We consider the right triangle displayed in Fig. 1ra). From the Angle-Side-Angle (ASA) theorem, this can be uniquely specified using the two angles $\{\theta, \phi\}$ and the hypotenuse $c$. We now construct a formula for the area of the triangle, $A_{c}$, using only these variables: $\{c, \theta, \phi\}$. Note that $c$ has dimensions of length, and $\{\theta, \phi\}$ are dimensionless. From dimensional analysis, the area of the triangle must have dimensions of length squared. As $c$ is
the only dimensional quantity, the formula for $A_{c}$ must be of the form:

$$
\begin{equation*}
A_{c}=c^{2} f(\theta, \phi) \tag{1}
\end{equation*}
$$

where $f(\theta, \phi)$ is an unknown dimensionless function. Note that $f(\theta, \phi)$ cannot depend on the length $c$ as this would spoil the dimensionless nature of $f(\theta, \phi)$.

We now observe that we can divide the original triangle of Fig. [1-a) into two similar triangles of hypotenuse $a$ and $b$ as displayed in Fig. (1-b). Again, using the ASA theorem, we can represent the area of these triangles, $A_{a}$ and $A_{b}$, in terms of the variables $\{a, \theta, \phi\}$ and $\{b, \theta, \phi\}$, respectively. Again from dimensional considerations, these areas must be proportional to $a^{2}$ and $b^{2}$; thus, we obtain:

$$
\begin{equation*}
A_{a}+A_{b}=a^{2} f(\theta, \phi)+b^{2} f(\theta, \phi) \tag{2}
\end{equation*}
$$

Because all three triangles are similar, their areas are described by the same $f(\theta, \phi)$. It is important to note that the function $f(\theta, \phi)$ is universal, dimensionless, and scale-invariant.

Finally, we use "conservation of area" to obtain our result. Specifically, since the area of the original triangle $A_{c}$ is equal to the sum of the combined $A_{a}$ and $A_{b}$,

$$
\begin{equation*}
A_{a}+A_{b}=A_{c} \tag{3}
\end{equation*}
$$

We can substitute Eqs. (1) and (2) to obtain our desired result:

$$
\begin{align*}
a^{2} f(\theta, \phi)+b^{2} f(\theta, \phi) & =c^{2} f(\theta, \phi) \\
a^{2}+b^{2} & =c^{2} \tag{4}
\end{align*}
$$

The last equation is, of course, the Pythagorean Theorem. Clearly, there are much simpler methods to prove this theorem; however, this method does illustrate the power of the dimensional analysis approach. ${ }^{3}$ Additionally, we gain a new perspective on the Pythagorean Theorem in this proof as it is linked to conservation of area.

There are instances, such as renormalizable field theory, where use of dimensional analysis tools are essential to making certain calculations tractable. The following example will illustrate some of these features.

## III. AN INFINITE LINE OF CHARGE

## A. Statement of the problem

For our next example we consider the calculation of the electric potential $V$ for the case of an infinite line of

[^263]

Figure 2: Coordinate system for an infinite line of charge running in the $y$-direction. We compute the potential $V(x)$ at a fixed perpendicular distance $x$ from the line of charge. The distance to the element of charge $d Q$ is $r=\sqrt{x^{2}+y^{2}}$.
charge with linear charge density $\lambda=Q / L$. The contribution to the electric potential from an infinitesimal charge $d Q$ is given by: ${ }^{4}$

$$
d V=\frac{1}{4 \pi \epsilon_{0}} \frac{d Q}{r}
$$

We choose our coordinate system (cf., Fig. (2) such that $x$ specifies the perpendicular distance from the wire, $y$ is the coordinate along the wire, and $r=\sqrt{x^{2}+y^{2}}$. Given $\lambda=Q / y$ we have $d Q=\lambda d y$ and can integrate along the length of the wire to obtain:

$$
\begin{equation*}
V(x)=\frac{\lambda}{4 \pi \epsilon_{0}} \int_{-\infty}^{+\infty} \frac{d y}{\sqrt{x^{2}+y^{2}}}=\infty \tag{5}
\end{equation*}
$$

Unfortunately, this integral is logarithmically divergent and a we obtain an infinite result.

## B. Scale invariance:

If we take a closer look at this integral, we will demonstrate that it is scale invariant; that is, if we rescale the argument $x$ by a constant factor $k,(x \rightarrow k x)$, the result is invariant.

$$
\begin{align*}
V(k x) & =\frac{\lambda}{4 \pi \epsilon_{0}} \int_{-\infty}^{+\infty} d y \frac{1}{\sqrt{(k x)^{2}+y^{2}}} \\
& =\frac{\lambda}{4 \pi \epsilon_{0}} \int_{-\infty}^{+\infty} d(y / k) \frac{1}{\sqrt{x^{2}+(y / k)^{2}}} \\
& =\frac{\lambda}{4 \pi \epsilon_{0}} \int_{-\infty}^{+\infty} d z \frac{1}{\sqrt{x^{2}+z^{2}}}  \tag{6}\\
& =V(x) \tag{7}
\end{align*}
$$

[^264]In the above we have implemented the rescaling $z=y / k$; since both $y$ and $z$ are dummy variables and the integration limits are infinite, the integral is unchanged. A consequence of this scale invariance is:

$$
\begin{equation*}
V\left(x_{1}\right)=V\left(x_{2}\right) \tag{8}
\end{equation*}
$$

At first glance, this result appears to be a disaster since the usual purpose of the electric potential is to compute the work $W$ via the formula

$$
W / Q=\Delta V=V\left(x_{2}\right)-V\left(x_{1}\right)
$$

or to compute the electric field via

$$
\vec{E}=-\vec{\nabla} V
$$

As Eq. (8) suggests $V\left(x_{2}\right)-V\left(x_{1}\right)=0$, this implies that our attempts to compute the work $W$ or the electric field $\vec{E}$ will be meaningless.

We now understand why it is fortunate that $V(x)$ is infinite as infinite numbers have some unusual properties. For example, for a finite constant $c$ we can write (schematically) $\infty+c=\infty$ which implies $\infty-\infty=c$. We now understand that even though we have $V\left(x_{1}\right)=$ $V\left(x_{2}\right)$, because these quantities are infinite we can still find that the difference is non-zero: $V\left(x_{2}\right)-V\left(x_{1}\right) \neq 0$. The challenge is that the difference of two infinite quantities is ambiguous; that is, how can tell if $\infty-\infty=c_{1}$ or $\infty-\infty=c_{2}$ is the correct physical result?

The solution is that we must regularize the infinite quantities so that we can uniquely extract the difference.

## IV. CUTOFF REGULARIZATION:

## A. Cutoff Regularization Computation

We will first regularize the integral using a simple cutoff method. That is, instead of considering an infinite wire, we will compute the potential for a finite wire of length $2 L$. In this instance, the potential becomes: ${ }^{5}$

$$
\begin{align*}
V(x) & =\frac{\lambda}{4 \pi \epsilon_{0}} \int_{-L}^{+L} d y \frac{1}{\sqrt{x^{2}+y^{2}}} \\
& =\frac{\lambda}{4 \pi \epsilon_{0}} \log \left[\frac{+L+\sqrt{L^{2}+x^{2}}}{-L+\sqrt{L^{2}+x^{2}}}\right] \tag{9}
\end{align*}
$$

We make the following observations.

- The result is finite.

[^265]- In addition to the physical length scale $x, V(x)$ depends on an artificial regulator $L$.
- We cannot remove the regulator $L$ without $V(x)$ becoming singular.
- The result for $V(x)$ violates a symmetry of the original problem-translation invariance.

## B. Computation of $E$ and $\delta V$

Even though $V(x)$ depends on the artificial regulator $L$, we observe that all physical quantities are independent of this regulator in the limit $L \rightarrow \infty$. Specifically, for the electric field we have:

$$
\begin{aligned}
E(x)= & \frac{-\partial V(x)}{\partial x}=\frac{\lambda}{2 \pi \epsilon_{0} x} \frac{L}{\sqrt{L^{2}+x^{2}}} \\
& \longrightarrow \frac{\lambda}{2 \pi \epsilon_{0} x}
\end{aligned}
$$

and for the potential difference (proportional to the electric work $W$ ) we have:

$$
\begin{equation*}
\delta V=V\left(x_{1}\right)-V\left(x_{2}\right) \longrightarrow \frac{\lambda}{L \rightarrow \infty} \log \left[\frac{x_{2}^{2}}{x_{1}^{2}}\right] \tag{10}
\end{equation*}
$$

## C. Broken translational symmetry:

Notice that the presence of the cutoff $L$ breaks the translation symmetry of the original problem. That is, for a truly infinite wire, our position in the $y$-direction is inconsequential; however, for a finite wire this is no longer the case. Specifically, if we shift our $y$-position by a constant $c$ to $y \rightarrow y^{\prime}=y+c$, our result becomes:

$$
\begin{align*}
V(x) & =\frac{\lambda}{4 \pi \epsilon_{0}} \int_{-L+c}^{+L+c} d y \frac{1}{\sqrt{x^{2}+y^{2}}}  \tag{11}\\
& =\frac{\lambda}{4 \pi \epsilon_{0}} \log \left[\frac{+(L+c)+\sqrt{(L+c)^{2}+x^{2}}}{-(L-c)+\sqrt{(L-c)^{2}+x^{2}}}\right]
\end{align*}
$$

Clearly we have lost the translation invariance $y \rightarrow y^{\prime}=$ $y+c$.

While preserving symmetries is not of paramount importance in this simple example, it is essential for certain field theory calculations. We now repeat the this calculation, but instead using dimensional regularization which will preserve the translational symmetry.

## D. Recap

In summary, we find that our problem is solved at the expense of 1 ) an extra scale $L$ which serves to both regu-

| $n$ | $\Omega(n)$ | $\Gamma(n / 2)$ |
| :---: | :---: | :---: |
| 1 | 2 | $\sqrt{\pi}$ |
| 2 | $2 \pi$ | 1 |
| 3 | $4 \pi$ | $\frac{\sqrt{\pi}}{2}$ |
| 4 | $2 \pi^{2}$ | 1 |

Table I: Angular integration measure as a function of dimension $n$. We recognize $\Omega(1)$ as the 1 -dimensional integration measure of $\int_{-1}^{+1} d r, \Omega(2)$ as the circumference of the unit circle, $\Omega(3)$ as the surface area of the unit sphere, and $\Omega(4)$ as the 3 -volume of the 4 -dimensional unit hypercube.
lates the infinities and provide an auxiliary length scale, and 2) a broken symmetry-translational invariance.

## V. DIMENSIONAL REGULARIZATION

## A. Generalization to arbitrary dimension

The central idea of dimensional regularization is to compute $V(x)$ in $n$-dimensions where $n$ is not necessarily an integer.[2, 3] We can generalize the integration of Eq. (5) by replacing the one-dimensional integration $d y=d^{1} y$ by the general $n$-dimension result:

$$
\begin{equation*}
d y \longrightarrow d^{n} y=\frac{d \Omega_{n}}{2} y^{n-1} d y \tag{12}
\end{equation*}
$$

where the angular integration measure is given by

$$
\begin{equation*}
\Omega_{n}=\int d \Omega_{n}=\frac{2 \pi^{n / 2}}{\Gamma\left(\frac{n}{2}\right)} \tag{13}
\end{equation*}
$$

It is instructive to verify that $\Omega_{n}$ yields the expected result for integer dimensions as tabulated in Table $\mathbb{I}$

## B. Computation of V in arbitrary dimensions

The generalized formula for $V(x)$ now reads: [6]

$$
\begin{equation*}
V(x)=\frac{\lambda}{4 \pi \epsilon_{0}} \int_{0}^{+\infty} d \Omega_{n} \frac{y^{n-1}}{\mu^{n-1}} \frac{d y}{\sqrt{x^{2}+y^{2}}} \tag{14}
\end{equation*}
$$

Note that we have introduced an auxiliary scale factor of $\mu^{n-1}$, where $\mu$ has units of length, to ensure $V(x)$ has the correct dimension. ${ }^{6}$ Replacing $n=1-2 \epsilon$ to facilitate expanding about $n=1$ we obtain

[^266]\[

$$
\begin{align*}
V(x) & =\frac{\lambda}{4 \pi \epsilon_{0}} \frac{\Gamma\left[\frac{1-n}{2}\right]}{\left(\frac{x}{\mu} \sqrt{\pi}\right)^{1-n}} \\
& =\frac{\lambda}{4 \pi \epsilon_{0}}\left(\frac{\mu^{2 \epsilon}}{x^{2 \epsilon}} \frac{\Gamma[\epsilon]}{\pi^{\epsilon}}\right) \tag{15}
\end{align*}
$$
\]

We make the following observations about the dimensionally regularized result.

- $V(x)$ depends on an artificial regulator $\epsilon$ which is dimensionless.
- $V(x)$ depends on an auxiliary scale $\mu$ which has dimensions of length.
- If we remove either the regulator $\epsilon$ or the auxiliary scale $\mu$ then $V(x)$ will become ill-defined.
- The dimensional regularization preserves the translation invariance of the original problem.

It is interesting to contrast this result with the cutoff regularization method where $L$ serves as both the regulator and the auxiliary scale.

## C. Computation of $E$ and $\delta V$

For the potential difference we find

$$
\begin{equation*}
\delta V=V\left(x_{1}\right)-V\left(x_{2}\right) \underset{\epsilon \rightarrow 0}{\longrightarrow} \frac{\lambda}{4 \pi \epsilon_{0}} \log \left[\frac{x_{2}^{2}}{x_{1}^{2}}\right] \tag{16}
\end{equation*}
$$

and for the electric field we obtain:

$$
\begin{align*}
E & =\frac{-\partial V(x)}{\partial x}=\frac{\lambda}{4 \pi \epsilon_{0}}\left[\frac{2 \epsilon \mu^{2 \epsilon} \Gamma[\epsilon]}{\left.\pi^{\epsilon} x^{1+2 \epsilon}\right]}\right. \\
\underset{\epsilon \rightarrow 0}{\longrightarrow} & \frac{\lambda}{2 \pi \epsilon_{0}} \frac{1}{x} \tag{17}
\end{align*}
$$

As before, we observe that all physical quantities are independent of both the regulator $\epsilon$ and the auxiliary scale $\mu$.

## D. The Renormalization Group Equation

The fact that the physical observables are independent of the un-physical auxiliary scale $\mu$ is simply a consequence of the renormalization group equation: ${ }^{7}$

$$
\begin{equation*}
\mu \frac{d \sigma}{d \mu}=0 \tag{18}
\end{equation*}
$$

[^267]where $\sigma$ represents any physical observable. Thus, the renormalization group equation implies that the electric field $\vec{E}=\vec{\nabla} V$ and the work $W=\delta V$ are also independent of the $\mu$ scale:
$$
\mu \frac{d E}{d \mu}=0 \quad \mu \frac{d W}{d \mu}=0
$$

These results are implicit in the final expressions for $E$ and $V$.

## E. Recap

In conclusion we find that the problem for $V(x)$ is solved at the expense of an artificial regulator $\epsilon$ and an auxiliary scale $\mu$. We also note the regulator $\epsilon$ and auxiliary scale $\mu$ are separate entities in contrast to the cutoff regularization method where the length $L$ plays both roles. Additionally, translational invariance symmetry is preserved; the fact that dimensional regularization respects symmetries makes this technique indispensable for field theory calculations involving gauge symmetries and Lorentz symmetries.

## VI. RENORMALIZATION

Having demonstrated two separate methods to regularize the infinities that enter the calculation of $V(x)$, we now turn to renormalization.

While physical quantities such as the work $W \sim \delta V$ and the electric field $\vec{E} \sim-\vec{\nabla} V$ are derived from $V(x)$, the potential itself is not a physical quantity. In particular, we can shift the potential by a constant $c, V \rightarrow V+c$, and the physical quantities will be unchanged.

To illustrate this point, let's expand $V(x)$ of Eq. (15) in powers of $\epsilon$ :

$$
V(x)=\frac{\lambda}{4 \pi \epsilon_{0}}\left[\frac{1}{\epsilon}+\ln \left[\frac{e^{-\gamma_{E}}}{\pi}\right]+\ln \left[\frac{\mu^{2}}{x^{2}}\right]+\mathcal{O}(\epsilon)\right]
$$

Let us now invent a Minimal Subtraction (MS) prescription. I have the freedom to shift $V(x)$ by a constant, and I design this to eliminate the $1 / \epsilon$ term:

$$
V_{M S}(x)=\frac{\lambda}{4 \pi \epsilon_{0}}\left[\ln \left[\frac{e^{-\gamma_{E}}}{\pi}\right]+\ln \left[\frac{\mu^{2}}{x^{2}}\right]+\mathcal{O}(\epsilon)\right]
$$

I can go even further and invent a Modified Minimal Subtraction $(\overline{M S})$ prescription to eliminate the $\ln \left[e^{-\gamma_{E}} / \pi\right]$ term as well:

$$
V_{\overline{M S}}(x)=\frac{\lambda}{4 \pi \epsilon_{0}}\left[\quad \ln \left[\frac{\mu^{2}}{x^{2}}\right]+\mathcal{O}(\epsilon)\right]
$$

After renormalization we can remove the regulator $(\epsilon \rightarrow$ 0 ), but not the auxiliary scale $\mu$; recall that without an
auxiliary scale to generate a dimensionless ratio $\mu / x$ we could not have any substantive $x$-dependence.

In addition to the $\mu$-dependence we will also have renormalization scheme dependence in $V(x)$. However, physical observables must be independent of the auxiliary scale $\mu$ and the particular renormalization scheme. For example, the computed potential differences yield identical results when calculated consistently in a single renormalization scheme:

$$
V_{M S}\left(x_{1}\right)-V_{M S}\left(x_{2}\right)=\delta V=V_{\overline{M S}}\left(x_{1}\right)-V_{\overline{M S}}\left(x_{2}\right)
$$

Here, the results of the Minimal Subtraction (MS) and the Modified Minimal Subtraction ( $\overline{M S}$ ) are identical for physical quantities.

However, if you mix renormalization schemes inconsistently you will obtain non-sensible results that are dependent on the choice of scheme: ${ }^{8}$

$$
V_{\overline{M S}}\left(x_{1}\right)-V_{M S}\left(x_{2}\right) \neq \delta V \neq V_{M S}\left(x_{1}\right)-V_{\overline{M S}}\left(x_{2}\right)
$$

## A. Connection to QFT

This elementary problem of the infinite line charge contains all the key concepts of the dimensional regularization and renormalization that we encounter in the full QFT radiative calculations. For example, in the radiative Quantum Chromodynamics (QCD) calculation of the Drell-Yan process ( $q \bar{q} \rightarrow \gamma^{*} \rightarrow \mu^{+} \mu^{-}$) we encounter the following infinite expression: ${ }^{9}$

$$
\begin{aligned}
\frac{D(\epsilon)}{\epsilon} & =\left(\frac{4 \pi \mu^{2}}{Q^{2}}\right)^{\epsilon} \frac{\Gamma(1-\epsilon)}{\Gamma(1-2 \epsilon)} \\
& \sim \frac{1}{\epsilon}-\ln \left(\frac{e^{+\gamma_{E}}}{4 \pi}\right)+\ln \left(\frac{\mu^{2}}{Q^{2}}\right)
\end{aligned}
$$

In this equation, $Q$ represents the characteristic energy scale; this is the independent variable that is analogous to $x$ in our example. While this is for a 4-dimensional QCD calculation, the structure of the divergent term is remarkably similar to our simple one-dimensional example above. For the QCD calculation, the Minimal Subtraction ( $M S$ ) prescription for this Drell-Yan calculation eliminates the $1 / \epsilon$ term, and the Modified Minimal Subtraction $(\overline{M S})$ prescription for this Drell-Yan calculation eliminates the $1 / \epsilon-\ln \left[e^{+\gamma_{e}} /(4 \pi)\right]$ so that only the $\ln \left[\mu^{2} / Q^{2}\right]$ remains.

[^268]| $D_{\text {eff }}$ | $E(r)$ | $V(r)$ | Example |
| :---: | :---: | :---: | :---: |
| 3 | $\frac{1}{r^{2}}$ | $\frac{1}{r}$ | Point charge |
| 2 | $\frac{1}{r^{1}}$ | $\ln r$ | Line charge |
| 1 | $\frac{1}{r^{0}}$ | $r$ | Sheet charge |

Table II: Example charge configurations that illustrate $D_{\text {eff }}=$ $\{3,2,1\}$ effective dimensions.

## VII. EXTRA DIMENSIONS

## A. E and V in arbitrary dimensions

In the above example, we used the mathematical trick of generalizing the number of integration dimensions from an integer to a continuous parameter. While we only let the dimension stray by $2 \epsilon$, it is useful to consider more drastic shifts as in the case of "Extra-Dimensions" which have recently been hypothesized.[11, 12] In this section, we provide an example of a dimensional transmutation; that is where the effective dimension $D_{\text {eff }}$ changes from one integer to another as we probe the system at different scales.

For example, we can generalize the $r$-dependence of the potential and electric field in for the case of $D$-dimensions as: ${ }^{10}$

$$
V(r) \sim \frac{1}{r^{D-2}} \quad E(r) \sim \frac{1}{r^{D-1}}
$$

A quick check will verify that this reproduces the usual expressions in ordinary $D=3$ spacial dimensions. Additionally, in 3-dimensions we can create charge distributions that mimic lower order spatial dimensions; this is illustrated in Table II For a (zero-dimensional) pointcharge in 3 -dimensions, according to Gauss's law the electric field lines spread out on a surface of $D-1=2$ dimensions, and we observe $E(r) \sim 1 / r^{2}$. Similarly, for a (onedimensional) line-charge, our space is now effectively $D=2$ dimensional; hence the electric field lines spread out on a surface of $D-1=1$ dimension, and we observe $E(r) \sim 1 / r$. Finally, for a (two-dimensional) sheetcharge, our space is now effectively $D=1$ dimensional; hence the electric field lines spread out on in $D-1=0$ dimensions, and we observe $E(r) \sim 1 / r^{0}=$ constant.

Figure 3 displays the electric field lines for a point charge confined to one infinite dimension $(x)$ and one finite (or compact) dimension ( $y$ ) of scale $R$. We observe that if we examine the electric field at scales small compared to the compact dimension $R(r \ll R)$, we find the the electric field lines spread out in 2 dimensions and we obtain the usual 2-dimensional result $\vec{E}(r) \sim 1 / r$; conversely, if we examine the electric field at distance scales

[^269]

Figure 3: Electric field for a point charge confined in one infinite dimension $(x)$ and one finite dimension $(y)$ of scale $R$.
large compared to the compact dimension $R(r \gg R)$, we find the 1-dimensional result $\vec{E}(r) \sim$ constant. In this example, the effective dimension of our space changes as we move from small $(D=2)$ to large length scales ( $D=1$ ).

## VIII. CONCLUSIONS

In this paper we have computed the potential of an infinite line of charge using dimensional regularization. By contrasting this calculation with the conventional cutoff
approach, we demonstrated that dimensional regularization respects the symmetries of the problem-namely, translational invariance. The dimensional regularization requires that we introduce a regulator $\epsilon$ and an auxiliary length scale $\mu$. We then renormalized the potential to eliminate the $1 / \epsilon$ singularities; this potential was finite and independent of the regulator $\epsilon$, but it depended on the particular renormalization scheme. However, we demonstrated that all physical observables $(E, \delta V)$ were scheme and scale invariant.

As this example exhibits many of the key features of dimensional regularization as applied to QFT, it provides an excellent opportunity to understand the virtues of this regularization method without the complications of gauge symmetries. As such, this example serves as an ideal pedagogical study.

## Foreword

The study of the fundamental structure of nuclear matter is a central thrust of physics research in the United States. As indicated in Frontiers of Nuclear Science, the 2007 Nuclear Science Advisory Committee long range plan, consideration of a future Electron-Ion Collider (EIC) is a priority and will likely be a significant focus of discussion at the next long range plan. We are therefore pleased to have supported the ten week program in fall 2010 at the Institute of Nuclear Theory which examined at length the science case for the EIC. This program was a major effort; it attracted the maximum allowable attendance over ten weeks.

This report summarizes the current understanding of the physics and articulates important open questions that can be addressed by an EIC. It converges towards a set of "golden" experiments that illustrate both the science reach and the technical demands on such a facility, and thereby establishes a firm ground from which to launch the next phase in preparation for the upcoming long range plan discussions. We thank all the participants in this productive program. In particular, we would like to acknowledge the leadership and dedication of the five co-organizers of the program who are also the co-editors of this report.

## Preface

This volume is based on a ten-week program on "Gluons and the quark sea at high energies", which took place at the Institute for Nuclear Theory (INT) in Seattle from September 13 to November 19, 2010. The principal aim of the program was to develop and sharpen the science case for an Electron-Ion Collider (EIC), a facility that will be able to collide electrons and positrons with polarized protons and with light to heavy nuclei at high energies, offering unprecedented possibilities for in-depth studies of quantum chromodynamics. Guiding questions were

- What are the crucial science issues?
- How do they fit within the overall goals for nuclear physics?
- Why can't they be addressed adequately at existing facilities?
- Will they still be interesting in the 2020 's, when a suitable facility might be realized?

The program started with a five-day workshop on "Perturbative and Non-Perturbative Aspects of QCD at Collider Energies", which was followed by eight weeks of regular program and a concluding four-day workshop on "The Science Case for an EIC".

More than 120 theorists and experimentalists took part in the program over ten weeks. It was only possible to smoothly accommodate such a large number of participants because of the extraordinary efforts of the INT staff, to whom we extend our warm thanks and appreciation. We thank the INT Director, David Kaplan, for his strong support of the program and for covering a significant portion of the costs for printing this volume. We gratefully acknowledge additional financial support provided by BNL and JLab.

The program was structured along several subtopics, which roughly correspond to the chapters in this report. For each topic, convenors were appointed, who played an important role in the scientific organization of the program weeks and in editing the corresponding chapters. We gratefully thank them for their work. Special thanks are due to Matt Lamont and Marco Stratmann, who took on the lion's share in the painstaking task of merging the different chapters and making final edits.

Last but not least, we thank all participants of the INT program and all authors of this report for the work and enthusiasm they put into their contributions. Thanks to their efforts, much progress has been achieved, and we hope that the community will keep this momentum going in the continuing effort to build a compelling case for an Electron-Ion Collider.

## Introduction

Understanding the fundamental structure of matter in the physical universe is one of the central goals of scientific research. Strongly bound atomic nuclei predominantly constitute the matter from which humans and the observable physical world around us are formed. In the closing decades of the twentieth century, physicists developed a beautiful theory, Quantum Chromodynamics (QCD), which explains all strongly interacting matter in terms of point-like quarks interacting by the exchange of gauge bosons, known as gluons. Experiments have verified QCD quantitatively in processes involving a very large momentum exchange between the sub-atomic participants. Further confidence is obtained from significant progress in numerical computations of the static properties of the theory, in particular the excellent agreement of theory with the mass spectrum of low lying hadron resonances.

However, more than thirty years after QCD was first proposed as the fundamental theory of the strong force, and despite impressive theoretical and experimental progress made in the intervening decades, the understanding of how QCD works in detail remains an outstanding problem in physics. Very little is known about the dynamical basis of hadron structure in terms of the fundamental quark and gluon fields of the theory. How do these fundamental degrees of freedom dynamically generate the mass, spin, motion, and spatial distribution of color charges inside hadrons with varying momentum resolution and energy scales? Deep Inelastic Scattering (DIS) experiments at the HERA collider revealed clearly that at high momentum resolution and energy scales, the proton is a complex, many-body system of gluons and sea quarks, a picture very different from a more familiar view of the proton as a few point-like partons (a term that collectively refers to both quarks and gluons), each carrying a large fraction of its momentum. This picture, which is confirmed at hadron colliders, raises more questions than it answers about the dynamical structure of matter. For instance, how is the spin- $1 / 2$ of the proton distributed in this many-body system of sea quarks and gluons? In the early universe, how did the many-body plasma of quarks and gluons cool into hadrons with several simple structural properties? Recreating key features of this quark-hadron transition in heavy ion collisions has been a major activity in nuclear physics, with several surprising findings including the realization that this matter flows with very little resistance as a nearly perfect fluid. A deep understanding of the two cited examples, among many others, ultimately requires detailed knowledge of the quark-gluon structure of hadrons and nuclei.

This report on the science case for an Electron-Ion Collider (EIC) is the result of a ten-week program at the Institute for Nuclear Theory (INT) in Seattle (from September

13-November 19, 2010), motivated by the need to develop a strong case for the continued study of the QCD description of hadron structure in the coming decades. Hadron structure in the valence quark region will be studied extensively with the Jefferson Lab 12 GeV science program, the subject of an INT program the previous year. The focus of the INT program was on understanding the role of gluons and sea quarks, the important dynamical degrees of freedom describing hadron structure at high energies. Experimentally, the most direct and precise way to access the dynamical structure of hadrons and nuclei at high energies is with a high luminosity lepton probe in collider mode. An EIC with optimized detectors offers enormous potential as the next generation accelerator to address many of the most important, open questions about the fundamental structure of matter. The goal of the INT program, as captured in the writeups in this report, was to articulate these questions and to identify golden experiments that have the greatest potential to provide definitive answers to these questions.

At resolution scales where quarks and gluons become manifest as degrees of freedom, the structure of the nucleon and of nuclei is intimately connected with unique features of QCD dynamics, such as confinement and the self-coupling of gluons. Information on hadron sub-structure in DIS is obtained in the form of "snapshots" by the "lepton microscope" of the dynamical many-body hadron system, over different momentum resolutions and energy scales. These femtoscopic snapshots, at the simplest level, provide distribution functions which are extracted over the largest accessible kinematic range to assemble fundamental dynamical insight into hadron and nuclear sub-structure. For the proton, the EIC would be the brightest femtoscope scale lepton-collider ever, exceeding the intensity of the HERA collider a thousand fold. HERA, with its center-of-mass (CM) energy of 320 GeV , was built to search for quark substructure. An EIC, with its scientific focus on studying QCD in the regime where the sea quarks and gluons dominate, would have a lower CM energy. In a staged EIC design, the CM energy will range from $50-70 \mathrm{GeV}$ in stage I to approximately twice that for the full design. In addition to being the first lepton collider exploring the structure of polarized protons, an EIC will also be the first electron-nucleus collider, probing the gluon and sea quark structure of nuclei for the first time.

Following the same structure as the scientific discussions at the INT, this report is organized around the following four major themes:

- The spin and flavor structure of the proton
- Three dimensional structure of nucleons and nuclei in momentum and configuration space
- QCD matter in nuclei
- Electroweak physics and the search for physics beyond the Standard Model

In this executive summary, we will briefly outline the outstanding physics questions in these areas and the suite of measurements that are available with an EIC to address these. The status of accelerator and detector designs is addressed at the end of the summary. Tables of golden measurements for each of the key science areas outlined are presented on page 12 , In addition, each chapter in the report contains a comprehensive overview of the science topic addressed. Interested readers are encouraged to read these and the individual contributions for more details on the present status of EIC science.

## The spin and flavor structure of the proton

To understand how the constituents of the proton carry the proton's spin has been a defining question in hadron structure for several decades now. The proton spin problem presents the formidable challenge of understanding an essential feature of how a complex strongly-interacting many-body system organizes itself to produce a simple result. It goes directly to the heart of exploring and understanding the QCD dynamics of matter. From the surprising finding by the European Muon Collaboration that very little of the proton spin is provided by the spins of quarks and anti-quarks combined, the exploration of nucleon spin structure has by now developed into a world-wide quest central to nuclear and particle physics. To provide definitive answers in this area will be among the key tasks of an EIC.

Significant progress can be expected from the unique capability of an EIC to reach small momentum fractions $x$ and large momentum resolution scales $Q$, with high precision. A suite of measurements will be available. A golden measurement of nucleon spin structure at an EIC will be the precision study of the proton's spin structure function $g_{1}^{p}\left(x, Q^{2}\right)$ and its scaling violations, over wide ranges in $x$ and $Q^{2}$. As studies in this report will demonstrate, global analyses of spin-dependent parton distributions will determine the gluon helicity distribution $\Delta g$ and the quark singlet $\Delta \Sigma$ down to values of $x$ of about $10^{-4}$. This vastly extended reach should allow for the determination of the gluon and quark/anti-quark spin contributions to the proton spin to about $10 \%$ accuracy or better. The accuracy to which processes such as deeply-virtual Compton scattering can independently provide information on the remaining orbital angular momentum contributions will be addressed further in the section on spatial imaging.

An EIC will provide unprecedented insight into the flavor structure of the nucleon, a key element in mapping the "landscape" of hadron structure. There are two powerful golden measurements available at an EIC to achieve this. One of these methods, Semi-Inclusive Deep-Inelastic Scattering (SIDIS) has been used in previous fixed-target lepton scattering experiments HERMES and COMPASS. (Polarized proton-proton collisions at RHIC employ $W$-boson production for flavor identification.) At an EIC, semi-inclusive measurements would extend to much higher $Q^{2}$ than in fixed-target scattering, where the reaction becomes significantly cleaner, less contaminated with higher-twist effects (a technical term for contributions power suppressed in $1 / Q^{2}$ ), and therefore more tractable theoretically. The kinematic coverage for SIDIS in $x$ and $Q$ will be similar overall to what can be achieved in inclusive DIS. With the high luminosity of an EIC, extractions of the light-flavor helicity distributions $\Delta u, \Delta d$ and their anti-quark distributions from SIDIS will be possible with exquisite precision. With dedicated studies of kaon production, the strange and anti-strange distributions will also be accessible. All this will likely give insights into the question why it is that the combined quark and anti-quark spin contribution to the proton spin turns out to be so small.

The other independent method for accessing the quark and antiquark helicity distributions at an EIC is electroweak DIS. At high $Q^{2}$, the DIS process also proceeds significantly via the exchange of $Z$ and $W^{ \pm}$bosons. This gives rise to novel structure functions that are sensitive to various different combinations of the proton's helicity distributions. Studies show that both neutral current and charged current interactions would be observable at an EIC. To fully exploit the potential of an EIC for such measurements, positron beams are required, albeit not necessarily polarized. Besides the new insights into nucleon structure this would provide, studies of spin-dependent electroweak scattering at short distances with an EIC would be interesting physics in and of itself, much in the line of past and ongoing
electroweak measurements at HERA, Jefferson Lab, and RHIC.
Polarized electron-proton physics can be expected to take center stage at an EIC because these would be the first such collider measurements. However, as studies in this report show, there is a large potential for unpolarized physics at an EIC. Thanks to its high luminosity and the feasibility for an energy scan, an EIC would vastly improve upon HERA data on measurements of the longitudinal structure function $F_{L}$. This quantity is a key observable for studies of gluon structure and the possible transition to a high parton density or saturation regime in the proton. At an EIC, several SIDIS measurements of flavor distributions and multi-particle correlations will be possible for the first time. In particular, pinning down the strange quark and antiquark content of the proton would close one of the last notable gaps in our knowledge of unpolarized parton densities. Extended rapidity coverage will also allow for detailed studies of the rapidity gap structure of hard diffractive final states. In addition, the very high luminosities will bring a vast improvement in the precision of measurements of the charm and beauty contributions to nucleon structure.

## Three dimensional structure of hadrons and nuclei: Transverse momentum distributions

Partons can have a momentum component transverse to the direction of their parent nucleon and there exists experimental evidence to support an average transverse momentum of a few hundred $\mathrm{MeV} / \mathrm{c}$. However, much of our understanding of nucleon structure is in terms of integrated parton distributions that are only sensitive to the momentum resolution of the probe. A rigorous theoretical framework for parton transverse momentum distributions (TMDs) has been developed recently which allows for a description of specific scattering cross sections in terms of these distributions. TMDs are an essential step toward a more comprehensive understanding of the parton structure of the nucleon in QCD. An EIC will enable precise and detailed measurements of TMDs over a broad kinematic range.

For the scattering processes of interest, the large scale $Q^{2}$ justifies, in a leading twist approximation, the factorized description of the cross section in terms of several calculable or measurable factors, yielding a predictive framework. TMDs are examples of such measurable factors. In such descriptions not only does the magnitude of the parton transverse momentum enter, but also the transverse momentum direction, yielding strikingly asymmetric distributions. Several recently observed angular asymmetries are most naturally described by asymmetric, spin direction dependent TMDs.

A golden measurement at an EIC will be the Sivers asymmetry, a particular angular correlation between the target polarization and the direction of a produced final state hadron in polarized SIDIS. At the parton level, the Sivers effect is a spin-orbit coupling effect in QCD and is described by a TMD that quantifies how strongly the transverse momentum from orbital motion is coupled to spin. The Sivers effect is especially interesting because it is a consequence of phase interference peculiar to the gauge structure of QCD. The gauge invariant Sivers TMD is non-zero only if gluonic initial or final state interactions are taken into account. There is a calculable process dependence, most strikingly evident in SIDIS and Drell-Yan lepton pair production where the polarized Sivers function in the former is equal in magnitude but opposite in sign to the latter. Factorization breaking is also expected in more complicated processes, such as hadron-hadron collisions with hadronic final states. This process dependence has not yet been demonstrated but several such experiments, in particular at RHIC, will study the Sivers and other TMD effects. The comparison of these
results with complementary information from an EIC will allow a detailed understanding of the nature and extent of factorization breaking for TMDs.

A goal at an EIC is to obtain a flavor-separated extraction of the Sivers TMD in an energy regime where its theoretical interpretation is unambiguous. Percent level azimuthal asymmetries measured by HERMES, COMPASS and at Jefferson Lab at rather modest $Q^{2}$ have enabled rough first estimates of the magnitude of the Sivers effect. With the 12 GeV upgrade program at Jefferson Lab, the valence (large $x$ ) region will be explored in detail, whereas sea quark and gluon contributions at small $x$ (down to $10^{-4}$ ) will be mapped out with an EIC. The large $Q^{2}$ reach of an EIC will allow for extensive study of evolution effects in TMDs, and at large $x(x \sim 0.2)$ will have overlap with preceding experiments. High energies and high precision will enable a good understanding of the $x$ dependence of the Sivers functions for each quark flavor, including antiquarks and gluons. In addition, the larger transverse momentum range of final state particles at an EIC allows for studies of weighted asymmetries that are cleaner to interpret theoretically but are beyond the reach of fixed target experiments. The extensive transverse momentum range will for the first time in polarized SIDIS, allow studies of the transition region between the TMD description at low transverse momentum and the description in terms of collinear quark-gluon-quark correlation functions (known as the Qiu-Sterman mechanism) at high transverse momentum. Finally, with respect to previous SIDIS experiments and future Jefferson Lab experiments, a larger variety of final states can be considered at an EIC, such as (multiple) jets or Dmesons, all of great interest in isolating quark and gluon contributions to the various TMD effects.

Now that angular asymmetries consistent with the TMD framework have been observed, the road towards full-fledged experimental studies of TMDs can be mapped out and the essential role of an EIC identified. Besides the Sivers effect, essential information on the unpolarized TMD $f_{1}$ is obtained from unpolarized scattering cross sections. For reasons we shall outline, this extraction of $f_{1}$ can be classified as another golden measurement. This TMD determines the $Q^{2}$ dependence of the unpolarized cross section, which has been predicted but not yet verified. Predictions of the $x$, transverse momentum, scale and flavor dependence of $f_{1}$ allow for non-trivial checks of the fundamental TMD formalism corroborating and complementing what one learns from the Sivers and other spin TMD effects. The unpolarized SIDIS measurements at an EIC will give detailed information on the difference between sea and valence quark contributions, and on the role of gluons. Extracting unpolarized gluon TMDs at small $x$ is especially interesting because of the recently discovered agreement between predictions in the TMD framework and previous computations of the same in the Color Glass Condensate formalism as we shall discuss later.

The proposed silver experiments are 1) the distribution of transversely polarized quarks inside transversely polarized hadrons, 2) spin-orbit correlations inside unpolarized hadrons (the Boer-Mulders TMD), and 3) the Collins TMD fragmentation function, which describes a similar spin effect in the fragmentation of quarks into unpolarized hadrons. All three quantities involve transverse quark spin, which distinguishes them from the Sivers effect which deals with unpolarized partons inside a transversely polarized proton. An EIC will be able to provide multi-dimensional representations of all these quantities and the observables they give rise to. The TMD chapter illustrates by means of concrete examples and calculations how much further TMD studies can be pushed with an EIC compared to the present status. A prime example is shown in figure 2.11 on page 108 .

## Three dimensional structure of nucleons and nuclei: Spatial imaging

The high luminosity and large kinematic reach of an EIC offers unique possibilities for exploring the spatial distribution of sea quarks and gluons in the nucleon and in nuclei. The "imaging" of partons is possible in suitable exclusive reactions. The transverse position of the quark or gluon on which the scattering took place is obtained by a Fourier transform from the transverse momentum of the scattered nucleon or nucleus. At the same time, the longitudinal momentum loss of the target is correlated with the longitudinal momentum fraction $x$ of the parton. By choosing particular final states, measurements at an EIC will be able to selectively probe the spatial distribution of sea quarks and gluons in a wide range of $x$. Such 'tomographic images' will provide essential insight into QCD dynamics inside hadrons, such as the interplay between sea quarks and gluons, the role of pion degrees of freedom at large transverse distances and, from a more general perspective, the mechanism for confinement in QCD.

The quantities that encode this tomographic information are generalized parton distributions (GPDs). The formalism of GPDs is applicable in the full range of $x$. An alternative description at small $x$ is the dipole formalism, which is expressed in terms of the amplitude for small color dipoles to scatter off gluons in the hadron target. GPDs allow direct comparison of tomographic images for sea quarks and gluons with their counterparts in the valence quark region, where the 12 GeV program at Jefferson Lab will obtain information of unprecedented accuracy.

Potential golden measurements for parton imaging at an EIC are deeply virtual Compton scattering and photo- or electro-production of $J / \psi$ mesons. For Compton scattering, there are a large number of observables that can be calculated with high precision, whereas a unique advantage of $J / \psi$ production is its sensitivity to gluons. A suite of further reaction channels play the role of "silver measurements", which will provide complementary information and in particular help separate different quark flavors. Among those exclusive channels whose cross sections grow with energy, deeply virtual Compton scattering demands the highest luminosity. Simulations performed during the INT program indicate that precise and multi-differential measurements of this process can be envisaged with the projected EIC luminosity (see figures 3.34, 3.35 and 3.37 on pages 203, 204 and 207). Detailed studies including detector effects will be required to establish the achievable experimental accuracy.

The envisaged configuration of an EIC interaction region and detector will provide data in a wide enough range of transverse momentum transfer to permit a Fourier analysis of observables. With this, exclusive cross sections and angular or polarization asymmetries will give direct quantitative information about the spatial distribution of partons in a specified range of $x$. Estimates indicate that transverse distances ranging from about 0.1 fm to 2 fm or higher will be accessible, provided that a good enough momentum resolution can be achieved experimentally. Such data will provide the basis for reconstructing generalized parton distributions and, ultimately, the joint distribution of partons in transverse position $b$ and longitudinal momentum fraction $x$. For this second step, an EIC's large lever arm in photon virtuality $Q^{2}$ at a given photon energy will be essential, since it is the scale evolution in $Q^{2}$ that carries the most detailed information about the longitudinal parton momentum.

Our current knowledge about the helicity distributions of quarks and gluons indeed suggests that the orbital angular momentum of partons plays a prominent role in the nucleon. Exclusive scattering on a transversely polarized target gives access to this degree of freedom
in parton tomography and allows one to study spin-orbit correlations at the parton level. An especially interesting aspect is the relation between a polarization induced asymmetry in transverse parton position and the Sivers asymmetry in transverse parton momentum. Such a relation is profoundly dynamical, and its quantitative exploration in the sea quark and gluon domain will be a highlight of exploring hadron structure and dynamics at an EIC. Deeply virtual Compton scattering will again play an essential role in this context, along with vector meson production channels. Quantitative estimates of the achievable statistical and systematic accuracy were not made during the INT program, but the necessary tools are now in place and results should be available soon.

Ji's angular momentum sum rule condenses the connection between generalized parton distributions and parton angular momentum into a single number for each quark flavor and for the gluon. To evaluate this sum rule from exclusive measurements is truly challenging for several reasons. The most serious among them is that one needs to reconstruct the full $x$ dependence of GPDs from observed scaling violations in $Q^{2}$. As already mentioned, the large kinematic coverage of an EIC provides a good starting point for such a program, but it remains to be seen which accuracy can be attained for the angular momentum. We regard this as a long-term endeavor, which will profit from the progress one can expect in the coming years from the 12 GeV program at Jefferson Lab.

## Physics opportunities in electron-nucleus collisions

An EIC would be the world's first $\mathrm{e}+\mathrm{A}$ collider. It will significantly extend parton studies of nuclear structure into the regime dominated by sea quarks and gluons. Prior fixed target DIS measurements on nuclei revealed that the ratio of nuclear to nucleon cross sections is significantly less than unity (normalized by the atomic mass number) both at large $x$ (the EMC effect) and at small $x$ (shadowing). These interesting nuclear phenomena were however only observed for valence and (to a lesser extent) sea quarks. The nuclear gluon distribution is very poorly constrained at all $x$ values, especially at $x<0.01$ where it is completely unknown. An EIC could reveal surprises in our fundamental understanding of the parton structure of nuclei in this terra incognita.

A fundamental feature of QCD is gluon saturation, which arises as a consequence of the fact that gluon distributions at a fixed $Q^{2}$ cannot grow rapidly indefinitely with decreasing $x$. The properties of matter in this novel saturation regime of strong color fields in QCD is described by a saturation scale which grows both with decreasing $x$ and with increasing nuclear size. Model estimates of this nuclear "oomph" give a saturation scale in a large nucleus at EIC energies to be of the same magnitude as the saturation scale in a proton at a TeV scale electron-proton collider; electron-nucleus collisions therefore provide an efficient method to explore saturation in QCD.

As a consequence of asymptotic freedom, the large saturation scale (relative to the intrinsic QCD scale $\Lambda_{Q C D}$ ) accessible at an electron-nucleus collider implies that the properties of saturated gluon matter at small $x$ can be computed systematically using weak coupling techniques and compared to experimental data. One such weak coupling approach is the Color Glass Condensate (CGC). Renormalization group (RG) methods in the CGC are used to compute observables in electron-nucleus collisions that are sensitive to the energy evolution of particular many-body gluon correlators. These correlators, classified as "dipole", "quadrupole" and "multipole" effective degrees of freedom from their color structure, are universal. Final states in proton-nucleus and nucleus-nucleus collisions can also
be expressed in terms of these objects. Properties of multipole degrees of freedom can be inferred from measurements of cross-sections for specific final states in one of these reactions and used as input in computations of cross-sections for other final states, thereby providing an important test of the validity and limits of the CGC effective theory. A further interesting possibility is that multipole correlators at very high energies become independent of the initial conditions specific to a particular nucleus that are inputs at a given $x$ scale to the RG evolution equations. While it appears unlikely that an EIC would have sufficient energy to access this asymptotic regime, DIS off different nuclei can provide important constraints on pre-asymptotic trends in that direction.

At large $x$ in nuclei, DIS corresponds to the virtual photon scattering off quarks, with the nucleus acting as an extended colored medium that interacts with the hard colored probe. Because the energy and momentum resolution of the probe can be accurately controlled in DIS, one can quantitatively address, with a precision unmatched at hadron colliders, interesting questions about the nature of multiple scattering and $p_{\perp}$ broadening, energy loss and fragmentation, and the propagation of heavy quarks and jets in colored media. Perturbatively calculable short distance physics can be isolated from the hadronization mechanism by tuning the energy and momentum resolution of the virtual photon probe to shed new light on the latter both in medium and in the vacuum. While some such studies have been performed previously at fixed target DIS facilities and in proton-nucleus collisions, the extended kinematic reach, collider geometry and precision probes will vastly add to their scope, allowing for definitive answers to enduring questions about in-medium properties of QCD. For instance, the propagation of heavy charm and beauty quarks in medium will be quantitatively studied in DIS for the first time. In addition to being interesting in their own right, DIS studies of parton propagation in "cold" QCD media are an important benchmark for a quantitative understanding of their role in the hot QCD medium produced at RHIC and the LHC.

An important opportunity to understand the role of gluons in the structure of short range nuclear forces is made possible by exclusive measurements with an EIC of open heavy flavor and quarkonium in DIS off light nuclei. Other interesting studies at large $x$ where the kinematic reach of an EIC will complement the Jefferson Lab 12 GeV program, including the EMC effect and generalized parton distributions for nuclei.

A number of experimental observables have been identified that can shed light on the compelling physics issues outlined. One set of golden measurements include the inclusive structure functions $F_{2}$ and $F_{L}$ for light and heavy nuclei. They will provide the first ever unambiguous measurements of nuclear gluon distributions. Studies of the evolution of quark singlet and gluon distributions with $x$ and $Q^{2}$ for light and heavy nuclei can systematically uncover the breakdown of leading twist evolution, the onset and development of non-linear saturation dynamics and enable the extraction of the corresponding saturation scale. Another set of golden measurements are provided by semi-inclusive DIS (SIDIS) off nuclei. Di-hadron correlations in particular, are very sensitive to non-linear QCD evolution, and allow for a clean extraction of the saturation scale. They will corroborate (or invalidate) claims of saturation seen in di-hadron correlations in deuteron-gold collisions; more generally, they enable the previously discussed tests of universality of multipole correlators at small $x$. Golden measurements at large $x$ are semi-inclusive production of light and heavy flavors and jets. These provide unique insight into energy loss and parton shower development in an extended colored medium, as well as into the dynamics of hadronization in this many-body environment. The heavy flavor and jet measurements will be the first of their kind in nuclear DIS; we note that feasibility studies for them are still in a preliminary stage.

In addition to these golden measurements, there are several important measurements classified as "silver" instead of gold only in a relative sense. The most important among these are the diffractive structure functions $F_{2, D}$ and $F_{L, D}$ which will be extracted for nuclei for the very first time. At HERA, these structure functions for protons constituted more than $15 \%$ of the cross-section; the predictions of saturation models is that this fraction will be significantly larger in nuclei. Exclusive production of vector mesons and deeply virtual Compton scattering probe the spatial distribution of partons in nuclei; at small $x$, they can help clarify the interplay between saturation and the effects of chiral symmetry breaking and confinement.

Finally, a frequently posed question is whether proton/deuteron-nucleus scattering can provide the same information content as electron-nucleus collisions. In the former, the computation of final states, in leading twist kinematics, contains convolutions over parton distributions in the nucleon projectile as well as that in the target. In addition, for a number of final states, a large number of parton scattering reactions are likely to contribute. This significantly compromises the accuracy to which one determines the parton structure of the target. For fundamental questions regarding the spatial distribution of partons and color singlet structures exchanged in hard diffractive scattering, there are essential qualitative differences in hadron-hadron and lepton-hadron processes arising from the lack of universality in key aspects of the dynamical structure of nucleons and nuclei. Thus while proton/deuteron-nucleus scattering at high energies has the strong potential to be a discovery machine for new QCD physics, uncovering the origins of such physics and its implications for our fundamental understanding of the parton structure of nuclei, will require an EIC.

## Electroweak interactions and physics beyond the Standard Model

While the physics of an EIC is primarily motivated by the study of strong interactions, its physics case is strengthened by its potential to contribute to electroweak studies as well. Experience has shown that a new accelerator that pushes the frontiers either in energy, and/or luminosity and intensity, is of interest for studies of electroweak physics. We have already mentioned that precision studies of (parity-violating) electroweak spin structure functions would be possible at an EIC, giving new insights into nucleon spin structure. However, the electroweak physics case for an EIC is broader as it would also allow measurements of parameters of electroweak theory. Studies presented in detail in the INT report suggest that for high energy and luminosity, there would be excellent prospects for extractions of the Weinberg angle, which should even be possible over a fairly wide range in $Q^{2}$ so that its running can be further studied in detail. In this way, an EIC would complement the precise LEP and SLD measurements on the $Z$-pole, atomic parity-violation measurements, the SLAC E158 Møller scattering data, and the NuTeV data whose final value is in fact around three standard deviations above the SM prediction. A comparison of EIC results for $\sin ^{2} \theta_{W}$ with those on the $Z$-pole in particular can be used to search for new physics effects. Some of the experimental systematics involved at an EIC are broadly understood, but may still need further work to clarify. A full "global survey" of electroweak parameters from EIC data - much in the spirit of the approach also taken at HERA - is still outstanding but planned. In addition, an EIC might possibly be able to open a direct window on beyond-Standard Model physics, assuming that conditions are favorable. Studies
indicate that the EIC might be able to perform a sensitive search for a third generation leptoquark in electron-tau conversion $e p \rightarrow \tau X$, with potential reach well beyond that in previous studies at HERA.

## EIC Accelerator Design

Two substantial, focused efforts at developing a design for an electron-ion collider in the U.S. based on existing accelerators are underway at Brookhaven National Laboratory and Thomas Jefferson National Accelerator Facility. At BNL, the eRHIC design utilizes a new linear electron accelerator to collide with the existing polarized proton and ion beams of the operating Relativistic Heavy Ion Collider (RHIC). At JLab, the ELIC design employs new electron and ion storage rings together with the 12 GeV upgraded existing CEBAF. Although based on two different, existing accelerators, because they are driven by the same science objectives, the two U.S. EIC design efforts have similar characteristics. The most important include:

- highly polarized (>70\%) electron and nucleon beams
- ion beams from deuterium to the heaviest nuclei - uranium or lead
- center of mass energies: from about 20 GeV to about 150 GeV
- maximum collision luminosity $\sim 10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$
- non-zero crossing angle of colliding beams without loss of luminosity (so-called crab crossing)
- cooling of the proton and ion beams to obtain high luminosity
- staged designs where the first stage would reach CM energies of about 70 GeV
- the possibility to have multiple interaction regions

It is clear from the EIC physics studies that with a luminosity of $\sim 10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, and operating for about a decade, ground breaking new experiments to probe our understanding of QCD will become feasible. This would require delivery of order $50 \mathrm{fb}^{-1}$ with polarized nucleon and heavy ion beams to experiments in about a decade. This would be 100 times more integrated luminosity than recorded over a decade at the only previous electron-proton collider, HERA at DESY. With a luminosity of $\sim 10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, precision imaging and electroweak experiments become feasible at an EIC.

The EIC accelerator designs being considered will require significant R\&D for realization. The cooling of the hadron beam is essential to attain the luminosities demanded by the science. The development of a new technique, coherent electron cooling, is underway at BNL while conventional electron cooling is being pushed to high RF power at JLab. Energy recovery linear accelerators at high energy and intensity are a key technology for an EIC. Further, the eRHIC design demands an increase in the intensity produced by polarized electron sources of over an order of magnitude beyond what is available at present. The ELIC design utilizes novel figure-8 storage rings for both electrons and ions.

In Europe, two electron-ion collider accelerators are under consideration. At the Large Hadron Collider at CERN, physicists are considering colliding an electron beam (either a
linac or ring) with an energy of about 70 GeV with the existing unpolarized proton and heavy-ion beams. The present LHeC design can reach a CM energy of about 1.4 TeV with a luminosity of $10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. At GSI in Germany, an Electron-Nucleon Collider (ENC) would be realized by colliding electrons in a 3 GeV storage ring with 15 GeV protons in the High Energy Storage Ring of the planned Facility for Antiproton and Ion Research (FAIR). The CM energy at an ENC is about 14 GeV and the expected luminosity is about $10^{32}$ $\mathrm{cm}^{-2} \mathrm{~s}^{-1}$. Thus, the two European colliders differ in CM energy by about two orders of magnitude, in colliding luminosity by about one order of magnitude, and have very different scientific objectives.

## EIC Detectors

Optimized detectors are essential to carry out the ground breaking experiments planned at an EIC. The design of EIC detectors is intimately connected to the design of the accelerator interaction regions (IR) through the location of magnets, configuration of crossing angles, and available space. A particular challenge is to detect forward-going scattered protons from exclusive reactions, as well as decay neutrons from the break-up of ions in incoherent diffraction. Past experience at colliders with lepton beams has shown that synchrotron radiation generated by bending the electron beam close to the IR can produce challenging backgrounds for detectors.

Detector concepts for an EIC are being developed and are guided both by the demands of the scientific program and by the experience with ZEUS and H1 at HERA. The EIC detector will certainly include a large central detector likely containing a solenoidal magnetic field (of order 4 T ); trackers for momentum and angular resolution; electromagnetic and hadronic calorimetry; particle identification involving Cerenkov detectors, and vertex detectors. Further, detectors in the forward and backward directions will be required to augment the large central detector. These are necessary to detect hadrons from low $x$ processes and will require particle identification, calorimetry (both electron and hadron) and possibly magnetic field. With multiple interaction regions, it may be more advantageous to consider different detectors (e.g. forward/backward vs. central, high luminosity vs. low luminosity) for different IRs.

