Lawrence Livermore National Laboratory, L-369 • Livermore CA 94550

ABSTRACT

We report the development and on-vehicle testing of an engineering prototype zinc/air battery. The battery is refueled by periodic exchange of spent electrolyte for zinc particles entrained in fresh electrolyte. The technology is intended to provide a capability for nearly continuous vehicle operation, using the fleet's home base for 10 minute refuelings and zinc recycling instead of commercial infrastructure. In the battery, the zinc fuel particles are stored in hoppers, from which they are gravity fed into individual cells and completely consumed during discharge. A six-celled (7V) engineering prototype battery was combined with a 6 V lead/acid battery to form a parallel hybrid unit, which was tested in series with the 216 V battery of an electric shuttle bus over a 75 mile circuit. The battery has an energy density of 140 Wh/kg and a mass density of 1.5 kg/L. Cost, energy efficiency, and alternative hybrid configurations are discussed.

INTRODUCTION

The use of electric storage batteries to power commercial and industrial fleet vehicles has a number of attractive features. The fleet's home base facilities and personnel constitute a pre-existing infrastructure for vehicle maintenance, battery recharging and technical support. Missions are often repetitive (or at least predictable), and daily usage can be high enough to allow rapid write-off of the generally high initial investment in electric propulsion. Examples of fleet electric vehicles include electric shuttle and transit busses, commercial delivery and passenger vans, enclosure-operated vehicles such as fork-lift trucks and mall shuttles, and specialty applications ranging from aircraft service vehicles to silent military equipment. To undertake long-duration missions (e.g., lasting a substantial fraction of the day), the batteries might be periodically exchanged, "opportunity" charged, or extended with heat engines. However, these approaches increase cost and servicing complexity while restricting mission flexibility.

Alternatively, the batteries may be mechanically recharged by a rapid exchange of fresh reactants for reaction products--while the products are externally recycled. In recent years, a number of efforts have been made to develop high energy density batteries which are refuelable or reconstructable [1-5], as a means of combining long range with a capability for nearly continuous use through periodic refueling.

The objectives of the battery development work reported here are: (1) develop an engineering prototype based upon our self-feeding cell invention [1]; (2) determine energy and power characteristics; (3) demonstrate rapid refueling; and (4) show that the self-feeding cell operates under representative road vibrations and accelerations.

MASTER

TECHNICAL APPROACH

System. Our approach is shown schematically in Figure 1. The battery consumes zinc metal and atmospheric oxygen, and produces a reaction product consisting of a liquid suspension of zinc oxides and potassium zincate in an alkaline electrolyte:

$$Zn + 1/2 \, O_2 \, (air) + KOH = KZnOOH_{aq} \qquad (1)$$

Refueling is accomplished by replacing the spent electrolyte with fresh electrolyte and zinc pellets. The spent electrolyte is reprocessed in equipment at the fleet's home base to recover zinc-depleted electrolyte and zinc fines, which are pressed into uniform 1 mm pellets. The cost of the recovery unit is small compared with the cost of the battery because it operates continuously and hence at a lower power level than the battery. In addition, it lacks the expensive air electrode of the zinc/air battery, which accounts for half the estimated battery cost of $50/kW.

## ZINC RECYCLE UNIT   ZINC/AIR BATTERY

Figure 1. The battery consists of a stack of bipolar cells which are gravity fed with zinc particles from overlying hoppers, and an electrolyte storage tank. Refueling exchanges spent electrolyte for fresh electrolyte with entrained zinc particles. Electrolysis equipment recycles zinc and fresh electrolyte from the spent electrolyte.

Self-feeding cell. During discharge, zinc pellets fall continuously from the overlying hopper into a narrow (<3 mm) opening at the top of each cell (Figure 2). Because the cell gap is only a few times larger than the particles, the particles do not close pack--even when subjected to strong vibrations. Rather, particle bridging and voids develop, which gives the bed an artificially low packing density of about 40%. Electrolyte flows upward through the cell and hopper to remove heat and reaction products. The expanded bed offers little resistance to electrolyte flow. The wedge-shape of the cell allows dissolving zinc particles to fall into an increasingly narrow gap to maintain the gap/particle size ratio (< 5) needed for bridging. The losses from air and electrolyte pumping and shunt currents sum to about 1% of gross power [7].

