and low interfacial recombination velocity $S \ll D/W$, the bulk and the interface recombination processes can be separated as follows:

$$1/\tau_{PL} = 1/\tau_{NR} + Bp/\phi(W) + 2S/W \quad (1)$$

The inverse bulk lifetime is described by the first two terms in (1) where τ_{NR} is the non-radiative lifetime and B is the radiative recombination coefficient. The radiative term is thickness-dependent due to the effect of reabsorption, as given by Asbeck's photon recycling factor $\phi(W)$.¹⁴ The factor ϕ monotonically increases with the active layer thickness, and hence in the limit of infinite thickness the PL decay constant approaches the non-radiative bulk lifetime. The photon recycling effect results in a deviation from the linear relation between $1/\tau_{PL}$ and $1/W$. This non-linearity is well pronounced in structures with very small S when radiative recombination dominates over interfacial recombination.¹⁵ Our experiments correspond to the opposite limit of large interfacial recombination, where $1/\tau_{PL}$ increases with $1/W$ linearly with a slope that is governed mostly by S and an offset that determines the inverse non-radiative bulk lifetime.

To estimate the contribution of radiative recombination, ϕ was calculated using the approach developed in Ref. 14 and is shown in Figure 2. The calculation was based on the measured absorption spectrum (inset in Figure 2). Assuming $B = 5 \times 10^{-11} \text{ cm}^3/\text{s}$ ¹² in the most critical case of $p = 2 \times 10^{17} \text{ cm}^{-3}$, the radiative lifetime ranges from approximately 0.3 to 0.7 μs for W varied from 1 to 5 μm . The measured inverse PL decay time $1/\tau_{PL}$ versus inverse active layer thickness ($1/W$) is shown in Figure 3, and demonstrates linear behavior (dashed lines) for all three sets of DHs. The interfacial recombination velocity that is extracted from the slope is slightly overestimated due to the contribution of radiative recombination. This contribution was subtracted from the linear fit and the results shown by solid lines reflect the actual interfacial recombination

velocity. Even in structures with the highest doping ($p = 2 \times 10^{17} \text{ cm}^{-3}$) the relative error in S does not exceed 5 %.

The slope of the $1/\tau_{PL}$ versus I/W plots was found to be quite sensitive to the doping level in the GaSb caps. This effect, considered in our previous work, was explained by accumulation of minority carriers at the GaSb/GaInAsSb heterointerface¹⁶ and experimentally confirmed the dominant role of interfacial recombination.

Values of non-radiative bulk lifetime τ_{NR} were determined from the y-intercepts in Figure 3. Table I summarizes the obtained recombination parameters for DHs with different doping concentrations. The nonradiative bulk lifetimes are made up of contributions from Shockley-Read-Hall (SRH) and Auger recombination processes. Under low excitation, SRH recombination in p -type materials proceeds via capture of minority electrons by deep (midgap) levels. In this commonly used approximation, the SRH lifetime is determined by the defect density and does not depend on the doping level.¹⁷ Consequently, the doping dependence of τ_{NR} is given by

$$1/\tau_{NR} = 1/\tau_{SRH} + C_p p^2 \quad (2)$$

where C_p is the Auger recombination coefficient. Figure 4 plots $1/\tau_{NR}$ versus the square of the acceptor concentration in the active region. Using a linear fit, both the Auger coefficient and the SRH lifetime were deduced, resulting in the values of $C_p = 2.3 \times 10^{-28} \text{ cm}^6/\text{s}$ and $\tau_{SRH} = 1.3 \text{ } \mu\text{s}$, respectively. Since the PL decay constants are determined with accuracy better than $\pm 1 \text{ ns}$, the error in C_p value is mostly controlled by the knowledge of

the doping concentration and reproducibility of growth. The standard error in C_p is estimated to be $\pm 0.8 \times 10^{-28} \text{ cm}^6/\text{s}$.

In summary, minority carrier lifetimes were measured directly by the study of the photoluminescence kinetics in *p*-type 0.54-eV GaInAsSb alloys for doping concentrations of up to $2 \times 10^{17} \text{ cm}^{-3}$, as typically used in TPV devices. Different recombination mechanisms were separated using the dependence of lifetime on the structure thickness and the doping concentration.
