Abstract
Thin, Pd-capped metallic films containing magnesium and first row transition metals (Mn, Fe, Co) switch reversibly from their initial reflecting state to visually transparent states when exposed to gaseous hydrogen or following cathodic polarization in an alkaline electrolyte. Reversion to the reflecting state is achieved by exposure to air or by anodic polarization. The films were prepared by co-sputtering from one magnesium target and one manganese, iron, or cobalt target. Both the dynamic optical switching range and the speed of the transition depend on the magnesium-transition metal ratio. Infrared spectra of films in the transparent, hydrided (deuterided) states support the presence of the intermetallic hydride phases Mg₃MnH₇, Mg₂FeH₆, and Mg₂CoH₅.

Following the discovery of the switchable mirror phenomenon in yttrium and lanthanum hydrides by Huiberts et al., similar behavior was found in rare earth-magnesium alloy films. Recently, metal-transparent hydride switching was also reported in rare earth-magnesium alloy films. In all of these systems, a thin Pd overlayer (generally > 5 nm) is applied to catalyze absorption and desorption of hydrogen and to protect the readily oxidized rare earth and/or Mg from oxidation. Infrared internal reflectance spectroscopy was used to characterize the transparent Ni-Mg hydride films as a mixture of Mg₂NiH₄ and MgH₂. Other ternary hydrides containing magnesium and a first row transition metal include Mg₂CoH₅, Mg₂Co₂H₁₁, Mg₂FeH₆, and Mg₃MnH₇. Mg₂CoH₅ and Mg₂FeH₆ have structures similar to that of the high-temperature, cubic form of Mg₂NiH₄, with a CaF₂-type metal atom arrangement. Cubic Mg₂FeH₆ contains octahedral FeH₆⁴⁻ units, while in tetragonal Mg₂CoH₅, square-pyramidal CoH₅⁴⁻ is present. This structural unit also appears in Mg₆Co₂H₁₁, along with saddle-like CoH₄⁵⁻ complexes. Mg₃MnH₇ contains nearly octahedral MnH₆⁵⁻ units bridged by Mg in trigonal prismatic coordination, along with an isolated hydride ion bonded only to Mg. Band structure calculations for Mg₂CoH₅ (Eg = 1.92 eV) and Mg₂FeH₆ (Eg = 1.8 eV) support experimental evidence for semiconductor behavior in these materials. Mg₃MnH₇ (calculated Eg = 2.56 eV) is orange in color, and is also presumably semiconducting. The enthalpies of formation of Mg₂CoH₅ and Mg₂FeH₆ are 86 and 98 kJ/mol of H₂, respectively. Dissociation pressures at 25°C are estimated to be 5 x 10⁻⁹ atm for Mg₂CoH₅, 4 x 10⁻¹¹ atm for Mg₂FeH₆, and 1 x 10⁻⁶ atm for MgH₂. No thermodynamic data are available for Mg₃MnH₇.

Mixed metal thin films of Co, Fe, and Mn with Mg were deposited by DC magnetron co-sputtering from separate 2 in diameter transition metal and Mg (99.98%) targets onto glass substrates with or without transparent conductive coatings. The base pressure was 1.4 x 10⁻⁷ Torr, process pressure 2 mTorr (Ar), target-to-substrate distance 7.5 cm, power levels for Mn-Mg deposition: Mn 15 W, Mg 40 W; for Fe-Mg: Fe 28 W, Mg 36 W; for Co-Mg: Co 29 W, Mg 35 W. The Pd over-layer was applied at 10 mTorr Ar pressure, Pd power 12 watts. Film thicknesses were measured by stylus

profilometry. Samples for mid-IR internal reflectance-absorbance spectroscopy were deposited on 25 mm diameter ZnSe discs. The spectra were obtained by reflectance from the Pd cap layer at 45° through the ZnSe substrates.

