\( \sigma \Delta T \) – adiabatic temperature change error

\( dT \) or \( \Delta T \) – temperature change

\( T_B \) – boiling temperature

\( T_C \) – Curie temperature

\( T_D \) – Debye temperature

\( T_M \) – melting temperature

\( T_{\text{min}} \) – minimal temperature

\( dU \) – internal energy change

\( V \) – volume

\( \alpha \) – calibration coefficient for \( ac \) susceptibility measurements

\( \chi'_{ac} \) – real part of \( ac \) susceptibility

\( \chi''_{ac} \) – imaginary part of \( ac \) susceptibility

\( \chi_d \) – differential magnetic susceptibility

\( \chi_{dc} \) – magnetic susceptibility

\( \gamma \) – electronic specific heat constant

\( \varphi \) – phase angle
\( \mu_n \) – Bohr magneton
\( \nu \) – voltage
\( \theta_n \) – PM Curie temperature
\( \omega \) – Angular frequency
1. INTRODUCTION

A study of a series of Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ alloys using dc and ac magnetic susceptibility, magnetization, heat capacity, and x-ray powder diffraction techniques revealed that the variation of the magnetic properties and crystal structures with composition is similar to that observed in the Gd$_3$(Si$_x$Ge$_{1-x}$)$_4$ system, except that the magnetic ordering temperatures are lower. The magnetic phase transition temperatures vary from ~ 46K (Dy$_3$Ge$_4$) to ~ 137K (Dy$_3$Si$_4$). The intermediate ternary phase Dy$_3$Si$_3$Ge undergoes a first order magnetic phase transition at ~ 65K. The value of magnetic entropy change for this composition is quite large (-34J/kgK for magnetic field change from 0 to 50kOe), compared to the values for the two end members (-7 J/kgK for Dy$_3$Ge$_4$ and 12.5J/kgK for Dy$_3$Si$_4$). The magnetization and ac susceptibility measurements showed that alloys with monoclinic crystal structure have a non-collinear ordering of the magnetic moments at low temperatures. The alloy Dy$_3$Si$_3$Ge appears to exhibit a FM phase transition below the Curie temperature at 65K. Also a series of critical fields are observed at low temperature during magnetization vs magnetic field measurements in all of the Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ alloys regardless type of crystal structure. The Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ alloys, where 0.67≤x≤1, may be useful magnetic refrigerant materials in the ~50 to ~160K temperature range.
2. BACKGROUND AND LITERATURE REVIEW

2.1 Thermodynamic and magnetic properties

2.1.1 Magnetocaloric Effect

The magnetocaloric effect, MCE, is the temperature change $dT$ of a magnetic material under adiabatic change of the magnetic field $dH$. This effect first was observed by Warburg late in the 19th century [1]. When we change the field $dH$, the performed magnetization work $\delta A_m$ is:

$$\delta A_m = \bar{M} dH,$$

where $\bar{M}$ is the magnetization.

The first law of thermodynamics defines the relationship between the work performed on (or by) the system, the amount of heat transfer to (or from) the system, and the change in internal energy of the system:

$$\delta A = \delta Q - dU,$$

where $\delta Q$ is amount of heat transfer to the magnetic material (under adiabatic conditions $\delta Q = 0$), $dU$ is the internal energy change of the magnetic material. Thus, if $\delta Q = 0$, the work performed by the internal energy change only is:

$$\delta A = dU,$$

In case, when the internal energy is dependent on temperature, this effect produces a temperature change in the magnetic material.

From the general principles of thermodynamics the following expression can be written for the infinitesimal gain in MCE [2]:

$$dT = -\frac{T(\partial \bar{M}(H,T)/\partial T)_H}{C(H,T)} dH.$$

Theoretically, maximum MCE value $dT$ for a field change $dH$ is reached when the maximum heat capacity value in this field is shifted with respect to a large value of $\partial \bar{M}/\partial T$. 

for the corresponding field and temperature changes. The thermodynamic approach is the simplest way to understand magnetocaloric effect.

Two other approaches commonly used are Landau's theory of second-order phase transitions and Weiss' mean-field approximation. Both these techniques describe the behavior of a number of magnetic quantities. However, they are inapplicable in the vicinity of the magnetic phase transition due to the critical fluctuation effects.

The experimental value of the MCE most often is determined by direct measurements or by calculation from the measured magnetization or heat capacity, both as a function of temperature and magnetic field. From direct method, we can only obtain the adiabatic temperature change vs magnetic field change. From indirect experiment measurements, we can calculate both adiabatic temperature change and the magnetic entropy change from experimental heat capacity data, and only the magnetic entropy change from experimental magnetization data [3, 4].

Technologically, the interest in MCE results from the possibility of employing materials with large $dT$ values in magnetic refrigeration. For instance, the Ames Laboratory (Iowa State University) and Astronautics Corporation of America have been collaborating for years to develop an advanced industrial prototype of magnetic refrigerator operating at room temperature [5].

In some PM materials the MCE is used to produce super low temperatures using the so-called adiabatic demagnetization method.

The above reasons and some other applications have given a push to the study of new materials with large MCE, such as nanocomposites [6], amorphous alloys [7], intermetallic compounds [8], and perovskite-type oxides [9-10].

### 2.1.2 Heat Capacity

The heat capacity of the system can be expressed as the ratio of the heat added to or taken from the system due to the resultant change in the temperature of the system either at constant volume, $C_v$, or at constant pressure, $C_p$:

$$C_v = \left( \frac{\delta Q}{dT} \right)_v = \left( \frac{dU}{dT} \right)_v$$
The total heat capacity of a magnetic material usually is described by three contributions in the form:

\[ C_{\text{total}} = C_L + C_e + C_M, \]

where \( C_L \) is the lattice heat capacity under constant pressure. For temperatures substantially lower than the Debye temperature \( T_D \), \( C_L \) is quite big [11]:

\[ C_L = \frac{12\pi^4}{5} N k_b \left( \frac{T}{T_D} \right)^3, \]

where \( \pi \approx 3.1416 \), \( N \) is the number of atoms, \( k_b \) is the Boltzmann’s constant, \( T_D \) is the Debye temperature.

\( C_e \) is the electronic heat capacity under constant pressure [2], and is given by:

\[ C_e = \gamma T, \]

where \( \gamma \) is the electronic specific heat constant.

The magnetic heat capacity, \( C_m(\bar{H},T) \), of a ferromagnet in the vicinity of its Curie temperature \( T_C \) is given by [12]:

\[ C_m(\bar{H},T) = -\frac{T}{dT}1.07R \left( \frac{\mu_0 \mu \bar{M}}{k_B T_C} \right)^{\frac{1}{2}} \]

For this study, the heat capacity were collected under constant pressure, \( C_p \equiv \left( \frac{\Delta Q}{\Delta T} \right)_p \), where \( \Delta Q \) is the amount of heat introduced into the calorimeter during a heat pulse, \( \Delta T \) is the resulting temperature rise of a sample, and the index \( P \) shows that the measurements were performed at a constant pressure [13].

\[ \text{2.1.3 Magnetization} \]

The magnetization, \( \bar{M} \), usually is defined as the magnetic moment, \( \bar{m} \), per unit volume, \( V \), induced by any external magnetic field.

\[ \bar{M} = \frac{\bar{m}}{V} \]
The magnetization of the material depends upon external magnetic field $\vec{H}$, the magnetic properties of the material, its shape and orientation in the external magnetic field. The relationship between magnetic field in the material $\vec{H}_m$ and external magnetic field $\vec{H}$ can be expressed as:

$$\vec{H}_m = \vec{H} - NM$$

where $N$ is demagnetization factor. In isotropic materials the direction of $\vec{M}$ is the same as the direction of $\vec{H}$. In the anisotropic materials the $\vec{M}$ and $\vec{H}$ directions are usually different.

### 2.1.4 dc and ac Susceptibility

**dc susceptibility:**

The dc magnetic susceptibility ($\chi_{dc}$) is a value, which characterize the relationship between magnetization of the magnetic material with magnetic field applied upon a material. In static magnetic field, we can describe $\chi$ as following [14]:

$$\chi_{dc} = \frac{\vec{M}}{\vec{H}}$$

Both positive and negative values of the magnetic susceptibility have been observed. Diamagnetic materials have negative values of magnetic susceptibility, where as in paramagnets, PM and FM the magnetic susceptibility is positive. DiaM and PM have small values ($-10^{-4} - 10^{-6}$) of $\chi_{dc}$, where as in a FM it can reach 1 to 1000. Also in a FM the dependence between $\vec{H}$ and $\chi_{dc}$ is stronger and more complicated then in a DiaM or PM. Therefore, in some cases it is better to introduce the differential magnetic susceptibility:

$$\chi_d = \frac{dM}{dH}$$

This susceptibility characterizes the magnetization at each point of the magnetization curve.

For a normal PM (substances, which contain permanent magnetic dipoles) the susceptibility obeys the Curie law:

$$\chi_{dc} = \frac{C}{T}$$
where $C$ is the Curie constant.

Experiments showed that most PM materials do not obey the Curie’s law, instead they have susceptibilities that can be fitted only to the Curie-Weiss law:

$$\chi = \frac{C}{T - \theta_p},$$

where $\theta_p$ is a paramagnetic Curie temperature.

**ac susceptibility**

In an alternating magnetic field,

$$\vec{H}(t) = \vec{H} + \vec{H}_1 \cos \omega t,$$

the magnetization may be represented by:

$$\vec{M}(t) = \vec{M}_0 + \vec{M}_1 \cos \omega t \cos \varphi + \vec{M}_1 \sin \omega t \sin \varphi,$$

where $\vec{H}$ is a static field, $\vec{M}_0$ is the equilibrium value of the magnetization in a static field, $\varphi$ is the phase angle by which the magnetization lags the field. Therefore:

$$\chi'_{ac} = \frac{\vec{M}_1 \cos \varphi}{\vec{H}_1},$$

and

$$\chi''_{ac} = \frac{\vec{M}_1 \sin \varphi}{\vec{H}_1}$$

the imaginary part of the ac susceptibility, so that

$$\frac{\chi''_{ac}}{\chi'_{ac}} = \tan \varphi.$$

Therefore,

$$\vec{M}(t) = \chi_{dc} \vec{H} + \chi'_{ac} \vec{H}_1 \cos \omega t + \chi''_{ac} \vec{H}_1 \sin \omega t$$

Both $\chi'_{ac}$ and $\chi''_{ac}$ depend on the frequency, $\omega$, and magnitude of the static field, $\vec{H}$. $\chi'_{ac}$ is called the high frequency susceptibility and the variation of $\chi'_{ac}$ with $\omega$ is called the PM dispersion. $\chi''_{ac}$ is proportional to the energy absorbed by the substance from the high frequency field.
Kramers and Kronig [15, 16] had shown that \( \chi'_{xc} \) and \( \chi''_{xc} \) are not independent of each other and related by the following equations:

\[
\chi'_{xc} (\omega_0) = \frac{2}{\pi} \int_0^\infty \frac{\omega \chi''_{xc} (\omega) d\omega}{\omega^2 - \omega_0^2} + \chi'_{xc} (\infty)
\]

and

\[
\chi''_{xc} (\omega_0) = -\frac{2}{\pi} \int_0^\infty \frac{\omega_0 \chi'_{xc} (\omega) d\omega}{\omega^2 - \omega_0^2}
\]
2.2 Previous Work on $R_5\text{Si}_4$ and $R_5\text{Ge}_4$

The first studies on the $R_5\text{Si}_4$ or $R_5\text{Ge}_4$ phases were performed by Smith et al. [17]. They investigated thirteen rare earth germanides and eleven rare earth silicides of 5:4 stoichiometry. They found that the Tb$_5$Si$_4$, Er$_5$Si$_4$, Y$_5$Si$_4$, Nd$_5$Ge$_4$, Sm$_5$Ge$_4$, Gd$_5$Ge$_4$, Tb$_5$Ge$_4$, Er$_5$Ge$_4$, and Y$_5$Ge$_4$ phases have the Sm$_5$Ge$_4$ orthorhombic crystal structure and that Nd$_5$Si$_4$ has a tetragonal structure [18]. They determined that most of the lanthanide phases have either the Zr$_5$Si$_4$ or Sm$_5$Ge$_4$ type structures. One year later Holtzberg et al. [19] confirmed the $R_5\text{Si}_4$ and $R_5\text{Ge}_4$ crystal structures, and reported the magnetic properties for these alloys, including the intermediate Gd$_5$(Si$_x$Ge$_{1-x}$)$_4$ phase. Thirty years later an intensive study of $R_5$($\text{Si},\text{Ge}_{1-x}$)$_4$ alloys was started at the Ames Laboratory due to the discovery of the giant MCE observed by Pecharsky and Gschneidner in Gd$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys [20].

