Actinide Chemistry Research Supporting the Waste Isolation Pilot Plant (WIPP): FY94 Results

C.F. Novak, Editor
Dept. 6119, Chemical Processes Department
Sandia National Laboratories
Albuquerque, NM 87185

ABSTRACT

This document contains six reports on actinide chemistry research supporting the Waste Isolation Pilot Plant (WIPP). These reports, completed in FY94, are relevant to the estimation of the potential dissolved actinide concentrations in WIPP brines under repository breach scenarios. Estimates of potential dissolved actinide concentrations are necessary for WIPP performance assessment calculations. The specific topics covered within this document are: the complexation of oxalate with Th(IV) and U(VI); the stability of Pu(VI) in one WIPP-specific brine environment both with and without carbonate present; the solubility of Nd(III) in a WIPP Salado brine surrogate as a function of hydrogen ion concentration; the steady-state dissolved plutonium concentrations in a synthetic WIPP Culebra brine surrogate; the development of a model for Nd(III) solubility and speciation in dilute to concentrated sodium carbonate and sodium bicarbonate solutions; and the development of a model for Np(V) solubility and speciation in dilute to concentrated sodium perchlorate, sodium carbonate, and sodium chloride media.

PREFACE

This report presents actinide chemistry research completed in fiscal year 1994 (FY94) in support of the Waste Isolation Pilot Plant (WIPP). This work provides information funded by the Actinide Source Term Program (ASTP) and the Gas Generation Program (GGP) that is relevant to estimation of the dissolved actinide concentrations that could be present in WIPP brines under repository breach scenarios.

FY94 was a transition year for actinide chemistry research for the WIPP. The research was refocused toward determining actinide-bearing solid phases, and the variation of dissolved concentrations in equilibrium with these solubility-controlling phases, as a function of background electrolyte concentrations. This information is interpreted with a thermodynamic formalism and the Pitzer activity coefficient model, which is valid to the high ionic strengths of WIPP brines. FY94 results represent a mix of the older and newer approaches to obtaining information necessary for estimating mobile dissolved actinide concentrations for the WIPP.

This document contains six reports:

- H.N. Erten, A.K. Mohammed, and G.R. Choppin, "Variation of Stability Constants of Thorium and Uranium Oxalate Complexes with Ionic Strength," SAND93-7112C;
- D.T. Reed, S. Okajima, and M.K. Richmann, "Stability of Plutonium(VI) in Selected WIPP Brines," SAND93-7114C,
- F.I. Khalili, V. Symeopoulos, J.-F. Chen, and G.R. Choppin, "Stability of Nd in Brine," SAND93-7113C;
- H. Nitsche, K. Roberts, R. Xi, T. Prussin, K. Becraft, I. Al Mahamid Al Rifai, H.B. Silber, S.A. Carpenter, R.C. Gatti, and C.F. Novak, "Long Term Plutonium Solubility and Speciation Studies in a Synthetic Brine," SAND93-3846C;
- L. Rao, D. Rai, A.R. Felmy, and R.W. Fulton, "Solubility of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ in Concentrated Sodium Carbonate and Sodium Bicarbonate Solutions," SAND94-1948J; and
- C.F. Novak and K.E. Roberts, "Thermodynamic Modeling of Neptunium(V) Solubility in $\text{Na-CO}_3\text{-HCO}_3\text{-Cl-ClO}_4\text{-H-OH-H}_2\text{O}$ Electrolytes," SAND94-0805C.

The first four papers (Erten et al., Reed et al., Khalili et al., Nitsche et al.) were presented at the Fourth International Conference on the Chemistry and Migration Behavior of Actinides and Fission Products in the Geosphere, "Migration '93," held in Charleston, South Carolina on 12-17 December 1993, and will be published in the Proceedings. The fifth paper (Rao et al.) has been accepted by the journal *Radiochimica Acta* for publication. The sixth paper (Novak and Roberts) was presented at the XVIII International Symposium on the Scientific Basis for Nuclear Waste Management, held in Kyoto, Japan, on 23-27 October 1994, and will be published in the Proceedings. Articles may appear in slightly different form in these publications.

Erten et al. measured the complexation of oxalate with thorium(IV) and with uranium(VI). Oxalate is one of the organic ligand constituents of transuranic waste intended to be stored in WIPP. Organic ligands hold the potential to increase actinide dissolved concentrations by forming aqueous complexes, and this work examined this phenomenon.

Reed et al. presents information on the stability of Pu(VI) in a brine environment both with and without carbonate present. These experiments were designed for gas generation studies, so the plutonium chemistry information that can be inferred from them is limited. However, this work demonstrates some of the Pu(VI) concentrations that can be maintained in WIPP brines, particularly the stabilizing role of the carbonate anion.

Khalili et al. documents measurements of the solubility of Nd(III), a chemical analog for Am(III) and Pu(III), in a WIPP Salado brine surrogate as a function of hydrogen ion concentration. Excess Nd(III) was added and allowed to precipitate while holding the hydrogen ion concentration constant. The steady-state dissolved concentrations were measured and the solid phase was characterized for each set of chemical conditions. The Nd(III) solid phases found in these experiments served to guide current study of the dissolved concentrations of +III actinides.

Nitsche et al. presents measurements of dissolved plutonium concentrations in a synthetic Culebra brine called H-17 Brine. Plutonium was added in five different forms, Pu(III), Pu(IV), Pu(V), Pu(VI), and Pu(IV)-polymer, and allowed to react in the brine for about 700 days. The

plutonium oxidation state was not controlled, although the hydrogen ion concentration was controlled and a constant $\text{CO}_2(\text{g})$ partial pressure was maintained. This work provides information on time scales required to reach steady-state, the steady-state oxidation state distribution of Pu in an oxic brine environment, the plutonium-bearing solid phases that formed, and the dissolved plutonium concentration under one set of chemical conditions.

Rao et al. determined the Nd(III) solid phases that control the neodymium solubility in sodium carbonate and sodium bicarbonate solutions. They developed a thermodynamic model using the Pitzer activity coefficient formalism to describe these data. This paper represents the type of research that is currently being performed to develop dissolved concentration models for actinides in WIPP brines. The thermodynamic parameters contained in this paper were based on available data. Additional data from experiments in progress may lead to refinement of the parameter values to describe chemical systems with greater composition ranges.

Novak and Roberts performed an extensive review of the literature to gather the existing data for the solubility and speciation of Np(V) in $\text{NaClO}_4/\text{Na}_2\text{CO}_3/\text{NaCl}$ solutions. Literature data was augmented with additional experiments, and a consistent dissolved concentration model was developed from this information. This model was compared with data for the solubility of Np(V) in two WIPP Culebra brines under one set of conditions. This work represents the type of assessment that is being performed for each of the actinides important to WIPP, in conjunction with laboratory work.

ABSTRACT

The extraction of Th(IV) and UO_2^{2+} by a solution of TTA and HDEHP, respectively in toluene has been used to obtain stability constants of their oxalate complexes at 298 K in 1, 3, 5, 7 and 9 M ionic strength (NaClO_4) solutions. The complexes formed were the MOx , MHOx , MOx_2 and $\text{M}(\text{HOx})_2$ ($\text{M} = \text{Th}, \text{UO}_2$) species. The values were analyzed by the Specific Interaction Theory and agreed to $I \leq 3 \text{ M}$ but required an additional term for fitting at $I > 3 \text{ M}$.

INTRODUCTION

The use of nuclear energy requires an ability to dispose safely of the resulting nuclear wastes. The solution chemistry of the actinides in connection with nuclear fuel reprocessing cycles as well as with their behavior in the environment associated with geological repositories is of major interest presently. The hydrolysis of actinide cations in natural waters can limit their solubility, lead to precipitation or sorption, and reduce complexation by other ligands in the waters. For modeling requirements, stability constant values are necessary for the ligands of interest in natural waters as well as hydrolysis constants. Normal titration techniques to determine such constants require relatively high metal ion concentrations which may be prevented by hydrolysis. Furthermore, such concentrations can lead to radiolysis which can complicate the measurements and perturb the results. These difficulties can be avoided by using solvent extraction techniques with tracer concentrations of the metal ions [1-4].

In this study, the stability constants of thorium and uranium oxalate complexes were measured over a range of ionic strengths.

The distribution coefficient, D , is defined for the extraction system as:

$$D = \Sigma [M]_o / \Sigma [M]_a \quad (1)$$

Assuming only a single organic phase species, MA_n , and the various species in the aqueous phase, equation (1) can be expressed by:

$$D = [MA_n]_o / ([M]_a + [ML]_a + [MHL]_a + [ML_2]_a + [M(HL)_2]_a + \dots) \quad (2)$$

where L is a complexing anion in the aqueous phase. This equation can be written, with the conventional symbols for stability constants, [5] as,

$$D = [MA_n]_o / [M]_a (1 + (\beta_{101} + \beta_{111} [H]) [L] + (\beta_{102} + \beta_{122} [H]^2) [L]^2 + \dots) \quad (3)$$

We define "apparent" stability constants as:

$$\beta_1^{app} \equiv \beta_{101} + \beta_{111} [H] \quad (4)$$

$$\beta_2^{app} \equiv \beta_{102} + \beta_{122} [H]^2 \quad (5)$$

The constant in the absence of complexation is:

$$D_o \equiv [MA_n]_o / [M]_a \quad (6)$$

This allows restating equation (3) as:

$$D_o/D = 1 + \beta_1^{app} [L] + \beta_2^{app} [L]^2 + \dots \quad (7)$$

A plot of β_1^{app} vs. [H] should give a straight line with an intercept equal to β_{101} and a slope of β_{111} while a plot of β_2^{app} vs. $[H]^2$ should be linear with an intercept of β_{102} and a slope of β_{122} .

EXPERIMENTAL

Reagents and Solutions

All reagents were analytical grade. A stock solution of 0.0010 M sodium oxalate (Aldrich) was prepared. Thenoyltrifluoroacetone, TTA, was purified by sublimation. A 0.01 M stock solution of TTA in toluene was stored in the dark. Di-(2-ethylhexyl) phosphoric acid, HDEHP, (Pfaltz and Bauer Co.) was purified by precipitation as $Cu(DEHP)_2$ using the procedure of McDowell et al. [6] The purified HDEHP was dissolved in toluene and standardized with standard NaOH solution. Sodium perchlorate (anhydrous, Mallinckrodt) was used for ionic strength adjustment without further purification.

^{230}Th tracer (from Oak Ridge National Laboratory) was prepared in a solution of pH 2 (HClO_4) such that 10 μL contained ca. 4.5×10^4 cpm. ^{233}U tracer (Oak Ridge National Laboratory) was evaporated to dryness and dissolved in a pH 3 (HClO_4) solution such that 10 μL of the solution had a count rate of 3.5×10^4 cpm. These count rates were obtained with the same efficiency as for the samples from the solvent extraction measurements. All solutions used in the experiments were filtered with a 0.45 μm microfiltration system. Contamination from airborne particles was reduced by performing the experimental manipulations in a laminar flow hood (Environmental Air Control, Inc.)

Silanizing

To minimize the sorption of the uranyl and thorium radiotracers on extraction vials, the latter were silanized according to the process in reference [3]. The 20 mL standard borosilicate scintillation vials were washed with 1 M NaOH, soaked in 3 M HCl, rinsed and dried at 100° C. The precleaned vials and their caps were silanized by shaking for 4-6 hours in a solution containing 5% trimethylchlorosilane and 5% hexamethyldisilazane in toluene. The vials were dried overnight at 120°C.

pCH Measurements

A research pH meter (Accumet 950, Fischer Scientific) was used with a combination glass electrode. The KCl solution in the salt bridge was replaced with NaCl solution, as the low solubility of KClO_4 at high ionic strengths causes erratic readings. The electrode was calibrated with 4.01 ± 0.01 and 7.00 ± 0.01 pH buffer

standards. The pH readings were converted to hydrogen ion concentration (pCH) using calibration curves obtained by a series of HClO_4 dilutions in 1 to 9 M NaClO_4 solutions.

Radioactive Tracer

The radioactive tracers used were checked for radioactive purity by alpha and gamma ray spectrometry. The alpha radioactivity in aliquots from the experiments was counted on a Packard Instrument Tri-Carb 4000 (Hewlett Packard Instruments) liquid scintillation counter using an emulsion scintillation cocktail (Ecolume, ICN Biomedicals Co.) for both aqueous and organic phases.

Experimental Procedure

Determination of the Dissociation Constants of Oxalic Acid

The pK_a values of oxalic acid were determined at 3, 5, 7, and 9 M ionic strengths by potentiometric (NaClO_4) titration. The titrations were carried out using 40 mL solutions in a 150 mL vessel. A water bath maintained at $25 \pm 0.2^\circ \text{C}$ was used for circulating water in the jacket of the titration vessel. The Gran method was used for calibrating the glass electrode at each ionic strength [7, 8]. A standardized solution of 0.1 M HClO_4 (in NaClO_4 of a certain ionic strength) was titrated against a volume V_0 of NaClO_4 of the same ionic strength as that of HClO_4 . The exact concentration of the titrant (HClO_4 in NaClO_4) was determined by titrating a known amount of Na_2CO_3 using bromocresol green as indicator. The titration used constant amounts of titrant for each addition. The data analysis of pK_a determination was done by using the Fortran program HNFITMQ [9].

Solvent Extraction Procedure

For each extraction experiment, 5.0 mL of pre-equilibrated aqueous solution adjusted to the appropriate pH were placed in silanized vials. Aliquots of oxalate stock solution were added to each vial followed by 5 mL of TTA and HEDHP in toluene. The concentration of the organic extractant was adjusted according to the ionic strength and pH of the solutions used. After addition of 10 μ L of either ^{230}Th or ^{233}U , the vials were shaken for 2 - 3 hours at room temperature. Kinetic measurements indicated that equilibrium was attained in these experiments in about 10 min. (Th) and 1 hr. (U). The vials were centrifuged and duplicate aliquots from both phases were taken for counting and pH measurement.

RESULTS

Dissociation Constants Of Oxalic Acid

The experimental acid dissociation constants of oxalic acid are given in Table I. pK_a values up to 3 M ionic strength are reported in the literature [10]. The pK_{a1} values have somewhat larger errors than those of pK_{a2} , reflecting the increased difficulty in determining the values for pK_{a1} .

The Thorium Oxalate Complexes

Speciation calculations of the oxalate ligand indicate that in the pH range of these studies the predominant species is the protonated anion HOx^- .

TABLE I

Dissociation Constants of Oxalic Acid at Different
Ionic Strengths (NaClO_4) and $T = 298\text{K}$.

<u>I (M)</u>	<u>pK_{a1}</u>	<u>pK_{a2}</u>
1	$1.04 \pm 0.04^{[10]}$	$3.56 \pm 0.02^{[10]}$
3	$1.3^{[10]}$	$3.81^{[10]}$
	$1.0 \pm 0.3 (\text{p.w.})$	$3.85 \pm 0.1 (\text{p.w.})$
5	2.19 ± 0.04	4.47 ± 0.01
7	2.61 ± 0.04	4.91 ± 0.01
9	2.26 ± 0.08	5.20 ± 0.01

Metal Oxalate Complexation

A series of experiments covering pH's from 1.5 to 4.0 were conducted at ionic strengths of 1, 3, 5, 7, and 9 M NaClO₄. The concentration of oxalate anion in each vial was calculated from the measured pcH, the total oxalate and the pK_a values of oxalic acid.