Minimizing the effects of systematic uncertainties is an important aspect of detector design. Absolute and relative luminosity determination is a key to extracting important observables, for instance the longitudinal structure function or small polarization asymmetries. Measurement of the polarization of electron and hadron beams has a high priority. As with the accelerator, R\&D for EIC detectors will be essential.

## Tables of golden measurements

| Spin and flavor structure of the nucleon |  |  |  |
| :---: | :---: | :---: | :---: |
| Deliverables | Observables | What we learn | Requirements |
| polarized gluon | scaling violations | gluon contribution | coverage down to $x \simeq 10^{-4} ;$ |

## Chapter 1

## The spin and flavor structure of the proton

Convenor and chapter editor:
M. Stratmann

### 1.1 Introduction and chapter overview

Marco Stratmann

Two weeks of the INT program on "Gluons and the Quark Sea at High Energies" were devoted to the physics of unpolarized and polarized parton distribution functions. A compelling set of physics opportunities at an EIC has emerged from lively discussions among the participants and subsequent interactions with the hadron structure community. This Chapter outlines the identified open fundamental questions in hadronic physics and the "golden measurements" and experimental requirements to thoroughly address them at a future EIC. The anticipated results will have a profound influence on our understanding of the spin and flavor structure of nucleons.

Sixteen years of operations at DESY-HERA had a transformational impact on the way we view the internal partonic content of nucleons and have led to various new developments in the field of Quantum Chromodynamics. The experiments have left a rich legacy of results, the most prominent ones being the strong rise of the gluon density at small momentum fractions $x$, the large portion of diffractive events, and the transition from high to low momentum transfer $Q$ for various processes. Likewise, vigorous experimental programs with polarized beams and targets in the past twenty-five years at all major laboratories have brought us closer to pinpoint the various contributions to the proton's spin. They also revealed novel, often puzzling phenomena which initiated new directions of research in spin physics such as transverse-momentum dependent parton densities; see Chapter 2.

In each case, the experimental progress was matched by considerable theoretical efforts in Quantum Chromodynamics. Most notable in this context are the level of precision reached in higher-order calculations in perturbative QCD and the much refined global analysis tools to reliably extract information on parton densities from data and to determine their uncertainties. Yet, there is still a significant lack of understanding on quite a few outstanding issues. An EIC will prove crucial in addressing them by making use of the anticipated high luminosities and the variability of beam energies.

Of course, due to the lower center-of-mass system energies of an EIC as compared to HERA one cannot extend the kinematic reach towards smaller values of $x$ for unpolarized electron-proton collisions. Also, over the next couple of years the CERN-LHC will provide a great deal of information on helicity-averaged parton densities in a broad range of $x$ from various different hard scattering processes up to very large resolution scales $Q$. The 12 GeV upgrade of the CEBAF facility at Jefferson Laboratory is designed to map parton distributions up to very large values of $x$ at scales $Q$ of a few GeV to test how well, for instance, counting rules apply. Therefore, we expect that most aspects of unpolarized parton densities will be sufficiently well known by the time an EIC is expected to turn on, with some important exceptions to be discussed below.

The situation is rather different for spin physics where the bulk of experimental information stems from fixed-target lepton-nucleon scattering experiments at rather low energies. Ideas to turn HERA into a polarized electron-proton collider never materialized. Existing experiments studying the helicity structure of the nucleon, like PHENIX and STAR at RHIC, will continue to add data in the next couple of years. In particular, measurements of double-spin asymmetries for di-jets in $p p$ collisions at 500 GeV should improve the current constraints on the polarized gluon density $\Delta g(x)$ and extend the covered $x$ range towards somewhat smaller values. Parity-violating, single-spin asymmetries for $W$ boson production should reach a level where they help to constrain the spin-dependent $u$ and $d$
quark and antiquark densities at medium-to-large $x$. At JLab-12 the focus is again on the large $x$ frontier at moderate values of $Q$ to address to what extent quarks obey helicity retention which predicts that in the limit $x \rightarrow 1$ quark and nucleon spins become fully aligned. Ultimately, all these efforts are limited by their kinematic coverage both in $x$ and in $Q$. Since the most fundamental open questions in spin physics concern the polarization of wee partons, see below, there are many opportunities for a high-energy polarized EIC to contribute significantly due to its unique capabilities to access values of $x$ down to about $10^{-4}$. This is central to finally determine and understand the role of quarks and gluons in the spin decomposition of the nucleon.

Factorization of experimental observables into non-perturbative parton densities and calculable hard scattering cross sections is the cornerstone for the theoretical application of QCD at high energies within perturbative methods. Available QCD calculations for inclusive and semi-inclusive deep-inelastic scattering processes will allow us to confront future high-statistics EIC data with theory at the necessary very high level of precision. A brief account of the status of perturbative QCD calculations for most of the key measurements at an EIC is given in Sec. 1.2.

Since the EIC is a natural extension of the physics program carried out at HERA both in terms of the anticipated significant increase in luminosity and the possibility to have polarized beams, we summarize the latest status of HERA data based on the recent combination of results from the H1 and ZEUS experiments in Sec. 1.3. This discussion also helps to expose the open questions about the structure of unpolarized nucleons an EIC can elucidate and which cannot be answered solely by measurements at the LHC. The most compelling ones comprise

- the longitudinal structure function $F_{L}$,
- the elusive strangeness and anti-strangeness densities,
- and heavy flavor contributions to deep-inelastic scattering.

A detailed account, including other second tier opportunities is given in Sec. 1.4.
An EIC could make the first precise measurement of $F_{L}$ in a kinematic range that overlaps both previous fixed-target and HERA data, none of which are very precise. $F_{L}$ is particularly sensitive to the gluon distribution and QCD dynamics at small $x$ which makes it a promising candidate to study the transition to the high parton density regime, i.e., the phenomenon of saturation, with an inclusive observable. While one does not expect non-linear effects to be of significant relevance in electron-proton collisions at an EIC, a measurement of $F_{L}$ provides the baseline for similar studies in electron-heavy ion collisions. Here, the onset of saturation effects is expected already at $x \simeq 10^{-3}$ which elevates $F_{L}$ to one of the golden measurements to be performed at the EIC; see Chapter 5 on QCD matter under extreme conditions for details. The determination of $F_{L}$ relies on an accurate measurement of the variation of the so-called reduced cross section for fixed values of $x$ and $Q$ at different c.m.s. energies $\sqrt{s}$. The large variability of beam energies at sustained large luminosities is a particular strength of an EIC and proves critical for this measurement. A first feasibility study for electron-proton collisions can be found in Sec. 1.6.

Semi-inclusive deep-inelastic production of identified pions and kaons is expected to be the most viable and promising way to determine differences among parton distribution functions for different quark flavors or between quarks and anti-quarks. Such measurements make use of the different probabilities for producing a certain hadron species from a given
quark flavor or gluon and have been successfully performed at fixed-target experiments such as HERMES. The EIC offers unprecedented opportunities to extend the kinematic reach toward small $x$ or large $Q$. In particular, the elusive strangeness density and a possible asymmetry between strangeness and anti-strangeness distributions can be deduced from charged kaon production yields. Prerequisites are excellent particle identification in most of the phase space and a thorough theoretical understanding of the hadronization of quarks and gluons into the observed hadrons. In collinear factorization, the latter information is encoded in non-perturbative fragmentation functions which are constrained by a wealth of available experimental data on single-inclusive hadron yields. Further significant progress on the quality of such fits is expected once upcoming data from $B$ factories and the LHC are included. In Sec. 1.5 we present a first feasibility study for charged kaon production at the EIC.

Heavy flavors, in particular charm quarks, can give a sizable contribution to deepinelastic scattering structure functions. Within the foreseen EIC kinematics, charm yields up to $10 \div 15 \%$ of the inclusive cross section. The theoretical framework for heavy quark production is much more complex than for light (massless) quarks due to the presence of multiple scales. The mass of the heavy quarks prevents them from having a partonic interpretation, and they can be only produced externally, for instance, by photon-gluon fusion. This framework yields a very good description of all available HERA data within the present uncertainties and is expected to be relevant also in the entire kinematic regime of an EIC. Nonetheless, one may introduce heavy quark densities for asymptotically large scales, i.e., $Q \gg m$, and smooth interpolation schemes have been devised which incorporate the correct threshold and asymptotic behavior. The relevant theoretical framework and recent progress on higher order calculations is briefly reviewed in Sec. 1.7.

The charm contribution to the longitudinal structure function $F_{L}$ is expected to be particularly sensitive to mass effects and has never been measured before. A first feasibility study within the kinematics of an EIC can be found in Sec.1.8. An EIC is also well suited to address the long-standing question of a possible relevance of a non-perturbative "intrinsic" charm contribution in the nucleon wave-function, mainly concentrated at large momentum fractions. Quantitative estimates based on models for an intrinsic charm contribution are promising and can be found in Sec. 1.9 ,

The physics opportunities with polarized lepton and proton beams are even more multifaceted and will address some of the most fundamental open questions in hadronic physics for which one has been seeking answers for more the two decades now. Thus, the anticipated results will have far-reaching impact on our understanding of the nucleon's spin structure. The unique capability of the EIC to reach small momentum fractions $x$ or large scales $Q$ in longitudinally polarized electron-proton collisions with high luminosity will enable us to explore in detail

- the polarized gluon distribution and its contribution to the proton's spin,
- the individual light quark helicity distributions in a broad kinematic range,
- novel electroweak structure functions,
- and the strangeness and anti-strangeness polarizations.

The latest status of global QCD fits to helicity dependent parton densities, which is not expected to improve much by the time the EIC would turn on, and the set of questions we want to address at the EIC are laid out in some detail in Sec. 1.10,

Precise measurements of the polarized structure function $g_{1}$ in a wide kinematic range will be a flagship measurement for the EIC. The gluon helicity distribution $\Delta g$ is strongly correlated with QCD scaling violations, i.e., the $Q$ dependence of $g_{1}$ at a given $x$. This will allow for a determination of $\Delta g$ down to unprecedented small values of $x$ of about $10^{-4}$. This in turn will eventually pinpoint the elusive gluon contribution to the spin of the proton, given by the integral of $\Delta g$ over all momentum fractions $x$, to about $10 \%$ accuracy or better. The striking quantitative impact on extractions of $\Delta g$ based on projected EIC data is demonstrated in Sec. 1.11. The same set of inclusive measurements will also provide a significantly better determination of the total quark contribution $\Delta \Sigma$ both as function of $x$ and the integral relevant for the nucleon spin sum.

Like in the unpolarized case, see Sec. 1.5, the best strategy to achieve a full flavor and quark-antiquark separation of polarized helicity densities is based again on semi-inclusive deep-inelastic hadron production. The kinematic coverage in $x$ and $Q$ is similar to what can be achieved in inclusive DIS, with the extra theoretical complication of the need for fragmentation functions to model hadronization. At medium-to-large values of $x$ one can address with precision certain interesting asymmetries in the polarized quark sea like $\Delta \bar{u}$ $\Delta \bar{d}$ (from charged pion yields) and perhaps even $\Delta s-\Delta \bar{s}$ (from charged kaon yields). The first quantity is predicted to be sizable in several model calculations of the nucleon but the precision of current experiments only gives a first hint of a possible non-zero asymmetry; the latter quantity may help to understand why the sum $\Delta s+\Delta \bar{s}$ appears to be much smaller in current experiments than expected. If $\Delta s$ and $\Delta \bar{s}$ have their spins anti-aligned, their sum could be small but the asymmetry would be sizable. Constraints from hyperon decay matrix elements and arguments based on $\mathrm{SU}(3)$ symmetry predict a significantly negative total ( $x$ integrated) strange quark polarization. To address the validity of this constraint and to access to what extent $\operatorname{SU}(3)$ symmetry is broken, one needs to determine $\Delta s$ down to small values of $x$ to obtain a reliable estimate of its $x$ integral. This is another unique measurement to be performed at the EIC.

First simulations of electroweak neutral and charged current deep-inelastic scattering at the EIC in Sec. 1.12 show that such measurements become feasible already with relatively modest integrated luminosities. The corresponding structure functions for polarized protons have never been measured before and probe combinations of quark flavors other than in one-photon-exchange dominating at low $Q$. To fully exploit the potential of the EIC for such measurements, positron beams are required, albeit not necessarily polarized. An effective source of polarized neutrons such as a Helium-3 beam would be highly desirable. When combined, these measurements will greatly aid the flavor decomposition of polarized parton densities at medium-to-large $x$, free of any hadronization ambiguities. At the highest c.m.s. energies and luminosities also photon- $Z$ boson interference contributions to structure functions should be accessible at the EIC. The production of charmed mesons in charged current DIS events is an alternative probe for the strange and anti-strange densities both unpolarized and polarized. This is discussed in Sec. 1.13

Table 1.1 summarizes the identified golden measurements, science deliverables, and experimental requirements in spin-dependent lepton-proton collisions at an EIC. Other, second tier measurements with polarization involve the currently unknown charm contribution to the deep-inelastic structure function $g_{1}$ which offers sensitivity to $\Delta g$ through photon-gluon fusion. Some expectations can be found in Sec. 1.11. If an effective neutron beam is available one can also attempt to determine the fundamental Bjorken sum rule at a few percent level. The Bjorken sum is probably one of the most precisely calculated quantities in perturbative QCD and provides an interesting link to the Adler $D$ function in electron-positron

| Deliverables | Observables | What we learn | Requirements |
| :---: | :---: | :---: | :---: |
| polarized gluon | scaling violations | gluon contribution | coverage down to $x \simeq 10^{-4} ;$ |

| novel electroweak <br> spin structure functions | inclusive DIS <br> at high $Q^{2}$ | flavor separation <br> at medium $x$ and large $Q^{2}$ | $\sqrt{s} \gtrsim 100 \mathrm{GeV} ; \mathcal{L} \gtrsim 10 \mathrm{fb}^{-1}$ <br> positrons; polarized ${ }^{3} \mathrm{He}$ beam |

Table 1.1. Golden measurements in polarized ep collisions at an EIC.
annihilation through the Crewther relation.
Finally, the production of hadronic final states in electron-proton collisions is dominated by the exchange of photons of almost zero virtuality. Photoproduction measurements and, in particular, the exploration of kinematic regimes where "resolved photon" contributions dominate was one of the great successes of the HERA physics program. Resolved processes, where the photon interacts with the proton through its non-perturbative source of partons, offer a fresh look at these densities which are so far mainly determined from imprecise LEP data. Given the anticipated high luminosity, an EIC can elevate these studies to a level of unprecedented precision, and, thanks to the polarized beams, allows one to investigate for the first time also the non-perturbative structure of circularly polarized photons. A good knowledge of the partonic structure of photons is essential for part of the physics program of a possible future linear collider. The general framework for photoproduction and two examples of physics studies are presented in Secs. 1.14 .1 .16 ,

To summarize, the physics goals of the EIC should be ambitious and must offer detailed answers to all the open fundamental questions concerning the spin and flavor structure of nucleons laid out above. The following sections will outline the path to achieve these goals. The program bears significant experimental challenges which all need to be carefully addressed to reach the desired unprecedented level of precision. With the exception of some of the electroweak structure function measurements, most observables will be quickly limited by systematic uncertainties, intrinsic ambiguities of the extraction method like, for instance, the Rosenbluth separation for $F_{L}$, and the way how well we can control QED radiative corrections to unfold the information one is actually interested in. Experimental aspects are discussed in Chapter 7.

### 1.2 Status of perturbative QCD calculations

Sven-Olaf Koch

### 1.2.1 Introduction

Deep-inelastic scattering (DIS) and the observed scaling violations are at the very center of the formulation of QCD as the gauge theory of the strong interactions [1, 2].

Over the decades the experiments using lepton and neutrino scattering off fixed targets at CERN, FNAL, SLAC, and JLAB as well as electron-proton collisions at the HERA collider at DESY have provided unique insight into the nucleon structure with the available high precision experimental data spanning a large kinematical range. Dramatic further improvements can be expected from the planned electron-ion collider EIC.

The key observables are either inclusive structure functions or differential cross sections in the semi-inclusive case, which parametrize the hard hadronic interaction in the QCD improved parton model. The particle data group (PDG) 3 provides a very readable account of DIS, including the definitions of kinematic variables, etc.

Figure 1.1. QCD factorization of the cross section for the scattering of a deeply virtual boson with (space-like) momentum $q\left(-q^{2}=Q^{2}>0\right)$ off a proton with momentum $P$ in their center-of-mass frame, see Eq. (1.1).

Precision predictions in perturbative QCD rest on the fact that we can separate the sensitivity to dynamics from different scales, i.e., the physics at scale of the proton mass from hard, high-energy scattering at a large scale $Q^{2}$. For lepton-proton DIS in the one-boson exchange approximation this is depicted in Fig. 1.1. For unpolarized DIS, this factorization at a scale $\mu$ allows to express the structure functions $F_{k}(k=2,3, L)$ as convolutions of parton distributions (PDFs) $f_{i}(i=q, \bar{q}, g)$ and short-distance Wilson coefficient functions $C_{k, i}$,

$$
\begin{equation*}
F_{k}\left(x, Q^{2}\right)=\sum_{i=q, \bar{q}, g} \int_{x}^{1} d z f_{i}\left(\frac{x}{z}, \mu^{2}\right) C_{k, i}\left(z, Q^{2}, \alpha_{s}(\mu), \mu^{2}\right), \tag{1.1}
\end{equation*}
$$

up to corrections of higher twist $\mathcal{O}\left(1 / Q^{2}\right)$. The coefficient functions $C_{k, i}$ are calculable perturbatively in QCD in powers of the strong coupling constant $\alpha_{s}$,

$$
\begin{equation*}
C=C^{(0)}+\alpha_{s} C^{(1)}+\alpha_{s}^{2} C^{(2)}+\alpha_{s}^{3} C^{(3)}+\ldots, \tag{1.2}
\end{equation*}
$$

with the expansion coefficients $C^{(0)}$ denoted as the leading order (LO), $C^{(1)}$ the next-toleading order (NLO) and so on. The PDFs $f_{i}$ describe the fraction $x=Q^{2} /(2 P \cdot q)$ of the nucleon momentum carried by the quark or gluon. PDFs are non-perturbative objects and have to be obtained from global fits to experimental data or determined, e.g., by lattice computations. Perturbation theory, however, provides information about their scale dependence, i.e., the well-known evolution equations,

$$
\frac{d}{d \ln \mu^{2}}\binom{f_{q_{i}}\left(x, \mu^{2}\right)}{f_{g}\left(x, \mu^{2}\right)}=\sum_{j} \int_{x}^{1} \frac{d z}{z}\left(\begin{array}{cc}
P_{q_{i} q_{j}}(z) & P_{q_{i} g}(z)  \tag{1.3}\\
P_{g q_{j}}(z) & P_{g g}(z)
\end{array}\right)\binom{f_{q_{j}}\left(x / z, \mu^{2}\right)}{f_{g}\left(x / z, \mu^{2}\right)}
$$

The splitting functions $P_{i j}$ are universal quantities in QCD and describe the different possible parton splittings in the collinear limit. Like the $C_{k, i}$ also the $P_{i j}$ can be computed in a power series in $\alpha_{s}$,

$$
\begin{equation*}
P=\alpha_{s} P^{(0)}+\alpha_{s}^{2} P^{(1)}+\alpha_{s}^{3} P^{(2)}+\ldots . \tag{1.4}
\end{equation*}
$$

Analogous formulae hold for the polarized DIS structure functions. In particular, for $g_{1}$ one may apply the obvious replacements $f_{i} \rightarrow \Delta f_{i}, C_{k, i} \rightarrow \Delta C_{g_{1}, i}$, and $P_{i j} \rightarrow \Delta P_{i j}$ in Eqs. (1.1)-(1.4). QCD factorization has also been established for (semi-)inclusive deepinelastic scattering (SIDIS), where the cross section $d^{2} \sigma / d x d Q^{2}$ is subject to a decomposition similar to Eq. (1.1). Although, in that case, the process dependent hard parton scattering cross sections need to be augmented by an additional prescription for the final state parton, e.g., a jet algorithm or fragmentation functions.

### 1.2.2 Current status

QCD predictions for DIS observables have reached over the years an unprecedented level of precision. All quantities in Eqs. (1.1)-(1.4) have been computed to higher orders in perturbation theory so that the effect of radiative corrections on those observables is well understood and largely under control. In the case of unpolarized DIS, the splitting functions $P_{i j}$ are known to NNLO [4, 5] and, likewise, the coefficient functions $C_{k, i}$ [6, 7, 8, 8]. For photon and charged current $W^{ \pm}$-boson exchange, even the hard corrections at order $\mathcal{O}\left(\alpha_{s}^{3}\right)$ are available [10, 11]. In the case of polarized DIS, the spin dependent splitting functions $\Delta P_{i j}$ at two loop order have been obtained some time ago [12, 13]. At NNLO, the polarized splitting functions $\Delta P_{q q}$ and $\Delta P_{q g}$ have been reported [14], and the coefficient functions $\Delta C_{g_{1}, i}$ are available from [15]. For semi-inclusive observables, the QCD corrections are typically known to NLO. This corresponds to $\mathcal{O}\left(\alpha_{s}^{2}\right)$ since the underlying Born cross section behaves as $d^{2} \sigma^{(0)} / d x d Q^{2} \sim \mathcal{O}\left(\alpha_{s}\right)$ due to the additional final state parton. Processes considered include, for instance, the electro-production of hadrons with high transverse momentum [16, 17] or single inclusive DIS jet cross sections [18].

The currently available QCD predictions for inclusive DIS and SIDIS put us in comfortable position to confront experimental data with theory at a very high level of precision. In these comparisons, we no longer test QCD. Rather we use perturbative QCD as an essential and established part of our theory toolkit to deduce important information about PDFs or the value of the strong coupling constant $\alpha_{s}\left(M_{Z}\right)$. Of course, this is a situation that, generally, needs to be addressed also beyond DIS, since experimental data from the unpolarized (anti-)proton-proton colliders Tevatron at FNAL and the LHC at CERN as well as from the polarized proton-proton collider RHIC at BNL help to further constrain the non-perturbative input to QCD precision predictions. See, e.g., the analyses of
unpolarized PDFs to NNLO in Refs. [19, 20, 21, 22] or recent studies of polarized PDFs in [23, 24, 25, 26, 27, 28].

Given the current status of perturbative QCD, experimental data from a future program of electron-ion collisions, EIC, can help to address and clarify a number of still open and yet very relevant questions; see also Secs. 1.4 and 1.11 . For the case of unpolarized PDFs improvements can be made with respect to the flavor asymmetry of sea quarks at low $x$ and the valence quarks at large $x$, by studying, e.g., electron-deuteron collisions. Much of the physics case here had already been investigated in an assessment of the experimental prospects of electron-deuteron scattering at HERA some time ago [29. More generally, the high luminosity of an EIC would further constrain PDFs, especially the gluon at low $x$ and $Q^{2}$. In this context, a precision measurements of the longitudinal structure function $F_{L}$, which is an observable predominantly driven by the gluon PDF is of high interest as it would complement and, eventually even supersede, existing experimental data, see, e.g., 30. New high statistics DIS experiments can also improve the current precision of strong coupling constant $\alpha_{s}$ measurements in space-like kinematics.

For polarized DIS, a very fundamental question still remains the understanding of the proton spin, in particular, whether the polarized gluon PDF $\Delta f_{g}$ provides a significant contribution. To that end, an extension of the kinematical coverage in $x$ and $Q^{2}$, as it could be achieved by an electron-ion collider, is of paramount importance. This would help to access higher scales in $Q^{2}$ in order to test the perturbative evolution Eq. (1.3). Likewise, access to an extended $x$-range allows for a better determination of moments of the $\Delta f_{i}$. They also enter, e.g., in the Bjorken sum rule for polarized electro-production, which is again an observable very well-known in perturbative QCD [31, 32]. Other issues of interest for polarized DIS in electron-ion collisions concern a reliable extraction of flavor structure as well as a study of strangeness PDFs, $\Delta f_{s}$.

### 1.2.3 Summary

We have briefly summarized the current status of perturbative QCD predictions for DIS experiments. To date, we can build on a very mature understanding of the theory, which could be confronted with experimental data from a future electron-ion collider in order to improve our knowledge about the fundamental structure of matter and the important dynamics of quarks and gluons in nucleons.

### 1.3 Unpolarized proton structure - HERA's legacy

Amanda Cooper-Sarkar (for the H1 and ZEUS Collaborations)

### 1.3.1 Introduction

HERA data provide the most insight into the behaviour of unpolarized parton distribution functions (PDFs) at present and as such represent an integral part of all global QCD analyses. The H1 and ZEUS experiments are combining their various sub-sets of data so as to provide a legacy of HERA results. The combination of inclusive cross section data from HERA-I and the PDF fit based on these data are already published [20]. In 2010 further data have been combined and PDF fits to the augmented data sets have been made available in preliminary form. In Sec. 1.3 .2 results from the published combination are reviewed. In Sec. 1.3.3 results from a combination of $F_{2}^{c \bar{c}}$ data are presented and their sensitivity to the mass of the charm quark and the choice of the heavy flavor scheme adopted in the global PDF fit is discussed. In Sec. 1.3.4 results from the combination of inclusive cross section data taken at lower proton beam energies are discussed. Finally, in Sec. 1.3 .5 an updated combination of all inclusive data from HERA-I and HERA-II running is shown and a PDF fit to these data is presented.

### 1.3.2 Inclusive data from HERA-I running (1992-2001)

The inclusive cross section data, from the HERA-I running period, for Neutral Current ( $\mathrm{NC)} \mathrm{and} \mathrm{Charged} \mathrm{Current} \mathrm{(NC)}, e^{+} p$ and $e^{-} p$ scattering have been combined 20]. The combination procedure pays particular attention to the correlated systematic uncertainties of the data sets such that resulting combined data benefits from the best features of each detector. The combined data set has systematic uncertainties which are smaller than its statistical errors and the total uncertainties are small ( $1-2 \%$ ) over a large part of the kinematic plane. The combined data is compared to the separate input data sets of ZEUS and H1 in Fig. 1.2 ,

These data are used as the sole input to a PDF fit called the HERAPDF1.0 [20. The motivations for performing a HERA-only fit are firstly, that the combination of the HERA data yields a very accurate and consistent data set such that the experimental uncertainties on the PDFs may be estimated from the conventional $\chi^{2}$ criterion $\Delta \chi^{2}=1$. Global fits which include dats sets from many different experiments often use inflated $\chi^{2}$ tolerances in order to account for marginal consistency of the input data sets. Secondly, the HERA data are proton target data so that there is no uncertainty from heavy target corrections or deuterium corrections and there is no need to assume that $d$ in the proton is the same as $u$ in the neutron since the $d$-quark PDF may be extracted from $e^{+} p$ CC data. Thirdly, the HERA inclusive data give information on the gluon, the Sea and the $u$ - and $d$-valence PDFs over a wide kinematic region: the low- $Q^{2} \mathrm{NC} e^{+} p$ cross-section data are closely related to the low- $x$ Sea PDF and the low- $x$ gluon PDF is derived from its scaling violations; the high$x u-$ and $d$-valence PDFs are closely related to the high- $Q^{2} \mathrm{NC} e^{ \pm} p, \mathrm{CC} e^{-} p$, and $\mathrm{CC} e^{+} p$ cross sections, respectively; the difference between the high- $Q^{2} e^{-} p$ and $e^{+} p$ cross-sections gives the valence shapes down to low $x, x \sim 10^{-2}$.

HERAPDF provides model and parametrisation uncertainties on the PDFs as well as experimental uncertainties; for details, see Ref. [20]. A major contribution to the total uncertainties in the HERAPDF1.0 set comes from the model uncertainty on the charm mass value. This can be improved using information from data on $F_{2}^{c \bar{c}}$.

Figure 1.2. HERA combined data points for the NC $e^{+} p$ cross section as a function of $Q^{2}$ in selected bins of $x$, compared to the separate ZEUS and H1 data sets input to the combination.

### 1.3.3 Charm data from HERA-I and II running

H1 and ZEUS have also combined their data on $F_{2}^{c \bar{c}}$ [20]. In Fig. 1.3 the combined data are compared to the separate data sets which go into the combination. These data are input to the HERAPDF fit together with the inclusive data which were used for HERAPDF1.0. The $\chi^{2}$ of this fit is sensitive to the value of the charm quark mass. Fig. 1.4 compares the $\chi^{2}$, as a function of this mass, for a fit which includes these data (left) to that for the HERAPDF1.0 fit (middle). However, it would be premature to conclude that the data can be used to determine the charm pole-mass. The HERAPDF formalism uses the ThorneRoberts (RT) variable-flavour-number (VFN) scheme for heavy quarks. This scheme is not unique, specific choices are made for threshold behaviour. In Fig. 1.4 (right) the $\chi^{2}$ profiles for the standard and the optimized versions of this scheme are compared to two alternative ACOT VFN schemes and the Zero-Mass VFN scheme. Each of these schemes favours a different value for the charm quark mass, and the fit to the data is equally good for all the heavy quark mass schemes; see Fig. 1.3 (right). However, the Zero-Mass scheme is $\chi^{2}$ disfavoured; see Ref. [20] for further details.

### 1.3.4 Low energy proton beam data from 2007

In $2007 \mathrm{NC} e^{+} p$ data were taken at two lower values of the proton beam energy in order to determine the longitudinal strucure function $F_{L}$. Some of the H1 and ZEUS data sets from these runs have now been combined [20] and the results for the $\mathrm{NC} e^{+} p$ cross section are shown in Fig. 1.5. These data have been input to the HERAPDF fit together with the inclusive data from HERA-I. The resulting PDFs are compared with those of HERAPDF1.0 in Fig. 1.5, The low energy data are sensitive to the choice of minimum $Q^{2}$ (standard cut $Q^{2}>3.5 \mathrm{GeV}^{2}$ ) for data entering the fit. If a somewhat harder cut, $Q^{2}>5 \mathrm{GeV}^{2}$, is made, a steeper gluon distribution results, see Fig. 1.5, whereas for the HERAPDF1.0 this variation of cuts results in PDFs which lie within the PDF uncertainty bands. This sensitivity is also present if an $x$ cut, $x>5 \times 10^{-4}$, or a "saturation inspired" cut, $Q^{2}>0.5 x^{-0.3}$, is made. This sensitivity may indicate the breakdown of the DGLAP formalism at low $x$ [33].

Figure 1.3. Left: HERA combined data points for $F_{2}^{c \bar{c}}$ compared to the separate ZEUS and H1 data sets. Right: HERA combined data points for $F_{2}^{c \bar{c}}$ compared to HERAPDF fits to these plus the inclusive DIS data, for various different heavy-quark-mass schemes.

Figure 1.4. The $\chi^{2}$ of the HERAPDF fit as a function of the charm mass $m_{c}^{\text {model }}$. Left and Middle: using the RT-standard scheme, when $F_{2}^{c \bar{c}}$ data are not included and included in the fit, respectively. Right: results for using various mass schemes in the fit to $F_{2}^{c \bar{c}}$ data.

Figure 1.5. Left: HERA combined data points for the $\mathrm{NC} e^{+} p$ cross-section for three different proton beam energies. Right: PDFs, $x u_{v}, x d_{v}, x S=2 x(\bar{U}+\bar{D})$, and $x g$ at $Q^{2}=10 \mathrm{GeV}^{2}$, for HERAPDF1.0 and for a HERAPDF fit which also includes the low-energy proton beam data, with the standard $Q^{2}$ cut, $Q^{2}>3.5 \mathrm{GeV}^{2}$, and for $Q^{2}>5.0 \mathrm{GeV}^{2}$.

### 1.3.5 High- $Q^{2}$ data from HERA-II running

Preliminary H1 data on NC and $\mathrm{CC} e^{+} p$ and $e^{-} p$ inclusive cross-sections and published ZEUS data on NC and CC $e^{-} p$ and CC $e^{+} p$ data, from HERA-II running, have been combined with the HERA-I data to yield an inclusive data set with improved accuracy at high $Q^{2}$ and high $x[34]$. The HERA-I data set and the new HERA I+II data sets are compared for CC $e^{-} p$ data in Fig. 1.6. This new data set is used as the sole input to a new PDF fit called the HERAPDF1.5 which uses the same formalism and assumptions as the HERAPDF1.0 fit [35]. These fits are superimposed on the corresponding data sets in the figure. Fig. 1.7 (left) shows the combined data for $\mathrm{NC} e^{ \pm} p$ cross-sections with the HERAPDF1.5 fit superimposed. The PDFs from HERAPDF1.0 and HERAPDF1.5 are compared in Fig. 1.7 (right). The improvement in precision at high $x$ is clearly visible.

### 1.3.6 Summary

The status of the combinations of H1 and ZEUS data has been discussed. HERA leaves rich legacy of results which are the basis for all present QCD analyses of unpolarized PDFs and define the goals for any future DIS experiment.

Figure 1.6. HERA combined data points for the CC $e^{-} p$ cross-section. Left: from the HERA-I run period. Right: from the HERA-I and II run periods. On each plot the HERAPDF fit which includes the corresponding data is illustrated: the HERAPDF1.0 fit on the left hand plot and the HERAPDF1.5 on the right hand plot.

Figure 1.7. Left: HERA combined data points for the NC $e^{ \pm} p$ cross-sections for data from the HERA-I and II run periods. The HERAPDF1.5 fit to these data is also shown on the plot. Right: Parton distribution functions from HERAPDF1.0 and HERAPDF1.5; $x u_{v}, x d_{v}, x S=2 x(\bar{U}+\bar{D})$ and $x g$ at $Q^{2}=10 \mathrm{GeV}^{2}$.

# 1.4 Unpolarized parton distribution functions: questions to be addressed at an EIC 

Marco Guzzi, Pavel Nadolsky, Fredrick Olness

### 1.4.1 Introduction

The Electron-Ion Collider (EIC) will operate at a time when the Large Hadron Collider (LHC) has established a new "gold standard" for perturbative QCD by measuring a variety of hard-scattering processes. High-luminosity EIC measurements will be very complementary to those at the LHC, as they will accurately probe various aspects of hadronic structure using independent experimental techniques. In the next few years, when next-to-next-to-leading order (NNLO) accuracy of QCD calculations becomes the norm, a variety of perturbative and nonperturbative effects need to be taken into account to match the precision of multi-loop radiative contributions. Some of these effects can be constrained solely by the LHC data; others need independent measurements, not affected by systematical uncertainties present at the LHC. With an integrated luminosity of $10 \mathrm{fb}^{-1}$ or more, the EIC will disentangle many such effects, including modifications of the nucleon structure within heavy-nuclei targets, flavor dependence of parton distribution functions (PDFs), and QCD dynamics at very large or small $x$.

As compared with previous lepton-nucleus experiments, the EIC will probe to smaller $x$ values with high precision. In contrast to the HERA ep collider, which explores the same $\left\{x, Q^{2}\right\}$ region, heavy-ion scattering will achieve much higher partonic densities that are a prerequisite for the onset of saturation. It will help delineate the kinematical boundary between the DGLAP factorization and saturated dynamics in the nuclear medium.

The $Q^{2}$ range of the EIC will cover the transition region from the perturbative to the non-perturbative regime. Here, we wish to learn how the perturbative parton-scattering picture valid at large momentum transfers matches on nonperturbative models describing the strongly-coupled resonance region. Understanding of this region is important for hadronic experiments at the intensity frontier.

### 1.4.2 Open Questions

Several questions about PDFs will likely remain open at the time of the EIC operation. Figure 1.8 shows the kinematic domains in $x$ and $Q^{2}$ probed by current experiment and the PDFs that are most strongly constrained in these reqions.

Nuclear PDFs. Several groups extract nuclear PDFs and their uncertainties by analyzing the global data on nuclear targets [36, 37, 38, 39, 40]. In their studies, they find that the nuclear corrections depend on the type of the nucleus (its atomic number $A$ ), flavor of the probed parton, and even the type of the probing boson. For example, it was found recently [41, 37] that the nuclear correction factors preferred by the $\nu \mathrm{Fe}$ DIS data by NuTeV [42] are surprisingly different from predictions based on the $\ell^{ \pm} \mathrm{Fe}$ charged-lepton results.

By performing deep inelastic scattering (DIS) both on proton and heavy-nuclei targets, the EIC can distinguish between intrinsic properties of the proton and those of the extended nuclear medium. A high-intensity EIC could use a variety of nuclear beams to precisely map the $A$-dependent nuclear correction factors in the $\left\{x, Q^{2}\right\}$ kinematic plane and clarify the behavior of nuclear corrections to NC DIS. Such information is of importance for determining the proton PDFs, in particular, the strange quark PDF that is constrained largely

Figure 1.8. Kinematic domains in $x$ and $Q^{2}$ probed by fixed-target and collider experiments, shown together with the PDFs that are most strongly constrained by the indicated regions [3]. DIS data off nuclear targets exist only in the fixed-target region.
from the NuTeV data. The nuclear correction affects the uncertainty in $s(x, Q)$, which is large at present and may limit the precision of electroweak studies in $W$ and $Z$ boson production at the LHC [43].

The topics of nuclear PDFs and saturation will be extensively discussed in the Chapter 5 devoted to $e A$ physics at an EIC.

Better constraints on the strangeness PDF. Despite extensive investigation, there remain large uncertainties in flavor differentiation of sea-quark PDFs both in the proton and nuclei. In particular, the strange quark+antiquark distribution in the proton, $s_{+}(x)=$ $s(x)+\bar{s}(x)$, and its asymmetry, $s_{-}(x)=s(x)-\bar{s}(x)$, are still poorly known [44, 45, 46, 22, 47, despite their significance for understanding of the nucleon structure. Existing constraints on the strangeness come predominantly from neutrino (semi-)inclusive DIS [48, 42]. At the EIC, both $s_{+}(x)$ and $s_{-}(x)$ can be probed in semi-inclusive DIS production of kaons; see Sec. 1.5 for some quantitative studies. This measurement will rely on a good understanding of fragmentation functions, which will be known much better by the time an EIC turns on.

The $d / u$ ratio at large $\mathbf{x}$. Because of its intermediate energy and high beam intensity, the EIC is ideal for studying parton distributions at large Bjorken $x(x>0.1)$, where separation of parton flavors is not fully understood despite many years of experiments. For example, even the ratio $d(x, Q) / u(x, Q)$ of the dominant up and down quark proton PDFs at $x>0.3$ has been recently put in doubt by contradicting constraints from DIS on deuteron targets [49, 50] and charged lepton asymmetry at the Tevatron [51, 52]. While the PDF analysis groups labor to understand these differences [22, 46, 53 (and new clean LHC measurements of the $d / u$ ratio in proton scattering are in the queue), the EIC will help to resolve this controversy by extracting the ratio $F_{2}^{n}(x, Q) / F_{2}^{p}(x, Q)$ from DIS data on various nuclear targets. Such measurement will help to separate several types of kinematical and nuclear corrections ([54], and references therein) that influence the $F_{2}^{n} / F_{2}^{p}$ ratio derived
from nuclear-target DIS.
Gluon PDF in the proton and charm production at large x. Even more uncertainty exists in the gluon $\operatorname{PDF} g(x, Q)$ at large $x$, where it can be larger than the down-quark $d(x, Q)$ at $x>0.5$ in some recent parametrizations for proton PDFs [55]. This ambiguity will be reduced by upcoming high- $p_{T}$ jet production at the LHC, but significant systematic limitations of both experimental and theoretical nature may persistent at the largest $x$, where the EIC could independently contribute. Production of heavy-quark $(c, b)$ pairs or heavy mesons $(J / \psi, \Upsilon)$ in deep-inelastic scattering could accurately probe the large- $x$ gluon PDF. The EIC detectors will have excellent charm tagging efficiency, in a relatively clean scattering environment as compared to the LHC.

Inclusive charm production is interesting in its own right, given that large radiative contributions are known to exist near the heavy-quark production threshold, i.e., at $Q$ comparable to the charm quark mass; see Sec. 1.7 for a detailed account of heavy quark contributions to DIS structure functions. The rate for charm production at large $x, x \gtrsim 0.1$, can be increased by up to an order of magnitude by nonperturbative intrinsic charm production suggested by light-cone models [56, 57]. An EIC will be a unique opportunity to cleanly test for the presence of intrinsic charm contributions; see Sec. 1.9 for some quantitative studies.

Transition to the high-density regime. There is a long-standing question of partonic saturation and recombination in the small- $x$ region. As a related phenomenon, BFKL [58, [59, 60] effects from large $\ln [1 / x]$ contributions may supersede the usual DGLAP evolution in the small-x regime. The EIC should be capable of probing the transition from DGLAP factorization to BFKL/saturation dynamics, particularly using heavy nuclei beams in order to produce large partonic densities; see Chapter 5 for details on $e A$ physics.

Perturbative-nonperturbative QCD boundary. The general kinematic parameters of an EIC would span across both the perturbative (large $Q^{2}$ ) region and the nonperturbative (small $Q^{2}$ ) region. The theoretical description of the physics in these two regions is very different, and precise EIC data might enable us to better connect these two disparate theoretical descriptions.

The longitudinal structure function. The longitudinal structure function $F_{L}=$ $F_{2}-2 x F_{1}$ is of special interest, in view that its leading $\mathcal{O}(1)$ term vanishes according to the Callan-Gross relation. The first non-vanishing, leading order contribution is of $\mathcal{O}\left(\alpha_{s}\right)$ and dominated by photon-gluon fusion. Hence, $F_{L}$ is particularly sensitive to the gluon distribution $g\left(x, Q^{2}\right)$. Corrections up to $\mathcal{O}\left(\alpha_{s}^{3}\right)$ are known [10, allowing for a consistent analysis of $F_{L}$ at NNLO accuracy. An EIC could make the first precise measurements of $F_{L}$ in a kinematic range that overlaps both the fixed-target and HERA collider data 30 which have large statistical uncertainties; see Sec. 1.6 for more details on such a measurement at an EIC.

Electroweak contributions to proton PDFs. Some, if not all, NLO electroweak effects will be included in future PDF analyses, as their magnitude is comparable to the size of NNLO QCD radiative contributions that will be routinely included. The QCD+EW PDFs require additional experimental input to constrain nonperturbative parametrizations for photon PDFs, as well as charge asymmetry effects (isospin violation) between PDFs for up-type quarks and down-type quarks at the initial scale $Q \approx 1 \mathrm{GeV}$. An EIC has the potential to contribute toward improving limits on electroweak PDF terms either directly or in combination with neutrino DIS measurements.

When extracting information about the proton PDFs from scattering on nuclear targets, we generally make use of isospin symmetry to relate the proton and neutron PDFs via a
$u \leftrightarrow d$ interchange. While the isospin symmetry is elegant, it is nonetheless approximate and can be violated at the level of a few percent [61, 62, 63, 64, 65, 66, 67, 41, 68]. Violation of the exact $p \leftrightarrow n$ isospin symmetry, or charge symmetry violation (CSV), invalidates the parton model relations that reduce the number of independent nonperturbative distributions; e.g., $u^{n}(x) \not \equiv d^{p}(x)$ and $u^{p}(x) \not \equiv d^{n}(x)$. It is important to be aware of the potential magnitude of isospin symmetry violation and its consequences for flavor separation of proton PDFs.

It is noteworthy that isospin symmetry is automatically violated both perturbatively and nonperturbatively. This is because the photon couples to the up quark distribution $u^{p}(x)$ differently than to the down quark distribution $d^{n}(x)$. These terms can be comparable to the NNLO DGLAP evolution effects [69, 70, 71].

Some combinations of structure functions, such as $\Delta F_{2} \equiv \frac{5}{18} F_{2}^{C C}\left(x, Q^{2}\right)-F_{2}^{N C}\left(x, Q^{2}\right)$ and $\Delta x F_{3}=x F_{3}^{W^{+}}-x F_{3}^{W^{-}}$, can be particularly sensitive to isospin violations, and an EIC can contribute to their measurement. For example, the EIC is capable of measuring precisely the structure function $F_{2}^{N C}$ mediated by the neutral-current $\gamma / Z$ exchange processes. Measurement of $F_{2}^{C C}$, mediated by the charged-current $W^{ \pm}$exchange, would rely on compensating the $M_{W}^{2} / Q^{2}$ suppression of the $W$ boson propagator with high intensity of the beams; see Sec. 1.12 for more details on electroweak structure function measurements at an EIC.

In separate experiments, $\Delta x F_{3}$ can be measured precisely via the neutrino-nucleon DIS process; as these measurements are performed with heavy nuclear targets, the nuclear correction factors can be the limiting factor as to the derived CSV constraint. Since an EIC will use a variety of nuclear targets, it can obtain very precise nuclear correction factors; this information could, in principle, be used together with the neutrino-nucleon DIS data to extract improved CSV limits.

The structure functions $\Delta F_{2}$ and $\Delta x F_{3}$ receive contributions from both heavy flavors as well as CSV contributions; improved understanding of the heavy-quark components (discussed previously) can indirectly contribute to better CSV limits 68].

The combination of high-statistics EIC measurements and constraints could thus yield important information on the fundamental charge symmetry.

### 1.5 Flavor separation from semi-inclusive DIS

Elke-Caroline Aschenauer, Marco Stratmann

### 1.5.1 Motivation and Method

The strangeness distribution and a possible asymmetry between strangeness and antistrangeness densities have been identified as two of the most compelling open questions in hadronic physics which are difficult to address without an EIC; see Sec. 1.4.

Existing constraints in global fits come predominantly from neutrino (semi-)inclusive DIS 48, 42] but both $s_{+}(x) \equiv s(x)+\bar{s}(x)$ and $s_{-}(x) \equiv s(x)-\bar{s}(x)$ are still only poorly known [46, 22, 72]. Figure 1.9 summarizes recent uncertainty estimates for $s_{ \pm}$from three global QCD fits.

Figure 1.9. Uncertainty bands for $s_{ \pm}$at $Q^{2}=2 \mathrm{GeV}^{2}$ for recent fits. Figure taken from [72].
Semi-inclusive DIS with identified charged kaons is expected to be a viable method to determine the elusive strange quark density and perhaps a possible asymmetry $s_{-}$experimentally. One can access basically the same a broad kinematic range in $x$ and $Q^{2}$ as in inclusive DIS. The HERMES collaboration has successfully performed such a measurement in the range $0.02<x<0.6$ at an average $Q^{2}$ of about 2.5 GeV [73]. Compared to $s(x)$ from most global PDF fits, they find a softer strangeness distribution in their LO analysis. Clearly, more data in a larger range of $x$ and $Q^{2}$ are necessary to clarify this issue.

The SIDIS measurement relies, however, on a good understanding of the hadronization mechanism which is encoded in non-perturbative, collinear parton-to-hadron fragmentation functions (FFs) $D_{i}^{H}$ if factorization is assumed in a pQCD calculation. Like PDFs, FFs are extracted from global QCD analyses. One can resort to a wealth of single-inclusive hadron production data obtained at different c.m.s. energies in $e^{+} e^{-}$annihilation and in $e p$ and $p p(p \bar{p})$ scattering. Pion FFs are currently known best with uncertainties of about $5 \div 10 \%$ depending on the flavor of the fragmenting parton [74]. Ambiguities for kaon FFs are about twice as large [74]. Significant progress on the quality of fits to FFs is expected once data from $B$ factories and the LHC become available. Also, NNLO evolution kernels are expected to become available in the near future [75], which will help to reduce theoretical scale ambiguities further.

All relevant SIDIS cross sections are known at least to NLO accuracy [76, 77, 78, 79], and the analytical expressions are relatively simple and easy to implement into global fits of PDFs, see, e.g., [80]. Schematically the unpolarized SIDIS cross section for the production of a hadron $H$ in the current fragmentation region reads

$$
\begin{equation*}
\frac{d \sigma^{H}}{d x d y d z}=\frac{2 \pi \alpha^{2}}{Q^{2}}\left[\frac{1+(1-y)^{2}}{y} 2 F_{1}^{H}\left(x, z, Q^{2}\right)+\frac{2(1-y)}{y} F_{L}^{H}\left(x, z, Q^{2}\right)\right] \tag{1.5}
\end{equation*}
$$

with $x$ and $y$ denoting the usual DIS variables, $-q^{2}=Q^{2}=S x y$, and $z=p_{H} \cdot p / p \cdot q$ the momentum fraction taken by the hadron $H$. Assuming factorization, the structure functions $F_{1, L}^{H}$ at a factorization scale $\mu \sim Q$ can be expressed as convolutions of non-perturbative PDFs $f_{j}(x, \mu)$ and FFs $D_{i}^{H}(z, \mu)$ with short-distance Wilson coefficients $C_{i j}^{1, L}(x, z, \mu)$.

### 1.5.2 Expectations for Charged Kaon Production at an EIC

Figures 1.10 and 1.11 show expectations for the $K^{+}$and $K^{-}$production cross section (1.5) at NLO accuracy, respectively, as a function of $x$ in bins of $Q^{2}$, using $0.01 \leq y \leq 0.95$ and $\sqrt{S}=70.7 \mathrm{GeV}$ (i.e., $5 \times 250 \mathrm{GeV}$ collisions at an EIC). To reduce uncertainties from kaon FFs, $z$ is integrated in the range $0.2 \leq z \leq 0.8$. The DSS set 74 is used. The solid lines are the statistical average over 100 replicas in the NNPDF2.0 neural network analysis [47] and the dashed lines reflect the corresponding PDF uncertainties.

Also shown in Figs. 1.10 and 1.11 are simulations based on the PYTHIA 81 event generator in the same kinematic range. Here, the CTEQ6L set of PDFs [82] has been used. The hadronic final state was simulated using JETSET based on LEP fragmentation settings and a suppression of $s \bar{s}$ pair production from the vacuum of 0.3 [PARJ (2)] compared to $u \bar{u}$ or $d \bar{d}$ creation. The results turn out to be remarkably similar to the NLO calculations based on collinear factorization despite the very different way hadronization is implemented in PYTHIA and the fact that only LO matrix elements are used, albeit matched with a parton shower. This gives us quite some confidence that the PYTHIA generator can be used to provide very reasonable estimates of yields for DIS-type processes at an EIC. In addition, it also tells us that the current DSS kaon FFs are doing a good job and include a realistic amount of "strangeness suppression". Already after one month of operation, corresponding to an integrated luminosity of about $20 \mathrm{fb}^{-1}$ the measurement will be limited by systematic uncertainties which need to be carefully studied. The statistical accuracy is significantly better than indicated by size of the points shown in the figures.

If one compares the results for $K^{+}$and $K^{-}$in Figs. 1.10 and 1.11 one finds hardly any difference at the smallest $x$ values in each $Q^{2}$ bin. At larger $x$ values, where $s_{-}$is largest, see Fig. [1.9, the yields for $K^{-}$are significantly lower than the ones for $K^{+}$. An EIC should be able to provide accurate measurements of both $s_{+}$and $s_{-}$in a broad kinematic range up to $Q^{2}$ values of a few hundred GeV .

Within the neural network approach it is in principle fairly straightforward to quantify by how much a new data set will reduce present PDF uncertainties. The original ensemble of replicas is constructed in such a way that all have the same weight. Information contained in new data sets can be incorporated without the need for refitting by reweighting each PDF in the ensemble by the probability that it agrees with the new data [47, 53]. Sets with small weights will become largely irrelevant in statistical averages. If too many sets receive small weights the accuracy of results from the new PDF ensemble will deteriorate, and the reweighting procedure becomes unreliable, necessitating a full refit. One reason for this to happen is, that the new data set contains significant new information which leads to much smaller uncertainties in certain kinematic regions. This is exactly what happens when one applies the reweighting method to the SIDIS data shown in Figs. 1.10 and 1.11 even if one assigns a fictitious $\mathcal{O}(5 \%)$ systematic uncertainty to each data point.

There are many other things which can be studied in SIDIS at an EIC. For instance, one can also bin in $z$ which makes the measurement more sensitive to the shape of the kaon FFs. This will provide a more stringent check whether FFs are universal functions in $e^{+} e^{-}, e p$, and $p p$ scattering. Pion yields will allow one to study other interesting and
relevant PDF combinations such as $\bar{u}(x)-\bar{d}(x)$. Similar measurements can be also done with longitudinally polarized beams which will give access to the helicity-dependent quark and antiquark densities, see Sec. 1.11. Detailed quantitative studies including more timeconsuming global QCD analyses with simulated SIDIS data for various c.m.s. energies are planned to quantify the impact of such measurements on our understanding of the spin and flavor structure of the nucleon. These studies should include also some estimates of the various sources of systematic uncertainties, like detector resolution, uncertainties in the particle identification, luminosity, and polarization measurements, details on these can be found in Sec. 7.3.

Figure 1.11. Same as in Fig. 1.10 but now for $K^{-}$production.

### 1.6 The longitudinal structure function $F_{L}$ at an EIC

Elke C. Aschenauer, Ramiro Debbe, Marco Stratmann

### 1.6.1 Motivation and Current Status of $F_{L}$ Results

The DIS reduced cross section $\sigma_{r}$ for one-photon-exchange can be represented as the sum of two independent structure functions $F_{2}$ and $F_{L}$ as follows

$$
\begin{equation*}
\sigma_{r} \equiv \frac{Q^{4} x}{2 \pi \alpha_{e m}^{2} Y_{+}} \frac{d^{2} \sigma}{d x d Q^{2}}=F_{2}\left(x, Q^{2}\right)-\frac{y^{2}}{Y_{+}} F_{L}\left(x, Q^{2}\right) \tag{1.6}
\end{equation*}
$$

where $Y_{+} \equiv 1+(1-y)^{2}$ depends on the inelasticity $y=Q^{2} /(s x)$ of the process.
$F_{L}$ is proportional to the cross section for probing the proton with a longitudinally polarized virtual photon and vanishes in the naive Quark Parton Model due to helicity conservation. Starting from $\mathcal{O}\left(\alpha_{s}\right)$, the longitudinal structure function differs from zero, receiving contributions from both quarks and gluons.

At low $x$, the gluon contribution due to photon-gluon fusion greatly exceeds the quark contribution. Therefore, measuring $F_{L}$ provides a rather direct way of studying the gluon density and QCD dynamics at small $x$, i.e., the transition to the high parton density regime. Measurements can be used to test several phenomenological and QCD models describing the low $x$ behavior of the DIS cross section, including color dipole models [83, 84, 85] and expectations from DGLAP fits performed at NLO and NNLO accuracy of QCD. Possible deviations from the DGLAP behavior in the small $x$, low $Q^{2}$ region can be studied by varying kinematic cuts to the data used in the fits.

The longitudinal structure function, or the equivalent cross section ratio $R=\sigma_{L} / \sigma_{T}=$ $F_{L} /\left(F_{2}-F_{L}\right)$, was first measured in fixed target experiments and found to be small at large $x, x \geq 0.01$, see, e.g., Ref. [86]. H1 [30] and ZEUS [87] have recently combined their measurements of $\sigma_{r}$ for three different proton beam energies [20], $E_{p}=920,575$, and 460 GeV , see Fig 1.5 in Sec. 1.3. The extracted $F_{L}$, shown in Fig. 1.12, covers a wide kinematic range, spanning $2.5<Q^{2}<800 \mathrm{GeV}^{2}$ and $0.0006<x<0.0036$. As can be seen, $F_{L}$ is clearly non-zero, and there is some mild tension with the HERAPDF1.0 fit based on DGLAP evolution [20] at the lowest values of $x$ and $Q^{2}$ where one expects non-linear effects to be relevant; see Chapter 5 on $e A$ physics. In this regime, predictions from the dipole model provide a better description of the data. However, the achieved statistical precision of the combined H1 and ZEUS measurement is too limited to be conclusive.