2.2.1 $Dy_5$($\text{Si},\text{Ge}_{1-x}$)$_4$

Smith et al. [17, 18] first reported lattice parameters and unit cell volumes for Dy$_5$Si$_4$ and Dy$_5$Ge$_4$, see Table 2.2.1. Both of these alloys had the Sm$_5$Ge$_4$-type orthorhombic crystal structure.

Year later Holtzberg et al. [19] confirmed previously the published results. Furthermore, from magnetic measurements they determined that Dy$_5$Si$_4$ has a FM phase transition near 140K and Dy$_5$Ge$_4$ has an AFM phase transition with Néel temperature around 40K. The magnetic data obtained by Holtzberg et al. for Dy$_5$Si$_4$ and Dy$_5$Ge$_4$ are presented in the Table 2.2.2.
In Table 2.2.2 $\theta_p$, $\theta_p$, is the PM Curie temperature; $T_c$, is the Curie temperature; $T_N$, is the Neel temperature; $\sigma_{4.2K, 25K}$ is the measured magnetic moment at 4.2K and 25kOe; $\sigma_{th}$ is the theoretical saturation moment; $C_M$, is the molar Curie constant; and $C_{M, th}$ is the theoretical molar Curie constant.

Fifteen years later the magnetic susceptibility of Dy$_5$Ge$_4$ between 300K and 1800K was reported by Batalin et al. [21]. They calculated the PM Curie temperature and magnetic effective moment for the germanide.

The electrical resistivity ($\rho$) of Dy$_5$Si$_4$ in the temperature range from 4.2K to 360K was reported by Serdyuk et al. [22]. They found that the functions $\rho(T)$ display distinct kinks at temperatures corresponding to the FM$\leftrightarrow$PM transitions. They also studied the heat capacity of the silicide, using a low-temperature adiabatic calorimeter. From an analysis of the $C_\rho(T)$ data above, $T_c$, they estimated the Debye temperature $\theta_D$. Using the Debye formula [23] they calculated the heat capacity, $C_\rho(T)$, in the vicinity of magnetic phase transition with Curie temperature, $T_C$.

In 1994, Eremenko et al. [24] using microstructural, X-ray and DTA analyses studied the structure and phase composition of the cast and annealed alloys of dysprosium with silicon. This was the first time the phase diagram for the dysprosium-silicon system was reported.

2.2.2 Gd$_5$(Si$_2$Ge$_{1-x}$)$_4$

The first crystallographic studies were done by Smith et al. [17, 18]. A year later the structure was confirmed by Holtzberg et al. [19]. Furthermore, Holtzberg et al. stated that an incomplete solid solubility in the system Gd$_5$Si$_4$ – Gd$_5$Ge$_4$ indicates that these alloys are not
isostructural. From magnetic measurements they showed that the silicide is FM with relatively high ordering temperature (~336 K), and that the germanide is AFM with ordering temperature (~94 K). However, the replacement of a small amount of Ge by Si in Gd₅Ge₄ produces a solid solution, which is FM at low temperatures and has intermediate transitions to AFM before becoming PM.

An extensive study of the Gd₅(SiₓGe₁₋ₓ)₄ alloy system was started at Ames Laboratory in 1996 by Pecharsky and Gschneidner due to the discovery of the giant magnetic entropy change in Gd₅Si₂Ge₂ alloy when subjected to a change in the magnetic field [20]. This effect (MCE or magnetic entropy change) exceeded the reversible (with respect to an alternating magnetic field) MCE in any known magnetic material. They also found [25] that as Ge is substituted for Si in Gd₅Si₂Ge₂ the Curie temperature is lowered and the giant MCE effect even become larger.

Pecharsky and Gschneidner reported [26] that the formation of the monoclinic phase at 0.24≤x≤0.5 is due to the large difference in bonding characteristics of Si and Ge in Gd₅Si₄-Gd₅Ge₄ pseudobinary system. For the composition Gd₅Si₂Ge₂ the lattice parameters of the monoclinic structure (space group $P1\overline{1}2_1/a$) are $a=7.5808\text{Å}$, $b=14.802\text{Å}$, $c=7.7799\text{Å}$, $γ=93.19°$ [26]. Furthermore, it was found that Gd₅Si₄ and Gd₅Ge₄ have significant difference in the atomic arrangement. Large shifts of all the atoms occur along the shortest crystallographic direction and the covalently bonded (Si,Ge)₂ pairs break upon transition from Gd₅Si₄ to Gd₅Ge₄.

The same authors also studied the effect of small amounts (~0.33 at.%) of Ga additions substituting for the non-magnetic Si and Ge in the compound Gd₅Si₂Ge₂. It was observed that the Curie temperature rose from 276K to 285K with MCE value staying the same. However, larger quantities of Ga led to a significant reduction in the MCE, even though the Curie temperature continued to rise [27]. Many 3d-metal (Fe, Co, Ni, Cu) and p-element (C, Al) additions reduced the MCE in Gd₅Si₂Ge₂ due to the changes in the thermodynamic nature of the magnetic phase transformations. In general, alloying additions rise the Curie temperature of the parent Gd₅Si₂Ge₂ alloy.

The studies of the magnetic and electrical properties of the Gd₅(SiₓGe₁₋ₓ)₄ compounds were reported in the following papers [28-34].
Various studies of the dc magnetization and dc/ac magnetic susceptibility of Gd$_3$(Si$_x$Ge$_{1-x}$) were also completed [35,36]. The spontaneous generation of voltage has been observed during the first-order magnetic-martensitic phase transition in this alloy system. The thermoelectric power was considered to be the major contributor to this effect.

Structural, electronic, and magnetic changes, which occur in the Gd$_3$(Si$_x$Ge$_{1-x}$)$_4$ system, bring about extreme changes of some properties, such as the MCE, magnetostriction, and magnetoresistance.

2.2.3 Previous work on R$_5$(Si$_x$Ge$_{1-x}$)$_4$, where R is rare earth other then Dy and Gd

A limited number of research papers have been published on the R$_5$(Si$_x$Ge$_{1-x}$)$_4$ phases with lanthanide metals other then Gd. The crystal structures of R$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys at room temperature are presented in the Table 2.2.5.

$\text{La}_5(\text{Si}_x\text{Ge}_{1-x})_4$ and $\text{Lu}_5(\text{Si}_x\text{Ge}_{1-x})_4$

The heat capacities of the $\text{La}_5(\text{Si}_x\text{Ge}_{1-x})_4$ and $\text{Lu}_5(\text{Si}_x\text{Ge}_{1-x})_4$ can be used to estimate the electronic and lattice contributions for other lanthanides [37]. Therefore, the pure magnetic contribution to the heat capacity can be estimated for different rare earth elements. The electronic specific heat constant, $\gamma$, and the Debye temperature, $\Theta_D$, were calculated for these intermetallic compounds [37].

$\text{Nd}_5(\text{Si}_x\text{Ge}_{1-x})_4$

In 1974, the phase diagram of the Nd-Ge system was reported as based on the microstructural, DTA, differential dilatometric, and X-ray phase analysis [38]. The formation of $\text{Nd}_5\text{Si}_4$ was studied using auger electron spectroscopy, X-ray diffraction, and Rutherford backscattering spectrometry [39]. The magnetization and $dc$ magnetic susceptibility were
reported for Nd$_3$(Si$_x$Ge$_{1-x}$)$_4$ alloys with $x=0, 0.25, 0.5, 0.75, 1$ compositions [37]. The MCE observed in the monoclinic phase Nd$_3$Si$_2$Ge$_2$ does not have first order phase transition, as found in Gd$_3$Si$_2$Ge$_2$ or in Dy$_3$Si$_2$Ge monoclinic alloys. It undergoes second order phase transition. The electronic specific heat constant, $\gamma = 2.6 \pm 1.5 \text{mJ/mol}$, and the Debye temperature, $\theta_D = 199 \pm 14K$ were also given [37].

**Tb$_5$(Si$_x$Ge$_{1-x}$)$_4$**

Physical properties of Tb$_5$Si$_4$ were reported for the first time in early eighties [22, 41]. The heat capacity, magnetization, susceptibility and electric resistance of Tb$_5$Si$_4$ were studied in terms of the RKKY and the molecular-field theories. The PM Curie temperature, the Curie-Weiss constant, and the molecular-field constant were determined [40]. From measurements of the electrical resistance and susceptibility, the effective mass of electrons, the s-f interaction constant, the Debye temperature, and the Fermi energy were established. The phase diagrams of the Tb-Ge and Tb-Si systems were reported in the papers [41] and [42], respectively.

More recent investigations [43] of the properties of Tb$_5$(Si$_x$Ge$_{1-x}$)$_4$ system showed that the alloys with monoclinic (P112$_1$/a) crystal structure ($x=0.4, 0.5, 0.6$) have a first-order phase transition to orthorhombic (Pnma) canted-FM structure. The strong coupling between crystallographic and magnetic degrees of freedom in the Tb$_5$(Si$_x$Ge$_{1-x}$)$_4$ compounds was experimentally observed [43]. The $\Delta S_m$ values of the alloys with monoclinic phase structure are more then twice as large as then the values of the two end members (Tb$_5$Si$_4$ and Tb$_5$Ge$_4$) [44, 45].

**Pr$_5$(Si$_x$Ge$_{1-x}$)$_4$, Ho$_5$(Si$_x$Ge$_{1-x}$)$_4$, Er$_5$(Si$_x$Ge$_{1-x}$)$_4$, Tm$_5$(Si$_x$Ge$_{1-x}$)$_4$, and Y$_5$(Si$_x$Ge$_{1-x}$)$_4**

Only a limited amount of well-established experimented data exist for the R$_5$(Si$_x$Ge$_{1-x}$)$_4$ phases for R = Pr, Ho, Er, Tm, and Y; these includes phase diagrams, and magnetic, electronic, and thermodynamic properties. [46-57].
2.3 Magnetocaloric Refrigeration

2.3.1 History

Magnetic cooling technique was first proposed by P. Debye [58] in 1926 for reaching temperatures below the boiling point of liquid helium. It was achieved by Giauque and MacDougall [59] in 1933 by cooling down to 0.25 K. In 1976, G.V. Brown [60] demonstrated a regenerative magnetic refrigerator operating near room temperature with a 50 K span. The efficiency of this refrigerator was low for two reasons: 1) the temperature gradient had to be maintained in a liquid with constant mixing; and 2) the cycle time of charging and discharging the magnet was too long. Currently work on near room temperature magnetic refrigeration is being conducted at the Astronautics Corporation of America in Wisconsin in conjunction with the Ames Laboratory [61]. Other magnetic refrigerator also being constructed and tested at the University of Victoria in Canada. The research on the magnetic refrigerant materials proceeds at the Ames Laboratory, the University of Quebec in Canada, and NIST (Gathersburg, MD) [62].

2.3.2 Basic principles

The MCE is the response of a solid to an applied magnetic field by changing the temperature of the material. This effect can be observed in any magnetic material. The maximum temperature change occurs near the magnetic ordering temperature. In a FM material the magnetic moments of the atoms are aligned upon the application of a magnetic field and as result the temperature rises. The material is cooled down when the magnetic moments become randomly oriented after removing the magnetic field. This process similar to the warming and the cooling of a gas in compression and expansion gaseous refrigerators. The refrigerant in magnetic refrigerators is a solid in a form of spheres. A low hazard fluid, e.g. water, antifreeze, or an inert gas provides the heat transfer. The demonstration of an operating magnetic refrigerator by the Astronautic corp. / Ames Laboratory team showed that it is possible to obtain cooling powers of 600W at 60% Carnot efficiencies with a large coefficient of performance near room temperature in magnetic fields ≤50kOe [63]. The
discovery of giant MCE in Gd$_3$(Si$_x$Ge$_{1-x}$)$_4$ series of alloys most likely will increase the performance of such refrigerator [26].