Typical curves showing the variation of 1/D with oxalate anion concentration at different pcH values are shown in Figure 1. The data were analyzed with Eq. 7 when nonlinear curves were obtained over higher oxalate ranges as this indicates the presence of both 1:1 and 1:2 complexes. From analysis of the curves, the apparent stability constants β_1^{app} and β_2^{app} were obtained as listed in Tables II, III and IV. These values represent results of at least two determinations. The relationship of these apparent stability constants to the β_{101} , β_{111} , β_{102} , and β_{122} stability constants are given by equations (4) and (5). Figure 2 is a plot of the apparent β_1^{app} as a function of hydrogen ion concentration. The intercept and slope of the linear least squares fit correspond to β_{101} and β_{111} , respectively. This technique where by the perturbation of complexing by oxalate due to competitive hydrolysis can be used only where hydrolysis has not proceeded too far. The deviation from linearity at low [H⁺] in Figure 2 reflects this problem which is also observed by a poor mass balance due to sorption and/or precipitation of the neutral hydroxide. The slope at higher [H⁺] values becomes unreliable due to small degree of complexation and the values at pcH 1.29 and 1.40 have not been included in Figure 2.

Figure 2. Variation of the apparent stability constant, β_1^{app} , for thorium plus oxalate complexes as a function of hydrogen ion concentration at 1 M ionic strength

The β_{101} , β_{102} , β_{111} , and β_{122} values are given in Tables V (a) and (b) where the errors indicated represent 1σ .

DISCUSSION

The bonding of Th(IV) to inorganic and organic ligands in complexes can be described by an ionic model. As a result the number of ligands as well as their geometric arrangement about the thorium cation are determined primarily by electrostatic and steric factors. The hydrolysis of Th(IV) can be extensive even in relatively acidic solutions ($\text{pH} \geq 1$). Since most organic ligands involving carboxylate groups (e.g., oxalate) require pH values of 3 or higher in order to provide enough ionization of the ligand for interaction, studies of thorium complexation are limited due to hydrolytic competition. Only a single study exists in the literature of the stability constants β_{101} and β_{102} of thorium-oxalate complexes in perchlorate solution [11] obtained from solubility measurements. Our values are not in agreement with these data.

Uranyl ion, UO_2^{2+} , does not hydrolyze as readily and has been studied more extensively than thorium. Stability constants for the UO_2^{2+} -oxalate system are available in the literature for 4 M ionic strength [11, 12, 13] and below. In the present work, we obtained a $\log \beta_{101}$ of 6.00 ± 0.05 which compares well with that reported at 4M [13].

The Nuclear Energy Agency has recommended [14] the use of Specific Ion Interaction Theory (SIT) in the analysis of stability

(b) Stability Constants of UO_2^{2+} + Ox Complexes

<u>I (M)</u>	<u>$\log \beta_{101}$</u>	<u>$\log \beta_{111}$</u>	<u>$\log \beta_{102}$</u>	<u>$\log \beta_{122}$</u>
1	5.99 ¹¹			
3	6.00 ± 0.05	7.57 ± 0.06	11.21 ± 0.18	
5	6.55 ± 0.28	9.22 ± 0.17	12.28 ± 0.11	18.86 ± 0.15
7	6.55 ± 0.33	10.43 ± 0.07	12.94 ± 0.40	20.04 ± 0.42
9	7.37 ± 0.05	10.06 ± 0.02	14.08 ± 0.11	19.48 ± 0.59

constants measured at different ionic strengths up to ca. 3m. In the SIT approach, the value of the stability constant at zero ionic strength, β^0 , is related to the value β^I at ionic strength I (in molality) by:

$$\log \beta^I = \log \beta^0 + \Delta Z^2 \cdot D - \Delta \epsilon \cdot I \quad (8)$$

Here,

$$\Delta Z^2 = (Z_{ML})^2 - Z_M^2 - Z_L^2 \quad (9)$$

and

$$D = 0.509 I^{1/2} / (1 + 1.5 I^{1/2}) \quad (10)$$

$$\Delta \epsilon = \epsilon_{ML} - \epsilon_M - \epsilon_L \quad (11)$$

Where Z is the charge on the designated species and ϵ is an interaction coefficient for the cation and anion pair. Values of $\log \beta$ predicted by the SIT agree well with the experimental values from 0 to ca. 3 M ionic strength. Above $I = 3$ M there is usually a growing difference between the experimental data and the SIT calculation.

Recently an extension of the SIT treatment has been proposed [15] to cover higher ionic strengths by including a quadratic term of the interaction, $+\Delta\delta \cdot I^2$, in equation (8). The results of extended SIT analysis of our data are given in Table VI which Figure 3 illustrates the extended SIT fitting of the ThOx^{2+} complex stability constant. This extension of the S.I.T. treatment to higher ionic strengths is empirical and, generally, analyses at such ionic strengths have used the Pitzer formalism [16]. We have

Plutonium / Waste Isolation Pilot Plant (WIPP) / Speciation / Spectroscopy

Abstract

The redox stability of plutonium (VI) in WIPP brine was investigated by monitoring the oxidation state as a function of time using a combination of absorption spectrometry, radiochemical counting and filtration. Studies were performed with Pu-239 and Pu-238 in four WIPP brines at concentrations between 10^{-3} and 10^{-8} M for durations as long as two years. Two synthetic brines, Brine A and ERDA-6, and two brines collected in the WIPP underground, DH-36 and G-Seep, were used. The stability of Pu(VI) depended on the brine composition and the speciation of the plutonium in that brine. When carbonate was present, a stable Pu(VI)-carbonate complex was observed. In the absence of carbonate, Pu(VI) hydrolytic species predominate. These species had a wide range of stability in the brines investigated. The reported results will help define the speciation of plutonium in WIPP brine and its potential for migration.

Introduction

Herein, we report the results of work that was done in support of gas generation experiments with Pu-spiked brines performed for the Waste Isolation Pilot Plant (WIPP) [1-4]. It is important to note that the primary objective of these experiments was to establish the stability of plutonium in solution rather than its solubility in WIPP brine. Qualitative information on the likely speciation of plutonium in the systems we studied is also reported. Both the speciation and stability data are limited and should be interpreted in the context of all the work being sponsored by the WIPP to address the issue of plutonium solubility.

*Currently resides in Woodridge Illinois

The WIPP, located in the Salado bedded salt formation in southeastern New Mexico in the northern portion of the Delaware Basin, is being investigated as a site for final disposal of transuranic (TRU) waste [5,6]. The predominant actinide in TRU waste will be plutonium-239 which is present at levels of up to 10 grams per waste drum. The most likely scenarios leading to plutonium migration from the WIPP are human intrusion and brine inundation which may mobilize the plutonium as an aqueous species. The speciation and solubility of plutonium under this latter scenario, therefore, are potentially important factors in evaluating the long-term performance of the WIPP.

The key parameters that define the speciation and solubility of plutonium in WIPP brines are redox conditions, pH, carbonate concentration, organics present, degree of aggregation, and inorganic complexation. The operational pH (pH_{Op}) of all four WIPP brines investigated was typically in the range of $\text{pH} = 6$ to 7 . This was measured by a Ross electrode and uncorrected for ionic strength. The actual pH in these systems is approximately 0.5 to 1 pH unit higher than we measured when corrected for ionic strength [7, 8]. In this pH range, Pu(VI) is readily hydrolyzed in the absence of strong complexants. Of the anions present in WIPP brines (e.g., halides, carbonate/bicarbonate, and sulfate), only the carbonate/bicarbonate species are expected to be important. The formation constants [9, 10] for these species are not well established in dilute systems and are less well-defined in high-ionic-strength media. Spectra obtained in our laboratory relevant to Pu(VI) speciation in WIPP brine are shown in Figure 1 and are consistent with those reported elsewhere [10-13].

Experimental

We established the redox stability of Pu(VI) in WIPP brine by monitoring the oxidation state as a function of time using absorption spectrometry. Studies were performed with $\sim 10^{-3}$, 10^{-4} , 10^{-6} , and 10^{-8} M Pu(VI) in four WIPP brines. Two of these were synthetic brines designated Brine A and ERDA-6. The other two were brines collected in the WIPP underground designated DH-36 and G-Seep. The composition of these brines is given in Table 1.

Fig. 1. Absorption spectra of Pu (VI) species relevant to WIPP brine: (a) 0.0029 M Pu (VI) in 0.01 M carbonate at $\text{pH}_{\text{OP}} = 6.9$, (b) Pu (VI) in presence of chloride at $\text{pH}_{\text{OP}} = 3$, (c) 2×10^{-4} M Pu(VI) aquo ion ($\text{pH}_{\text{OP}} = 2.8$) and hydrolytic species ($\text{pH}_{\text{OP}} = 6.9$)

¹Based on recipe provided by the WIPP

²As-received analysis of brine collected underground at the WIPP

³Obtained using a combination Ross electrode and uncorrected for ionic strength

Plutonium-239, >99% isotopic purity, was received from Oak Ridge National Laboratory and oxidized to the VI state in 50 mg quantities by taking to near-dryness in perchloric acid. The Pu(VI) was dissolved in triple-distilled water and analyzed for oxidation-state purity using absorption spectrometry. We used the absorption at 622 nm with $\epsilon = 7.5 \text{ M}^{-1}\text{cm}^{-1}$ [13] to estimate the plutonium concentration and establish the dilution sequence needed to prepare a solution with the desired plutonium concentration in the WIPP brine.

The pH_{OP} of the stock solution prepared in this way was typically about 1. This was adjusted to a near-neutral pH_{OP} , to match the pH_{OP} of the brine, by adding sodium hydroxide. This solution was sequentially diluted twice into the brine of interest to minimize change in the concentration of the bulk constituents of the brine. After each dilution, the solution was checked for evidence of precipitation. This twice-diluted Pu-spiked brine typically had a plutonium concentration of $\sim 10^{-3} \text{ M}$ and corresponds to the $2 \times 10^{-3} \text{ M}$ solutions identified in Table 2. Additional brine was added to a final volume of 30 to 1000 mL to generate samples with lower plutonium concentrations. These solutions were equilibrated for 3-7 days before taking a sample for alpha scintillation counting. This was done with a Packard Model 2050 alpha scintillation counter by adding a small aliquot of the Pu-spiked brine to Ultima-Gold cocktail and comparing the results against a series of plutonium stock samples prepared in the same way from NIST-traceable plutonium standards. The scintillation-counting data were within 10% of the predicted plutonium concentration based on the dilution sequence utilized.

The two brines collected underground at the WIPP were DH-36 and G-Seep. These had been collected by Sandia National Laboratories (WIPP/SNL), stored in 1 Liter bottles, and subsequently shipped to Argonne. The twenty 1-Liter bottles received for each brine were opened and combined into a single 5-Gallon (18.9 L) polyethylene jug. This jug had been pre-rinsed with high-purity water and two liters of the groundwater. Prior to use, the groundwater in the jug was stirred and coarse filtered, using a glass frit, in room air. There was no attempt to control P_{CO_2} throughout the handling.

filtration, and addition of the brines to the vessels. We confirmed that the groundwaters did not initially contain significant levels of carbonate by analyzing the head space in the jug above the brine for carbon dioxide. All groundwaters were stored in sealed vessels in the dark at room temperature (21 ± 2 °C).

Approximately 3 mL of the Pu-spiked brine was placed in a 1x1- cm gas-tight quartz cuvette for spectrometric analysis. These samples were also kept in the dark at room temperature (21 ± 2 °C) and periodically analyzed to monitor changes in the absorption spectrum. Absorption spectra were obtained with either a Hitachi model 340 or a Varian CARY-5 spectrometer and recorded digitally for analysis. On the Hitachi spectrometer, visible and NIR spectra were obtained independently. This is denoted in the Figures by a dashed line. The Pu(VI) absorption in the high concentration plutonium samples (10^{-3} M), had an optical density greater than 0.1. The reference for these spectra was the same brine used to make up the plutonium-containing samples in a similar cuvette. For the $\sim 10^{-4}$ M Pu-spiked brines, where the absorbance was low, both reference and sample spectrum were taken in the same cuvette to minimize cell-to-cell differences in absorbance.

Results and Discussion

The stability experiments performed are listed in Table 2. Also included are the corresponding alpha-scintillation counting data. We report data that were obtained over a period of up to 26 months. Some of these experiments, however, are still ongoing.

Stability of Pu(VI) in Brine A

The majority of the stability experiments were performed in Brine A which was the only brine investigated that had significant levels of carbonate in solution. Spectra and counting data were obtained when the total plutonium concentration exceeded 10^{-4} M. When the concentration was on the order of 10^{-6} M or less, only counting data were obtained, since the absorbance was too low to detect.

Based on the counting data, there was no significant decrease in the plutonium concentration as a function of time for all the plutonium isotopes and concentrations investigated. Filtering the solution through 0.2 μ filters did not affect the total concentration measured.

Absorption spectra for the carbonate complex in Brine A are shown, as a function of time, in Figure 2. At plutonium concentrations greater than 10^{-4} M, a plutonium(VI)-carbonate complex was observed that was stable with time. This solution was also filtered through a 0.2- μ filter and re-analyzed spectrometrically. No change in the spectrum was observed. There was no spectral evidence for Pu(V) or Pu(IV) carbonate species although we cannot preclude the possibility of their existence at low concentrations (< 10% of the total plutonium).

The absorption spectrum obtained in Brine A is most similar to that obtained for the Pu(VI) carbonate species (see Figure 1). It is characterized by a blue-shifted absorption band at 806 nm. The apparent extinction coefficient for the species we have observed was approximately 40 $M^{-1}cm^{-1}$ which is comparable to that published for the carbonate complex [11]. Some evidence of Pu(VI) hydrolytic species can be seen in the higher resolution CARY-5 spectrum (Fig. 2c). It is not surprising that a carbonate species is predominant in Brine A since this brine contains 0.011 M sodium bicarbonate and the pH_{OP} of the brine is greater than 7.

Based on our data, we are proposing that the Pu(VI) species in Brine A is primarily a carbonate complex. Detailed library spectra, however, do not exist that would permit a more specific species assignment. Both Pu(VI) in Brine A and Pu(VI) in the carbonate/bicarbonate system have a broad absorption at 570 nm. In the 800-850 nm regime however, significant differences are apparent. The full-width half-height of the 806 nm absorption is 10 nm for Brine A compared with 30 nm in the carbonate/ bicarbonate system. In addition to this, there is greater complexity in the band structure in the bicarbonate/carbonate sample.