### 1.6.2 Measurement Strategy and Experimental Challenges

The measurement of $F_{L}$ relies on an accurate determination of the variation of the reduced cross section (1.6) for common values of the ( $x, Q^{2}$ ) bin centers at different beam energies, i.e., c.m.s. energies $\sqrt{s}$. Relative normalizations and systematic uncertainties of the different data sets for $\sigma_{r}$ have to be well under control.
$F_{L}$ and $F_{2}$ can be extracted simultaneously from $\sigma_{r}$ by plotting $\sigma_{r}$ for fixed values of $\left(x, Q^{2}\right)$ as a function of $y^{2} / Y_{+} . F_{L}$ is then determined as the slope of the line fitted to the measurements of $\sigma_{r}$ for different values of $\sqrt{s}: F_{L}\left(x, Q^{2}\right)=-\partial \sigma_{r}\left(x, Q^{2}, y\right) / \partial\left(y^{2} / Y_{+}\right)$. Likewise, $F_{2}$ is the intercept of the fitted line with the $y$ axis: $F_{2}\left(x, Q^{2}\right)=\sigma_{r}\left(x, Q^{2}, y=0\right)$. All measurements at HERA are observed to be consistent with the expected linear dependence [30, 87, 20]. At any given value of $Q^{2}$, the lowest possible $x$ values are only accessed by

Figure 1.12. Combined H1 and ZEUS extraction of $F_{L}$ [20] as a function of $Q^{2}$ averaged over $x$ compared to the HERAPDF1.0 fit and predictions from dipole models.
the highest $\sqrt{s}$, and the slope related to $F_{L}$ cannot be determined. Hence, the Rosenbluth separation limits the kinematic coverage of $F_{L}$ at small $x$. At larger values of $x$, measurements of $\sigma_{r}$ for various different $\sqrt{s}$ are available and the slopes can be straightforwardly extracted.

The contribution of $F_{L}$ to the reduced cross section (1.6) can be sizable only at large values of $y$. For low values of $y, \sigma_{r}$ is very well approximated by the structure function $F_{2}$ [30, 87, 20. Low $y$ data can be used to normalize data sets taken at different c.m.s. energies relative to each other. For measurements at high $y$ the reconstruction of the DIS kinematics using the scattered lepton, the so called "electron method", has the best resolution and was used at HERA.

In the large $y$ region, $y \gtrsim 0.5$, and low $x$ the electron method is prone to large QED radiative corrections which can reach a level of more than $50 \%$ of the Born cross section. Studies based on the DJANGO [88] and HECTOR [89] programs for HERA kinematics show that the largest radiative contributions arise because of hard initial-state radiation (ISR) from the incoming lepton [30]. The radiated photon usually escapes in the beam pipe and the $E-P_{z}$ of the event is reduced. Therefore, hard ISR can be efficiently suppressed to a level of about $10 \%$ at HERA with only a slight residual dependence on $y$ by requiring $E-P_{z}$ close to the nominal value of twice the electron beam energy implied by energymomentum conservation [30]. $E-P_{z}$ can be reconstructed from the measured final-state particles. At the highest $y, y \gtrsim 0.7$, corrections increase due to QED Compton events which can be rejected by certain topological cuts. All cross section measurements at HERA are corrected for QED radiation up to $\mathcal{O}\left(\alpha_{e m}\right)$ using HERACLES [90] which is included in the DJANGOH package; further details can be found in Sec. 7.3,

Kinematically, for low $Q^{2}$, large values of $y$ correspond to low energies of the scattered lepton. Selecting high $y$ events is thus further complicated due to a possibly large background from energy deposits of hadronic final state particles leading to fake electron signals. However, the cut on $E-P_{z}$ also suppresses such type of backgrounds. In addition, electron tracking, which is foreseen for an EIC detector, will largely eliminate fake electron signals as an additional cut on $E / p \simeq 1$ can be placed to identify the lepton.

Extractions of $F_{L}$ are certainly the most demanding inclusive structure function measurements but an EIC will have many advantages compared to HERA, in particular, the possibility to vary $\sqrt{s}$ in a wide range for high luminosity collisions. Also, much better detector capabilities, for instance, concerning the electron, are foreseen. One can also take

Figure 1.13. Projected uncertainties for an extraction of $F_{2}$ and $F_{L}$ from a Rosenbluth separation for data taken at three different c.m.s. energies. Also shown are theoretical expectations at NNLO based on the ABKM09 set of PDFs [19] (see text).
advantage of all the analysis techniques and Monte Carlo codes developed for HERA to deal with QED radiative corrections.

### 1.6.3 Expectations for the EIC

Pseudo-data for the reduced cross section (1.6) have been generated using the Monte Carlo generator LEPTO 91 for the first stage of an EIC ( 5 GeV electrons on 100, 250, and 325 GeV protons). The CTEQ6L set of PDFs 82 has been used in the simulations. The hadronic final state was simulated using JETSET [81]. We note that the current pseudo-data do not include any simulations of QED radiative effects and reflect statistical uncertainties which could be achieved by running one month at each of the beam energy settings with the projected luminosities for eRHIC. In addition, a $1 \%$ systematic uncertainty is added.

Figure 1.13 shows the structure functions $F_{L}$ and $F_{2}$ extracted from the pseudo-data of the reduced cross section by means of a Rosenbluth separation, requiring a minimum scattered lepton momentum of $0.5 \mathrm{GeV}, Q^{2}>1 \mathrm{GeV}^{2}, 0.01<y<0.90$, and $0.5^{\circ}<\theta<$ $179.5^{\circ}$. To guide the eye, the expected uncertainties are placed on theoretical expectations for $F_{2, L}$ at NNLO accuracy using the ABKM09 set of PDFs [19]. One should note that these PDFs use only data with $Q^{2}>2.5 \mathrm{GeV}^{2}$ in their fit and, hence, the behavior of $F_{2, L}$ in the lowest $Q^{2}$ bin must be taken with a grain of salt and are only for illustration. The extracted uncertainties take detector smearing of the scattered electron momentum into account. The momentum resolution was taken from ZEUS, i.e., $\delta p / p=0.85 \%+0.25 \% \times p$.

### 1.6.4 Summary and To-Do Items

Like for most inclusive and semi-inclusive measurements at the EIC, an extraction of $F_{L}$ will be dominated by systematic uncertainties which need to be thoroughly addressed. This is work in progress. It is planned to study the unfolding of $F_{L}$ in great detail both in $e p$ and $e A$ scattering, including QED radiative corrections and a full simulation of the detector. This will elucidate to what extent the methods developed and used at HERA [30, 87, 20] are suited for high precision measurements of $F_{L}$ aimed at the EIC. In any case, it will be crucial to design the relevant detector components very carefully to optimize

- the luminosity measurement and its relative calibration for running at different c.m.s. energies,
- the lowest lepton momentum we can detect ( 0.5 GeV would be desirable),
- the identification of the scattered lepton to suppress potential background from misidentified hadrons,
- the resolution in momentum and scattering angle of the scattered lepton, and
- the acceptance for the hadronic final state to suppress events which have a photon radiated from the incoming or outgoing lepton as well as quasi real photo-production events.

Details on the design of the detector are given in Sec. 7.3. Also, it will be possible to extract $\mathrm{F}_{L}$ from the EIC data alone, but the combination of the EIC reduced cross section measurements with the ones from HERA may provide an even better lever arm in a larger $x, Q^{2}$ range. This needs to be investigated.

Finally, we note that even for statistically very precise measurements of $\sigma_{r}$, the Rosenbluth separation of $F_{L}$, i.e., the determination of the slope with respect to $y^{2} / Y_{+}$, can lead to significantly larger uncertainties if the measured values of $\sigma_{r}$ have very similar $y^{2} / Y_{+}$. This source of uncertainties needs be minimized by optimizing the binning in $y$ and the set of different c.m.s. energies $\sqrt{s}$. Studies is this direction are ongoing as well.

### 1.7 Theoretical status of inclusive heavy quark production in DIS

Sergey Alekhin, Johannes Blümlein, Sven-Olaf Moch

### 1.7.1 Introduction

Heavy quark production gives a sizable contribution to the unpolarized DIS structure functions at small $x$, see, e.g., [92, 93, 94, 95]. For the foreseen EIC kinematics of DIS it yields up to $10 \%$ of the inclusive cross section. Therefore in order to employ the full potential of the small- $x$ EIC data for phenomenology one has to provide an accurate theoretical description of heavy-quark electro-production within perturbative QCD.

For the light-parton contributions to DIS structure functions a theoretical accuracy of $O$ (few \%) is achieved, with the complete QCD corrections up to 3-loops being available, see also Sec. 1.2, In the case of the fixed-flavor-number scheme (FFNS) the heavy flavor corrections are available only to $O\left(\alpha_{s}^{2}\right)$. This can be a bottleneck for the analysis of high-precision data. Therefore, progress in the higher-order calculations of heavy-quarkproduction coefficient functions is quite important for the EIC phenomenology. For the variable-flavor-number scheme (VFNS) the massive quarks are considered on the same footing as the massless ones. Furthermore, the heavy-quark PDFs appearing in the VFNS are derived from the light-parton PDFs and the appropriate massive operator-matrix elements (OMEs). The VFNS coefficient functions are known up to 3-loop accuracy due but the massive OMEs are only available to the NLO corrections. This limits the theoretical accuracy of the VFNS as well.

In the following we summarize the state-of-art in calculations of the NNLO corrections to the unpolarized heavy-quark coefficient functions and to the massive OMEs. The FFNS and VFNS are compared to the available HERA data and to each other. We also discuss the implementation of the running-mass scheme for the NLO and NNLO heavy-quark coefficient functions and the resulting improvement in the perturbative stability related to this definition.

### 1.7.2 General framework

The heavy flavor corrections to deep-inelastic structure functions emerge in the Wilson coefficients for the respective processes, i.e., they contribute in terms of virtual and final state effects. Heavy quarks have no strict partonic interpretation since partons are massless, and by virtue of this, infinitely long lived, with the possibility to move collinear to each other. Adopting this picture, heavy quarks can be singly or pair produced from massless partons and the gauge bosons of the Standard Model as final states. This description is called FFNS, which is the genuine scheme in any quantum-field theoretic calculation. The DIS structure functions $F_{i}\left(x, Q^{2}\right)$ obey the representation

$$
\begin{equation*}
F_{i}\left(x, Q^{2}\right)=\left[\sum_{k=q_{l, g}}\left[C_{i, \text { light }}^{k}\left(x, Q^{2} / \mu^{2}\right)+C_{i, \text { heavy }}^{k}\left(x, Q^{2} / \mu^{2}, m_{h}^{2} / \mu^{2}\right)\right] \otimes f^{k}\left(\mu^{2}\right)\right](x), \tag{1.7}
\end{equation*}
$$

where $q_{l}$ and $g$ label the massless quarks and gluons, $f^{k}\left(\mu^{2}\right)$ are the PDFs, $C_{i, \text { light(heavy }}^{k}$ the massless (massive) Wilson coefficients, $h=c, b$ the charm and bottom quarks, and $\otimes$ denotes the Mellin convolution. Other approaches derive from this description.

In case of unpolarized DIS the LO contributions were given in [96, 97, 98, 99] and the NLO corrections were calculated in semi-analytic form in [100, 101]. For asymptotic values $Q^{2} \gg m_{h}^{2}$ one may obtain the massive Wilson coefficients in analytic form. This is due to a factorization theorem [102] relating the massive Wilson coefficients $C_{i, \text { heavy }}^{k}$ to universal massive OMEs and the massless Wilson coefficients [77, 6, 103, 10]. As comparisons up to NLO showed [102], these representations are valid for the structure function $F_{2}\left(x, Q^{2}\right)$ if $Q^{2} / m_{h}^{2} \gtrsim 10$. To $O\left(\alpha_{s}^{2}\right)$ the Wilson coefficients were obtained in [102, 104, 105] at general values of the Mellin variable $N$. A first contribution to the 3-loop corrections was given in [106] by the $O\left(\alpha_{s}^{2} \varepsilon\right)$ terms which contribute to the logarithmic terms $O\left(\ln ^{k}\left(Q^{2} / m_{h}^{2}\right)\right), k=$ $1,2,3$, in $O\left(\alpha_{s}^{3}\right)$. A large number of even Mellin-moments for all unpolarized 3-loop massive OMEs have been calculated in [107] up to $N=10 \ldots 14$ depending on the respective channel. For the structure function $F_{L}\left(x, Q^{2}\right)$ the asymptotic 3-loop corrections were given in [108] for general values of $N$. However, they are valid at $1 \%$ accuracy at much higher scales of $Q^{2} / m_{h}^{2} \gtrsim 800$ only. All logarithmic terms at $O\left(\alpha_{s}^{3}\right)$ for the heavy flavor Wilson coefficients contributing to the structure function $F_{2}\left(x, Q^{2}\right)$ are known [109, 110]. More than this, all the contributions to the constant terms emerging from lower order contributions by renormalization have been calculated, cf. 107] for details. Due to the size of the constant contributions phenomenological applications for the kinematic range available at HERA and the EIC cannot be based on only the logarithmic contributions. QCD corrections to charged current heavy flavor production have been considered in [111, 112, 113 .

### 1.7.3 FFNS and VFNS

The logarithmic contributions in the heavy flavor Wilson coefficients $\propto \ln ^{k}\left(Q^{2} / m_{h}^{2}\right)$ never become large enough in the kinematic region of HERA or the EIC that their resummation would be required [114]. Nonetheless one may introduce a description changing the number of light flavors effectively, which refers to the universal contributions to the heavy flavor Wilson coefficients, consisting of the twist-2 parton densities and the massive OMEs [115, 107, 116, 117. This requires the knowledge of also the gluonic OMEs to 3-loop order [107].

By matching at typical scales $\mu_{f}$ one performs the transition from $n_{f}$ to $n_{f}+1$ massless flavors using the asymptotic relations. In this way one may introduce a heavy quark density. The corresponding representation, which is obtained in terms of a reformulation of the FFNS, is called zero mass variable flavor number scheme (ZMVFNS). It is unique up to the choice of the matching point(s). An important issue is the choice of the scale $\mu_{f}$, for which very often $\mu_{f} \simeq m_{h}$ is used. In Ref. [118] it was shown, however, comparing exact and flavor number matched calculations that this scale is process dependent and often very different scales have to be chosen. In this context various problems arise. Because of the value of the charm to bottom mass ratio, $m_{c}^{2} / m_{b}^{2} \sim 1 / 9$, power corrections due to $m_{c}^{2}$ usually cannot be neglected at scales $\mu^{2} \simeq m_{b}^{2}$. Therefore, sequential decoupling of both charm and bottom quarks is problematic. Furthermore, starting at $O\left(\alpha_{s}^{3}\right)$, Feynman diagrams with both bottom and charm quarks contribute, which cannot be attributed to either the charm or the bottom quark PDF [119. The description of the FFNS, on the other hand, is still possible. Therefore, representations based on the ZMVFNS remain approximations to which one may refer for specific applications. Furthermore, it applies only for the asymptotic case $Q^{2} \gg m_{h}^{2}$.

For the description of data one would like to have a smooth description of the structure

Figure 1.14. Comparison of $F_{2}^{c}$ computed in different schemes to H1 and ZEUS data: GMVFNS in the BMSN prescription (solid lines), 3-flavor scheme (dot-dashed lines), and 4-flavor scheme (dashed lines). The vertical dotted line denotes the position of $m_{c}=1.43 \mathrm{GeV}$. Taken from Ref. [19].
functions at both large and low values of $Q^{2}$, which is called the general mass variable flavor number scheme (GMVFNS). Here, a smooth interpolation is provided by the BMSN scheme [116, 19] given by

$$
\begin{equation*}
F_{2}^{h, \mathrm{BMSN}}\left(n_{f}+1\right)=F_{2}^{h, \text { exact }}\left(n_{f}\right)+F_{2}^{h, \mathrm{ZMVFNS}}\left(n_{f}+1\right)-F_{2}^{h, \text {,asymp }}\left(n_{f}\right), \tag{1.8}
\end{equation*}
$$

where exact corresponds to [100, 101], asymp to its asymptotic form for $Q^{2} \gg m_{h}^{2}$, and ZMVFNS to the value in the zero mass variable flavor scheme. In Fig. 1.14 the transition is shown for values of $x$ between 0.00018 and 0.03 for the kinematics at HERA according to (1.8) (see Ref. [120] for phenomenological variants of the GMVFNS).

### 1.7.4 The massive NNLO corrections and the running mass

The radiative corrections to the massive Wilson coefficients are known to be sizable. In particular, near the production threshold $s \simeq 4 m_{h}^{2}$, where large Sudakov double logarithms $\alpha_{s}^{k} \ln ^{2 k}\left(1-4 m_{h}^{2} / s\right)$ dominate at each order, one may wish to apply resummations; see Refs. [121, 122, 123] for details.

Another aspect at higher orders concerns the definition of the heavy quark mass, since it is a scheme dependent quantity. It is of particular interest to investigate which choice of scheme leads to the best convergence of the perturbative series. Upon conversion of the conventionally used on-shell (pole) mass for heavy quark DIS to the running mass $m_{h}(\mu)$ in the $\overline{\mathrm{MS}}$-scheme, one observes a considerable improvement of scale stability and convergence of the perturbative expansion. The latter aspect is demonstrated in Fig. 1.15, Here one uses the Wilson coefficients to NLO and refers to the approximate result valid in the threshold region [121, 122, 123 to give an estimate for the NNLO value, see Ref. [124].

Figure 1.15. The mass dependence of $F_{2}^{c}$ for $Q^{2}=10 \mathrm{GeV}^{2}, x=10^{-3}$, and $\mu_{r}=\mu_{f}=\sqrt{Q^{2}+4 m_{c}^{2}}$ using the PDFs of [19. $m_{c}$ is taken in the on-shell scheme (left) and in the $\overline{\mathrm{MS}}$ scheme (right) at LO (blue), NLO (green), and $\mathrm{NNLO}_{\text {approx }}$ (red); from Ref. [124].

Figure 1.16. The combined HERA data on $F_{2}^{c}$ in comparison with the prediction of a fit 124 performed in the running-mass scheme 125 .

Figure 1.17. The 1- $\sigma$ error bands (shaded area) for our NNLO 4-flavor (left panel) and 5 -flavor (central and right panels) $s, c$, and $b$ quark distributions in comparison to the corresponding MSTW2008 NNLO PDFs [22] (dashed lines); from Ref. 19].

The phenomenological impact of the mass scheme re-definition was checked for the ABKM fit of Ref. [19]. In a variant of this fit [124] the heavy-quark electro-production was considered in the running mass scheme and with the approximate NNLO corrections taken into account. $m_{c}$ was fitted to the DIS data simultaneously with the PDG world average [3] added to the fit as an additional constraint. In this way the value of $m_{c}\left(m_{c}\right)=$ $1.18 \pm 0.06 \mathrm{GeV}$ was obtained. The corresponding predictions for the semi-inclusive structure function $F_{2}^{c \bar{c}}$ are in good agreement with the preliminary HERA data in a wide kinematical region, cf. Fig. 1.16. This result gives an additional justification of the validity of the FFNS up to $Q^{2} \sim 1000 \mathrm{GeV}^{2}$, i.e., in the entire kinematic range relevant for an EIC.

### 1.7.5 Heavy-flavor PDFs

For applications at high-energy hadron colliders, schemes with 4- and 5-light flavors need to be considered. The necessary charm- and bottom PDFs are generated perturbatively. In Fig. 1.17 the results for the $s, c$, and $b$ quark flavors are shown at NNLO accuracy as determined in two global fits to the world data [19, 22]. The 1- $\sigma$ error bands correspond to the analysis of [19]. The central values of the MSTW08 distributions turn out to lie below those found in the ABKM09 analysis for the $c$ and $b$ quark distributions in the whole kinematic range of HERA due to the smaller gluon density [22]. The strange quark distribution still exhibits large errors; see also Sec. 1.5. Measurements at the EIC are expected to considerably improve both the strange and charm quark densities thanks to the much higher luminosities than at HERA.

## $1.8 \quad F_{2, L}$ (charm) at an EIC

Elke C. Aschenauer, Marco Stratmann

Section 1.7 gave an outline of the theoretical status of heavy flavor contributions to DIS structure function and a comparison to HERA data. The mass $m_{h}$ of the heavy quark introduces extra theoretical complications including the need for a smooth prescription to cover both the threshold ( $Q \simeq m_{h}$ ) and the asymptotic ( $Q \gg m_{h}$ ) region, the scheme used for $m_{h}$ (on-shell or $\overline{\mathrm{MS}}$ ), and the actual value of $m_{h}$ used in the calculations.

Detailed experimental results from the EIC, in particular, for the so far unmeasured charm contribution to $F_{L}$, will help to refine the current theoretical understanding. In the entire kinematic domain of the EIC one expects the FFNS to be applicable for $F_{2}^{c}$; see Sec. 1.7. Differences between the exact, massive FFNS results, and the ZMVFNS are expected to be much more pronounced for $F_{L}^{c}$, see, e.g., Fig. 7 in [114], than for $F_{2}^{c}$ shown in Fig. 1.14.

The extraction of $F_{L}^{c}$ requires a Rosenbluth separation and should proceed along very similar lines as discussed already in Sec. 1.6. The extra experimental complication is the requirement to detect a charm quark in the final state. A quantitative feasibility study is still ongoing. We note that the detection of charmed mesons is important also for other physics topics. Therefore the design of the detector foresees to have particle identification for pions and kaons to fully reconstruct charmed mesons via their $K \pi$ decay channel. In addition, a micro-vertex detector is expected to provide a vertex resolution of $5 \mu \mathrm{~m}$ to separate charmed mesons from B- and other mesons by measuring a displaced decay vertex. Using such techniques for a measurement of $F_{L}$ requires to detect a second decay lepton with a displaced vertex in addition to the scattered lepton. This, together with good lepton identification, should provide a high charmed meson detection efficiency. The required luminosities for a precise measurement of $F_{2, L}^{c}$ will scale with the achieved charm detection efficiency of the EIC detectors and the smaller reduced cross section for charm as compared to the fully inclusive $\sigma_{r}$ studied in Sec. [1.6. To illustrate the relative size of $F_{L}^{c}$ and $F_{2}^{c}$ we present in Fig. 1.18 some theoretical expectations at NLO accuracy based on the ABKM set of PDFs [19] see Sec. 1.7 for details.

Figure 1.18. Expectations for $F_{2, L}^{c}\left(x, Q^{2}\right)$ in bins of $Q^{2}$ using the ABKM set of PDFs [19].

### 1.9 Probing intrinsic charm at the EIC

Marco Guzzi, Pavel Nadolsky, Fredrick Olness

In the variable flavor number (VFN) factorization scheme [126, 127, 68, heavy quark flavors are actively included in the PDF evolution via gluon splitting to a heavy quark pair $g \rightarrow Q \bar{Q}$. While the heavy quark PDF $f_{Q}(x, \mu)$ is often taken to vanish below the mass threshold $\left(\mu<m_{Q}\right)$, there is the possibility that the proton contains non-vanishing heavy quark constituents even for scales below $m_{Q}$; this component of the heavy quark PDF is identified as the intrinsic parton distribution [56, [57, 128, 129], in contrast to the extrinsic distribution generated by gluon splitting $g \rightarrow Q \bar{Q}$.

While we can introduce intrinsic parton distributions for both charm and bottom quarks, we will focus here on the intrinsic charm (IC). Operationally, the total charm PDF is then composed as $f_{c}(x, \mu)=f_{c}^{e x t}(x, \mu)+f_{c}^{\text {int }}(x, \mu)$. For the extrinsic component, we generally take the boundary condition $f_{c}^{e x t}(x, \mu)=0$ for $\mu<m_{c}$, i.e., we do not need to assume an initial functional form for $f_{c}^{e x t}$, as it is determined purely by the gluon evolution.

Conversely, for the IC component $f_{c}^{\text {int }}$ we do need to assume a functional form. Here, we consider two typical shapes of $f_{c}^{i n t}$ at the initial scale $\mu=m_{c}$, assuming $m_{c}=1.3 \mathrm{GeV}$.

- In the BHPS model [56, 57, 130, the intrinsic charm is concentrated at large $x$.
- In sea-like models [129], the intrinsic charm is spread over all $x$ values.

Sample distributions of IC PDFs were obtained in a global QCD fit of hadronic data [129. We display them in Fig. [1.19] In these models, the momentum fraction carried by the charm can be varied in some range. Roughly, an intrinsic momentum fraction of $2 \%$ or $3 \%$ is at the outer limit of what is allowed in the context of a global fit.

Figure 1.19. Left, middle: charm PDFs for the BHPS model, at $\mu=2$ and 100 GeV . The upper dashed curve is for a momentum fraction of $2 \%$, and the lower for $0.57 \%$. The shaded band is the CTEQ6.5 PDF uncertainty. Right: charm PDFs for the sea-like model. The upper curve is for a momentum fraction of $2.4 \%$, and the lower for $1.1 \%$. Figs. are taken from [129.

For heavy quark production in the threshold region $\left(\mu \sim m_{Q}\right)$, the magnitude of the intrinsic component will be large on the relative scale compared to the extrinsic contribution. At higher $\mu$ scales, the DGLAP evolution will increase the extrinsic component via $g \rightarrow Q \bar{Q}$ splitting. However, the distinctive shape of the BHPS distribution, with its characteristic large- $x$ enhancement, remains clearly evident even at much higher scales $\mu \gg m_{c}$.

We now consider two different c.m.s. energies for an EIC [131] and investigate the degree to which one can distinguish the IC component based on measurements of the charm

Figure 1.20. Charm contribution to the reduced NC $e^{-} p$ DIS cross section at $\sqrt{s}=45$ and 105 GeV . For each IC model, curves for charm momentum fractions of $1 \%$ and $3.5 \%$ are shown. For comparison we display the number of events $d N_{e} / d x$ for $10 \mathrm{fb}^{-1}$, assuming perfect charm tagging efficiency.
contribution to the DIS cross section. Alternatively, the IC can be searched for by measuring the longitudinal structure function $F_{L}$ or angular distributions [132]. In Fig. 1.20 we display the reduced cross section $\sigma_{r, c}$ for semi-inclusive DIS charm production at an EIC. The reduced charm cross section is defined as in Eq. (1.6). The probed ranges of $y$ are displayed in the figures.

The number of events for a conservative integrated luminosity $\mathcal{L}=10 \mathrm{fb}^{-1}$ has been computed as $d N_{e} / d x=\mathcal{L}\left\langle d \sigma_{c} / d x\right\rangle$ where $\left\langle d \sigma_{c} / d x\right\rangle$ is the average cross section in a $Q$ bin of size 0.15 GeV , evaluated at NLO accuracy. The shaded band represents the error on the cross section induced by the CTEQ6.6 PDF uncertainty 43.

For both BHPS and sea-like IC, we observe that the cross sections significantly exceed the nominal CTEQ6.6 values. While a momentum fraction of $3.5 \%$ is easily distinguished, even the intrinsic charm models with $1 \%$ can be resolved with moderate integrated luminosities.

## Acknowledgments

We appreciate a discussion with J. Pumplin.

# 1.10 Status of helicity-dependent PDFs and open questions to be addressed at an EIC 

Rodolfo Sassot, Marco Stratmann

### 1.10.1 Introduction

Helicity-dependent or polarized PDFs (pPDFs) tell us precisely how much quarks and gluons with a given momentum fraction $x$ tend to have their spins aligned with the spin direction of a nucleon in a helicity eigenstate. Their knowledge is essential in the quest to answer one of the most basic and fundamental questions in hadronic physics, namely how the spin of a nucleon is composed of the spins and orbital angular momenta of its constituents.

The nucleon spin structure can be best understood in high-energy scattering experiments where quarks and gluons behave as almost free particles at scales $\mu>\Lambda_{Q C D}$. The relevance of pPDFs or research in spin physics in general is reflected in more than a dozen vigorous experimental programs in the wake of the unexpected finding that only very little of the proton spin is actually carried by its three valence quarks almost twenty-five years ago. The experiments have measured with increasing precision various observables sensitive to different combinations of quark and gluon polarizations in the nucleon. This progress was matched by advancements in corresponding theoretical higher order calculations in the framework of pQCD and phenomenological analyses of available data. Potentially large sea quark and/or gluon polarizations were initially thought to be ways to account for the "missing" proton spin, but at the same time, both turned out to be challenging to access experimentally.

The most comprehensive global fits include all available data taken in spin-dependent DIS, semi-inclusive DIS (SIDIS) with identified pions and kaons, and proton-proton collisions. They allow for extracting sets of pPDFs consistently at NLO accuracy along with estimates of their uncertainties [25, 26]. Contributions from the orbital angular momenta of quarks and gluons completely decouple from such type of experimental probes and need to be quantified by other means. Here, transverse momentum-dependent PDFs or generalized PDFs appear to be the most promising approaches which will be discussed elsewhere in Chapters 2 and 3, respectively.

Despite the impressive progress made in the past couple of years both experimentally and theoretically many fundamental questions related to the proton's helicity structure still remain unanswered and shall be summarized below; addressing them and providing answers is a prime target for an EIC.

Present fixed-target experiments suffer from their very limited kinematic coverage in $x$ and $Q^{2}$, which is insufficient to precisely study, for instance, QCD scaling violations for the polarized DIS structure function $g_{1}\left(x, Q^{2}\right)$ which in turn can be linked to the $x$ dependence of the polarized gluon density $\Delta g(x)$. There are numerous other opportunities for an EIC to further our understanding of the nucleon spin structure which will be listed below and discussed in some details in Secs. 1.11, 1.12, and 1.13,

### 1.10.2 Current status of global pPDF fits - baseline for EIC projections

Unlike unpolarized PDF fits, where a separation of different quark flavors is obtained from inclusive DIS data taken with neutrino beams, differences in polarized quark and

Figure 1.21. COMPASS results [133, 134 for SIDIS spin asymmetries on a deuteron (left) and proton target (right) compared to DSSV and DSSV + fits (see text).
antiquark densities are at present determined exclusively from SIDIS data and hence require knowledge of fragmentation functions. Recently published SIDIS data from the COMPASS collaboration [133, 134] extend the coverage in $x$ down to about $x \simeq 5 \times 10^{-3}$, almost an order of magnitude lower than the kinematic reach of the HERMES data used in the DSSV global analysis of 2008 [25, 26]. For the first time, the new results comprise measurements of identified pions and kaons in the final state taken with a longitudinally polarized proton target. Clearly, these data can have a significant impact on fits of pPDFs and estimates of their uncertainties.

In particular, the COMPASS kaon data will serve as an important check of the validity of the strangeness density obtained in the DSSV analysis, which instead of favoring a negative polarization as in most fits based exclusively on DIS data, prefers a vanishing or perhaps even slightly positive $\Delta s$ in the measured range of $x$. One reason for concern is the dependence on fragmentation functions. Even though pion fragmentation functions are rather well constrained [74] by data, kaon fragmentation functions suffer from much larger uncertainties, and this could explain the unexpected result for $\Delta s$ obtained in the DSSV analysis.

Figure 1.21 shows a comparison between the new SIDIS spin asymmetries from COMPASS [133, 134 and the DSSV fit of 2008 [25, 26]. Also shown is the result of re-analysis at NLO accuracy based on the updated data set. This fit, henceforth called "DSSV+", will serve as baseline pPDFs when quantifying the potential impact of projected EIC data on our knowledge of the nucleon spin structure in Sec. 1.11. The differences between the original and the updated fit are hard to notice for both identified pions and kaons. In terms of $\chi^{2}$ values, the original DSSV analysis amounts to 392 units for the original set of 467 data points used in the fit [74]. Adding both deuteron and proton data from COMPASS (88 points) it goes up to 456 and drops by about 4 units upon refitting (DSSV+), which is not really a significant improvement for a PDF analysis in view of non-Gaussian theoretical uncertainties. Recall that in the DSSV analysis a $\Delta \chi^{2} \simeq 9$ (corresponding to $\Delta \chi^{2} / \chi^{2}=2 \%$ ) was tolerated as a faithful, albeit conservative estimate of PDF uncertainties.

In Fig. 1.22 we compare the individual sea quark densities obtained in the original and

Figure 1.22. DSSV and DSSV + sea quark pPDFs and uncertainty bands at $Q^{2}=10 \mathrm{GeV}^{2}$. Also shown is $\Delta g$. The vertical lines indicate the $x$ region constrained by RHIC $p p$ data.
updated DSSV analyses. As can be seen, except for $\Delta s$, the new central fits fall well within the $\Delta \chi^{2}=1$ uncertainty bands of DSSV. The gluon distribution is hardly affected by the new SIDIS data. For DSSV+ we only give the new uncertainty bands (dashed lines) referring to the $\Delta \chi^{2} / \chi^{2}=2 \%$ tolerance criterion.

Although it may seem that the new SIDIS data have little impact on the fit, this is not the case if one studies individual $\chi^{2}$ profiles in more detail. Figure 1.23 shows the contributions to $\Delta \chi^{2}$ from various data sets against variations of the truncated first moments for $\Delta \bar{u}$ and $\Delta \bar{d}$ in the range $0.001 \leq x \leq 1$. Compared to the original DSSV fit one notices a trend towards smaller net polarization as the best fit values shift towards zero. This is induced by the new COMPASS SIDIS data. Both pions and kaons pull in the same direction and to a common smaller best fit value. There is, however, some mild tension with older SIDIS sets, but this is well within the tolerance of the fit and most likely caused by the different $x$ ranges covered by the different data sets. In addition, one finds a significant reduction in the uncertainties, as determined by the width of the $\chi^{2}$ profiles at a given $\Delta \chi^{2}$.

A much debated feature of the strangeness pPDF obtained in the DSSV fit is its unexpected small value at medium-to-large $x$ which, when combined with a node at intermediate $x$, still allows for acquiring a significant negative first moment at small $x$, in accordance with expectations from $\mathrm{SU}(3)$ symmetry (hyperon decay constants $F$ and $D$ ) and fits to DIS data only (see, e.g., Ref. [23]). To investigate the possibility of a node in $\Delta s(x)$ further we present in Fig. 1.24 the $\chi^{2}$ profiles for two different intervals in $x$ : $0.001 \leq x \leq 0.02$ and $0.02 \leq x \leq 1$. Again, the new COMPASS SIDIS data have quite some impact on the profiles but the central value for the combined range, $0.001 \leq x \leq 1$, does not shift from its original DSSV value.

The profiles in Fig. 1.24 clearly show that for $0.001 \leq x \leq 0.02$ the result for $\Delta s$ is a compromise between DIS and SIDIS data, the latter favoring much less negative values.

Figure 1.23. $\chi^{2}$ profiles for the first moments of $\Delta \bar{u}$ and $\Delta \bar{d}$ truncated to $0.001 \leq x \leq 1$.

Figure 1.24. $\chi^{2}$ profiles for the truncated first moment of $\Delta s$ in two different $x$ intervals.

For $0.02 \leq x \leq 1$ everything is determined by SIDIS data and all sets consistently ask for a small, slightly positive strange quark polarization. There is no hint of a tension with DIS data as they do not provide a useful constraint at medium-to-large $x$. We note that at low $x$, most SIDIS sets give indifferent results except the new COMPASS data which extend towards the smallest $x$ values so far and actually do show some preference for a slightly negative value for $\Delta s$. This exemplifies the need for measurements at small $x$. Clearly, all current extractions of $\Delta s$ from SIDIS data show a significant dependence on kaon FFs, see, e.g., Ref. [133, 134]. Better determinations of $D^{K}(z)$ are highly desirable, but should be possible with forthcoming data from $B$-factories, DIS multiplicities, and LHC data. We also notice that in the range $x \gtrsim 0.001$ the hyperon decay constants, the so-called $F$ and $D$ values, do not play a significant role in constraining $\Delta s$ as can be deduced from their relative contribution to $\Delta \chi^{2}$ in Fig. 1.24 . Computations of $\mathrm{SU}(3)$ breaking effects in axial current matrix elements [135, 136], and, more recently, also first lattice results for the first moment of $\Delta s+\Delta \bar{s}$ [137] point towards a sizable breaking of $\operatorname{SU}(3)$ symmetry. To study its validity of one needs to probe $\Delta s(x)$ at smaller values of $x$ at an EIC.

An interesting recent development is that the LSS group produced an update of their pPDF fit using for the first time DIS and SIDIS data simultaneously [28]. As in the DSSV analysis they also utilize DSS fragmentation functions [74]. Their functional form is also very similar to the one used in DSSV and DSSV+. As in their previous analyses they carefully include target mass corrections and phenomenological higher twist corrections for inclusive DIS data. Nevertheless, their obtained pPDFs are very similar to the best fit of DSSV shown in Fig. 1.22. Their strange quark polarization also changes sign as in DSSV but is overall slightly smaller in magnitude. LSS finds non negligible higher twist corrections to inclusive DIS data, however, these conclusions are not fully shared by another recent analysis of polarized DIS data [23]. Ref. [23] also provides an extraction of $\alpha_{s}$ from polarized DIS data. There are also interesting first attempts to perform a pPDF analysis based on neural networks [138, 139 similar to successful global fits of unpolarized data [47. This would provide independent estimates of pPDF uncertainties not biased by the choice of a particular functional form.

### 1.10.3 Open Questions

The status of pPDFs outlined above will likely not change much until the time of EIC operations. Most of the remaining, compelling open questions in spin physics related to pPDFs will be still with us and can be only addressed by extending the kinematic coverage to smaller values of $x$; see the items listed below.

Existing experiments, like PHENIX and STAR at RHIC, will continue to add data in the next couple of years. Parity-violating, single-spin asymmetries for $W$ boson production should reach a level where they help to constrain $\Delta u, \Delta \bar{u}, \Delta d$, and $\Delta \bar{d}$ at large $x$, $0.07 \leq x \leq 0.4$ at scales $Q \simeq M_{W}$ much larger than typically probed in SIDIS [140]. Measurements of double spin asymmetries for di-jets in $p p$ collisions at 500 GeV should improve the current constraints on $\Delta g(x)$ and extend them towards somewhat smaller values of $x$. The strangeness polarization is, however, very hard to access in polarized $p p$ collisions. In the future, JLab12 will add very precise DIS data at large $x$. They will allow us to challenge ideas like helicity retention [141, 142 which predict that $\Delta f(x) / f(x) \rightarrow 1$ as $x \rightarrow 1$. Currently, only $\Delta u / u$ exhibits this trend, while $\Delta d / d$ remains negative up to $x \simeq 0.6$.

We expect an EIC to make significant contributions on the following topics:
Polarized gluon density $\boldsymbol{\Delta g}(\mathbf{x})$ : precise data for the DIS structure function $F_{2}$ in a broad kinematic range in $x$ and $Q^{2}$ from HERA provide the world's best and theoretically cleanest constraint on the unpolarized gluon density; see Sec. 1.3. One of the most important results of HERA was to establish the strong rise of the gluon density at small $x$ which could not be anticipated from previous fixed-target results.

Figure 1.25 summarizes the current situation for polarized DIS. The kinematic coverage is limited to the fixed-target regime. There are no data below $x \simeq 0.005$, and the lever-arm in $Q^{2}$ is very limited, in particular, for the smallest $x$ values. As a consequence, $\Delta g(x)$ is basically unconstrained at small $x$ as is reflected in the large uncertainty band shown in Fig. 1.22. There are theoretical arguments that $\Delta g(x) \simeq x g(x)$ at small $x$ [141] but they cannot be verified experimentally due to the lack of data

The fact that current RHIC data favor a very small gluon density in $0.05 \lesssim x \lesssim 0.2$ [25], perhaps with a node, also greatly complicates the determination of the first moment, $\int_{0}^{1} \Delta g\left(x, Q^{2}\right) d x$, which enters in the fundamental proton spin sum rule in its light-cone gauge formulation [143, 144]. Since contributions to the moment largely cancel in the measured $x$ range, the unmeasured small $x$ region may contribute significantly even up to one unit of

Figure 1.25. Scaling violations for the structure function $x g_{1}^{p}$ in bins of $x$. Experimental data are compared to various fits at NLO accuracy. Figure taken from [23].
$\hbar$.
Precise measurements of the structure function $g_{1}\left(x, Q^{2}\right)$ in a wide kinematic range will be a flagship measurement for an EIC. The polarized gluon density is strongly correlated with QCD scaling violations, $d g_{1}\left(x, Q^{2}\right) / d \ln Q^{2} \simeq-\Delta g\left(x, Q^{2}\right)$, i.e., a large positive $\Delta g$ at small $x$ is expected to drive $g_{1}$ towards large negative values for $x \simeq 10^{-(3 \div 4)}$. A precise DIS measurement will also constrain the quark singlet density $\Delta \Sigma\left(x, Q^{2}\right)$ and its first moment, i.e., the total quark spin contribution to the proton spin, much better.

Complete flavor separation: given the significant impact present SIDIS data already have in global analyses of pPDFs, it is easy to imagine that an EIC with its extended kinematic coverage can turn SIDIS measurements into a precision tool for detailed studies of $\Delta u, \Delta \bar{u}, \Delta d, \Delta \bar{d}, \Delta s$, and $\Delta \bar{s}$. For instance, a precise determination of a possible asymmetry in the light quark sea, $\Delta \bar{u}(x)-\Delta \bar{d}(x)$ will challenge expectations from model calculations. Again, current QCD fits have revealed rather complicated functional forms with possible nodes for the quark densities which need to be studied more precisely.

Prerequisites are a detector with excellent particle ID in an as large as possible portion of phase space and an improved theoretical knowledge of FFs, in particular, for kaons. For the latter, significant progress will be made by the time the EIC turns on. In any case, there will be also plenty of opportunities to further constrain them at an EIC if necessary.

Novel electroweak probes in DIS: At large enough $Q^{2}$ and with the envisioned luminosities of up to $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ an EIC has the unique opportunity to access polarized electroweak structure functions via charged and neutral current DIS measurements. These novel probes depend on various combinations of polarized quark PDFs and provide an alternative way of separating different quark flavors for $x \gtrsim 10^{-2}$. Prerequisites are both electron and positron beams to fully exploit charged current (CC) DIS, i.e., the pPDF combinations probed in the exchange of $W^{-}$and $W^{+}$bosons. Also, one needs to be able
to reconstruct $x$ and $Q^{2}$ from the final state hadrons in the absence of a scattered lepton in CC DIS.

Strangeness polarization, $\Delta \mathrm{s}-\Delta \overline{\mathrm{s}}$, and $\mathrm{SU}(3)$ symmetry: As mentioned already, the surprisingly small strangeness density determined from SIDIS data has triggered a lot of discussions recently. It is certainly of outmost importance to precisely map $\Delta s(x)$ and $\Delta \bar{s}(x)$ down to sufficiently small values of $x$ to reliably determine their first moments. If $\mathrm{SU}(3)$ symmetry is approximately valid, one expects a significantly negative first moment for strangeness; if, on the other hand, $\mathrm{SU}(3)$ symmetry is badly broken at a $20 \div 30 \%$ level, $\Delta s(x)$ can remain small and perhaps even slightly positive down to small $x$. Ideas have been put forward that $\Delta s(x)$ and $\Delta \bar{s}(x)$ may have opposite polarizations which could explain the smallness of $\Delta s+\Delta \bar{s}$ in DIS but would result in a potentially sizable $\Delta s-\Delta \bar{s}$.

At an EIC there are different strategies to determine $\Delta s$ and $\Delta \bar{s}$. The most promising one is through SIDIS production of charged kaons. Once $K^{+}$and $K^{-}$yields are known with high precision and uncertainties for kaon FFs are well understood one can attempt an extraction of $\Delta s(x)$ and $\Delta \bar{s}(x)$ in a large range of $x$. Alternatively, one can study charm production in CC DIS with a polarized proton target. If one has electron and positron beams available, the yields of $D$ and $\bar{D}$ mesons should be related to $\Delta s(x)$ and $\Delta \bar{s}(x)$, respectively.

Heavy flavor contributions to $\mathrm{g}_{1}$ : for presently available data, any contribution from heavy quarks, i.e., charm and bottom, can be safely ignored. From HERA we know, however, that at sufficiently small values of $x$ and large enough $Q^{2}$, charm quarks can contribute as much as $20 \div 25 \%$ to a measurement of $F_{2}$. It is important to determine the charm contribution to $g_{1}$ at small $x$ experimentally and to properly include it in future global analyses. Since $g_{1}^{c}$ is mainly driven by photon-gluon-fusion it can be also a viable probe of $\Delta g$ in the small $x$ region.

Bjorken sum rule: the Bjorken sum rule is certainly one of the best known quantities in perturbative QCD. Corrections up to $\mathcal{O}\left(\alpha_{s}^{4}\right)$ have been calculated [32]. There is also a nontrivial connection to Adler's $D\left(Q^{2}\right)$ function defined in $e^{+} e^{-}$annihilation through the generalized Crewther relation [145, 32] involving the QCD $\beta$ function which incorporates the deviation from the limit of exact conformal invariance. It is certainly important and legitimate to ask to what level of precision an EIC can verify this fundamental sum rule.

Since the Bjorken sum rule relates the moments of the $g_{1}$ structure functions for protons and neutrons, it first of all requires an "effective neutron target" such as Helium-3. Perhaps the biggest challenge is then to develop a polarimeter to control its polarization with high accuracy. Most likely this will be the limited factor for a measurement of the Bjorken sum.

In addition, the sum rule involves the first moments of $g_{1}$, i.e., one has to worry about possible extrapolation uncertainties for $x \rightarrow 0$. However, since the Bjorken sum is a nonsinglet quantity, contributions from the small $x$ region should be under control up to a $1 \div 2 \%$ once a measurement down to $x \simeq 10^{-4}$ can be performed. At this level of accuracy one may also expect contributions to matter which break isospin symmetry.

### 1.11 Opportunities in spin physics at an EIC

Elke C. Aschenauer, Rodolfo Sassot, Marco Stratmann

Here, we demonstrate how an EIC can address the fundamental open questions concerning the proton's helicity structure raised in the previous Section. A detailed, quantitative discussion of novel electroweak effects in polarized DIS can be found in Secs. 1.12 and 1.13

### 1.11.1 Scaling violations in inclusive DIS and their impact on $\Delta \mathrm{g}(\mathrm{x})$

A precise determination of the polarized gluon distribution $\Delta g\left(x, Q^{2}\right)$ in a broad kinematic regime is a primary goal for the EIC. Current determinations of $\Delta g$ suffer from both a limited $x$ coverage and fairly large theoretical scale ambiguities in polarized $p p$ collisions for inclusive (di)jet [146, 147] and pion production [148, 149]. Several channels are sensitive to $\Delta g$ in $e p$ scattering at collider energies such as DIS jet [150, (151] or charm [152, 153, 154] production but QCD scaling violations in inclusive polarized DIS have been identified as the golden measurement.

The inclusive structure function $g_{1}\left(x, Q^{2}\right)$ is the most straightforward probe in spin physics and has been determined in various fixed-target experiments at medium-to-large values of $x$ in the last two decades. It is also the best understood quantity from a theoretical point of view. Unlike for most other processes, full NNLO corrections of the relevant hard scattering coefficient functions are available [15], and partial results for the polarized splitting functions at NNLO have been reported in [14] recently. A consistent framework up to NNLO accuracy will be in place by the time of first EIC operations and is required in order to limit the size of residual theoretical scale uncertainties to the anticipated unprecedented level of precision for a polarized DIS experiment. To achieve the latter, systematic uncertainties need to be controlled extremely well which imposes stringent requirements on the detector performance, acceptance, and the design of the interaction region. Necessary, on-going studies comprise the detection of scattered electrons down to small momenta of $\mathcal{O}(0.5 \mathrm{GeV})$ to access small $x$, the required resolution in momentum and angle of the scattered lepton, and the unfolding of QED radiative corrections, see Sec. 7.3,

For studying scaling violations $d g_{1}\left(x, Q^{2}\right) / d \log Q^{2}$ efficiently, it is not only essential to have good precision but also to cover the largest possible range in $Q^{2}$ for any given fixed value of $x$. The accessible range in $Q^{2}$ is again linked (via the inelasticity $y$ ) to the capabilities of detecting electrons in an as wide as possible range of momenta and scattering angles. For a detailed discussion of the kinematic coverage at the EIC see Sec. 7.3,

Figure 1.26 highlights the main motivation for a measurement of $g_{1}$ at the EIC. The significant uncertainty in $\Delta g\left(x, Q^{2}\right)$ at $x \lesssim 0.01$ shown in Fig. 1.22 translates into a large spread of predictions for the behavior of $g_{1}$ at small $x$. The spin-dependent scale evolution is such that $d g_{1}\left(x, Q^{2}\right) / d \log Q^{2}$ at low $x$ is strongly correlated with the negative of $\Delta g\left(x, Q^{2}\right)$, i.e., a positive gluon distribution drives $g_{1}$ at small $x$ to more and more negative values as $Q^{2}$ increases, and vice versa. Hence, a precision measurement of $g_{1}$ and its logarithmic scale dependence will determine $\Delta g\left(x, Q^{2}\right)$ at small $x$, hereby dramatically reducing the extrapolation uncertainties of the integral $\int_{0}^{1} \Delta g\left(x, Q^{2}\right) d x$ entering the proton spin sum rule. Depending on the shape of $\Delta g\left(x, Q^{2}\right)$ in the unmeasured region, it is currently still possible to accommodate up to one unit of $\pm \hbar$ at small $x$ [25, 26], i.e., twice the proton spin! Having determined the functional form of $\Delta g\left(x, Q^{2}\right)$ down to about $10^{-4}$, even extreme extrapolations to $x \rightarrow 0$ are not expected to contribute anymore significantly to the integral

Figure 1.26. Spread of predictions for $g_{1}(x)$ induced by the current uncertainty in $\Delta g(x)$.
$\int_{0}^{1} \Delta g\left(x, Q^{2}\right) d x$.
To quantify the impact of polarized DIS measurements on our knowledge of the gluon density we have performed a series of global QCD analyses based on realistic pseudo-data for various c.m.s. energies at a first stage of eRHIC: 5 GeV electrons on $50,100,250$, and 325 GeV protons. The simulations are based on the PEPSI Monte Carlo code [155] using the GRSV "std" set of polarised PDFs [24]. The statistical precision of the data sets for 100-325 GeV protons corresponds to about two months of running at the anticipated luminosities for eRHIC with an assumed operations efficiency of $50 \%$. For $5 \times 50 \mathrm{GeV}$ an integrated luminosity of $5 \mathrm{fb}^{-1}$ was assumed. Demanding a minimum $Q^{2}$ of $1 \mathrm{GeV}^{2}$, $W^{2}>10 \mathrm{GeV}^{2}$, the depolarization factor of the virtual photon to be $D(y)>0.1$, and $0.1 \leq y \leq 0.95$, the highest $\sqrt{s} \simeq 70 \div 80 \mathrm{GeV}$ allows one to access $x$ values down to about $2 \times 10^{-4}$. As can be seen from the kinematic plots in Sec. 7.3, the lever-arm in $Q^{2}$ more and more diminishes if smaller $x$ values are probed. For instance, choosing $Q_{\text {min }}^{2}=2 \mathrm{GeV}^{2}$ would limit the $x$ range to $x \gtrsim 4 \times 10^{-4}$ at the first stage of eRHIC. Clearly, one wants to utilize $Q^{2}$ values as low as possible in a QCD analysis but once actual EIC data become available one needs to systematically study how far down $Q_{\min }^{2}$ can be pushed before the pQCD framework breaks down. We plan to investigate the impact of the $Q_{\min }^{2}$ cut on constraining $\Delta g$ based on analyses with the pseudo-data. At small enough $x$ one may observe also deviations from standard DGLAP evolution as we will discuss briefly below. A full eRHIC with energies of up to 30 GeV electrons on 325 GeV protons is certainly desirable as it would cover the most interesting kinematic region around $x=10^{-4}$ at larger values of $Q^{2}$.

The l.h.s. of Fig. 1.27 shows the $x$ and $Q^{2}$ coverage for one of the simulated data sets for the spin asymmetry $A_{1}$. The statistical uncertainties are in general way too small to be visible. For the smallest $x$ and $Q^{2}$ values, the expected size of the asymmetries is of the order of a few times $10^{-3}$, which sets the scale for the required experimental precision. On the r.h.s. of Fig. 1.27 we show the $Q^{2}$ dependence of the structure function $g_{1}$ for various bins in $x$. As can be seen, combining the data sets for the different c.m.s. energies extends the coverage in $x$ and $Q^{2}$. We note that present fixed-target data, cf. Fig. 1.25, all fall in the lower right corner of the plot but have some overlap with the projected EIC data.

The pseudo-data for the spin asymmetry $A_{1}$ have been added to a global QCD fit of helicity-dependent PDFs based on the DSSV framework [25, [26]. We have used the projected uncertainties to randomize the pseudo-data by one sigma around their central

Figure 1.27. left: generated pseudo-data for $A_{1}$ in bins of $Q^{2}$ for $5 \times 250 \mathrm{GeV}$ collisions; right: $g_{1}$ as a function of $Q^{2}$ for fixed $x$ for 5 GeV electrons on three different proton energies.

Figure 1.28. $\chi^{2}$ profiles for the truncated $x$ integral of $\Delta g$ (l.h.s.) and uncertainty bands for $x \Delta g$ referring to $\Delta \chi^{2} / \chi^{2}=2 \%$ (r.h.s.) with and without including the generated EIC pseudo-data in the fit.
values determined by the DSSV set of PDFs. To demonstrate the impact of the generated EIC data on $\Delta g$, we show on the l.h.s. of Fig. 1.28 the $\chi^{2}$ profile for the first moment of $\Delta g$ truncated to the range $10^{-4} \leq x<1$ where EIC DIS data with $Q^{2}>1 \mathrm{GeV}^{2}$ can potentially constrain its value. As can be inferred from the plot, the fit based on all presently available DIS, SIDIS, and RHIC $p p$ data set (labeled as "DSSV+" and described in the previous Section) only very marginally constrains the integral. Adding in the projected data for
$5 \times 250 \mathrm{GeV}$, shown in Fig. 1.27, already greatly improves the $\chi^{2}$ profile. Including all four EIC data sets determines the integral very well; recall that the width of the profile determines the uncertainty for a given, tolerated increase $\Delta \chi^{2}$. To achieve such a level of accuracy, the data sets with the highest $\sqrt{s} \simeq 70 \div 80 \mathrm{GeV}$ are most critical in the fit as they probe the smallest $x$ values.

Even more impressive is the reduction of the ambiguities on the $x$ shape of $\Delta g\left(x, Q^{2}\right)$ shown on the r.h.s. of Fig. [1.28, The currently completely undetermined shape for $x \lesssim 0.01$ can be mapped precisely to an accuracy of about $\pm 10 \%$ (or better) for $\gtrsim 10^{-4}$. Below $\approx$ $2 \times 10^{-4}$ the shown $\Delta g\left(x, Q^{2}\right)$ and its uncertainties are not constrained by the projected EIC data and merely result from an extrapolation of the used functional form. We note that since one needs to control all sources of uncertainties extremely well it might be advantageous to measure and analyze polarized cross sections instead of spin asymmetries traditionally used so far. This should greatly simplify the theoretical analysis as one does not need any information on unpolarized PDFs or the ratio of $\sigma_{L} / \sigma_{T}$ anymore. There are also first, very interesting attempts to analyze polarized DIS data within the methodology of neural networks [138, 139], which provides a less biased way to estimate PDF uncertainties than standard approaches based on pre-defined functional forms.

As was mentioned above, one expects to find deviations from DGLAP evolution at sufficiently small values of $x$. In contrast to the unpolarized case, the dominant contribution of gluons mixes with quarks also at $x \ll 1$. From DGLAP evolution one expects for the small $x$ behavior of gluons and quarks

$$
\begin{equation*}
\Delta q\left(x, Q^{2}\right), \Delta g\left(x, Q^{2}\right) \simeq \exp \left[\text { const } \times \alpha_{s} \ln \left(Q^{2} / \mu^{2}\right) \ln (1 / x)\right]^{1 / 2} \tag{1.9}
\end{equation*}
$$

assuming for simplicity a fixed coupling $\alpha_{s}$. In [156, 157] it was demonstrated that this simple behavior can strongly underestimate the rise at small $x$ due to other potentially large double logarithmic contributions of the type $\alpha_{s} \ln ^{2}(1 / x)^{n}$ in the $n$-th order of $\alpha_{s}$ which are beyond the standard DGLAP framework. This gives rise to a power-like behavior of $g_{1}$ at small $x$ of the form $g_{1}\left(x, Q^{2}\right) \sim(1 / x)^{\mathcal{O}\left(\alpha_{s}\right)}$. There are qualitative arguments that in the polarized case the relevance of these logarithms in $1 / x$ is larger than the difference between DGLAP and BFKL evolution in the unpolarized case [156, 157]. However, more detailed quantitative studies are still lacking, and it remains to be seen if the kinematic reach of an EIC is large enough to actually observe deviations from DGLAP in polarized DIS. Clearly, any such estimate will strongly depend upon the initial input distributions, and eventually one needs data to clarify the relevance of small $x$ enhancements. Finally, we note that in Ref. [158] the leading small $x$ logarithms were combined with DGLAP evolution, and some effects of running coupling were addressed in [159].

### 1.11.2 Charm Contribution to $\mathrm{g}_{1}$

As discussed in Sec. 1.7 in the context of unpolarized DIS structure functions, the contributions from heavy flavors require a special theoretical framework. For the kinematic regime covered at the EIC it is expected that effects of the finite heavy quark mass play an important role and should not be neglected. This is, of course, particularly relevant not too far from threshold, i.e., for $Q^{2}$ less than a few times $m_{h}^{2}$.

