ABSTRACT

We studied the reaction of phenyl radicals (C₆H₅) with propylene (C₃H₆) exploiting a high temperature chemical reactor under combustion-like conditions (300 Torr, 1,200-1,500 K). The reaction products were probed in a supersonic beam by utilizing tunable vacuum ultraviolet (VUV) radiation from the Advanced Light Source and recording the photoionization efficiency (PIE) curves at mass-to-charge ratios of m/z = 118 (C₉H₁₀⁺) and m/z = 104 (C₈H₈⁺). Our results suggest that the methyl and atomic hydrogen losses are the two major reaction pathways with branching ratios of 86 ± 10 % and 14 ± 10 %. The isomer distributions were probed by fitting the recorded PIE curves with a linear combination of the PIE curves of the individual C₉H₁₀ and C₈H₈ isomers. Styrene (C₆H₅C₂H₃) was found to be the exclusive product contributing to m/z = 104 (C₈H₈⁺), whereas 3-phenylpropene, cis-1-phenylpropene, and 2-phenylpropene with branching ratios of 96 ± 4 %, 3 ± 3 %, and 1 ± 1 % could account for signal at m/z = 118 (C₉H₁₀⁺). Although searched for carefully, no evidence of the bicyclic indane molecule could be provided. The reaction mechanisms and branching ratios are explained in terms of electronic structure calculations nicely agreeing with a recent crossed molecular beam study on this system.
As precursors of soot as well as their importance in combustion, atmospheric and interstellar chemistry, the formation routes to polycyclic aromatic hydrocarbons (PAHs) have received considerable attention. It is widely accepted that the phenyl radical, C6H5(X2A1), represents a crucial building block to yield the second ring thus initiating the formation of PAHs and related molecules such as (partially) hydrogenated and/or dehydrogenated PAHs in combustion systems. In detail, PAHs have been suggested to be formed via hydrogen abstraction - acetylene addition (HACA) sequences or via phenyl addition - cyclization pathways (PAC). Alternative pathways have been investigated via kinetic studies and crossed beam experiments of phenyl radicals with unsaturated hydrocarbons. Very recently, indane has been identified as one of the products in a low-pressure premixed toluene/oxygen/argon fuel rich flames by Li et al. at 2009. The aromatic, bicyclic indane molecule as well as its α-methylstyrene (2-phenylpropene) and 1-phenylpropene isomers are considered as important reaction intermediates and toxic byproducts in the combustion of fossil fuel (Figure 1). The reaction of the phenyl radical (C6H5) with propylene (C3H6) presents a potential synthetic routes to synthesize C9H10 isomers and to access the C9H11 potential energy surface.

As early as in 1972, Hefter et al. investigated this system in liquid propylene at 183 K utilizing electron spin resonance. In 2006, Park et al. conducted a kinetics study exploiting cavity ring-down spectroscopy at temperatures between 296 and 496 K combined with ab initio calculations; in 2008, Kaiser et al. conducted a crossed beam experiment of this system at elevated collision energies of 130 to 190 kJ mol⁻¹. All three studies agreed that this reaction was initiated by an addition of the phenyl radical predominantly to the C1-carbon atom of the propylene molecule at the =CH₂ unit to form a doublet radical intermediate; the latter ejected a hydrogen atom via a rather loose exit transition state forming solely monocyclic C9H10 isomers. No methyl group loss was observed at elevated collision energies. Most recently, our group re-investigated this reaction utilizing a crossed beam method at a much lower collision energy of about 45 kJ mol⁻¹. The methyl group loss channel yielding styrene was successfully identified, and a fraction of the methyl versus hydrogen loss channels of 68 ± 6% to 32 ± 10% was derived experimentally agreeing nicely with RRKM theory. Apart from crossed beam and flame studies, reactions carried out under pyrolytic conditions present an excellent
complementary approach to simulate combustion-like conditions and to investigate the formation mechanisms of PAHs. In 2008, Shukla et al. conducted an investigation on the basis of a kinetic analysis of gas phase products of pyrolysis of benzene with and without addition of acetylene. Reactions were conducted in a flow tube, and the products were probed in situ by a direct sampling mass spectrometric technique using vacuum ultraviolet (VUV) single photon ionization (SPI) time of flight mass spectrometry (TOF-MS). The authors found that the PAC pathway presented a highly efficient growth mechanism to form PAHs. The products included PAHs up to 454 amu (C_{36}H_{22}). Especially, acetylene was mixed with benzene to understand the impact of HACA on the PAC pathways; this resulted in an enhancement of PAH production in spite of trapping of active and chain-carrier species such as the phenyl radical by acetylene to form phenylacetylene. The comparison of both the HACA and PAC mechanisms concluded that PAC is a highly efficient mechanism for the growth of PAHs.