We believe that the best explanation for the observed stability of the Pu(VI)-carbonate species is the presence of carbonate rather than radiolysis. In the absence of carbonate (see later discussions

Fig. 2. Absorption spectra of 3×10^{-4} M Pu (VI) in WIPP Brine A at (a) 0, (b) 475, and (c) 945 days. Spectra a and b were obtained on the Hitachi model 340 spectrometer and spectrum c was obtained using the Varian CARY-5 spectrometer (note different wavelength scale).

for ERDA-6 brine and the higher concentration samples for G-Seep and DH-36 brines), we observed autoreduction of Pu(VI) to a Pu(V/VI) mixture in solutions with comparable activity (i.e. the same dose rate). This phenomena was also reported elsewhere [14] in brine systems. Here there was a relatively rapid reduction of Pu(VI) due to radiolysis followed by a slower re-oxidation to Pu(VI) that was attributed to the radiolytic formation of oxygen chlorides in the brine. This initial reduction was not observed in our experiments when carbonate was present. The stability of the Pu(VI) carbonate complex in WIPP brine, however, is consistent with theoretical predictions [15] and experimental results [14] reported elsewhere. It has also been partly corroborated by results reported by others in the WIPP Project [16].

Stability of Pu(VI) in ERDA-6 Brine

The stability and speciation of Pu(VI) in ERDA-6 brine was significantly different than that observed in Brine A because of the absence of carbonate and bicarbonate. The absorption spectra of Pu(VI) in ERDA-6, as a function of time, are shown in Figure 3. The sample was analyzed spectroscopically at 6, 77, 280 and 294 days after preparation.

The absorption spectra shown in Figure 3 are most similar to those for the hydrolytic species [see Figure 1]. At this pH, the Pu(VI)-chloride complex would not be expected to successfully compete with hydrolysis [17]. The best interpretation of the 845 nm band is that it corresponds to a Pu(VI) species that is predominantly hydrolytic in nature. Further detailed studies are, however, needed to more fully evaluate the effect of ionic strength on band structure.

The redox stability of the Pu(VI)-hydrolytic species observed in ERDA-6 was less than, but comparable to, that observed for the Pu(VI)-carbonate complex in Brine A. There is a loss of approximately 25-30% of the absorbance at 845 nm when the 6-day and 295-day spectra are compared. The total concentration of plutonium in this brine remained constant in both unfiltered and

Fig. 3. Absorption spectra of 1.1×10^{-4} M Pu (VI) in ERDA-6 brine at (a) 6, and (b) 294 days after sample preparation.

0.2- μ filtered solutions, based on alpha-scintillation counting data. Reduction to Pu(V) is postulated, but 3×10^{-5} M Pu(V) would not be observable spectroscopically ($\epsilon = 19 \text{ M}^{-1}\text{cm}^{-1}$ at 569 nm).

Stability of Pu(VI) in DH-36 Brine

The samples taken from the gas generation experiments GG-B3-41 and GG-B3-42 were spectroscopically analyzed to evaluate the stability of Pu(VI) in DH-36 brine. There was no longer any spectroscopic evidence for Pu(VI) six days after sample preparation. There was, however, a small absorption ($\text{OD} = 0.0015$) apparent at 569 nm that corresponds to Pu(V). This would account for approximately 75% of the plutonium initially present in solution. In spectra obtained at 280 and 295 days after sample preparation, the absorption spectrum was featureless. There was no evidence for either Pu(V) or Pu(VI). This suggests that reduction of the plutonium had proceeded to lower oxidation states of plutonium where polymerization would be expected. The speciation of the plutonium species remaining in solution was not established.

To determine the rate at which Pu(VI) was reduced in DH-36 brine, a new sample was prepared and spectroscopically monitored. These time-dependent spectra are shown in Figure 4. The initial concentration of plutonium was 1.9×10^{-4} M and the pH_{Op} was 6.1. Initially, the 845-nm band characteristic of the Pu(VI) hydrolytic species was observed. Two hours after sample preparation approximately 25% of the Pu(VI) was reduced to Pu(V). Three days after sample preparation, there was no spectroscopic evidence for Pu(VI), however, an increase in the Pu(V) absorption was observed.

At higher plutonium concentrations (0.0035 M), both filtered and unfiltered solutions of Pu(VI) in DH-36 brine were monitored spectroscopically for 337 days. For both solutions, the absorption spectrum was most similar to those of the Pu(VI) hydrolytic species and ERDA-6 brine. There were no significant differences noted between the filtered and unfiltered samples.

The long-term redox stability of Pu(VI) at this higher plutonium concentration was much greater than that noted at concentrations an order of magnitude lower. After 337 days, the spectrum

Fig. 4. Absorption spectra of $\sim 10^{-4}$ M Pu(VI) in DH-36 brine at (a) time = 0, (b) after 2 hrs, and (c) at 3 days after sample preparation.

obtained indicated that there were approximately equimolar concentrations of Pu(V) and Pu(VI) in solution, estimated to be 0.0011 and 0.0014 M respectively. This finding contrasts with the complete and rapid reduction observed at $\sim 10^{-4}$ M plutonium concentrations. Autoradiolysis at comparable plutonium concentrations resulted in complete conversion of Pu(VI) to Pu(IV) for low ionic strength solutions at $\text{pH}_{\text{OP}} = 3$ [13]. The combination of higher pH, high ionic strength, and the radiolytically-induced changes in the brine stabilized the Pu(V/VI) against autoreduction to Pu(IV). This was presumably due to the radiolytic formation of oxygen chlorides in the brine [14].

Although there are a number of questions raised by these results that cannot be fully resolved, there are some observations related to the redox stability and speciation of Pu(VI) in DH-36 that were made. First, the initial speciation of Pu(VI) appears to be a hydrolytic species. This proposed assignment is based on spectral comparisons with Pu(VI) in ERDA-6 and non-complexing medias. This species is rapidly reduced at plutonium concentrations of $\sim 10^{-4}$ M. This reduction is fast relative to autoradiolysis and is caused by a reducing agent in the brine. We could not establish the nature of the reducing agent or the plutonium species generated, although a Pu(IV) aggregate, perhaps a polymeric species, is likely at the near-neutral pH of the brine.

At concentrations of plutonium $> 10^{-3}$ M, the predominant species were Pu(V) and hydrolyzed Pu(VI). These oxidation states of plutonium have persisted for a year. The concentration of Pu(VI) and Pu(V) appear to reach steady-state with time.

Stability of Pu(VI) in G-Seep brine

The samples of 10^{-4} M Pu(VI) in G-Seep brine were taken from the gas generation experiments GG-B2-41 and GG-B2-42. The time-dependent spectra are presented in Figure 5. Six days after sample preparation, the dominant species appears to be the Pu(VI) hydrolytic species, with a maximum absorption at 845 nm. The estimated concentration of this species was 4×10^{-5} M, about 40% of the

Fig. 5. Absorption spectra of 1.1×10^{-4} M Pu (VI) in G-Seep brine at (a) 6, (b) 77, and (c) 280 days after sample preparation.

total plutonium initially present in solution. An absorption band at shorter wavelength was also present.

At 77 days, there was no spectral evidence of Pu(VI). After 280 days, there was no absorbance characteristic of dissolved plutonium species. Based on the alpha-scintillation counting results, however, over half the plutonium originally present in solution was still there. The nature of this plutonium species was not established.

As with the DH-36 brine sample, a 0.0035 M Pu(VI) solution in G-Seep brine was prepared. Plutonium solutions for both the filtered and unfiltered brine were monitored the same way. No significant differences were observed between the spectra obtained. At this higher plutonium concentration the hydrolytic species appears to be predominant, with an absorption band at ~ 845 nm. A slow decrease in the concentration of this species was noted with time, along with a corresponding increase in the concentration of Pu(V) at 569 nm. After 337 days, the concentration of the Pu(VI) hydrolytic species was 0.0014 M and the concentration of Pu(V) was 0.0008 M. Additionally, the total plutonium concentration decreased by 40%.

Discussion and Summary of Observations

Plutonium at concentrations of $\sim 10^{-4}$ M remained in solution in both synthetic brines investigated. In Brine A, a Pu(VI)-carbonate complex was observed that has been stable for over two years. This complex appears to stabilize Pu(VI) towards autoreduction to Pu(V). In ERDA-6, the Pu(VI) species was predominantly hydrolytic in nature and was partly reduced to Pu(V) over the course of a year.

Pu(VI) was significantly less stable in the WIPP brines collected underground. In DH-36, Pu(VI) was rapidly reduced at total Pu concentrations of $\sim 10^{-4}$ M or less. This occurred in the timeframe of a few hours. The reducing agent in this process was not identified. It was likely due to the presence of trace constituents, such as reduced metals or organics, in the groundwater. At plutonium concentrations above 10^{-3} M, Pu(VI) was much more stable in both DH-36 and G-Seep.

When reduction occurred in DH-36, most of the plutonium remained in solution as an undefined species that did not absorb strongly in the visible-NIR range. The loss of plutonium was probably due to precipitation of plutonium phases. The absence of absorption bands characteristic of Pu(III, IV, V, VI) for the plutonium remaining in solution suggests that a colloidal or polymeric species may be present. This, however, was not directly established in our work. In G-Seep, the initial species was also predominantly hydrolytic. This was reduced to Pu(V) which was subsequently reduced to an unidentified species that mostly remained in solution.

Finally, it is important to qualify these results relative to the conditions expected in the WIPP. Since the Pu(VI) in our studies is introduced at high initial concentrations, we potentially have a radiolysis-dominated system that is more oxidizing than that expected in the WIPP. Reducing agents introduced by waste emplacement itself, such as organic waste, iron etc., will potentially have an important effect on the reduction and/or removal of plutonium. These factors also need to be taken into account to more fully establish the expected speciation and solubility of plutonium in the WIPP.

Acknowledgement

The authors wish to acknowledge Larry Brush (SNL) and Martin Molecke (SNL) who directed this work and provided many useful comments and suggestions; Craig Novak for providing comments on the data reported; and Hans Weger for the providing the Pu(VI)-chloride spectrum reported.

ABSTRACT

The solubility of Nd(III) has been measured at 23 ± 3 °C in a synthetic brine at pcH 6.4, 8.4, 10.4 and 12.4. The brine consisted predominantly of (Na+K)Cl and MgCl₂ with an ionic strength of 7.8M (9.4m) a solid compound of Nd(III) at each pcH was assigned from X-ray diffraction patterns. The log values of the experimental solubilities decrease from -3 at pcH 6.4 to -5.8 at pcH 8.4; at pcH 10.4 and 12.4 the solubility was below the detection limit of -7.5. The experimental solubility does not follow closely the variation with pcH estimated from modeling of the species in solution in equilibrium with the Nd solid using S.I.T.

INTRODUCTION

The solubility of the radionuclides in radioactive wastes is necessary information for assessment of the disposal of such wastes. Among these radionuclides plutonium is of major interest because of the long half life of the major isotope ($A=239$). The interpretation of data on the solubility of plutonium is made rather difficult by the uncertainty of its redox behavior as well as lack of knowledge about the solids likely to be formed. To aid in such interpretation, it is useful to study species of fixed oxidation state whose chemical behavior resembles closely that of plutonium in that oxidation state. Appropriate oxidation state analogs are Nd(III), Th(IV) and U(VI) - as uranyl, UO_2^{2+} - for Pu(III), Pu(IV) and Pu(VI). Th(IV) and U(VI) are also of interest as they constitute part of the radionuclide content of most nuclear wastes.

We have reported on the solubilities of Th(IV) (1) and U(VI) (2) in a synthetic brine of relevance to the WIPP repository site. In this paper we report the results of a similar investigation of the solubility of Nd^{3+} in the same synthetic brine at pCH values between 6.4 and 12.4.

EXPERIMENTAL

Reagents and Solutions: The synthetic brine was prepared from analytical reagents with distilled, deionized water according to the formulation in Table 1. The neodymium salt was reagent grade

TABLE 1

Components of Synthetic Brine

<u>Compound</u>	<u>Grams per Liter</u>
NaCl	100.
Na ₂ SO ₄	6.2
NaHCO ₃	0.96
NaBr	0.52
KCl	57.2
CaCl ₂	1.66
MgCl ₂ .6H ₂ O	292.1
Na ₂ B ₄ O ₇ .10H ₂ O	2.0
Ionic Strength	7.8 M (9.4m)

$\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ (Aldrich). All other chemicals were also reagent grade and used without further purification.

The solutions were prepared at pcH 6.3 with 1.3 L of brine in each of 2 beakers (N.B., $\text{pcH} = -\log [\text{H}^+ \text{ concentration}]$). The pcH was adjusted to 6.3 with concentrated HCl solution and 3.2 millimoles of $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ added. Most of the Nd(III) precipitated as the amorphous hydroxide immediately. This constituted an "oversaturation" experiment. All measurements were performed at laboratory temperature, $23 \pm 3^\circ\text{C}$.

Solubility: Initially, the solubilities at pcH 6.3 and 8.4 were studied by oversaturation as follows. The pcH of 1.3 L of the synthetic brine was adjusted to 6.3 by addition of concentrated HCl to two breakers followed by addition of 3.2 millimoles of $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ to each. To the same volume of brine in two other breakers, saturated NaOH solution was added to adjust the pcH to 8.4, then 3.7 moles $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ were added to each.

Solutions of brine at pcH 10.4 were prepared (oversaturation) in two ways:

- a) without massive brine solid. The pcH of 2 L of brine was adjusted to ca. 10 by adding 265 mL of saturated NaOH solution. The solids formed, mainly $\text{Mg}(\text{OH})_2$, were removed by filtration and NaCl was added to the filtrate in order to readjust the ionic strength. Two samples of 0.5 L each of the filtrate solution were transferred to separate beakers after which 2.0 millimoles of $\text{NdCl}_3 \cdot 6\text{H}_2\text{O}$ were added to each. Finally, the pcH was adjusted to 10.4. This procedure

retained the ionic strength at 9.4 m with the Mg^{2+} replaced by Na^+ .

- b) with massive brine solid. In each of two beakers, 1.3 L of the brine added had the pcH adjusted to 10.4 by saturated NaOH solution followed by addition of 2.0 mmoles of $NdCl_3 \cdot 6H_2O$. In these experiments, the precipitation of the Mg^{2+} results in a decreased ionic strength to ca. 5.3 m.

For the experiments at pcH 12.4, samples with and without brine solid were used.

- a) without massive brine solid. Two samples of 0.5 L of the filtrate prepared for the pcH 10.4 experiments were transferred into two plastic bottles and the pcH adjusted to 12.4 with saturated sodium hydroxide. After addition of 1.8 mmole of $NdCl_3 \cdot 6H_2O$ to each bottle, they were flushed with N_2 and tightly closed. As at pcH 10.4, the ionic strength was maintained but the brine constituents have changed.
- b) with massive brine solids. The brine was prepared as described for the pcH 10.4 samples with adjustment of the pcH to 12.4. As at pcH 10.4, the ionic strength was reduced (to ca. 5.3 m).

The pcH 8.4 undersaturation experiments were conducted with the solutions from the experiments at pcH 10.4 without massive solid after steady state had been attained at that pcH. The pcH was adjusted to 8.4 with concentrated HCl and sampling continued.

All the bottles were flushed with nitrogen and tightly capped. After reopening and sampling, the bottles were flushed again with N_2 and resealed.