Refueling. The 1 mm particles are too heavy to be easily levitated into a uniform slurry by flowing electrolyte in the battery. Rather, the particles are pushed along the base of a horizontal fill tube common to a multicell stack by the impulse of flowing electrolyte. The

particles fall through slots (6 x 16 mm) leading into the hoppers. Because the anodes may be shorted through particles in the fill tube, it is necessary to shut off the air supply to the cells during filling and to continue electrolyte flow after filling to remove excess zinc and electrolyte from the fill tubes.

Zinc recovery and recycle Using a combined electrochemical and mechanical process, zinc pellets were produced from recycled battery reaction product. Zinc was recovered from spent battery reaction products by deposition onto a nickel substrate under conditions of current density and flow resulting in a porous deposit called "mossy zinc." This deposit is approximately 15-20 % metal. It does not adhere to the electrode but detaches under its own weight to collect at the bottom of the electrolysis cell. The deposit is pressed into 1 mm x 1 mm cylindrical pellets of 60% density using a simple pin and die press. Details of the process will be reported in a later publication. Experimental work reported here uses commercial 0.5- or 1 mm cut wire as fuel.

Figure 2. Zinc pellets or particles are stored in hoppers above individual cells, and are gravity fed into the cells. Packing and clogging in the bed are prevented by the formation of bridges and voids, allowing electrolyte to circulate freely and with low hydraulic resistance.

TECHNICAL RESULTS

Battery components. Our electrochemical cell is comprised of two components: (1) A plastic frame contains the hopper, channels for air and electrolyte circulation, seals and a porous separator [9]. (2) A bipolar plate supports both anode and cathode [8] and is provided with feed-throughs to electrically connect the adjacent cells. Up to 12 cells can be combined with the electrolyte storage tank (Figure 3). The number of cells determines power; the size of the storage tank determines energy content.

The plastic frame is shown in Figure 4. The electrode area (250 cm^2) and hopper volume (150 cm^3) are chosen to yield a peak power of about 125 W and a nominal energy of up to 525 Wh (at 1.2 kW/m^2) -- a combination anticipated for the shuttle bus application requiring a 5-10 hour rate and modest power. (Electrode area, hopper volume and storage tank volume can be varied independently to match vehicle power and energy requirements.) The long electrolyte

channels between cells reduce shunt losses for a 12 cell stack to below 0.5% of gross power. Electrolyte flows upwards at a phase velocity of 1 cm/s, while air flows downwards at 4 times the rate required by stoichiometry for 6 kA/m^2--the maximum cell current density.

The bipolar plate supports a metal basket attached to the anode surface and a ribbed frame on the cathode surface to hold the air electrode. The plate was fabricated from electronic circuit board (62 mil; both sides copper-clad; glass-filled epoxy resin).

Refueling. Refueling of a 12-cell stack of 250 cm^2 cells was developed before discharge tests. The particles were fed into the assembled stack (Figure 3) through two internal 2.5 cm diameter tubes, driven by combine flow of 4.5 L/min with a total pressure drop of 2 kPa across the stack. As shown in Figure 5, the cells filled sequentially at a rate of 4 cells per minute. Three parallel sets of three 12-cell stacks connected in hydraulic series can thus be refueled in under 10 minutes and will contain 56.7 kWh of deliverable energy [6].

Figure 3. The twelve-cell stack and electrolyte tank is shown here, assembled for refueling tests. Cooling fins (Aavid Engineering, Inc. NH) were added to the storage tank prior to discharge tests on 3- and 6-celled units.

Cell Discharge. Self-feeding cells have been tested in 80-, 250-, 600-, and 1000 cm² sizes [7]. The voltage and power curves of Figure 6 were taken in an 80 cm² cell. The structure

Figure 5. Cells of a 12-cell stack were filled sequentially with 0.5 mm zinc cut wire entrained in two parallel flows. The rate of fill was 4 cells per minute plus a 1.2 minute startup time.

Figure 4. The frame component depicted here was used in the bipolar cell stack. This plastic frame includes the hopper, the cell, and internal passages for electrolyte and air flow.

and wedge angle of this cell were reproduced in the 250-cm^2 cell used in laboratory refueling and in vehicle tests. After refueling tests on the twelve-cell stack, this stack was disassembled for tests in multiples of 1, 3, and 6 cells together with the same storage tank (sized for 12 cells) and auxiliaries.

The three cell stack was discharged for five hours then held on standby for 12 days, while the cells remained filled with cold, supersaturated electrolyte and the air flow was shut off. No deterioration in the polarization curves was noted following reactivation. This indicates that the strongly reducing potential of the oxygen-depleted zinc-filled cells does not cause deterioration of the separator or the air electrode catalyst.