For all presently available DIS data, the charm contribution to $g_{1}$ can be safely neglected and, hence, is usually not included in any of the QCD analyses except for the fit presented in Ref. [23]. The relevant coefficient functions for $\gamma^{*} g \rightarrow c \bar{c} X$ have been calculated only to LO accuracy [152] so far which is not sufficient for the anticipated experimental precision.

Figure 1.29. LO expectations for $g_{1}^{c}$ (l.h.s.) and $A_{1}^{c}$ (r.h.s) for the $Q^{2}=10 \mathrm{GeV}^{2}, m_{c}=1.35 \mathrm{GeV}$, and using the DSSV and GRSV "std" sets of PDFs. The shaded band corresponds to the $\Delta \chi^{2} / \chi^{2}=2 \%$ uncertainty estimate of DSSV.

The computation of the NLO corrections is, however, work in progress and results should become available for more detailed quantitative studies soon.

For spin dependent DIS the heavy quark contributions are expected to be smaller than in the helicity-averaged case but, of course, will very much depend on the currently unknown size of $\Delta g\left(x, Q^{2}\right)$ at small $x$. There is also an interesting constraint on the gluonic Wilson coefficient for heavy quark production, demanding a vanishing first moment when regulated dimensionally or with a quark mass [160, 161]. This leads to a non-trivial oscillating pattern for $g_{1}^{c}$ depending on the sign of $\Delta g$ which will look rather different in the case that $\Delta g$ itself changes sign within the $x$ range probed.

Figure 1.29 shows some expectations for the spin asymmetry $A_{1}^{c}$ for DIS charm production (r.h.s.) and the charm contribution to the structure function $g_{1}$ (l.h.s.) both computed at LO accuracy with two different polarized gluon distributions. For a small $\Delta g$ with a node, as in the best fit of DSSV, the charm contribution turns out to be at most at the percent level even at collider kinematics, and the corresponding spin asymmetry is most likely too small, $\mathcal{O}\left(\right.$ few $\left.\times 10^{-5}\right)$, to be measured directly. For a larger gluon distribution at small $x$, as in the GRSV fit, or for a gluon within the current uncertainty band of DSSV, asymmetries can be significantly larger, reaching $\mathcal{O}$ (few $\times 10^{-3}$ ), and at $x=10^{-3}$ and $Q^{2} \simeq 10 \mathrm{GeV}^{2}$ charm quarks can contribute about $10 \div 15 \%$ to the inclusive $g_{1}$. The experimental aspects for detecting charmed mesons have beed discussed already in Sec. 1.8 and apply also here.

### 1.11.3 Remark on the Bjorken sum rule

The Bjorken sum rule

$$
\begin{equation*}
\int_{0}^{1} d x\left[g_{1}^{p}\left(x, Q^{2}\right)-g_{1}^{n}\left(x, Q^{2}\right)\right]=\frac{1}{6} C_{B j}\left[\alpha_{s}\left(Q^{2}\right)\right] g_{A} \tag{1.10}
\end{equation*}
$$

is not only one of the most fundamental relations in QCD but presumably also one of the best known quantities in pQCD. Corrections up to $\mathcal{O}\left(\alpha_{s}^{4}\right)$ have been calculated [162, 31, 32]. Given the anticipated precision of DIS measurements at the EIC, it is natural to ask what can be achieved concerning the Bjorken sum. The major obstacle is, of course, the need for an effective, longitudinally polarized neutron beam. One conceivable option would be to run
with ${ }^{3} \mathrm{He}$ but developing a method to measure its polarization to the required percent level is certainly an extremely challenging $R \& D$ task requiring novel ideas. From the theoretical side it might be advantageous to analyze the data not in terms of PDFs but directly on the structure function level with the help of so called "physical anomalous dimensions" 163 . This reduces not only the number of parameters but also theoretical scale uncertainties.

Figure 1.30. The truncated ("running") $x$ integral for the non-singlet combination $\Delta q_{3}$ related to the Bjorken sum normalized to the full first moment for two values of $Q^{2}$.

From present fixed target experiments the sum rule is currently verified to about $10 \%$, which sets the target for any future measurement to the $1 \div 2$ percent level. One of the current limitations is the extrapolation uncertainty from the unmeasured small $x$ region. Since the Bjorken sum probes a non-singlet (NS) quark combination, the small $x$ uncertainties are considerably less severe than for $\Delta g\left(x, Q^{2}\right)$, but to reduce them to a level of about $2 \%$, measurements of $g_{1}^{p, n}$ down to $x \simeq 10^{-4}$ are required. This is illustrated in Fig. [1.30 where we show the "running" $x$ integral for the relevant NS quark combination $\Delta q_{3}$ normalized to its full first moment, assuming the functional form from the DSSV analysis. At the required $1 \div 2 \%$ level of accuracy one might start to see deviations from (1.10) due to isospin and charge symmetry violations. Very little is known about these effects, and, if experimentally feasible, measurements could reveal genuine new insights into the hadronic structure.

The fundamental relation (1.10) between a high-energy measurement of DIS structure functions and a low-energy quantity like the axial charge $g_{A}$ by itself warrants an experimental exploration at the EIC. From a more theoretical perspective one might argue that since $\mathcal{O}\left(\alpha_{s}^{4}\right)$ corrections are available, a precision measurement of the Bjorken sum can be turned into one of the most accurate determinations of $\alpha_{s}$. One can easily convince oneself, however, that this does not work out. Changing $\alpha_{s}$ by about one percent, translates only in a $0.1 \%$ change of the Bjorken sum, which is impossible to resolve experimentally. Perhaps more interesting is the non-trivial connection of the Bjorken sum rule to the Adler $D\left(Q^{2}\right)$ function which naturally appears, for instance, in the $e^{+} e^{-}$annihilation into hadrons [164]. These two, seemingly unrelated quantities are connected through the generalized Crewther relation [145, 32]. For large enough $Q^{2}$, the Adler function can be expanded as a power series in $\alpha_{s}$ like $C_{B j}\left[\alpha_{s}\left(Q^{2}\right)\right]$ in (1.10), and results are available up to $\mathcal{O}\left(\alpha_{s}^{4}\right)$ as well [165].

Figure 1.31. Projected spin asymmetries for pion and kaon production in SIDIS for beam energies of $5 \times 250 \mathrm{GeV}$ and various bins in $Q^{2}$.

The Crewther relation then states for the NS part of the $D$ function that

$$
\begin{equation*}
D\left[\alpha_{s}\left(Q^{2}\right)\right] C_{B j}\left[\alpha_{s}\left(Q^{2}\right)\right]=3\left[1+\frac{\pi \beta\left(\alpha_{s}\right)}{\alpha_{s}} K\left[\alpha_{s}\left(Q^{2}\right)\right]\right] \tag{1.11}
\end{equation*}
$$

where $\beta$ denotes the QCD beta function, and the first four terms in the expansion of $K\left[\alpha_{s}\left(Q^{2}\right)\right]$ are known. The term proportional to $\beta$ in (1.11) describes the deviation from the limit of exact conformal invariance of QCD [145, 166]. We also note that since the Bjorken sum rule can be measured down to small values of $Q^{2}$ it provides a way to define an effective strong coupling constant [167, 168] which is by construction gauge and scheme invariant and approaches the standard running of $\alpha_{s}$ in the perturbative domain.

### 1.11.4 Opportunities in semi-inclusive DIS

As has been mentioned in Sec. 1.10, the flavor separation of polarized PDFs in current fits is largely based on pion and kaon yields in SIDIS. An EIC can easily extend the existing kinematic coverage in the same way as for inclusive DIS. Prerequisites for exploiting SIDIS as a precision tool at the EIC, such as good particle identification and well constrained fragmentation functions, have been already discussed in Sec. 1.5 for the unpolarized case.

Figure 1.31 shows projected data for the longitudinal spin asymmetry in SIDIS with identified pions and kaons in the same $Q^{2}$ bins as used for inclusive DIS studies in Fig. 1.27, The simulation is based on the PEPSI Monte Carlo [155] using the GRSV "std" set of polarised PDFs [24]. The following cuts have been applied to model some detector and acceptance effects: $Q^{2}>1 \mathrm{GeV}^{2}, 0.1<y<0.95$, photon depolarization factor $D(y)>0.1$, $W^{2}>10 \mathrm{GeV}^{2}, 0.2<z<0.8, p_{H}>1.5 \mathrm{GeV}$, and $1^{\circ}<\theta_{H}<179^{\circ}$. The momentum cut on the detected hadron $H$ is placed to ensure to be above the PID Cherenkov threshold. The statistical precision reflects one month of running at the luminosities anticipated for
the first stage of eRHIC. Again, these measurements will be limited by systematic uncertainties, which have to be addressed in detail. In addition to the sources of systematic uncertainties present for inclusive DIS, the detector performance for the identification of different produced hadron species is most critical for SIDIS. Additional sets of data have been generated for other combinations of electron and proton beam energies. They are currently being implemented into the same global QCD analysis framework used to analyze the projected inclusive DIS data above. Plots similar to those for the $\chi^{2}$ profile of the truncated $x$ integral and the $x$ dependent uncertainty bands for $\Delta g\left(x, Q^{2}\right)$ in Fig. 1.28 will be prepared to quantify the impact of SIDIS data on our knowledge of helicity-dependent quark densities. We expect that all light quark and anti-quark flavors, i.e., $\Delta u, \Delta \bar{u}, \Delta d$, $\Delta \bar{d}, \Delta s$, and $\Delta \bar{s}$, can be determined with a precision close to the one obtained for $\Delta g\left(x, Q^{2}\right)$ in Fig. 1.28 ,

Although knowledge of individual quark and anti-quark flavors is in principle not required for an understanding of the proton spin sum rule, where only the total quark singlet $\Delta \Sigma$ enters, it would provide deeper insight into the question why the observed total quark polarization is considerably smaller than in naive quark models. Here, it is essential to understand in detail how sea quarks are polarized, i.e., whether they have a preference for spinning "against" the direction of the proton spin thereby diluting the total quark polarization. Current QCD fits [25, [26] start to reveal rather complicated patters of polarization at medium-to-large $x$ with possible sign changes but the statistical precision and kinematic reach of the fixed-target data is not sufficient for any definitive conclusions.

Figure 1.32. $x(\Delta \bar{u}-\Delta \bar{d})$ at $Q^{2}=10 \mathrm{GeV}^{2}$ along with the uncertainty bands from DSSV, results from earlier global fits, and predictions from the chiral quark soliton model [169, 170].

To give an example, Fig. 1.32 shows the current significance of a possible asymmetry in the light quark sea, $\Delta \bar{u}(x)-\Delta \bar{d}(x)$. Given the well-established pronounced difference between $\bar{u}$ and $d$ in the spin-averaged case, a precise determination of $\Delta \bar{u}(x)-\Delta d(x)$ is of of particular interest. Different patterns of symmetry breaking in the light anti-quark sea polarizations have been predicted qualitatively by a number of models of nucleon structure. For instance, within the large- $N_{c}$ limit of QCD as incorporated in the chiral quark soliton model [169, [170, [171, 172 ] one expects $|\Delta \bar{u}-\Delta \bar{d}|>|\bar{u}-\bar{d}|$. In addition, charged kaon data should help to clarify issues related to $\mathrm{SU}(3)$ symmetry and the polarized strangeness density $\Delta s\left(x, Q^{2}\right)$ by providing sufficient input to determine its first moment reliably.

### 1.12 Electroweak structure functions at the EIC

Abhay Deshpande, Krishna Kumar, Felix Ringer, Seamus Riordan, Swadhin Taneja, Werner Vogelsang

### 1.12.1 Motivation and Introduction

The use of charged leptons to probe the structure of nucleons through electroweak interactions has proven to be an invaluable tool in our exploration of the strong force. Experiments on deep inelastic scattering (DIS) $e p \rightarrow e X$, which dominantly proceeds via the exchange of a virtual photon between the electron and the nucleon, have established the existence of quarks and provided detailed studies of the short range aspects of the strong coupling.

It is well known that neutral current ( NC ) interactions can also be mediated by the $Z$-bosons of the weak interactions, and their interference with the photon. This gives rise to parity violating effects, which offer complementary access to nucleon structure. This has been a theme at parity violating electron scattering experiments, both at fixed target facilities [173, 3] and at HERA [174, 175]. For an unpolarized target, the NC parity violating asymmetry is given by

$$
\begin{equation*}
A_{\mathrm{beam}} \equiv \frac{\sigma_{R}-\sigma_{L}}{\sigma_{R}+\sigma_{L}} \tag{1.12}
\end{equation*}
$$

where $\sigma_{R}\left(\sigma_{L}\right)$ denotes the cross section for right- (left-) handed electrons. For fixed-target experiments, where the virtuality $Q$ of the exchanged boson is typically much smaller than the $Z$-boson mass $M_{Z}$, only $\gamma Z$-interference is relevant, and one obtains

$$
\begin{equation*}
A_{\text {beam }} \sim \frac{G_{F} M_{Z}^{2}}{2 \sqrt{2} \pi \alpha} \frac{Q^{2}}{Q^{2}+M_{Z}^{2}} \underset{Q^{2} \ll M_{Z}^{2}}{\simeq} 10^{-4} Q^{2}\left[\mathrm{GeV}^{2}\right], \tag{1.13}
\end{equation*}
$$

with the Fermi constant $G_{F}$ and the fine structure constant $\alpha$. At modern fixed target facilities, measured asymmetries were typically of the order of $10^{-4}$ or less [173]. At HERA, on the other hand, with its enormous kinematic reach in $Q^{2}$, also contributions by pure $Z$-exchange play a role [174].

Charged current (CC) interactions in DIS lepton scattering measurements have been performed at HERA in $e^{ \pm} p$ collisions [174] and at various neutrino scattering experiments [176]. They are inaccessible at fixed target charged lepton beam facilities where $Q^{2} \ll M_{W}^{2}$.

An EIC provides a number of advantages in the study of structure functions through electroweak interactions over previous and existing facilities. As the asymmetries and relative likelihood of $Z^{0}$ and $W^{ \pm}$exchange monotonically increase with $Q^{2}$, larger c.m.s. energies are more favorable for such measurements. Additionally, advances in accelerator and source technologies should provide luminosities on the order of $\sim 10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, two orders of magnitude higher than what was available at HERA. A new feature will be the ability for bunch-by-bunch variation of the sign of the longitudinal polarization of both the electron and hadron beams. A broader $Q^{2}$ and $y$ acceptance than at fixed target facilities, and variable beam energy, also allow for separation of the various structure functions. High precision is possible over a broad range in Bjorken- $x, 0.01 \lesssim x \lesssim 0.4$, whereas fixed target facilities typically are sensitive only to $x>0.1$.

## Polarized Hadrons

Arguably the most important feature at the EIC is the availability of polarized ${ }^{1} \mathrm{H}$, and potentially ${ }^{2} \mathrm{H}$ and ${ }^{3} \mathrm{He}$, beams with rapid polarization flips, which offers access to
electroweak spin structure functions that may provide additional constraints on polarized PDFs. The counterpart of $A_{\text {beam }}$ in (1.12) with polarized protons has never been measured before, and neither have spin asymmetries in CC interactions. Both would in principle be accessible at the EIC.

The theoretical study of electroweak spin-dependent structure functions dates back to the seventies [177, 178, 179, 180, 181, 182, 183, 184, 185]. Renewed interest arose in the nineties in the context of a possible polarized ep program at HERA [186, 187, 188, 189 , 190, 191, 192, 193, 194, 195, 196, 197, 198, and later in terms of studies for a neutrino factory [199. Parity-violating spin structure functions were shown to contain rich information on polarized PDFs. For example, as we shall discuss in more detail in the next section, for CC interactions via $W^{-}$exchange in the parton model, two structure functions $g_{1}^{W^{-}}$and $g_{5}^{W^{-}}$contribute to the spin asymmetry [196, 197]:

$$
\begin{equation*}
A^{W^{-}}=\frac{2 b g_{1}^{W^{-}}+a g_{5}^{W^{-}}}{a F_{1}^{W^{-}}+b F_{3}^{W^{-}}} \tag{1.14}
\end{equation*}
$$

where $a=2\left(y^{2}-2 y+2\right), b=y(2-y)$, and

$$
\begin{equation*}
g_{1}^{W^{-}}(x)=\Delta u(x)+\Delta \bar{d}(x)+\Delta c+\Delta \bar{s}(x), \quad g_{5}^{W^{-}}(x)=-\Delta u(x)+\Delta \bar{d}(x)-\Delta c+\Delta \bar{s}(x) . \tag{1.15}
\end{equation*}
$$

In Eq. (1.14), $F_{1}^{W^{-}}$and $F_{3}^{W^{-}}$are the corresponding unpolarized CC structure functions. Extraction of $g_{1}^{W^{-}}$and $g_{5}^{W^{-}}$hence offers new and independent constraints on the quark and anti-quark helicity distributions, with $g_{1}^{W^{-}}$measuring singlet contributions, while $g_{5}^{W^{-}}$is a flavor non-singlet. If additionally positrons and polarized neutrons are available, which is possible at the EIC, one could obtain a full flavor decomposition of the nucleon polarized quark and anti-quark sector. For instance, for proton scattering $g_{1}^{W^{-}}+g_{1}^{W^{+}}$provides the full quark singlet distribution $\Delta \Sigma$, whose first moment gives the quark and anti-quark spin contribution to the proton's spin. Likewise, $g_{5}^{W^{-}}+g_{5}^{W^{+}}$determines the "valence" distributions $\Delta q-\Delta \bar{q}$. Adding neutrons, one has, for example, $g_{5, p}^{W^{+}, p}-g_{5, n}^{W^{+}, n}=\Delta u+$ $\Delta \bar{u}-(\Delta d+\Delta \bar{d})$, which satisfies a sum rule equally fundamental as the Bjorken sum rule:

$$
\begin{equation*}
\int_{0}^{1} d x\left[g_{5}^{W^{+}, p}-g_{5}^{W^{+}, n}\right]=\left(1-\frac{2 \alpha_{s}}{3 \pi}\right) g_{A} \tag{1.16}
\end{equation*}
$$

where we have included the first-order QCD correction [193]. NC structure functions offer independent insights into nucleon structure. For example, for the $\gamma-Z$ interference contribution, the structure function $g_{1}$ becomes to good approximation $g_{1}^{\gamma Z} \propto \Delta u+\Delta \bar{u}+\Delta d+$ $\Delta \bar{d}+\Delta s+\Delta \bar{s}$ and thus again probes the full quark and anti-quark singlet. The structure function $g_{5}$, on the other hand, probes the valence densities: $g_{5}^{\gamma Z} \propto 2 \Delta u_{v}+\Delta d_{v}$.

We present a few first studies of the prospects for measurements of electroweak spin structure functions in CC and NC scattering at an EIC. These are not meant to present an exhaustive assessment of all the opportunities the EIC would provide in this area.

### 1.12.2 Electroweak Deep Inelastic Scattering

## Structure Functions and Parton Model Expressions

In the determination of cross sections and asymmetries, we follow closely the PDG review 3]. The spin-averaged DIS cross section for $Q^{2} \gg M^{2}$, where $M$ is the mass of the nucleon, is
given by

$$
\begin{equation*}
\frac{d^{2} \sigma^{i}}{d x d y}=\frac{2 \pi \alpha^{2}}{x y Q^{2}} \eta^{i}\left[Y_{+} F_{2}^{i} \mp Y_{-} x F_{3}^{i}-y^{2} F_{L}^{i}\right] \tag{1.17}
\end{equation*}
$$

where $i$ is for NC or CC and $Y_{ \pm}=1 \pm(1-y)^{2}$. We have introduced the longitudinal structure function $F_{L}^{i}=F_{2}^{i}-2 x F_{1}^{i}$, which vanishes to lowest order according to the CallanGross relation. The NC structure functions for $e^{ \pm} N$ scattering can be represented as the sums of the photon, $Z^{0}$, and interference contributions:

$$
\begin{equation*}
F_{2}^{\mathrm{NC}}=F_{2}^{\gamma}-\left(g_{V}^{e} \pm \lambda g_{A}^{e}\right) \eta_{\gamma Z} F_{2}^{\gamma Z}+\left(g_{V}^{e}{ }^{2}+g_{A}^{e}{ }^{2} \pm 2 \lambda g_{V}^{e} g_{A}^{e}\right) \eta_{Z} F_{2}^{Z} \tag{1.18}
\end{equation*}
$$

and

$$
\begin{equation*}
x F_{3}^{\mathrm{NC}}=-\left(g_{A}^{e} \pm \lambda g_{V}^{e}\right) \eta_{\gamma Z} x F_{3}^{\gamma Z}+\left[2 g_{V}^{e} g_{A}^{e} \pm \lambda\left(g_{V}^{e}{ }^{2}+g_{A}^{e} 2\right)\right] \eta_{Z} x F_{3}^{Z} . \tag{1.19}
\end{equation*}
$$

Here and above, the sign $\pm$ is commensurate to the lepton charge. We have

$$
\begin{equation*}
\eta_{\gamma}=1 ; \quad \eta_{\gamma Z}=\left(\frac{G_{F} M_{Z}^{2}}{2 \sqrt{2} \pi \alpha}\right)\left(\frac{Q^{2}}{Q^{2}+M_{Z}^{2}}\right) ; \quad \eta_{Z}=\eta_{\gamma Z}^{2} \tag{1.20}
\end{equation*}
$$

and $g_{V}^{e}=-\frac{1}{2}+2 \sin ^{2} \theta_{W}, g_{A}^{e}=-\frac{1}{2} . \lambda= \pm 1$ is the electron/positron helicity.
The spin-averaged structure functions can be written as

$$
\begin{align*}
& {\left[F_{2}^{\gamma}, F_{2}^{\gamma Z}, F_{2}^{Z}\right]=x \sum_{q}\left[e_{q}^{2}, 2 e_{q} g_{V}^{q}, g_{V}^{q} 2+g_{A}^{q} 2\right](q+\bar{q}),} \\
& {\left[F_{3}^{\gamma}, F_{3}^{\gamma Z}, F_{3}^{Z}\right]=\sum_{q}\left[0,2 e_{q} g_{A}^{q}, 2 g_{V}^{q} g_{A}^{q}\right](q-\bar{q}),} \tag{1.21}
\end{align*}
$$

where $e_{q}$ is the fractional electric charge of the quark, $g_{V}^{q}= \pm \frac{1}{2}-2 e_{q} \sin ^{2} \theta_{W}$, and $g_{A}^{q}= \pm \frac{1}{2}$, with the + sign for up-type quarks and the - sign for down-type quarks.

For $Q^{2} \ll M_{Z}^{2}$, the pure $Z$ contribution can be neglected, and one finds in this limit

$$
\begin{equation*}
A_{\text {beam }}=\frac{G_{F} Q^{2}}{2 \sqrt{2} \pi \alpha}\left[g_{A}^{e} \frac{F_{1}^{\gamma Z}}{F_{1}^{\gamma}}+g_{V}^{e} \frac{Y_{-}}{2 Y_{+}} \frac{F_{3}^{\gamma Z}}{F_{1}^{\gamma}}\right] \tag{1.22}
\end{equation*}
$$

For the case of a polarized target, there are similar spin dependent structure functions. The difference $\Delta \sigma$ of cross sections for the two nucleon helicity states is

$$
\begin{equation*}
\frac{d^{2} \Delta \sigma^{i}}{d x d y}=\frac{8 \pi \alpha^{2}}{x y Q^{2}} \eta^{i}\left[Y_{+} x g_{5}^{i} \pm Y_{-} x g_{1}^{i}-y^{2} g_{L}^{i}\right], \tag{1.23}
\end{equation*}
$$

where again $i$ is for NC or CC and where $g_{L}^{i}=g_{4}^{i}-2 x g_{5}^{i}$. We note that, like $F_{L}$, the latter quantity vanishes to $\mathcal{O}\left(\alpha_{s}^{0}\right)$ [178]. The NC spin dependent structure functions are

$$
\begin{align*}
g_{5}^{\mathrm{NC}} & =-\left(g_{V}^{e} \pm \lambda g_{A}^{e}\right) \eta_{\gamma Z} g_{5}^{\gamma Z}+\left(g_{V}^{e}{ }^{2}+g_{A}^{e}{ }^{2} \pm 2 \lambda g_{V}^{e} g_{A}^{e}\right) \eta_{Z} g_{5}^{Z} \\
g_{1}^{\mathrm{NC}} & =\lambda g_{1}^{\gamma}-\left(g_{A}^{e} \pm \lambda g_{V}^{e}\right) \eta_{\gamma Z} g_{1}^{\gamma Z}+\left(2 g_{V}^{e} g_{A}^{e} \pm \lambda\left(g_{V}^{e}{ }^{2}+g_{A}^{e} 2\right)\right) \eta_{Z} g_{1}^{Z} \tag{1.24}
\end{align*}
$$

Their components can be written as

$$
\begin{align*}
& {\left[g_{1}^{\gamma}, g_{1}^{\gamma Z}, g_{1}^{Z}\right]=\frac{1}{2} \sum_{q}\left[e_{q}^{2}, 2 e_{q} g_{V}^{q}, g_{V}^{q}{ }^{2}+g_{A}^{q}{ }^{2}\right](\Delta q+\Delta \bar{q}),} \\
& {\left[g_{5}^{\gamma}, g_{5}^{\gamma Z}, g_{5}^{Z}\right]=\sum_{q}\left[0, e_{q} g_{A}^{q}, g_{V}^{q} g_{A}^{q}\right](\Delta q-\Delta \bar{q}) .} \tag{1.25}
\end{align*}
$$

The spin asymmetry for scattering an unpolarized lepton off a polarized nucleon is then given by

$$
\begin{equation*}
A_{\mathrm{L}}=\eta^{\gamma Z}\left[g_{V}^{e} \frac{g_{5}^{\gamma Z}}{F_{1}^{\gamma}} \mp \frac{Y_{-}}{Y_{+}} g_{A}^{e} \frac{g_{1}^{\gamma Z}}{F_{1}^{\gamma}}\right] \tag{1.26}
\end{equation*}
$$

In the CC case, we have

$$
\begin{equation*}
\eta_{\mathrm{CC}}=(1 \pm \lambda)^{2} \eta_{W}=\frac{(1 \pm \lambda)^{2}}{2}\left(\frac{G_{F} M_{W}}{4 \pi \alpha} \frac{Q^{2}}{Q^{2}+M_{W}^{2}}\right)^{2} \tag{1.27}
\end{equation*}
$$

For $W^{-}$exchange (electron scattering), the structure functions (assuming four active flavors) are in the parton model:

$$
\begin{align*}
F_{2}^{W-}=2 x(u+\bar{d}+\bar{s}+c), & F_{3}^{W-}=2(u+\bar{d}+\bar{s}+c), \\
g_{1}^{W-}=\Delta u+\Delta \bar{d}+\Delta \bar{s}+\Delta c, & g_{5}^{W-}=-\Delta u+\Delta \bar{d}+\Delta \bar{s}-\Delta c . \tag{1.28}
\end{align*}
$$

For $W^{+}$exchange, one replaces $u \leftrightarrow d$ and $s \leftrightarrow c$. The spin asymmetries for electron and positron scattering then take the simple parton model forms

$$
\begin{equation*}
A_{W^{-}}=\frac{\Delta u+\Delta c-(1-y)^{2}(\Delta \bar{d}+\Delta \bar{s})}{u+c+(1-y)^{2}(\bar{d}+\bar{s})}, \quad A_{W^{+}}=\frac{(1-y)^{2}(\Delta d+\Delta s)-\Delta \bar{u}-\Delta \bar{c}}{(1-y)^{2}(d+s)+\bar{u}+\bar{c}} . \tag{1.29}
\end{equation*}
$$

By measuring over a range in $y$, one can perform a separation of the $\Delta u+\Delta c, \Delta d+\Delta s$ quark or anti-quark combinations.

## Next-to-leading Order QCD Corrections

The NLO QCD corrections to the spin-dependent structure functions have been computed in Refs. [192, 193. To NLO, the expression for a given structure function can be cast into the generic form [199]

$$
\begin{align*}
& g_{1}^{\mathrm{NLO}}\left(x, Q^{2}\right)=\Delta C_{q, 1} \otimes g_{1}^{\mathrm{LO}}+f_{\Sigma} \Delta C_{g} \otimes \Delta g \\
& \frac{g_{4}^{\mathrm{NLO}}\left(x, Q^{2}\right)}{2 x}=\Delta C_{q, 4} \otimes\left[\frac{g_{4}^{\mathrm{LO}}}{2 x}\right], \\
& g_{5}^{\mathrm{NLO}}\left(x, Q^{2}\right)=\Delta C_{q, 5} \otimes g_{5}^{\mathrm{LO}} \tag{1.30}
\end{align*}
$$

where the symbol $\otimes$ denotes a convolution, and $g_{i}^{\mathrm{LO}}$ is the LO (parton model) expression for the respective structure function. The coefficient functions to NLO in the MS scheme can be found in [192, 193]. The factor $f_{\Sigma}$ in Eq. (1.30) is the sum over the coefficient of each quark or anti-quark distribution in the LO expression for $g_{1}$. For example, for the electromagnetic $g_{1}^{\gamma}$ with four flavors, $f_{\Sigma}=10 / 9$, while for $g_{1}^{W^{-}}$one has $f_{\Sigma}=4$. Needless to say that when including the NLO corrections in the calculation of the structure functions, one also has to perform the evolution of the polarized PDFs to NLO [12, 200, 13]. For the most part of our study, we will only use the LO expressions for the structure functions, which are expected to be entirely sufficient for estimating the sensitivities at an EIC. We will, however, briefly investigate the typical size of the NLO corrections in Figs. 1.36 and 1.40 below.

Figure 1.33. Total NC and CC cross sections for $Q^{2}>1 \mathrm{GeV}^{2}$ as functions of the $e p \sqrt{s}$.

### 1.12.3 Measurements of Parton Distribution Functions

In the following, we will present estimates for rates and spin asymmetries for electroweak DIS at an EIC. For the spin-averaged case, we use the CTEQ6.5 [201] unpolarized PDFs. For the helicity PDFs we use the ones of [25]. We note that the latter do not contain a charm quark distribution.

## Basic kinematics and machine considerations

Proposed EIC parameters allow for electron energies of $5-30 \mathrm{GeV}$ and ion energies of $50-325 \mathrm{GeV}$. Figure 1.33 shows the spin-averaged NC and CC total cross sections for electron and positron scattering, as functions of the $e p$ c.m.s. energy $\sqrt{s}$. We have integrated over all $Q^{2}>1 \mathrm{GeV}^{2}$, based on a simple theoretical LO calculation. One can see that the cross section of course rises with energy, but relatively mildly so. Therefore, measurements of electroweak structure functions may well be feasible in collisions at energies significantly lower than those at HERA.

The upper two plots in Figure 1.34 show distributions of the CC cross section in $\log \left(Q^{2}\right)$ and $\log (x)$, respectively, at three different c.m.s. energies. One can see that the largest statistical weight would be at $x \sim 0.1$ and $Q^{2} \sim 1000 \mathrm{GeV}^{2}$, which is a consequence of the $W$-propagator factor in Eq. (1.27). Binning in $x$ and $Q^{2}$ of course allows to investigate more detailed distributions, see below. For NC interactions, the $\gamma$-exchange contribution dominates the spin-averaged cross section and strongly pushes the $Q^{2}$ distribution towards $Q^{2} \rightarrow 0$ (see center row of the figure). Taking the parity-violating electron beam-helicity difference of cross sections, however, essentially singles out the $\gamma Z$-interference contribution. For this piece, which of course is much smaller than the full spin-averaged cross section, the $Q^{2}$ distribution levels off towards $Q^{2} \rightarrow 0$, as follows from the expressions in Sec. 1.12 .2

Figure 1.34. Top row: Distributions of the CC spin-averaged cross section in $Q^{2}$ (left) and $x$ (right). We have applied the cuts $Q^{2} \geq 1 \mathrm{GeV}^{2}$ and $0.1 \leq y \leq 0.9$. Center row: same for the NC case. Bottom row: Same for the NC parity-violating electron beam-helicity difference of cross sections.

Figure 1.35. Left: Total number of CC events for $20 \times 250 e^{-} p$ scattering for an integrated luminosity of $10 \mathrm{fb}^{-1}$. Right: Binned NC event rate as function of the electron scattering angle, for $20 \times 325$ $e^{-} p$ collisions at $\mathcal{L}=1 \times 10^{33} / \mathrm{s} / \mathrm{cm}^{2}$.
and as shown in the bottom row of Fig. 1.34
In CC electron scattering, $e^{-} p \rightarrow \nu_{e} X$, the neutrino remains undetected. To identify a CC event and to reconstruct $x$ and $Q^{2}$, the final-state hadrons must then be reconstructed instead. The detectors must hence be optimized to detect resulting hadronic jet formation. There will likely be some additional detection and reconstruction efficiency associated with this type of analysis. The discussion of the specific requirements is beyond the scope of this study, and we will assume that this reconstruction is possible. In practice, CC measurements could be performed simultaneously with the NC ones, though at a reduced duty factor if the electron helicity is flipped, as the interaction is purely $V-A$. We also assume that polarized positron beams would be available at an EIC.

For the following analysis, we will consider configurations of $E_{e}[\mathrm{GeV}] \times E_{\mathrm{ion}}[\mathrm{GeV}]$ with $20 \times 325$ and $20 \times 250$. For each of these, a luminosity of about $\sim 1 \times 10^{34} / \mathrm{s} / \mathrm{cm}^{2}$ was considered, with estimates for machine availabilities, detector acceptance and efficiency, and beam polarization. Based on an expected five year run time, we consider a realistic effective integrated luminosity of $100 \mathrm{fb}^{-1}$ for NC processes and $10 \mathrm{fb}^{-1}$ for CC. For the studies below, a Monte Carlo simulation framework was developed to evaluate rates and asymmetries of both the NC and CC processes. No detector responses have yet been included, and a full azimuthal acceptance was assumed. In all analyses we consider a minimum scattered electron energy of 2 GeV within $3^{\circ}<\theta<177^{\circ}$ scattering angle. The smaller integrated luminosity for CC studies is because of a factor of 2 loss due to helicity flips and also because efficiency of hadron jet and kinematic reconstruction has not yet been studied.

Of practical importance is to evaluate how well a separation of the structure functions can be done at individual points in $x$, though it remains for a future Monte Carlo study to evaluate the $x$ resolution after reconstruction. We bin all data in $20 x$ bins logarithmically spaced from $10^{-5}$ to 1 . When binned in $Q^{2}$, we use 20 bins from 2 to $5 \times 10^{4} \mathrm{GeV}^{2}$. These $Q^{2}$ bins were also used in determining any $y$ dependence. Figure 1.35 (left) shows the total number of events expected for CC interactions in $e^{-} p$ scattering at $\sqrt{s}=141 \mathrm{GeV}$ and $\mathcal{L}=10 \mathrm{fb}^{-1}$, binned in $x$.

Typical rates in NC scattering are up to 1 kHz , as shown in the right part of Fig. 1.35 for $\sqrt{s}=161 \mathrm{GeV}$. The highest rate occurs in the forward direction of the electron beam. Here, pipeline electronics will likely be necessary in order to avoid significant deadtime effects.

Figure 1.36. CC spin dependent structure functions $g_{1}^{W^{-}}, g_{5}^{W^{-}}$, and $g_{4}^{W^{-}} / 2 x$, at $Q^{2}=100 \mathrm{GeV}^{2}$. The dashed lines show the LO results (the one for $g_{4}^{W^{-}} / 2 x$ is not shown in this case, since it coincides with that for $g_{5}^{W^{-}}$), while the solid curves are NLO. For comparison, we also show the electromagnetic $g_{1}^{\gamma}$.

## Polarized Parton Distributions from CC Interactions

As follows from Eq. (1.29), CC processes in electron scattering off polarized targets offer a unique method to extract combinations of $\Delta u+\Delta c$ and $\Delta \bar{d}+\Delta \bar{s}$. With positron beams, one could also extract $\Delta d+\Delta s$ and $\Delta \bar{u}+\Delta \bar{c}$. For the present analysis, we have assumed a $100 \%$ polarized electron/positron source. As mentioned before, we have assumed only $10 \mathrm{fb}^{-1}$ integrated luminosity, making our estimates somewhat conservative.

In Fig. 1.36 we show the spin structure functions $g_{1}^{W^{-}}, g_{5}^{W^{-}}$, and $g_{4}^{W^{-}} / 2 x$, at $Q^{2}=$ $100 \mathrm{GeV}^{2}$, using the PDFs of [25]. Results are shown both at LO (dashed) and at NLO (solid). One observes that the NLO corrections are well under control. To guide the eye, also the ordinary electromagnetic structure function $g_{1}^{\gamma}$ is shown. Figure 1.37(left) displays the asymmetry $A_{W^{-}}$for CC $e^{-} \vec{p}$ scattering, as function of $x$. Different data points at same $x$ correspond to different bins in $Q^{2}$. As mentioned above, we have chosen here 20 bins in $Q^{2}$, spaced logarithmically from $2 \mathrm{GeV}^{2}$ to $5000 \mathrm{GeV}^{2}$. The lower asymmetries correspond to the lower bins in $Q^{2}$. Thanks to the simple structure of the LO expressions for the cross sections, the asymmetries in CC interactions become very large in the valence region, much larger than those in the NC case to be discussed below. On the other hand, as we saw in Figs. 1.34 and 1.35, event rates are much more suppressed at lower $Q^{2}$ and therefore $x$. The right part of Fig. 1.37 gives the resulting values for the relative uncertainty $\delta A_{W^{-}} / A_{W^{-}}$ of the asymmetry. Here we have summed over all $Q^{2}$ bins. The results shown look very promising, with better than $10 \%$ measurements appearing feasible all the way down to $x \sim 10^{-2}$. It is worth keeping in mind that relative polarimetry uncertainties at an EIC are also expected to be at the $0.5-1 \%$ level for electrons and $2-3 \%$ level for hadrons, so that these might become the dominant sources of uncertainty in the regions where the statistical $\delta A_{W^{-}} / A_{W^{-}}$is very small, especially at high $x$.

Using Eq. (1.29), the asymmetries give direct access to the polarized quark and antiquark distributions. As we discussed, higher-order QCD corrections (and also Cabibbosuppressed contributions) will somewhat modify the expressions in Eq. (1.29). However, for a first estimate use of Eq. (1.29) as a means to gauge the sensitivity to the distributions

Figure 1.37. Left: spin asymmetry for $\mathrm{CC} e^{-} \vec{p}$ scattering, as function of $x$ for various bins in $Q^{2}$. Right: resulting relative uncertainties of the asymmetry.
is justified. The additional contributions will not make a qualitative difference and can be systematically included in future studies. If furthermore full knowledge of the unpolarized parton distributions is assumed, then extraction of the sums of the two up-type quarks and down-type anti-quarks can be performed by a linear fit in $(1-y)^{2}$. The results of such fits are shown for electron and positron running in Figs. 1.38 and 1.39, respectively. We note that if a polarized deuterium or ${ }^{3} \mathrm{He}$ beam were available, additional opportunities would arise; $e^{-} \vec{n}$ scattering would probe the combinations $\Delta u+\Delta d+2 \Delta c$ and $\Delta \bar{d}+\Delta \bar{u}+2 \Delta \bar{s}$. At larger $x$ where the sea quarks are suppressed relative to the valence quarks, $e^{-} \vec{p}$ and $e^{-} \vec{n}$ scattering could be used to separate the valence polarizations.

## Structure Functions and Polarized PDFs from NC Interactions

Again we first show the spin-dependent structure functions; see Figure 1.40. As the contributions from pure $Z$-exchange are small, we only consider the electromagnetic $g_{1}^{\gamma}$, and the $\gamma-Z$ interference contributions $g_{1}^{\gamma Z}$ and $g_{4,5}^{\gamma Z}$, whose expressions were given in Eq. (1.25).

The left part of Fig. 1.41 shows the parity-violating spin asymmetry in Eq. (1.22), obtained for a polarized lepton beam scattering off an unpolarized proton beam, as function of $x$ in various different $Q^{2}$ bins. The lower (upper) asymmetries correspond to $Q^{2} \sim 2 \mathrm{GeV}^{2}$ $\left(Q^{2} \sim 4000 \mathrm{GeV}^{2}\right)$. As one can see, typical asymmetries range from $10^{-4}$ to 0.1 . The right part of the figure gives the resulting values for the relative uncertainty $\delta A_{\text {beam }} / A_{\text {beam }}$ of the asymmetry. Here we have summed over all $Q^{2}$ bins and assumed an integrated luminosity of $\mathcal{L}=100 \mathrm{fb}^{-1}$. The relative uncertainty is found to be near $2 \%$ over a relatively wide range in $x$; the relative electron polarization uncertainty achievable with modern polarimetry techniques should be better than this.

According to Eq. (1.22), measurement of the asymmetry $A_{\text {beam }}$ gives access to $F_{1}^{\gamma Z}$ and $F_{3}^{\gamma Z}$. Figure 1.42 presents the expected relative uncertainties for these structure functions, corresponding to the results shown in Fig. 1.41. Figure 1.43 shows the corresponding result for the case of $\vec{e}^{-} D$ scattering, for the structure function $F_{1}^{\gamma Z}$. Due to the suppression by the electron vector coupling, the uncertainty of $F_{3}^{\gamma Z}$ is about an order of magnitude worse than that of $F_{1}^{\gamma Z}$. The sensitivity is maximized in the region of $x \sim 0.01-0.4$. The approved PVDIS experiment using the SoLID spectrometer in Hall A at Jefferson Lab [202] anticipates achieving an extraction of $A_{\text {beam }}$ with relative accuracy $\approx 0.5-1 \%$ over several bins in $x$ in the range of $0.2 \leq x \leq 0.7$, both from proton and deuterium targets. The

Figure 1.44. Same as Fig. 1.41, but for unpolarized electrons on polarized protons.
products of the quarks' electric charges and their vector charges are approximately equal for up-type and down-type quarks, $e_{u} g_{V}^{u} \approx e_{d} g_{V}^{d} \approx 0.1$. Therefore, one has from Eq. (1.21) that $F_{1}^{\gamma Z} \propto u+\bar{u}+d+\bar{d}+s+\bar{s}$, both for proton and deuterium. On the other hand, for the corresponding products of the charges and axial charges one finds $e_{u} g_{A}^{u} \approx 2 e_{d} g_{A}^{d}$, and hence in the valence region $F_{3}^{\gamma Z} \propto 2 u_{v}+d_{v}$ for protons and $\propto u_{v}+d_{v}$ for deuterium. While $F_{3}^{\gamma Z}$ could thus give a clean separation of the $u$ and $d$ valence distributions, its contribution to the beam asymmetry is unfortunately suppressed.

Of significant interest are measurements of $g_{1}^{\gamma Z}$ and $g_{5}^{\gamma Z}$, which contain complementary information on the polarized PDFs. Similarly to what we discussed for the case of $F_{1}^{\gamma Z}$, one finds that to a good approximation $g_{1}^{\gamma Z} \propto \Delta u+\Delta \bar{u}+\Delta d+\Delta \bar{d}+\Delta s+\Delta \bar{s}$, which would in principle make this structure function an complementary probe of the quark and anti-quark singlet and spin contribution to the proton spin. Furthermore, $g_{5}^{\gamma Z}$ offers probes of the valence regime. According to Eq. (1.23), $g_{1}^{\gamma^{Z}}$ and $g_{5}^{\gamma Z}$ may be accessed by flipping the proton helicity while leaving the electron polarization unchanged. The corresponding spin asymmetries, obtained after summing over the electron helicities, are unfortunately overall much smaller than their counterparts with polarized electron and unpolarized proton. They are shown in Fig. 1.44, along with the their expected relative uncertainties, computed again for $\mathcal{L}=100 \mathrm{fb}^{-1}$. The best sensitivity is in the valence quark region, $x>0.1$. Even here, it remains at the $10 \%$ level. This directly translates into similar uncertainties for the structure functions $g_{1}^{\gamma Z}$ and $g_{5}^{\gamma Z}$, which are shown in Fig. 1.45. In the valence region, where

Figure 1.45. Structure functions $g_{1}^{\gamma}$ and $g_{5}^{Z Z}$ (top) and their relative uncertainties resulting from Fig. 1.44 (bottom).
sea quarks are irrelevant, we have $g_{1}^{\gamma Z} \propto \Delta u_{v}+\Delta d_{v}$ and $g_{5}^{\gamma Z} \propto 2 \Delta u_{v}+\Delta d_{v}$, which may provide a separation of $\Delta u$ and $\Delta d$.

Finally, assuming perfect knowledge of $\Delta u$ and $\Delta d$ and their anti-quark distributions from other sources, one might ask if an extraction of $\Delta s+\Delta \bar{s}$ from $g_{1}^{\gamma Z}$ and $g_{5}^{\gamma Z}$ could be possible. This quantity, and in particular its integral, is a key ingredient to nucleon spin structure and for understanding why quarks and anti-quarks combined appear to carry little of the proton spin. Constraints on $\Delta s+\Delta \bar{s}$ are presently available from an $\mathrm{SU}(3)$ symmetry analysis of hyperon $\beta$-decays, and from kaon production in semi-inclusive DIS, which are both inflicted with sizable uncertainties and in fact show some tension (for discussion, see [26]). The result for the extraction of $\Delta s+\Delta \bar{s}$ from electroweak DIS at the EIC is shown in Fig. 1.46. As can be seen, a non-zero measurement would be challenging for the assumed $100 \mathrm{fb}^{-1}$ integrated luminosity. Nevertheless, this measurement might become interesting if independent methods of extracting $\Delta s+\Delta \bar{s}$ were to provide surprising results. If this measurement is deemed sufficiently interesting and important, larger integrated luminosities will indeed help, since the measurement will continue to remain statistics limited, provided relative hadron polarization errors can be kept at the $3 \%$ level or better.

### 1.12.4 Summary

We have performed a basic analysis of the potential of an EIC in terms of measurements of structure functions in electroweak NC and CC scattering. Precise measurements of the CC functions $F_{1}^{W}, F_{3}^{W}, g_{1}^{W}$, and $g_{5}^{W}$ become feasible with a relatively modest integrated luminosity. These measurements will greatly aid the flavor decomposition of polarized and

Figure 1.46. Results for the $x(\Delta s+\Delta \bar{s})$ distribution extracted from the $A_{\mathrm{L}}$ spin asymmetry under the assumption that all other helicity distributions are known.
unpolarized PDFs in the region $x \gtrsim 0.01$. NC structure functions become accessible with good precision at high integrated luminosities. Measurements of $F_{1}^{\gamma Z}$ and $F_{3}^{\gamma Z}$ seem to be of limited use in improving present or approved measurements. At the highest luminosities and center of mass energies, $g_{1}^{\gamma Z}$ and $g_{5}^{\gamma Z}$ become accessible; these structure functions have never before been measured. The combined analysis of the new CC and NC structure functions with electrons and positrons as well as with polarized protons and neutrons at these highest luminosities could potentially open a new window into precision QCD tests of the spin structure of the nucleon; this will be the focus of future experimental and theoretical investigations.

### 1.13 Charged current charm production and the strange sea

Marco Stratmann

### 1.13.1 Basic idea

The leading order contribution to CC charm production in $e^{+} p$ DIS is given by the $\mathcal{O}\left(\alpha_{s}^{0}\right)$ parton model process $W^{+} s^{\prime} \rightarrow c$, where $s^{\prime}$ denotes the Cabibbo-Kobayashi-Maskawa (CKM) "rotated" combination $s^{\prime} \equiv\left|V_{c s}\right|^{2} s+\left|V_{c d}\right|^{2} d$. Due to the smallness of $\left|V_{c d}\right|^{2}$ [3] the process is expected to be essentially sensitive to the strange sea content. Only at large $x$, where quark sea contributions are less relevant, the $\left|V_{c d}\right|^{2}$ suppression is balanced by the valence enhancement of the well-known $d(x)$ density. Likewise, in $e^{-} p$ DIS, the process $W^{-} \bar{s}^{\prime} \rightarrow \bar{c}$ predominantly probes the anti-strange density $\bar{s}(x)$. With a polarized proton beam one can access also $\Delta s(x)$ and $\Delta \bar{s}(x)$.

Current determinations of $s(x)$ rely mainly on fixed-target neutrino scattering off nuclear targets with potentially large uncertainties, see Fig. 1.9 in Sec. 1.5. Much less is known about the longitudinally polarized $\Delta s(x)$ so far, see Sec. 1.10. Due to the limited luminosity and charm detection efficiency, charm production in CC DIS could not be studied at HERA. CC DIS would provide an independent way to extract the unpolarized and polarized strange sea distributions at much larger scales, typically $Q \sim M_{W}$, than probed in semi-inclusive kaon production, cf. Sec. 1.5. On the downside, such a measurement requires also a positron beam, though not polarized.

Next-to-leading order QCD corrections also complicate the simple picture for CC charm production and may deteriorate the sensitivity to strangeness. Apart from the $\mathcal{O}\left(\alpha_{s}\right)$ corrections to the LO process $W^{+} s^{\prime} \rightarrow c$, the genuine NLO, gluon induced subprocess $W^{+} g \rightarrow c \bar{s}^{\prime}$ has to be taken into account as well. It contributes significantly to the charm production cross section in certain regions of phase space and hence dilutes the sensitivity to the strange sea. In addition, a proper theoretical calculation also needs to take into account the mass of the produced heavy (charm) quark, as was also discussed in the context of $F_{2, L}^{c}$ in Sec. 1.7 . In order to make contact with experiment, a fully inclusive calculation [203, 111] is not entirely sufficient, and one should compute also the momentum $z$ spectrum of the detected charmed $D$ mesons. In the unpolarized case this was achieved in [204]. The corresponding polarized results can be found in Ref. [205. Imposing a lower cut $z_{\text {min }}$ on the $D$ meson momentum fraction was shown to considerably reduce gluon-initiated NLO contributions and enhance the sensitivity to the strange sea.

Concerning the mass $m_{c}$ of the charm quark, it turns out that the naive "rescaling prescription" [206], i.e., $s(x) \rightarrow s(\xi)$ where $\xi \equiv x\left(1+m_{c}^{2} / Q^{2}\right)$, applies also at NLO accuracy as it allows for a consistent factorization of all initial-state collinear singularities.

### 1.13.2 Sensitivity to the Strange Sea

So far, detailed phenomenological studies have been provided only for HERA kinematics [205], and they still need to be updated for EIC kinematics. However, these projections are sufficient to demonstrate the idea of the measurement and give a rough estimate of the size of cross sections and spin asymmetries. From the studies of inclusive CC electroweak DIS structure functions in Sec. 1.12 we already know that such measurements appear to be feasible at an EIC despite its lower c.m.s. energy than HERA even with moderate integrated luminosities of about $10 \mathrm{fb}^{-1}$.

Figure 1.47. The $z$ integrated polarized cross section for CC charm production in $e^{-} p$ and $e^{+} p$ collisions and the corresponding spin asymmetry $A^{D}$ for ( $\mathbf{a}, \mathbf{b}$ ): $0<z<1$, ( $\mathbf{c}, \mathbf{d}$ ): $0.2<z<1$, using the GRSV "std" and "val" sets of PDFs. Projected uncertainties are for $70 \%$ polarization, $100 \%$ charm detection efficiency, and an integrated luminosity of $5 \mathrm{fb}^{-1}$.

As an example, Fig. 1.47 shows the sensitivity of CC charm ( $D$ meson) production in $e^{-} p$ and $e^{+} p$ collisions at $\sqrt{S}=300 \mathrm{GeV}, Q^{2}>500 \mathrm{GeV}^{2}$, and $0.01 \leq y \leq 0.9$, to the choice of $\Delta s$. The momentum fraction of the detected $D$ meson has been integrated using $z_{\min }=0$ (upper row) and 0.2 (lower row). The GRSV valence set [24] has a very small positive $\Delta s(x)$ in the relevant region $x \gtrsim 0.01$, roughly comparable to what is nowadays obtained from fixed target SIDIS data, e.g., in the DSSV analysis [25, 26]; see Sec. 1.10, On the contrary, the GRSV standard set has a sizable negative strangeness polarization as favored by fits including only inclusive DIS data [23]. Other PDFs, in particular the gluon density, are very similar in both GRSV sets. Note that $\Delta s(x)=\Delta \bar{s}(x)$ is assumed in all current polarized PDF analyses due to the lack of data constraining them separately.

The solid and dashed lines in Fig. 1.47 show the results for $e^{-} p$ scattering for GRSV standard and valence PDFs, respectively. Within the projected statistical uncertainties, obtained for $70 \%$ proton polarization, $100 \%$ charm detection efficiency, and an integrated luminosity of $5 \mathrm{fb}^{-1}$, differences in $\Delta \bar{s}(x)$ can be easily resolved. The dot-dashed and dotted lines show the results for a corresponding measurement with positron beams. Having results for both $W^{-}$and $W^{+}$exchange, one should be able to study a possible asymmetry in $\Delta s(x)-$ $\Delta \bar{s}(x)$. The results presented here need to be backed up with more detailed simulations of CC charm production for EIC kinematics.

### 1.14 Photoproduction processes at an EIC

Hubert Spiesberger, Marco Stratmann

The production of hadronic final states in ep collisions is dominated by photoproduction where the electron is scattered by a small angle producing photons of almost zero virtuality $\left(Q^{2} \simeq 0\right)$. At LO of pQCD , the dominant process for the production of high- $p_{T}$ hadrons, jets, or heavy quarks is often photon-gluon fusion, $\gamma g \rightarrow q \bar{q}$. Here, the photon interacts directly with a gluon from the nucleon. Besides this so-called "direct" photoproduction channel, the scattering can proceed also via "resolved" processes. In this case, the photon acts as a source of partons which interact with the partons in the nucleon through any of the standard $2 \rightarrow 2$ LO QCD hard scattering processes such as $g g \rightarrow g g$ or $q \bar{q} \rightarrow q \bar{q}$. The large number of possible subprocesses can make the resolved contribution sizable in certain regions of phase space. Examples for a direct and a resolved process are shown in Fig. 1.48.

At LO, the two interaction mechanisms in Fig. 1.48 both contribute at $\mathcal{O}\left(\alpha_{e m} \alpha_{s}\right)$ but otherwise appear to be independent. Starting from NLO, however, the separation into direct and resolved contributions becomes factorization scheme dependent. This is due to soft and collinear singularities appearing in a perturbative approach. These singularities have to be identified and consistently factorized into non-perturbative PDFs of the nucleon and the photon. This procedure is not unique, and it is therefore important that the direct and resolved parts are treated together consistently. Only their sum is an experimentally meaningful and measurable cross section. For a theoretical review on photoproduction, see, e.g., Ref. [208].

The differential cross section for electron-nucleon scattering, $d \sigma_{e N}$, at a c.m.s. energy $\sqrt{s}$ is related to the photoproduction cross section $d \sigma_{\gamma N}$ through

$$
\begin{equation*}
d \sigma_{e N}(\sqrt{s})=\int_{y_{\min }}^{y_{\max }} d y f_{e \gamma}(y) d \sigma_{\gamma N}(y \sqrt{s}) . \tag{1.31}
\end{equation*}
$$

Here, $f_{e \gamma}$ is the energy spectrum of the exchanged photon which in the Weizsäcker-Williams approximation is given by

$$
\begin{equation*}
f_{e \gamma}(y)=\frac{\alpha_{e m}}{2 \pi}\left[\frac{1+(1-y)^{2}}{y} \ln \frac{(1-y) Q_{\max }^{2}}{y^{2} m_{e}^{2}}+2(1-y)\left(\frac{y m_{e}^{2}}{(1-y) Q_{\max }^{2}}-\frac{1}{y}\right)\right] . \tag{1.32}
\end{equation*}
$$

The photon flux $f_{e \gamma}$ depends $y=E_{\gamma} / E_{e} . Q_{\max }$ and the range $y_{\min } \leq y \leq y_{\max }$ are determined by cuts in the experimental analysis. Typically, a lower cut $y_{\text {min }}=\mathcal{O}(0.1)$ is

Figure 1.48. Example of a gluon-initiated direct and resolved contributions to photoproduction at LO (taken from Ref. [207]).
applied in order to exclude low-mass hadronic final states, and an upper limit on $y$, e.g., $y_{\max }=0.7 \div 0.9$, is used to reduce the kinematic range where radiative corrections are expected to be large.