Measurement of pH: A glass combination electrode with the reference cell filled with a modified brine was used in order to minimize liquid junction effect. The brine used in the reference cell did not contain Na_2SO_4 , $NaHCO_3$, nor $Na_2B_4O_7 \cdot 10H_2O$ to avoid their buffering effect. The electrode was calibrated for proton concentrations by the Gran method (3).

Separation and Analysis: Initially, a process of hydroxide precipitations and elution from columns of anion resin was used. Twenty mL samples of the brine had 300 mg of Fe(III) added followed by precipitation with concentrated sodium hydroxide solution. After precipitate washing, acid dissolution and alkali reprecipitation, the washed precipitate was dissolved in sufficient concentrated HCl solution to yield an 8 M HCl solution. This solution was placed on the top of a column of Dowex-1 anion exchange resin. A second volume of 8 M HCl washed all the Nd(III) through while retaining the Fe(III). The eluant was evaporated to dryness and redissolved in 0.1 M HCl. This solution, 20 mL, was passed through a column of Dowex-50 cation exchange resin followed by passage of 100 mL of 0.1 M HCl. This was followed by elution of the Nd(III) with 35 mL of 6M HCl solution. The yield of Nd(III) was found to be 100($\pm$ 4)% using spiked brine samples. The concentration of Nd(III) in the eluant was measured using Arsenazo-

III (4) on a Cary-14 rebuilt (On-Line) spectrometer. The detection limit was 3×10^{-8} M Nd(III).

In the later experiments, a simpler method was used which involved extraction of Nd(III) from the brine using a 1-butanol solution of Chlorophosphonazo III (5). The Cary-14 was used for the spectrophotometric determination of the concentration of Nd(III) in the butanol phase. The detection limit for Nd(III) by this method was 5×10^{-7} M and the recovery efficiency was $96 \pm 4\%$.

X-Ray Measurements: Samples of the solid present at steady state were dried and analyzed by X-ray diffraction with a Siemens spectrometer using $\text{CuK}\alpha(1.54\text{\AA})$ radiation.

RESULTS AND DISCUSSION

The powder X-ray diffraction patterns were matched for spacing and relative intensity of the lines with the patterns of a number of lanthanide compounds. The result was a best match with the solids listed in Table 2.

The variation of solubility with time is shown for the pcH 6.4 and 8.4 systems in Figure 1. For pcH 10.4 and 12.4, the solubilities were below the analytical limit ($\leq 3 \times 10^{-8}$ M) for all measurements. The measured steady state solubilities are listed in Table 2. For the pcH 6.4 and 8.4 solutions, the spectra indicate the presence of amorphous $\text{Nd}(\text{OH})_3$. At pcH 10.4 in the absence of massive brine solids, $\text{Nd}_2(\text{CO}_3)_3 \cdot 8\text{H}_2\text{O}$ was indicated by the X-ray data as the controlling solid phase. It was more difficult to detect the presence of neodymium compounds in the presence of massive

10.4	a & b less than $3 (\pm 3) \times 10^{-8}$	≥ 100 /with solid	uncertain
12.4	a & b less than $3 (\pm 3) \times 10^{-8}$	≥ 100 /without solid	$\text{NdO}(\text{OH}) +$ $\text{Nd}(\text{OH})_3$
12.4	a & b less than $3 (\pm 3) \times 10^{-8}$	≥ 100 /with solid	uncertain

Figure 1. Plot of the total concentration in solution as a function of time.

amounts of solid (mostly $\text{Mg}(\text{OH})_2$, NaCl and KCl) at $\text{pCH} = 10.4$ and 12.4 due to its low contribution to the total solid phase. At $\text{pCH} 12.4$ in the absence of massive solids, the solid phase best fitted spectra of a mixture of $\text{NdO}(\text{OH})$ and $\text{Nd}(\text{OH})_3$.

The modeling calculations of neodymium solubility in brine as a function of pCH were based on thermodynamic data from various sources (e. g. ref. 6 and 7). The actual values are listed in Table 3. The computer codes used for specification were Halsaftall (8) and Solgaswater (9). Activity coefficients corrections were made using the Specific Interaction Theory (SIT) (10). In these calculations, the solid phase limiting the $\text{Nd}(\text{III})$ solubility at each pCH value is $\text{Nd}(\text{OH})_{3(\text{am})}$ for $\text{pCH} 6.4$ and 8.4 , $\text{Nd}(\text{CO}_3)_3 \cdot 8\text{H}_2\text{O}$ for $\text{pCH} 10.4$ and $\text{Nd}(\text{OH})_3 + \text{NdO}(\text{OH})$ for $\text{pCH} 12.4$.

The experimental solubilities are presented in Figure 2. Also shown are two lines representing the calculated solubility; the dashed line assumes $\text{Nd}(\text{OH})_3$ is the highest hydrolytic species in solution while the solid line was calculated with the inclusion of $\text{Nd}(\text{OH})_4^-$ (11). The experimental solubility decreases from $\text{pCH} 6.4$ to $\text{pCH} 10.4$. At $\text{pCH} 10.4$ and 12.4 we can report only upper limits. At these latter pCH values, there is rather serious disagreement between the experimental and calculated values which may reflect problems of estimation of the stability constants and solubility constants by SIT for the high ionic strength of the brine. Figure 3 shows the calculated concentrations of the major solution species as a function of pCH . Chloride complexation of $\text{Nd}(\text{III})$ was not included in Figure 3 as it would be relatively constant in these

systems. The curves in Figure 3 suggest that the disagreement at pcH 10.4 and 12.4 is due to incorrect values of the constants used to calculate the concentrations of $\text{Nd}(\text{OH})_{3(\text{aq})}$ and the solubility product for $\text{NdO}(\text{OH})$. $\text{Nd}(\text{CO}_3)_2^-$ was calculated to form at about 10^{-9} M at pcH 6, increase to a constant value of 10^{-8} M from pcH 7.2 to 9.3, then decrease rapidly. It is not shown in Figure 3 as the lower limit is 10^{-7} M. $\text{Nd}(\text{OH})_4^-$ was not included in the speciation in Figure 3 as the comparison of the trend with pcH of the experimental solubilities indicate that $\text{Nd}(\text{OH})_4^-$ is not significant.

Abstract

The rate at which elements can be transported in groundwater systems is governed in part by the solubility of the element in the groundwater. This report documents plutonium solubility experiments, conducted over the past two years at the Lawrence Berkeley Laboratory, in a brine simulant relevant to the Waste Isolation Pilot Plant. Approximately 1 to 2.5 mL of five stock solutions containing single oxidation states of plutonium (Pu(IV)-polymer, Pu^{3+} , Pu^{4+} , PuO_2^+ , and PuO_2^{2+}) were added to ~75 mL of synthetic H-17 Brine in five reaction vessels. Initial plutonium concentrations ranged from 1.3×10^{-4} to 5.1×10^{-4} M (moles per liter) total plutonium. Because these initial concentrations were far above the plutonium solubility limit in H-17 Brine, plutonium-containing solids precipitated. Aqueous plutonium concentrations were measured over time until steady-state was reached, requiring over 300 days in H-17 Brine. Steady-state plutonium concentrations ranged from 3.0×10^{-8} to 7.6×10^{-7} M, and the predominant plutonium oxidation state in solution was Pu(VI). The solid phase from the initially Pu(IV)-polymer experiment remained polymeric-Pu(IV). The solids that formed in the initially Pu^{3+} and Pu^{4+} experiments were crystalline yet remain unidentified. The solids that formed in the initially PuO_2^+ and PuO_2^{2+} experiments appear to be sodium plutonyl(V) carbonates.

Introduction

Understanding the behavior of dissolved plutonium in natural systems is important for assessing the performance of proposed nuclear waste repositories. Migration of dissolved plutonium depends upon the plutonium oxidation state and concentrations of groundwater constituents that can complex with the plutonium. In addition, the total dissolved plutonium concentration depends on the plutonium-bearing solid phase(s) that control solubility. Particularly for plutonium in brine systems, little experimental data exists for demonstrating either oxidation states or the solubility-controlling solids. This paper documents steady-state plutonium concentrations, oxidation state distributions, and solubility-controlling solids in a complex synthetic groundwater.

This solubility study was undertaken in support of the Waste Isolation Pilot Plant (WIPP), a U.S. Department of Energy facility intended to demonstrate the safe geologic disposal of defense-generated transuranic nuclear waste. The WIPP is located deep underground in a bedded salt formation in southeastern New Mexico. The little groundwater that exists in the WIPP vicinity range from seawater-like (~ 0.8 molal ionic strength) brines to highly concentrated (~ 8 molal) brines.¹ The chemical behavior of actinides in a variety of groundwaters from near the WIPP Site is being examined to support WIPP solubility and retardation studies.

This paper documents solubility studies of ^{239}Pu in H-17 Brine, a simulant of brine taken from near the WIPP Site. Plutonium in five different initial forms (Pu(IV)-polymer , Pu^{3+} , Pu^{4+} , PuO_2^+ , and PuO_2^{2+}), was added to the brine in five separate reaction vessels, in sufficient quantity to ensure initial supersaturation with Pu. The experiments were conducted under oxic conditions with a fixed carbon dioxide overpressure, and the nominal hydrogen ion concentration was controlled over the length of the experiments. Total dissolved concentrations of plutonium were monitored over time until steady-state conditions were established. Aqueous

plutonium oxidation state distributions were determined several times during the experiments, and the solid phases were characterized.

Experimental

Reagent grade chemicals were used to make synthetic H-17 Brine, with the composition as listed in Table 1. The anhydrous salts were dried in an oven at 110°C for four hours before use. Salts were massed on a Galaxy 400 analytical balance that had been calibrated using an NIST standardized mass set. All salts except sodium bicarbonate were added to a 1 L class "A" volumetric flask, the flask was flushed with argon for ~10 minutes, and freshly distilled, deionized water was added. All solids dissolved with stirring over night. The NaHCO_3 was added immediately before saturating the water simulant with the $\text{CO}_2/\text{O}_2/\text{Ar}$ gas mixture.

Because the concentration of total inorganic carbon (TIC) in solution can change in response to the carbon dioxide content of gas over the solution, special care was taken to preserve the intended TIC concentration of H-17 Brine. This was accomplished by equilibrating the solutions with gas mixtures of (2634 ± 91) ppm CO_2 . The gas mixtures also contained $(20.75 \pm 0.88)\%$ oxygen to provide an oxic environment, with the balance made up of argon.

We measured the brine pH during saturation with carbon dioxide with a Ross glass combination pH electrode (Orion Research Incorporated, Boston, MA) to establish an operational pH that could be routinely measured with a glass electrode. This is not the actual $\text{p}[\text{H}^+]$, or pCH , of the brine, but rather an operational pH_{OP} that we maintained during the solubility experiments. The electrode was calibrated with NIST traceable standard buffers of 7 and 10 before being placed into the H-17 Brine. Figure 1 shows the change in the measured pH_{OP} during the saturation with the $\text{CO}_2/\text{O}_2/\text{Ar}$ gas mixture. After eight hours of saturation with the gas mixture, the initial pH_{OP} of 8.06 stabilized to $\text{pH}_{\text{OP}}=7.14$.

The ^{239}Pu stock solution was prepared by dissolving plutonium metal in 6 M

Pu(VI)	7.08 ± 0.09	(7.64 ± 2.31) × 10 ⁻⁷	404 ± 15

Figure 1. The operational pH measured by glass electrode in H-17 Brine during saturation with a gas mixture of 2634 ± 91 ppm CO_2 , 20.75 ± 0.88 percent O_2 , with the balance made up of Ar.

hydrochloric acid. The solution was purified from possible metal contaminants by anion exchange chromatography. The oxidation states Pu(III), Pu(IV), Pu(V), and Pu(VI) were prepared by electrochemical adjustment of the plutonium stock solution.²⁻³ The presence of a single oxidation state was verified by absorption spectrophotometry.⁴ Before use, all stock solutions were filtered through 0.22 μ m polyvinylidene difluoride syringe filter units (Millipore Corporation, Bedford, MA) to remove possible suspended particles (e.g., dust or silica) that could sorb the plutonium to form pseudocolloids.

The Pu(IV)-polymer was prepared by oxidizing a Pu(III) stock solution, (pH=2.5), at +1.1 volts versus a normal hydrogen electrode to Pu(IV) that immediately polymerized and settled out of solution.

The equilibration vessels were 90 mL Teflon perfluoralkoxy (PFA) cells (Savillex Corporation, Minnetonka, MN) with ports at the top to accommodate a pH electrode, a 1/16"-diameter Teflon line for the gas mixture, and an opening for withdrawing samples. Five individual reaction vessels were prepared to accommodate the five forms of plutonium stock solution to be studied.

Approximately 1 to 2.5 mL of each plutonium stock solution were added to 70 mL H-17 at the start of the experiment. The pH_{OP} of the solutions was measured weekly and maintained at 7.14 $\pm$ 0.10. When required, the pH_{OP} in the reaction vessels was adjusted with small amounts (usually between 5 and 50 μ L) of HCl or NaOH (0.5-1 M). The electrodes were removed from the plutonium solutions after each pH_{OP} measurement.

Quantitative separation of the aqueous phase from any solids or suspended particles is necessary for an accurate assessment of dissolved concentrations. For this process, we routinely used Centricon-30 (Amicon Corporation, Danvers, MA) centrifugal filters that contain a YM-type membrane with a calculated pore size of 4.1 nm. Filters were tested for plutonium retention by filtering 500 μ L of the

solubility solution and counting the filtrate. Another 500 μL of solution was filtered through the same filter, and the second filtrate was assayed. This was repeated until a total volume of 2000 μL had passed through the filter. Plutonium retention would be indicated by an increase in assayed concentration with each successive filtration step. Figure 2 shows that the filters did not retain the dissolved plutonium species present at the initiation of the five solubility experiments. Because plutonium concentrations and speciation may change over the course of the experiment, another test for filter retention was performed after ~ 150 days of reaction time, and again the results showed no significant retention of plutonium. Routine separations were performed after presaturating the filters with 500 μL of solution.

Concentration measurements of the aqueous portions were made by γ -spectroscopy with a low-energy germanium counting system of Lawrence Berkeley Laboratory design, or with a liquid scintillation counter (Pharmacia LKB Nuclear Incorporated, Gaithersburg, MD, Model Rackbeta 1219). With the germanium counter, plutonium was analyzed for the uranium L x-rays resulting from the α -decay of the plutonium. Possible contributions to the L x-rays from the decays of other radionuclides, also present in small amounts, were corrected by subtraction.⁵ The liquid scintillation counter (LSC) can discriminate between possible β -radiation and the plutonium α -radiation. The LSC was calibrated with plutonium standards of similar chemical compositions.