The six cell stack (the largest discharged) was tested on board the electric bus, with the storage tank half filled with electrolyte. The power and voltage of the stack (averaged per cell) are plotted against current density in Figure 7. Superimposed are the voltage and power curves for the 80 cm^2 cells (Figure 6). The difference in voltage and power density is attributed to the use of conductive silver-loaded epoxy resin cement to connect air electrodes to their substrates rather than the solder connection used in the smaller cells. The 10 °C lower temperature of operation also lowered the power density because of the lower electrolyte conductivity.

Figure 6. Power densities and voltages are given for discharge of the 80 cm^2 cell at a temperature of 65 °C. Curves are for three levels of electrolyte ampere-hour loading: (a) 36 Ah/liter; (b) 54 Ah/liter; and (c) 126 Ah/liter. The cell configuration and wedge angle were replicated in the 250 cm^2 cells.

Vehicle Test Configuration and Results. On-vehicle tests were conducted in order to demonstrate the operation of the self-feeding cells under typical driving vibrations and accelerations, and to demonstrate a multicell level of system integration. The Santa Barbara Metropolitan Transit District (SBMTD) provided us with a 22 foot electric shuttle bus (Figure 9) for purposes of conducting this test. One 6-cell (7 V) battery was cabled in electrical parallel with a lead/acid battery consisting of three cells (6V; Chloride Motive Power, Ltd., Model

S32Y11) to form the basic unit of a parallel-configured dual-battery hybrid power source. This unit was placed in series with 108 lead/acid cells of the same model (216 V) which normally provide all power. Both batteries in the hybrid unit were protected against reverse polarization with 300 A diodes. Current and voltage were monitored for each zinc/air cell, for the zinc/air stack, and for the drive train. A second on-board computer allowed measurement of power and total energy use with a 4-second time constant for the battery train. The bus was driven on a paved street around a 2 mile loop for 5 hours (including a 1 hour rest) until the lead/acid battery train was 80% discharged. Test conditions and salient results are reported in Table 1.

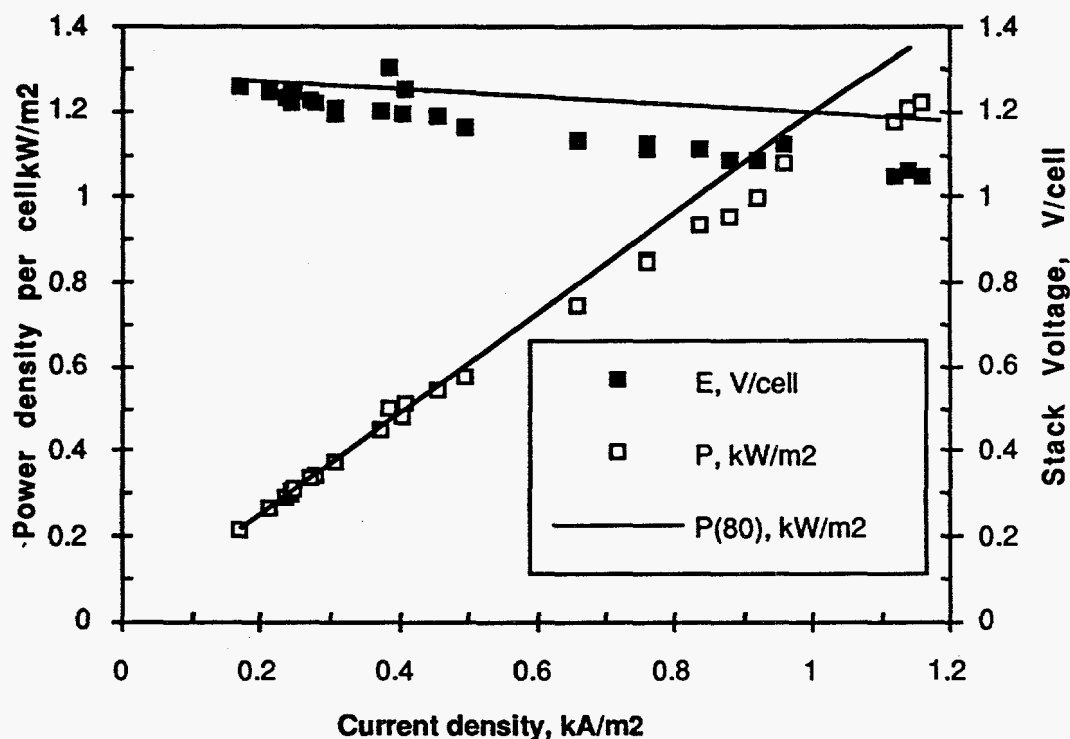

Figure 7. Cell voltage and power density (averaged per cell) are plotted against current density for the 6 cell stack at 55±1 °C. The power density and voltage curves from Figure 6 are superimposed. The difference reflects the lower temperature of operation and the use of a poorly conductive silver epoxy cement to bond the air electrode to its supporting conductor.