The photoproduction cross section is then obtained as the sum of its direct and resolved parts, $d \sigma_{\gamma N}=d \sigma_{\gamma N}^{\mathrm{dir}}+d \sigma_{\gamma N}^{\text {res }}$, as convolutions $\otimes$ of the appropriate partonic hard scattering cross sections $d \sigma_{a b}$ with the PDFs $f_{a / \gamma}\left(x_{\gamma}\right)$ and $f_{b / N}\left(x_{N}\right)$ of the photon and nucleon, respectively, at a factorization scale $\mu_{f}$, i.e.,

$$
\begin{equation*}
d \sigma_{\gamma N}^{\mathrm{res}}=\sum_{a, b} f_{a / \gamma}\left(x_{\gamma}, \mu_{f}\right) \otimes f_{b / N}\left(x_{N}, \mu_{f}\right) \otimes d \sigma_{a b}\left(x_{\gamma}, x_{N}, \mu_{f}\right) . \tag{1.33}
\end{equation*}
$$

$d \sigma_{\gamma N}^{\text {dir }}$ can be obtained from (1.33) by replacing the photon PDFs by a $\delta$-function and considering only photon-parton scattering processes $d \sigma_{\gamma b}$ in the sum.

The resolved process is accompanied by a hadronic remnant of the photon which carries the fraction $1-x_{\gamma}$ of the photon energy. At LO, the presence of a hadronic remnant could be used to distinguish different event topologies for the two mechanisms. In addition, for two-jet final states $x_{\gamma}$ can be reconstructed experimentally from the measured transverse momenta and rapidities of the jets. It is customary to define

$$
\begin{equation*}
x_{\gamma}^{\mathrm{obs}} \equiv\left(E_{\mathrm{T}}^{\mathrm{jet}} e^{-\eta^{\mathrm{jet}} \mathrm{t}_{1}}+E_{\mathrm{T}}^{\mathrm{jet} t_{2}} e^{-\eta^{\mathrm{jet}} \mathrm{t}_{2}}\right) /\left(2 y E_{e}\right) . \tag{1.34}
\end{equation*}
$$

However, at higher orders of pQCD , initial- and final-state radiation of additional partons will also give rise to hadrons emitted in the direction of the incoming photon. Moreover, non-perturbative hadronization may contribute to the appearance of hadrons in the same kinematic region. Both effects lead to a reduction of the experimentally determined value of $x_{\gamma}$. Therefore a unique separation of the direct and resolved parts is not possible anymore. Nevertheless, the variable $x_{\gamma}$ can still be used to define kinematic regimes where direct (large $x_{\gamma}$ ) or resolved (small $x_{\gamma}$ ) contributions dominate.

At HERA, photoproduction has been used to test pQCD and the presence of both direct and resolved photon processes for final-states comprising hadrons, jets, prompt photons, and heavy quarks. Generally, the data are well described by NLO calculations in regimes expected to be dominated by the direct process. Kinematic regions where resolved processes are sizable are somewhat less well described; for a review see, e.g., [209]. This is mainly due to the fact that the photon PDFs needed for the calculation of the resolved contribution are significantly less well constrained by data than the partonic structure of protons. Only data for inclusive DIS off a quasi-real photon target, i.e., $\gamma^{*}\left(Q^{2}\right) \gamma$ scattering in $e^{+} e^{-}$[210], have been used in fits of photon PDFs so far, see, e.g., [211]. No attempts have been made to perform global analyses or to quantify uncertainties at a level similar to current fits of proton PDFs. Any additional, more precise data are therefore of vital importance for an improved understanding of the theoretical description of photoproduction processes and a reliable determination of photon PDFs. The latter are of great phenomenological relevance at a possible future linear $e^{+} e^{-}$collider to describe processes involving quasi-real photons.

The next two sections show some examples how an EIC can contribute to further our knowledge of photoproduction processes both in unpolarized and in polarized electronproton scattering.

### 1.15 Expectations for charm quark photoproduction

Hubert Spiesberger

The description of heavy quark production in the framework of perturbative QCD is complicated due to the presence of several large scales, like the transverse momentum $p_{T}$ of the produced charmed meson, the momentum transfer $Q$ in DIS, or the mass of the produced heavy hadron. Depending on the kinematic range considered, the mass $m_{c}$ of the charm quark may have to be taken into account. Different calculational schemes (see, e.g. [212, [213], and references therein) have been developed to obtain predictions from pQCD, depending on the specific kinematical region and the relative importance of the different scales.

In the case of relatively small transverse momentum, $p_{T} \lesssim m_{c}$, the fixed-flavor number scheme (FFNS) is usually applied. Here one assumes that the light quarks and the gluon are the only active flavors and the charm quark appears only in the final state. The charm quark mass can explicitly be taken into account together with the $p_{T}$ of the produced heavy meson; this approach is therefore expected to be reliable when $p_{T}$ and $m$ are of the same order of magnitude.

In the complementary kinematical region where $p_{T} \gg m_{c}$, calculations are usually based on the zero-mass variable-flavor-number scheme (ZM-VFNS) where $m_{c}=0$ and the charm quark acts as an active parton with its own PDF; see also Sec. 1.7. The charmed meson is produced not only by fragmentation from the charm quark but also from the light quarks and the gluon. The fragmentation process is described with the help of scale-dependent fragmentation functions (FFs), $D(z, \mu)$, which determine the probability that the produced heavy meson carries the fraction $z$ of the momentum of the parton it is produced from. The predictions obtained in this scheme are expected to be reliable only in the region of large $p_{T}$ since all terms of the order $m_{c}^{2} / p_{T}^{2}$ are neglected in the hard scattering cross section.

A unified scheme that combines the virtues of the FFNS and the ZM-VFNS is the so-called general-mass variable-flavour-number scheme (GM-VFNS) [212, 213]. In this approach the large logarithms $\ln \left(p_{T}^{2} / m_{c}^{2}\right)$ are factorized into the PDFs and FFs and summed to all orders by the well-known DGLAP evolution equations. At the same time, massdependent power corrections are retained in the hard-scattering cross sections, as in the FFNS. In order to conform with standard $\overline{\mathrm{MS}}$ factorization, finite subtraction terms must be supplemented to the results of the FFNS. As in the ZM-VFNS, one has to take into account processes with incoming charm quarks, as well as light quarks and gluons in the final state which fragment into the heavy meson. It is expected that this scheme is valid not only in the region $p_{T}^{2} \gg m_{c}^{2}$, but also in the kinematic region where $p_{T}$ is only a few times larger than $m_{c}$. The basic features of the GM-VFNS are described in Ref. [214]. Analytic results for the required hard scattering cross sections can be found in Refs. [213, 215, 216, 217.

Next, we present theoretical predictions [214] for the photoproduction of $D^{*}$-mesons in $e p$ scattering at the EIC. We assume an experimental analysis with $Q_{\max }=1 \mathrm{GeV}$ in Eq. (1.32). Since the cross section is dominated by low $Q^{2}$, our results should not depend too strongly on the precise value of $Q_{\max }$. The relevant direct and resolved hard scattering cross sections are calculated at NLO accuracy. For the photon PDFs we use the parametrization of Ref. [218] with the standard set of parameter values, and for the proton PDF we have chosen the CTEQ6.5 set [201]. For the FFs we use the Global-GM set of Ref. [219] based on a fit to the combined Belle [220], CLEO [221], ALEPH [222], and OPAL [223, 224] data. We choose the renormalization and factorization scales to be equal and use $\mu_{r}=\mu_{f}=m_{T}$,

Figure 1.49. $d \sigma / d \eta$ for the production of $D^{*}$ mesons at the EIC for two settings of beam energies integrated over transverse momenta $3 \mathrm{GeV} \leq p_{T} \leq 5 \mathrm{GeV}$. The different curves are explained in the text.
where $m_{T}=\sqrt{m_{c}^{2}+p_{T}^{2}}$ is the transverse mass and $m_{c}=1.5 \mathrm{GeV}$. In Ref. [214] we studied scale uncertainties for photoproduction at HERA, as well as ambiguities due to various possible choices for input variables, such as the proton and photon PDFs, the $D^{*}$ FFs, and the dependence on $m_{c}$.

In our calculation of the differential cross section $d \sigma / d \eta$ (where $\eta$ is the rapidity of the observed heavy meson, $D^{* \pm}$ ) we use $E_{p}=325 \mathrm{GeV}$ and consider two choices for the energy of the electron beam: $E_{e}=5 \mathrm{GeV}$ (left panel of Fig. 1.49) and $E_{e}=30 \mathrm{GeV}$ (right panel). The transverse momentum $p_{T}$ is integrated over the range $3<p_{T}<5 \mathrm{GeV}$. The results show that the higher electron beam energy would lead to an increase of the cross section by roughly a factor of three and the rapidity distribution is shifted towards the backwards region, as expected.

The figure shows a split-up of the total cross section into contributions from different subprocesses. From top to bottom, the curves correspond to the total cross section (full line), the direct contribution (long dashed), the total resolved part (dotted), the contribution due to charm in the photon (dash-dot-dotted) and charm in the proton (long double-dashed), and, finally, the part due to resolved subprocesses with light partons in the initial state. The direct contribution, which is sensitive mainly to the gluon distribution in the proton, is dominating throughout the shown range of $p_{T}$ and $\eta$. The resolved part is mainly due to the charm content of the photon, in particular, at negative rapidities. Here one may hope that measurements at an EIC, in particular, for the option with the highest $\sqrt{s}$, will contribute to a better determination of the photon PDFs.

The total cross sections for charm production at an EIC are not very different from those measured at HERA; however, an increase in the precision of corresponding measurements can be expected due to the higher luminosity. Apart from providing a better testing-ground for pQCD , one may expect that the experimental information will contribute to an improved determination of the charm content of the proton and, perhaps, the charm FFs.

### 1.16 Polarized photoproduction at an EIC

Barbara Jäger, Marco Stratmann

The framework for photoproduction outlined in Sec. 1.14 can be readily extended to longitudinally polarized ep collisions by replacing all unpolarized hard scattering cross sections and PDFs with their helicity-dependent counterparts. The energy spectrum of circularly polarized photons is given by [225]

$$
\begin{equation*}
\Delta f_{e \gamma}(y)=\frac{\alpha_{e m}}{2 \pi}\left[\frac{1-(1-y)^{2}}{y} \ln \frac{Q_{\max }^{2}(1-y)}{m_{e}^{2} y^{2}}+2 m_{e}^{2} y^{2}\left(\frac{1}{Q_{\max }^{2}}-\frac{1-y}{m_{e}^{2} y^{2}}\right)\right] \tag{1.35}
\end{equation*}
$$

The polarized beams available at an EIC offer unique opportunities for studying the spin structure of circularly polarized photons in photoproduction processes. Such measurements could yield also valuable, complementary information on the gluon helicity density of the proton as we shall demonstrate below.

To study the sensitivity of an EIC to the parton content of polarized photons, which is completely unmeasured so far, we consider two extreme models [226] based on the current knowledge of the unpolarized $f^{\gamma}\left(x, \mu_{0}\right)$ [211] and the positivity constraint $\left|\Delta f^{\gamma}\left(x, \mu_{0}\right)\right| \leq$ $f^{\gamma}\left(x, \mu_{0}\right)$. In the "minimal" scenario we assume $\Delta f^{\gamma}\left(x, \mu_{0}\right)=0$ at a scale $\mu_{0} \simeq 1 \mathrm{GeV}$ and we saturate the bound in the "maximal" scenario, i.e., $\Delta f^{\gamma}\left(x, \mu_{0}\right)=f^{\gamma}\left(x, \mu_{0}\right)$.

We present results of NLO calculations for single-inclusive jet photoproduction at a c.m.s. energy of $\sqrt{s}=100 \mathrm{GeV}$. In order to compute the cross section for jet production, an algorithm has to be specified describing the formation of jets by the final-state partons produced in the hard scattering. A frequently adopted choice is to define a jet as the deposition of the total transverse energy of all final-state partons that fulfill $\left(\eta-\eta^{i}\right)^{2}+$ $\left(\phi-\phi^{i}\right)^{2} \leq R^{2}$, where $\eta^{i}$ and $\phi^{i}$ denote the pseudo-rapidities and azimuthal angles of the particles and $R$ the jet cone aperture. We work in the so-called "small-cone approximation" [227, 228, 229, 230, 231] which can be considered as an expansion of the jet cross section in terms of $R$ of the form $A \log R+B+\mathcal{O}\left(R^{2}\right)$. Neglecting $\mathcal{O}\left(R^{2}\right)$ pieces, the evaluation and phase-space integration of the partonic cross sections can be performed analytically. This approximation has been shown [231, [232, 233, 147] to account extremely well for jet observables up to cone sizes of about $R \approx 0.7$ in related $p p$-scattering reactions by explicit comparison to calculations that take $R$ fully into account.

Figure 1.50 presents our results 234 for the expected NLO double-spin asymmetry $A_{L L}^{j e t}$ for single-inclusive jet photoproduction at $\sqrt{S}=100 \mathrm{GeV}$ for two different choices of proton helicity densities [24, 25] and the two extreme sets of polarized photon densities introduced above. In (1.35) we chose $Q_{\max }^{2}=1 \mathrm{GeV}^{2}$ and the range of photon energies is limited to $0.2 \leq y \leq 0.85$; see also Sec. 1.14. The jet transverse momentum is integrated over for $p_{T}>4 \mathrm{GeV}$, and the factorization and renormalization scales are chosen to be $p_{T}$.

For single-inclusive observables, the rapidity-differential cross sections and the spin asymmetry are particularly interesting, since the relevant ranges of momentum fractions of the partons in the photon and the proton are related to the rapidity of the observed jet. As explained, e.g., in Ref. [235], if counting positive rapidity in the forward direction of the proton, large momentum fractions $x_{\gamma} \simeq 1$ are probed at large negative values of $\eta$. In this region, the direct contribution is expected to be largest and the photon structure is dominated by the purely perturbative "pointlike" QED part [226] which does not depend on the unknown non-perturbative input. As can be seen in Fig. 1.50, measurements of $A_{L L}^{j e t}$

Figure 1.50. Pseudo-rapidity dependence of the NLO QCD spin asymmetry for single-inclusive jet photoproduction at $\sqrt{S}=100 \mathrm{GeV}$ integrated over $p_{T}>4 \mathrm{GeV}$ for two different choices of proton helicity PDFs and two extreme sets of polarized photon densities. Taken from Ref. [234].
for negative $\eta$ can provide valuable information on the proton's spin structure, in particular, the gluon helicity density due to the dominance of gluon-induced processes. On the other hand, at large positive rapidities, $A_{L L}^{j e t}$ is particularly sensitive to the parton content of the resolved photon, $x_{\gamma} \ll 1$, as is also exemplified in the figure. The size of $A_{L L}^{j e t}$ increases if the lower cut for the jet transverse momentum is raised to larger values. The range in $p_{T}$ where jets can be reliably reconstructed at an EIC still needs to be investigated in detail.

If one has determined the proton helicity PDFs from elsewhere, see Sec. 1.11, the prospects for learning about the parton content of polarized photons are excellent. We note that the latter may become relevant in estimates of photon induced cross sections at a future linear collider if the lepton beams will be longitudinally polarized. Resolved photon contributions also complicate current extractions of $\Delta g(x, \mu)$ in polarized-lepton nucleon scattering experiments at fixed-target energies [236, 237]. We have estimated the expected size of statistical uncertainties in case of the related single-inclusive pion photoproduction at an EIC in Ref. [238]. Measurements appear to be feasible already with very moderate integrated luminosities of a few $\mathrm{fb}^{-1}$ thanks to the sizable cross sections for small $Q^{2}$.

We note that other promising observables, like di-jet production where one has a better control of the range of $x_{\gamma}$ probed, see Sec. 1.14, or heavy quark production still need to be studied. Some theoretical results and simulations, mainly for HERA energies, can be found in Refs. [235, 239, 225].

## Chapter 2

# Three-dimensional structure of the proton and nuclei: transverse momentum 

Convenors and chapter editors:
D. Hasch, F. Yuan

### 2.1 Introduction and chapter summary

Mauro Anselmino, Andreas Metz, Peter Schweitzer

The exploration of the internal structure of the nucleon in terms of quarks and gluons, the fundamental degrees of freedom of Quantum Chromodynamics (QCD), has been and still is at the frontier of hadronic high energy physics research. After four decades of Deep Inelastic Scattering (DIS) experiments of high energy leptons off nucleons, our knowledge of the nucleon structure has made impressive progress. To leading order in the electromagnetic coupling constant $\alpha_{\text {QED }} \sim \frac{1}{137}$ the lepton with initial momentum $l$ interacts via one photon exchange with the quarks inside the nucleon. By observing the momentum $l^{\prime}$ of the lepton in the final state one obtains information about the quark and gluon content of the nucleon.

This information is encoded in the Parton Distribution Function (PDF) $f_{1}^{a}\left(x, Q^{2}\right)$ where $x=Q^{2} /(2 P \cdot q)$ is the fraction of the nucleon momentum $P$ which is carried by the parton with $Q^{2}=-q^{2}$ and $q=l-l^{\prime}$. This PDF can be interpreted as the number density of partons of type $q$ inside the nucleon, carrying a momentum fraction $x$. Similar information has been obtained about the number density of longitudinally polarized partons inside longitudinally polarized nucleons, the helicity distribution $g_{1}^{a}\left(x, Q^{2}\right)$. The successful prediction of the scale $\left(Q^{2}\right)$ dependence of the PDFs is one of the great triumphs of QCD.

However consolidated our understanding of the nucleon structure from DIS experiments is, it is basically one-dimensional. From DIS we 'only' learn about the longitudinal motion of partons in a fast moving nucleon or, which is equivalent, about their momentum distributions along the light-cone direction singled out by the hard momentum flow in the process (i.e., in DIS, of the virtual photon). In DIS the nucleon is seen as a bunch of fast-moving quarks, antiquarks and gluons, whose transverse momenta are not resolved. A fast moving nucleon is Lorentz-contracted but its transverse size is still about 1 fm , which is a large distance on the strong interaction scale.

It makes therefore sense to ask questions like: how are quarks spatially distributed inside the nucleon? How do they move in the transverse plane? Do they orbit, and carry orbital angular momentum? Is there a correlation between orbital motion of quarks, their spin and the spin of the nucleon? How can we access information on such spin-orbit correlations, and what will this tell us about the nucleon? Recent theoretical progress has put many of these questions on a firm field-theoretical basis. We do not know all answers, yet, but we have now a much better idea on how to get them. The past decade has also witnessed tremendous experimental achievements which lead to fascinating new phenomenological insights into the structure of the nucleon.

The above questions address two complementary aspects of the nucleon structure: the description of quarks in the transverse plane in momentum space and in coordinate space. The field-theoretical tools adequate to describe the former are the Transverse Momentum Dependent Parton Distribution Functions (TMD PDFs, or, shortly, TMDs). The fieldtheoretical objects tailored to describe the spatial distributions of quarks in the transverse plane are the Generalized Parton Distributions (GPDs), which are discussed in chapter 3.1. The focus of this chapter is on the TMDs, their theoretical properties and phenomenological implications.

Several fascinating topics are related to the study of TMDs:

- 3D-imaging. The TMDs depend on the intrinsic motion of partons inside the nucleon and allow the reconstruction of the nucleon structure in momentum space. Such an
information, when combined with the analogous information on the parton spatial distribution from GPDs, leads to a complete 3-dimensional imaging of the nucleon.
- Orbital motion. Most TMDs would vanish in the absence of parton orbital angular momentum. The possibility of learning about the orbital motion of quarks inside a nucleon emerges from the study of TMDs.
- Spin-orbit correlations. Most TMDs and related, observable, azimuthal asymmetries, are due to couplings of the transverse momentum of quarks with the nucleon (or the quark) spin. Spin-orbit correlations, similar to those in hydrogen atoms, can therefore be studied.
- QCD gauge invariance and universality. The origin of some TMDs and the related spin asymmetries, when considered at partonic level, reveal fundamental properties of QCD, mainly its color gauge invariance. This interpretation leads to expect some clear differences, between TMDs, in different processes (universality breaking). A test of such ideas is crucial for our understanding of QCD at work.

### 2.1.1 What are TMDs?

The 'simplest' TMD is the unpolarized function $f_{1}^{q}\left(x, k_{\perp}\right)$ which describes, in a fast moving nucleon, the probability to find a quark carrying the longitudinal momentum fraction $x$ of the nucleon momentum, and a transverse momentum $k_{\perp}=\left|\boldsymbol{k}_{\perp}\right|$. It is formally related to the collinear ('integrated') PDF by $\int \mathrm{d}^{2} \boldsymbol{k}_{\perp} f_{1}^{q}\left(x, k_{\perp}\right)=f_{1}^{q}(x)$ (notice that, for brevity, the dependence of TMDs and PDFs on auxiliary scales is often not indicated).

This and other quark TMDs are defined in terms of the unintegrated quark-quark correlator [240, 241]

$$
\begin{equation*}
\Phi_{i j}^{q}\left(x, \boldsymbol{k}_{\perp}, \boldsymbol{S}\right)_{\eta}=\left.\int \frac{d z^{-} d^{2} z_{\perp}}{(2 \pi)^{3}} \mathrm{e}^{i k \cdot z}\langle\boldsymbol{P}, \boldsymbol{S}| \bar{\psi}_{j}^{q}(0) \mathcal{W}_{\eta}(0, z) \psi_{i}^{q}(z)|\boldsymbol{P}, \boldsymbol{S}\rangle\right|_{z^{+}=0} \tag{2.1}
\end{equation*}
$$

in which the gauge link operator $\mathcal{W}_{\eta}(0, z)$ ensures the color gauge invariance of the matrix element. $\mathcal{W}_{\eta}(0, z)$ depends on a path. Factorization theorems give the prescription along which path the positions 0 and $z$ of the quark fields have to be connected, and the index $\eta$ indicates that strictly speaking $\mathcal{W}_{\eta}(0, z)$ depends on the process, as it will be further discussed. The light-cone coordinates are defined as $a^{\mu}=\left(a^{-}, a^{+}, \boldsymbol{a}_{\perp}\right)$ with $a^{ \pm}=\frac{1}{\sqrt{2}}\left(a^{0} \pm\right.$ $\left.a^{3}\right)$ and $\boldsymbol{a}_{\perp}=\left(a^{1}, a^{2}\right)$.

The power and rich possibilities of the TMD approach arise from the simple fact that $\boldsymbol{k}_{\perp}$ is a vector, which allows various correlations with the other vectors involved: the nucleon momentum $\boldsymbol{P}$ and the nucleon spin $\boldsymbol{S}$. A systematic description of the information content of the correlator was initiated in [242, 243, 244]. Of particular importance are 'leading-twist' TMDs, i.e. TMDs which enter in observables without power suppression. In this context, a TMD or observable is said to be twist-t if its contribution to a cross section is suppressed by the factor $(M / Q)^{t-2}$ [245] in addition to kinematic overall factors ( $M$ represents a generic hadronic scale including the transverse momentum.).

The leading-twist TMDs are associated with the large + component of the nucleon momentum (in a frame where the nucleon moves fast). For a spin $\frac{1}{2}$ particle like the nucleon there are 8 leading-twist TMDs, namely (we suppress the $\eta$ process dependence
label)

$$
\begin{align*}
\frac{1}{2} \operatorname{tr}\left[\gamma^{+} \Phi^{q}\left(x, \boldsymbol{k}_{\perp}, \boldsymbol{S}\right)\right] & =f_{1}^{q}\left(x, k_{\perp}\right)-\frac{\varepsilon^{j k} k_{\perp}^{j} S_{T}^{k}}{M} f_{1 T}^{\perp q}\left(x, k_{\perp}\right)  \tag{2.2}\\
\frac{1}{2} \operatorname{tr}\left[\gamma^{+} \gamma_{5} \Phi^{q}\left(x, \boldsymbol{k}_{\perp}, \boldsymbol{S}\right)\right] & =S_{L} g_{1 L}^{q}\left(x, k_{\perp}\right)+\frac{\boldsymbol{k}_{\perp} \cdot \boldsymbol{S}_{T}}{M} g_{1 T}^{q}\left(x, k_{\perp}\right)  \tag{2.3}\\
\frac{1}{2} \operatorname{tr}\left[i \sigma^{j+} \gamma_{5} \Phi^{q}\left(x, \boldsymbol{k}_{\perp}, \boldsymbol{S}\right)\right] & =S_{T}^{j} h_{1}^{q}\left(x, k_{\perp}\right)+S_{L} \frac{k_{\perp}^{j}}{M} h_{1 L}^{\perp q}\left(x, k_{\perp}\right) \\
& +\frac{\left(k_{\perp}^{j} k_{\perp}^{k}-\frac{1}{2} \boldsymbol{k}_{\perp}^{2} \delta^{j k}\right) S_{T}^{k}}{M^{2}} h_{1 T}^{\perp q}\left(x, k_{\perp}\right)+\frac{\varepsilon^{j k} k_{\perp}^{k}}{M} h_{1}^{\perp q}\left(x, k_{\perp}\right)(2.4)
\end{align*}
$$

Dirac structures other than those above yield higher twist TMDs [246, 247]. TMDs of antiquarks and gluons are defined similarly in terms of correlators analogous to (2.1). The notation used in Eqs. (2.2)-(2.4) follows [243, 244, 245], where the common subscript 1 is used to indicate twist-2 TMDs. (Notice that in the TMD literature also a different notation is often used, in which, for instance, $\Delta^{N} f_{q / p^{\uparrow}}\left(x, k_{\perp}\right)=-\left(2 k_{\perp} / M\right) f_{1 T}^{\perp q}\left(x, k_{\perp}\right)$. We refer to [248] for an overview.)

The leading twist TMDs (2.2 (2.4) have partonic interpretations. The gamma-structures signal the quark polarizations. $\gamma^{+}$describes unpolarized quarks, thus Eq. (2.2) gives the number density of unpolarized quarks inside an unpolarized (first term) or transversely polarized (second term) proton. $\gamma^{+} \gamma_{5}$, which appears in Eq. (2.3), singles out longitudinally polarized quarks, either in a longitudinally (first term) or transversely polarized (second term) proton. Finally, in Eq. (2.4), the gamma-factor $i \sigma^{+j} \gamma_{5}$ selects transversely polarized quarks inside transversely polarized (first and third terms), longitudinally polarized (second term) or unpolarized (fourth term) protons.

### 2.1.2 Partonic interpretation and properties of the TMDs

As they are the central focus of interest in this Chapter, let us further elaborate on the leading order TMDs and their partonic interpretation. We also introduce the Transverse Momentum Dependent Fragmentation Functions (TMD FFs). The TMDs contain information on the longitudinal and transverse (or intrinsic) motion of quarks and gluons inside a fast moving nucleon. When adding the spin degree of freedom they link the parton spin (say a quark, $\boldsymbol{s}_{q}$ ) to the parent proton $\operatorname{spin}(\boldsymbol{S})$ and to the intrinsic motion $\left(\boldsymbol{k}_{\perp}\right)$. The correlator (2.1) restricted to leading twist defines the most general spin dependent TMD, which we denote by $f_{1}^{q}\left(x, \boldsymbol{k}_{\perp} ; \boldsymbol{s}_{q}, \boldsymbol{S}\right)$, and may depend on all possible combinations of the pseudo-vectors $\boldsymbol{s}_{q}, \boldsymbol{S}$ and the vectors $\boldsymbol{k}_{\perp}, \boldsymbol{P}$ which are allowed by parity invariance. At leading order in $1 / Q$, there are eight such combinations, leading to the eight independent TMDs in Eqs. (2.2/2.4).

A similar correlation between spin and transverse motion can occur in the fragmentation process of a transversely polarized quark, with spin vector $\boldsymbol{s}_{q}$ and three-momentum $\boldsymbol{k}_{q}$, into a hadron with longitudinal momentum fraction $z$ and transverse momentum $\boldsymbol{P}_{\perp}$ (with respect to the quark direction); such a mechanism is called the Collins effect [249] and appears in the fragmentation function via a $\boldsymbol{s}_{q} \cdot\left(\boldsymbol{k}_{q} \times \boldsymbol{P}_{\perp}\right)$ term. For a quark fragmentation into a spinless hadron there are two independent leading-twist transverse momentum dependent fragmentation functions.

We briefly list here the eight leading-twist Transverse Momentum Dependent Partonic Distributions of a proton and the two Fragmentation Functions (for a final spinless hadron),
which are the main objects in our investigation of the nucleon momentum structure.

- $f_{1}^{a}\left(x, k_{\perp}\right)$ is the unpolarized, $k_{\perp}$ dependent distribution of parton $a$ inside a proton. Its integrated version is the usual PDF measured in DIS. Common notations are $q(x)=\int d^{2} \boldsymbol{k}_{\perp} f_{1}^{q}\left(x, k_{\perp}\right)$, and $g(x)=\int d^{2} \boldsymbol{k}_{\perp} f_{1}^{g}\left(x, k_{\perp}\right)$ for quarks of flavor $q$ and gluons respectively.
Most experimental and theoretical efforts have so far been dedicated to $q\left(x, Q^{2}\right)$ and $g\left(x, Q^{2}\right)$; these are by now the best known partonic distributions, and the comparison of the predicted $Q^{2}$ dependence with data has been a great success for perturbative QCD.
- $g_{1 L}^{a}\left(x, k_{\perp}\right)$ (or simply $g_{1}^{a}$ ) is the unintegrated helicity distribution: the difference between the number density of partons $a$ with the same and opposite helicity of the parent proton. Common notations for the integrated helicity distributions are $\Delta q(x)=\int d^{2} \boldsymbol{k}_{\perp} g_{1 L}^{q}\left(x, k_{\perp}\right)$ for quarks and similarly $\Delta g(x)$ for gluons. See the relevant discussions in section 1.10 .
The $\Delta q(x)$ 's are not so well known as the corresponding $q(x)$, as they require polarized DIS, but have been measured by several experiments. The least known of the helicity distributions is the gluon one, $\Delta g(x)$, despite some attempts to measure it.
- $h_{1}^{q}\left(x, k_{\perp}\right)$ is the analogue of the helicity distribution, for transverse nucleon spin, i.e. the transversity distribution. The integrated version has several notations in the literature $\Delta_{\perp} q(x)=h_{1}^{q}(x)=\int d^{2} \boldsymbol{k}_{\perp} h_{1}^{q}\left(x, k_{\perp}\right)$ for quarks of flavor $q$. There is no transversity distribution for gluons in a spin $\frac{1}{2}$ hadron.
The unpolarized, the helicity and the transversity distributions are the only three independent PDFs which survive in the collinear limit, $\boldsymbol{k}_{\perp}=0$. The transversity distribution is chiral-odd and needs to be coupled to another chiral-odd quantity to be observed. So far only one extraction of the $u$ and $d$ quark transversities is available in the literature [250], obtained by a combined fit of SIDIS and $e^{+} e^{-}$data.
A good knowledge of the transversity distributions for quarks and antiquarks would allow computation of the tensor charge, given by $\int_{0}^{1} d x\left[h_{1}^{q}(x)-h_{1}^{\bar{q}}(x)\right]$, a non perturbative quantity for which lattice and model computations exist.
- $f_{1 T}^{\perp a}\left(x, k_{\perp}\right)$ is the Sivers function [251, appearing in the distribution of unpolarized partons $a$ inside a polarized proton. It links the parton intrinsic motion to the proton spin:

$$
\begin{equation*}
f_{1}^{a}\left(x, \boldsymbol{k}_{\perp} ; \boldsymbol{S}\right)=f_{1}^{a}\left(x, k_{\perp}\right)-\frac{k_{\perp}}{M} f_{1 T}^{\perp a}\left(x, k_{\perp}\right) \boldsymbol{S} \cdot\left(\hat{\boldsymbol{P}} \times \hat{\boldsymbol{k}}_{\perp}\right) . \tag{2.5}
\end{equation*}
$$

The Sivers function offers new information and plays a crucial role in our understanding of the nucleon structure. Its observation, already confirmed, is a clear indication of parton orbital motion; the opposite values for $u$ and $d$ quarks is argued to be linked to the nucleons' anomalous magnetic moments; its very origin and expected process dependence are related to fundamental QCD effects. Due to its importance the Sivers TMD for quarks will be discussed at length in Sec. 2.2 and for gluons in Sec. 2.3, Theoretical issues concerning $f_{1 T}^{\perp a}$, its origin and relation with basic QCD properties like the color gauge links and color gauge invariance will be treated in Sec. [2.4.

- $h_{1}^{\perp q}\left(x, k_{\perp}\right)$ is the Boer-Mulders function [244, appearing in the distribution of polarized quarks $q$ inside an unpolarized proton:

$$
\begin{equation*}
f_{1}^{q}\left(x, \boldsymbol{k}_{\perp} ; \boldsymbol{s}_{q}\right)=\frac{1}{2} f_{1}^{q}\left(x, k_{\perp}\right)-\frac{k_{\perp}}{2 M} h_{1}^{\perp q}\left(x, k_{\perp}\right) \boldsymbol{s}_{q} \cdot\left(\hat{\boldsymbol{P}} \times \hat{\boldsymbol{k}}_{\perp}\right) . \tag{2.6}
\end{equation*}
$$

This function has the striking peculiarity that it might give unexpected spin effects even in unpolarized processes, as it singles out polarized quarks from unpolarized protons and neutrons. It will be discussed in Sec. 2.5.

- The remaining three TMDs, $g_{1 T}^{a}\left(x, k_{\perp}\right), h_{1 L}^{\perp q}\left(x, k_{\perp}\right)$ and $h_{1 T}^{\perp q}\left(x, k_{\perp}\right)$ are related to double spin correlations in the PDFs; respectively, the amount of longitudinally polarized partons in a transversely polarized proton, of transversely polarized quarks in a longitudinally polarized proton, and of transversely polarized quarks in a transversely (but in a different direction) polarized proton. Neglecting higher-twist terms, some approximate relationships with the other TMDs can be obtained [252]. They will briefly be discussed in Sec. 2.6,
- $D_{1}^{a}\left(z, P_{\perp}\right)$ (also denoted as $D_{h / a}$ ) is the unpolarized, $P_{\perp}$ dependent, parton $a$ fragmentation function (into a hadron $h$ ). Its integrated version $D_{1 h}^{a}(z)=\int d^{2} \boldsymbol{P}_{\perp} D_{1}^{a}\left(z, P_{\perp}\right)$ is the usual FF.
- $H_{1}^{\perp q}\left(z, P_{\perp}\right)$ is the Collins function [249], describing the fragmentation of a polarized quark into a spinless (or unpolarized) hadron:

$$
\begin{equation*}
D_{1}^{q}\left(z, \boldsymbol{P}_{\perp} ; \boldsymbol{s}_{q}\right)=D_{1}^{q}\left(z, P_{\perp}\right)+\frac{P_{\perp}}{z M_{h}} H_{1}^{\perp q}\left(z, P_{\perp}\right) \boldsymbol{s}_{q} \cdot\left(\hat{\boldsymbol{p}}_{q} \times \hat{\boldsymbol{P}}_{\perp}\right) \tag{2.7}
\end{equation*}
$$

The Collins effect has been observed by several experiments and is well established. It is considered as a universal property of the quark hadronization process and it plays a crucial role in many spin effects. Its chiral-odd nature makes it the ideal partner to access chiral-odd TMDs like the transversity distribution and the Boer-Mulders function. All these will be discussed in Sec. 2.5.

### 2.1.3 How do we obtain information on TMDs?

Our guiding experiments involve again lepton-nucleon scattering at high energy, with the difference, with respect to the usual DIS, that one observes in the final state a hadron in addition to the scattered lepton, $\ell(l)+N(P) \rightarrow \ell\left(l^{\prime}\right)+h\left(P_{h}\right)+X$, the so-called SemiInclusive Deep-Inelastic Scattering (SIDIS). In this case the hadron, which results from the fragmentation of a scattered quark, 'remembers' the original motion of the quark, including the transverse one, and offers new information.

In general, SIDIS depends on six kinematic variables. In addition to the variables for inclusive DIS, $x, y=(P \cdot q) /(P \cdot l)$, and the azimuthal angle $\phi_{S}$ describing the orientation of the target spin vector for transverse polarization, one has three variables for the final state hadron, which we denote by $z=\left(P \cdot P_{h}\right) /(P \cdot q)$ (longitudinal hadron momentum), $P_{h T}$ (magnitude of transverse hadron momentum), and the angle $\phi_{h}$ for the orientation of $\boldsymbol{P}_{h T}$ (see also Fig. 2.1). In the one-photon exchange approximation, the SIDIS cross section can be decomposed in terms of structure functions [242, 247, 254, 255] where, largely following

Figure 2.1. Illustration of the kinematics, especially the azimuthal angles, for SIDIS in the target rest frame [253. $\boldsymbol{P}_{h T}$ and $\boldsymbol{S}_{T}$ are the transverse parts of $\boldsymbol{P}_{h}$ and $\boldsymbol{S}$ with respect to the virtual photon momentum $\boldsymbol{q}=\boldsymbol{l}-\boldsymbol{l}^{\prime}$.
the notation of [247], one has

$$
\begin{align*}
\frac{d \sigma}{d x_{B} d y d \phi_{S} d z_{h} d \phi_{h} d P_{h T}^{2}} \propto & \left\{F_{U U, T}+\varepsilon \cos \left(2 \phi_{h}\right) F_{U U}^{\cos 2 \phi_{h}}\right. \\
& +S_{\|} \varepsilon \sin \left(2 \phi_{h}\right) F_{U L}^{\sin 2 \phi_{h}}+S_{\|} \lambda_{\ell} \sqrt{1-\varepsilon^{2}} F_{L L} \\
+ & \left|S_{\perp}\right|\left[\sin \left(\phi_{h}-\phi_{S}\right) F_{U T, T}^{\sin \left(\phi_{h}-\phi_{S}\right)}+\varepsilon \sin \left(\phi_{h}+\phi_{S}\right) F_{U T}^{\sin \left(\phi_{h}+\phi_{S}\right)}\right. \\
& \left.\quad+\varepsilon \sin \left(3 \phi_{h}-\phi_{S}\right) F_{U T}^{\sin \left(3 \phi_{h}-\phi_{S}\right)}\right] \\
& \left.+\left|\boldsymbol{S}_{\perp}\right| \lambda_{e} \sqrt{1-\varepsilon^{2}} \cos \left(\phi_{h}-\phi_{S}\right) F_{L T}^{\cos \left(\phi_{h}-\phi_{S}\right)}+\ldots\right\} \tag{2.8}
\end{align*}
$$

In Eq. (2.8), $\varepsilon$ is the degree of longitudinal polarization of the virtual photon which can be expressed through $y$ [247], $S_{\|}$denotes longitudinal target polarization, and $\lambda_{e}$ is the lepton helicity. The structure functions $F_{X Y}(X$ and $Y$ refer to the lepton and the nucleon, respectively: $U=$ unpolarized; $L, T=$ longitudinally, transversely polarized) merely depend on $x, z$, and $P_{h T}$. The third subscript $F_{X Y, T}$ specifies the polarization of the virtual photon. By choosing specific polarization states and weighting with the appropriate azimuthal dependence, one can extract each structure function in (2.8) as pioneering experiments have already unambiguously shown.

For TMD studies one is interested in the kinematic region defined by

$$
\begin{equation*}
P_{h T} \simeq \Lambda_{\mathrm{QCD}} \ll Q \tag{2.9}
\end{equation*}
$$

for which the structure functions can be written as certain convolutions of TMDs. In this region, the components in Eq. (2.8) appear at leading order when expanding the cross section in powers of $1 / Q$, while additional ones show up at sub-leading order [242, 247, 254, 255]. Measuring the structure functions in Eq. (2.8) allows one to obtain information on all eight leading quark TMDs. To be specific, one has (for a spinless final state hadron) [247, 255],

$$
\begin{array}{ll}
F_{U U} \sim \sum_{q} e_{q}^{2} f_{1}^{q} \otimes D_{1}^{q} & F_{L T}^{\cos \left(\phi-\phi_{S}\right)} \sim \sum_{q} e_{q}^{2} g_{1 T}^{q} \otimes D_{1}^{q} \\
F_{L L} \sim \sum_{q} e_{q}^{2} g_{1 L}^{q} \otimes D_{1}^{q} & F_{U T}^{\sin \left(\phi-\phi_{S}\right)} \sim \sum_{q} e_{q}^{2} f_{1 T}^{\perp q} \otimes D_{1}^{q} \\
F_{U U}^{\cos (2 \phi)} \sim \sum_{q} e_{q}^{2} h_{1}^{\perp q} \otimes H_{1}^{\perp q} & F_{U T}^{\sin \left(\phi+\phi_{S}\right)} \sim \sum_{q} e_{q}^{2} h_{1 T}^{q} \otimes H_{1}^{\perp q} \tag{2.12}
\end{array}
$$

$$
\begin{equation*}
F_{U L}^{\sin (2 \phi)} \sim \sum_{q} e_{q}^{2} h_{1 L}^{\perp q} \otimes H_{1}^{\perp q} \quad F_{U T}^{\sin \left(3 \phi-\phi_{S}\right)} \sim \sum_{q} e_{q}^{2} h_{1 T}^{\perp q} \otimes H_{1}^{\perp q} \tag{2.13}
\end{equation*}
$$

where $e_{q}$ is the charge of the struck quark in units of the elementary charge. Notice that the four chiral-even TMDs couple to the well known unpolarized fragmentation function $D_{1}$, while the chiral-odd TMDs couple to the (chiral-odd) Collins function $H_{1}^{\perp}$. In the subsequent sections the major focus will be on $F_{U T}^{\sin \left(\phi-\phi_{S}\right)}$ containing the Sivers function.

The factorized expressions for the structure functions in Eqs. (2.10) -(2.13) hold in this form in the parton model approximation. If loop corrections are included, one not only obtains a nontrivial higher order term describing the hard scattering part of the process but also a leading-twist contribution arising from soft gluon emission (soft factor) [240, 256, 257, 258, 259, 260. In the case of inclusive DIS such soft gluon effects cancel between real and virtual radiative corrections, but they survive in the SIDIS cross section for $P_{h T} \simeq \Lambda_{\mathrm{QCD}}$. While the hard coefficient enters the structure functions in a simple multiplicative way, the soft factor gets convoluted with the parton distributions and the fragmentation functions. The presence of uncanceled soft gluon emission also requires to somewhat generalize the field-theoretical definition of TMDs given above. More details about this point will be presented in Sec. 2.4.

Almost all existing analyses of TMD-observables are based on the parton model approximation. This is sufficient for getting a good first idea about the general features of the TMDs and also at the present stage of the data, which often are plagued by considerable uncertainties. However, precision studies will be necessary to reveal features of QCD dynamics. The parton model approach will then be no longer appropriate, and one will have to deal with soft gluon effects, especially when high quality data from the EIC become available that will cover a large kinematic range.

### 2.1.4 Gauge invariance, universality, and beyond

Local gauge invariance is the underlying principle of the Standard Model of Particle Physics. In the case of QCD it is the $\mathrm{SU}(3)$ gauge invariance associated with the color degree of freedom of the quarks which matters. This color gauge invariance plays a particularly crucial role for TMDs. Here a brief introduction to this topic is given, while especially in Sec. 2.4 more details about this very active and fascinating field can be found.

As discussed in Sec. 2.1.1, in order to have a gauge invariant definition of TMDs a gauge link (Wilson line) has to be inserted between the two quark fields showing up in the correlator in Eq. (2.1). This is not specific for TMDs but applies also to, e.g., ordinary PDFs. However, two features are unique in the case of TMDs: first, certain TMDs are non-zero only if the Wilson line is taken into account [261, 262, 263, 264]. Second, the Wilson line depends on the process, which leads to a nontrivial universality behavior of TMDs [262].

The mere existence of two TMDs depends on the presence of the Wilson line - the Sivers function $f_{1 T}^{\perp}$ and the Boer-Mulders function $h_{1}^{\perp}$. They are also denoted as naive timereversal odd (T-odd) functions. (This term is not related to real violation of T-invariance but, roughly speaking, is associated with a nontrivial phase at the amplitude level of a process.)

The Wilson line is automatically generated when carrying out factorization. In the case of SIDIS, it arises due to the exchange of (infinitely many) gluons between the active struck quark and the remnants of the target. Since in DIS these exchanges happen after the
virtual photon strikes the quark one also talks about final state interactions (FSI). On the other hand, for the Drell-Yan process, there exist corresponding gluon exchanges before the photon-quark interaction, which we call initial state interactions (ISI). As a consequence, the Wilson-lines for the two processes are running along different paths. This in turn endangers the universality (process-independence) of TMDs, which is a crucial prerequisite for factorization being of any practical use.

Although the paths of the Wilson lines are different, the TMDs for both processes can be related by using the parity and time-reversal transformation [262. One finds that the six T-even TMDs are actually universal, while the T-odd TMDs are non-universal. However, this non-universality is well under control and 'merely' consists of a sign change [262],

$$
\begin{equation*}
\left.f_{1 T}^{\perp}\right|_{\text {DY }}=-\left.f_{1 T}^{\perp}\right|_{\text {DIS }},\left.\quad h_{1}^{\perp}\right|_{\text {DY }}=-\left.h_{1}^{\perp}\right|_{\text {DIS }} \tag{2.14}
\end{equation*}
$$

In other words, the predictive power of factorization is maintained. The experimental check of this sign change is currently one of the outstanding topics in hadronic physics.

We are now in a position to further motivate why the study of the Sivers effect should play a central role in the EIC science case. First, the Sivers function not only tells us something about the three-dimensional structure of the nucleon, a particular spin-orbit correlation, etc. Its physics is also intimately related to the gauge invariance of QCD. Second, existing data for non-zero transverse single-spin asymmetries in SIDIS and in proton-proton collisions can be explained on the basis of the Sivers effect. In other words, the physics of FSI/ISI is the key to describing these asymmetries (which can be as large as $40 \%$ ) in QCD. Third, according to our present knowledge, in SIDIS the Sivers function is easier to measure than the Boer-Mulders function. Fourth, the check of the predicted sign reversal in (2.14), strictly speaking, is more direct for $f_{1 T}^{\perp}$ than for the chiral-odd $h_{1}^{\perp}$. In the latter case input from models is required.

Quite some progress was made in recent years to further elucidate this physics associated with the underlying gauge structure of QCD. In particular, for hadron-hadron collisions with hadronic final states the presence of both ISI and FSI may unable any kind of (standard) TMD-factorization [265, 266, 267, 268, 269, 270, 271, 272. The consequences of a breakdown of TMD-factorization are far-reaching. For instance, in such a case also the so-called QCD resummation technique [273], which is widely used whenever there is more than one physical momentum scale in a process, becomes questionable. Moreover, if the sign reversal of the Sivers function in Eq. (2.14) is not confirmed by experiment, the general procedure of applying QCD to hard scattering processes may have to be revisited. Further striking developments in this rather new field can be expected, and only the close interplay between lepton-nucleon scattering and hadronic collisions will allow us to fully explore this physics, as is also obvious from the relations (2.14).

### 2.1.5 TMDs and orbital angular momentum

The helicity PDFs $g_{1}^{a}(x)$ are still not well known, especially in the sea quark and gluon sector, but by now one fact seems clear: the spin of quarks and gluons accounts only for a part of the nucleon spin. A substantial fraction of the nucleon spin must be due to orbital angular momentum (OAM). It is important to keep in mind that in gauge theories there is no unique decomposition of the nucleon spin into contributions due to the spin and OAM of quarks and gluons [143, 274]. Nevertheless it is possible [274, 275] to learn about OAM from GPDs which describe the dynamics of partons in the transverse plane in position space.

TMDs provide complementary information on the dynamics of partons in the transverse plane in momentum space, and one naturally expects TMDs to teach us about parton OAM. That the OAM of partons plays an important role is well known: in the light-cone wave function of the nucleon components with OAM $L_{z} \neq 0$ must be present in order to have a non-zero anomalous magnetic moment [276, 277], and the situation is similar for several other quantities [278]. Model calculations have also shown that the leading twist TMDs $f_{1 T}^{\perp q}, g_{1 T}^{q}, h_{1}^{\perp q}, h_{1 L}^{\perp q}, h_{1 T}^{\perp q}$ and many sub-leading twist TMDs would vanish without different components in the nucleon wave function with $\Delta L_{z} \neq 0$. But although OAM seems to play a crucial role also for many TMDs, so far no rigorous connection between the OAM contribution of partons and the nucleon spin could be established.

### 2.1.6 Further important topics

In this subsection some further important aspects about TMDs are briefly discussed; more details will be presented in the other Sections of this TMD Chapter.

## Models and lattice QCD

Model calculations have had a particularly strong impact on the TMD field. It suffices to recall the calculations in the quark-diquark model [261] which helped to establish the existence of the Sivers effect within QCD and the TMD factorization framework [262]. Models may allow to see more clearly the relevant aspects of TMDs which are obscured in the much more complicated QCD dynamics. We encountered one promising instance of that above, in Sec. 2.1.5. Model results have, however, also very practical applications. Nearly nothing is known about most of the TMDs. Models provide information on the sign and magnitude of TMDs, or possible (model) relations among different TMDs. This information can be applied to make predictions for the planned experiments, and in this way help to better explore the opportunities of the available and planned facilities. The importance of model studies is discussed in Sec. 2.4

Lattice QCD is in principle a powerful approach. What can be handled presently in lattice studies are calculations of the matrix element in the integrand of the correlator in Eq. (2.1), i.e., TMDs in Fourier-space. Most readily accessible is information on $x$-integrated TMDs such as $\int d x f_{1}^{q}\left(x, k_{\perp}\right)$ [279, 280]. The caveat is that lattice results presently available have been obtained with a simplified gauge-link in the correlator (2.1). This simplified gauge-link differs from the link-geometry dictated by factorization in a particular scattering process. Investigations with more realistic gauge-links are ongoing.

## Gluon TMDs

In addition to the eight TMDs for quarks, there also exist eight TMDs for gluons [248, 281, 282. The most prominent one is the unpolarized gluon TMD, which is a widely used ingredient of many calculations in high-energy processes. Because of the initial and final state interactions, the universality of this object is nontrivial and has attracted renewed interest lately [283]. Moreover, linearly polarized gluons for an unpolarized nucleon can, in principle, be explored through, e.g., heavy quark pair production in $\ell p$-collisions [284]. A particularly important role is played by the Sivers function for gluons, which will be discussed in quite some detail in Sec. 2.3. Experimentally, the sector of gluon TMDs is largely unexplored so far, and the EIC could provide extremely valuable information in this respect.

## Moments of TMDs

Momentum moments of some of the TMDs are of particular interest because of their relation to certain collinear 3-parton correlators, which appear in the QCD-description of, e.g., SIDIS structure functions at large $P_{h T} \simeq Q$ or weighted asymmetries (see Sec. 2.2). For instance, in the case of the Sivers function one can consider the moment [264, 285]

$$
\begin{equation*}
f_{1 T}^{\perp(1)}(x) \equiv \int d^{2} \boldsymbol{k}_{\perp} \frac{\boldsymbol{k}_{\perp}^{2}}{2 M^{2}} f_{1 T}^{\perp}\left(x, \boldsymbol{k}_{\perp}^{2}\right)=\pi T_{F}(x, x) \tag{2.15}
\end{equation*}
$$

where $T_{F}$ represents a quark-gluon-quark correlator. These correlation functions were also introduced in the literature to describe the single-spin asymmetries in hard scattering processes in the collinear factorization framework [286, 287, 288, 289]. Equation (2.15) is a model-independent result which allows one to relate different observables. A corresponding relation holds for the Boer-Mulders function [264, 285]. Also the moments $g_{1 T}^{(1)}$ and $h_{1 L}^{\perp(1)}$ can be expressed through collinear 3-parton correlators [290].

## Integrated/weighted observables

In Sec. 2.1.3 leading-twist soft gluon effects were mentioned. Such effects can cancel if the components in Eqs. (2.8) are integrated upon the transverse momentum $P_{h T}$ of the hadron. For instance, a cancellation occurs for the unpolarized structure function $F_{U U}$, and also for the term associated with $F_{U T}^{\sin \left(\phi_{h}-\phi_{S}\right)}$ which is related to the Sivers effect [291]. In the latter case the integration needs to be done with a proper weight factor (a more elaborate account on this topic will be given in Sec. (2.2). Such weighted observables are therefore rather attractive from a theoretical point of view. They depend on moments of the TMDs just discussed above and as such provide additional complementary information. The EIC would be ideal for seriously studying these interesting observables.

## Structure functions from low to high transverse momenta

While at low $P_{h T}$ the SIDIS structure functions can be described by means of TMDfactorization, for $P_{h T} \simeq Q$ collinear factorization is the appropriate framework. Recently, a lot of progress has been made to understand the quantitative relation between TMDfactorization on the one hand and collinear factorization on the other in the region $\Lambda_{\mathrm{QCD}} \ll$ $P_{h T} \ll Q$ where both approaches apply [292, 293, 294, 295, 296, 297]. An extended discussion of these aspects, with a focus on the EIC, will also be given in Sec. 2.2,

## Higher twist TMDs

The focus of present research is on the leading-twist TMDs. However, there is also a lot of important information encoded in twist-3 TMDs, which contain detailed information on the quark-gluon correlators. Experimentally, such twist-3 effects can be explored by measuring sub-leading structure functions appearing in the general decomposition of the SIDIS cross section (2.8) [242, 247, 254, 255]. In fact, the first clear single-spin phenomena in SIDIS, which crucially vitalized the field, were sub-leading twist observables. Although studied in numerous works, these first data on single-spin asymmetries in SIDIS remain basically unexplained. Some aspects of the interesting topic of higher twist TMDs will be discussed in more detail in Sec. 2.6.

| Deliverables | Observables | What we learn | Phase I | Phase II |
| :---: | :---: | :---: | :---: | :---: |
| Sivers + unp. | SIDIS with Tran. | Quant. Interf. | valence+sea | 3D Imaging of |
| TMD quarks | polarization/ion; | Multi-parton \& | quarks, overlap | quarks \& gluon; |
| and gluon | di-hadron (di-jet) | Spin-Orbit | with the fixed | $Q^{2}\left(P_{\perp}\right)$ range |
|  | heavy flavor | correlations | target exp. | QCD dynamics |
| Chiral-odd | SIDIS with Tran. | $3^{\text {rd }}$ basic quark | valence+sea | $Q^{2}\left(P_{\perp}\right)$ range |

### 2.1.7 TMDs and the EIC

Despite the tremendous progress in understanding TMDs and the related physics, without a new lepton-hadron collider many aspects of this fascinating field will remain untouched or at least on a qualitative level. Existing facilities either suffer from a much too restricted kinematic coverage or from low luminosity or from both. Based on the present status of research we see the following potential in an EIC:

- clean quantitative measurements of TMDs in the valence region due to high luminosity, and ability to go to sufficiently large $Q^{2}$ in order to suppress potential higher twist contaminations. Primordial orbital motion is expected for valence quarks.
- related to the wide kinematic coverage and the high luminosity, ability to provide multi-dimensional representations of the observables, which is basically impossible on the basis of current experiments.
- production and possible observation of jets with significantly larger particle multiplicities, allowing for the study a larger variety of hadronic final states.
- first access to TMDs for antiquarks.
- (first) access to TMDs for gluons, for instance through dihadron correlations, dijet correlations, or semi-inclusive production of quarkonium.
- systematic study of perturbative QCD techniques (for polarization observables). Tests and studies of QCD evolution properties of TMDs.

We strongly believe that the EIC will bring our knowledge of the partonic structure of the nucleon to an entirely new level. Keeping in mind deeply QCD rooted effects, like the (potential) sign-change of the Sivers function, the EIC can be expected to stimulate further developments in the application of perturbative QCD to other hard scattering processes. A series of "golden" and "silver" measurements are outlined in table 2.1. The significance of these points is further enhanced by newly planned (polarized) Drell-Yan experiments, which will study complementary physics aspects.

### 2.2 Sivers function

Christine Aidala, Elke Aschenauer, Alessandro Bacchetta, Thomas Burton, Leonard Gamberg, Delia Hasch, Min Huang, Zhong-Bo Kang, Yuji Koike, Bernhard Musch, Alexei Prokudin, Xin Qian, Gunar Schnell, Kazuhiro Tanaka, Anselm Vossen, Feng Yuan

We choose the example of the Sivers function to illustrate the physics case for TMD distributions at the EIC. This function incorporates all new facets and intriguing physical aspects of TMD distributions outlined in the introduction and discussed in more detail in the following sections. We start this discussion with a brief review of the peculiarities of the Sivers function thereby illustrating the crucial role TMDs play in our understanding of the nucleon structure.