The oxidation state of plutonium is one of the most important controlling factors for solubility. Although each experiment started with a single oxidation state, the oxidation states can and, in general, do change during solubility experiments. Unfortunately, the steady-state plutonium concentrations in H-17 Brine were below the detection limit of conventional methods such as absorption spectrophotometry, so a series of organic extractions was used as an indirect method

Figure 2. Results of filtration experiments with Centricon-30 filters. The lack of change in concentrations indicates there was no significant retention of plutonium on the filters upon initiating the experiments.

for determining the distribution of the aqueous plutonium among its oxidation states. Table 3 lists the methods that we used. The method is based upon an earlier scheme,⁶ but for these solubility experiments we replaced thenoyltrifluoroacetone (TTA) with 1-phenyl-3-methyl-4-benzoy-pyrazol-5-one (PMBP)⁷ because PMBP was more efficient as an extractant and was more resistant to decomposition by oxidants such as dichromate. All extractions were successfully tested on known oxidation states of plutonium in H-17 Brine. For the solubility experiments, each of the four separations was carried out independently to minimize the potential for changing the steady state distribution.

The oxidation potential, E_h , of each solution was measured at steady state with a platinum electrode versus a $Ag/AgCl/saturated\ NaCl$ reference. The platinum electrode was cleaned with 6 M nitric acid before and after each measurement. The electrode setup was checked with "Zobell's Solution" before and after each measurement.⁸⁻⁹

The solids were analyzed by x-ray powder diffraction. A few micrograms of each actinide precipitate were placed in a 0.33-mm diameter quartz capillary tube. The tube was mounted in an 11.46-cm diameter Debye-Scherrer camera and then irradiated with x-rays from a Norelco III x-ray generator (Philips Electronics, Inc.). Copper K_{α} radiation filtered through nickel was used.

Results and Discussion

1. Solubility

The experimental results for dissolved plutonium concentrations are shown in Figure 3. The steady-state pH values, plutonium concentrations, and E_h values are given in Table 2.

The dissolved concentrations in the initially Pu(III), Pu(IV), Pu(V), and Pu(IV)-polymer experiments dropped by two to three orders of magnitude within about 50 days. After that time, the concentrations changed no more than an order

Table 3. Methods Used for Determining Plutonium Oxidation States in H-17 Brine.

(a) p = Pu(IV) polymer

Figure 3. Total dissolved plutonium concentrations versus time for five initial forms of aqueous plutonium in H-17 Brine.

of magnitude over 600 additional days. The initially Pu(VI) experiment behaved very differently, remaining significantly higher in its aqueous plutonium concentration for about 250 days before a similar drop in aqueous plutonium occurred. After approximately 350 days of reaction time, the concentrations for the initially Pu(III), (IV), (V), and (VI) experiments were all within a factor of 1.6 of one another, their average being $\sim 5 \times 10^{-7}$ M. The plutonium concentration in the initially Pu(IV)-polymer experiment was an order of magnitude lower, 4.3×10^{-8} M. Note that true steady state conditions in H-17 Brine were not reached even after nearly 700 days of equilibration time.

Steady-state concentrations listed in Table 2 are the averages of the individual concentration measurements from days 279 to 668 for the initially Pu(IV)-polymer experiment, from 419 to 680 for the initially Pu(III) experiment, from 413 to 674 for the initially Pu(IV) experiment, from 290 to 679 for the initially Pu(V) experiment, and from 252 to 680 for the initially Pu(VI) experiment. The error listed with each average concentration is the standard deviation.

The five H-17 experiments were oxidic, with measured Eh values from 400 to 500 mV versus a normal hydrogen electrode. These measurements are very general and are of limited value because they represent a combination of many redox reactions in each of these solubility experiments. Only with elaborate chemical modeling can these overall potentials be explained.

2. Oxidation State Determinations

Results of oxidation state determinations performed at steady state in the solubility experiments are shown in Figure 4. These determinations were performed after approximately 350 days of reaction time and after steady-state conditions were met. The results show Pu(VI) as the predominant oxidation state in solution at steady state regardless of the oxidation state used at the start of the experiments. We also found smaller, but significant, amounts of Pu(V) in some of

Figure 4. Plutonium oxidation state distributions in five different H-17 Brine experiments at steady-state conditions.

the solutions. These observed valence distributions cannot be explained by disproportionation equilibria and complex stabilization.¹⁰ It is possible that reaction products formed by α -radiolysis of H-17 Brine may cause the predominance of high oxidation states in the plutonium solutions. We confirmed the oxidation state results shown in Figure 4 later in the experiments, using the same separation scheme.

3. Identification And Characterization Of Solids

The solids formed in the H-17 oversaturation experiments were examined after approximately 600 days of reaction time. From visual observations, it appeared that the solids formed in the initially Pu(IV)-polymer, Pu(III), and Pu(IV) experiments were very much the same. They each resembled the green polymeric-plutonium(IV) used to start the initially Pu(IV)-polymer solubility experiment. The crystalline component in the solids that formed in the initially Pu(V) and Pu(VI) experiments also appeared to be the same; they were both a tan, crystalline powder.

To determine if the green solids we obtained were polymeric-plutonium(IV), we tried dissolving very small portions of the solids in 1 M HCl. We then filtered the solutions through Amicon Centriprep-30 centrifugal filters (4.1 nm). We assayed the acidified plutonium solutions before and after filtration to determine the relative amount of solid that dissolved in 1 M HCl. Crystalline solids like plutonium hydroxides or plutonium carbonates will immediately dissolve in 1 M HCl; whereas, polymeric-plutonium(IV) will not dissolve. The filtration will remove any undissolved solids larger than 4.1 nm from the solution. We expected that for the initially Pu(IV)-polymer experiment, very little solid, if any, would dissolve and/or pass through the filter. Only 14 percent of the acidified plutonium solid passed through the filter. This may have been a crystalline component or possibly carbonate complexed plutonium on the surface of the polymeric-plutonium(IV) that did dissolve. It also may have been polymeric-plutonium(IV) that was smaller than

4.1 nm and passed through the filter without dissolving. In either case, eighty-six percent of the solid did not dissolve and is most likely Pu(IV)-polymer.

For the initially Pu(III) and Pu(IV) experiments, 76 and 73 percent of the respective solids dissolved and/or passed through the filter. These results show that approximately three quarters of the plutonium solids that formed in these two experiments may not be polymeric-plutonium(IV). If this component has a higher solubility than polymeric-plutonium(IV), it would explain why the steady-state aqueous plutonium concentrations in the initially Pu(III) and Pu(IV) experiments are an order of magnitude higher than that found in the initially Pu(IV)-polymer experiment.

Ninety-three and 100 percent of the respective solids from the initially Pu(V) and Pu(VI) experiments dissolved and/or passed through the filters. These solids are believed to have dissolved because they effervesced upon contact with acid. This also implies that these plutonium solids contained carbonate. The seven percent of the solid from the initially Pu(V) experiment that did not dissolve or pass through the filter is probably polymeric-plutonium(IV), which explains the small amount of the green solid we found with the crystalline component.

To further characterize these plutonium solids, we isolated small portions of the plutonium solids for x-ray powder diffraction. Microgram amounts of the dried plutonium solids were encapsulated in quartz capillaries and then analyzed by x-ray powder diffraction. The d-spacings and relative intensities for the powder patterns of the dried plutonium solids are listed in Table 4. We also washed another portion of the solids with distilled water followed by ethanol to try removing any salts, such as NaCl, that may have coprecipitated from the brine. Although washing may perturb the crystal structure of the plutonium solids, the respective powder patterns show little change between washed and unwashed samples.

We compared the x-ray powder diffraction patterns with reference patterns

published in the literature to assign the lines. They were compared to patterns of crystalline PuO_2 ,¹¹ $\text{PuO}_3 \cdot 0.8\text{H}_2\text{O}$,¹² KPuO_2CO_3 ,¹³ $\text{NH}_4\text{PuO}_2\text{CO}_3$,¹³ and PuO_2CO_3 .¹⁴

The three solids from the initially Pu(IV)-polymer, Pu(III), and Pu(IV) dissolved concentration experiments in H-17 Brine produced powder patterns with the same diffraction lines. Because very little of the solid produced in the initially Pu(IV)-polymer experiment dissolved in acid, we conclude that the solid taken from the end of the experiment was composed mostly of Pu(IV)-polymer. However, most of the solids produced in the initially Pu(III) and Pu(IV) experiments did dissolve in 1 M HCl and/or pass through the filter, so we conclude that these solid phases are possibly crystalline or Pu(IV)-polymer smaller than 4.1 nm. The x-ray powder diffraction patterns did not match any of the published reference patterns for plutonium compounds. We indexed the d-spacings to determine the lattice structure and found that a cubic lattice structure, like that of sodium chloride, for example, will produce these diffraction lines.

The crystalline precipitates from the H-17 Brine experiments containing initially PuO_2^+ and PuO_2^{2+} had identical x-ray powder diffraction patterns, and this pattern compared well with patterns of KPuO_2CO_3 ¹³ and $\text{NH}_4\text{PuO}_2\text{CO}_3$.¹³ However, considering that the sodium content in H-17 Brine is nearly 80 times greater than the potassium content, we conclude that these solids are more likely sodium plutonyl(V) carbonates, $\text{NaPuO}_2\text{CO}_3(\text{s})$. No reference powder pattern was found for $\text{NaPuO}_2\text{CO}_3(\text{s})$, but the $\text{NaPuO}_2\text{CO}_3$ unit cell lattice structure was reported in comparison with the analogous potassium and ammonium solids.¹⁵ Precipitation of plutonyl(V) with carbonate results in hexagonal, orthorhombic, or monoclinic solids depending on the size of the accompanying cation involved. Larger accompanying cations, like ammonium, favor the formation of a hexagonal crystal lattice. The potassium cation forms an orthorhombic solid; whereas, the

smaller alkali cation, sodium, precipitates the plutonyl(V) carbonate as a monoclinic solid. We indexed the powder pattern from the solid obtained in the initially Pu(V) and Pu(VI) oversaturation experiments with hexagonal, orthorhombic, and monoclinic crystal lattices. Only a monoclinic crystal lattice was able to produce calculated d-spacings that agreed with the experimental powder patterns.

Conclusions

These studies demonstrate a successful methodology for accurately determining the solubility or dissolved concentrations of plutonium in brines. The measurement of dissolved concentrations in solubility studies is obviously not a "quick and dirty" process. The experiments documented here required on the order of three to four months to reach an approximate steady state; true equilibrium was not achieved even after almost two years of reaction time.

We determined that the steady-state dissolved plutonium concentrations ranged from 2×10^{-7} to 8×10^{-7} moles per liter for the H-17 Brine experiments started with initially Pu(III), Pu(IV), Pu(V), and Pu(VI). The steady-state dissolved plutonium concentration in the initially Pu(IV)-polymer experiment was an order of magnitude lower at 3×10^{-8} moles per liter.

The oxidation state determinations were conclusive in that we were able to determine the relative amounts of all four of the primary plutonium oxidation states in each of the experiments. We found the dominant oxidation state for the soluble plutonium in all five of the experiments to be Pu(VI) (70-90%). The remainder of the soluble plutonium was composed of mostly Pu(V) with only traces of Pu(IV) and Pu(III) being present.

As for the solid phases, we found that for the initially Pu(IV)-polymer experiment the steady-state solid appears to be primarily polymeric-plutonium(IV) with a small amount of an unidentified component. The solids produced in the initially Pu(III) and Pu(IV) experiments are primarily an unidentified precipitate

with some polymeric-plutonium(IV). The solids produced in the initially Pu(V) and Pu(VI) experiments dissolved easily in acid, effervescing as they dissolved. Both of the powder patterns closely match the published patterns for the potassium and ammonium plutonyl(V) carbonates, but they could only be indexed with a monoclinic crystal lattice, suggesting that these two solids are sodium plutonyl(V) carbonates.

ABSTRACT

The stable solid phases and carbonate complexes of neodymium in concentrated carbonate and bicarbonate solutions were identified by equilibration of $\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}$ or $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ with sodium carbonate (0.1 to 2.0 M) and sodium bicarbonate solutions (0.1 to 1.0 M) for a period of more than 100 days. In all the experiments, $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ was found to be the final equilibrium solid phase. A thermodynamic model, based on the Pitzer's specific ion-interaction approach, was developed to interpret the solubility data. In this model, the solubility data of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ were explained by assuming the formation of NdCO_3^+ , $\text{Nd}(\text{CO}_3)_2^-$, and $\text{Nd}(\text{CO}_3)_3^{3-}$ species. Ion interaction parameters for $\text{Na}^+ - \text{Nd}(\text{CO}_3)_2^-$ and $\text{Na}^+ - \text{Nd}(\text{CO}_3)_3^{3-}$ were developed as required to fit the data in concentrated solutions. The logarithm of the $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ solubility product ($\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c}) = \text{Na}^+ + \text{Nd}^{3+} + 2\text{CO}_3^{2-} + 6\text{H}_2\text{O}$) was

calculated to be -21.40. Based on the model calculations, $\text{Nd}(\text{CO}_3)_3^{3-}$ was the predominant aqueous neodymium species in 0.1 to 2 M sodium carbonate solutions, while both $\text{Nd}(\text{CO}_3)_2^-$ and $\text{Nd}(\text{CO}_3)_3^{3-}$ were important neodymium species in 0.1 to 1 M sodium bicarbonate solutions. This model also provided satisfactory interpretation of the solubility data of the analogous Am(III) system in less concentrated carbonate and bicarbonate solutions.

1. Introduction

Thermodynamic data on stable solid phases, solubility limits, and aqueous speciation are essential in understanding and predicting the transport of radionuclides in aqueous systems. The solid-liquid phase equilibria of trivalent actinides and lanthanides in carbonate-bicarbonate systems have been studied because 1) some natural aqueous systems have high CO_2 partial pressures (0.03 to 10%) [1,2], which result in high aqueous concentrations of carbonate and bicarbonate, and 2) these cations form strong aqueous carbonato complexes under certain conditions [3,4,5,6], which could increase the aqueous concentrations of these cations and significantly enhance their mobility.

The available thermodynamic data for carbonate systems involving trivalent actinides and lanthanides are highly diverse and complex. Silva and Nitsche [7] determined $\text{AmOH}(\text{CO}_3)(\text{c})$ to be the stable phase in solutions equilibrated with 0.03% CO_2 (pH about 6). Bernkopf and Kim [5] reported that $\text{AmOH}(\text{CO}_3)(\text{c})$ was the thermodynamically stable solid phase in solutions with total carbonate concentrations of at least 0.1 M. However, Shiloh et al. [6] found $\text{Am}_2(\text{CO}_3)_3(\text{s})$ to be the stable phase in 0.1 to 0.6 M K_2CO_3 . Firsching and Mohammadzadel [8] determined the solubility of rare earth carbonates ($\text{Ln}_2(\text{CO}_3)_3$, Ln = lanthanides) in H_2O with a pH range of 4.6 to 6.2 and reported pK_{sp} values ranging from 28.25 to 35.45. Their data showed an abnormally high solubility for $\text{Er}_2(\text{CO}_3)_3$ relative to its neighboring rare earth analogs. This abnormality remains unexplained and questionable. Recently, Meinrath and co-workers [9,10,11] and Runde et al. [12] determined conditional solubility products of different Am(III) and Nd(III) carbonates in 0.1 and 0.3 M NaClO_4 solutions maintained at different CO_2 partial pressures

(0.03 to 100%) and pH values (4 to 9). In these systems, either $\text{MOH}(\text{CO}_3)(\text{s})$ or $\text{M}_2(\text{CO}_3)_3(\text{s})$ (where M is Am or Nd) was found to be the stable solid. Runde and Kim [13] reported $\text{NaAm}(\text{CO}_3)_2(\text{s})$ to be the stable solid phase in 5 M NaCl solution of neutral pH under 0.01 atm CO_2 partial pressure. Furthermore, Kim et al. [14] used time-resolved laser-induced fluorescence spectroscopy to characterize europium(III) and curium(III) carbonate solids and their aqueous carbonate complexes in 0.1 M NaClO_4 solutions, with pH from 4 to 10 and under 1 to 100% CO_2 partial pressure. In an attempt to summarize literature data on the solubility of three different solids ($\text{Am}(\text{OH})_3$, AmOHCO_3 , and $\text{Am}_2(\text{CO}_3)_3$), Vitorge [15] discussed the utilization of the specific ion interaction (SIT) method to extrapolate the conditional K_{sp} values to zero ionic strength, in which some difficulties and uncertainties were involved because of insufficient experimental data.