Table 2 tabulates the weights of the components and reactants used in the test. Energy yield is determined by the amount of consumable zinc with the electrolyte as the limiting reactant. The weights of the test cells are reported. One-half of the weight of the 12-cell tank was counted for this 6-cell test. Air pumps, scrubbers and motors will serve the entire vehicle battery array; accordingly, the value reported is based on available equipment pro-rated from 55 kWh scale down to the 6-cell battery. A specific energy of 127 Wh/kg is indicated for the test equipment. The listing for production units (141 Wh/kg) is based on the same chemistry and configuration, but with 10% additional zinc and electrolyte. The production battery figure also assumes use of lightened cell frames constructed of filled polymers and transfer plates of 40 mil board with removal of unused cladding. We can fill the production cell hoppers to capacity and increase electrolyte and tank size accordingly, which leads to an energy density of 150 Wh/kg. These differences will be seen to be insignificant for a bus battery, as this spread (127-150 Wh/kg) corresponds to about a 1 % spread in resultant vehicle weights with the same range.

Table 1. Test Conditions and Results for on-vehicle test of zinc/air in dual-battery hybrid power source

| Parameter	Value	Comments
Bus test weight	5700 kg	includes crew and test equip.
Pb/acid drive battery weight	2030	108, 2-V Chloride Power cells plus 3 cells parallel with 6-cell Zn/air
Duration of test drive	5.0 hours	(includes ~ 1 hour rest; 75 stops)
Distance driven	120.7 km	
Time-average speed	24 km/h	(average drive speed ~ 30 km/h)
Cycle length	3.22 km	
Total energy consumption	35.748 kWh	at battery terminals, including test unit
Energy processed from test unit	966 Wh	at unit terminals
Energy from zinc	554 Wh	at zinc/air terminals
Energy from Pb and controls	412 Wh	incl. ~ 12 Wh dissipated in controls
Fraction of energy from Zn	57-58%	
Initial charge of zinc battery	3300 Wh	Electrolyte is limiting reactant
Depth of discharge of zinc	17%	
Figure 8. Instantaneous power, integrated power from zinc/air and time-averaged total energy from parallel unit is plotted against drive time for a 330 s, 3.22 km (2 mile) cycle. (Cycle No. 32). This part of the on-vehicle test was conducted at lower-than-optimum temperature of 42 °C.

While the peak rated power of the cells (750 W) and weight (26 kg) might suggest a low "specific power" of only 30 W/kg, such a conclusion would be misleading. The weight and volume of this kind of battery is dominated by the weight and volume of reactants and not by the weight and volume of the cells. Tripling the electrode area for the same tank and amount of reactants would triple the power to 2.25 kW. However this increase would add < 3 kg (or 10%) to weight to the battery -- an amount representing the additional electrodes and support (lower

part of the cell, Figure 4). Unlike secondary and reconstructable zinc/air batteries, the energy and power of this battery are independent parameters and can be adjusted to meet the needs of the vehicle. Specific power has no unique meaning here, and cannot be used as a scale factor.

Rather, weight and volume can be estimated from the separate coefficients for peak power and nominal energy. The coefficients 2.8 kg/kW-peak and 6.5 kg/kWh-nominal can be derived from the "production" column in Table 2. The corresponding volume coefficients are 3 L/kW-peak and 4 L/kWh-nominal. Thus the weight of a 27 kW-peak battery delivering 46.8 kWh of energy at 80% DOD is 456 kg and occupies about 315 L (11 ft^3). Because of the zinc reserve in each cell, the battery can be discharged to 100% DOD without harm.

Table 2. Battery component weights (6-cell stack and down-sized tank); Peak rated power, 750 W.

Component	Test equipment kg	Production units kg	Projected units kg
Cells, empty (6)	2.8	1.7	1.5
Zinc (consumed fuel)	3.3	3.6	4.8
Zinc (cell reserve)	0.3	0.3	0.3
Electrolyte: 250 AH/L, set as limiting reactant)	15.2	16.5	22
Tank (1/2 of 12-cell)	2.4	1.5	2.0
Auxiliaries[b]	2.0	2.0	1.5
Total weight	26	25.6	32.1
Energy yield[a]	3300 Wh	3600 Wh	4800 Wh
Specific Energy	127 Wh/kg	141 Wh/kg	150 Wh/kg

[a]Based on consumable zinc fuel; excludes undischarged zinc reserve of 8-10% in cells.