One of the biggest obstacle to the development of magnetic refrigerators is the cost of the superconducting or the permanent magnet. Therefore for now, commercial uses would be limited to large-scale operations only. However, if the MCE can be sufficiently enhanced, the device may be able to run efficiently enough with the weaker field generated by a permanent magnet. Then small size refrigerators will be used in wide range applications.
3. EXPERIMENTAL TECHNIQUES AND SAMPLES

3.1 Samples

3.1.1 Preparation of the Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ alloys from the initial components (Dy, Si, Ge)

A total of 11 alloys with the Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ stoichiometry (where 0≤x≤1) were prepared. The samples were obtained using an electric--arc-melting furnace with a water-cooled copper hearth in an argon atmosphere. The initial materials used pure components of Dy, Ge, and Si. The dysprosium was prepared and analyzed for impurities by the Materials Preparation Center (Ames Laboratory). The chemical analysis of the metal was found to be 99.9 at.\% (99.99 wt.\%) pure with the major impurities shown in the Table 3.1.1. The silicon and germanium were purchased from CERAC. The purity of these semiconductors was claimed as 99.99+ wt.\%.

Total weight of each arc-melted alloy was in the range between 7 and 12 grams (see Table 3.1.2). All alloys were arc-melted 6-7 times. Each time the alloy was turned over.

Because of the high melting point of the Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ and high vapor pressure of Dy some vaporization of Dy metal was observed during arc-melting. The losses of dysprosium were confirmed on X-ray diffraction. In order to compensate for the losses of the material, an excess of 1.1\% – 1.5\% Dy was added in each alloy before arc-melting, see Table 3.1.2.

*a*where $m_{\text{after}}$ is the mass of the sample after arc melting.

As seen in Table 3.1.2, after arc-melting the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ samples contained about a 1% excess Dy.

The samples were quite brittle and easily ground to powder. The most brittle samples were Ge-based solid solutions with the orthorhombic crystal structure.

Several alloys, which were prepared first and showed extra x-ray diffraction peaks due to the presence of second phases, were subjected to heat treatment at about 1000°C. Unfortunately, this procedure did not significantly improve their phase compositions. Therefore, the alloys, which were used in this study, were not heat-treated, and were selected for their phase purity on the basis of X-ray powder diffraction and optical metallographic analyses.

3.1.2 Samples preparation for magnetic and heat capacity measurements

For the magnetic measurements (i.e. ac/dc susceptibilities and dc magnetization) the mass of the samples weighed between 0.15g and 0.2g. Long and thin rectangular shapes of
the samples were intended to reduce the demagnetization factor. However this was achieved in less than 50% of the cases. Many of the measurements were performed on specimens which have an arbitrary shape.

The specimens for the heat capacity measurements were cut into a rectangular parallelepiped. The sizes of the samples were: length 8-11 mm, width 6-8 mm, and height 2-3 mm, and the weights varied from 0.8g to 1.8g.

3.1.3 Optical metallographic analysis

Optical metallographic analyses were used to analyze the microstructure and phase purity of the Dy₅(SiₓGe₁₋ₓ)₄ alloys.

First images of the microstructure of the alloy were obtained by using an ordinary optical microscope. Unfortunately, the distinctions between grains, different phases and impurities were not evident. On these micrographs, it was possible to observe only severe microcracks in the bulk material were observed in these micrographs. Therefore, the Differential Interference Contrast (DIC) illumination method was used. This microscopic technique uses a beam-splitting double-quartz prism, which is placed ahead of the objective, together with a polarizer and analyzer in the 90° crossed positions. The two light beams are made to coincide at the focal plane of the objective, revealing height differences as variations in color. The prism can be moved, shifting the interference image through the range of Newtonian colors. By using this technique we observed grains, grain boundaries, cracks, imperfections, etc.

A 100X DIC optical micrograph of Dy₅Ge₄ alloy is shown on the Figure 3.1.1. We can observe many imperfections as well as a number of cracks. These cracks make the specimen very fragile and difficult to measure such physical properties as the heat capacity, magnetization, and ac/dc susceptibility. During heat capacity measurements the bulk polycrystal specimen breaks into pieces during 3K to 350K thermocycling and/or application of strong magnetic fields above 20 kOe. This behavior is very typical for all Ge-rich alloys with orthorhombic crystal structure. Therefore, all Dy₅(SiₓGe₁₋ₓ)₄ alloys within the composition range 0≤ₓ≤0.622 have similar microstructures, i.e. large number of cracks. Several examples for different alloy composition are shown in Figure 3.1.2 and Figure 3.1.3.
The micrograph for the Dy$_5$Si$_3$Ge alloy with the monoclinic crystal structure is shown in Figure 3.1.4. Even though the number of microcracks are less, the alloys with $0.675 \leq x \leq 0.775$, the samples still have a lot of hollow areas. Therefore, these specimens also easily fell apart during thermocycling and/or application of magnetic field.

The least fragile samples among all the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys were silicon rich samples within the composition range vary from 0.822 to 1. Two of them are shown on Figure 3.1.5 and Figure 3.1.6. Even though it was easier to carry out measurements on these materials, which have the Gd$_5$Si$_4$-type orthorhombic crystal structure, they still broke into pieces several times during heat capacity measurements.

Figure 3.1.6 100X DIC illumination optical micrograph of the Dy₂Si₄ as cast alloy
3.2 X-ray Diffraction

The collected X-ray powder diffraction data were used to determine the crystal structures, space group symmetry, lattice parameters \((a, b, c, \text{ and } y)\), unit cell volume, density, the number of atoms, atomic coordinates, and positions of the atoms in the unit cell of the investigated alloys. The X-ray diffraction data were collected using an automated Scintag powder diffractometer using Cu-K\(\alpha\) radiation with a graphite monochromator attached to the detector. All scans were made in the two-theta angular range of 20 to 90 degrees. The powder samples for the x-ray measurements were prepared by grinding several polycrystals into a powder using a mortar and pestle. After grinding the powder was evenly distributed over a greased quartz slide. The slide was attached to the diffractometer’s sample holder parallel to the horizontal surface. The diffraction data were analyzed using the CSD crystallographic software [64].
3.3 Magnetic Measurements

Most of the magnetic measurements were performed on a LakeShore Model 7225 ac susceptometer / dc magnetometer. Only few measurements were done on an Oxford Instruments MagLab 2000. For the most part, the data collected on the Oxford magnetometer were used to check the data obtained on the LakeShore magnetometer.

3.3.1 LakeShore Model 7225 ac susceptometer / dc magnetometer specifications [65]

1) Temperature Range: from 4.2K to 325K
2) ac/dc Magnetic Field (Primary Coil):
   + Range: 4-digit selectable from 0.1Am⁻¹ (0.00125Oe) to 1600Am⁻¹ (20Oe) RMS, both ac and dc
   + Frequency: 1Hz to 1kHz, 1Hz step; 1kHz to 10kHz, 10Hz steps
3) ac susceptibility sensitivity: to 2x10⁻⁸emu in terms of equivalent magnetic moment
4) dc moment sensitivity: 9x10⁻⁵emu
5) 56kOe superconducting Magnet:
   + Field Range: ±56,000gauss (±56kOe)
   + Field Resolution: <1.0gauss, -56,000 to +56,000gauss (-56kOe to + 56kOe)
   + Remnant Field: 15gauss (<0.5gauss after demagnetization cycle) (15kOe)
6) Helium Capacity: 60liters
7) Static Boil-Off: 0.45liter/hour (nominal static boil-off)
8) A disposable nylon sample holder screws to a nylon rod at the end of the 0.25inch stainless steel sample rod. The stainless steel insert attaches to a stepping motor at the top of the cryostat. Nylon sample holder can hold up to 3.6mm x 13mm sample, including powder and bulk samples.
9) Data acquisition/control and analysis software: ACS7000 ac susceptibility software and DCM7000 dc moment software control the temperature of the sample, ac/dc magnetic fields, and stepping motor
Figure 3.3.1 Model 7225 ac susceptometer / dc magnetometer block diagram [65]

3.3.2 Oxford Instruments MagLab 2000 specifications [66]
1) Two inserts for different temperature ranges: a) from 2K to 400K, b) from 300K to 900K
2) A superconducting magnet with maximum field of 90kOe
3) Two cryogenic jackets: a) with liquid helium around a superconducting magnet, b) with liquid nitrogen for overall shielding
4) Two sample rods for different temperature ranges; it is positioned by the motor drive unit
5) A PC automatic software Object Bench version 3.7; which controls the temperature, ac/dc magnetic fields, and motor drive unit
The basic physical and engineering principles of ac/dc susceptibility and dc magnetization measurements are the same for both of these apparatuses.

3.3.3 ac susceptibility measurements

For ac susceptibility measurements, the principle of operation involves applying a small alternating magnetic field on the sample. It is achieved by driving an ac current through a primary coil. Two secondary coils, which located inside the primary coil, are balanced so the coils produces identical signals when there is no sample present in either coil. Therefore, the subtraction of the signals of two coils gives us zero. When the magnetic material is placed into one of the coils the resulting induced voltage in the coil is effected. This voltage \((v)\) is directly proportional to the magnetic susceptibility of the sample. Therefore, when the voltage signals are subtracted the resultant is no longer zero. The measured voltage and magnetic susceptibility have following relationship [65]:

\[
v = \left(\frac{V}{\alpha}\right)^{\frac{1}{2}} f H \chi,
\]

where \(v\) is the measured RMS voltage, \(\alpha\) is the calibration coefficient, \(V\) is the sample volume, \(f\) is the frequency of ac field, \(H\) is the RMS magnetic field, and \(\chi\) is the volume susceptibility of sample. Therefore, the sample susceptibility is given by:

\[
\chi = \frac{\alpha v}{(V f H)}.
\]

An improved accuracy of the magnetic susceptibility can be achieved by correcting for the demagnetization effect. This phenomenon is caused by the shape of the material due to the differences between the internal magnetic field in the sample and the applied magnetic field. The true internal magnetic susceptibility is given by the following relationship [65]:

\[
\chi_{int} = \chi \left(1 - D\chi\right),
\]

where \(D\) is the demagnetization factor and \(\chi\) is measured susceptibility.

The complex susceptibility with real and imaginary components arises from the phase difference \((\phi)\) between the input signal \((E_{in})\) and the reference signal \((E_{out})\) [65]:

\[
E_{out} = E_{in} \cos \phi
\]
The phase angle $\varphi$ has two contributions: 1) the circuit itself (in the case of ideal inductors there is a 90° phase shift in the circuit), and 2) the signal due to the sample. Therefore, the real $\chi'$ and the imaginary $\chi''$ internal susceptibilities are interdependent on both the real and imaginary measured susceptibilities and have a form:

$$
\chi'_{\text{int}} = \frac{\chi'(1 - D\chi') + D\chi''^2}{(1 - D\chi')^2 + D^2\chi''^2},
$$

$$
\chi''_{\text{int}} = \frac{\chi''}{(1 - D\chi')^2 + D^2\chi''^2}.
$$

The dc magnetic moment measurements is done by utilizing an extraction technique. A sample is moved through a pair of pickup coils at a given moment ($dt$), which induces a voltage ($v$). This voltage proportional to the moment ($m$) with a calibration factor $\alpha$. It has a form:

$$
m = -\alpha \int v dt,
$$

where

$$
v = \frac{\partial \varphi}{\partial t},
$$

and therefore,

$$
m = \alpha \varphi,
$$

where $m$ is the magnetic moment, $\alpha$ is the calibration coefficient, $dt$ is the time interval, and $\varphi$ is rate of flux change.

It is difficult to estimate the accuracy of magnetic measurements, because the manufacturer provided no such data. However, measurements of standards (such as Pt) show that the accuracy of the magnetometer is better than 1%. From magnetization data, using the Maxwell relation the isothermal magnetic entropy change ($\Delta S_m(T)$) as a function of temperature was calculated:

$$
\Delta S_m(T) = \int_0^{H_b} \left( \frac{\partial M}{\partial T} \right)_H dH.
$$
3.4 Heat Capacity Measurements

The heat capacity from ~3.5K to 350K in zero magnetic field and in magnetic fields of 20, 50, 75, and 100kOe was measured by using an automatic small sample calorimeter [13]. The basic components of the calorimeter are:

1) an insert with low temperature liquid helium pot, which allows to cool the sample holder to be cooled to about ~3K,
2) 120kOe superconducting magnet with a cryostat,
3) current sources and voltage measuring devices,
4) a high speed vacuum pumping system (vacuum down to 10^{-7}Torr), and
5) an IBM-PC to run the collecting data automatic program.