The Sivers function $f_{1 T}^{\perp a}\left(x, k_{\perp}\right)$, appearing in the distribution of unpolarized partons $a$ inside a polarized nucleon:

$$
\begin{equation*}
f_{1}^{a}\left(x, \boldsymbol{k}_{\perp} ; \boldsymbol{S}\right)=f_{1}^{a}\left(x, k_{\perp}\right)-\frac{k_{\perp}}{M} f_{1 T}^{\perp a}\left(x, k_{\perp}\right) \boldsymbol{S} \cdot\left(\hat{\boldsymbol{P}} \times \hat{\boldsymbol{k}}_{\perp}\right) \tag{2.16}
\end{equation*}
$$

describes the correlation between the momentum direction of the struck parton and the spin of its parent nucleon and is hence related to the orbital motion of partons inside the nucleon. This correlation generates a dipole pattern in the transverse $k_{\perp}$-plane. We illustrate this fascinating aspect of certain TMDs in providing a three-dimensional imaging of the nucleon in momentum space by choosing a specific configuration for the vectors involved in Eq. (2.16). Taking for example $\hat{\boldsymbol{P}} \equiv \frac{\mathbf{P}}{|\mathbf{P}|}=(0,0,-1)$ and the spin of the proton along the $y$ direction, so that $S=(0,1,0)$ and the transverse momentum of the parton $k_{\perp}=\left(k_{\perp x}, k_{\perp y}, 0\right)$, yields a typical "dipole" modulation of the distribution:

$$
\begin{equation*}
f_{1}^{a}\left(x, \boldsymbol{k}_{\perp} ; \boldsymbol{S}\right)=f_{1}^{a}\left(x, k_{\perp}\right)+\frac{k_{\perp x}}{M} f_{1 T}^{\perp a}\left(x, k_{\perp}\right) \tag{2.17}
\end{equation*}
$$

The $f_{1}$ term provides an axially symmetric contribution, while the second term containing $f_{1 T}^{\perp}$ gives rise to the dipole pattern. A superposition of both effects results in a distribution that is shifted away from the center (distorted) in the $k_{\perp}$-plane as shown in fig. 2.2. This distortion turns out to be of opposite sign for up and down quarks.

The Sivers function manifests the importance of initial and final state interaction effects in hard scattering processes as the presence of these effects is required for the existence of a non-zero Sivers function. Their inclusion in the TMD factorization approach yields a peculiar breaking of the universality of the Sivers function. As introduced in sec. 2.1.4 and detailed in sec. 2.4.1, this non-universality is well under control and 'merely' consists of a sign change of the Sivers function when appearing in the Drell-Yan process as compared to DIS. The experimental verification of this sign change is currently one of the outstanding topics in hadronic physics and presents a crucial test for our understanding of hadron production in high-energy reactions. We will therefore briefly review the prospects for measurements of the Sivers effect in Drell-Yan in sec. 2.2.3.

A further intriguing aspects of the Sivers function is its connection to the orbital angular momentum in the nucleon. A non-zero quark Sivers function involves a transition between initial and final nucleon states that differ by one unit of orbital angular momentum. This property together with the potential for a three-dimensional imaging, puts the Sivers function in close relation to the GPD $E$ discussed in chapter 3. In particular, it was proposed that there is a dynamical relation called "chromodynamic lensing", where

Figure 2.2. Spin density in the transverse-momentum plane for unpolarized quarks in a transversely polarized nucleon, as described by the Sivers function. The left panel is for up quarks and the right one for down quarks. The model calculation of Ref. [298] was used.
the spatial distortion of the transverse quark distribution (in a transversely polarized proton) leads to a distortion in transverse momentum distribution described by the Sivers function [299, 300, 301].

### 2.2.1 What do we know so far from experiments?

Though the Sivers function was first suggested to explain the surprisingly large singlespin asymmetries measured in $p p$ collisions, our guiding experiments for obtaining unambiguous information about this function, and most of the other TMDs, involve high-energy lepton-nucleon scattering with the observation of one or more hadrons in coincidence with the scattered lepton (semi-inclusive DIS). In addition, model calculations of TMDs, discussed in sec. 2.4. guide Ansätze for global fits of TMD parameterizations and provide an interpretation of the various aspects of TMDs.

In this section, after a brief review of the results from $p p$ collisions, we will summarize available semi-inclusive DIS measurements of observables related to the Sivers effect and present phenomenological extractions of the Sivers function from data. The following section will then highlight the potential of an EIC for a detailed and systematic exploration of the various aspects of the quark Sivers functions illustrative of TMDs in general.

## Transverse-spin effects in proton-proton collisions

Historically, the surprisingly large left-right asymmetries observed in hadronic reactions with transversely polarized protons initiated the idea about a transverse momentum dependence of quark distributions in polarized protons. The pioneering measurements 302, 303] of these large (up to 0.3-0.4 in magnitude) transverse-spin asymmetries in inclusive forward production of pions in $p p$ collisions $p^{\uparrow} p \rightarrow \pi+X$, have been extensively confirmed by experiments at FermiLab [304, 305, 306, 307, 308] and at RHIC (BNL) at much higher center-of-mass energies of up to $\sqrt{s}=200 \mathrm{GeV}$ [309]. The observation of such asymmetries was frequently quoted as a puzzle or challenge for theory. In fact, for a long time, transverse single-spin asymmetries were assumed to be negligible in hard scattering processes [310].

The work of [251] introduced a transverse momentum dependent quark distribution, now termed the Sivers function, which provides a mechanism for the observed asymmetries that does not vanish at high energies.

A rich variety of single-spin asymmetries for identified hadrons $\left(\pi^{ \pm}, \pi^{0}, K^{ \pm}, p, \bar{p}\right)$ measured over a wide kinematic range is now available from the BRAHMS, PHENIX and STAR experiments at RHIC (BNL) [311, 312, 313, 314, 315, 316, 317, 318. The results exhibit a general pattern: sizable asymmetries are measured at forward-rapidity and for positive Feynman $x_{F}>0.3$ which increase in magnitude with increasing $x_{F}$ and $P_{h T}$. In contrast, for negative $x_{F}$ and at mid-rapidity all asymmetries are found to be consistent with zero.

Several mechanisms have been suggested to explain these asymmetries. At large values of $P_{h T}$ collinear factorization involving twist-3 distributions can be applied. However, the intrinsic prediction of a $1 / P_{h T}$ fall-off has yet to be confirmed. An alternative approach using a generalized parton model that takes intrinsic transverse momentum dependences into account has been used to describe existing data, achieving a fairly successful description of the observed asymmetries for pion production in $p p$ collisions 319. If less inclusive measurements are performed, with an observed soft momentum scale in addition to a hard scale, one can attempt to describe the data using a TMD approach in pQCD. However, as discussed in sec. 2.4.1, the presence of both initial and final state interactions in hadronhadron collisions may prevent any kind of (standard) TMD-factorization. More insight might be gained regarding the intricate color structure of $p p$ reactions for example by measuring di-jet production. In di-jet production both large scales (e.g., jet $p_{T}$ ) and small scales (e.g., $\Delta p_{T}$ of nearly back-to-back jets) can be observed. To assess factorization breaking due to color interactions in $p p$ collisions, the experimental measurements can be compared to calculations using TMDs extracted from DIS and Drell-Yan, for which TMDfactorization has been demonstrated. Little experimental information currently exists on these processes, but they are part of the physics program at RHIC.

Many questions still need to be answered, but it is clear that for a strict assessment of whether the TMD Ansatz is indeed possible and appropriate to describe results from hadronic collisions, more precise parameterizations of the Sivers function and, hence, more precise data on the Sivers effect in a well-understood process like DIS is needed.

## Semi-inclusive Deep-Inelastic Scattering

In semi-inclusive DIS, the Sivers function leads to single-spin asymmetries in the distribution of hadrons in the azimuthal angles illustrated in fig. [2.1. The azimuthal modulations of the SIDIS cross section are given in Eq. (2.8). The Sivers effect manifests itself as a $\sin \left(\phi_{h}-\phi_{S}\right)$ modulation and requires transverse polarization of the target nucleon. The additional information provided by the azimuthal angle $\phi_{S}$ of the transverse component of the target-proton spin about the virtual photon direction allows for an unambiguous extraction of the Sivers effect. Experimentally, the so-called Sivers amplitude $2\left\langle\sin \left(\phi_{h}-\phi_{S}\right)\right\rangle_{U T}^{h}$ [253], which projects out the structure function $F_{U T, T}^{\sin \left(\phi_{h}-\phi_{S}\right)}$ in Eq. (2.8) for a specific hadron $h$, is extracted from the asymmetry

$$
\begin{equation*}
A_{U T}^{h}\left(\phi_{h}, \phi_{S}\right) \equiv \frac{1}{\left|\mathbf{S}_{T}\right|} \frac{d \sigma^{h}\left(\phi_{h}, \phi_{S}\right)-d \sigma^{h}\left(\phi_{h}, \phi_{S}+\pi\right)}{d \sigma^{h}\left(\phi_{h}, \phi_{S}\right)+d \sigma^{h}\left(\phi_{h}, \phi_{S}+\pi\right)}, \tag{2.18}
\end{equation*}
$$

where the subscript $U$ indicates an unpolarized lepton beam and $T$ a transversely polarized target nucleon. This amplitude has so far been extracted by three polarized fixed-target experiments as summarized in Tab.[2.2. From these measurements, fig. [2.3]shows a selection

| experiment (laboratory) | $\sqrt{s}$ in GeV | target type | hadron types | references |
| :--- | :---: | :---: | :---: | :---: |
| COMPASS (CERN) | 18 | deuteron | $h^{ \pm}, \pi^{ \pm}, K^{ \pm}, K^{0}$ | $[320,321]$ |
|  |  | proton | $h^{ \pm}$ | $[322$ |
|  |  | proton | $\pi^{ \pm}, K^{ \pm}$ | prelim. 323 |
| HERMES (DESY) | 7.4 | proton | $\pi^{ \pm}$ | $[324$ |
|  |  | proton | $\pi^{ \pm},\left(\pi^{+}-\pi^{-}\right), \pi^{0}, K^{ \pm}$ | $[325]$ |
| HallA (JLab) | 3.5 | neutron | $\pi^{ \pm}$ | prelim. [326] |

Table 2.2. Summary of currently available measurements of Sivers asymmetry amplitudes from lepton-nucleon DIS experiments, their center-of-mass energy, transversely polarized target type, and analyzed hadron types.
of results that are significantly non-zero and help in determining the shape of the Sivers function. All other asymmetry amplitudes listed in Tab. 2.2 are small or consistent with zero.

The results have so far been interpreted in the parton model as a convolution of distribution and fragmentation functions, where the Sivers amplitude can be approximated by

$$
\begin{equation*}
2\left\langle\sin \left(\phi_{h}-\phi_{S}\right)\right\rangle_{U T}^{h}\left(x_{B}, y, z_{h}, P_{h T}\right)=-\frac{\sum_{q} e_{q}^{2} f_{1 T}^{\perp q}\left(x, k_{\perp}^{2}\right) \otimes_{\mathcal{W}} D_{1}^{q}\left(z, P_{\perp}^{2}\right)}{\sum_{q} e_{q}^{2} f_{1}^{q}\left(x, k_{\perp}^{2}\right) \otimes D_{1}^{q}\left(z, P_{\perp}^{2}\right)} \tag{2.19}
\end{equation*}
$$

Here the sums run over the quark flavors, the $e_{q}$ are the quark charges, and $f_{1}\left(x, k_{\perp}^{2}\right)$ and $D_{1}\left(z, P_{\perp}^{2}\right)$ are the spin-independent quark distribution and fragmentation functions, respectively. The symbol $\otimes\left(\otimes_{\mathcal{W}}\right)$ represents a (weighted) convolution integral over intrinsic and fragmentation transverse momenta, $\boldsymbol{k}_{\perp}$ and $\boldsymbol{P}_{\perp}$ respectively, as explicitely given in (2.21).

A qualitative picture of the Sivers function can already be derived from the measured asymmetry amplitudes. The non-zero results shown in fig. 2.3 are obtained with a proton target. As scattering off $u$ quarks dominates these data due to the charge factor, the positive Sivers amplitudes for $\pi^{+}$and $K^{+}$suggest a large and negative Sivers function for up quarks. This is supported by the positive amplitudes of the pion difference asymmetry, which originates mainly from the difference $\left(f_{1 T}^{\perp d_{v}}-4 f_{1 T}^{\perp u_{v}}\right)$ in the Sivers functions for valence down and up quarks and is dominated by the contribution from valence $u$ quarks. The vanishing amplitudes for $\pi^{-}$require cancellation effects, e.g. from a $d$ quark Sivers function opposite in sign to the $u$ quark Sivers function. Such cancellation effects between Sivers functions for up and down quarks are supported by the vanishing asymmetry amplitudes extracted from deuteron data by the COMPASS collaboration. An interesting facet of the data shown in fig. 2.3 is the magnitude of the $K^{+}$amplitudes, which are nearly twice as large as those of the $\pi^{+}$. Again, on the basis of $u$ quark dominance, one might naively expect that the $\pi^{+}$and $K^{+}$amplitudes should be similar. Their difference in size may thus point to a significant role of other quark flavors, e.g. sea quarks.

Phenomenological analyses of HERMES and COMPASS data [327, 328, 329, 330, 331, 332 , confirm the picture drawn above as discussed in the following. So far, only the analysis of Ref. [327] makes use of a subset of the most recent data listed in Tab. 2.2 and all fits have yet to be updated for the results from proton data from COMPASS and the first neutron data from HallA.

Figure 2.3. Sivers amplitudes for $\pi^{+}, K^{+}$and the pion-difference (as denoted in the panels) from HERMES 325 and for $\pi^{+}$and $K^{+}$from COMPASS 323] measured with a proton target. Inner error bars present statistical uncertainties and full error bars the quadratic sum of statistical and systematic uncertainties. Note that the average kinematics in each bin differs for HERMES and COMPASS.

## Phenomenological extractions and models of the Sivers function

The strong impact and success of model calculations and lattice QCD on the TMD field is discussed in detail in sec. 2.4 and sec. 4.1. respectively. Models provide information on the magnitudes and signs of TMDs and guide Ansätze for global fits of TMD parameterizations. For example, from chiral models [333] and the QCD limit of a large number of colours (large $N_{c}$ limit) [334] a Sivers function for up and down quarks of equal size but with opposite $\operatorname{sign}\left(f_{1 T}^{\perp u}=-f_{1 T}^{\perp d}\right)$ is predicted.

Phenomenological analyses provide extractions of TMDs from data. As discussed in sec. 2.1.3, existing analyses of TMD observables are so far based on the parton model approximation, where the measured amplitudes of the SIDIS cross section in Eq. (2.8), are expressed as convolutions of distribution $f^{q}$ and fragmentation functions $D^{q}$. For the Sivers amplitude it reads

$$
\begin{equation*}
F_{U T, T}^{\sin \left(\phi_{h}-\phi_{S}\right)} \propto \sum_{q} e_{q}^{2} f_{1 T}^{\perp q}\left(x, k_{\perp}^{2}\right) \otimes \mathcal{W} D_{1}^{q}\left(z, P_{\perp}^{2}\right) \tag{2.20}
\end{equation*}
$$

where $\otimes \mathcal{W}$ is defined as

$$
\begin{equation*}
\otimes_{\mathcal{W}} \equiv \int d^{2} \boldsymbol{k}_{\perp} d^{2} \boldsymbol{P}_{\perp} \delta^{(2)}\left(z \boldsymbol{k}_{\perp}+\boldsymbol{P}_{\perp}-\boldsymbol{P}_{h T}\right) \mathcal{W} \tag{2.21}
\end{equation*}
$$

with the kinematic factor $\mathcal{W}$ depending on the involved transverse momenta. This convolution can be resolved by either employing a particular model for the transverse momentum

Figure 2.4. Up and down quark Sivers distributions extracted from HERMES (and for the full line also from COMPASS) data using three different parameterizations [329, 330, 331] (see text). The left and right panels show, respectively, the first and the $1 / 2$ moment. The curves indicate the 1 -sigma regions of the various parameterizations. None of three parameterizations makes use of the latest experimental results listed in Tab. 2.2,
dependence or by integrating over the transverse momentum $P_{h T}$ using a proper weight factor in the extraction of the asymmetry amplitudes which involves $P_{h T}$, building for example $2\left\langle\frac{P_{h T}}{M_{p}} \sin \left(\phi_{h}-\phi_{S}\right)\right\rangle_{U T}^{h}$. The latter approach is very attractive but experimentally challenging for measurements at current fixed target facilities as it requires full $P_{h T}$ coverage, which cannot be obtained at any of the existing experiments. An EIC would be the ideal facility to study such weighted asymmetries and to seriously explore the advantages of these observables, as further discussed in sec. 2.2.7.

An intuitive and common Ansatz for the transverse momentum dependence of distribution and fragmentation functions, which provides an analytic solution of (2.21), is a Gaussian distribution like

$$
\begin{equation*}
f_{1 T}^{\perp q}\left(x, k_{\perp}^{2}\right)=f_{1 T}^{\perp q}(x) \frac{1}{\pi\left\langle k_{\perp}^{2}\right\rangle} \exp \left(-\frac{\boldsymbol{k}_{\perp}^{2}}{\left\langle k_{\perp}^{2}\right\rangle}\right), \quad D_{1}^{q}\left(z, P_{\perp}^{2}\right)=D_{1}^{q}(z) \frac{1}{\pi\left\langle P_{\perp}^{2}\right\rangle} \exp \left(-\frac{\boldsymbol{P}_{\perp}^{2}}{\left\langle P_{\perp}^{2}\right\rangle}\right) \tag{2.22}
\end{equation*}
$$

with typical values for $\left\langle k_{\perp}^{2}\right\rangle$ and $\left\langle P_{\perp}^{2}\right\rangle$ of 0.2 to $0.3 \mathrm{GeV}^{2}$.
The Sivers function was among the first to be extracted from data, as it couples to the usual unpolarized fragmentation function $D_{1}^{q}$. This fragmentation function is reasonably well parameterized [335, 336] using precise data from electron-positron annihilation into charged hadrons and, most recently, also from single-hadron production in $p p$ collisions and semi-inclusive DIS [74], which provide complementary information on the flavour dependence of the fragmentation process.

Figure 2.4 shows the extraction of the up and down quark Sivers distributions using three different parameterizations for the Sivers function [329, 330, 331, presenting $k_{\perp}-$ moments defined as

$$
\begin{equation*}
f^{(1)}(x) \equiv \int d^{2} \boldsymbol{k}_{\perp} \frac{\boldsymbol{k}_{\perp}^{2}}{2 M^{2}} f\left(x, k_{\perp}^{2}\right) \quad \text { and } \quad f^{(1 / 2)}(x) \equiv \int d^{2} \boldsymbol{k}_{\perp} \frac{\left|\boldsymbol{k}_{\perp}\right|}{2 M} f\left(x, k_{\perp}^{2}\right) . \tag{2.23}
\end{equation*}
$$

The parameterization from Ref. [329] (full line) is based on a combined fit to previous HERMES and COMPASS data, while the other two fit HERMES data only but describe

Figure 2.5. The Sivers function for $u$ quarks extracted from recent experimental data 327. Vertical lines indicate the region where experimental data are available. The band represents the 2 -sigma range for the chosen parameterization. The dashed blue lines indicate the positivity bound.
the COMPASS data well when using the obtained parameters to calculate the asymmetries for COMPASS kinematics. All three extractions use the parameterization from Ref. [335] for the unpolarized fragmentation function. The two curves of each set indicate the 1-sigma regions of the various parameterizations, taking into account solely statistical uncertainties of the data sets employed in the fit. The three approaches describe the HERMES Sivers asymmetries equally well. The differences in size and shape of the extracted Sivers up and down quark distributions hence reflect the model dependence of the fit results. The parameterization of 331 imposes the constraint from the large $N_{c}$ limit, which results in the symmetric parametrization of up and down Sivers distributions, shown in the left panel of fig. 2.4 with dashed lines. None of the extractions involve parameterizations for sea quarks as they could not be constrained by the data used in the fits.

However, the recent, surprisingly large, Sivers asymmetry amplitudes for $K^{+}$measured by HERMES, which were found to be nearly twice as large as those of the $\pi^{+}$, might hint at a possibly important role of sea quarks. In Ref. [327], the sensitivity of these data to sea quark contributions was tested. A fit including Sivers functions for only up and down quarks was compared with a second fit that allowed also for sea quark contributions ( $\bar{u}, \bar{d}, s, \bar{s}$ ) to the Sivers amplitude. Both fits describe the data with equally good $\chi^{2}$, demonstrating that their precision is not yet good enough to independently constrain the Sivers function for six quark flavours. In this analysis, the usage of new parameterizations of the fragmentation functions from Ref. [74] was essential for obtaining a good description of the kaon data.

The available parameterizations of the Sivers function for up and down quarks 327, [328, 331, 332 agree, within their large uncertainties, with calculations based on a lightcone model 298 and on a diquark spectator model 337, 338, while predictions based on the bag model [339] appear to be too small in magnitude for both the up and down quark Sivers function (see also sec. 2.4).

## Open issues in extractions of the Sivers function

Figure 2.5 illustrates our current knowledge of the Sivers function. So far, only the up and down quark Sivers functions can be constrained with relatively large uncertainties within the range $0.004<x<0.5$ using basic parameterizations for their shapes.

The precision of current data permits neither constraints of the Sivers functions for
sea quarks nor an employment of more flexible functional forms, which would also allow for a sign change as suggested by a spectator model (see fig. 2.22 in sec. 2.4). The band in fig. [2.5 represents the 2 -sigma range for the chosen parameterization and reflects the precision of the data, but does not account for model uncertainties or for variations of the functional form of the parameterizations. Also not estimated so far, is any uncertainty stemming from the Gaussian Ansatz used to resolve the convolution in (2.21). For example, the average value, $\left\langle k_{\perp}^{2}\right\rangle$, of the quark intrinsic transverse momentum used in this Ansatz might be flavour dependent, and both $\left\langle k_{\perp}^{2}\right\rangle$ and $\left\langle P_{\perp}^{2}\right\rangle$ dependent on the energy scale. The latter is particularly relevant for the fragmentation functions, which are extracted from data collected at much higher energy than the available SIDIS asymmetry data used in the fits. The EIC would provide both TMD observables at substantially higher scale than any fixed target DIS experiment and unique data sets of hadron production for a flavour tagging in the fragmentation process and a study of its transverse momentum dependence.

At this stage of analysis, also specific known issues of experimental data are ignored. For example, the limited precision of currently available SIDIS data usually allows only for presenting the results as a function of one kinematic variable while integrating over the others within the experimental acceptance. Hence, the asymmetry amplitudes from a specific experiment, presented for different kinematic variables are correlated. Moreover, the experimental acceptance usually does not provide a full coverage in $P_{h T}$. Thus, the 'unweighthed' asymmetry amplitudes extracted as function of $x$ or $z$ present only partial $P_{h T}$ moments in contrast to theoretical considerations. A fully differential analysis of SIDIS data, which requires high statistic datasets, would resolve these issues.

Turning our essentially qualitative picture of the Sivers function and the related physics into a quantitative description, which goes beyond the tree-level approximation, requires new facilities providing high precision polarized data over a wide kinematic range as discussed in the following section.

### 2.2.2 The Sivers function at the EIC

A systematic and detailed study of the Sivers function, and TMDs in general, can only be performed on the basis of precise spin- and azimuthal-asymmetry amplitude measurements in semi-inclusive DIS over a wide kinematic range. The availability of experimental results that are fully differential in the kinematic variables $x, Q^{2}, z$ and $P_{h T}$ would be a great asset for phenomenological analyses, as they permit testing the underlying perturbative QCD techniques and assumptions. Particle identification over the full momentum range and measurements with both proton and (effective) neutron targets would allow for a full flavour separation of the distribution functions under study.

Planned experiments at the upcoming JLab12 facility aim at providing high precision semi-inclusive DIS data in the valence quark region at relatively low $Q^{2}$, taken with transversely polarized neutrons (HallA) [340, protons and deuterons (CLAS12) 341. The expected high luminosities should allow for fully differential extractions of the relevant azimuthal and transverse-spin asymmetries. The kinematic range of JLab12 experiments will be complementary to COMPASS measurements [342], partially overlap with those of HERMES, and provide data in the so-far unexplored high- $x$ region.

The kinematic coverage of these experiments is compared in fig. 2.6 with the coverage of an EIC for an energy setting of $\sqrt{s}=50 \mathrm{GeV}$. As discussed in sec. 7.1]and sec. [7.2, the ability to vary the energy of both the electron and proton (ion) beams at the EIC provides variable energy in the range $\sqrt{s}=15-65 \mathrm{GeV}$ or $\sqrt{s}=45-200 \mathrm{GeV}$ depending on the realization

Figure 2.6. [color online] Kinematic coverage in $x$ and $Q^{2}$ for the EIC for an energy setting of $\sqrt{s}=50 \mathrm{GeV}$ compared to the coverage of COMPASS, HERMES and future JLab12 experiments represented by the red, purple and black hatched areas, respectively.
options under discussion. This ability puts the EIC in the unique position of accessing the valence region at much larger $Q^{2}$ than current and near-future experiments (thereby suppressing potential higher twist contaminations) while also accessing low $x$ down to values of about $10^{-5}$, where sea quarks and gluons could be studied in detail. The expected high luminosity will allow for a fully differential analysis over almost the whole wide kinematic range. In this section we will illustrate this potential for fully differential analyses of TMD observables and test the sensitivity to sea quark distributions. The unique features of the EIC for access to TMDs for gluons, a study of the evolution properties of TMDs, and of the transition from low to high transverse momenta will be discussed, using the Sivers function as an example, in secs. 2.3, 2.4.2 and 2.2.5, respectively.

## Generation of pseudo-data

The projections presented in the following for the Sivers asymmetry where estimated using either modified existing Monte Carlo generators or standard parameterizations of the unpolarized parton distribution and fragmentation functions. Events were generated for $Q^{2}>1 \mathrm{GeV}^{2}, 0.01<y<0.9$ and $0.1<z<0.9$, over the full kinematically allowed range in $x$. At this stage no cuts were applied on the scattered electron or produced hadron. Events were divided into four-dimensional $\left(x, Q^{2}, z, P_{h T}\right)$ bins and the mean asymmetry in each bin was evaluated. Full acceptance in azimuth was assumed and statistical uncertainties of $\sqrt{2 / N}$ were assigned in each bin. More details about the simulations can be found in 343. For all projections shown in the following, no losses due to detector acceptance were applied, but an overall operational efficiency of $50 \%$ was assumed. The transverse proton beam polarization is set to $70 \%$. No estimate of systematic uncertainties is applied.

Most of the projections will be given for an integrated luminosity of $4 \mathrm{fb}^{-1}$ or $30 \mathrm{fb}^{-1}$. These statistics would be achieved in approximately one week to one month ( $4 \mathrm{fb}^{-1}$ ) or

Figure 2.7. Projected accuracy for $\pi^{+}$production in semi-inclusive DIS off the proton for a particular $P_{h T}$ and $z$ range as indicated in the figure. The position of each point is according to its $Q^{2}$ and $x$ value, within the range $0.05<y<0.9$. The projected event rate, represented by the error bar, is scaled to the (arbitrarily chosen) asymmetry value at the right axis. The blue squares, black triangles and red dots represent the $\sqrt{s}=140 \mathrm{GeV}, \sqrt{s}=50 \mathrm{GeV}$ and $\sqrt{s}=15 \mathrm{GeV}$ EIC configurations, respectively. Event counts correspond to an integrated luminosity of $30 \mathrm{fb}^{-1}$ for each of the three configurations.
one month to six month ( $30 \mathrm{fb}^{-1}$ ) for luminosities ranging from $1 \times 10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ to $3 \times$ $10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. Therefore the statistical precision in the figures presented here should be understood as that achievable in a relatively brief period of operation for an EIC.

## Four-dimensional mapping of the phase space

The great potential of the EIC for obtaining a fully differential mapping of almost the entire phase space relevant for TMD studies is illustrated in figs. 2.7 and 2.8. A wide $x$ and $Q^{2}$ range can be mapped using different beam energies. The projected accuracy for single $\pi^{+}$production is given for a four-dimensional binning in the kinematic variables $x$, $Q^{2}, z$ and $P_{h T}$, using three different energy configurations for the EIC $(\sqrt{s}=15,50$ and 140 GeV ) and an integrated luminosity of $30 \mathrm{fb}^{-1}$ for each configuration. Events are selected for $0.05<y<0.9$ and $W^{2}>5 \mathrm{GeV}^{2}$. For a clearer view and explanation of the presented projections, we show in fig. 2.7 one of the panels from fig. 2.8 corresponding to a specific $z$ and $P_{h T}$ range. In both figures, the position of each point is according to its $x$ and $Q^{2}$ value (abscissa and left ordinate, respectively) and each panel is for a specific $z$ and $P_{h T}$ bin as indicated in the figure. The projected event rate is represented by the error bar scaled with respect to the (arbitrarily chosen) asymmetry value given at the right ordinate.

The simulations demonstrate that a four-dimensional mapping of TMD observables for pions over the whole phase space of main interest, meaning $P_{h T}$ values of up to about 1 GeV , could be achieved in about 3-5 month of running for each energy configuration. Kaon rates

Figure 2.8. Four-dimensional representation of the projected accuracy for $\pi^{+}$production in semiinclusive DIS off the proton. Each panel corresponds to a specific $z$ bin with increasing value from left to right and a specific $P_{h T}$ bin with increasing value from top to bottom, with values given in the figure. The position of each point is according to its $Q^{2}$ and $x$ value, within the range $0.05<y<0.9$. The projected event rate, represented by the error bar, is scaled to the (arbitrarily chosen) asymmetry value at the right axis. Blue squares, black triangles and red dots represent the $\sqrt{s}=140 \mathrm{GeV}, \sqrt{s}=50 \mathrm{GeV}$ and $\sqrt{s}=15 \mathrm{GeV}$ EIC configurations, respectively. Event counts correspond to an integrated luminosity of $30 \mathrm{fb}^{-1}$ for each of the three configurations.
are typically a factor $4-5$ lower than those for pions and a similar quality of data can be achieved within a correspondingly longer running time.

The strategy for a full flavour separation of the Sivers distribution, and TMD distributions in general, involves both pion and kaon identification over almost the whole momentum range and measurements with proton and effective neutron targets. For the latter, the usage of polarized ${ }^{3} \mathrm{He}$ ions is foreseen for both EIC concepts. Compared to the projections shown in fig. [2.8, the dilution factor of $1 / 3$ has to be compensated with higher luminosities (respectively longer running times). The resulting different phase space for the neutron measurements compared with the proton case due to the $Z / A$ factor entering the momentum distribution and the expected lower center-of-mass energy (by about $2 / 3$ ) because of the different rigidities of the beams can be compensated to a large extent by using the different beam energy settings.

In addition, valuable and necessary information about the transverse momentum dependence of the fragmentation process will be obtained from the same data using a fully differential extraction of the individual hadron multiplicities.

## Sensitivity to sea quarks

Among the unique features of the EIC is its sensitivity for an exploration of the Sivers function for sea quarks, which are expected to play an important role in the lower $x$ region.

Figure 2.9. Simulated Sivers asymmetry amplitudes for $\pi^{+}$, obtained with an energy of $\sqrt{s}=140$ GeV , as a function of $x$ in bins in $z, P_{h T}$ and for a single bin in $Q^{2}$ as given in the panels. Closed blue (open black) dots correspond to (non-)zero Sivers functions for sea quarks. Error bars represent the projected accuracy corresponding to an integrated luminosity of $4 \mathrm{fb}^{-1}$.

We investigate this sensitivity by generating two sets of events, one with and one without contributions from sea quarks. As the Sivers distribution is essentially unknown, it was parameterized via a constant multiplied by the unpolarized PDF with independent constants for $u, d$ and sea quarks. The Sivers asymmetry is returned by the generator on an event-by-event basis. The unpolarized PDFs of [82] and the fragmentation functions of [74] were used.

In both cases, the same parameterization for up and down quark Sivers functions was used, which were set equal to $25 \%$ of the unpolarized distribution, but with opposite sign, i.e. $f_{1 T}^{\perp u}(x)=-0.25 f_{1}^{u}(x)$ and $f_{1 T}^{\perp d}(x)=0.25 f_{1}^{d}(x)$. In the first data set, the Sivers functions for sea quarks were also set to $25 \%$ of the corresponding unpolarized distribution. In the second data set the sea quark Sivers distributions were fixed to zero. This allowed for a comparison of the case in which the sea quark Sivers function was significant compared to that of the valence quarks with the case of a vanishing sea quark contribution.

Figure 2.9shows the asymmetry amplitudes for $\pi^{+}$, obtained with an energy of $\sqrt{s}=140$ GeV , for a single bin in $Q^{2}$ as a function of $x$, binned in $z$ and $P_{h T}$ as indicated in the panels. Open black dots represent the case of non-zero Sivers functions for sea quarks and closed blue dots the case of vanishing contributions. Error bars correspond to an integrated luminosity of $4 \mathrm{fb}^{-1}$, already yielding sufficient precision to resolve small resulting differences in the asymmetry. Because of their different quark content, kaon production is expected to have a higher sensitivity to sea quark contributions. Figure 2.10 shows the asymmetry amplitudes

Figure 2.10. Simulated Sivers asymmetry amplitudes for $K^{+}$, obtained with an energy of $\sqrt{s}=140$ GeV , as a function of $x$ in bins in $z, P_{h T}$ and for a single bin in $Q^{2}$ as given in the panels. Closed blue (open black) dots correspond to (non-)zero Sivers functions for sea quarks. Error bars represent the projected accuracy corresponding to an integrated luminosity of $4 \mathrm{fb}^{-1}$.
for $K^{+}$where indeed both scenarios are more distinct. As for $\pi^{+}$, the estimate is based on an integrated luminosity of $4 \mathrm{fb}^{-1}$ and obtained with an energy of $\sqrt{s}=140 \mathrm{GeV}$.

The study demonstrates that even a relatively brief running of the EIC provides the potential to distinguish zero and non-zero Sivers functions for sea quarks. Note that these parameterizations are intended not as a prediction of what asymmetries will actually be seen at an EIC, but as an indicator of sensitivity given the expected statistical precision.

## Impact of the EIC

The EIC will be the unique facility for exploring the Sivers function (and TMDs in general) for sea quarks and the gluon, to study the evolution properties of TMD distributions and to investigate experimentally the transition from low to high transverse momenta. As discussed in sec. 2.2.1, our current knowledge is restricted to an essentially qualitative picture of the Sivers function. Available data permit to constrain parameterizations for up and down quarks only, employing relatively simple functional forms.

We illustrate the expected impact of data from the EIC using the parameterization from Ref. [327] as an arbitrarily chosen model of the Sivers function. This parameterization, denoted theor ${ }_{i}=F\left(x_{i}, z_{i}, P_{h T}^{i}, Q_{i}^{2} ; \mathbf{a}_{\mathbf{0}}\right)$ with the $M$ parameters $\mathbf{a}_{\mathbf{0}}=\left\{a_{1}^{0}, \ldots, a_{M}^{0}\right\}$ fitted to

Figure 2.11. [color online] Comparison of the precision (2- $\sigma$ uncertainty) of extractions of the Sivers function for $u$ quarks (left) and $d$ quarks (right) from currently available data [327] (grey band) and from pseudo-data generated for the EIC with energy setting of $\sqrt{s}=45 \mathrm{GeV}$ and an integrated luminosity of $4 \mathrm{fb}^{-1}$ (dark grey band around the red line). The uncertainty estimates are for the specifically chosen underlying functional form (see text for details).
existing data, serves to generate a set of pseudo-data in each kinematic bin $i$

$$
\begin{equation*}
f\left(\text { value }_{i} ; \text { theor }_{i}, \sigma_{i}^{2}\right)=\frac{1}{\sqrt{2 \pi \sigma_{i}^{2}}} e^{-\left(\text {value }_{i}-\text { theor }_{i}\right)^{2} / 2 \sigma_{i}^{2}} \tag{2.24}
\end{equation*}
$$

In each $x_{i}, Q_{i}^{2}, z_{i}$ and $P_{h T}^{i}$ bin, the obtained values, value ${ }_{i}$, for the Sivers function are distributed using a Gaussian smearing with a width $\sigma_{i}$ corresponding to the simulated event rate at an energy of $\sqrt{s}=45 \mathrm{GeV}$ obtained with an integrated luminosity of $4 \mathrm{fb}^{-1}$. For illustration of the obtainable statistical precision the event rate for the production of $\pi^{+}$in semi-inclusive DIS was used.

This new set of pseudo-data was then analysed like the real data in Ref. [327]. Figure 2.11 shows the result for the extraction of the Sivers function for $u$ and $d$ quarks. The central value of $f_{1 T}^{\perp u}$, represented by the red line, follows by construction the underlying model. The 2-sigma uncertainty of this extraction, valid for the specifically chosen functional form, is indicated by the dark grey area, which is hardly seen around the red line. This precision, obtainable with an integrated luminosity of $4 \mathrm{fb}^{-1}$, is compared with the uncertainty of the extraction from existing data, represented by the light grey band and shown before in fig. 2.5.

Remembering that the event rate of the generated pseudo-data is achievable in a brief period of operation for an EIC, the impressive impact of the EIC on studies of TMDs is greatly illustrated.

### 2.2.3 TMDs in Drell-Yan processes

One of the intriguing facets of the Sivers effect is its peculiar breaking of universality, as discussed in secs. 2.1.4 and 2.4. The symmetry properties of QCD require a reversal of sign of the Sivers function when appearing in the Drell-Yan process, the production of dilepton pairs in the collision of two hadrons, as compared to DIS. The important test of this fundamental QCD prediction remains outstanding, its invalidation would have profound consequences for our understanding of high-energy reactions involving hadrons. It is thus

Figure 2.12. The correlation of the quark and antiquark momentum fractions, $x_{1}$ and $x_{2}$, in DrellYan for different rapidity bins in proton-proton collisions at $\sqrt{s}=500 \mathrm{GeV}$.
not surprising to see the Drell-Yan process appear as a milestone measurement in the update for the future spin program at RHIC [344.

The Drell-Yan process with unpolarized hadrons has been studied at numerous fixedtarget experiments [345, 346, 347, 348, 349. There are several proposals for future polarized Drell-Yan measurements, either at fixed-target experiments (CERN, FermiLab, GSI, and J-Parc), but also at colliders (BNL, GSI). So far no measurement exists for Drell-Yan with transverse hadron polarization to isolate the Sivers effect, unlike the case for the related mechanism of the Boer-Mulders function. Being a naive-T-odd distribution the latter also involves a reversal of sign when going from DIS to Drell-Yan. For the BoerMulders function data from the Drell-Yan process exist. In particular the violation of the Lam-Tung relation [350 is a substantial hint of the Boer-Mulders effect, as discussed in sec. 2.5.2. However, being also a chiral-odd distribution, presents an additional challenge for experimental measurements and their interpretation, given that a second, presently poorly constrained, chiral-odd function is needed. In the case of Drell-Yan the other chiralodd function is a second Boer-Mulders function, making it especially tricky to look for the sign change between Drell-Yan and DIS.

Among the proposed measurements of the Sivers effect in Drell-Yan two have timescales of a few years from now. One is an experiment set at IP2 of RHIC (BNL) where transversely polarized "beam" protons will interact with effectively unpolarized "target" protons1 344]. At the COMPASS experiment at CERN it is not the beam-in this case consisting of pions - that will be polarized but the target [342]. This configuration is the theoretically more challenging one of the two as the partonic structure of the pion enters besides the structure of the proton.

The choice of measuring Drell-Yan single-spin asymmetries at a collider like RHIC has various advantages. Among others, the asymmetries depend only weakly on the partonic momentum $x_{2}$ of the (anti)quark in the unpolarized nucleon. When integrated over $x_{2}$ the cross section increases with the center-of-mass energy $\sqrt{s}$ as one can reach lower values of $x_{2}$ where anti-quarks are more abundant. Furthermore, it is easier to differentiate between "forward" and "backward" production at a collider allowing easy access to the valence region of the (transversely polarized) beam nucleon. In fig. 2.12, we show the correlation of the quark and antiquark momentum fractions, $x_{1}$ and $x_{2}$, in the Drell-Yan (DY) process

[^270]

Figure 2.13. Sivers asymmetries for the Drell-Yan process at RHIC, as a function rapidity for $\sqrt{s}=500 \mathrm{GeV} 351$.
for different rapidity bins in proton-proton collisions at $\sqrt{s}=500 \mathrm{GeV}$. The plot assumes an invariant mass range of the DY lepton pair between the $J / \psi$ and the Upsilon. To select DY at masses below the $J / \psi$ and/or at rapidities below 2.0 will be experimentally extremely challenging due to the dominance of the QCD $2 \rightarrow 2$ processes $\left(>10^{8}\right)$. The expected single-spin asymmetry, $A_{N}$, is presented in fig. 2.13 as a function of rapidity, $y$, for $\sqrt{s}=500 \mathrm{GeV}$ and integrated over the range $4 \div 9 \mathrm{GeV}$ in the invariant mass of the di-lepton pair [351]. The estimate makes use of a recent "DIS" Sivers function parameterization from fits to COMPASS and HERMES data 332. Asymmetries of this size should be readily measurable with a limited data set. Nevertheless, one should keep in mind that the change of sign applies to the flavor-dependent Sivers function. For a stringent test of this sign change it is therefore of utter importance not only to measure the Sivers effect in DIS and Drell-Yan, but to perform a flavor-decomposition of the Sivers effect as well. In $p p$ collisions one will be mainly sensitive to the $u$-quark Sivers function due to the charge factor. Using pion beams one can vary the sensitivity to the various quark flavors via the choice of the pion charge as the valence anti-quark flavor in the pion will either be an anti- $u$ or an anti- $d$. This will help in a subsequent flavor decomposition of the Sivers effect in Drell-Yan.

### 2.2.4 Single-spin asymmetry in the collinear factorization: Twist-three mechanism

The quark Sivers function discussed in the last subsection is also closely related to the twist-3 quark-gluon-quark correlation functions in the collinear factorization approach which can generate large single spin asymmetries in hard scattering process, in particular, in inclusive hadron production in $p p$ collisions. The single-transverse spin asymmetry in the process like $p p \rightarrow \pi X$ is among the simplest spin observables in hadronic scattering. One scatters a beam of transversely polarized protons off unpolarized protons and measures the numbers of pions produced to either the left or the right of the plane spanned by the momentum and spin directions of the initial polarized protons. Measurements of single-spin asymmetries in hadronic scattering experiments over the past three decades have shown spectacular results. Large asymmetries of up to several tens of percents were observed at forward (with respect to the polarized initial beam) angles of the produced pion. Despite the
conceptual simplicity of $A_{N}$, the theoretical analysis of single-spin asymmetries in hadronic scattering is remarkably complex. The reason for this is that the asymmetry for a singleinclusive reaction like $p p \rightarrow \pi X$ is power-suppressed as $1 / \ell_{\perp}$ in the hard scale set by the observed large pion transverse momentum. Power-suppressed contributions to hardscattering processes are generally much harder to describe in QCD than leading-twist ones. In the case of the single-spin asymmetry, a complete and consistent framework could be developed [286, 288, 289, 352]. It is based on a collinear factorization theorem at nonleading twist that relates the single-spin cross section to convolutions of twist-three quarkgluon correlation functions for the polarized proton with the usual parton distributions for the unpolarized proton and the pion fragmentation functions, and with hard-scattering functions calculated from an interference of two partonic scattering amplitudes: one with a two-parton initial state and the other with a three-parton initial state.

In the following, we briefly describe the collinear factorization formalism for the twist3 single-spin-dependent cross section in the semi-inclusive deep inelastic scattering, ep $\rightarrow$ $e h X$. This factorization applies when the transverse momentum of the final state hadron is large compared to the non-perturbative scale $\Lambda_{\mathrm{QCD}}$. The usual leading twist spin-average cross section for this process can be schematically written as

$$
\begin{equation*}
d \sigma \sim \sum_{a, b} f_{a}(x, \mu) \otimes D_{h / b}(z, \mu) \otimes \hat{\sigma}^{a b}(x, z, Q, \mu), \tag{2.25}
\end{equation*}
$$

where $f_{a}(x, \mu)$ and $D_{h / b}(z, \mu)(a, b=q, \bar{q}, g)$ are, respectively, the parton density in the nucleon and the fragmentation function for $b \rightarrow h$, convoluted with the hart part $\hat{\sigma}^{a b}$. The twist-3 cross section relevant for SSA in $e p^{\uparrow} \rightarrow e h X$ takes the factorized form,

$$
\begin{align*}
d \sigma^{\mathrm{tw} 3} & \sim \sum_{a, b} G_{a}^{(3)}\left(x_{1}, x_{2}, \mu\right) \otimes D_{h / b}(z, \mu) \otimes \hat{\sigma}_{1}^{a b}\left(x_{1}, x_{2}, z, Q, \mu\right) \\
& +\sum_{a, b} \delta f_{a}(x, \mu) \otimes D_{h / b}^{(3)}\left(z_{1}, z_{2}, \mu\right) \otimes \hat{\sigma}_{2}^{a b}\left(x, z_{1}, z_{2}, Q, \mu\right) \tag{2.26}
\end{align*}
$$

where $\otimes$ represents the appropriate convolution, similarly as the twist-2 factorization formula (2.25), with the relevant momentum fractions $x_{1,2}, z, x, z_{1,2}$ integrated over. $G_{a}^{(3)}\left(x_{1}, x_{2}, \mu\right)$ is the twist-3 distribution function in the transversely-polarized nucleon $p^{\uparrow}$, and $D_{h / b}^{(3)}\left(z_{1}, z_{2}, \mu\right)$ is the twist-3 fragmentation function for the hadron $h$; the latter function is chiral-odd, combined with the chiral-odd transversity distribution $\delta f_{a}(x, \mu)$ for $p^{\uparrow}$. (In the TMD approach, the first term in (2.26) is described in terms of the Sivers function, and the second term is described using the Collins function.) These twist-3 distribution and fragmentation functions describe the multi-parton correlations in the nucleon and in the fragmentation process, respectively, and thus provides us with an opportunity to reveal the more detailed internal structure of hadrons beyond the parton-model picture. Each twist-3 function has its own logarithmic scale dependence, which differs from that of the twist-2 functions; for the corresponding $\mu$-dependence, see section (2.4.3).

For $G_{a}^{(3)}\left(x_{1}, x_{2}, \mu\right)$ with $a=q$ in (2.26), two independent quark-gluon correlation functions, $G_{F}\left(x_{1}, x_{2}\right)$ and $\widetilde{G}_{F}\left(x_{1}, x_{2}\right)$, participate. They are defined as dimensionless, real, Lorentz-scalar functions in terms of nucleon matrix element associated with the gluon field strength tensor $F^{\alpha \beta}$ as well as the quark field $\psi$ on the light-cone 352, 353. Similarly, the twist-3 purely gluonic correlation functions $O\left(x_{1}, x_{2}\right)$ and $N\left(x_{1}, x_{2}\right)$ as $G_{g}^{(3)}\left(x_{1}, x_{2}, \mu\right)$ in (2.26), are defined through the gauge-invariant lightcone correlation of three field-strength
tensors [354. Thus, a complete set of the twist-3 correlation functions in the transverselypolarized nucleon is now provided by $G_{F}\left(x_{1}, x_{2}\right), \widetilde{G}_{F}\left(x_{1}, x_{2}\right), O\left(x_{1}, x_{2}\right)$ and $N\left(x_{1}, x_{2}\right)$, taking into account all symmetry constraints in QCD. We note that the twist-3 correlation functions, $T_{F}\left(x_{1}, x_{2}\right), T_{G}^{(f, d)}(x, x)$, etc., used in the literature [355, 356, 357] can be expressed by the above correlation functions.

Another origin of SSA is in the fragmentation process for the final hadron, as represented in terms of the twist-3 fragmentation function $D_{h / b}^{(3)}\left(z_{1}, z_{2}, \mu\right)$ of (2.26), which is also defined as a multi-parton light-cone correlation function (see [297]).

For SIDIS, ep $\rightarrow e h X$, the large transverse-momentum $P_{h T}$ of the hadron $h$ should come from a perturbative mechanism, i.e. from the recoil from the hard (unobserved) final-state partons. Then, the factorization formula (2.26) is derived in the LO perturbative QCD, manifesting their gauge invariance at the twist-3 level, and a practical procedure to calculate the relevant partonic hard part $\hat{\sigma}_{i}^{a b}$ is provided in [352, 354, 297]: an extra gluon, which emanates from nonperturbative multi-parton correlation and carries the momentum fraction $x_{2}-x_{1}$, participates in the partonic hard scattering. The coupling of this gluon allows an internal propagator in the partonic subprocess to be on-shell, and this produces the required imaginary phase. The results for those partonic subprocesses imply [352, 358, 359,

$$
\begin{aligned}
& \frac{d^{5} \sigma^{\mathrm{tw} 3}}{d x_{B} d Q^{2} d z_{h} d P_{h T}^{2} d \phi_{h}}=\sin \left(\phi_{h}-\phi_{S}\right) F^{\sin \left(\phi_{h}-\phi_{S}\right)}+\sin \left(2 \phi_{h}-\phi_{S}\right) F^{\sin \left(2 \phi_{h}-\phi_{S}\right)} \\
&\left.\quad+\sin \phi_{S} F^{\sin \phi_{S}}+\sin \left(3 \phi_{h}-\phi_{S}\right) F^{\sin \left(3 \phi_{h}-\phi_{S}\right)}+\sin \left(\phi_{h}+\phi_{S}\right) F^{\sin \left(\phi_{h}+\phi_{\phi} \phi_{2}\right.}, 27\right)
\end{aligned}
$$

with the azimuthal angles $\phi_{h}$ and $\phi_{S}$ of $P_{h T}$ and $S_{\perp}$, respectively, measured from the lepton plane; the five azimuthal dependences in (2.26) are similar as those in the TMD approach. Here, each structure function $F^{\sin (\cdots)}$ is expressed in a factorized form, convoluted with $G_{F}(x, x)$ and $d G_{F}(x, x) / d x$. The similar twist-3 effects from $G_{F}$ and $\widetilde{G}_{F}$ have been investigated for SSA in Drell-Yan and direct photon productions, and hadron production in $p p$ collisions.

Charm production in SIDIS and $p p$ collisions is useful to study the twist-2 gluon distributions in the nucleon, since the $c \bar{c}$-pair creation through the photon-gluon or gluon-gluon fusion is their driving subprocess. Likewise, the three-gluon correlation functions can be probed by SSA in these processes. From this point of view, the three-gluon contribution to SSA in $D$-meson production processes, $e p^{\uparrow} \rightarrow e D X$ and $p^{\uparrow} p \rightarrow D X$, have been studied in [356, 357, 354, 360]. For both processes, the twist-3 cross sections for SSA can be derived entirely as the gluonic pole contribution leading to $x_{1}=x_{2}$, and thus receive the contributions $O(x, x), O(x, 0), N(x, x)$ and $N(x, 0)$ (and their derivatives) 354, 360]. The result for $e p^{\uparrow} \rightarrow e D X$ has five azimuthal dependences like in (2.27) [354].

So far, RHIC at BNL reported a significant amount of data of $A_{N}$ for $p^{\uparrow} p \rightarrow h X$ ( $h=\pi, K, \eta, D, J / \Psi)$. Given that the NLO QCD in collinear factorization can provide a reasonable description of the corresponding unpolarized cross section, we expect that one can apply the above twist-3 formalism to analyze the $A_{N}$ data [289, 355, 361]. The complete LO QCD formula for $A_{N}$ from the twist-3 quark-gluon correlation functions to $p^{\uparrow} p \rightarrow h X$ has been derived: It consists of the contribution associated with $G_{F}(x, x)$ and $d G_{F}(x, x) / d x\left(\widetilde{G}_{F}(x, x)=0\right)$ 355, and the contribution 362 associated with $G_{F}(x, 0)$ and $\widetilde{G}_{F}(x, 0)$. Phenomenological analysis of RHIC data shows that both contributions are important, although the main contribution comes from the $G_{F}(x, x)$ contribution [289, 355], the $G_{F}(x, 0)\left(\widetilde{G}_{F}(x, 0)\right)$ contribution also plays an important role, and the combination of both contributions provides a reasonable description of the RHIC data, shedding light on

Figure 2.14. Left: kinematics for $D$-meson events showing the momentum vs. polar angle distribution for the electron and $D$ (or equivalently $\bar{D}$ ) meson in the laboratory frame. Right: Projected accuracy for transverse single-spin asymmetries from single $D$ meson production using an energy of $\sqrt{s}=50 \mathrm{GeV}$ and an integrated luminosity of $370 \mathrm{fb}^{-1}$.
the behavior of $G_{F}$ and $\widetilde{G}_{F}$ 361. There are also some initial efforts to calculate the twist-3 fragmentation contribution to $A_{N}$ 363. Global analysis of RHIC and future EIC data is expected to reveal more details on the role of the multi-parton correlations, including the three-gluon correlation functions.

The potential of the EIC for measuring transverse single-spin asymmetries in charm production is illustrated in fig. 2.14. In the simulation, based on the PYTHIA event generator, the main decay channel for $D$ mesons, $D \rightarrow \pi^{+} K^{-}$, with a branching ratio of $3.8 \pm 0.1 \%$ is investigated. Events are selected for $P_{h T}>1 \mathrm{GeV}$ and $Q^{2}>1 \mathrm{GeV}$ within $0.05<y<0.9$ and $1.86<M_{D}<1.87$. The signal-to-background ratio for the reconstructed $D$ mesons strongly depends on the detector resolution. In this study, we assume a momentum resolution of $0.8 \% \cdot \frac{p}{10 \mathrm{GeV}}$ and a resolution of the polar and azimuthal angles of 0.3 mrad and 1 mrad , respectively. The resulting resolution of the reconstructed invariant mass of the $D$ meson is 1.8 MeV yielding an overall signal-to-background ratio of about 1.6 to 1 . The overall detection efficiency for this triple coincidence process is assumed to be $60 \%$. The polarization of the proton beam is set to $80 \%$.

The projected accuracy for measuring transverse single-spin asymmetries in single $D$ meson production is shown in fig. 2.14 (right) as a function of $z$ for different regions in $Q^{2}$, $x$ and $P_{h T}$, as indicated in the figure, together with model calculations of the asymmetry from Ref. [356]. An energy of $\sqrt{s}=50 \mathrm{GeV}$ and an integrated luminosity of $370 \mathrm{fb}^{-1}$ were used. The study demonstrates a very promising feasibility of extracting observables involving charm production. It will significantly benefit from higher energies up to $\sqrt{s}=200$ GeV .

In summary, the twist-3 collinear factorization framework provides us with a systematic way for describing SSA in the region of large transverse-momentum $P_{h T}$ of the final hadron, and is thus complementary to the TMD description of SSA which is valid in the low $P_{h T}$ region. For the twist-3 distribution functions in the transversely-polarized nucleon, relevant to SSA, there are two independent quark-gluon correlation functions and the two indepen-
dent three-gluon correlation functions, all of which are process-independent. Twist-3 cross section formulae for SSA are available for many important processes, which can be used for confronting with the RHIC and EIC data and may serve to reveal multi-parton correlation effects in QCD hard processes.

### 2.2.5 Unifying the Mechanisms for the Sivers effect

Recent developments have shown that the TMD approach and the collinear factorization approach can be unified to describe the Sivers effect for the single transverse-spin asymmetries in semi-inclusive DIS. The TMD approach covers the kinematic region $P_{h T} \ll Q$ where $Q \gg \Lambda_{\mathrm{QCD}}$, while the twist-3 approach covers the large $P_{h T}$ region, $P_{h T} \gg \Lambda_{\mathrm{QCD}}$. A natural question here is whether the two mechanisms give rise to equivalent (or consistent) SSA in the overlapping region, $\Lambda_{\mathrm{QCD}} \ll P_{h T} \ll Q$. To address this issue, we first recall the relation between the Sivers function $f_{1 T}^{\perp}\left(x, k_{\perp}\right)$ and the quark-gluon correlation function $G_{F}(x, x)$ [364: $\int d \boldsymbol{k}_{\perp}^{2} \boldsymbol{k}_{\perp}^{2} f_{1 T}^{\perp}\left(x, k_{\perp}\right)=\pi M_{N}^{2} G_{F}(x, x)$, which indicates that the two mechanisms are closely related.