In summary, a literature survey indicates that 1) several different solid compounds may form, depending on the system conditions such as pH, partial pressure of CO_2 , concentrations of total carbonate and other species (e.g. Na^+); 2) a large variability exists in values of data on solubility products and stability constants for aqueous complexes; 3) most of the studies provided only the conditional solubility products in particular electrolyte media and at specific ionic strengths. The validity of extrapolation of those conditional constants to the reference state (zero ionic strength) remains uncertain.

To provide reliable thermodynamic information on the solid-liquid equilibria in the $\text{Na}^+ - \text{Am}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system, Felmy et al. [16] determined the solubility of $\text{AmOH}(\text{CO}_3)(\text{c})$ at low total carbonate concentrations (<0.1 M) over a wide pH range and reinterpreted the available solvent extraction data for americium-carbonate complexes. A thermodynamic model was developed and shown to be consistent with the solubility data

in that work and the solvent extraction data of Bidoglio [4]. As an extension of that work and as a further effort to improve the thermodynamic models for the carbonate systems, the $\text{Na}^+ - \text{Nd}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system at high carbonate and bicarbonate concentrations (0.1 M to near saturation) were studied. Our objectives were to 1) identify the thermodynamically stable solid phases under the experimental conditions, and 2) obtain the thermodynamic data on the stable solid phase and aqueous complexes and develop the necessary ion interaction parameters to describe this wide range of solubility data.

2. Materials and Procedures

2.1 Stock Solutions and Reagents

All chemical reagents used in this work were A.R. grade or higher. Double-distilled acids (HNO_3 and HCl) were used when needed. Distilled and deionized water was used to prepare all solutions.

2.2 Characterization of $\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}(\text{s})$

Neodymium carbonate ($\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}$, 99.99% purity) was purchased from Aldrich Chemical Company. X-ray diffraction (XRD) patterns of this solid indicated that 60% (by weight) of this solid was $\text{Nd}_2(\text{CO}_3)_3 \cdot 2.5\text{H}_2\text{O}$ while the rest was unidentified neodymium carbonate compounds, possibly $\text{Nd}_2(\text{CO}_3)_3$ with different numbers of H_2O molecules. This material was used without further purification as the initial solid in one series of the solubility experiments.

2.3 Preparation and Characterization of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$

$\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ was prepared by the following procedure based on the paper by Mochizuki et al. [17]. Into 30 mL of 0.3 M NdCl_3 solution (pH about 3.2), 30 mL of 1.0 M sodium acetate/1.0 M acetic acid buffer (pH about 5) was added and mixed thoroughly. Then, about 240 mL of 1 M Na_2CO_3 solution was slowly added into this buffered NdCl_3 solution with vigorous stirring. The final pH of the suspension was about 7. The polyethylene bottle containing the suspension was shaken on an orbital shaker for 4 to 7 days. The suspension was then centrifuged and the precipitate was washed twice with deionized water before it was analyzed by XRD. The XRD patterns of the prepared compound were in good agreement with those for $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ reported by Mochizuki et al. [17]. To avoid any phase changes, the washed "wet" $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ was directly transferred into the centrifuge tubes for solubility experiments.

2.4 Solubility Experiments

Two series of solubility experiments were performed, with $\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}(\text{s})$ and $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ as the initial solids, respectively. In each series, two sets of experiments were conducted: one set contained sodium carbonate in a concentration range of 0.1 to 2.0 M, the other set contained sodium bicarbonate in a concentration range of 0.1 to 1.06 M. As a result, the pH of the solutions in the first set was around 11, while that in the second set was around 8. The solubility experiments were carried out in 50 mL polypropylene centrifuge tubes, each containing enough initial solid to guarantee excess solid phase materials remaining after the system reached equilibrium. After the initial pH

was measured, these centrifuge tubes were continuously shaken on an orbital shaker until the scheduled sampling and analysis.

The equilibration periods for the first series ($\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}$ as the initial solid) were 15, 48, 78, and 110 days, while the equilibration periods for the second series ($\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ as the initial solid) were 14, 46, 76, and 111 days.

2.5 Analyses

At the end of each equilibration period, the pH of the suspensions was measured with a combination glass electrode calibrated against standard pH buffers to determine the relative acid-base properties of the solutions. The suspensions were then centrifuged at about 2,000 g for 7 to 10 minutes. Samples of the supernatants were filtered through membranes (approximate pore size = 0.0018 μm , effective molecular-weight cutoff = 25,000) based on the procedure developed by Rai et al. [18,19]. The procedure is as follows: 1) the filters were washed with deionized water; 2) 2.0 mL of the supernatant was passed through the filters to saturate any possible adsorption sites on the filters and filtration containers (this filtrate was discarded); 3) 6.0 mL of the supernatant was filtered. Of the 6.0 mL of final filtrate, 1.0 mL was used for analysis of total inorganic carbon with a coulometric CO_2 analyzer. The remaining 5.0 mL of filtrate was acidified with concentrated nitric acid and used for analysis of sodium and neodymium. Sodium was determined by inductively coupled plasma spectroscopy (ICP), while neodymium was analyzed by the inductively coupled plasma spectroscopy - mass spectrometry (ICP-MS) technique, with indium-115 as the internal standard. The analytical errors in neodymium concentrations are estimated to be less than 10% in all cases.

At the end of the sampling periods (110 and 111 days for the two series of experiments, respectively), wet samples of the solid phases were taken and analyzed by XRD.

3. Results and Discussion

The change in aqueous neodymium concentrations as a function of equilibration periods ranging from 14 to 111 days indicates that neodymium concentrations reached steady states in about 15 days in the sodium carbonate systems (Figures 1a and 1b) and in 46 to 48 days in the sodium bicarbonate systems (Figures 1c and 1d). As a result, the data obtained from 14- and 15-day samplings of the sodium bicarbonate systems were not included in the subsequent development of the thermodynamic model.

In the bicarbonate systems containing $\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}$ as the initial solid (Figure 1c), the neodymium concentrations at the 15-day sampling were lower than the steady state concentrations. This is understandable because the equilibrium was approached from undersaturation. However, when $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ was used as the initial solid, the neodymium concentrations at the 14-day sampling were much higher than the steady state concentrations (Figure 1d). This is most likely because the $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ was added in the "wet" form after washing with deionized water (pH about 6). The solubility of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ at pH 6 is expected to be significantly higher than the final equilibrium concentrations in these sodium bicarbonate systems at a pH of about 8. In other words, the solid-liquid equilibrium was approached from oversaturation when "wet" $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ was used as the initial solid.

Figure 1. Measured neodymium concentrations as functions of equilibration time and concentrations of sodium carbonate or sodium bicarbonate.

All the solid samples from the systems using $\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}$ as the initial solid and several representative solid samples from the systems using $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ as the initial solid were analyzed by XRD. The XRD patterns of all the samples are consistent with those for $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}$ [17].

The observations can be summarized as follows: 1) steady state concentrations were reached in 15 to 48 days, 2) final steady-state concentrations were similar when approached from undersaturation or oversaturation, and when obtained from $\text{Nd}_2(\text{CO}_3)_3 \cdot x\text{H}_2\text{O}$ or $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ as the initial solid, 3) the final solid at the steady state was found to be $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$. Based on these observations, we concluded that the steady-state neodymium concentrations represent the equilibrium solubility of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ under the experimental conditions. Therefore, only the steady state data were used in the thermodynamic analysis.

3.1 Thermodynamic Analysis and the Solubility Product of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$

In the $\text{Na}^+ - \text{Nd}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system, the equilibrium neodymium concentrations, i.e., the observed total $[\text{Nd}]_{\text{aq}}$, were the sum of the concentrations of all aqueous neodymium species, which were in simultaneous equilibria with the solid phase. The aqueous species included Nd^{3+} , neodymium hydroxy species, and various neodymium carbonate species. The observed changes in $[\text{Nd}]_{\text{aq}}$ as functions of $[\text{NaHCO}_3]$ or $[\text{Na}_2\text{CO}_3]$ were the overall effect of changes in ligand concentration and changes in the activity coefficients of various species in those equilibria. The dissolution of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ can be expressed by the following reaction:

where Nd^{3+} is in simultaneous equilibria with other species such as

To evaluate these equilibria simultaneously based on the experimental data, a nonlinear least-squares program (NONLIN) was used in combination with a chemical equilibrium program (GMIN) [16]. The NONLIN is based upon the algorithm of Harvie and associates [20,21]. Details of the minimization procedure have been outlined in previous publications [22,23]. In the current system, the quantity minimized was the statistical summation of $f(\chi)$ over all experimental points, where $f(\chi)$ was defined as

$$\begin{aligned} f(\chi) &= (\mu/RT)_{\text{solid}} - (\mu/RT)_{\text{solution}} \\ &= (\mu^\circ/RT)_{\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}} - \{(\mu^\circ/RT)_{\text{Na}^+} + (\mu^\circ/RT)_{\text{Nd}^{3+}} + 2(\mu^\circ/RT)_{\text{CO}_3^{2-}} + \\ &\quad 6(\mu^\circ/RT)_{\text{H}_2\text{O}} + \ln(m_{\text{Na}^+} \gamma_{\text{Na}^+}) + \ln(m_{\text{Nd}^{3+}} \gamma_{\text{Nd}^{3+}}) + 2\ln(m_{\text{CO}_3^{2-}} \gamma_{\text{CO}_3^{2-}})\} \quad (4) \end{aligned}$$

where μ° is the standard chemical potential, R is the gas constant, T is temperature in degrees Kelvin, m denotes the molality of the subscripted species, and γ refers to the activity coefficient of the subscripted species.

In Eq.4, all μ°/RT values were from literature except for $(\mu^\circ/RT)_{\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}}$. The $[\text{Na}^+]$ was determined by ICP analysis. The $[\text{Nd}^{3+}]$ and $[\text{CO}_3^{2-}]$ were calculated using the NONLIN program with the μ°/RT values for various aqueous species involved in the aqueous equilibria. The μ°/RT values used in the evaluation are listed in Table 1. Preliminary calculations that included the neodymium hydroxy species $(\text{Nd}(\text{OH})_i^{(3-i)+}, i = 1, 2, 3)$ indicated that these species were not significant in the concentrated carbonate or bicarbonate solutions. As a result, the μ°/RT values for $\text{Nd}(\text{OH})_i^{(3-i)+}$ were not included in Table 1.

Besides the necessary μ°/RT values, the activity coefficients in Eq.4 had to be calculated to evaluate the experimental data. In this study, the ion-interaction model of Pitzer et al. [26,27] was used to calculate the activity coefficients because of its broad applicability to solutions with zero to high ionic strengths. Based on Pitzer's model, the effects of the specific ion interactions on the excess solution free energy are represented within the activity coefficient expressions. A detailed description of these expressions are given elsewhere [24, 28]. The complete set of parameters defining the non-ideal behavior of electrolytes include $\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$ and C^ϕ for each cation-anion pair, Θ_{ij} for each cation-cation or anion-anion pair, ψ_{ijk} for each cation-cation-anion and anion-anion-cation triplet, and λ_{in} and δ_{ijn} for each ion-neutral and ion-ion-neutral interactions. Some of these interaction parameters for the $\text{Na}^+ - \text{Nd}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system were available from the literature [24] and are summarized in Table 2.

Felmy et al. [16] previously developed a thermodynamic model that provided satisfactory interpretation of the solubility of $\text{AmOH}(\text{CO}_3)(\text{c})$ in less concentrated sodium

carbonate and bicarbonate solutions (< 0.1 M). In that model, the interactions between Na^+ and $\text{Am}(\text{CO}_3)_3^{3-}$ were considered by including $\beta^{(1)}$ and $\beta^{(0)}$ parameters. The $\beta^{(1)}$ for Na^+ - $\text{Am}(\text{CO}_3)_3^{3-}$ interaction was fixed at the literature $\beta^{(1)}$ value of 8.1 for Na^+ - AsO_4^{3-} interaction, on the assumption that these two interactions were analogous. The $\beta^{(0)}$ was then adjusted to 0.24 to fit the solvent extraction data of Bidoglio [4]. Ideally, the same model might be applicable to the Nd(III) system, because Nd(III) has been demonstrated to be a good analog for trivalent actinide species [28,29]. However, when the model was tested with the solubility data for Nd(III) in the concentrated carbonate and bicarbonate solutions, it was found that 1) some adjustments of $\beta^{(0)}$ and/or $\beta^{(1)}$ for Na^+ - $\text{Nd}(\text{CO}_3)_3^{3-}$ seemed to be necessary, and 2) including the Na^+ - $\text{Nd}(\text{CO}_3)_2^-$ interaction into the model significantly improved the fitting of the present experimental data, especially for the sodium bicarbonate systems. It appeared that such ion interactions could not be ignored when $\text{Nd}(\text{CO}_3)_2^-$ became a major aqueous neodymium species. Because $\beta^{(0)}$ and $\beta^{(1)}$ may be redundant in these solutions, improvements on the fitting could be achieved by adjusting either of them, but not both simultaneously. For the Na^+ - $\text{Nd}(\text{CO}_3)_3^{3-}$ interaction, we decided to fix $\beta^{(1)}$ at the same value as in the Am-carbonate and bicarbonate model [16] and adjust $\beta^{(0)}$ and C^ϕ . For the Na^+ - $\text{Nd}(\text{CO}_3)_2^-$ interaction, only $\beta^{(1)}$ was included and adjusted because it significantly improved the fitting of the Nd(III) data in the lower sodium bicarbonate concentration region. The standard chemical potentials for aqueous Nd(III)-carbonate species were fixed at the values calculated for the analogous Am(III) species by Felmy et al. [16].