One of the most sensitive and difficult part to build and to repair in the automatic small sample calorimeter is the copper sample holder. It is made from a low-oxygen pure copper (99.99+wt%Cu). It has a clamp-like holder design, where the sample is tightly held to a round copper plate using a copper screw. The intermediate layer between the sample and the plate is a mixture of 50:50 (by volume) Apiezon-N grease and fine silver powder. It is used to improve the thermal conductivity between sample and sample holder. A temperature sensor (CERNOX) is placed in a small copper clamp and glued there with GE7031 varnish. Such a design provides better thermal contact. A heater (a thin film strain gauge) is attached to the sample holder using a silver epoxy, providing as best contact between these two surfaces as possible. The sample holder is connected to a helium pot by an alligator clamp, which gives a reliable thermal contact. When the alligator clamp is open the sample has contact only with four thin bad thermoconducting (Ø 0.15mm) nylon threads, which hold the sample holder tight in the design position.

Heat capacity during the experiment can be expressed in the form:

\[ C_p \equiv \left( \frac{\Delta Q}{\Delta T} \right)_p, \]

where \( \Delta Q \) is the amount of heat introduced into the sample holder and sample during a heat pulse, \( \Delta T \) is the resulting temperature rise, and \( P \) is the constant pressure index.
The accuracy of heat capacity data was ±1-2% (typically it is less the 1%) due to the large number of cracks in the samples. The total entropy, \( S_{\text{total}}(T, H_i) \), was calculated using the measured heat capacity data, \( C_p(T, H_i) \), by the formula [67]:

\[
S_{\text{total}}(T, H_i) = \int_0^T \frac{C_p(T, H_i)}{T} dT + S_0(H_i),
\]

where \( S_0(H_i) \) was defined as equal to 0 (i.e. field independent), and \( H_i \) is a fixed magnetic field, i.e. \( \mu_0 H = 0, 20, 50, 75, \) or 100 kOe.

Numerical integration was started at a selected low temperature, \( T_{\text{min}} \), for all fields to minimize the effect of a varying experimented starting temperature (i.e. the lowest experimental data point which varies from min to max). Therefore:

\[
S_{\text{total}}(T, H_i) = \int_0^{T_{\text{min}}} \frac{C_p(T, H_i)}{T} dT + \int_{T_{\text{min}}}^T \frac{C_p(T, H_i)}{T} dT
\]

Where \( C_p(T, H_i) \) is the extrapolated value of heat capacity from \( T = T_{\text{min}} \) to \( T = 0K \).

The errors in temperature measurements were assumed to be negligibly small compared to the errors in heat capacity \( \sigma C_p(T, H_i) \). Therefore the errors in total entropy, \( \sigma S_{\text{total}}(T, H_i) \), can be expresses as [67]:

\[
\sigma S_{\text{total}}(T, H_i) = \int_0^{T_{\text{min}}} \frac{\sigma C_p(T, H_i)}{T} dT + \int_{T_{\text{min}}}^T \frac{\sigma C_p(T, H_i)}{T} dT
\]

The magnetic entropy change \( \Delta S_m(T) \) was calculated as the difference between two isotherms. The adiabatic temperature rise \( \Delta T(T) \) was calculated as the difference between \( S_{\text{total}}(T, 0) \) and \( S_{\text{total}}(T, H_i) \). The errors \( \sigma \Delta S_m \) and \( \sigma \Delta T \) are [68]:

\[
\sigma \Delta S_m(T) = \sigma S(T, 0) + \sigma S(T, H_i)
\]

and

\[
\sigma \Delta T(T) = \frac{\sigma S(T, 0)}{\left( \frac{dS(T, 0)}{dT} \right)} + \frac{\sigma S(T, H_i)}{\left( \frac{dS(T, H_i)}{dT} \right)}
\]
4. DATA ANALYSIS AND RESULTS

4.1 Crystal Structure

To date three different crystal structures have been determined in the Dy₃(SiₓGe₁₋ₓ)₄ alloy system [31, 69]. Dy₃Ge₄, Dy₃SiGe₂, Dy₃Si₂Ge₂, and Dy₃Si₂.₅Ge₁.₅ alloys have the Sm₅Ge₄-type orthorhombic crystal structure. Dy₃Si₁.₇Ge₁.₃, Dy₃Si₂.₉Ge₁.₁, Dy₃Si₃Ge, and Dy₃Si₃.₁Ge₀.₉ alloys have Gd₃Si₂Ge₂-type monoclinic structure. Dy₃Si₃.₅Ge₀.₇, Dy₃Si₃.₅Ge₀.₅, and Dy₃Si₄ have the orthorhombic Gd₃Si₄-type crystal arrangement. The observed, calculated and difference between the observed and calculated crystal structures of Dy₅Si₄, Dy₅Si₃.₅Ge₀.₅, Dy₅Si₃Ge, Dy₅Si₂.₅Ge₁.₅, Dy₅Si₂Ge₂, Dy₅SiGe₃, and Dy₅Ge₄ diffraction patterns are shown in Figures 4.1.1 – 4.1.7, respectively. The calculated intensity values were determined by using a full profile least-squares refinement [64]. All positional parameters and the overall thermal displacement parameters were refined.

Figure 4.1.6  The observed and calculated X-ray powder diffraction data profiles and their difference of the Dy$_5$SiGe$_3$ as cast alloy

Figure 4.1.7  The observed and calculated X-ray powder diffraction data profiles and their difference of the Dy$_5$Ge$_4$ as cast alloy
Figure 4.1.1 and Figure 4.1.2 are typical X-ray diffraction patterns for the orthorhombic Gd$_5$Si$_4$-type crystal structure. This phase exists in the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys for 0.822 ≤ x ≤ 1 composition range.

In Figure 4.1.3 is shown X-ray powder diffraction of a typical monoclinic Gd$_5$Si$_2$Ge$_2$-type crystal structure formed in Dy$_5$Si$_3$Ge compound. Calculated and observed intensity vs angle 2θ match well with each other. No significant extra peaks were found in the X-ray patterns.

The full profile least-squares analysis shows that the structure of Dy$_5$Si$_3$Ge differs from the other crystal structures of the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloy system. When we tried to use the lattice and atomic parameters of either the Si or the Ge orthorhombic crystal systems as a starting model for the full profile least squares refinement for the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$, it was unsuccessful. The answer showed clearly that the crystal structure of this intermetallic compound is quite different from orthorhombic Sm$_5$Ge$_4$ type. Therefore, the initial crystallographic data and structure refinement parameters were taken from the reported by Pecharsky and Gschneidner [26] for the Gd$_5$Si$_2$Ge$_2$ alloy with the monoclinic crystal structure with the P112$_1$/a phase group. This space group is a subgroup of Pnma, where the glide plane n and the mirror plane m are absent. Even though both Gd$_5$Si$_4$ and Gd$_5$Ge$_4$ alloys crystallize in the Pnma space group, the intermediate group of alloys have the monoclinic P112$_1$/a crystal structure. Both the orthorhombic (Pnma) and monoclinic (P112$_1$/a) types of diagrams are considered to be quite complex and difficult to identify.

Figures 4.1.4 - 4.1.7 show the X-ray diffraction diagrams for the orthorhombic Sm$_5$Ge$_4$-type crystal structure. The calculated and measured X-ray diffraction profiles show that the phase purity of the specimens is within acceptable limits. There are no extra peaks with large intensity values in the observed X-ray profiles.

The samples of the Dy$_5$Si$_4$, Dy$_5$Si$_3$Ge$_{0.5}$, Dy$_5$Si$_3$Ge$_{0.7}$, Dy$_5$Si$_{1.1}$Ge$_{0.9}$, Dy$_5$Si$_3$Ge, Dy$_5$Si$_2$Ge$_{1.1}$, Dy$_5$Si$_2$Ge$_{1.3}$, Dy$_5$Si$_2$Ge$_{1.5}$, Dy$_5$Si$_3$Ge$_2$, Dy$_5$Si$_3$Ge, and Dy$_5$Ge$_4$ compounds were considered to be single-phase pattern with an admixture of other phases being less then 3%. Some deviations in intensity of peaks between observed and calculated profiles are probably due to the texture of the powders.
Comparison of X-ray data for the different crystal structures in the Dy$_3$(Si$_x$Ge$_{1-x}$)$_4$ system (i.e. Dy$_3$Si$_4$, Dy$_3$Si$_3$Ge, and Dy$_3$Ge$_4$) are shown in Figure 4.1.8. The presentation of crystallographic data of the orthorhombic Gd$_3$Si$_4$-type, the monoclinic Gd$_3$Si$_3$Ge$_2$-type, and the orthorhombic Sm$_3$Ge$_4$-type crystal structures gives us the distinctions between these three structures. A full profile Rietveld analysis [70] of the experimental X-ray data was performed on the samples used in this study and the results are given in Table 4.1.1. The initial lattice and atomic parameters for Dy$_3$Si$_4$ and Dy$_3$Ge$_4$ were taken from Smith et al. [18]. The lattice parameters ($a$, $b$, $c$, and $\gamma$), unit cell volume ($V$), density ($\rho$) and number of atoms in the unit cell were calculated for all seven compounds. The X-ray diffraction measurements were taken using Cu $\alpha_1$ radiation with wavelength 1.5406Å. The $2\theta$ range and the number of free parameters presented in the table were utilized for the full profile least–square refinement. The results are in good agreement with previous work presented in Table 2.2.1 [18,19].

The atomic positions in the polycrystals Dy$_3$Si$_4$, Dy$_3$Si$_3$Ge, Dy$_3$Si$_2$Ge$_2$, Dy$_3$Si$_2$Ge$_{1.5}$, Dy$_3$SiGe$_3$, Dy$_3$Si$_3$Ge$_{0.5}$, and Dy$_3$Ge$_4$ were calculated and are listed in Table 4.1.2. The sites that the Dy and Si (Ge) atoms occupy in these alloys are given in this table. In the two orthorhombic structures there are three different coordinating polyhedra for Dy atoms in the unit cell and three for the Si (Ge) atoms. In the monoclinic crystal structure there are 5 different sites in the unit cell for the Dy and 4 for the Si (Ge) atoms. The increase of the different coordinating polyhedra with decrease of symmetry of crystal is typical.

In Table 4.1.2 it is seen that the constraint positional parameter $y = \frac{1}{4}$ in orthorhombic crystal structure becomes a free parameter in the monoclinic system. This is due to the losses of the glide plane $n$ and the mirror plane $m$ during the phase transformation from the orthorhombic to the monoclinic crystal structure.

In Table 4.1.1 it is evident that even though the volume, positions of the atoms, and the shape of the unit cell remain about the same for the monoclinic Dy$_3$Si$_3$Ge phase compared to the orthorhombic Dy$_3$Si$_4$ and Dy$_3$Ge$_4$ structures to one of the angles of the unit cell is 93°, compared to 90° for the other structure.

**Figure 4.1.9**  Lattice parameters vs composition change in the as cast Dy$_5$(Si$_{1-x}$Ge$_x$)$_4$ system
The phase relations of the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ pseudobinary system were established from 11 arc-melted compositions. The lattice parameters and the unit cell volume as a function of Si concentration are shown in Figures 4.1.9 and 4.1.10, respectively. It is seen that the orthorhombic crystal structures have the ranges between $0 \leq x \leq 0.622$ and $0.822 \leq x \leq 1$. The lattice parameters change more rapidly when concentration of Si lies in the interval $0.622 \leq x \leq 0.822$, where alloys with the monoclinic crystal structure form. The exact values of compositions of Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ at which the crystal structure change from orthorhombic to monoclinic and back to orthorhombic were not determined due to the difficulty of preparing pure phases of these alloys. During arc-melting vaporization of Dy-metal was observed, which shift the designed stoichiometry of the alloy.

The dependencies of lattice parameters and volume unit cell change with composition follow a linear behavior, except for the transition from orthorhombic (I) to monoclinic, and monoclinic to orthorhombic (II) crystal structures. At these phase boundaries the biggest change in the unit cell occurs along the axis $a$. From Figure 4.1.10 we can see, that the
overall unit cell volume is increased by $-4.1\%$ with a composition change from $x=1$ (Dy$_3$Si$_4$) to $x=0$ (Dy$_3$Ge$_4$).