Recently, we studied the reaction of phenyl (C_{6}H_{5}) with methylacetylene (CH_{3}CCH) and allene (H_{2}CCCH_{2}) exploiting a high temperature chemical reactor under combustion-like conditions (300 Torr, 1,200-1,500 K). The product isomer distributions were probed utilizing tunable VUV radiation from the Advanced Light Source (ALS) by recording the photoionization efficiency (PIE) curves at mass-to-charge of m/z = 116 (C_{9}H_{8}^{+}) of the products in a supersonic expansion. Branching ratios were derived by fitting the recorded PIE curves with a linear combination of the individual C_{9}H_{8} isomer PIE curves. In both reactions, the aromatic indene molecule was identified. In this paper we expand on these studies systematically by decreasing the carbon-to-hydrogen ratio of the closed shell reactant from 0.75 (methylacetylene, allene) to 0.5 (propylene) and report on the results of the phenyl-propene reaction utilizing the very same pyrolytic reactor. Recall that in case of distinct structural isomers, the adiabatic ionization energy (IE) and the corresponding PIE curves, which report the ion signal of m/z = 116 (C_{9}H_{10}^{+}) of a distinct isomer versus the photon energy, can differ dramatically. By photoionizing the neutral C_{9}H_{10} products in the supersonic molecular beam via tunable vacuum ultraviolet (VUV) radiation from the Advanced Light Source at various photon energies, we measured PIEs of m/z = 118 (C_{9}H_{10}^{+}) and m/z = 104 (C_{8}H_{8}^{+}). These PIE curves are the result of a linear combination of the individual isomer PIE curves present in the supersonic beam and hence we can identify the products formed in the reactions of phenyl radicals with propylene and extract their branching ratios.
2. Experimental

The central device of the experiments is a resistively heated high temperature ‘chemical reactor’ incorporated into the molecular beams end station at the Chemical Dynamics Beamline (9.0.2.) of the Advanced Light Source. Briefly, this setup allows a simulation of combustion-relevant conditions such as temperature and pressure as well as chemical reactions to form combustion-relevant molecules such as PAHs and their isomers in situ. Here, a continuous beam of phenyl radicals (C$_6$H$_5$) was generated in situ via quantitative pyrolysis of nitrosobenzene (C$_6$H$_5$NO; Aldrich) - held at 293 K - seeded in neat propylene carrier gas (C$_3$H$_6$; Sigma), which was expanded at a pressure of 300 Torr through a 0.1 mm orifice into a resistively heated silicon carbide (SiC) tube with an inner diameter of 1 mm and a length of 20 mm. A heating current of 1.3 A was applied to the silicon carbide tube reflecting an operating power of 20 W. An independent temperature calibration of the pyrolytic source with pure helium carrier gas coupled to a time-of-flight mass spectrometer and chopper wheel suggested temperatures of 1,200 – 1,500 K of the silicon carbide tube. In the present experiments, we would like to stress that propylene did not only act as a seeding gas, but also as a reactant with the pyrolytically generated phenyl radicals. Considering the length of the tube of 2.0 ± 0.1 cm and a thermal, non-supersonic velocity of the propylene reactant at 1,350 ± 150 K inside the tube of 900 ± 50 ms$^{-1}$, we estimate a residence time of the reactants in the silicon carbide tube of 24 ± 2 µs. The setup allows an analysis of the in situ generated products. Here, after passing a 2 mm skimmer located 10 mm downstream from the silicon carbide nozzle, quasi continuous tunable VUV radiation from the ALS crossed the neutral molecular beam at the extraction region of a Wiley–McLaren Reflectron Time-of-Flight (Re-TOF) mass spectrometer 55 mm downstream. The ions of the photoionized molecules were then extracted and collected by a microchannel plate detector in the Re-TOF mode utilizing a multi channel scaler. The PIE curves were obtained by plotting the integrated relevant ion counts at a desired mass-to-charge, m/z, versus the photoionization energy between 8.0 and 10.1 eV in steps of 0.1 eV. The signal was normalized to the photon flux. Based on calibrated PIE curves of expected products of a well-defined molecular mass and their acyclic isomers (m/z = 118; C$_9$H$_{10}$), the recorded PIE curves were then fit via a linear combination with known PIE curves of various C$_9$H$_{10}$ isomers to extract the nature of the products formed and their branching ratios.
In order to fit the PIE curve at m/z = 118 (C₉H₁₀) obtained during the phenyl – propylene experiment, we also recorded the PIE curves of the individual C₉H₁₀ isomers, which are not available from the literature (Electronic Supplementary Material) (Figure 1). Briefly, the PIE curves of five C₉H₁₀ isomers indane (TCI, 98%), 3-phenylpropene (TCI, 98%), cis/trans-1-phenylpropene (TCI, 98%), and α-methylstyrine (2-phenylpropene) (Sigma Aldrich, 98%) were recorded also at the Chemical Dynamics Beamline (9.0.2.) of the Advanced Light Source. For each isomer, a continuous beam of the C₉H₁₀ isomer was generated by passing helium (Airgas, 99.999 %) carrier gas with a pressure of 300 Torr through a home-made stainless steel bubbler, which contained the individual C₉H₁₀ isomer at 293 K. This gas mixture expanded through a 0.1 mm orifice into the source chamber before passing a 2 mm skimmer 10 mm downstream to reach the detector chamber. As for the reaction products, the ions of the photoionized molecules were then extracted and collected by a microchannel plate detector in the Re-TOF mode. Individual PIE curves were obtained by plotting the integrated ion counts m/z = 118 versus the photoionization energy between 8.00 eV and 10.10 eV in steps of 0.025/0.01 eV. The signal was normalized to the photon flux. The PIE curves of the five C₉H₁₀ isomers are presented in the Electronic Supplementary Material. The ionization energies were derived to be 8.42, 8.40, 8.28, 8.38, and 8.23 eV for indane, 3-phenylpropene, cis/trans-1-phenylpropene, and α-methylstyrine, respectively. These values can be compared with NIST data of 8.45, 8.2~8.7, 8.5, 8.3 and 8.3, respectively.45