Different models were tested, and the simplest model that was consistent with the solubility data in this study and those in Felmy et al. [16] is given in Table 3. The negative value of $\beta^{(1)}$ for the $\text{Na}^+\text{-Nd}(\text{CO}_3)_2^-$ interaction implies that there is a strong associative interaction between Na^+ and $\text{Nd}(\text{CO}_3)_2^-$, which is not surprising because the equilibrium solid phase was $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$. We do not have a satisfactory interpretation for the opposite signs of $\beta^{(0)}$ and $\beta^{(1)}$ for the $\text{Na}^+\text{-Nd}(\text{CO}_3)_3^{3-}$ interaction on the basis of the currently available data. However, the opposite signs might indicate that some other interactions have not been entirely accounted for by the present model. Nevertheless, the current model provides a satisfactory interpretation of the available data over a wide range of concentrations. A better understanding of these systems requires more extensive studies in mixed electrolyte media.

The value of μ°/RT for $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ was calculated to be -1425.726 by this model, which corresponds to a K_{sp} value of $10^{-21.40}$ for the reaction

This model provides a satisfactory fit to the solubility data of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ in both the sodium carbonate and bicarbonate solutions (Figure 2).

Whether or not trivalent lanthanides and actinides form bicarbonato complexes in these systems has been a controversial subject in the literature. Bidoglio [4] represented his solvent extraction data in terms of aqueous complexes including $\text{Am}(\text{HCO}_3)_2^{2+}$ and $\text{Am}(\text{HCO}_3)_2^+$. However, the spectrophotometric experiments of Nitsche and Silva [29] did

Table 3 Additional Ion-Interaction Parameters Developed in This Study

Species	Ion-Interaction Parameters		
	$\beta^{(0)}$	$\beta^{(1)}$	$C^\dagger$
$\text{Na}^+ \text{-Nd}(\text{CO}_3)_3^{3-}$	-0.94	8.10	0.418
$\text{Na}^+ \text{-Nd}(\text{CO}_3)_2^-$	0	-8.37	0

Figure 2. Solubility of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ in sodium carbonate and sodium bicarbonate solutions.

not support the existence of such complexes. Felmy et al. [16] found that both their solubility data and Bidoglio's solvent extraction data [4] could be well interpreted without invoking the americium bicarbonate complexes. In this study for the $\text{Na}^+ - \text{Nd}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system, the inclusion of $\text{Nd}(\text{HCO}_3)_2^{2+}$ and/or $\text{Nd}(\text{HCO}_3)_2^-$ complexes into the model did not provide satisfactory interpretation of the experimental data. As a result, these complexes were not invoked.

3.2 Application of the Present Model in Less Concentrated Carbonate and Bicarbonate Systems

Developing a model that is applicable to systems covering a wide concentration range is desirable. Because the interaction parameters in the present model (Table 3) were developed based on the data for concentrated sodium carbonate and sodium bicarbonate solutions (0.1 M to near saturation), the applicability of this model needed to be tested in less concentrated solutions. Based on the assumption that Nd(III) is a good analog of Am(III), this model was tested with the experimental solubility data [16] for the $\text{Na}^+ - \text{Am}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system at lower carbonate and bicarbonate concentrations (< 0.1 M) and over a wide pH range (Figure 3). The tests for the data in the pH region below 9.5 indicated that the predictions made with the present model are in very good agreement with the original data and with the previous model proposed by Felmy et al. [16] (Figure 3a and 3b). However, the predictions made with the two models deviate slightly from each other in the higher pH region. Nevertheless, even in the higher pH region (Figure 3c), the present model provides satisfactory predictions.

Figure 3. Comparison of the predictions for the Na⁺-Am³⁺-HCO₃⁻-CO₃²⁻-OH⁻-H₂O system by the previous and the present models.

3.3 Solution Speciation and Stable Solid Phases

Four aqueous Nd(III) species, i.e., Nd^{3+} , $\text{Nd}(\text{CO}_3)^+$, $\text{Nd}(\text{CO}_3)_2^-$, and $\text{Nd}(\text{CO}_3)_3^{3-}$, are invoked in this model. The model predicts that in the sodium carbonate solutions with $[\text{Na}_2\text{CO}_3] > 0.1 \text{ M}$, $\text{Nd}(\text{CO}_3)_3^{3-}$ is the only predominant species in the aqueous phase, while in the sodium bicarbonate solutions with $[\text{NaHCO}_3] > 0.1 \text{ M}$, both $\text{Nd}(\text{CO}_3)_2^-$ and $\text{Nd}(\text{CO}_3)_3^{3-}$ exist in significant concentrations. Efforts were made to obtain experimental evidence for the existence of these neodymium species by the extended X-ray absorption fine structure (EXAFS) technique. Only a few samples with high carbonate concentrations were analyzed because the $[\text{total Nd}]_{\text{aq}}$ in other samples were too low for this technique. Preliminary analysis indicated that there are probably three carbonate groups in the primary coordination sphere of Nd(III) in the concentrated carbonate solutions, which is consistent with the prediction by the present model.

In the previous work on the $\text{Na}^+ - \text{Am}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system at lower carbonate and bicarbonate concentrations ($< 0.1 \text{ M}$) [16], the stable solid phase was found to be the hydroxycarbonato compound of Am(III), $\text{AmOH}(\text{CO}_3)(\text{c})$ ($K_{\text{sp}} = 10^{-22.5}$). However, in this study on the $\text{Na}^+ - \text{Nd}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system at higher carbonate and bicarbonate concentrations, the stable solid phase was found to be $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$, with a K_{sp} value of $10^{-21.4}$. It is interesting to use the available thermodynamic data and predict the stable regions for these two types of solid phases, i.e., $\text{NaM}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ and $\text{MOH}(\text{CO}_3)(\text{c})$ (M is Am or Nd). The phase transition between $\text{NaM}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ and $\text{MOH}(\text{CO}_3)(\text{c})$ can be expressed by the following reaction:

This equilibrium depends on several factors such as pH and concentrations of carbonate and sodium ion. From the available chemical potential values for the species participating in this reaction, the equilibrium constant (K_{eq}) for equation 6 can be calculated. Based on this reaction, if $\{\log[\text{Na}^+] + \log[\text{CO}_3^{2-}]\}$ is plotted against pH, the equilibrium between these two solid phases will be represented by a straight line with a slope of +1 and an intercept of $\log K_{\text{eq}}$. Figure 4 is such a plot, and it shows the equilibrium line dividing the two phases. Experimental points for $\text{NaM}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ from this work and those for $\text{MOH}(\text{CO}_3)(\text{c})$ in literature are also included in the plot. As Figure 4 indicates, most of the experimental points consistently fall in the right region for the identified solid phase. Only a few points from the $\text{Na}^+ - \text{Am}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system [16] seem to be in the wrong phase region. Those points correspond to the solubility data for the two highest carbonate concentration solutions at 30 and 44 days of aging in the $\text{Na}^+ - \text{Am}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system [16]. Felmy et al. noticed that those data points significantly deviated from their model prediction (Figure 9 in Felmy et al. [16]). Probably the uncertainty in identifying the solid phases for those few points is responsible for these discrepancies.

4. Summary

$\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ was identified to be the thermodynamically stable solid phase in sodium carbonate and sodium bicarbonate solutions (0.1 M to near saturation). The solubility product of $\text{NaNd}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ was calculated based on the thermodynamic model developed for the present $\text{Na}^+ - \text{Nd}^{3+} - \text{HCO}_3^- - \text{CO}_3^{2-} - \text{OH}^- - \text{H}_2\text{O}$ system. This model is

Figure 4. Phase transition between $\text{NaM}(\text{CO}_3)_2 \cdot 6\text{H}_2\text{O}(\text{c})$ and $\text{MOH}(\text{CO}_3)(\text{c})$.

in good agreement with the solubility data for the Am(III) and Nd(III) carbonate systems covering a wide range of carbonate concentrations (dilute to near saturation). Values of Pitzer parameters for the ion interactions of $\text{Na}^+\text{-Nd}(\text{CO}_3)_3^{3-}$ and $\text{Na}^+\text{-Nd}(\text{CO}_3)_2^-$ were developed. Further testing of this model is planned in mixed electrolyte solutions of sodium chloride - sodium bicarbonate and sodium chloride - sodium carbonate.

Acknowledgments

The work described in this report was done for Sandia National Laboratories under Contract No. AF-3339. The authors are thankful to C.F.Novak, the Sandia Project Manager, for his encouragement and technical support throughout this study. Thanks are also due to J.E. Amonette and J.P.Zipperer for the EXAFS analysis, and to K.L.Manke for editorial assistance.

ABSTRACT

Safety assessments of nuclear waste repositories often require estimation of actinide solubilities as they vary with groundwater composition. Although a considerable amount of research has been done on the solubility and speciation of actinides,^{1,2} relatively little has been done to unify these data into a model applicable to concentrated brines. Numerous authors report data on the aqueous chemical properties of Np(V) in NaClO₄, Na₂CO₃, and NaCl media, but a consistent thermodynamic model for predicting these properties is not available. To meet this need, a model was developed to describe the solubility of Np(V) in Na-Cl-ClO₄-CO₃ aqueous systems, based on the Pitzer activity coefficient formalism for concentrated electrolytes. Hydrolysis and/or carbonate complexation are the dominant aqueous reactions with the neptunyl ion in these systems. Literature data for neptunyl ion extraction and solubility are used to parameterize an integrated model for Np(V) solubility in the Np(V)-Na-CO₃-HCO₃-Cl-ClO₄-H-OH-H₂O system. The resulting model is tested against additional solubility and extraction data, and compared with Np(V) solubility experiments in complex synthetic brines.

THE PITZER ACTIVITY COEFFICIENT MODEL

The Pitzer activity coefficient model³ is a semi-empirical formalism describing the thermodynamics of electrolyte systems. Model parameterizations exist for brine evaporite systems^{4,5} and, in a more limited fashion, for +III and +IV actinides in brines.^{6,7,8,9} The model is general enough to describe solutions from dilute to high concentration, and is formalized for complex electrolytes such as natural brines. Activity coefficients are represented by a virial expansion which, truncated to binary interactions, has the form

$$\ln \gamma_m = z_m^2 F + 2 \sum_{a=1}^{N_a} m_a B_{ma}(I) \quad \text{for cation "m"}$$

where F represents the Debye-Hückel term, N_a is the number of anions, and z_m is the charge on cation m . A similar expression holds for anions. The complete forms of the equations and extensive discussion are given elsewhere.^{3,4} The second virial coefficients $B_{ma}(I)$ are functions of the ionic strength, and are given by the relationship

$$B_{ma}(I) = \beta_{ma}^{(0)} + \beta_{ma}^{(1)} g(\alpha_{ma}\sqrt{I}) + \beta_{ma}^{(2)} g(12\sqrt{I}) \quad \text{for cation "m," anion "a"}$$

where $\beta_{ma}^{(0)}$, $\beta_{ma}^{(1)}$, and $\beta_{ma}^{(2)}$ are parameters that are important at high, intermediate, and low ionic strength, respectively, and $g(y)$ is a decaying exponential function of the argument. When only the $\beta_{ma}^{(0)}$ coefficient is nonzero, this model is similar to SIT,¹⁰ although a species molality, not the total ionic strength, multiplies this coefficient. The following sections discuss the process of determining $\beta_{ma}^{(0)}$ and $\beta_{ma}^{(1)}$ values and standard chemical potentials for the Np(V) system.

DEVELOPING AND TESTING THE NP(V) SOLUBILITY MODEL

Brief descriptions of the data used to parameterize and test the model are given below. Selection of data sets for model development was based in part on evaluations in reviews or compilation for actinides.^{1,11,12} Experimental details can be found in the source reports. Data interpretation was performed using the computer code NONLIN (developed by A.R. Felmy, uses

the MINPACK nonlinear least-squares programs in combination with a chemical equilibrium program based on the Gibbs free-energy minimization procedure of Harvie et al.¹³; comparison of the parameterization with the experimental data were made using either NONLIN (Versions MacNONLIN 94.05.13b for solubility and MacNONLINex 94.07.09 for extraction) or FMT (FMT Version 1.0, a geochemical transport code under development by C.F. Novak).

The general parameterization process begins with the least complex data sets, or data sets from which one can determine the fewest number of parameters. As each parameter is generated, it is tested whenever possible by comparison against independent data. When an acceptable fit is obtained, these parameter values are fixed and held constant through the remaining parameter determinations. The data sets used to parameterize and test the Np(V) solubility model are summarized in Table I. Most of the data in Table I were taken at 25°C, although several of the experiments were at 20°C,¹⁴ as is the work first reported here. The slight temperature dependence of the equilibrium constants and Pitzer ion interaction parameters over this small temperature range were neglected in this study. In total, the model parameterization calculated eight standard chemical potentials and six ion interaction parameters. Fixed parameters from the literature are in Table II; calculated standard chemical potentials and ion interaction parameters are in Tables III and IV.

Neptunyl Interactions with Perchlorate and Chloride (Data Series P1, P2; T1, T2)

Data measuring the extraction of Np(V) with sodium dinonylnaphthalenesulfonate (NaDNNS) from 0.2 - 5M NaClO₄ or NaCl solutions¹⁵ were used to determine interaction parameters between NpO₂⁺ and ClO₄⁻, and NpO₂⁺ and Cl⁻. The experimental distribution coefficients $D = m_{\text{Np(o)}}/m_{\text{Np(aq)}}$ are shown in Fig. 1a along with the fitted models. Note that neither Cl⁻ nor ClO₄⁻ complexes were required to fit the data. These values are used to predict Np(V) extraction equilibria in NaCl/NaClO₄ mixtures at 2M total ionic strength¹⁶ and 5M total ionic strength,¹⁵ where D^0 is the measured distribution coefficient when no Cl⁻ is present. Fig. 1b shows that the model prediction compares quite well with experimental values.

Figure 1. Solvent extraction data of Np(V) with NaDNNS from (a) NaCl or NaClO₄ media,¹⁵ with the fitted model $\beta_{\text{NpO}_2^+-\text{ClO}_4^-}^{(0)} = 0.312$ and $\beta_{\text{NpO}_2^+-\text{Cl}^-}^{(0)} = 0.169$; (b) NaCl/NaClO₄ mixtures maintained at 2M and 5M constant ionic strength.^{16,15} Predicted lines use parameter values obtained in Fig. 1a.

Neptunyl Hydroxide Solids and Neptunyl Hydrolysis (Data Series P3; T3)

The solubility of NpO₂OH(am/aged) in 0.1, 1, and 3M NaClO₄ as a function of OH⁻ concentration were investigated,^{17,18} and the data are plotted in Fig. 2. The solubility of

Table I. Experimental systems used to parameterize (P) and test (T) the Np(V) solubility model. A single value was determined for each of the fourteen parameters using data in the P series. These values were tested as often as appropriate against the data listed as the T series. The final two experimental systems provided an overall comparison of the model with data.