A more explicit relation for the SSA in the two approaches has also been derived for the Sivers cross section, $F^{\sin \left(\phi_{h}-\phi_{S}\right)}$ in (2.27) 292, 294, 295): In the TMD approach, $F^{\sin \left(\phi_{h}-\phi_{S}\right)}$ is expressed in terms of the Sivers function $f_{1 T}^{\perp}\left(x, k_{\perp}\right)$. In the large $k_{\perp}$-region, relevant to $\Lambda_{\mathrm{QCD}} \ll P_{h T} \ll Q$, the $k_{\perp}$-dependence of $f_{1 T}^{\perp}\left(x, k_{\perp}\right)$ can be generated perturbatively, such that $f_{1 T}^{\perp}\left(x, k_{\perp}\right)$ is expressed as the convolution of the corresponding perturbative coefficient functions with the nonperturbative correlation functions $G_{F}$ and $\widetilde{G}_{F}$. By inserting this form of $f_{1 T}^{\perp}\left(x, k_{\perp}\right)$ into the TMD factorization formula for $F^{\sin \left(\phi_{h}-\phi_{S}\right)}$, one obtains the cross section written in terms of $G_{F}$ and $\widetilde{G}_{F}$, and this expression turns out to be identical to the leading $P_{h T}$ behavior of the twist-3 mechanism for $F^{\sin \left(\phi_{h}-\phi_{S}\right)}$ in the overlap region $\Lambda_{\mathrm{QCD}} \ll P_{h T} \ll Q$. From these studies, the two mechanisms for single-spin asymmetries represent a unique QCD effect over the entire $P_{h T}$ region. The same equivalence was also shown for the SSA in the Drell-Yan process. It should be noted that the sign of the Sivers function changes from SIDIS to the Drell-Yan case, while the twist-3 quark-gluon correlation functions are process-independent. The connection between the two mechanisms is also consistent with such process-(in)dependence [293].

The contribution from the twist-3 fragmentation function in (2.26) gives rise to the structure function $F^{\sin \left(\phi_{h}+\phi_{S}\right)}$ in (2.27), and dominates the leading $P_{h T}$ behavior of $F^{\sin \left(\phi_{h}+\phi_{S}\right)}$ compared to that from the quark-gluon correlation functions. This leading $P_{h T}$ behavior in $F^{\sin \left(\phi_{h}+\phi_{S}\right)}$ turns out to be identical to the corresponding contribution from the Collins function in the TMD approach, similarly as the above equivalence for $F^{\sin \left(\phi_{h}-\phi_{S}\right)}$ [297].

These are nontrivial and important results, which demonstrate that we indeed have a unique picture for single transverse-spin asymmetries in DIS and hadronic collisions. The discussion can be further generalized to other structure functions in SIDIS as well.

To analyze the general power behavior of the structure functions, it is important to realize that the power expansions are done in two different ways in the above two descriptions. At low $q_{T}$, first we expand in $\left(q_{T} / Q\right)^{n-2}$ and neglect terms with $n$ bigger than a certain value (so far, analyses have been carried out only up to $n=3$, i.e., twist- 3 ). To study the behavior at intermediate $q_{T}$ we further expand in $\left(M / q_{T}\right)^{k}$. Vice versa, at high $q_{T}$ we first expand in $\left(M / q_{T}\right)^{n}$ (also in this case, analyses are available up to $n=3$, i.e., twist-3). To study the intermediate- $q_{T}$ region, we further expand in $\left(q_{T} / Q\right)^{k-2}$. We can encounter two different situations:

- Type-I observables, where the leading terms at high and low transverse momentum have the same behavior. For instance,

$$
\begin{equation*}
F\left(q_{T}, Q\right)=A\left[\frac{q_{T}}{Q}\right]^{0}\left[\frac{M}{q_{T}}\right]^{2}+B\left[\frac{q_{T}}{Q}\right]^{2}\left[\frac{M}{q_{T}}\right]^{2}+\ldots \tag{2.28}
\end{equation*}
$$

where the term $A$ is leading in both the low- and high- $q_{T}$ calculations. In this case, the calculations at high and low transverse momentum must yield exactly the same result at intermediate transverse momentum [273, 292. If a mismatch occurs, it means that one of the calculations is incorrect or incomplete.

- Type-II observables, where the leading terms at high and low transverse momentum have different behavior. For instance,

$$
\begin{equation*}
F\left(q_{T}, Q\right)=A^{\prime}\left[\frac{q_{T}}{Q}\right]^{0}\left[\frac{M}{q_{T}}\right]^{4}+B^{\prime}\left[\frac{q_{T}}{Q}\right]^{2}\left[\frac{M}{q_{T}}\right]^{2}+\ldots \tag{2.29}
\end{equation*}
$$

where the first term is leading and the second term sub-leading in the low- $q_{T}$ calculation, whereas the reverse holds in the high- $q_{T}$ calculation. In this case, if the calculations at high and low transverse momentum are performed at their respective leading order, they describe two different mechanisms and will not lead to the same result at intermediate transverse momentum. In order to "match", the calculations should be carried out in both regimes up to the sub-subleading order. We could call this situation an "expected mismatch", since it is simply due to the difference between the two expansions.

In Tab. 2.3 we list the power behavior of the structure functions at intermediate transverse momentum, as obtained from the limits of the low- $q_{T}$ and high $-q_{T}$ calculation. For details of the calculation, we refer to [296]. The structure functions with a "yes" or "no" in the last column of Tab. 2.3 are type-I observables, where on the basis of power counting we know that two calculations describe the same physics and should therefore exactly match. In these cases, the high $q_{T}$ calculation describes the perturbative tail of the low- $q_{T}$ effect. The two mechanisms need not be distinguished. Using resummation it should be possible to construct expressions for these observables that are valid at any $q_{T}$. Six of these structure functions have been calculated explicitly.

For the functions identified as type-II in the last column of Tab. 2.3, the low $-q_{T}$ and high- $q_{T}$ calculations at leading order pick up two different components of the full structure function. They therefore describe two different mechanisms and do not match. For such type-II observables, if one aims at studying the leading-twist contribution from transverse momentum distributions, some considerations have to be kept in mind:

- the leading contribution from the high- $q_{T}$ calculation (often referred to as a pQCD or radiative correction) is a competing effect that has to be taken into account 365, 366, 367];
- $q_{T}$-weighted asymmetries enhance the high- $q_{T}$ mechanism and thus are not appropriate to extract type-II TMDs;
- it is at present impossible to construct an expression that extends the high- $q_{T}$ calculation to $q_{T} \approx M$, since this requires a smooth merging into unknown twist- 4 contributions, which most probably cannot be factorized (see also Ref. [368]);

| structure function | low- $q_{T}$ <br> power | high- $q_{T}$ <br> power | exact <br> match | structure <br> function | low- $q_{T}$ <br> power | high- $q_{T}$ <br> power | exact <br> match |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $F_{U U, T}$ | $1 / q_{T}^{2}$ | $1 / q_{T}^{2}$ | yes | $F_{U T, T}^{\sin \left(\phi_{h}-\phi_{S}\right)}$ | $1 / q_{T}^{3}$ | $1 / q_{T}^{3}$ | yes |
| $F_{U U}^{\cos 2 \phi_{h}}$ | $1 / q_{T}^{4}$ | $1 / Q^{2}$ | type II | $F_{U T}^{\sin \left(\phi_{h}+\phi_{S}\right)}$ | $1 / q_{T}^{3}$ | $1 / q_{T}^{3}$ | yes |
| $F_{U L}^{\sin 2 \phi_{h}}$ | $1 / q_{T}^{4}$ |  | (type II) | $F_{U T}^{\sin \left(3 \phi_{h}-\phi_{S}\right)}$ | $1 / q_{T}^{3}$ | $1 /\left(Q^{2} q_{T}\right)$ | type II |
| $F_{L L}$ | $1 / q_{T}^{2}$ | $1 / q_{T}^{2}$ | yes | $F_{L T}^{\cos \left(\phi_{h}-\phi_{S}\right)}$ | $1 / q_{T}^{3}$ |  | (yes) |

Table 2.3. Behavior of SIDIS structure functions in the region $M \ll q_{T} \ll Q$, as deduced from the low- $q_{T}$ calculation based on TMD factorization and the high- $q_{T}$ calculation based on collinear factorization. Empty fields indicate that no calculation is available. The last column indicates whether the expressions match exactly, do not match exactly, or should not be expected to match. In parentheses: expected answers based on analogy, rather than actual calculation.

- it is desirable from the experimental point of view to build observables that are least sensitive to the effect of radiative corrections.

We stress that the above considerations apply not only to semi-inclusive DIS, but also to Drell-Yan and $e^{+} e^{-}$annihilation [369], which have been already used to extract the BoerMulders and Collins functions [367, 370.

In summary, at the moment there is the hope to build descriptions of the structure functions that go from low to high transverse momentum for the five structure functions with a "yes" in the last column of Tab. 2.3.

### 2.2.6 From low to high transverse momentum

Based on the above results, we can write down a unique formula for the transverse momentum dependence. Following the procedure of [273], the differential cross section for the spin dependent SIDIS process can be written as,

$$
\begin{equation*}
\frac{d \Delta \sigma\left(S_{\perp}\right)}{d y d x_{B} d z_{h} d^{2} P_{h T}}=\frac{d \Delta \sigma^{\mathrm{TMD}}}{d y d x_{B} d z_{h} d^{2} P_{h T}}+\left(\frac{d \Delta \sigma^{\mathrm{CO}}}{d y d x_{B} d z_{h} d^{2} P_{h T}}-\left.\frac{d \Delta \sigma^{\mathrm{CO}}}{d y d x_{B} d z_{h} d^{2} P_{h T}}\right|_{P_{h T} \ll Q}\right) \tag{2.30}
\end{equation*}
$$

which is valid in the whole transverse momentum region at leading power of $1 / Q^{2}$. In the above equation, the first term comes from the TMD factorization formalism, and the second term from the collinear factorization, CO, with the twist-three quark-gluon correlations contributions. The second term will dominate the SSA at large transverse momentum, and its $q_{T}$-dependence can be calculated from perturbative QCD. On the other hand, at low transverse momentum $P_{h T} \ll Q$, the second term vanishes, because the two contributions are exactly the same in this limit, and cancel each other out. Experimentally, if we can study the transverse momentum dependence of the SSA for a wide range, we shall explore the transition from the perturbative region to the nonperturbative region.

The potential of the EIC for a study of this transition is illustrated in fig. [2.15, which shows the projected accuracy for single $\pi^{+}$production for a four-dimensional binning in the kinematic variables $x, Q^{2}, z$ and $P_{h T}$, using three different energy configurations for the EIC $(\sqrt{s}=15,50$ and 140 GeV$)$ and an integrated luminosity of $120 \mathrm{fb}^{-1}$ for each configuration. Events are selected for $0.05<y<0.9$ and $W^{2}>5 \mathrm{GeV}^{2}$ and for the $z$ range of $0.30<z<0.35$, as example. An overall detection efficiency of $50 \%$ and a beam polarization of $70 \%$ are assumed. The position of each point is according to its $x$ and $Q^{2}$

Figure 2.15. Four-dimensional representation of the projected accuracy for single $\pi^{+}$production in semi-inclusive DIS off the proton focussing on the transition region from low to high $P_{h T}\left(q_{T} \approx\right.$ $\left.P_{h T} / z_{h}\right)$ as indicated in the panels. The position of each point is according to its $Q^{2}$ and $x$ value for a specific bin in $z$ of $0.30<z<0.35$ and within the range $0.05<y<0.9$. The projected event rate, represented by the error bar, is scaled to the (arbitrarily chosen) asymmetry value at the right axis. Blue squares, black triangles and red dots represent the $\sqrt{s}=140 \mathrm{GeV}, \sqrt{s}=50 \mathrm{GeV}$ and $\sqrt{s}=15$ GeV EIC configurations, respectively. Event counts correspond to an integrated luminosity of 120 $\mathrm{fb}^{-1}$ for each of the three configurations.
value (abscissa and left ordinate, respectively) and each panel is for a $P_{h T}$ bin as indicated in the figure. The projected event rate is represented by the error bar scaled with respect to the (arbitrarily chosen) asymmetry value given at the right ordinate. The parameterization of Ref. [371] was used to simulate the cross section in the transition region. The simulation demonstrates that the transition region $q_{T} \approx P_{h T} / z_{h} \sim 4 \div 8 \mathrm{GeV}$ can be explored in great detail. Energies up to $\sqrt{s}=200 \mathrm{GeV}$ and longer running times will allow for exploring even higher values of $P_{h T}$.

The most important example to study the transition between low and high transverse momentum and the role of resummation is the structure function $F_{U U, T}$. The doublelongitudinal structure function $F_{L L}$ is the only other example where the theoretical framework has been developed at the same level [372].

Fig. 2.16 shows an example of resummation results for DIS at a high-energy EIC option. These results give us an idea of the extension of the region of intermediate transverse momentum (and therefore also of the regions of high and low transverse momentum). This extension obviously depends on experimental kinematics, in particular on $Q^{2}$. As a lower boundary of this region we can consider the values of $q_{T}$ where the nonperturbative component of the Sudakov factor becomes relevant. As an upper boundary we can consider the values of $q_{T}$ for which the fixed-order cross section becomes comparable to the resummed cross section. From fig. 2.16 we can estimate that the intermediate-transverse-momentum region corresponds to $4 \mathrm{GeV} \lesssim q_{T} \lesssim 8 \mathrm{GeV}$.

A lot remains to be done to better pin down the nonperturbative Sudakov factors, their functional form, their flavor dependence, and their errors. This should be a high-priority

Figure 2.16. Unpolarized SIDIS cross section for EIC kinematics from Ref. [372]. Shown are: the fixed-order result, the resummation results with different high- $b$ regularizations and different values of the nonperturbative Sudakov factor.
task for the EIC. The same is true for the doubly-longitudinally polarized case, where the nonperturbative components are unknown.

To conclude this section, we mention that the same program of resumming radiative contributions should be pursued also for the Sivers, Collins, and $F_{L T}^{\cos \left(\phi_{h}-\phi_{S}\right)}$ structure functions. At the moment the only discussion of similar topics is done in sec. 9 of Ref. [369]. However, we can expect developments in this direction in the near future and hope to obtain an expression of the above-mentioned structure functions that includes transverse-momentum resummation and describes the physics in the whole transverse-momentum spectrum.

### 2.2.7 Weighted Asymmetries

Currently, experimental studies in semi-inclusive DIS have limited access to single-spin asymmetries at large transverse momentum, and most of the data are in the low transverse momentum region, where the TMD formalism dominates. In phenomenological studies, in order to compare with the experimental data, one has to make model assumptions for the transverse momentum dependence of the distribution and fragmentation functions. However, there is a class of observables that does not require detailed model assumptions about transverse momentum dependence. These are transverse momentum weighted single-spin asymmetries, which transform the convolutions in the factorized cross section into simple products [244, 373].

Staying for the moment in the framework of collinear factorization, an example for a weighted differential cross section at leading order in $\alpha_{s}$ is

$$
\begin{equation*}
\int d^{2} P_{h T} \frac{P_{h T}}{z_{h} M_{P}} \sin \left(\phi_{h}-\phi_{S}\right) \frac{d \Delta \sigma^{\mathrm{TMD}}\left(S_{\perp}\right)}{d x_{B} d y d z_{h} d^{2} \vec{P}_{h T}}=\sigma_{0} \sum_{q} e_{q}^{2} \frac{g_{s}}{2 M_{P}} T_{F}^{q}(x) D(z) \tag{2.31}
\end{equation*}
$$

where $e_{q}$ is the electric charge for a quark of flavor $q$, and where $T_{F}(x)$ is the Qiu-Sterman matrix element of the quark-gluon correlation function, and has been defined above. With the standard choice of $P_{h T}$-weights $w_{1}=P_{h T} / z_{h} M_{P}$ for the numerator and $w_{0}=1$ for the
denominator, the $P_{h T}$-weighted Sivers-asymmetry thus becomes

$$
\begin{equation*}
\frac{\left\langle\frac{P_{h T}}{z_{h} M_{P}} \sin \left(\phi_{h}-\phi_{S}\right)\right\rangle_{\mathrm{UT}}}{\langle 1\rangle_{\mathrm{UU}}}=\frac{\frac{1}{Q^{4}}\left(1-y+\frac{y^{2}}{2}\right) \frac{x_{B}}{2 M_{P}} \sum_{q} e_{q}^{2} g_{s} T_{F}^{q}(x) D(z)}{\frac{1}{Q^{4}}\left(1-y+\frac{y^{2}}{2}\right) x_{B} \sum_{q} e_{q}^{2} f_{1}(x) D(z)} . \tag{2.32}
\end{equation*}
$$

We can go beyond the above leading order results and establish a collinear factorization formalism for the weighted single transverse spin dependent cross section. A similar study has been performed for the Drell-Yan lepton pair production process, where a next-to-leading order perturbative corrections have been obtained [291]. We expect similar calculations for SIDIS shall appear soon.

Recently, a generalization to employ Bessel functions as weights $w_{n} \propto J_{n}\left(\left|\mathbf{P}_{h T}\right| \mathcal{B}_{T}\right)$ has been suggested [374. The Sivers asymmetry with generalized weights reads

$$
\begin{align*}
& \frac{\left\langle\frac{2 J_{1}\left(\left|\mathbf{P}_{h T}\right| \mathcal{B}_{T}\right)}{z M \mathcal{B}_{T}} \sin \left(\phi_{h}-\phi_{s}\right)\right\rangle_{U T}}{\left\langle J_{0}\left(P_{h T} \mathcal{B}_{T}\right)\right\rangle}= \\
& \quad-2 \frac{\frac{1}{Q^{4}}\left(1-y+\frac{y^{2}}{2}\right) \sum_{q} e_{q}^{2} \tilde{f}_{1 T}^{\perp(1) q}\left(x, z^{2} \mathcal{B}_{T}^{2}\right) \tilde{D}\left(z, \mathcal{B}_{T}^{2}\right)}{\frac{1}{Q^{4}}\left(1-y+\frac{y^{2}}{2}\right) \sum_{q} e_{q}^{2} \tilde{f}_{1}\left(x, z^{2} \mathcal{B}_{T}^{2}\right) \tilde{D}_{1}\left(z, \mathcal{B}_{T}^{2}\right)}, \tag{2.33}
\end{align*}
$$

where now $\tilde{f}_{1 T}^{\perp(1) q}, \tilde{f}_{1}^{q}$ and $\tilde{D}$ are TMDs and TMD FFs Fourier transformed with respect to transverse momentum. In the asymptotic limit $\mathcal{B}_{T} \rightarrow 0$, we recover the conventional weighted asymmetry Eq. (2.32), and the Fourier transformed TMDs and FFs can be identified with the moments in that equation.

An important advantage of the generalized weights is that a non-zero choice of the parameter $\mathcal{B}_{T}$ can reduce the sensitivity to large transverse momenta. This property also applies to the Fourier transformed TMDs and TMD FFs entering the asymmetries. The new approach thus avoids the problem of divergent $k_{\perp}$-integrals that affects moments of TMDs and TMD FFs. Additionally, the analysis in Ref. 374 shows that soft factors appearing beyond tree level cancel out of the weighted asymmetry.

We conclude that an EIC presents a unique opportunity to obtain the necessary coverage and resolution in $P_{h T}$ to explore the nucleon spin structure in the language of weighted asymmetries.

### 2.3 Transverse polarization effects with gluons

Daniël Boer, Stanley J. Brodsky, Piet J. Mulders, Cristian Pisano, Markus Diehl, Bo-Wen Xiao, Feng Yuan

The gluon Sivers function shares the same characteristic features as its counterpart in the quark sector, the quark Sivers function, as discussed in the last section. Among the important information we can obtain from this distribution is the spin-orbit correlation of gluons inside the nucleon, which will help us to understand the gluon spin contribution to the proton spin. The EIC is the unique machine to map out in much detail the gluon distribution, including the spin-dependent and spin-averaged transverse momentum dependent distributions. In this section, we will focus on the gluon Sivers function. The study of this distribution is strongly related to other measurements such as the gluon GPDs and the unintegrated gluon distributions of nucleon/nucleus at small- $x$.

Various processes in DIS can be used to probe the transverse momentum dependent gluon distributions, such as heavy quark and quarkonium production. Also the dijet/dihadron correlation has been proposed as a promising probe for the gluon Sivers function and other TMD gluon distributions.

In Ref. [375], it was suggested to use the dijet-correlation to study the gluon Sivers function in $p p$ collisions. However, because of both initial and final state interaction effects involved in $p p$ scattering, the factorization of this process is shown to be broken (see detailed discussions in next section). On the other hand, for the DIS processes, because only one hadron is involved in the initial state, the dijet-correlation process could be factorized in the same spirit as the semi-inclusive hadron production discussed in the previous sections.

We consider here the dijet/quark-antiquark production in DIS

$$
\begin{equation*}
\gamma^{*} N^{\uparrow} \rightarrow H_{1}\left(k_{1}\right)+H_{2}\left(k_{2}\right)+X, \tag{2.34}
\end{equation*}
$$

where $N$ represents the transversely polarized nucleon, $H_{1}$ and $H_{2}$ are the two final state particles with momenta $k_{1}$ and $k_{2}$, respectively. We are interested in the kinematic region where the transverse momentum imbalance between them is much smaller than the individual transverse momenta: $k_{\perp}=\left|\boldsymbol{k}_{1 T}+\boldsymbol{k}_{2 T}\right| \ll P_{J T}$ where $\boldsymbol{P}_{J T}$ is defined as $\left(\boldsymbol{k}_{1 T}-\boldsymbol{k}_{2 T}\right) / 2$. This is referred to as the (back-to-back) correlation limit. An important advantage of taking this correlation limit is that we can apply the power counting method to obtain the leading order contribution of $k_{\perp} / P_{J T}$ where the differential cross section directly depends on the TMD gluon distribution. As illustrated in Fig. [2.17, with transverse spin in the dijet plane, the correlation between the two jets will lead to a preferred direction in the transverse plane. This will signal the gluon Sivers effect if the process is dominated by the gluonic subprocesses.

As demonstrated in Ref. [283], the TMD gluon distribution in the quark-antiquark jet correlation in the DIS process of (2.34) follows the original gluon distribution definition of Ref. [241],

$$
\begin{equation*}
x f_{1}^{g}\left(x, k_{\perp}\right)=\int \frac{d \xi^{-} d^{2} \xi_{\perp}}{(2 \pi)^{3} P^{+}} e^{i x P^{+} \xi^{-}-i k_{\perp} \cdot \xi_{\perp}}\langle P| F^{+i}\left(\xi^{-}, \xi_{\perp}\right) \mathcal{L}_{\xi}^{\dagger} \mathcal{L}_{0} F^{+i}(0)|P\rangle \tag{2.35}
\end{equation*}
$$

where $F^{\mu \nu}$ is the gauge field strength tensor $F_{a}^{\mu \nu}=\partial^{\mu} A_{a}^{\nu}-\partial^{\nu} A_{a}^{\mu}-g f_{a b c} A_{b}^{\mu} A_{c}^{\nu}$ with $f_{a b c}$ the antisymmetric structure constants for $S U(3)$, and the gauge-link follows the similar definition as that for the quark distribution but in the adjoint representation. The physics behind

Figure 2.17. Back-to-back dijet correlation can be used to probe the TMD gluon distributions.
this factorization is the following. The virtual photon scatters on the nucleon target and produces a quark-antiquark pair through the partonic process $\gamma^{*} g \rightarrow q \bar{q}$. In the correlation limit, the quark-antiquark pair stays close in the coordinate space, and act as a color-octet object, which effectively behaves like a single gluon. In particular, the net effect of the final state interactions between the nucleon target and the quark-antiquark pair is exactly the same antisymmetric structure $f_{a b c}$ as in the TMD gluon definition of Eq. (2.35). This is totally different from the analogous QED process where the final state interactions cancel out completely with the fermion-antifermion pair.

In the following, we will present some recent phenomenological studies on the gluon TMDs from the quark-antiquark correlation in DIS processes. We expect more interesting results shall be obtained in the near future.

### 2.3.1 The gluonic Sivers effect in dihadron production

The production of a pair of hadrons with high transverse momenta in DIS is sensitive to the transverse-momentum dependent gluon distribution. In particular, it has a transverse target spin asymmetry due to the gluon Sivers function. The relevant parton-level subprocess is $\gamma^{*} g \rightarrow q \bar{q}$, and to eliminate contributions from $\gamma^{*} q \rightarrow q g$ and $\gamma^{*} \bar{q} \rightarrow \bar{q} g$ we focus on charm production.

As a straight forward generalization of the unpolarized case recently studied in 283], the cross section for the dijet/c $\bar{c}$ production from a nucleon with transverse polarization $S_{\perp}$ can be written as

$$
\begin{equation*}
\frac{d \sigma^{\gamma_{T, L}^{*} p \rightarrow c \bar{c}+X}}{d z d^{2} k_{1 T} d^{2} k_{2 T}}=\frac{H^{\gamma_{T, L}^{*} g \rightarrow c \bar{c}}}{z \bar{z}}\left[f_{1}^{g}\left(x, k_{\perp}\right)+\frac{\left(\boldsymbol{S}_{\perp} \times \boldsymbol{k}_{\perp}\right)^{3}}{M} f_{1 T}^{g \perp}\left(x, k_{\perp}\right)\right] . \tag{2.36}
\end{equation*}
$$

Here, $f_{1}^{g}$ is the usual gluon TMD, $f_{1 T}^{g \perp}$ the gluon Sivers distribution and $\bar{z}=1-z$. Again, we are interested in the back-to-back correlation limit. The gluon momentum fraction is then given by $x / x_{B} \approx 1+\left(P_{J T}^{2}+m_{c}^{2}\right) /\left(z \bar{z} Q^{2}\right)$, where $m_{c}$ is the charm quark mass. The hard-scattering cross sections $H^{\gamma_{T, L}^{*} g \rightarrow c \bar{c}}$ for transverse and longitudinal photons depend on $P_{h T}^{2}, Q^{2}, z$ and $m_{c}$ and can be found in [283].

It may be possible to study the cross section (2.36) experimentally through the production of two heavy-quark jets, but the interpretation of this process requires a quantitative
understanding of the relative transverse momentum between a reconstructed jet and the heavy quark it originates from. As an alternative, we consider here the production of two heavy hadrons, e.g. $D$ mesons. Its cross section reads

$$
\begin{align*}
& \frac{d \sigma_{T, L}^{*} p \rightarrow h_{1} h_{2}+X}{d z_{1} d z_{2} d^{2} P_{h_{1} T} d^{2} P_{h_{2} T}}=\int_{z_{1}}^{1-z_{2}} d z \frac{H^{\gamma_{T, L}^{*} g \rightarrow c \bar{c}}}{z^{2} \bar{z}^{2}} \int d^{2} \lambda_{1 T} d^{2} \lambda_{2 T}\left[f_{1}^{g}\left(x, k_{\perp}\right)\right. \\
& \left.\quad+\frac{\left(\boldsymbol{S}_{\perp} \times \boldsymbol{k}_{\perp}\right)^{3}}{M} f_{1 T}^{g \perp}\left(x, k_{\perp}\right)\right] D^{h_{1} / c}\left(\frac{z_{1}}{z}, \frac{z_{1}}{z} \lambda_{1 T}\right) D^{h_{2} / \bar{c}}\left(\frac{z_{2}}{\bar{z}}, \frac{z_{2}}{\bar{z}} \lambda_{2 T}\right) \tag{2.37}
\end{align*}
$$

where

$$
\begin{equation*}
\boldsymbol{k}_{1 T}=\boldsymbol{\lambda}_{1 T}+\frac{z}{z_{1}} \boldsymbol{P}_{h_{1} T}, \quad \quad \boldsymbol{k}_{2 T}=\boldsymbol{\lambda}_{2 T}+\frac{\bar{z}}{z_{2}} \boldsymbol{P}_{h_{2} T} . \tag{2.38}
\end{equation*}
$$

Here $h_{1}$ is the hadron containing a $c$ quark and $h_{2}$ the one containing a $\bar{c}$, with $\boldsymbol{P}_{h_{1} T}, \boldsymbol{P}_{h_{2} T}$ denoting their transverse momenta and $z_{1}, z_{2}$ their momentum fractions w.r.t. the virtual photon. The fragmentation functions $D\left(z, P_{\perp}\right)$ depend on the momentum fraction $z$ and the relative transverse momentum $P_{\perp}$ of the hadron with respect to the quark or antiquark.

The parton-level variables $\boldsymbol{k}_{1 T}, \boldsymbol{k}_{2 T}$ and $z$ are not directly measurable, but a detailed analysis of the kinematics [376] reveals that they can be partly determined from the hadronic final state. In particular, one can define variables $\boldsymbol{k}_{\perp}^{\prime}, \boldsymbol{P}_{T}^{\prime}$ and $z^{\prime}$ that are measurable and closely related to $\boldsymbol{k}_{\perp}=\boldsymbol{k}_{1 T}+\boldsymbol{k}_{2 T}, \boldsymbol{P}_{T}=\left(\boldsymbol{k}_{1 T}-\boldsymbol{k}_{2 T}\right) / 2$ and $z$, respectively. The cross product ( $\boldsymbol{S}_{\perp} \times \boldsymbol{k}_{\perp}$ ) in (2.37) gives rise to an angular modulation

$$
\begin{equation*}
\frac{d \sigma^{\gamma^{*} p \rightarrow h_{1} h_{2}+X}}{d k^{\prime} d \phi_{S, k^{\prime}}} \approx A\left(k_{\perp}^{\prime}\right)+B\left(k_{\perp}^{\prime}\right) \sin \left(\phi_{S k^{\prime}}+\gamma\right), \tag{2.39}
\end{equation*}
$$

where $\phi_{S k^{\prime}}$ is the azimuthal angle between $\boldsymbol{S}_{\perp}$ and $\boldsymbol{k}_{\perp}^{\prime}$. The coefficient $B\left(k^{\prime}\right)$ depends on the gluon Sivers function, as well as the phase $\gamma$.

To estimate the possible size of the Sivers asymmetry, we follow [377] and assume

$$
\begin{equation*}
f_{1 T}^{g \perp}\left(x, k_{\perp}\right)=\frac{2 \sigma M}{k_{\perp}^{2}+\sigma^{2}} f_{1}^{g}\left(x, k_{\perp}\right), \quad \quad f_{1}^{g}\left(x, k_{\perp}\right)=\frac{e^{-k_{\perp}^{2} / \sigma^{2}}}{\pi \sigma^{2}} f_{1}^{g}(x) \tag{2.40}
\end{equation*}
$$

with $\sigma=800 \mathrm{MeV}$ and the integrated gluon distribution $f_{1}^{g}(x)$ from MSTW 2008 [22]. This Ansatz saturates the positivity bound $\frac{k_{\perp}}{M}\left|f_{1 T}^{g \perp}\left(x, k_{\perp}\right)\right| \leq f_{1}^{g}\left(x, k_{\perp}\right)$ at $k_{\perp}=\sigma$ and undershoots it for all other values of $k_{\perp}$. We consider the production of $D$ meson pairs and take a fragmentation function $D\left(z, P_{\perp}\right)=D(z) e^{-P_{\perp}^{2} / \sigma^{2}} /\left(\pi \sigma^{2}\right)$ with the same Gaussian width as in (2.40). We take $D(z) \propto z^{\alpha}(1-z)^{\beta} e^{\gamma z(1-z)}$ with $\alpha=2.86, \beta=1.57, \gamma=5.66$, which gives a fair description of the $D^{0}$ spectrum observed in $e^{+} e^{-}$annihilation [221, 220]. In Fig. 2.18 we show the transverse target spin asymmetry

$$
\begin{equation*}
A\left(k_{\perp}^{\prime}, \phi_{S k^{\prime}}\right)=\frac{d \sigma\left(k_{\perp}^{\prime}, \phi_{S k^{\prime}}\right)-d \sigma\left(k_{\perp}^{\prime}, \phi_{S k^{\prime}}+\pi\right)}{d \sigma\left(k_{\perp}^{\prime}, \phi_{S k^{\prime}}\right)+d \sigma\left(k_{\perp}^{\prime}, \phi_{S k^{\prime}}+\pi\right)} \tag{2.41}
\end{equation*}
$$

for the process $\gamma^{*} p \rightarrow D^{0} \bar{D}^{0}+X$ summed over transverse and longitudinal photon polarization. We find that the phase shift $\gamma$ in (2.39) is tiny. The asymmetry is found to be sizable with our Ansatz, which suggests that DIS production of heavy meson pairs at EIC has good sensitivity to the gluon Sivers function.

Figure 2.18. The transverse target asymmetry (2.41) for $\gamma^{*} p \rightarrow D^{0} \bar{D}^{0}+X$. The kinematics is specified by $W=100 \mathrm{GeV}, Q^{2}=16 \mathrm{GeV}^{2}, z_{1}=z_{2}=0.3,0.25<z^{\prime}<0.75$ and $5 \mathrm{GeV}<P_{T}^{\prime}<$ 40 GeV .

### 2.3.2 Probing the linear polarization of gluons in unpolarized hadrons

Gluons inside unpolarized hadrons can be linearly polarized provided they have a nonzero transverse momentum. The simplest and theoretically safest way to probe this TMD distribution of linearly polarized gluons is through $\cos 2 \phi$ asymmetries in heavy quark pair or dijet production in electron-hadron collisions. Future EIC or LHeC experiments are ideally suited for this purpose. Here we estimate the maximum asymmetries for EIC kinematics.

Linearly polarized gluons in an unpolarized hadron, carrying a light-cone momentum fraction $x$ and transverse momentum $\boldsymbol{k}_{\perp}$ w.r.t. to the parent's momentum, are described by the TMD $h_{1}^{\perp g}\left(x, k_{\perp}\right)$ [281, 284, 378. Unlike the quark TMD $h_{1}^{\perp q}$ of transversely polarized quarks inside an unpolarized hadron (also frequently referred to as Boer-Mulders function) [244], $h_{1}^{\perp g}$ is chiral-even and $T$-even. This means it does not require initial or final state interactions (ISI/FSI) to be non-zero. Nevertheless, as any TMD, $h_{1}^{\perp g}$ can receive contributions from ISI or FSI and therefore can be process dependent, in other words, non-universal, and its extraction can be hampered in non-factorizing cases.

Thus far no experimental studies of $h_{1}^{\perp g}$ have been performed. As recently pointed out, it is possible to obtain an extraction of $h_{1}^{\perp g}$ in a simple and theoretically safe manner, since unlike $h_{1}^{\perp q}$ it does not need to appear in pairs [284. Here we will discuss observables that involve only a single $h_{1}^{\perp g}$ in semi-inclusive DIS to two heavy quarks or to two jets, which allow for TMD factorization and hence a safe extraction. The corresponding hadroproduction processes run into the problem of factorization breaking [272, 284].

Again, we consider heavy quark production, $e(\ell)+h(P) \rightarrow e\left(\ell^{\prime}\right)+Q\left(k_{1}\right)+\bar{Q}\left(k_{2}\right)+X$, where the four-momenta of the particles are given within brackets, and the heavy quark-antiquark pair in the final state is almost back-to-back in the plane perpendicular to the direction of the exchanged photon and hadron. The calculation proceeds along the lines explained in Refs. [378, 379]. We obtain for the cross section integrated over the angular distribution of

Figure 2.19. Upper bounds of the asymmetry ratio $R$ in equation (2.44) as a function of $\left|\boldsymbol{P}_{J T}\right|$ at different values of $Q^{2}$, with $y=0.01$ and $z=0.5$.
the back-scattered electron $e\left(\ell^{\prime}\right)$ :

$$
\begin{equation*}
\frac{d \sigma}{d y_{1} d y_{2} d y d x_{B} d^{2} \boldsymbol{k}_{\perp} d^{2} \boldsymbol{P}_{J T}}=\frac{\alpha^{2} \alpha_{s}}{\pi s M_{T}^{2}} \frac{\left(1+y x_{B}\right)}{y^{5} x_{B}}\left(A+\frac{\boldsymbol{k}_{\perp}^{2}}{M^{2}} B \cos 2 \phi\right) \delta\left(1-z_{1}-z_{2}\right)( \tag{2.42}
\end{equation*}
$$

The kinematics are the same as in the last subsection with the heavy quark mass $M_{Q}$, $M_{i T}^{2} \approx M_{T}^{2}=M_{Q}^{2}+P_{J T}^{2}$ and the rapidities $y_{i}$ for the quark momenta along photon-target direction. The azimuthal angles of $\boldsymbol{k}_{\perp}$ and $\boldsymbol{P}_{J T}$ are denoted by $\phi_{\perp}$ and $\phi_{T}$, respectively, and $\phi \equiv \phi_{\perp}-\phi_{T}$. The functions $A$ and $B$ depend on $y, z\left(\equiv z_{2}\right), Q^{2} / M_{T}^{2}, M_{Q}^{2} / M_{T}^{2}$, and $\boldsymbol{k}_{\perp}^{2}$. The angular independent part $A$ involves only the unpolarized TMD gluon distribution $f_{1}^{g}$, while the magnitude $B$ of the $\cos 2 \phi$ asymmetry is determined by $h_{1}^{\perp g}\left(x, k_{\perp}\right)$. Since $h_{1}^{\perp g}$ is completely unknown, we estimate the maximum asymmetry that is allowed by the bound [284]

$$
\begin{equation*}
\left|h_{1}^{\perp g(2)}(x)\right| \leq \frac{\left\langle k_{\perp}^{2}\right\rangle}{2 M^{2}} f_{1}^{g}(x), \tag{2.43}
\end{equation*}
$$

where the superscript (2) denotes the $n=2$ transverse moment (defined as $f^{(n)}(x) \equiv$ $\left.\int d^{2} \boldsymbol{k}_{\perp}\left(\boldsymbol{k}_{\perp}^{2} / 2 M^{2}\right)^{n} f\left(x, \boldsymbol{k}_{\perp}^{2}\right)\right)$. The maximal (absolute) value of the asymmetry ratio

$$
\begin{equation*}
R=\left|\frac{\int d^{2} \boldsymbol{k}_{\perp} \boldsymbol{k}_{\perp}^{2} \cos 2\left(\phi_{\perp}-\phi_{T}\right) d \sigma}{\int d^{2} \boldsymbol{k}_{\perp} \boldsymbol{k}_{\perp}^{2} d \sigma}\right|=\frac{\int d \boldsymbol{k}_{\perp}^{2} \boldsymbol{k}_{\perp}^{4}|B|}{2 M^{2} \int d \boldsymbol{k}_{\perp}^{2} \boldsymbol{k}_{\perp}^{2} A} \tag{2.44}
\end{equation*}
$$

is depicted in Fig. 2.19 as a function of $\left|\boldsymbol{P}_{J T}\right|$ at different values of $Q^{2}$ for charm (left panel) and bottom (right panel) production, where we have selected $y=0.01, z=0.5$, and taken $M_{c}^{2}=2 \mathrm{GeV}^{2}, M_{b}^{2}=25 \mathrm{GeV}^{2}$. Such large asymmetries, together with the relative simplicity of the suggested measurement (polarized beams are not required), would probably allow an extraction of $h_{1}^{\perp g}\left(x, k_{\perp}\right)$ at the EIC (or LHeC).

### 2.4 Theory highlights

Igor O. Cherednikov, Zhong-Bo Kang, Piet J. Mulders, Barbara Pasquini, Ted Rogers, Peter Schweitzer, Nicolaos G. Stefanis, Jian-Wei Qiu

The candidates for the golden measurement at the EIC are the spin-dependent Sivers function $f_{1 T}^{\perp}$, as well as the unpolarized quark distribution $f_{1}$. The proposed silver candidates are the transversity, the Boer-Mulders, and the Collins functions. All these objects are transverse-momentum dependent parton densities that describe the inner structure of hadrons by taking into account the longitudinal and the transversal partonic degrees of freedom.

In the last few years, there has been tremendous progress on the theory developments for the transverse momentum dependent parton distributions. In particular, there have been intensive investigations on the QCD factorization and the associated universality of the TMD parton distributions in various hard processes; the energy scale dependence for the TMD distributions and related quark-gluon correlation functions. In this section, we will highlight these developments.

### 2.4.1 Gauge-links, TMD-factorization, and TMD-factorization breaking

In this section, we discuss some basic features of transverse momentum dependent parton distribution functions. In hard processes, parton distribution functions and fragmentation functions are expressed as matrix elements of nonlocal combinations of quark or gluon fields. In the collinear situation that all transverse momenta of partons are integrated over in the definitions, the nonlocality is in essence light-like. These correlation functions are convoluted with the squared amplitude for the partonic subprocess (in essence the partonic cross section) of a hard process. When the transverse momenta of partons are involved, the non-locality in the matrix elements includes a transverse separation, and a transverse momentum dependent (TMD) factorization theorem is needed. In all cases the definitions of the non-perturbative functions include gluon contributions resummed into gauge-links (or Wilson lines) that bridge the nonlocality.

It is important to realize that the appearance of the gauge-links is a consequence of the systematic resummation of extra gluon contributions in the derivations of factorization, so their structure is dictated by the requirements of factorization.

In processes like $\ell+H \longrightarrow \ell^{\prime}+h+X$ (semi-inclusive DIS), $\ell+\bar{\ell} \longrightarrow h_{1}+h_{2}+X$ (annihilation process) or $H_{1}+H_{2} \longrightarrow \ell+\bar{\ell}+X$ (Drell-Yan process) one has, at leading power in the hard scale, a simple underlying hard process, which is a virtual photon (or weak boson) coupling to a parton line. The color flow from the hard part to collinear or soft parts is simple. Additional gluons with polarizations collinear to the parton momenta are resummed into gauge-links, which exhibit the interesting behavior that for transverse momentum dependent functions they bridge the transverse separation between the nonlocal field combinations at lightcone past or future infinity. Which gauge-link is relevant in a particular non-perturbative function depends on the color flow in the full process. For a quark distribution function one has a link via (future) lightcone $+\infty$ if the color flows into the final state, and a link via (past) lightcone $-\infty$ if the color is annihilated by another incoming parton.

QCD factorization theorems are central to understanding high energy hadronic scattering cross sections in terms of the fundamentals of perturbative QCD. In addition to
providing a practical prescription for order-by-order calculations, derivations of factorization provide a solid theoretical underpinning for concepts like PDFs and FFs which are crucial in the quest to expand the basic understanding of hadronic structure. The most natural first attempt at a TMD-factorization formula is simply to extend the classic parton model intuition familiar from collinear factorization. For the semi-inclusive deep inelastic scattering (SIDIS) cross section, for example, the cross section might be written schematically as

$$
\begin{equation*}
d \sigma \sim|\mathcal{H}|^{2} \otimes \Phi\left(x, \boldsymbol{k}_{\perp}\right) \otimes D\left(z, \boldsymbol{P}_{\perp}\right) \delta^{(2)}\left(\boldsymbol{q}_{T}+\boldsymbol{k}_{\perp}-\boldsymbol{P}_{\perp}\right) . \tag{2.45}
\end{equation*}
$$

Here $\Phi\left(x, \boldsymbol{k}_{\perp}\right)$ is the TMD PDF while $D\left(z, \boldsymbol{P}_{\perp}\right)$ is the TMD FF, with the usual probability interpretations, and $|\mathcal{H}|^{2}$ represents the hard part. The momentum $\boldsymbol{q}_{T}$ is the small momentum sensitive to intrinsic transverse momenta, $\boldsymbol{k}_{\perp}$ and $\boldsymbol{P}_{\perp}$, carried by the colliding proton and the produced hadron. The $\otimes$ symbol denotes all relevant convolution integrals, and the $x$ and $z$ arguments are the usual longitudinal momentum fractions.

In a perturbative derivation of factorization, a small-coupling perturbative expansion of the cross section is analyzed in terms of "leading regions", and the sum is shown order-by-order to separate into the factors of Eq. (2.45). The precise field theoretic definitions of the correlation functions, $\Phi\left(x, \boldsymbol{k}_{\perp}\right)$ and $D\left(z, \boldsymbol{P}_{\perp}\right)$, should emerge naturally from the requirements of factorization. In the hard part $|\mathcal{H}|^{2}$, all propagators must be off-shell by order the hard scale $Q$ so that asymptotic freedom applies, and small-coupling perturbation theory is valid, with non-factorizing higher-twist contributions suppressed by powers of $Q$. Such factorization theorems are well-established for inclusive processes that utilize the standard integrated correlation functions (see [380] and references therein), but TMDfactorization theorems involve other subtleties, particularly with regard to the definitions of the TMD PDFs and FFs and their associated gauge-links.

In cases where there is a more complex color flow such as is often the case when the underlying hard process involves multiple color flows and/or if the incoming partons are gluons, this can potentially lead to a more complex gauge-link structure including traced closed loops or looping gauge-links. For situations in which only one TMD correlation function is studied, these structures have been examined in [265, [267, 381, 382] for two-totwo partonic subprocesses. In situations that involve several TMD functions, factorization using separate TMD functions fails completely.

To understand the issues that arise in defining TMDs, it is instructive to start with a review of the definition of the standard integrated quark PDF. It is

$$
\begin{equation*}
f(x ; \mu)=\text { F.T. }\langle p| \bar{\psi}\left(0, w^{-}, \mathbf{0}_{t}\right) \gamma^{+} V_{[0, w]}\left(u_{\mathrm{J}}\right) \psi(0)|p\rangle, \tag{2.46}
\end{equation*}
$$

where "F.T." stands for the Fourier transform from coordinate space to momentum space. The above definition contains UV divergences which must be renormalized. This gives dependence on an extra scale $\mu$, and ultimately results in the well-known DGLAP evolution equations for the integrated PDF. For a gauge invariant definition, the PDF must contain a path ordered exponential of the gauge field that connects the points 0 and $\left(0, w^{-}, \mathbf{0}_{t}\right)$. This is the gauge-link and its formal definition is

$$
\begin{equation*}
V_{[0, w]}\left(u_{\mathrm{J}}\right)=P \exp \left(-i g t^{a} \int_{0}^{w^{-}} d \lambda u_{J} \cdot A^{a}\left(\lambda u_{J}\right)\right) . \tag{2.47}
\end{equation*}
$$

The path of the gauge-link is determined by the light-like vector $u_{\mathrm{J}}=\left(0,1, \mathbf{o}_{t}\right)$. That is, the gauge-link follows a straight path connecting 0 and $\left(0, w^{-}, \mathbf{0}_{t}\right)$ along the exactly

Figure 2.20. (a) Target-collinear gluons in a graph for SIDIS. (b) Factorization of extra gluons into gauge-link contributions.
light-like minus direction. In Feynman graph calculations, the contribution from the gaugelink corresponds to the so-called "eikonal factors," which have definite Feynman rules that follow naturally from factorization proofs. After a sum over graphs, and the application of appropriate approximations and Ward identity arguments, extra collinear gluons like those shown in Fig. [2.20(a) for SIDIS factor into gauge-link contributions. In Fig. 2.20(b), the eikonal factors are shown as gluon attachments from the target-collinear bubble to a double line.

The most natural first try at extending the PDF definition in Eq. (2.46) to the TMD case is to simply leave the integration over transverse momentum in the TMD PDF definition undone. That is, instead of Eq. (2.46) one may try

$$
\begin{equation*}
\Phi\left(x, \boldsymbol{k}_{t}\right)=\text { F.T. }\langle p| \bar{\psi}\left(0, w^{-}, \boldsymbol{w}_{t}\right) \gamma^{+} U_{[0, w]}\left(u_{J}\right) \psi(0)|p\rangle . \tag{2.48}
\end{equation*}
$$

The separation is now 0 and $\left(0, w^{-}, \boldsymbol{w}_{t}\right)$ - it has acquired a transverse component and the Fourier transform is now in both $w^{-}$and $\boldsymbol{w}_{t}$. As a result, the structure of the gauge-link $U_{[0, w]}\left(u_{J}\right)$ must also be modified from the simple straight light-like $V_{[0, w]}\left(u_{\mathrm{J}}\right)$ gauge-link of Eq. (2.46). The eikonal attachments on either side of the cut in Fig. 2.20 still give minusdirection Wilson lines, but now in order to have a closed link there must also be a small transverse detour at light-cone infinity. This detour arises naturally from boundary terms that are needed as subtractions to make higher twist contributions gauge invariant [263, 264].

The gauge-link structure in Eq. (2.48), with its two exactly light-like legs and a transverse link at infinity is commonly cited as the gauge-link that is necessary for the definition of the TMD PDFs. However, there are a number of further subtleties, and we will find that the definition needs to be modified. One complication is that rapidity divergences, which in collinear factorization would cancel in the sum of graphs, remain uncanceled in the definition of the TMD correlation functions. Rapidity divergences correspond to gluons moving with infinite rapidity in the direction opposite the containing hadron, and remain even when infrared gluon mass regulators are included. (For a more complete review of these and related issues, see for example [259, [383].) The most common way to regularize the lightcone divergences is to make the gauge links slightly non-light-like. In the coordinate space picture, the gauge-link therefore becomes more like the tilted hook shape. This introduces a new arbitrary rapidity parameter - the "tilt" of the gauge-link. A generalization of renormalization group techniques is needed to recover predictability in the factorization formula. A system of evolution equations for the TMD case was developed by Collins, Soper
and Sterman (CSS) and has been successfully applied to specific processes [240, 241, 273].
A complete treatment of TMD-factorization involves soft gluons, which give rise to an extra "soft factor" $S(\boldsymbol{q})$ in the factorization formula of Eq. (2.45). The TMD-factorization formula then becomes

$$
\begin{equation*}
d \sigma \sim|\mathcal{H}|^{2} \otimes \Phi\left(x, \boldsymbol{k}_{\perp}\right) \otimes D\left(z, \boldsymbol{P}_{\perp}\right) \otimes S\left(\boldsymbol{h}_{T}\right) \delta^{(2)}\left(\boldsymbol{q}_{T}+\boldsymbol{k}_{\perp}-\boldsymbol{P}_{\perp}-\boldsymbol{h}_{T}\right) . \tag{2.49}
\end{equation*}
$$

The soft factor describes the role of gluons with nearly zero center-of-mass rapidity. One difficulty with the usual presentation of the CSS formulation is that the explicit appearance of a soft factor seems somewhat counter to the basic parton model intuition wherein all nonperturbative effects are associated with functions for each external hadron with simple and specific probabilistic interpretations. A natural hope is that, with an appropriate sequence of redefinitions, the role of the soft gluons can be absorbed into the definitions of the PDFs and FFs. The recent work of Collins [384 has shown how this is possible. Indeed, this treatment of the soft factor is necessary for a completely correct factorization derivation with fully consistent definitions for the correlation functions.

While the CSS formalism has been implemented for specific spin independent processes (see, for example, [385]), much work remains to be done in tabulating and classifying the TMDs. This is especially true for cases that involve spin. Work in this direction has been started in [260].

## TMD-factorization breaking

The discussion has focussed on situations where factorization is known to hold. There are also, however, situations where TMD-factorization is now known to break down [265, 267, 268, 270, 271, 272, 381, 382. The key issue is the failure of the usual Ward identity arguments that ordinarily allow eikonalized gluons to be factorized and identified with a particular gauge-link structure in the definitions of the TMDs. A hint of what leads to TMD-factorization breaking is already suggested by the well-known overall relative sign flip in the Sivers function for SIDIS as compared to the Drell-Yan (DY) process [261, 262. The difference comes because in the SIDIS TMD-factorization formula, the gauge link in the Sivers function is future pointing, whereas it is past pointing in the DY case. At the level of Feynman graphs, the difference can be seen in the fact that the "extra" gluons which contribute to the gauge-link attach before the hard scattering in one case, and after the hard scattering in the other. This illustrates that the direction of the flow of color through the eikonal lines is a critical factor in the definition of the correlation functions.

In the more complicated hadro-production processes, $H_{1}+H_{2} \rightarrow H_{3}+H_{4}+X$, where $H_{3}$ and $H_{4}$ may be either jets or hadrons, a reasonable first approach would be to trace the flow of color through the eikonal factors and use analogous arguments to what we used for SIDIS and DY in the previous section. One finds that the resulting structures are not simply the future or past pointing gauge-links familiar from SIDIS or DY, but rather are complicated and highly process dependent objects [265, 267, 381, 382]. That this corresponds (at least) to a breakdown of universality is most directly seen in an explicit spectator model calculation. For example, one may consider an Abelian scalar-quark / Dirac spectator model with multiple flavors as in [270]. Then, in addition to the standard gauge-link attachments, there are extra gluon attachments that do not cancel in a simple Ward identity argument, and which give contributions that are not consistent with having a simple gauge-link like what is found SIDIS or DY (opposite pointing).

Therefore, it is clear that there is at least a violation of universality in the hadroproduction of hadrons. The natural next approach to try is to maintain a basic factorization structure, but to loosen the requirement that the TMDs be universal, resulting in a kind of "generalized" TMD-factorization formalism. That is, the cross section might still be expected to factorize order-by-order into a hard part and well-defined, albeit non-universal, matrix elements for each separate external hadron [268]. However, a careful order-by-order consideration of multiple gluons in the derivation of TMD-factorization shows that even this is not possible [272]. If, for example, one extends the model of [270] to allow the gluons to carry color (while still considering a hard part that involves only the exchange of a colorless boson) then it is straightforward to see that the flow of color spoils the possibility of factorizing the graph into TMD PDFs with separate gauge-links for each TMD, regardless of what kind of gauge-link geometries are allowed. Therefore, the problem with factorization in the hadro-production of hadrons is more than just a problem with universality - separate correlation functions cannot even be defined in a way that is consistent with factorization.

The root of the problem is a failure of Ward identity arguments, which normally allow "extra" gluons to be factorized after a sum over graphs. The Ward identity arguments are only valid after an appropriate sequence of contour deformations on the momentum integrals. In the case of hadro-production of hadrons the necessary deformations are prohibited. In other cases where the direction of color flow may at first appear to pose a problem for factorization (such as in $e+p \rightarrow h_{1}+X$ and $e+p \rightarrow h_{1}+h_{2}+X$ ), the necessary contour deformations are possible and factorization holds. (See the explanation in chapter 12 of 384.)

To summarize, we list the status of TMD-factorization for various well-known processes with a check mark for processes where factorization appears to be valid and !! where it has been shown to fail:
$\checkmark$ Semi-inclusive DIS $\left(e+p \rightarrow e^{\prime}+h_{1}+X\right)$.
$\checkmark$ Drell-Yan (up to overall minus signs for some spin-dependent TMDs).
$\checkmark$ Back-to-Back hadron or jet production in $e^{+} e^{-}$annihilation.
$\checkmark$ Back-to-back hadron or jet production in DIS $\left(e+p \rightarrow e^{\prime}+h_{1}+h_{2}+X\right)$.
!! Hadro-production of back-to-back jets or hadrons $\left(H_{1}+H_{2} \rightarrow H_{3}+H_{4}+X\right)$.
In cases where TMD-factorization is valid, there is still much work left to be done (and much potential insight to be gained) in terms of implementing the evolution of precisely defined TMDs [260]. Much already exists for the case of unpolarized scattering, but even here the most complete and formal identification of evolution effects with separate TMDs has only recently been clarified in [384]. For polarization dependent functions, it is also important to include evolution, but to date there has been very little work that accounts for evolution in actual fits to data.

Finally, the experimental search for TMD-factorization breaking effects opens the possibility of new and exciting insights into the transverse dynamics of hadronic collisions. The breakdown of TMD-factorization in the hadro-production of hadrons implies that unexpected and exotic correlations between partons in different hadrons can exist. Calculations that allow for experiments to distinguish between factorization and factorization-breaking scenarios are therefore very important, and a quantitative understanding of factorization (via the methods of [283], for example) are part of the next step toward understanding hadronic structure in high energy collisions.