The positions of the atoms in the unit cell of the Dy$_3$Si$_4$, Dy$_5$Si$_3$Ge, and Dy$_5$Ge$_4$ structure are shown in Table 4.1.3. Three independent atomic coordinates were found for Dy (Dy1, Dy2, Dy3), and 3 were found for Si – Ge (Si-Ge1, Si-Ge2, Si-Ge3) for these alloys with the orthorhombic crystal structure. When the monoclinic system occurs each of the three 8-fold sites from the parent orthorhombic structure are split into pairs of independent 4-fold sites with the first 4-fold site maintaining the same positional parameters as in parent orthorhombic structure. For Dy it means that 8Dy$_2$ and 8Dy$_3$ were split into 4Dy$_2a$, and 4Dy$_2b$, 4Dy$_3a$ and 4Dy$_3b$ (The meaning of the symbols are presented in Table 4.1.3). The Si – Ge atoms change from 8Si-Ge3 to 4Si-Ge$_3$ and 4Si-Ge$_3b$. The abbreviations $^x$, $^y$, $^z$ are presented in Table 4.1.3 as atomic coordinates for Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys with the monoclinic crystal structure. It helped to express the differences, which were mention above. The symbols $^y$→$^z$ and $^z$→$^y$ in Table 4.1.3 represent the switch of the y axis to the z axis and the z axis to the y axis when we calculated positions of the atoms in the unit cell for the alloys with monoclinic crystal structure.

</table>
The projections of the crystal structures of Dy$_3$Si$_4$, Dy$_3$Si$_3$Ge, and Dy$_3$Ge$_4$ along the $c$-axes are shown in Figures 4.1.11, 4.1.12, and 4.1.13, respectively. There are total of 36 atoms in the unit cell. The Si (Ge) atoms are shown as solid circles and the Dy atoms are drawn as open circles. The size of the circles varies with the value of $z$ ($0 \leq z \leq 1$). The larger circles have a larger value of the $z$ coordinate. In Figure 4.1.12 a small distortion of ~3° of the unit cell is observed. A large shift along crystallographic axis (especially along axis $x$) is observed when comparing Dy$_3$Si$_4$ to Dy$_3$Ge$_4$.

Figure 4.1.11 The z-axis projection of the crystal structure of Dy$_3$Si$_4$

4.2 Magnetic Properties

4.2.1 dc magnetic susceptibility measurements

The dc magnetic susceptibility have been measured for nine Dy₅( Si₅Ge₁₋ₓ)₄ alloys. These data allowed us to determine an approximate temperatures of the magnetic phase transition for each alloy. The paramagnetic Curie temperature (θₚ) can be estimated from the intercept for 1/χ = 0 from a Curie-Weiss plot of 1/χ vs T in different dc magnetic fields. Based on the calculated paramagnetic Curie temperatures the magnetic phase transition region can be investigated in detail using other techniques.

The inverse dc magnetic susceptibility vs temperature of the alloys with the Gd₃Si₄-type orthorhombic crystal structure in 10, 20, 30, 40, and 50kOe dc magnetic fields are shown in Figure 4.2.1 and Figure 4.2.2. Based on these two data sets the paramagnetic Curie temperatures for the Dy₂Si₄ and Dy₂Si₃.₅Ge₀.₅ were calculated and found equal to θₚ ≈ 130 K.

![Figure 4.2.1](image)

**Figure 4.2.1** The inverse dc magnetic susceptibility vs temperature for Dy₅Si₄ as cast alloy in 10, 20, 30, 40, and 50kOe dc magnetic fields.
Figure 4.2.2 The inverse dc magnetic susceptibility vs temperature for Dy$_{5}$Si$_{3.5}$Ge$_{0.5}$ as cast alloy in 10, 20, 30, 40, and 50 kOe dc magnetic fields

and $\theta_p \equiv 125$ K, respectively. Therefore, the paramagnetic Curie temperature is decreased with an increasing amount of Ge.

The inverse dc magnetic susceptibility vs temperature of the alloys with the Gd$_5$Si$_2$Ge$_2$-type monoclinic crystal structure in 10, 20, 30, 40, and 50 kOe dc magnetic fields are shown in Figures 4.2.3, 4.2.4, and 4.2.5. Based on these three sets of data the paramagnetic Curie temperatures for the Dy$_5$Si$_2$Ge, Dy$_5$Si$_{2.9}$Ge$_{1.1}$, and Dy$_5$Si$_{2.7}$Ge$_{1.3}$ alloys were calculated and found equal to $\theta_p \equiv 65$ K, $\theta_p \equiv 62$ K, and $\theta_p \equiv 58$ K, respectively.

The inverse dc magnetic susceptibility vs temperature of the alloys with Sm$_5$Ge$_4$-type orthorhombic crystal structure in 10, 20, 30, 40, and 50 kOe dc magnetic fields are shown in Figures 4.2.6, 4.2.7, 4.2.8, and 4.2.9. Using an interpolation technique for the data presented on these graphs, the paramagnetic Curie temperatures for the Dy$_5$Si$_{2.5}$Ge$_{1.5}$, Dy$_5$Si$_2$Ge$_2$, Dy$_5$SiGe$_3$, and Dy$_5$Ge$_4$ alloys were calculated and found equal to $\theta_p \equiv 55$ K, $\theta_p \equiv 45$ K, $\theta_p \equiv 40$ K, and $\theta_p \equiv 35$ K, respectively.
Figure 4.2.3 The inverse dc magnetic susceptibility vs temperature for Dy$_5$Si$_3$Ge as cast alloy in 10, 20, 30, 40, and 50kOe dc magnetic fields

Figure 4.2.8  The inverse *dc* magnetic susceptibility vs temperature for Dy$_5$SiGe$_3$ as cast alloy in 10, 20, 30, 40, and 50kOe *dc* magnetic fields
The inverse dc magnetic susceptibility vs temperature for Dy$_5$Ge$_4$ as cast alloy in 10, 20, 30, 40, and 50kOe dc magnetic fields.

The dc magnetic susceptibility for all measured alloys obey linear behavior in the PM region (i.e. for the temperatures above the temperature of magnetic phase transition). The paramagnetic Curie temperatures ($\theta_p$) for the Dy$_5$Si$_4$, Dy$_5$Si$_3.5$Ge$_0.5$, Dy$_5$Si$_3$Ge, Dy$_5$Si$_2.9$Ge$_{1.1}$, Dy$_5$Si$_2.7$Ge$_{1.3}$, Dy$_5$Si$_2.5$Ge$_{1.5}$, Dy$_5$Si$_2$Ge$_2$, Dy$_5$SiGe$_3$, Dy$_5$Ge$_4$ alloys are presented in the Table 4.2.1. The anomalies at low temperature for the Dy$_5$Si$_2$Ge$_2$, Dy$_5$SiGe$_3$, and Dy$_5$Ge$_4$ suggests that a FerriM or an AFM structure occurs in these magnetic materials.

4.2.2 ac susceptibility measurements

The 20e ac field, 125Hz frequency real and imaginary components of the susceptibility vs temperature dependencies in 0kOe applied dc magnetic field for Dy₅Si₄ alloy, which form the Gd₅Si₄ orthorhombic structure, are shown in Figure 4.2.10. The sample was demagnetized each time at the beginning of ac susceptibility measurements. The data were collected under heating and cooling conditions. The temperature range was varied from ~5K to ~325K. The thermocycling allowed us better understand the physical properties below magnetic phase transition temperature of the alloy. Plots with large and open symbols represent the graph measurements with decreasing temperature. Plots with small and solid symbols represent the measurements with increasing temperature. As seen there is no change in $\chi'$, and $\chi''$ data upon cooling and heating the sample during measurements. The ac susceptibility maximum peaks were observed in the region of magnetic phase transformation for Dy₅Si₄ alloy. The temperature of the maxima was determined as 137K.

The 20e ac field, 125Hz frequency real and imaginary susceptibility vs temperature dependencies in an 1kOe applied dc magnetic field for Dy₅Si₄ alloy are shown in Figure 4.2.11. The sample was demagnetized each time at the beginning of ac susceptibility measurements. The data were collected under heating and cooling conditions. The temperature range was varied from ~5K to ~325K. The thermocycling did not effect the magnetic properties of the sample. Plots with large and open symbols represent the measurements with decreasing temperature. Plots with small and solid symbols represent the measurements with increasing temperature. The ac susceptibility maximum peaks were observed in the region of magnetic phase transition for this alloy.

A comparison of the real and imaginary components of the 20e ac field with 125Hz frequency ac susceptibility 0kOe and 1kOe applied dc magnetic fields is shown in Figure 4.2.12. The maxima of the real and imaginary components of the ac susceptibility in the 1kOe dc magnetic field is shifted to lower temperatures and have a smaller value then in the 0kOe dc magnetic field.
Figure 4.2.10 Real and imaginary components of ac susceptibility in 0kOe dc field, 20e ac field at 125Hz frequency during heating and cooling for Dy$_5$Si$_4$

Figure 4.2.11 Real and imaginary components of ac susceptibility in 1kOe dc magnetic field, 20e ac field at 125Hz frequency during heating and cooling for Dy$_5$Si$_4$
Figure 4.2.12 Comparison of $ac$ susceptibility in 0kOe and 1kOe $dc$ magnetic field, 20e $ac$ field at 125Hz frequency during heating and cooling for Dy$_5$Si$_4$

The 20e $ac$ field at 125Hz frequency real and imaginary susceptibility vs temperature dependencies in a 0kOe applied $dc$ magnetic field for Dy$_5$Si$_3$.Ge$_{0.5}$ alloy, which has the orthorhombic Gd$_3$Si$_4$-type structure, are shown in Figure 4.2.13. The sample was demagnetized each time at the beginning of $ac$ susceptibility measurements. The data were collected in the temperature interval from ~5K to ~200K under heating. The shape of the curves in Figure 4.2.13 are similar to the shape of $ac$ susceptibility vs temperature plots for Dy$_5$Si$_4$ alloy, but the relative values of the $\chi'_ac$ and $\chi''ac$ are more than twice as small. The maximum peak, 133K, of the real component $ac$ susceptibility was observed in the region of magnetic phase transition for this alloy.
The real and imaginary components of the ac susceptibility vs temperature for the Dy\textsubscript{5}Si\textsubscript{3}Ge alloy are shown in Figure 4.2.14. The measurements were performed in a 0kOe applied dc magnetic field, using a 20e alternating current field at 125Hz frequency, and under heating and cooling conditions. The sample was demagnetized each time at the beginning of the ac susceptibility measurements. Temperature range was varied from ~5K to ~200K. Plots with large and open symbols represent measurements with decreasing temperature, while those with small and solid symbols represent measurements with increasing temperature. Both values of the real and imaginary ac susceptibility components of the heating curves are visibly smaller than those taken on the cooling. The real part of ac susceptibility during cooling is broadening in the temperature interval from ~57K to ~65K, indicating a small temperature hysteresis. The maximum peak of the real component ac susceptibility was determined to the 75K.

![Figure 4.2.13 Real and imaginary components of ac susceptibility in 0kOe dc magnetic field, 20e ac field at 125Hz frequency during heating and cooling for Dy\textsubscript{5}Si\textsubscript{3}Ge\textsubscript{0.5}](image-url)

Figure 4.2.13 Real and imaginary components of ac susceptibility in 0kOe dc magnetic field, 20e ac field at 125Hz frequency during heating and cooling for Dy\textsubscript{5}Si\textsubscript{3}Ge\textsubscript{0.5}
The 20e ac field at 125Hz frequency real and imaginary components of ac susceptibility vs temperature dependencies in 1kOe applied dc magnetic field for the Dy$_3$Si$_3$Ge alloy, which has the monoclinic Gd$_5$Si$_2$Ge$_2$-type structure, are shown in Figure 4.2.15. The sample was demagnetized each time at the beginning of ac susceptibility measurements. The data were collected under heating and cooling conditions. The temperature range was varied from ~5K to ~120K. Curves with large and open symbols represent measurements with decreasing temperature. Plots with small and solid symbols represent measurements with increasing temperature. The broadening of the maximum with increasing magnetic field from 0kOe to 1kOe was observed for the Dy$_3$Si$_3$Ge alloy. Therefore, the value of the temperature hysteresis increases with the application of magnetic field.