[b]Auxiliaries (air pumps, motors and scrubbers) serve entire battery arrays; quoted values are pro-rated to 6-cells.

Table 3. Comparison of lead/acid and zinc/air (specific energy, 141 Wh/kg) in shuttle bus on SBMTD urban duty cycle.

Battery	Test weight kg (lb)	Battery weight[a] kg (lb)	Battery volume, L (ft^3)	Required energy[b] kWh	Efficiency, %	Energy use kWh	Range km (mi)
Lead/ acid	5682 (12,500)	1977 (4,350)	794 (28)	46.8	70	66.8	116 (72)
Zn/Air	4161 (9,154)	456 (1,003)	315 (11)	46.8	60	78	158 (98)
Zn/Air	4052 (8,914)	347 (763)	248 (9)	33.4	60	56	116 (72)

[a]Zinc/air weight is weight to deliver required energy at 80% exhaustion of consumable reactants from a battery of specific energy, 141 Wh/kg.

[b]Vehicle energy-use scale factor is 256 kJ/tonne-km (104 Wh/ton-mile) for the urban driving cycle.

In Table 3, we have calculated the weight and volume of the zinc/air battery that might be used on the SBMTD shuttle bus in its current duty cycle. Keeping either delivered energy constant (at 80% DOD) or the range constant, we have calculated reduced vehicle mass and total AC energy consumption using a vehicular specific energy consumption rate of 104 Wh/ton-mile (SBMTD data, from the Santa Barbara Waterfront Route). Keeping range constant, the vehicle gross weight drops by 1600 kg--equivalent to 20 passengers. Despite the lower energy efficiency of the zinc/air battery, total energy use is 20% lower than that of the lead/acid-powered bus because of the lower vehicle mass, all else being equal. The scaling of the zinc/air battery is

based on the mass and volume coefficients of power and energy, with energy computed at 80% exhaustion of available energy. Tire and brake life and handling are also improved by weight reduction. The number of cells is fixed at 216 (1.23 V nominal) and the peak rated power is 27 kW. The power can be altered by altering the cell size or the number of cells.

ECONOMY, ENERGY USE AND HYBRID CONFIGURATIONS

Any detailed cost estimate is beyond the scope of this work. However, the 20% reduction in weight and energy use for fixed range and mission (passenger-miles) indicates a significant reduction of energy cost and tire and brake ware. The cost of zinc/air battery is dominated (>50%) by the cost of the air electrode and its supporting structure, which we estimate to be $50/kW-peak + $2/kWh-capacity from a large-scale cathode production cost of $120/m^2 (using continuous production techniques and cobalt macrocyclic catalysts).

The zinc battery described in Table 3 has sufficient power for the bus, giving the vehicle a power/weight ratio of 6.8 W/kg-gross (vs. the 5.2 W/kg-gross available with lead/acid). Nonetheless, consideration of a power leveled, parallel hybrid is encouraged for three reasons: (1) the power/weight ratio can be increased greatly, giving the vehicle greater route flexibility and highway-safe acceleration; (2) regenerative braking becomes possible, increasing efficiency by ca. 10 %; and (3) the life of the air electrode is maximized when current peaks are avoided. The electrodes used in this test operated without failure or serious deterioration for over 12,000 hours in a 7.5 M KOH + 1 M aluminate electrolyte at 60 °C and 2 kA/m^2[8].

CONCLUSIONS

The essential objectives of this on-vehicle test were met. The self-feeding cells functioned correctly over the 5 hour test, without becoming clogged or starved. The refueling tests (on the 12 cell stack) showed filling rates of 4 cells/minute, which allows any number of parallel sets of 36 cells (19 kWh per set) to be filled in parallel in 10 minutes. The battery functioned in a hybrid with the 6 V lead/acid pack, which was subjected to a rigid (high impedance) current source and a pulse-width modulated controller. The indicated specific energy (based on the electrolyte reactant limited to 250 Ah/L) was 141 Wh/kg, for laboratory test cells reduced to commercial production techniques. A disappointing feature of this work was the lower power obtained from the stack--the consequence of the use of conductive silver-epoxy rather than low-melting solder, cold bonding, or leaf metal bonding techniques used elsewhere for connecting air electrode screen substrates to conductors. Subsequent tests of the battery will correct this deficiency.