$\text{NpO}_2\text{OH(aged)}$ is lower than $\text{NpO}_2\text{OH(am)}$, and the system shows amphoteric behavior. These data can be interpreted using the solubility and hydrolysis reactions

Because the solubility was determined in relatively high NaClO_4 concentrations, the data interpretation requires the ion interaction parameters for $\text{NpO}_2^+-\text{ClO}_4^-$, calculated in the previous section. Although these data, Fig. 2, represent two solid phases with different standard chemical potentials, the hydrolysis behavior is independent of the solid phase and thus must be the same for both. The "low" pH data ($\log(m_{\text{OH}^-}) < -3$) were used to determine standard chemical potentials for the solid phases in Reactions 1 and 2, see Table III. The agreement between the model and the solubility data at low pH values as a function of NaClO_4 concentration, Fig. 2, indicates that the $\beta^{(0)}$ value determined from solvent extraction data is reliable. The standard chemical potential for $\text{NpO}_2(\text{OH})_2^-$ was fitted from the high m_{OH^-} values where this species dominates; the standard chemical potential for $\text{NpO}_2\text{OH(aq)}$ was fitted from the intermediate m_{OH^-} values, also in Table III. No ion interaction parameters between hydrolysis species and either Na^+ or ClO_4^- were required.

Figure 2. Data^{17,18} used to calculate standard chemical potentials for neptunium hydroxide solid and hydrolysis species, and to build confidence in the value for $\beta_{\text{NpO}_2^+-\text{ClO}_4^-}^{(0)}$.

The reliability of the standard chemical potential for $\text{NpO}_2\text{OH(am)}$ and the Pitzer ion interaction parameter for NpO_2^+ with Cl^- determined above were tested using data that we measured for the solubility of $\text{NpO}_2\text{OH(am)}$ in NaCl solutions; see the Appendix for details. Good agreement between the measured and predicted solubility of $\text{NpO}_2\text{OH(am)}$ in NaCl solutions (Fig. 3) indicates that the values for $(\mu_i^0/RT)_{\text{NpO}_2\text{OH(am)}}$ and $\beta_{\text{NpO}_2^+-\text{Cl}^-}^{(0)}$ are reliable.

Figure 3. Experimental data and model predictions of $\text{NpO}_2\text{OH(am)}$ solubility in NaCl solutions.

Standard Chemical Potentials for $\text{NaNpO}_2\text{CO}_3(\text{s})$, $\text{NpO}_2\text{CO}_3^-$, and $\text{NpO}_2(\text{CO}_3)_2^{3-}$; and Ion Interactions for $\text{Na}^+-\text{NpO}_2\text{CO}_3^-$ and $\text{Na}^+-\text{NpO}_2(\text{CO}_3)_2^{3-}$ (Data Series P4, P5; T5, T6)

Neptunyl complexation with carbonate and the solubility of $\text{NaNpO}_2\text{CO}_3(\text{s})$ in several media under different conditions have been reported by various authors.^{14,15,19,20,21} These data were used to develop and test the model for neptunyl complexation with carbonate. The bulk of the data was taken at constant $\text{CO}_2(\text{g})$ pressure in 0.1, 1.0, 3.0, and 5.0M NaClO_4 (Neck et al.¹⁵; Kim et al.²⁰), although Maya²¹ reported solubility both in solutions with fixed total inorganic carbon and with fixed $\text{CO}_2(\text{g})$ partial pressure. During analysis, a discrepancy of up to 1.1 log units was noted in some of the data^{15,20} between the reported hydrogen ion and carbonate concentrations and the Harvie-Møller-Weare model⁴ predictions. This may indicate the need for improved models describing the solubility of $\text{CO}_2(\text{g})$ in NaClO_4 media, or a lack of equilibrium between the CO_2 in the gas and aqueous phases. This discrepancy rendered it unrealistic to use pH/pcH values and fixed $\text{CO}_2(\text{g})$ pressures for parameterization, thus the reported carbonate concentrations were considered primary data. This interpretation is reasonable because the data of Maya,²¹ in which Np(V) solubilities were measured both for fixed solution composition and solutions in equilibrium with a gas phase, overlie the data from Kim et al.²⁰ for 1.0M NaClO_4 solutions. These data, plotted in Fig. 4, were used to calculate thermodynamic parameters for $\text{NaNpO}_2\text{CO}_3(\text{s})$, $\text{NpO}_2\text{CO}_3^-$, and $\text{NpO}_2(\text{CO}_3)_2^{3-}$. The behavior of the neptunyl ion in the presence of carbonate can be described by the reactions

Data for $\log(m_{\text{CO}_3^{2-}}) < -5$, where Reaction 5 dominates, were used to determine the standard chemical potential of the solid, and to test the value for $\beta_{\text{NpO}_2^+-\text{ClO}_4^-}$. The mono- and bis-carbonato species dominate in the intermediate carbonate concentration range, $-5 < \log(m_{\text{CO}_3^{2-}}) < -2.5$; these data were used to calculate $(\mu_f^\circ/\text{RT})_{\text{NpO}_2\text{CO}_3^-}$, $(\mu_f^\circ/\text{RT})_{\text{NpO}_2(\text{CO}_3)_2^{3-}}$, and the binary ion

interaction parameters $\beta_{\text{Na}^+-\text{NpO}_2\text{CO}_3}^{(0)}$ and $\beta_{\text{Na}^+-\text{NpO}_2(\text{CO}_3)_2}^{(0)}$. These parameter values were tested against extraction data,¹⁹ producing the favorable comparison shown in Fig. 5. The region where $\log(m_{\text{CO}_3^{2-}}) > -2.5$ is discussed in the following section.

Figure 4. Data^{15,20,21} for parameterizing/testing the model for neptunyl-carbonate reactions.

Figure 5. Comparison of model with data¹⁹ for extraction of neptunyl carbonate complexes in 1.0M NaClO₄.

Standard Chemical Potential for $\text{NpO}_2(\text{CO}_3)_3^{5-}$ and $\text{Na}^+-\text{NpO}_2(\text{CO}_3)_3^{5-}$ Ion Interactions (Data Series P6; T7)

Calculating thermodynamic parameters for the neptunyl triscarbonato species requires data extending to high carbonate concentration. Ueno and Saito¹⁴ examined the solubility of $\text{NaNpO}_2\text{CO}_3(\text{s})$ in 0.05 to 1.6 M Na_2CO_3 solutions. Although $\text{Na}_3\text{NpO}_2(\text{CO}_3)_2(\text{s})$ has been reported to be the stable phase in these high concentration ranges,¹¹ $\text{NaNpO}_2\text{CO}_3(\text{s})$ was most probably the metastable equilibrium solid over the reported one to two day equilibration period. Assuming the $\text{NaNpO}_2\text{CO}_3(\text{s})$ solid phase, and using the thermodynamic parameters

previously developed in this paper, these solubility data are well represented by the triscarbonato species from Reaction 8 and the ion interaction parameters $\beta_{\text{Na}^+-\text{NpO}_2(\text{CO}_3)_3}^{(0)}$ and $\beta_{\text{Na}^+-\text{NpO}_2(\text{CO}_3)_3}^{(1)}$, as shown by the comparison in Fig. 6. The predicted solubilities of $\text{NaNpO}_2\text{CO}_3(\text{s})$ in NaClO_4 solutions are consistent with the data sets given in Fig. 4 for $\log(m_{\text{CO}_3^{2-}}) > -2.5$, where the species $\text{NpO}_2(\text{CO}_3)_3^{5-}$ is also important. Thus the solid phase identified by Ueno and Saito is supported, and values for the neptunyl triscarbonato complex can be calculated from these data. Although $\text{NpO}_2(\text{CO}_3)_2^{3-}$ never dominates under the conditions of Fig. 6, this species is dominant under the conditions of Fig. 4 for $-4 < \log(m_{\text{CO}_3^{2-}}) < -2$.

Figure 6. Data¹⁴ and model fit of $\text{NaNpO}_2\text{CO}_3(\text{s})$ solubility in Na_2CO_3 solutions.

thermodynamic equilibrium constants for the hydrolysis system, Reactions 1 through 4, are $\log K_{\text{sp}} = -8.72$, $\log K_{\text{sp}} = -9.32$, $\log \beta_{101} = 2.58$, and $\log \beta_{102} = 4.27$, respectively; the thermodynamic equilibrium constants for the carbonate system, Reactions 5 through 8, are $\log K_{\text{sp}} = -11.3$, $\log \beta_{101} = 5.39$, $\log \beta_{102} = 5.81$, and $\log \beta_{103} = 5.19$, respectively. Comparison with parameter values reported for 1-1, 3-1, and 5-1 electrolytes²² show that all the values for activity coefficient parameters are reasonable, e.g., our calculated value for the 5:1 electrolyte $\beta_{\text{Na}^+-\text{NpO}_2(\text{CO}_3)_3}^{(1)} = 16$ compares favorably with the value $\beta_{\text{Na}^+-\text{P}_3\text{O}_{10}}^{(1)} = 21.66$ of Pitzer.²²

TESTING THE PREDICTIVE ABILITY OF THE MODEL

Although the model explains many simple data sets, additional testing of the model is necessary to generate confidence that the model can predict total dissolved Np(V) concentrations in complex natural systems. Two comparisons are given here to provide some confidence in this model, and indicate some directions for future work.

Most of the data used to develop this model were obtained in NaClO_4 media; little data in NaCl media were available. However, in natural systems, NaCl is likely to be the dominant electrolyte, and thus it is essential to establish the applicability of this model to sodium chloride solutions. Then, is it possible that the solubility behavior of Np(V) in more complex natural brines, e.g., containing small amounts of K-Mg-Ca-SO_4 , can be approximated by this model. These points are tested against additional experimental data.

The solubility of $\text{NaNpO}_2\text{CO}_3(\text{s})$ is reported¹⁵ as a function of pH in 5M NaCl at constant $\log P_{\text{CO}_2(\text{g})}$ of -3.5 . In contrast with these authors' similar data in NaClO_4 , the reported hydrogen ion and carbonate concentrations are consistent with the Harvie-Møller-Weare model.⁴ Thus the system can be modeled as open to the gas phase. A comparison of these data with the model developed above is presented in Fig. 7 along with calculated species concentrations. The model follows the trend of the data quite well, especially for high carbonate concentrations, but is offset for lower carbonate concentrations, particularly in the region where the mono- and biscarbonate species dominate. Although this may indicate that additional species are necessary to describe this system, there was no need to invoke neptunyl chloride species to describe the simpler experimental systems above. Possible reasons for the discrepancy between the observed and calculated concentrations, include: (1) the assumption that carbonate speciation in concentrated

DISCUSSION OF MODEL AND PARAMETERS

The model developed here is a comprehensive, unified description of Np(V) solubility behavior in $\text{Na-CO}_3\text{-Cl-ClO}_4$ media. The model is based on the formation of important aqueous species and binary cation-anion interactions between neptunyl species and bulk solution ions. The model is a synthesis of, and explains, nine different data sets representing two types of experiments. Model species and parameters are summarized in Tables III and IV. The

sodium perchlorate solutions can be described without any carbonate, bicarbonate, or carbonic acid ion interaction parameters with perchlorate may be poor, (2) the standard chemical potential may be different for this solid phase; (3) additional specific ion interaction parameters, e.g., $\text{NpO}_2^+-\text{Na}^+-\text{Cl}^-$ or $\text{NpO}_2\text{CO}_3^--\text{Cl}^-$, may be required; or (4) equilibrium may not have been attained. Additional experiments at different NaCl concentrations in NaCl/ Na_2CO_3 media are needed to refine the values for ion interaction parameters for this system.

Figure 7. Comparison of model with $\text{NaNpO}_2\text{CO}_3(\text{s})$ solubility data¹⁵ in 5M NaCl.

A further test of this model is comparison with solubility measurements in complex synthetic brines. Oversaturation experiments with $^{237}\text{Np}(\text{V})$ were conducted in the brines AISinR and H-17, with molal concentrations: Na^+ (0.64, 2.5), K^+ (0.0082, 0.032), Mg^{2+} (0.022, 0.078), Ca^{2+} (0.017, 0.031), Cl^- (0.58, 2.6), SO_4^{2-} (0.080, 0.080), B (0.0028, 0.0042), Br^- , (0, 0.0010); with $\text{PCO}_2(\text{g})$ as 0.0019 and 0.0028 atm, respectively. These ongoing experiments are similar to others conducted with Pu in these same brines.²³ Sufficient amounts of Np(V) were added to cause oversaturation and precipitation of a neptunium solid phase. The operational hydrogen ion concentration was controlled within ± 0.1 units, and the aqueous neptunium concentration was monitored. Approximate steady-state aqueous concentration were reached after about 400 days. The solid phases were characterized by X-ray diffraction as $\text{NaNpO}_2\text{CO}_3(\text{s})$. These brines are predominantly sodium chloride, so previous electrode titrations, as discussed in the Appendix, were used as pH/pC_H calibrations. The measured total dissolved Np(V) concentration in AISinR Brine at $-\log(m_{\text{H}^+}) = 7.7 \pm 0.2$ is 2×10^{-6} molal; the model predicts 6×10^{-6} to 2×10^{-5} molal. The measured total dissolved Np(V) concentration in H-17 Brine at $-\log(m_{\text{H}^+}) = 7.8 \pm 0.2$ is 1×10^{-6} molal; the model predicts 2×10^{-6} to 3×10^{-6} molal. The comparison is very good, with an order of magnitude or less difference between measured and calculated values. Although more data in complex brines are required to support the model, this work suggests the building block approach will prove successful for predicting dissolved Np(V) concentrations in complex brines.

CONCLUDING REMARKS

The Np(V) solubility model developed here explains many different data sets from different types of experiments. As such, it appears to be robust and may be usable to obtain order-of-magnitude estimates of neptunium solubility in predominantly NaCl groundwaters.

Additional experimental measurement of Np(V) chemistry in NaCl/Na₂CO₃ media would allow refinement of the model and improve the predictive ability in high chloride systems.

APPENDIX

Green NpO₂OH(am) was synthesized¹⁷ and added to 0.3, 0.6, 1.0, 1.8, 3.0, and 5.6m NaCl solutions and allowed to react for 37 days. Experiments, including solution preparations, were performed in an argon atmosphere glove box using freshly distilled, deionized water to avoid introduction of carbon dioxide. No conversion to NpO₂OH(aged) was noted, although this conversion was seen in concentrated NaClO₄ within this time span¹⁷. Phases were separated by filtering aliquots of solution through presaturated 4.1 nm filters (Amicon Corp., Danvers, MA). Aqueous neptunium concentrations were determined by γ -pulse height analysis of the 29.38 keV gamma emission from the ²³⁷Np in the supernatant. Hydrogen ion concentrations were measured using a Ross combination pH electrode (Orion Research Inc., Boston, MA) at the time of each assay. The operational pH read by the glass electrode was related to the actual proton concentration in each NaCl solution by earlier potentiometric titration of standardized solutions of HCl with NaOH, both adjusted to the desired NaCl concentration.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Gregory R. Choppin, David L. Clark, Andrew R. Felmy, and Dhanpat Rai for the technical interaction that contributed much to the form and substance of this work. Experimental work was performed at the Lawrence Berkeley Laboratory by Philip Torretto, Traudel Prussin, Herbert B. Silber, Scott A. Carpenter, David E. Hobart, and Heino Nitsche. Robert L. Paolino digitized data where necessary. This work was supported by the United States Department of Energy under Contract DE-AC04-94AL85000.