![Figure 4.2.14 Real and imaginary components of ac susceptibility in 0kOe dc magnetic field, 20e ac field at 125Hz frequency during heating and cooling for Dy$_3$Si$_3$Ge](image-url)
Figure 4.2.15 Real and imaginary components of ac susceptibility in 1kOe dc magnetic field, 2Oe ac field at 125Hz frequency during heating and cooling for Dy$_5$Si$_3$Ge
A comparison of the real and imaginary \(ac\) susceptibility vs temperature dependencies in 0kOe and 1kOe \(dc\) magnetic fields during heating for the \(\text{Dy}_5\text{Si}_3\text{Ge}\) alloy is shown in Figure 4.2.16. The measurements were done in 20e \(ac\) field with frequency 125Hz. The application of magnetic field significantly decreases the value of the maximum for both the real and imaginary components of \(ac\) susceptibility (see Figure 4.2.16).

![Figure 4.2.16 Comparison of \(ac\) susceptibility in 0kOe and 1kOe \(dc\) magnetic field, 20e \(ac\) field at 125Hz frequency during heating and cooling for \(\text{Dy}_5\text{Si}_3\text{Ge}\) ](image_url)
Comparison of the real component \( ac \) susceptibility vs temperature in 20e and 50e \( ac \) fields at 125Hz frequency for \( \text{Dy}_2\text{Si}_3\text{Ge} \) alloy are shown in Figure 4.2.17. An increase of the \( ac \) field provides an increase of the real part of the \( ac \) susceptibility, by ~2.5 times. However, the broadening and shifting of the maximum was not observed with the increase of the \( ac \) field.

The real and imaginary parts of \( ac \) susceptibilities vs temperature dependencies for \( \text{Dy}_5\text{Si}_{1.5}\text{Ge}_{1.5}, \text{Dy}_5\text{Si}_2\text{Ge}_2, \) and \( \text{Dy}_5\text{Si}_3\text{Ge}_3 \) alloys with the Sm\(_3\)Ge\(_4\)-type orthorhombic crystal structure are shown in Figure 4.2.18, Figure 4.2.19, and Figure 4.2.20, respectively. The measurements were done in a 0kOe applied \( dc \) magnetic field, 20e \( ac \) field with frequency 125Hz, upon heating from ~5K to ~120K. The specimens were demagnetized each time at the beginning of \( ac \) susceptibility measurements. The relative values of \( ac \) susceptibility for the germanium-rich compounds are much smaller than for the silicon-rich compounds and alloys with monoclinic crystal structure. The relative \( ac \) susceptibility value gradually decreases with increasing amount of Ge in the alloys.

Figure 4.2.19  Real and imaginary component of $ac$ susceptibility in 0kOe $dc$ magnetic field, 2Oe $ac$ field at 125Hz frequency during heating for Dy$_5$Si$_2$Ge$_2$
Figure 4.2.20 Real and imaginary component of ac susceptibility in 0kOe dc magnetic field, 2Oe ac field at 125Hz frequency during heating for Dy$_5$SiGe$_3$

The real and imaginary components of ac susceptibility for Dy$_5$Ge$_4$ in a 2Oe ac field with frequency 125Hz under heating and cooling conditions in 0kOe and 1kOe applied dc magnetic fields are shown in Figures 4.2.21 and 4.2.22 respectively. The sample were demagnetized each time at the beginning of ac susceptibility measurements. It was found from the collected data that the behavior of this alloy does not depend on thermocycling (i.e. heating or cooling). The temperature range of the measurements varied from ~5K to ~100K. Curves with the large and open symbols represent measurements taken with decreasing of temperature, while the small and solid symbols were measured on heating.

A comparison of the real and imaginary components of the ac susceptibility vs temperature of Dy$_5$Ge$_4$ alloy in 0kOe and 1kOe applied dc magnetic fields is shown in Figure 4.2.23. The real part of ac susceptibility in 1 kOe applied dc magnetic field is more than three times smaller then the real part of ac susceptibility in 0kOe dc magnetic field. The imaginary
part of ac susceptibility in both dc magnetic fields almost lie on a perfect straight line with values close to zero and have essentially the same value in the temperature interval from 5K to 100K.

Based on the information presented in Figures 4.2.10 to 4.2.23 we make the following conclusions; that (1) the temperature hysteresis in 0kOe and 1kOe applied dc magnetic fields was observed only in alloys with monoclinic crystal structure. The small temperature hysteresis in Dy$_3$Si$_3$Ge under a 0kOe applied dc magnetic field is increased with application of a 1kOe dc magnetic field. (2) The silicides and germanides do not showed any signs of temperature a hysteresis. (3) The compounds with the monoclinic crystal structure become non-collinear magnetic materials below magnetic phase transition temperature. The applied dc field has tendency to freeze the magnetic moments in the samples with monoclinic crystal structure, such as Dy$_3$Si$_3$Ge.

![Figure 4.2.21 Real and imaginary components of ac susceptibility in 0kOe dc magnetic field, 2Oe ac field at 125Hz frequency during heating and cooling for Dy$_3$Ge$_4$](image-url)

Figure 4.2.23 Comparison of ac susceptibility in 0kOe and 1kOe dc magnetic field, 20e ac field at 125Hz frequency during heating and cooling for Dy₅Ge₄
4.2.3 Magnetization vs temperature measurements

The magnetization vs temperature dependencies for the alloys Dy₅Ge₄, Dy₅Si₃Ge, and Dy₅Si₄ are shown in Figure 4.2.24. Measurements were performed under an applied magnetic field of 1 kOe during heating and cooling. Curves with large and open symbols were taken on cooling, and those with small and solid symbols on heating.

The Dy₅Ge₄ and Dy₅Si₄ magnetization vs temperature curves do not exhibit a temperature hysteresis. The magnetization vs temperature curves for the Dy₅Si₄ alloy show typical ferromagnetic behavior. The type of magnetic phase transition of Dy₅Ge₄ does not appear to be obvious, but it is clearly not FM. Referring to the literature data, this alloy was reported to have an AFM structure below critical temperature. The positive value of paramagnetic Curie point and the shape of the ac susceptibility no temperature curves do not support the statement that it is an AFM transition. At the same time, the value of magnetization is small and linear relationship of magnetic moment vs magnetic field exists at 5K. More in-depth investigations need to make for the germanides using other magnetic measurement techniques. For now, we can only state that this structure appears to have non-collinear spin interactions. It is difficult, if not impossible, to determine exact magnetic structures of these compounds without neutron diffraction measurements.

Due to the freezing of the magnetic moments with the application of a dc magnetic field a significant effect was observed in the magnetization vs temperature during heating and cooling of the Dy₅Si₃Ge alloy (see Figure 4.2.24). This and the ac susceptibility data for this compound suggest that the ordering may be FM with some coercivity below magnetic phase transition. Such behavior probably occurs as a result of the pinning of domain walls motion by lattice defects.
Figure 4.2.24 The magnetization vs temperature for Dy$_3$Ge$_4$ (orthorhombic-I), Dy$_5$Si$_3$Ge (monoclinic), and Dy$_5$Si$_4$ (orthorhombic-II) alloys in 1kOe applied dc magnetic field.

For these measurements all samples were cooled down to 5K in zero dc field, and when 5K was reached the 1kOe dc field was turned on. Therefore, the samples were demagnetized before each measurements.
4.2.4 Magnetization vs dc magnetic field measurements

The dependencies of magnetization vs $dc$ magnetic field for the alloys Dy$_5$Si$_4$ and Dy$_5$Si$_3.5$Ge$_{0.5}$ with the Gd$_5$Si$_4$-type orthorhombic crystal structure are shown in Figure 4.2.25 and Figure 4.2.26, respectively. The magnetization for these alloys has almost reached saturation at the low temperatures ($\sim$5K) and in high magnetic fields ($\sim$56kOe). It still can increase and reach bigger value. The difference between the measured maximum value at 56kOe and the saturation magnetization is much smaller in Dy$_5$Si$_4$ than in germanium-rich alloys and alloys with the monoclinic crystal structure. The curves exhibit a linear behavior at temperatures above magnetic phase transition, i.e. in the PM region.

The $dc$ magnetization vs the $dc$ magnetic field curves for the Dy$_5$Si$_3$Ge alloy with the Gd$_5$Si$_4$Ge$_2$-type monoclinic crystal structure are shown in Figure 4.2.27. The curves exhibit a linear behavior in the PM region.
Figure 4.2.26 Magnetization vs $dc$ magnetic field dependencies for Dy$_2$Si$_3$Ge$_{0.5}$

Figure 4.2.27 Magnetization vs $dc$ magnetic field dependencies for Dy$_2$Si$_3$Ge
The magnetization curves vs dc magnetic field for Dy$_5$Si$_2$Ge$_2$, Dy$_5$SiGe$_3$, and Dy$_5$Ge$_4$ which have Sm$_5$Ge$_4$-type orthorhombic crystal structure, are presented in Figures 4.2.28, 4.2.29, 4.2.30, 4.2.31, and 4.2.32, respectively. In all of these graphs, above magnetic phase transition temperature (i.e. in PM region) the magnetization shows a linear behavior. It is also seen that the magnetization is far from saturation at 56kOe at low temperatures.

The magnetization vs magnetic field data also allow one to calculate the magnetic entropy change (magnetocaloric effect) for these alloys.
Figure 4.2.29 Magnetization vs rf magnetic field dependencies for Dy$_5$Si$_{2.5}$Ge$_{1.5}$

Figure 4.2.30 Magnetization vs dc magnetic field dependencies for Dy$_5$Si$_2$Ge$_2$
Figure 4.2.31 Magnetization vs *dc* magnetic field dependencies for Dy$_5$SiGe$_3$

Figure 4.2.32 Magnetization vs *dc* magnetic field dependencies for Dy$_5$Ge$_4$
It is characteristic for all of the compounds of the \( \text{Dy}_5(\text{Si}_x\text{Ge}_{1-x})_4 \) series to exhibit metamagnetic transitions at \(-5\text{K}\). In Figures 4.2.25 - 4.2.32 it is obvious to see several “step-like” transitions with the application of external magnetic field at low temperatures for the first time, i.e. after the sample have been zero field cooled to 5K. Furthermore, hysteresis was observed in the magnetization vs magnetic field curves in all of the compounds of low temperature. The maximum hysteresis was measured in \( \text{Dy}_5\text{Si}_3\text{Ge} \) with the monoclinic crystal structure.

The magnetization curves vs temperature and the values of critical fields for 7 alloys at 5K are shown in Figure 4.2.33 and Table 4.2.2. The critical fields \( (H_c) \) of the metamagnetic transitions are very distinct. An increase in the number of critical fields and a decrease in value of magnetization with an increase in the germanium context in the alloy are evident. The value of first critical field also strongly depends upon the composition. For example, \( H_c (\text{Dy}_5\text{Si}_4) \approx 4\text{kOe} \) and \( H_c (\text{Dy}_5\text{Si}_2\text{Ge}_2) \approx 20\text{kOe} \). The “step-like” transitions, in our opinion, are transformations of a non-collinear magnetic structures, which occur by

exchange interactions with positive and negative values and magnetocrystalline anisotropy. More experiments have to be done to finalize our conclusions about this phenomenon.

### 4.2.5 Magnetic entropy change calculations

The magnetic entropy change \((-\Delta S_m\)) as a function of temperature for the Dy₅Si₄ and Dy₅Si₁₋₃Ge₀.₅ with GdSi₄-type orthorhombic crystal structure for the changes in magnetic field of \(\Delta H = 10, 20, 30, 40,\) and 50kOe are shown in Figure 4.2.34 and Figure 4.2.35. The magnetic entropy change was calculated from the magnetization vs temperature data presented in Figures 4.2.25 and 4.2.26. The maximum values of \(-\Delta S_m\) for the Dy₅Si₄ alloy were determined at \(T \approx 141K\) and found equal to:

\[-\Delta S_m(\Delta H = 10kOe) \approx 3.7 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 20kOe) \approx 6.4 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 30kOe) \approx 8.7 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 40kOe) \approx 10.8 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 50kOe) \approx 12.6 \frac{J}{kg \cdot K}.\]

The maximum values of \(-\Delta S_m\) for the Dy₅Si₁₋₃Ge₀.₅ alloy were determined at \(T \approx 136K\) and found equal to:

\[-\Delta S_m(\Delta H = 10kOe) \approx 3 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 20kOe) \approx 5.6 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 30kOe) \approx 7.7 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 40kOe) \approx 9.6 \frac{J}{kg \cdot K},\]
\[-\Delta S_m(\Delta H = 50kOe) \approx 11.3 \frac{J}{kg \cdot K}.\]
Figure 4.2.34 The magnetic entropy change vs temperature of Dy$_5$Si$_4$ calculated from magnetization data for various magnetic field changes.