Switching from the as-deposited mirror state to the transparent state was achieved by exposing the films to a dry gas stream containing 4% hydrogen in argon or helium. The mirror state was recovered by exposing the films to ambient air. Electrochemical switching was carried out in aqueous alkaline electrolyte (1-5 M KOH, Pt counter electrode, HgO/Hg reference), with in situ measurement of optical transmission spectra or photopic transmittance. Film compositions were determined by Rutherford backscattering spectrometry (RBS) and particle induced x-ray emission (PIXE).

The freshly deposited films were amorphous by X-ray diffraction (XRD) in every case, showing only weak reflections due to Pd. No changes were observed in the XRD patterns of films maintained in a 4% H2 atmosphere. The films were highly reflecting in the metallic state (Fig. 1) and had very low transmittance (Fig.2). The sharp drop in reflectance around 350 nm is due to absorption by the substrate. In the transparent states, there is some contribution to the reflectance from the Pd layer, which remains metallic but is somewhat more transparent when loaded with hydrogen.11 Co-Mg hydride films were strongly absorbing below 500 nm, due in part to their higher reflectance in this region. The maximum transmittance depended upon the thicknesses of both the mixed metal film and the Pd overlayer, as well as on the atomic ratio of transition metal (T) to Mg. Cosputtering from offset sources produced films with position-dependent T:Mg atomic ratios ranging from about 1:1 to 1:10. Regions with ratios greater than about 1:2 did not switch completely and remained reflecting in appearance. For Fe:Mg between 1:2 and 1:7, switching was rapid; the maximum transparency was found at around 1:5. For Mn:Mg the maximum transparency was observed at ca. 1:6. For all three mixtures, areas with T:Mg ratios lower than about 1:12 did not switch at all.

Gasochromic switching from the metallic to the transparent state generally was complete in less than 10 s. The reverse transition in air required 30 to 120 s. Electrochromic switching was somewhat slower. The electrochemical hydrogen loading behavior of these mixed metal films was similar to that of Ni-Mg films.3 The return to the mirror state, however, was somewhat slower and in some Fe-Mg and Mn-Mg samples appeared to proceed in two steps. This may be due to the greater thermodynamic stability of the more hydrogen-rich ternary compounds relative to MgH2 (74 kJ/mol H2).12 Switching speeds deteriorated gradually with cycling (thirty or more cycles were observed), but were found to be stabilized by the use of dry, CO2-free air for hydrogen removal.

Internal reflectance-absorbance infrared spectra for the three hydride mixtures are shown in Figure 3. In each case, a composition gradient existed from one side of the sample to the other. Spectra taken from regions with different transition metal-to-magnesium ratios were identical except that the intensities of all observed absorption bands varied directly with the absolute quantity of the transition metal present. No contribution to the spectra from free MgH2 was evident. MgH2, having the rutile structure, does not contain isolated structural units, and therefore has only no identifiable absorption bands within the accessible spectral range. The similarity between the spectra of the Fe-Mg and Mn-Mg hydrides is due to the fact that both ternary hydrides contain an octahedral MH6 unit. The higher frequencies of the FeH64- vibrations relative to those for MnH65- are consistent with the higher positive charge on Fe (+2) vs. Mn (+1), and shorter Fe-H bond length (1.49 Å vs. 1.63 Å). In all cases, the frequency ratios between corresponding peaks in the hydride and deuteride spectra range from 1.25 to 1.37. These vibrations involve primarily motion of the hydrogen (deuterium) atoms, hence the reduced
mass for each mode is approximately that of the light atoms. The spectrum of Mg₂CoH₅ is somewhat more complicated due to the lower symmetry of the square pyramidal CoH₅⁴⁻. The vibrational frequencies, like the Co-H bond lengths of 1.51 Å (equatorial) and 1.59 Å (axial) are intermediate between those of Mg₃FeH₆ and Mg₃MnH₇.

The switching mechanism in the three systems studied appears, as in the case of Ni-Mg films, to be reversible formation of a mixture of MgH₂ and the previously known ternary hydrides. The dramatic changes in both transmittance and reflectance in these materials may lead to useful applications in architectural heat and light control as well as in optoelectronics.