3. Results and Discussion

The mass spectra of the species formed in the supersonic expansion and the PIE curves of m/z = 118 (C₉H₁₀⁺) and = 104 (C₈H₈⁺) are shown in Figures 2 and in Figure 3, respectively. Apart from signal at m/z = 30 (NO) and m/z = 42 (C₃H₆), the mass spectrum depicts peaks at m/z = 104 and 118 corresponding to C₈H₈⁺ and C₉H₁₀⁺, respectively. These products are formed via the methyl and hydrogen loss channels, respectively, in the reaction of phenyl radicals with propylene (equations (1) and (2)). The branching ratios of both channels are estimated from the peak intensities and scaled photon absorption cross sections ⁴⁶ to be about 86 ± 10 % : 14 ± 10 %.

(1) \[ \text{C}_6\text{H}_5 + \text{C}_3\text{H}_6 \rightarrow \text{C}_8\text{H}_8 + \text{CH}_3 \]

(2) \[ \text{C}_6\text{H}_5 + \text{C}_3\text{H}_6 \rightarrow \text{C}_9\text{H}_{10} + \text{H} \]
Note that the peak at m/z = 94 might correspond to phenol, which is likely produced in the reactions involving the nitrogen monoxide by-product formed in the pyrolysis of nitrosobenzene.

As discussed above, the major products of the phenyl-propene reaction hold the molecular formulae C₈H₈ and C₉H₁₀. We attempt now to fit the recorded PIEs with a linear combination of PIEs of the corresponding isomers. The PIE curve of m/z = 104 (C₈H₈) can be reproduced exclusively with the literature PIE curve of styrene (C₆H₅C₂H₃). The experimentally recorded PIE curve of m/z = 118 (C₉H₁₀) can be principally fit with the PIE of the 3-phenylpropene isomer. Fractions of cis-1-phenylpropene and 2-phenylpropene at the few per cent level slightly improve the fit with an overall branching ratio of 3-phenylpropene, cis-1-phenylpropene, and 2-phenylpropene of 96 ± 4 %, 3 ± 3 %, and 1 ± 1 %. Noticeably, there is no evidence of the formation of the bicyclic indane molecule. This is in contrary to the phenyl-allene/propyne reactions, in which the bicyclic indene molecule was identified.43