Figure 4.2.35 The magnetic entropy change vs temperature of Dy$_5$Si$_{3.5}$Ge$_{0.5}$ calculated from magnetization data for various magnetic field changes.
The typical caret-like shape of magnetic entropy change for the Dy₅Si₃Ge alloy confirms that the magnetic structure of this alloy is FM below ~14 K. Two other prepared alloys [Dy₅Si₃.5Ge₀.₅ and Dy₅Si₃.₃Ge₀.₇], which belong to this phase region show a similar magnetic entropy change behavior.

The magnetic entropy change as a function of temperature for the Dy₅Si₃Ge alloy with the monoclinic crystal structure for the changes in magnetic field of ΔH = 10, 20, 30, 40, and 50 kOe are shown in Figure 4.2.36. It was calculated from the data presented in Figure 4.2.27. The maximum values of −ΔSₚ for the Dy₅Si₃Ge alloy were determined at T ≈ 65 K and found equal to: −ΔSₚ(ΔH = 10 kOe) ≈ 10.7 J/kg · K.
\[
-\Delta S_m(\Delta H = 20\text{kOe}) \equiv 26\frac{J}{\text{kg} \cdot \text{K}}, \quad -\Delta S_m(\Delta H = 30\text{kOe}) \equiv 31.5\frac{J}{\text{kg} \cdot \text{K}}, \\
-\Delta S_m(\Delta H = 40\text{kOe}) \equiv 34.3\frac{J}{\text{kg} \cdot \text{K}}, \quad -\Delta S_m(\Delta H = 50\text{kOe}) \equiv 36.4\frac{J}{\text{kg} \cdot \text{K}}.
\]

The alloys, which belong to the monoclinic phase region apparently undergo a first order phase transition similar to what is observed in corresponding Gd$_5$(Si$_x$Ge$_{1-x}$)$_4$ monoclinic phase. This first order phase transition brings about a quite narrow but much larger MCE compared to that of the second order phase transition in Dy$_5$Si$_4$. It is seen in Figure 4.2.35 for the Dy$_5$Si$_3$Ge composition that the $-\Delta S_m$ peak value exceeds that of Dy$_5$Si$_4$ by $\sim 300\%$, which justifies its classification as a giant magnetocaloric effect. It is difficult to determine whether the mechanism of the giant magnetocaloric effect in Dy$_5$Si$_3$Ge is similar to or different from that observed in the Gd$_5$Si$_2$Ge$_2$ material. More studies, including low-temperature crystallography, are required to verify if magnetic ordering here is accompanied by a change of the material’s crystal structure.

The magnetic entropy change as a function of temperature for the Dy$_5$Si$_{2.5}$Ge$_{1.5}$, Dy$_5$Si$_2$Ge$_2$, Dy$_5$SiGe$_3$, and Dy$_5$Ge$_4$ alloys with the orthorhombic Sm$_5$Ge$_4$-type crystal structure for the changes in magnetic field of $\Delta H = 10, 20, 30, 40,$ and $50\text{kOe}$ are shown in Figures 4.2.37, 4.2.38, 4.2.39, and 4.2.40, respectively. The $-\Delta S_m$ values were calculated from the data presented in Figures 4.2.29, 4.2.30, 4.2.31, and 4.2.32.

A negative maximum of $-\Delta S_m = -0.14\frac{J}{\text{kg} \cdot \text{K}}$ for the Dy$_5$Si$_{2.5}$Ge$_{1.5}$ alloy (Figure 4.2.37) was found at $T \equiv 51K$ in $\Delta H = 10\text{kOe}$, which then broadens, increases in magnitude towards positive value, and shifts towards lower temperature for a larger magnetic field change. The positive maximum values of $-\Delta S_m$ for the Dy$_5$Si$_{2.5}$Ge$_{1.5}$ alloy were determined at $T \equiv 59K$ and found equal to: $-\Delta S_m(\Delta H = 10\text{kOe}) \equiv 0.6\frac{J}{\text{kg} \cdot \text{K}}, \\
-\Delta S_m(\Delta H = 20\text{kOe}) \equiv 1.9\frac{J}{\text{kg} \cdot \text{K}}, \quad -\Delta S_m(\Delta H = 30\text{kOe}) \equiv 3.5\frac{J}{\text{kg} \cdot \text{K}}, \\
-\Delta S_m(\Delta H = 40\text{kOe}) \equiv 5.3\frac{J}{\text{kg} \cdot \text{K}}, \quad -\Delta S_m(\Delta H = 50\text{kOe}) \equiv 7.1\frac{J}{\text{kg} \cdot \text{K}}.$
A negative maximum of $-\Delta S_m = -0.73 \frac{J}{kg \cdot K}$ for the Dy$_3$Si$_2$Ge$_2$ alloy (Figure 4.2.38) was found at $T \approx 51K$ in $\Delta H = 10kOe$, which then broadens, increases in magnitude (i.e. becomes more negative) at $\Delta H = 20kOe$, and for larger magnetic field changes shifts towards lower temperature. The positive maximum values of $-\Delta S_m$ for the Dy$_3$Si$_2$Ge$_2$ alloy were observed at $T \approx 56K$ and found equal to: $-\Delta S_m(\Delta H = 10kOe) \approx 0.5 \frac{J}{kg \cdot K}$,

$-\Delta S_m(\Delta H = 20kOe) \approx 1.7 \frac{J}{kg \cdot K}$, $-\Delta S_m(\Delta H = 30kOe) \approx 3.5 \frac{J}{kg \cdot K}$,

$-\Delta S_m(\Delta H = 40kOe) \approx 5.5 \frac{J}{kg \cdot K}$, $-\Delta S_m(\Delta H = 50kOe) \approx 7.4 \frac{J}{kg \cdot K}$.

The negative maximum of $-\Delta S_m = -0.56 \frac{J}{kg \cdot K}$ for the Dy$_3$SiGe$_3$ alloy (Figure 4.2.39) was found at $T \approx 47K$ in $\Delta H = 10kOe$, which then broadens, become more negative, and shifts towards lower temperatures for larger magnetic field changes. The positive maximum values of $-\Delta S_m$ for the Dy$_3$SiGe$_3$ alloy were observed at $T \approx 52K$ and found equal to: $-\Delta S_m(\Delta H = 10kOe) \approx 0.4 \frac{J}{kg \cdot K}$, $-\Delta S_m(\Delta H = 20kOe) \approx 1.4 \frac{J}{kg \cdot K}$,

$-\Delta S_m(\Delta H = 30kOe) \approx 2.9 \frac{J}{kg \cdot K}$, $-\Delta S_m(\Delta H = 40kOe) \approx 4.6 \frac{J}{kg \cdot K}$,

$-\Delta S_m(\Delta H = 50kOe) \approx 6.4 \frac{J}{kg \cdot K}$.

The negative maximum of $-\Delta S_m = -0.97 \frac{J}{kg \cdot K}$ for the Dy$_3$Ge$_4$ alloy (Figure 4.2.40) was found at $T \approx 45K$ in $\Delta H = 10kOe$, which then broadens, become more negative, and shifts towards lower temperatures, for larger magnetic field changes. The positive maximum values of $-\Delta S_m$ for the Dy$_3$Ge$_4$ alloy were determined at $T \approx 50K$ and found equal to: $-\Delta S_m(\Delta H = 10kOe) \approx 0.3 \frac{J}{kg \cdot K}$, $-\Delta S_m(\Delta H = 20kOe) \approx 1.3 \frac{J}{kg \cdot K}$,

$-\Delta S_m(\Delta H = 30kOe) \approx 2.9 \frac{J}{kg \cdot K}$, $-\Delta S_m(\Delta H = 40kOe) \approx 4.9 \frac{J}{kg \cdot K}$,

$-\Delta S_m(\Delta H = 50kOe) \approx 6.9 \frac{J}{kg \cdot K}$.
Figure 4.2.37 The magnetic entropy change vs temperature of Dy$_5$Si$_{2.5}$Ge$_{1.5}$ calculated from magnetization data for various magnetic field changes.

Figure 4.2.38 The magnetic entropy change vs temperature of Dy$_5$Si$_2$Ge$_2$ calculated from magnetization data for various magnetic field changes.
Figure 4.2.39 The magnetic entropy change vs temperature of Dy$_5$SiGe$_3$ calculated from magnetization data for various magnetic field changes.

Figure 4.2.40 The magnetic entropy change vs temperature of Dy$_5$Ge$_4$ calculated from magnetization data for various magnetic field changes.
The alloys from the Dy₅Ge₄-based solid solution region display an unusual magnetocaloric behavior (see Figures 4.2.37 - 4.2.40). For example, for the Dy₅Ge₄ alloy, at the lowest temperatures, a negative $-\Delta S_m$ peak exist for all magnetic field changes between 0kOe and 50kOe. For the lowest magnetic field change (from 0kOe to 10kOe), a negative $-\Delta S_m$ peak of -1 J/kgK is observed at ~45K, which then broadens, increases in magnitude (i.e. become more negative), and shifts towards lower temperature for larger magnetic field changes. The positive $-\Delta S_m$ peak occurs at ~50K and continuously increases in a magnitude as the magnetic field change rises. Such behavior, i.e. the existence of a negative and a positive MCE peaks, indicates that there is a considerable degree of FerriM or AFM in the magnetic structure of this material. Similar behaviors were reported for some heavy lanthanides and their intermetallic compounds [71-73].

In Figure 4.2.41 we summarized the results of $-\Delta S_m$ for seven different compositions in the Dy₅Si₄-Dy₅Ge₄ system for magnetic field change from 0 to 50kOe. As seen the MCE behavior is distinctly different for the different phase regions, but it is qualitatively similar for the alloys belonging to the same phase region.

The magnetic phase transition temperature vs Si concentration (solid circles) along with magnetic entropy change at transition temperature vs Si concentration (open circles) are shown in Figure 4.2.42. Similar to the behavior for the Gd₅(SiₓGe₁₋ₓ)₄ system, the Curie temperature gradually decreases in the Dy₅Si₄-based alloys with the Gd₅Si₄-type orthorhombic crystal structure, O(II). In Dy₅Ge₄-based alloys with Sm₅Ge₄-type orthorhombic crystal structure, O(I), the transition temperature also decreases at a slow rate in relation to composition, which is quite different from behavior in the Gd₅(SiₓGe₁₋ₓ)₄ system [25]. The magnetic properties, e.g. the magnetic entropy change, of the Dy₅(SiₓGe₁₋ₓ)₄ alloys are different for the alloys from the different crystal structure regions. For the Dy₅(SiₓGe₁₋ₓ)₄ system the orthorhombic regions have the maximums values of the magnetic entropy change which are smaller than those for the Gd₅(SiₓGe₁₋ₓ)₄ alloys. The Dy₅(SiₓGe₁₋ₓ)₄ alloys with monoclinic crystal structure the magnetic entropy change is comparable with those for the Gd₅(SiₓGe₁₋ₓ)₄ alloys and the shape of the maximum is similar for both of these systems.
Figure 4.2.41 The magnetic entropy change calculated from magnetization of different alloys from the Dy₅(SiₓGe₁₋ₓ)₄ system for a magnetic field change from 0kOe to 50kOe.

Table 4.2.3 lists magnetic ordering temperature determined from the MCE behavior and from the \( ac \) magnetic susceptibility measurements in 20e \( ac \) field with 125Hz frequency. The two different transition temperatures apparent from the magnetocaloric effect in the Dy\(_3\)Ge\(_4\)-based solid solution region are indistinguishable from the \( ac \) magnetic susceptibility data, due to a small temperature differences between them.