In an attempt to understand the predominant formation of 3-phenylpropene and styrene, we inspected the underlying potential energy surface (PES).34 As predicted computationally, the phenyl-propene reaction is likely initiated either by the phenyl addition of the phenyl radical with its unpaired electron to the sterically less hindered CH₂ group of the propylene molecule to form the i₁ intermediate located 152 kJ mol⁻¹ below the reactants via a 6.3 kJ mol⁻¹ barrier; alternatively, phenyl can add to the CH group of propylene yielding the i₂ intermediate, which is almost isoenergetic to i₁ and placed 147 kJ mol⁻¹ below the reactants via a higher 11.3 kJ mol⁻¹ barrier. Both i₁ and i₂ intermediates are interconvertible via intermediate i₃. Intermediate i₁ can eject a hydrogen atom from the methyl group to form the 3-phenylpropene product. This reaction channel is overall exoergic by 13 kJ mol⁻¹. From the i₂ intermediate, a methyl group can be ejected to yield the styrene product. Besides those two major reaction pathways highlighted via bold arrows in Figure 4, two minor pathways were identified. First, i₁ can lose a hydrogen atom from the adjacent CH₂ group to form cis-1-phenylpropene molecule; this channel is exoergic by 24 kJ mol⁻¹. Further, i₂ can emit atomic hydrogen and form 2-phenylpropene. It can be seen that in order to access the bicyclic indane molecule, the reaction has to go through a multi-step pathway involving i₁ → i₄ → i₇ → indane + H; more importantly, the barrier between i₁ and i₄ is located 21 kJ mol⁻¹ above the reactants; due to this barrier, the pathway to form indane is less likely than yielding 3-phenylpropene and styrene. Also, intermediate i₁ is critical to form indane.
However, considering the barriers for the competing pathways $i1$ might follow, $i1$ rather fragments to 3-phenylpropene plus atomic hydrogen instead of pursuing the reaction sequence $i1 \rightarrow i4 \rightarrow i7 \rightarrow$ indane plus hydrogen. This reaction scheme correlates well with our experimental results, in which styrene and 3-phenylpropene are identified as the two major products, as well as the cis-1-phenylpropene and 2-phenylpropene molecules possibly existing at small fractions at the per cent level. Also, no indane molecule was observed. Compared to the recent crossed beam reaction, of phenyl with propylene, the results also agree very nicely. First, the branching ratios of the methyl and hydrogen loss pathways were determined to be $68 \pm 16\%$ and $32 \pm 10\%$, respectively, under single collision conditions at a collision energy of about $45$ kJ mol$^{-1}$. Further, the crossed beam reaction did not depict any evidence of indane formation.

We would like to highlight that little is known about the combustion chemistry of the phenylpropene system. As a matter of fact, although the reaction product styrene has been detected in combustion flames, the 3-phenylpropene molecule, formed via the phenyl radical – atomic hydrogen replacement pathway, has not been included in any of the commonly used combustion chemistry models. Nevertheless, these species could contribute to molecular-weight growth in combustion processes: hydrogen-abstraction reactions from the experimentally observed phenylpropene isomers provide conceivable pathways to phenyl-substituted allyl radicals: 1-phenylallyl and 2-phenyl-allyl. Similar to benzene and fulvene formation via the propargyl - allyl or allyl - allyl reactions, phenyl-substituted allyl radicals could provide pathways to biphenyl or triphenyl involving reactions with propargyl (or allyl) or phenyl-substituted allyl radicals. Likewise, hydrogen atoms as present in combustion flames, might change the spectrum of the primary reaction products and could lead via hydrogen addition – isomerization – hydrogen elimination to the indane molecule. Alternatively, the indane molecule as observed in combustion flames might be formed via hydrogenation of indene, with the latter being formed in the phenyl – allene and phenyl – methylacetylene reactions.

4. Conclusions

We investigated the combustion-relevant reaction of phenyl radicals ($C_6H_5$) with propylene ($C_3H_6$) exploiting a high temperature chemical reactor under combustion-like conditions at
temperatures of about 1,200 to 1,500 K. The reaction products were probed in a supersonic beam by utilizing tunable VUV radiation from the Advanced Light Source and recording the PIE curves at mass-to-charge ratios of m/z = 118 (C\textsubscript{9}H\textsubscript{10}\textsuperscript{+}) and m/z = 104 (C\textsubscript{8}H\textsubscript{8}\textsuperscript{+}). Our results indicate that the methyl and atomic hydrogen losses are the two major reaction pathways with branching ratios of 86 ± 10 % and 14 ± 10 %. Styrene (C\textsubscript{8}H\textsubscript{8}C\textsubscript{2}H\textsubscript{3}) was found to be the exclusive product contributing to m/z = 104 (C\textsubscript{8}H\textsubscript{8}\textsuperscript{+}), whereas 3-phenylpropene, cis-1-phenylpropene, and 2-phenylpropene with branching ratios of 96 ± 4 %, 3 ± 3 %, and 1 ± 1 % could account for signal at m/z = 118 (C\textsubscript{9}H\textsubscript{10}\textsuperscript{+}). No evidence of the bicyclic indane molecule could be provided. These isomers could contribute to molecular-weight growth in combustion processes since hydrogen-abstraction reactions from the phenyl-propene isomers provide viable pathways to phenyl-substituted allyl radicals. These are: 1-phenyl-allyl and 2-phenyl-allyl. These phenyl-substituted allyl radicals could provide pathways to biphenyl or triphenyl involving reactions with propargyl (or allyl) or phenyl-substituted allyl radicals.