Figure 4.2.42 The magnetic phase transition temperature vs Si concentration and magnetic entropy change at critical temperatures diagrams of the Dy\(_8\)(Si\(_x\)Ge\(_{1-x}\))\(_4\) alloy estimated from magnetic entropy change.
4.3 Caloric Properties

Even though heat capacity were measured on most of the prepared alloys the collected data were accepted as valid for only three of the samples; Dy$_5$Ge$_4$, Dy$_5$Si$_3$Ge$_{0.5}$, Dy$_5$Si$_4$. Reasonable values of $-\Delta S_m$ and $\Delta T$ were possible only for the last two samples. The problems in collecting heat capacity data were due to the fact that 1) the samples were very brittle, especially alloys with the Sm$_3$Ge$_4$-type orthorhombic crystal structure and with the Gd$_5$Si$_2$Ge$_2$-type monoclinic crystal structure. A large number of microcracks were observed in these samples. Typical heat capacity data for the specimens with such imperfections are shown in Figure 4.3.1. Data plotted with small solid circles represents the heat capacity of the sample in a bulk form. Even though the first order magnetic phase transition can be observed, the individual points are quite scattered from the fitted smoothed line (much more than is normally observed for a good quality sample). This phenomenon is

![Figure 4.3.1](image)

**Figure 4.3.1** The heat capacity of the Dy$_5$Si$_3$Ge in a form of bulk material (solid small circles) and a compacted mixture of powder of this alloy and Ag (open large circles) from ~3.5K to 350K in zero dc magnetic field.
due to the cracks and imperfections found in the sample. The second curve in Figure 4.3.1 shows the heat capacity of a mixture of Dy$_5$Si$_3$Ge and pure Ag-metal powders compacted into a tablet under high pressure. However, the first order phase transition, which observed in the bulk alloy shows here as a second order lambda-like peak. Therefore, these samples can not be measured using a mixture of the alloy and Ag powders. 2) A second problem of not having satisfactory quality heat capacity data for the Dy$_5$Si$_4$-Dy$_5$Ge$_4$ pseudobinary system arises from a large magnetostriction effect observed in these alloys. Even though, direct measurements of magnetostriction were not performed on the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys, indirect signs provide a basis for this conclusion. The first sign of this effect is that the sample broke into several pieces, usually when a strong magnetic field (above 50kOe) was applied on the heat capacity sample. This was typically observed on the Ge-rich alloys. Therefore, when some parts of the alloy fell off the sample holder, the total heat capacity became quite small (see Figure 4.3.2). On the graph the solid small circles represent the heat capacity data for the Dy$_5$Ge$_4$ alloy in 0kOe magnetic field and the open large circles show the heat capacity data in a 75kOe magnetic field when there was almost no sample left in the sample holder. As a result, the value of heat capacity on the plot is much smaller over the entire all temperature interval and the magnetic heat capacity at the ordering temperature was not observed.

Another good example of this phenomenon is shown in Figure 4.3.3. The solid small circles represent the heat capacity data for the Dy$_5$Si$_4$ alloy in 0kOe magnetic field. The open large circles represent the heat capacity data for the Dy$_5$Si$_4$ alloy in a 75kOe magnetic field, when several pieces fell off of the sample holder during the measurements.
Figure 4.3.2 The heat capacity of the Dy$_5$Ge$_4$ alloy from ~3.5K to 350K in 0kOe and 75kOe dc magnetic fields

Figure 4.3.3 The heat capacity of the Dy$_5$Si$_4$ alloy from ~3.5K to 350K in 0kOe and 75kOe dc magnetic fields
The heat capacity vs temperature from ~3.5K to ~350K in 0, 20, and 50kOe dc magnetic fields of the Dy₅Ge₄ alloy are shown in Figure 4.3.4. The distinct feature of this alloy's heat capacity is the presence of a λ-type anomaly in the 35K-50K temperature region with a shape that corresponding to a second order magnetic phase transition. The decrease of heat capacity peak value with increase the value of magnetic field is another indicator that the transition has second order nature. The heat capacity data points are quite scattered and therefore it was not possible to calculate the magnetic entropy change and adiabatic temperature change.

Figure 4.3.4  The heat capacity of the Dy₅Ge₄ alloy from ~3.5K to 350K in 0, 20, and 50kOe dc magnetic fields
The measured heat capacities vs temperature in 0, 20, 50, 75, and 100kOe dc magnetic fields of Dy$_3$Si$_{3.5}$Ge$_{0.5}$ are shown in Figure 4.3.5. The values of the heat capacity maximum decreased at ~132K with application of dc magnetic field. The heat capacity maximum completely disappeared when 100kOe dc magnetic field was applied. The shape and the behavior of the heat capacity maxima are characteristic of a second order magnetic phase transition. The dc magnetic fields shifted the temperature of the heat capacity maximum towards higher temperatures while broadening it, which is characteristic for ferromagnets. Based on these heat capacity measurements the magnetic entropy change and adiabatic temperature change were calculated for the Dy$_3$Si$_{3.5}$Ge$_{0.5}$ alloy. First, the total entropy ($S_{\text{total}}$) as a function of temperature were determined at each of the different magnetic fields including $H = 0$ kOe. From $S_{\text{total}}$ vs $T$, the magnetic entropy change ($\Delta S_m$ vs $T$) and adiabatic temperature change ($\Delta T$ vs $T$) were evaluated and are presented in Figures 4.3.6 and 4.3.7, respectively. The peaks on both plots occurs at the Curie temperature of this alloy (~134K). The values of $\Delta S_m$ are large, but much less then for intermediate alloys with monoclinic crystal structure in the Dy$_3$Si$_{3.5}$Ge$_{0.5}$ system.
Figure 4.3.5  The heat capacity of the Dy$_5$Si$_3$Ge$_{0.5}$ alloy from ~3.5K to 350K in 0, 20, 50, 75, and 100kOe dc magnetic fields

Figure 4.3.6  Magnetic entropy change of the Dy$_5$Si$_3$Ge$_{0.5}$ alloy from ~3.5K to 350K for dc magnetic field changes up to 100kOe as determined from heat capacity measurements
The maxima of magnetic entropy change for the Dy₅Si₃.₅Ge₀.₅ alloy as shown in Figure 4.3.6 have the following values depending on applied magnetic fields:

\[-\Delta S_m (\Delta H = 20 \text{kOe}) \equiv 3.9 \frac{J}{\text{kg} \cdot \text{K}}, \quad -\Delta S_m (\Delta H = 50 \text{kOe}) \equiv 10 \frac{J}{\text{kg} \cdot \text{K}},\]

\[-\Delta S_m (\Delta H = 75 \text{kOe}) \equiv 13.5 \frac{J}{\text{kg} \cdot \text{K}}, \quad \text{and} \quad -\Delta S_m (\Delta H = 100 \text{kOe}) \equiv 17.4 \frac{J}{\text{kg} \cdot \text{K}}.\]

The maxima of adiabatic temperature change for the Dy₅Si₃.₅Ge₀.₅ alloy as shown in Figure 4.3.7 have the following values depending on applied magnetic fields:

\[\Delta T (\Delta H = 20 \text{kOe}) \equiv 2.3 \text{K}, \quad \Delta T (\Delta H = 50 \text{kOe}) \equiv 4.9 \text{K}, \quad \Delta T (\Delta H = 75 \text{kOe}) \equiv 6.7 \text{K}, \quad \text{and} \quad \Delta T (\Delta H = 100 \text{kOe}) \equiv 8.8 \text{K}.\]

It is also important to note that \(-\Delta S_m\) and \(\Delta T\) in the temperature interval from 0K and 50K exhibit a non-monotonic behavior. The origin of this anomaly is not obvious.

![Figure 4.3.7 Adiabatic temperature change of the Dy₅Si₃.₅Ge₀.₅ alloy from 3.5K to 350K for dc magnetic field changes of 0-20, 0-50, 0-75, and 0-100kOe as determined from heat capacity measurements](image-url)
Figure 4.3.8  The heat capacity of the Dy$_5$Si$_4$ alloy from $-3.5$K to 350K in 0, 20, and 50kOe dc magnetic fields

The 0, 20, and 50kOe dc magnetic fields heat capacity of the Dy$_5$Si$_4$ alloy are shown in Figure 4.3.8. The value and the shape of the heat capacity peak is almost identical to the value and the shape of the heat capacity for Dy$_5$Si$_3.5$Ge$_{0.5}$ alloy. Both alloys have the Gd$_5$Si$_4$-type orthorhombic crystal structure. The temperature of the heat capacity maximum observed at 137K. It is a second order magnetic phase transition with the characteristic $\lambda$-shape curve in vicinity of the Curie temperature. The data are only slightly scattered from the fitted smoothed heat capacity. Therefore, it is possible to calculate the magnetic entropy change and adiabatic temperature change for this alloy. Increasing the magnetic field broadens and shifts the heat capacity maximum of Dy$_5$Si$_4$ alloy towards higher temperatures. This behavior is typical for FM materials.
Figure 4.3.9  Magnetic entropy change of the Dy$_2$Si$_4$ alloy from -3.5K to 350K for dc magnetic field changes of 0-20kOe and 0-50kOe as determined from heat capacity measurements.

The magnetic entropy change in 20kOe and 50kOe dc magnetic fields are shown in Figure 4.3.9. The curves are typical for the alloys with a composition in the 0.822≤x≤1 range. There is a non-monotonic temperature interval from ~3.5K to ~20K for the 50kOe field change. The maximum $\Delta S_m$ value at 140K is equal to 5.5J/kgK in dc magnetic field 20kOe, and 11.9J/kgK in dc magnetic field 50kOe.

The adiabatic temperature change of Dy$_2$Si$_4$ in 20kOe and 50kOe magnetic fields are shown in Figure 4.3.10. The maximum value of $\Delta T$ at 140K is equal to 2.7K in dc magnetic field 20kOe and 6K in dc magnetic field 50kOe. The non-monotonic behavior from 4K to 20K is shown on the graph. A small negative value of magnetocaloric effect from 224K to 350K in 20kOe dc magnetic field is evident in Figure 4.3.10, but considering the experimental error this may not be real.
Figure 4.3.10 Adiabatic temperature change of the $Dy_5Si_4$ alloy from 3.5K to 350K for $dc$ magnetic fields changes of 0-20kOe and 0-50kOe as determined from heat capacity measurements.

The comparison of magnetic entropy change calculated from the magnetization and heat capacity data of $Dy_5Si_4$ and $Dy_5Si_{3.5}Ge_{0.5}$ in 50kOe magnetic field are shown in Figure 4.3.11 and 4.3.12. The temperatures of the $-\Delta S_m$ maximums calculated from the magnetization and heat capacity data are in a good agreement for both types experiments and equal to: 141K ($Dy_5Si_4$) and 136K ($Dy_5Si_{3.5}Ge_{0.5}$) respectively. The values of $-\Delta S_m$ calculated from different experiments for both these alloys are lying within an error range.

Figure 4.3.12 The magnetic entropy change calculated from magnetization and heat capacity data of the Dy$_3$Si$_{3.5}$Ge$_{0.5}$ alloys for a magnetic field change from 0 to 50kOe.
5. CONCLUSIONS

Polycrystals of the intermetallic compound of the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ system, where $x = 0, 0.25, 0.5, 0.625, 0.675, 0.725, 0.75, 0.775, 0.825, 0.875,$ and 1, have been prepared by electric-arc-melting on water-cooled copper hearth in an argon atmosphere.

A study of phase relationships and crystallography in the pseudobinary system Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ using X-ray powder diffraction data and optical metallography was completed. It revealed that silicides in the composition range from 0.825 to 1 crystallize in the Gd$_5$Si$_4$-type crystal structure; germanides in the composition range from 0 to 0.625 crystallize in the Sm$_5$Ge$_4$-type structure, and alloys with intermediate composition range from 0.675 to 0.775 crystallize in the monoclinic Gd$_5$Si$_2$Ge$_2$-type structure.

The $-\Delta S_m$ values were determined from magnetization measurements for 7 alloys. The alloys with a monoclinic crystal structure which belong to an intermediate phase region have large MCE value, which exceeds those observed in the other two phase regions by 300 to 500%.

The nature of the observed magnetic and structural transformations in the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ system seems to be similar with those reported for the Gd$_5$(Si$_x$Ge$_{1-x}$)$_4$ system. However, the interval and concentration range of three different phase regions in the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ system are different from that observed in Gd-based alloys.

A non-collinear ordering of magnetic moments at low temperature was observed for the alloys with monoclinic crystal structure. The Dy$_5$Si$_3$Ge alloy exhibited FM phase transition below Curie temperature.

A series of magnetic transitions were observed at low temperature in the Dy$_5$(Si$_x$Ge$_{1-x}$)$_4$ alloys. The number of transitions increased and the magnetization decreased with increasing germanium content in the alloys.

The $-\Delta S_m$ and $-\Delta T$ values were calculated from heat capacity data for Dy$_5$Si$_3$Ge$_{0.5}$ and Dy$_5$Si$_4$ alloys only, due to the fragile nature of the germanides-rich samples.

Based on the MCE values, the alloys from the orthorhombic Dy$_5$Si$_4$-based solid solution and the intermediate monoclinic phase regions may be useful magnetic refrigerant materials in the temperature range ~50K to ~160K.