### 2.4.2 Evolution of transverse-momentum-dependent densities

Much of the success of QCD collinear factorization relies on our ability to calculate the short-distance partonic dynamics in QCD perturbation theory order-by-order in powers of $\alpha_{s}$ and the universality as well as the scale evolution of the non-perturbative collinear parton distribution and correlation functions. With its dependence on the parton's transverse momentum, TMDs carry much richer information on the partonic structure of a hadron than what collinear PDFs could provide. Like the case of collinear factorization, the predictive power of the TMD factorization formalism also requires our ability to calculate the short-distance dynamics and the evolution of TMDs. However, the theoretical framework for calculating the evolution of TMDs and radiative corrections to short-distance dynamics has not been fully established. All existing parameterizations of TMDs are extracted from SIDIS data at relatively low $Q^{2}$. The available hard scale $Q^{2}$ at a future EIC is expected to be much larger. The TMDs, like PDFs, depend on the momentum scale $Q^{2}$ where they are probed. Understanding the $Q^{2}$ dependence of the TMDs is crucial for testing the TMD factorization formalism and for extracting correct information on the partonic structure of hadrons at the EIC. However, the $Q^{2}$-dependence of TMDs in the existing TMD factorization formalism is very different from the factorization scale $\mu_{F}^{2}$ dependence of the PDFs. The factorization scale is not a physical scale. Any factorized physical cross section should not be sensitive to the choice of the factorization scale. The perturbatively calculated factorization scale dependence of PDFs is necessarily compensated by the same scale dependence in the high order short-distance partonic dynamics. On the other hand, the TMDs in the existing proved TMD factorization formalism are effectively physical quantities. They are connected to a physical observable by a partonic scattering cross section without strong interaction and a soft factor which can be absorbed into the redefinition of TMDs [384. Unlike the DGLAP evolution equation of PDFs, the $Q^{2}$-dependence of TMDs cannot be derived by a simple renormalization group equation. The $Q^{2}$-dependence of TMDs was systematically studied in the context of the transverse momentum $\left(q_{T}\right)$ distribution of the Drell-Yan process and the two-jet momentum imbalance in $e^{+} e^{-}$collisions [273]. The $Q^{2}$-dependence was derived by resumming $\ln ^{2}\left(Q^{2} / q_{T}^{2}\right)$-type large logarithms perturbatively in the impact parameter $b_{T}$-space (a Fourier transform of the parton's transverse momentum space). The CSS formalism was extended to SIDIS [386, 387, as well as spin observables [257, 388]. With the proof that the soft factor of the TMD factorization formalism could be absorbed into the redefinition of TMDs [384, the CSS resummation formalism was recently applied to the TMDs directly [260]. Within the CSS formalism, it is not the $Q^{2}$-dependence of TMDs that is derived but rather the $Q^{2}$-dependence of the Fourier transformed TMDs at small $b_{\perp}$. In order to obtain the $Q^{2}$-dependence of TMDs, one has to perform the Fourier transform from the impact parameter $b_{\perp}$-space to the parton's transverse momentum $k_{T}$-space. The procedure of Fourier transform requires necessarily input from the nonperturbative large $b_{\perp}$ region, which could significantly reduce the predictive power of the TMDs [389]. Various treatments/models for the extrapolation into the large $b_{\perp}$ region have been proposed to fit the existing data [385]. For the precision study of TMDs at the EIC, it is very important to examine the universality of the nonperturbative extrapolation to the large $b_{\perp}$ region and its dependence on the observed kinematic variables; and most important, the predictive power of the formalism [389]. In order to understand the $Q^{2}$-dependence of spin-dependent TMDs, a careful generalization of the CSS resummation formalism to $\boldsymbol{k}_{\perp}$-dependent TMDs is needed [388], which is necessary for the study of asymmetries generated by the TMDs at the EIC.

### 2.4.3 QCD Evolution for the Correlation Functions

As introduced in Sec. [2.2, a collinear factorization formalism at twist-3 is relevant for describing the SSAs of high $P_{h T}$ particle production. Even though the phenomenological applications of this approach have been successful, the theoretical calculations so far have been mainly limited to the "bare" parton model, that is, to the zeroth order of perturbation theory without any QCD corrections. These leading order (LO) calculations have some disadvantages: they strongly depend on the choice of the renormalization as well as the factorization scale, while the physically observed SSAs should not depend on the choice of these scales. The strong dependence on the choice of these scales is an artifact of the LO perturbative calculation, and a significant cancellation of the scale dependence between the leading and the next-to-leading (NLO) contribution is expected from the QCD factorization theorem. As demonstrated by many examples, NLO contributions are typically very important in hadronic processes, and often offer a more comprehensive test of the relevant QCD factorization formalism.

To move forward to the NLO QCD dynamics, it is necessary to study the evolution (or the scale dependence) of the universal long distance distributions and to evaluate the perturbative short-distance contribution beyond the LO. The evolution equation of the twist-3 distribution functions have been derived by different groups [290, 291, 390, 391]. Recently the evolution equations for the twist-3 fragmentation functions have also become available [392]. A first NLO calculation for the short-distance hard part function has been presented in [291].

As emphasized in Sec. 2.3, there are close connections between the twist-3 collinear factorization formalism and the TMD factorization formalism. The twist-3 correlation functions are closely related to the relevant TMD functions. Even though the Collins-Soper evolution equations have been derived for all the leading-twist TMD functions [393, these evolution equations are available in $b$-space ( $b$ is conjugate to the transverse momentum $k_{\perp}$ ). How these evolution equations are transformed into the scale (or energy) dependence of the SSAs (thus leading to a similar Collins-Soper-Sterman transverse momentum resummation) is not yet fully understood.

The evolution equations of twist-3 distribution functions, particularly for the so-called soft-gluonic-pole correlation functions have been derived in [290, 291, 390, 391. Among them, $T_{F}\left(x_{1}, x_{2}\right)$ and $T_{F}^{(\sigma)}\left(x_{1}, x_{2}\right)$ are the most discussed ones and they are related to the Sivers and Boer-Mulders functions [264:

$$
\begin{align*}
T_{F}(x, x) & =-\left.\int d^{2} k_{\perp} \frac{\left|\boldsymbol{k}_{\perp}\right|^{2}}{M_{p}} f_{1 T}^{\perp}\left(x, k_{\perp}^{2}\right)\right|_{\mathrm{DIS}}, \\
T_{F}^{(\sigma)}(x, x) & =-\left.\int d^{2} k_{\perp} \frac{\left|\boldsymbol{k}_{\perp}\right|^{2}}{M_{p}} h_{1}^{\perp}\left(x, k_{\perp}^{2}\right)\right|_{\mathrm{DIS}}, \tag{2.50}
\end{align*}
$$

where $M_{p}$ is the nucleon mass. The evolution equations for both $T_{F}(x, x)$ and $T_{F}^{(\sigma)}(x, x)$ have the following generic form:

$$
\begin{equation*}
\frac{\partial T\left(x, x, \mu^{2}\right)}{\partial \ln \mu^{2}}=\frac{\alpha_{s}}{2 \pi} \int \frac{d x^{\prime}}{x^{\prime}}\left[A(\hat{\xi}) T\left(x^{\prime}, x^{\prime}, \mu^{2}\right)+B\left(x, x^{\prime}\right) T\left(x, x^{\prime}, \mu^{2}\right)\right], \tag{2.51}
\end{equation*}
$$

where $T$ represents either $T_{F}$ or $T_{F}^{(\sigma)}$, and $\hat{\xi}=x / x^{\prime}$. As can be seen in (2.51), the evolution equation for the diagonal correlation function $\left(x_{1}=x_{2}=x\right)$ is not a closed equation since it also depends on the off-diagonal piece (the $B\left(x, x^{\prime}\right)$ term). The diagonal $A(\hat{\xi})$ terms are typically similar to the relevant twist-2 splitting kernel: for $T_{F}$, it is the same as the $q \rightarrow q$
splitting kernel for the unpolarized distribution functions; for $T_{F}^{(\sigma)}$, it is the same as the splitting kernel for the transversity distribution. It might be worth pointing out that there are some discrepancies for the evolution equation of $T_{F}$ in the literature: Ref. 391 contains additional contributions compared to [290, 291, 390]. One additional piece corresponds to a contribution from the mixing between a gluon state and quark-antiquark state, which are missing in [290, 291, 390] and could be easily reproduced. Another term [ $-N_{c} T_{F}(x, x)$ ] seems difficult to reconcile at the moment, and further study is needed to resolve this discrepancy.

Similarly, one could study the evolution of the three-gluon correlation functions. For an initial effort, see [390]. They receive contributions from themselves, as well as from the quark-gluon correlation functions $T_{F}$. Even though our information on three-gluon correlation functions is very scarce, one can not rule out the possibility that they might be large since they could be generated through the QCD radiation from the quark-gluon correlation. It is also worth pointing out that we now have data from PHENIX on the SSA of $J / \Psi$ [313], which turns out to be non-zero and gives some indication that three-gluon correlation functions might be sizable. It has been suggested that open charm production in a future Electron Ion Collider (EIC) with broader kinematics could be used to unravel the three-gluon correlation functions.

Within the same method, one could study the evolution equations for the twist-3 fragmentation functions. The two most important ones are related to the first transverse-momentum-moment of the Collins function $H_{1}^{\perp}\left(z, z^{2} k_{\perp}^{2}\right)$ and the polarizing fragmentation function $D_{1 T}^{\perp}\left(z, z^{2} k_{\perp}^{2}\right)$ [297, 394]:

$$
\begin{equation*}
\hat{H}(z)=-z^{3} \int d^{2} k_{\perp} \frac{\left|\boldsymbol{k}_{\perp}\right|^{2}}{M_{h}} H_{1}^{\perp}\left(z, z^{2} k_{\perp}^{2}\right), \quad \hat{T}(z)=-z^{3} \int d^{2} k_{\perp} \frac{\left|\boldsymbol{k}_{\perp}\right|^{2}}{M_{h}} D_{1 T}^{\perp}\left(z, z^{2} k_{\perp}^{2}\right), \tag{2.52}
\end{equation*}
$$

with both $H_{1}^{\perp}$ and $D_{1 T}^{\perp}$ from the convention in [243]. These twist-3 fragmentation functions belong to the more general two-argument fragmentation functions denoted as $\hat{H}_{F}\left(z, z_{1}\right)$ and $\hat{T}_{F}\left(z, z_{1}\right)$, for details on the operator definitions, see [392]. The evolution equation for $\hat{H}(z)$ takes the following generic form (same form for $\hat{T}(z)$ ):

$$
\begin{equation*}
\frac{\partial \hat{H}\left(z_{h}, \mu^{2}\right)}{\partial \ln \mu^{2}}=\frac{\alpha_{s}}{2 \pi} \int \frac{d z}{z}\left[A(\hat{z}) \hat{H}\left(z, \mu^{2}\right)+\int \frac{d z_{1}}{z_{1}^{2}} \mathrm{PV}\left(\frac{1}{\frac{1}{z}-\frac{1}{z_{1}}}\right) B\left(z_{h}, z, z_{1}\right) \hat{H}_{F}\left(z, z_{1}, \mu^{2}\right)\right] \tag{2.53}
\end{equation*}
$$

where $\hat{z}=z / z_{h}$, and in the case of $\hat{H}\left(z_{h}, \mu^{2}\right), A(\hat{z})$ is the same as the evolution kernel for the transversity distribution; while for $T\left(z_{h}, \mu^{2}\right), A(\hat{z})$ is the same as the $q \rightarrow q$ splitting kernel for the unpolarized fragmentation function.

We have reviewed the evolution equations for the twist-3 distribution and fragmentation functions. Particularly for those related to the first transverse-momentum-moment of the Sivers and Boer-Mulders function, and Collins and polarizing fragmentation function. These evolution equations are generally not a closed set of equations. However, the diagonal pieces are very similar to those appearing in the evolution of leading-twist distribution and fragmentation functions. For the Sivers function and polarizing fragmentation function, this piece is the same as for the unpolarized distribution functions. For the Boer-Mulders function and Collins function, this piece is the same as for transversity. The evolution equations of these functions will transform into the scale dependence of the spin observables, which could be studied at EIC. With a wide coverage in $x$ and $Q^{2}$, EIC offers a great opportunity to study these scale dependences - a direct test of QCD dynamics.

### 2.4.4 Non-perturbative studies of TMDs in effective approaches

TMDs are matrix elements of certain non-local QCD light-front operators in hadron states and can only be calculated using non-perturbative frameworks. Several low-energy QCD-inspired models have been employed. Although they all have in common that they strongly oversimplify the complexity of the QCD dynamics in hadrons, studies in different models based on often complementary assumptions, help to unravel non-perturbative aspects of TMDs. Insights into non-perturbative properties are of particular interest when confirmed in various models. The practical value of model results is that they can be used to predict new observables, or to guide educated Ansätze for fits of TMD parameterizations. Especially in the context of TMDs one should not underestimate the conceptual importance of model calculations. Model calculations demonstrated the existence of effects [261, paved the way towards an understanding of universality in the fragmentation process [395], established new TMDs [396, 397, see [398 for a review. The distinction of T-even and T-odd TMDs is important also from the point of view of modeling. In order to model the former it is sufficient to use a model with explicit quark degrees of freedom. In contrast, the modeling of T-odd TMDs requires the explicit presence of gauge-field degrees of freedom.

In the following we will briefly review TMD models, though a detailed classification of all models in which TMDs have been studied would go far beyond the scope of this section.

## Models of TMDs

An interesting model is QCD in the multicolor limit, i.e. one works with $N_{c} \rightarrow \infty$ instead of $N_{c}=3$ colors. In the large- $N_{c}$ limit the nucleon can be described as a classical soliton of the chiral field [399]. Also for $N_{c} \rightarrow \infty$ QCD cannot be solved (in $3+1$ dimensions). But certain symmetry properties of the soliton field are known [399] and can be used to derive relations which compare the relative magnitudes of different flavor combinations 334,

$$
\begin{align*}
\left(f_{1}^{u}+f_{1}^{d}\right) & \gg\left|f_{1}^{u}-f_{1}^{d}\right|, & & \left|f_{1 T}^{\perp u}-f_{1 T}^{\perp d}\right| \gg\left|f_{1 T}^{\perp u}+f_{1 T}^{\perp d}\right|, \\
\left|g_{1}^{u}-g_{1}^{d}\right| & \gg\left|g_{1}^{u}+g_{1}^{d}\right|, & & \left|g_{1 T}^{\perp u}-g_{1 T}^{\perp d}\right| \gg\left|g_{1 T}^{\perp u}+g_{1 T}^{\perp d}\right|, \\
\left|h_{1}^{u}-h_{1}^{d}\right| & \gg\left|h_{1}^{u}+h_{1}^{d}\right|, & & \left|h_{1 L}^{\perp u}-h_{1 L}^{\perp d}\right| \gg\left|h_{1 L}^{\perp u}+h_{1 L}^{\perp d}\right|, \\
\left|h_{1}^{\perp u}+h_{1}^{\perp d}\right| & \gg\left|h_{1}^{\perp u}-h_{1}^{\perp d}\right|, & & \left|h_{1 T}^{\perp u}-h_{1 T}^{\perp d}\right| \gg\left|h_{1 T}^{\perp u}+h_{1 T}^{\perp d}\right|, \tag{2.54}
\end{align*}
$$

where the not indicated arguments of the TMDs scale with $N_{c}$ as $x \sim 1 / N_{c}$ and $k_{\perp} \sim N_{c}^{0}$. Analogous relations hold for antiquarks (334. In (2.54) the respectively 'large' flavor combinations are one order in $N_{c}$ enhanced compared to the 'small' ones. For known distribution functions the hierarchies in (2.54) are roughly supported in nature 400. The large- $N_{c}$ prediction [334] also proved useful as a guideline for a first extraction of the Sivers function from SIDIS [328]. Conclusions about gluon TMDs can also be drawn. For instance, $f_{1 T}^{\perp g}$ is predicted to be one order in $N_{c}$ suppressed with respect to the quark Sivers distributions [328, which seems supported by phenomenology 401, 402].

The first quark model to give practical results on T-even TMDs was the quark-diquark spectator model 403]. The basic idea of this model is to make a spectral decomposition of the correlation function which defines the TMDs, and to evaluate it in the spectator approximation, i.e. by truncating the sum over intermediate states to a single on-shell spectator with definite mass. The spectator can have the quantum numbers of a scalar (spin 0) isoscalar or axial-vector (spin 1) iso-vector diquark, and it plays the role of an effective particle which effectively takes into account non-perturbative effects related to the
sea and gluon content of the nucleon. The nucleon-quark-diquark coupling is described by an effective vertex which may contain a model-dependent form factor. This class of models with various vertex functions and different choices for the axial-vector diquark polarization states have been used extensively in literature [337, 404, 405, 406]. These results for TMDs can also be interpreted in terms of overlap of light-cone wave functions (LCWFs) for the diquark [407]. The advantage of the spectator model is that the complicated many-particle system can be effectively treated by a simple two-particle technique. However, the price to pay is that basic properties like the momentum and quark-number sum rules cannot be satisfied simultaneously, since the number of quarks "seen" in the spectator model is only one. This fundamental limitation can be resolved only by considering the diquark not as an elementary particle, but as formed by two quarks which play the role of active particles (see, e.g., ref. [408]).

A different approach consists in exploiting LCWFs to model the three-quark structure of the nucleon. The three-quark LCWFs encode the bound state quark properties of hadrons, including their momentum, spin and flavor correlations, in the form of universal processand frame-independent amplitudes. Such amplitudes have also the important property to be eigenstates of the total quark orbital-angular momentum $L_{z}^{q}$ [278, 407] and therefore, allow for mapping in a transparent way the multipole pattern in $\boldsymbol{k}_{\perp}$ associated with each TMD [409, 410. In particular, $f_{1}^{q}, g_{1 L}^{q}$ and $h_{1}^{q}$ describe monopole distributions with $\Delta L_{z}^{q}=0$ between the initial and final nucleon states, with $f_{1}^{q}, g_{1 L}^{q}$ containing $S, P$ and $D$ wave contributions, and $h_{1}^{q}$ only $S$ and $P$ waves. The other twist-2 T-even TMDs are non-diagonal in the orbital angular momentum, with $g_{1 T}^{q}$ and $h_{1 L}^{q}$ describing dipole distributions due to the interference of $S-P$ and $P-D$ waves, and $h_{1 T}^{\perp q}$ being related to a quadrupole shape due to a transfer of two units of orbital angular momentum [411, 301. Two phenomenologically successful models were used to compute the quark LCWFs: the light-cone constituent quark model (LCCQM) 409] and the chiral quark-soliton model ( $\chi$ QSM) 412, 413, 414, 415. In the LCCQM one describes the baryon state in terms of three free on-shell valence quarks. The three-quark state is however not on-shell, i.e. $M \neq \sum_{i} \omega_{i}$, where $\omega_{i}$ is the energy of free quark $i$ and $M$ is the physical mass of the bound state. The motion of the quarks inside the nucleon is described by a momentum-dependent function which is assumed to have a simple analytical expression, with free parameters fitted, e.g., to the anomalous magnetic moments and the axial charge of the nucleon. In the $\chi$ QSM quarks are not free but bound by a relativistic chiral mean field (semi-classical approximation). This field creates a discrete level in the one-quark spectrum and distorts at the same time the Dirac sea. Despite the different model assumptions in LCCQM and $\chi$ QSM, it turns out that the corresponding LCWFs are very similar in structure. It should be noticed that the $\chi \mathrm{QSM}$ naturally incorporates higher Fock states and it has been applied to describe the unpolarized TMD for both quark and antiquarks [416.

A different model used to compute TMDs is the bag model. In its simplest version it describes the nucleon as three non-interacting massless quarks confined inside a sphere. This is therefore the only quark model discussed so far which incorporates confinement, which is modeled by the bag boundary condition, i.e. in some sense the boundary condition mimics gluons [418]. All twist-2 and twist-3 T-even TMDs were studied in this model in 419], and a complete set of linear and non-linear relations among them was derived. Another remarkable insight was that the bag model strongly supports the Gaussian $k_{\perp}$-dependence of TMDs observed in phenomenology [420].

A physical picture nearly "opposite" to the bag model is provided by the covariant

Figure 2.21. Results for $h_{1}^{q}(x)$ (left panels), $h_{1 L}^{\perp(1) q}$ (middle panels) and $h_{1 T}^{\perp(1) q}$ (right panels) as functions of $x$ within different models at low scales for up (upper panels) and down quarks (lower panels). Dashed curves: spectator model of ref. 403. Dotted curves: bag model of ref. 417. Solid curves: light-cone constituent quark model of ref. [298].
parton model 421, 422, 423]. In this approach the partons are free, and assumed to be described in terms of 3D spherically symmetric momentum distributions in the nucleon rest frame. Compliance of the model with relations derived from QCD equations of motion allows the existence of only two such covariant momentum distributions: one describes unpolarized and the other polarized quarks. All twist-2 TMDs are described in terms of these two covariant distributions. This also implies relations among TMDs discussed in [421]. The most interesting aspect of the model is that the symmetry of the covariant momentum distributions tightly connects longitudinal and transverse parton momenta. As a consequence, it is possible to predict the $x$ - and $k_{\perp}$-dependence of TMDs from the $x$ dependence of known PDFs [423]. Interestingly, also this model supports the Gaussian $k_{\perp}$-dependence. An important feature is that the covariant parton model yields results which refer to a large scale. Other parton model approaches in the context of TMDs were discussed in [424, 425, 426].

TMDs in the non-relativistic limit were studied for an arbitrary number of colors $N_{c}$ in [421. In this context we recall the popular non-relativistic model prediction $h_{1}^{q}(x)=g_{1}^{q}(x)$. The non-relativistic model makes similar predictions for other TMDs. In particular, it naturally explains why in many models the integrated pretzelosity function, $h_{1 T}^{\perp q}(x)$, is so large compared to other TMDs.

Results for selected T-even TMDs computed within different models are shown in Fig. 2.21, In order to model T-odd TMDs one needs to invoke also gauge-boson degrees of freedom. We shall devote a separate section to that. But before that we discuss relations among TMDs.

In QCD all TMDs are independent functions. However, in a large class of quark models [409, 403, 405, 413, 414, 415, 419, 421, 422, 423, there appear relations among different TMDs. In fact, certain relations, the so-called 'LIRs' ('Lorentz-invariance relations') must hold in any consistent quark model framework without gauge-field degrees of freedom. The 14 T-even leading- and subleading-twist TMDs can be expressed in terms of 9 independent 'quark-nucleon scattering amplitudes' which implies the relations [243, 427] (see 428] for a review).

## T-odd TMDs

T-odd TMDs emerge from the gauge-link structure of the parton correlation functions which describe initial/final-state interactions (ISI/FSI) via soft-gluon exchanges between the struck parton and the target remnant. Here we will summarize the status of model calculations for the two leading-twist T-odd TMDs, namely the Sivers function $f_{1 T}^{\perp}$ and the Boer-Mulders function $h_{1}^{\perp}$. Both these functions require orbital angular momentum in the nucleon, since they involve a transition between initial and final nucleon states whose orbital angular momentum differ by $\Delta L_{z}^{q}= \pm 1$. Following the first calculation which explicitly predicted a non-zero Sivers function within a scalar-diquark model [261], more refined calculation of the T-odd TMDs were performed in the spectator models with both scalar and axial-vector diquark [337, 404, 429, 430, 431, 432, 433, 434. Other model calculations include the bag model [339, 435, 436], the non-relativistic constituent quark model 437] and a light-cone constituent quark model [298]. Within all these models, the FSI/ISI are approximated by taking into account only the leading contribution due to the one-gluon exchange mechanism. As a result, the final expressions for the T-odd functions are proportional to the strong coupling constant, which plays the role of a global normalization factor with different values depending on the intrinsic hadronic scale of the model. Meanwhile, we also notice that it may be not appropriate to use a perturbative coupling for these non-perturbative calculations. A non-perturbative approach was studied in refs. 438, 439, where T-odd distributions were obtained from the non-perturbative chromomagnetic quarkgluon interaction induced by instantons. A complementary approach is also to take into account the physics of the FSI/ISI by constructing augmented LCWFs which incorporate the rescattering effects by acquiring an imaginary (process-dependent) phase 440. Finally we remark that an interesting way to circumvent the no-go theorem concerning the modeling of T-odd TMDs in chiral quark models [44] was discussed in 333 where the role of gluons is played by a 'hidden vector-meson gauge symmetry'.

Recently, interesting studies were presented, which go beyond the one-gluon exchange approximation by resumming all order contributions [338, 442, 443]. This is achieved using approximate relations between TMDs and GPDs. In particular, the T-odd TMDs are described via factorization of the effects of FSIs, incorporated in a so-called "chromodynamics lensing function", and a spatial distortion of impact parameter space parton distributions [444, 299, 300]. While such relations are fulfilled from lowest order contributions in spectator models [282, 300, they are not expected to hold in general [445, 446]. However, the interesting novelty in the approach of refs. [338, 442, 443] is the calculation of the lensing function using non-perturbative eikonal methods which permit to take into account higher order gluonic contributions from the gauge-link.

A non trivial constraint in modeling or fitting the Sivers function is given by the Burkardt sum rule [447. This sum rule is related to momentum conservation, which requires that the first transverse-momentum moment of the Sivers function, i.e. the net transverse momentum due to final state interactions, should vanish. In the bag model this sum rule is violated by a few percent [339, 435], since the bag states are not good momentum eigenstates. Analogously, the non-relativistic calculation in constituent quark models leads to a small violation of the sum rule. In spectator models, the sum rule is expected to be fulfilled only when taking into account both the quark and the diquark as explicit degrees of freedom 432]. On the other side, it was proven to hold in light-cone constituent quark models [298].

In fig. [2.22 the results from different models for the first transverse-momentum moment of the Sivers and Boer-Mulders functions are compared with phenomenological parametriza-

Figure 2.22. Results for the (1)-moments of the quark Sivers (upper panels) and Boer-Mulders (lower panels) functions as function of $x$. The different curves correspond to the results after (approximate) evolution from the model scale to $Q^{2}=2.5 \mathrm{GeV}^{2}$. Solid curves: light-cone constituent quark model of ref. [298]. Dashed curves: spectator model of ref. [337. Dotted curves: bag model of ref. [339, 436]. In the case of the Sivers function, the lighter and darker shaded areas indicate statistical uncertainties of the parameterizations of ref. [332 and 328, 331. For the Boer-Mulders function the dashed-dotted curves are the results of the phenomenological parametrization of refs. 366, 367.
tions [328, 332, 331, valid at an average scale of $Q^{2}=2.5 \mathrm{GeV}^{2}$, extracted by a fit to available experimental data for pion and kaon production in semi-inclusive deep inelastic scattering. The model results are evolved from the corresponding hadronic scale to $Q^{2}=2.5$ $\mathrm{GeV}^{2}$, by employing those evolution equations which seem most promising to be able to simulate the correct evolution, which is presently not available. In particular, we evolved the (1)-moment of the Sivers function by means of the evolution pattern of the unpolarized parton distribution, while for the (1)-moment Boer-Mulders function we used the evolution pattern of the chiral-odd transversity. Within the large error bar, the results of both the LCCQM and spectator model for the Sivers function are compatible with the parameterizations for both up and down quark, although the shapes of the distributions and the magnitude of the up- and down-quark contributions are quite different. On the other hand, the bag model predicts much smaller results, for both the Sivers and Boer-Mulders functions. In all the models the Boer-Mulders function has the same sign for both the up and down contributions, confirming theoretical expectations [334, 448]. Furthermore, the up and down contributions to the Boer-Mulders function are expected to have the same order of magnitude within the available parametrizations [366, 367, 370, 449. This is confirmed from the predictions of the LCCQM and bag model, while it is at variance with the spectator model where the up distribution is more than twice bigger than the down distribution. However, we note that the available data do not allow yet a full fit of $h_{1}^{\perp}$ with its $x$ and $k_{\perp}^{2}$ dependence and the available phenomenological parameterizations are only first attempts to extract information on this distribution. New experimental data will play a crucial role to better constrain these analyses.

### 2.5 Chiral-odd partonic densities

Harut Avakian, Alessandro Bacchetta, Andreas Metz, Marco Radici

Half of the leading-twist TMDs are denoted by the letter $h$, which means that they describe the distribution of transversely polarized partons. In the helicity basis for a spin $\frac{1}{2}$ nucleon, where the unpolarized distribution $f_{1}$ and the helicity distribution $g_{1}$ have their well known probabilistic interpretation, transverse polarization states are given by linear combinations of positive and negative helicity states. Since helicity and chirality are the same at leading twist [245], they are called chiral-odd distributions.

One of the four leading-twist chiral-odd TMDs, the transversity distribution $h_{1}$, survives the integration upon transverse momentum. From the experimental point of view, transversity is quite an elusive object. In any observable the chiral-odd transversity needs to be coupled to a chiral-odd nonperturbative partner. In SIDIS, as discussed in Sec. 2.1, $h_{1}$ can appear in the leading-twist part of the cross section together with the chiral-odd Collins fragmentation function $H_{1}^{\perp}$, which can be determined separately, e.g., by measuring azimuthal asymmetries of the distribution of back-to-back pions in two-jet events in electronpositron annihilations, i.e. $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X$ [250, 369]. Another promising approach to access transversity is semi-inclusive production of pion pairs, $e p^{\uparrow} \rightarrow e^{\prime}\left(\pi^{+} \pi^{-}\right) X$ [450, where the chiral-odd partner of $h_{1}$ is represented by the chiral-odd Dihadron Fragmentation Function (DiFF) $H_{1}^{\varangle}$ 451].

Among the remaining chiral-odd quark distributions, the so-called Boer-Mulders function attracted great interest from both experiment and theory. It shares some common features as the quark Sivers function discussed in Sec. 2.2. In this section, we will dedicate one subsection to briefly describe this function, including the unique opportunity of exploring it using unpolarized hadrons.

### 2.5.1 The quark transversity distribution

At leading twist, three collinear distribution functions are needed to describe the quark distribution in the nucleon. Transversity is a leading-twist collinear PDF and enjoys the same status as $f_{1}$ and $g_{1}$ [452, 418. An important difference between $h_{1}$ and $g_{1}$ is that in spin- $\frac{1}{2}$ hadrons there is no gluonic function analogous to transversity. The most important consequence is that $h_{1}^{q}$ for a quark with flavor $q$ does not mix with gluons in its evolution and it behaves as a non-singlet quantity; this has been verified up to NLO, where chiral-odd evolution kernels have been studied so far [453, 454, 455].

The tensor charge of the nucleon is defined as the sum of the Mellin moments $\delta q\left(Q^{2}\right)=$ $\int d x\left[h_{1}^{q}\left(x, Q^{2}\right)-h_{1}^{\bar{q}}\left(x, Q^{2}\right)\right]$. Contrary to the axial charge - which is related to $g_{1}^{q}\left(x, Q^{2}\right)$ - it has a nonvanishing anomalous dimension: it evolves with the hard scale $Q^{2}$ [418]. It has been calculated on the lattice [456] and in various models [408, 457, 458, 459, 460], and was found to be sizable. For a more comprehensive review, we refer to Ref. 461.

The extraction of transversity is of fundamental interest for obtaining a complete description of the nucleon structure even for the case when internal transverse momenta are integrated over. To achieve this goal, it is crucial to cover the widest possible range in $\left(x, Q^{2}\right)$, to measure the related asymmetries differential in the relevant kinematic variables and to be able to perform a flavor separation.

| experiment (laboratory) | $\sqrt{s}$ in GeV | target type | hadron types | references |

Table 2.4. Summary of currently available measurements of Collins asymmetry amplitudes from lepton-nucleon DIS experiments, their center-of-mass energy, transversely polarized target type, and analyzed hadron types.

## The Collins effect

As discussed in Sec. 1, at tree-level and leading-twist, the SIDIS $F_{U T}^{\sin \left(\phi_{h}+\phi_{S}\right)}$ structure function of Eq. (2.8) can be described as a convolution between the transversity $h_{1 T}^{q}$ and the Collins fragmentation function $H_{1}^{\perp q}$, i.e.,

$$
\begin{equation*}
F_{U T}^{\sin \left(\phi_{h}+\phi_{S}\right)} \sim \sum_{q} e_{q}^{2} h_{1 T}^{q} \otimes H_{1}^{\perp q} \tag{2.55}
\end{equation*}
$$

In order to project out the structure function $F_{U T, T}^{\sin \left(\phi_{h}+\phi_{S}\right)}$ in Eq. (2.8), the so-called Collins amplitude $2\left\langle\sin \left(\phi_{h}+\phi_{S}\right)\right\rangle_{U T}^{h}$ for a specific hadron $h$ is extracted from the asymmetry

$$
\begin{equation*}
A_{U T}^{h}\left(\phi_{h}, \phi_{S}\right) \equiv \frac{1}{\left|\mathbf{S}_{T}\right|} \frac{d \sigma^{h}\left(\phi_{h}, \phi_{S}\right)+d \sigma^{h}\left(\phi_{h}, \phi_{S}+\pi\right)}{d \sigma^{h}\left(\phi_{h}, \phi_{S}\right)+d \sigma^{h}\left(\phi_{h}, \phi_{S}+\pi\right)}, \tag{2.56}
\end{equation*}
$$

where the subscript $U$ indicates an unpolarized lepton beam and $T$ a transversely polarized target nucleon. The azimuthal angles are illustrated in Fig. 2.1. This amplitude has so far been extracted by three polarized fixed-target experiments as summarized in Table 2.4 . From these measurements, Fig. 2.23 shows a selection of results that are significantly nonzero and help in determining both the shape of transversity and the relative size and sign of the Collins fragmentation function. All other asymmetry amplitudes listed in Table 2.4 are small or consistent with zero.

For the second unknown in Eq. (2.55), the Collins fragmentation function, model calculations are available [382, 463, 464, 465, 466, 467, 468, 469]. However, for a modelindependent extraction of transversity from the SIDIS asymmetry amplitudes we need to determine the Collins function from an independent source. This is represented by the measurement of azimuthal asymmetries in the distribution of back-to-back pions in two-jet events in electron-positron annihilations, i.e. $e^{+} e^{-} \rightarrow \pi^{+} \pi^{-} X 470$.

The relevant vectors and angles involved in $e^{+} e^{-}$annihilations leading to back-to-back jets are depicted in Fig. 2.24 (left panel). The following asymmetry can be measured [250, 369

$$
\begin{equation*}
A_{12}\left(z_{1}, z_{2}, \theta_{2}, \phi_{1}+\phi_{2}\right)=1+\frac{\sin ^{2} \theta}{1+\cos ^{2} \theta} \cos \left(\phi_{1}+\phi_{2}\right) \frac{\sum_{q} e_{q}^{2} H_{1}^{\perp(1) q}\left(z_{1}\right) H_{1}^{\perp(1) \bar{q}}\left(z_{2}\right)}{\sum_{q} e_{q}^{2} D_{1}^{q}\left(z_{1}\right) D_{1}^{\bar{q}}\left(z_{2}\right)} . \tag{2.57}
\end{equation*}
$$

Figure 2.23. Collins amplitudes for $\pi^{+}, \pi^{-}$and $K^{+}$(as denoted in the panels) from HERMES 462 and COMPASS 323 measured with a proton target. Inner error bars present statistical uncertainties and full error bars the quadratic sum of statistical and systematic uncertainties. Note that the average kinematics in each bin differs for HERMES and COMPASS and the sign of the COMPASS asymmetries have been reversed.

Pioneering measurements of this spin-dependent fragmentation function have been performed by the BELLE Collaboration (KEK) 472, 471. Experimentally, double ratios of asymmetries for like-sign (L), unlike-sign (U) and any charged (C) pion pairs are built in order to cancel (to a large extent) contributions from the experimental acceptance and radiative effects. The resulting asymmetries, $A^{U L}$ and $A^{U C}$, are then sensitive to different combinations of the favored and unfavored Colllins fragmentation functions as given in [471]. These asymmetries are presented in Fig. [2.24 as function of $z_{2}$ for four bins of $z_{1}$ for the light quarks $(u, d, s)$, where $z_{1}$ and $z_{2}$ are for a hadron in each of the back-to-back jets.

The experimental results shown in Figs. 2.23 and 2.24 are striking. First, they clearly demonstrate that the Collins effect as a manifestation of chiral-odd and naïve T-odd mechanisms is different from zero and not suppressed, both in SIDIS and in $e^{+} e^{-}$annihilations. Second, the results for oppositely charged pions (hadrons) in Fig. 2.23 suggest a very peculiar feature for the Collins fragmentation function. As scattering off $u$ quarks dominates these data due to the charge factor, the large magnitude of $\pi^{-}$amplitudes being of similar size than the $\pi^{+}$ones but having opposite sign, can only be understood if the disfavored Collins function $H_{1}^{\perp}$ unfav is large and of opposite sign to the favored one. Opposite signs for the favored and unfavored Collins functions are also supported by the different size of $A^{U L}$ and $A^{U C}$ asymmetries from BELLE in Fig. 2.24. They can be understood in light of the string model of fragmentation [463] (and also of the Schäfer-Teryaev sum rule [473). If a favored pion is created at the string end by the first break, an unfavored pion from the

Figure 2.24. Left: the kinematics of $e^{+} e^{-}$annihilation leading to back-to-back jets along the $\hat{\boldsymbol{z}}$ axis (jet frame), $P_{1}$ is the momentum of a hadron in one jet, $P_{2}$ is the momentum of a hadron in the other jet. Right: Collins asymmetry $A_{12}$ for the double ratios for like-sign (L), unlike-sign (U) and any charged (C) pion pairs as function of $z_{2}$ in bins of $z_{1}$ from BELLE 471. $A^{U L}$ and $A^{U C}$ are sensitive to different combinations of the favored and unfavored Collins fragmentation functions.
next break is likely to inherit transverse momentum in the opposite direction.
The extraction of transversity and Collins functions from available data faces the same issues as discussed for the Sivers function in Sec. 2.2 .1 for resolving the convolution in Eq. (2.55) and the same strategies are applied here. Employing the Gaussian Ansatz in Eq. (2.22) both transversity and Collins function have been extracted [250, 474] from (part of) the experimental data discussed before. The new COMPASS proton or Hall-A neutron data are not yet included in this fit. The results of this global analysis are presented in Fig. 2.25 for $u$ and $d$ transversity distributions (left panel) and favored and unfavored Collins fragmenation functions (right panel). The decrease in the presented uncertainties for the specifically chosen parametrization, which is the same as in [250, 474], is due to the new BELLE and HERMES data. The extracted favored and unfavored Collins functions confirm the features discussed before.

## Dihadron Fragmentation Functions

A complementary approach to transversity is provided by semi-inclusive two-hadron production, $e p^{\uparrow} \rightarrow e^{\prime}\left(h_{1} h_{2}\right) X$, where the two unpolarized hadrons with momenta $P_{1}$ and $P_{2}$ emerge from the fragmentation of the struck quark. The underlying mechanism differs from the Collins mechanism in that the transverse spin of the fragmenting quark is transferred to the relative orbital angular momentum of the hadron pair. Consequently, this mechanism does not require transverse momentum of the hadron pair and collinear factorization applies.

Dihadron fragmentation functions were introduced in Ref. [475] and studied for the polarized case in Refs. [450, 476, 477]. The decomposition of the SIDIS cross section in terms of quark distributions and dihadron fragmentation functions was carried out to leading twist in Ref. 451 and to sub-leading twist in Ref. [478].

The kinematics is similar to the one in single-hadron SIDIS except for the final hadronic

Figure 2.25. Left: transversity $x h_{1}^{q}(x)$ for $u$ (upper panel) and $d$ (lower panel) quarks. Right: the normalized Collins functions $\sqrt{2} H_{1}^{\perp(1 / 2)}(z) / D_{1}(z)$ for favored (upper panel) and unfavored (lower panel) fragmentation. The light grey band represents the uncertainty for the extraction in Ref. 250 and the dark grey band from the updated analysis 474. Blue lines indicate the Soffer and positivity bound for transversity and Collins function, respectively.
state, where now $z=z_{1}+z_{2}$ is the fractional energy carried by the hadron pair and we introduce the vectors $P_{h}=P_{1}+P_{2}$ and $R=\left(P_{1}-P_{2}\right) / 2$ (see Fig. 2.26), together with the pair invariant mass $M_{h}$, which must be considered much smaller than the hard scale (e.g., $P_{h}^{2}=M_{h}^{2} \ll Q^{2}$ ). We shall often use the quantity [479],

$$
\begin{equation*}
|\boldsymbol{R}|=\frac{1}{2} \sqrt{M_{h}^{2}-2\left(M_{1}^{2}+M_{2}^{2}\right)+\left(M_{1}^{2}-M_{2}^{2}\right)^{2}} \tag{2.58}
\end{equation*}
$$

where $P_{1}^{2}=M_{1}^{2}, P_{2}^{2}=M_{2}^{2}$ and $R_{T}^{2}$ is related to $M_{h}^{2}$ [479].
In analogy with the Collins function, the expression for unpolarized hadrons ( $h_{1}, h_{2}$ ) produced by a transversely polarized quark reads

$$
\begin{equation*}
D_{h_{1} h_{2} / q^{\uparrow}}\left(z, M_{h}^{2}, \boldsymbol{R}_{T}\right)=D_{1}^{q}\left(z, M_{h}^{2}\right)-H_{1 s p}^{\Varangle q}\left(z, M_{h}^{2}\right) \frac{\boldsymbol{S}_{\perp q} \cdot\left(\hat{\boldsymbol{p}} \times \boldsymbol{R}_{T}\right)}{M_{h}} \tag{2.59}
\end{equation*}
$$

Choosing $\hat{\boldsymbol{p}} \| \hat{z}$ and $\boldsymbol{S}_{\perp q} \| \hat{y}$, a positive $H_{1 s p}^{\Varangle q}$ means that hadron $h_{1}$ is preferentially emitted along $-\hat{x}$ and hadron $h_{2}$ along $\hat{x}$.

Since $\boldsymbol{R}_{T}=\boldsymbol{R} \sin \theta$, where in the c.m. frame of the hadron pair $\theta$ is the angle between $P_{1}$ and the direction of $P_{h}$ in the laboratory frame (for more details, see refs. 479, 480, 481, [482]), the relevant asymmetry that should be measured in SIDIS is

$$
\begin{align*}
A_{U T}^{\sin \left(\phi_{R}+\phi_{S}\right) \sin \theta} & \equiv 2 \frac{\int d \cos \theta d \phi_{R} d \phi_{S} \sin \left(\phi_{R}+\phi_{S}\right)\left[d \sigma\left(\phi_{R}, \phi_{S}\right)-d \sigma\left(\phi_{R}, \phi_{S}+\pi\right)\right] / \sin \theta}{\int d \cos \theta d \phi_{R} d \phi_{S}\left[d \sigma\left(\phi_{R}, \phi_{S}\right)+d \sigma\left(\phi_{R}, \phi_{S}+\pi\right)\right]} \\
& \sim \frac{|\boldsymbol{R}|}{M_{h}} \frac{\sum_{q} e_{q}^{2} h_{1}^{q}(x) H_{1 s p}^{\Varangle q}\left(z, M_{h}^{2}\right)}{\sum_{q} e_{q}^{2} f_{1}^{q}(x) D_{1}^{q}\left(z, M_{h}^{2}\right)} . \tag{2.60}
\end{align*}
$$

As in the single-hadron production case, transversity can be extracted from the asymmetry (2.60) only if the unknown $H_{1 s p}^{\Varangle}$ is independently determined from the $e^{+} e^{-}$annihilation producing, in this case, two hadron pairs: $e^{+} e^{-} \rightarrow\left(\pi^{+} \pi^{-}\right)_{\text {jet } 1}\left(\pi^{+} \pi^{-}\right)_{\text {jet2 }} X$ with kinematics

Figure 2.26. Kinematics for the production of two hadrons (left) and for the $e^{+} e^{-} \rightarrow$ $\left(\pi^{+} \pi^{-}\right)_{\text {jet1 }}\left(\pi^{+} \pi^{-}\right)_{\text {jet2 }} X$ process (right).
depicted in Fig. 2.26 (right). The relevant signal is similar to that of the Collins function, except that each transverse polarization of the quark-antiquark pair is now correlated to the azimuthal orientation of the plane formed by the momenta of the corresponding hadron pairs, suggesting that $H_{1}^{\varangle}$ is related to the concept of handedness of the jet containing a specific pair 483, 484, 485.

The leading-twist cross section of this process contains many terms [485], among which there is one involving the product of $H_{1 s p}^{\Varangle q}$ for the quark $q$ and of $\bar{H}_{1 s p}^{\Varangle q}$ for the $\bar{q}$ partner, weighted by $\cos \left(\phi_{R}+\bar{\phi}_{R}\right)$. Thus, we can properly weight the cross section and extract this contribution by defining the so-called Artru-Collins azimuthal asymmetry [485, 482
$A^{\cos \left(\phi_{R}+\bar{\phi}_{R}\right)}\left(\cos \theta_{2}, z, M_{h}^{2}, \bar{z}, \bar{M}_{h}^{2}\right)=\frac{\sin ^{2} \theta_{2}}{1+\cos ^{2} \theta_{2}} \frac{\pi^{2}}{32} \frac{|\boldsymbol{R}||\overline{\boldsymbol{R}}|}{M_{h} \bar{M}_{h}} \frac{\sum_{q} e_{q}^{2} H_{1 s p}^{\Varangle q}\left(z, M_{h}^{2}\right) \bar{H}_{1 s p}^{\Varangle q}\left(\bar{z}, \bar{M}_{h}^{2}\right)}{\sum_{q} e_{q}^{2} D_{1}^{q}\left(z, M_{h}^{2}\right) \bar{D}_{1}^{q}\left(\bar{z}, \bar{M}_{h}^{2}\right)}$,
where the dihadron fragmentation functions $D_{1}^{q}$ and $H_{1 s p}^{\Varangle q}$ are the same universal functions appearing in the SIDIS asymmetry of equation (2.60).

Pioneering measurements of $A_{U T}^{\sin \left(\phi_{R}+\phi_{S}\right) \sin \theta}$ from HERMES 481] gave evidence for a non-zero dihadron fragmentation function $H_{1 s p}^{\Varangle q}$ as shown in Fig. 2.27. The $M_{h}$ dependence does not exhibit any sign change and rules out the model of Ref. [476]: interference patterns in semi-inclusive $\pi^{+} \pi^{-}$production are different from those in $\pi^{+} \pi^{-}$elastic scattering. Calculations based on the spectator model [480, 486] are compatible with data. They, however, overestimate the asymmetries if $h_{1}^{q}$ is taken from the parametrization 474] discussed in Fig. 2.25. This estimate is presented in Fig. 2.27 by the grey band where the model $H_{1 s p}^{\Varangle q}$ is reduced by a factor $\alpha=0.32 \pm 0.06$ in order to reproduce the magnitude of the asymmetry.

Preliminary SIDIS data are also available from the COMPASS Collaboration using transversely polarized deuteron and hydrogen [487] targets. While $A_{U T}^{\sin \left(\phi_{R}+\phi_{S}\right) \sin \theta}$ is basically vanishing on the deuteron, the proton data show a signal larger than the HERMES results in Fig. 2.27, which might be due to different kinematics.

Last but not least, results from pioneering measurements of the $A^{\cos \left(\phi_{R}+\bar{\phi}_{R}\right)}$ asymmetry related to the dihadron fragmentation function became recently available from the BELLE

Figure 2.27. The spin asymmetry for the semi-inclusive production of a pion pair in deep-inelastic scattering on a transversely polarized proton 481. The grey band presents a fit to the data involving the dihadron FF calculated in the spectator model of Ref. [480] and on the parametrization for $h_{1}$ from Ref. 474.

Collaboration in Ref. 488.
For a real breakthrough of this promising approach to transversity, much more data over wide kinematic range are needed. We only mention that the SIDIS cross section does now depend on nine kinematic variables compared to six for the single-hadron case, which calls even more for a multi-dimensional analysis for a bias-free extraction of the asymmetries.

## Collins effect at EIC

The exploration of chiral-odd structures using the Collins effect is far from being complete. Several aspects need to be significantly improved. The $x$ dependence is largely unconstrained due to the lack of SIDIS asymmetries outside the range $0.005 \lesssim x \lesssim 0.3$. The antiquark and sea-quark content of transversity in the proton is completely unknown. Together with the loose constraints on the $x$ dependence, this missing piece of information makes the calculation of the tensor charge still unsatisfactory. Also the transverse momentum dependence of both the transversity and the Collins function has a significant degree of arbitrariness. Lastly, the $Q^{2}$ range of HERMES and COMPASS measurements is approximately the same: it would be desirable to study the $A_{U T}^{\sin \left(\phi_{h}+\phi_{S}\right)}\left(Q^{2}\right)$ dependence in a wide range of $Q^{2}$.

All these remarks call for more data in order to enlarge the phase space and perform a multi-dimensional analysis in all relevant kinematic variables simultaneously. An ambitious program is planned at JLab12, that would aim for exploring $A_{U T}^{\sin \left(\phi_{h}+\phi_{S}\right)}$ in the valence region with high luminosity [340, 341]. The EIC would be the ideal facility to carry out this program over a uniquely wide range in $x$ and $Q^{2}$. This potential for a mapping of the multi-dimensional phase-space in an unprecedented kinematic range is illustrated by the studies presented in Sec. 2.2 .2 and are equally valid for transversity.

The promising and complementary approach of extracting transversity with help of the dihadron fragmentation function will even more profit from the high energy option of an EIC. Fig. 2.28 shows the projected accuracy for semi-inclusive kaon pair production at an energy $\sqrt{s}=140 \mathrm{GeV}$ and for an integrated luminosity of $30 \mathrm{fb}^{-1}$. The PYTHIA event generator has been used to obtain the SIDIS event rate, and an overall detection efficiency of $50 \%$ and beam polarization of $70 \%$ were assumed. Data are shown as function of $x$ for the various different $z$ and $M_{K K}$ bins indicated in the panels. The invariant mass range of the kaon pair, $M_{K K}$, is chosen for the vicinity of the $\phi$ meson, which provides unique access

Figure 2.28. Projected accuracy, represented by the error bars, for semi-inclusive kaon pair production obtained with an energy of $\sqrt{s}=140 \mathrm{GeV}$ for an integrated luminosity of $30 \mathrm{fb}^{-1}$, as a function of $x$ in bins in $z, M_{K K}$ and for a single bin in $Q^{2}$ as indicated in the panels.
to strange quark distributions.
Furthermore, the general picture obtained so far would significantly profit from data available over a wide $Q^{2}$ range which can only be provided by the EIC. This picture obtained so far, is based on a tree-level analysis of transverse-momentum dependent azimuthal (spin) asymmetries occurring at very different energies: while the average scale of SIDIS experiments is approximately $2.5 \mathrm{GeV}^{2}$, the BELLE measurement was performed at the typical bottonium mass, i.e. $Q^{2} \sim 100 \mathrm{GeV}^{2}$. Beyond tree level, the evolution effects with running scale were included (at LO) only in the modification of the $x$ and $z$ dependence of the various functions. At low $\boldsymbol{P}_{h T}^{2} / Q^{2}\left(Q_{T}^{2} / Q^{2}\right.$ for $e^{+} e^{-}$annihilation, where $Q_{T}=\left|\boldsymbol{q}_{T}\right|$ is the transverse momentum of the virtual photon), the correct $Q^{2}$ dependence beyond tree level of transverse-momentum dependent structure functions should be studied extending the Collins-Soper-Sterman formalism mentioned in Sec. 2.2.6 [273]. A quantitative attempt to go in this direction was presented in Ref. 369, where it was estimated that transversemomentum resummation produces a suppression of the tree level result by almost a factor 5 at BELLE energies. Therefore, the extraction of the Collins function using the tree level formula could significantly underestimate its actual magnitude. In order to fit the available SIDIS asymmetries, a larger $H_{1}^{\perp}$ would automatically imply a transversity smaller than that one illustrated in Fig. 2.25.

### 2.5.2 Boer-Mulders function

The Boer-Mulders function $h_{1}^{\perp}$ [244] can be considered as the counterpart of the Sivers function $f_{1 T}^{\perp}$ : while $f_{1 T}^{\perp}$ describes the distribution of unpolarized quarks in a transversely polarized target, $h_{1}^{\perp}$ describes the distribution of transversely polarized quarks in an unpolarized target. Both functions are T-odd, and therefore vanish if the gauge-link is not taken into account in their operator definition, which makes them somewhat unique among the TMDs. Put it differently, their existence depends on the presence of initial and/or final state interactions between the active partons of a process and the target remnants (see the corresponding discussion in Sec. [2.4.1]. It is expected that both TMDs change their sign when going from SIDIS to the Drell-Yan process [262]. There is, however, one important difference between them. The Sivers function is chiral-even, whereas the Boer-Mulders function is chiral-odd. Since the elementary interactions of the Standard Model do not change the chirality (helicity) of fermions, one has to couple the Boer-Mulders function - like any other chiral-odd object too - to another nonperturbative chiral-odd correlator in order to generate a non-zero observable. This implies that $h_{1}^{\perp}$, in general, is harder to measure than $f_{1 T}^{\perp}$.

On the other hand, in the case of the Boer-Mulders function no polarized target is required, which makes this distribution rather attractive. In fact, it is believed that the Boer-Mulders effect is essential for understanding data on the angular distribution of the unpolarized Drell-Yan process [489]. To be more specific, the general structure of the DrellYan cross section reads (see [490] and references therein)

$$
\begin{equation*}
\frac{1}{\sigma_{D Y}} \frac{d \sigma_{D Y}}{d \Omega}=\frac{3}{4 \pi} \frac{1}{\lambda+3}\left(1+\lambda \cos ^{2} \theta+\mu \sin 2 \theta \cos \phi+\frac{\nu}{2} \sin ^{2} \theta \cos 2 \phi\right), \tag{2.62}
\end{equation*}
$$

where the angles $\theta$ and $\phi$ characterize the orientation of the lepton pair in a dilepton rest frame like the Collins-Soper frame 491. What attracted particular attention is the so-called Lam-Tung relation between the coefficients $\lambda$ and $\nu$ [350, 492],

$$
\begin{equation*}
\lambda+2 \nu=1 \tag{2.63}
\end{equation*}
$$

This relation is exact if one computes the Drell-Yan process to $\mathcal{O}\left(\alpha_{s}\right)$ in the standard collinear perturbative QCD framework. Even at $\mathcal{O}\left(\alpha_{s}^{2}\right)$ the numerical violation of (2.63) is small [493]. However, data for $\pi^{-} N \rightarrow \mu^{-} \mu^{+} X$ taken at CERN [345, 346] and at Fermilab [494] were found to clearly violate the Lam-Tung relation. In particular, an unexpectedly large $\cos 2 \phi$ modulation of the cross section was observed. Various explanations of this experimental result have been put forward, with the most favorable one being based on intrinsic transverse motion of partons leading to the Boer-Mulders effect [489]. The product of two Boer-Mulders functions - one for each initial state hadron - contributes to the $\cos 2 \phi$ term in the cross section in (2.62) (489). An ultimate understanding of the angular distribution in (2.62), and thus also of the role played by the Boer-Mulders function, is of crucial importance if one keeps in mind that, from a theoretical point of view, the Drell-Yan process is the cleanest hard hadron-hadron reaction.

Several model calculations have been carried out for the Boer-Mulders function of both the nucleon [282, 298, 337, 338, 404, 429, 435, 436 and the pion 443, 446, 495], where the treatments for the nucleon comprise spectator models, the MIT bag model, and constituent quark models. In the case of the nucleon two general features emerge: first, the BoerMulders function comes out to be as large as the Sivers function or even larger. Second, it has the same sign for up-quarks and down-quarks. This finding nicely agrees with a
model-independent analysis according to which $h_{1}^{\perp u}=h_{1}^{\perp d}$ to leading order of an expansion in powers of $1 / N_{c}$, with $N_{c}$ being the number of colors [334].

A lot of attention has been paid to an intuitive relation between the Boer-Mulders function and (a specific linear combination of) chiral-odd Generalized Parton Distributions in impact parameter space [496, 497]. (This connection between two types of parton distributions is the analogue of a corresponding relation involving the Sivers function which was proposed earlier [444, 299].) The intuitive picture is compatible with the two general results from model calculations discussed above. In particular, it also suggests a significant size for the Boer-Mulders function in the valence region. In Quantum Field Theory one can make such a relation quantitative in the framework of simple spectator models [282, 433, 300]. However, according to current knowledge, a general model-independent relation cannot exist 445, 446].

The Boer-Mulders function describes the strength of a correlation between the transverse momentum and the transverse spin of the active quark. This correlation generates a dipole pattern in the transverse $k_{\perp}$-plane - like the correlations associated with $f_{1 T}, g_{1 T}$, and $h_{1 L}^{\perp}$ do. One way of visualizing the Boer-Mulders effect is by looking at the density

$$
\begin{equation*}
\rho_{h_{1}^{\perp}}^{q}\left(\boldsymbol{k}_{\perp}, \boldsymbol{s}_{\perp}\right)=\int d x \frac{1}{2}\left[f_{1}^{q}\left(x, \boldsymbol{k}_{\perp}^{2}\right)+\frac{\epsilon_{\perp}^{i j} s_{\perp}^{i} k_{\perp}^{j}}{M} h_{1}^{\perp q}\left(x, \boldsymbol{k}_{\perp}^{2}\right)\right] \tag{2.64}
\end{equation*}
$$

describing the distribution of transversely polarized quarks in an unpolarized nucleon [298]. The quark polarization is specified by the spin vector $s_{\perp}$. Note that the longitudinal momentum fraction has been integrated over. In Eq. (2.64), the $f_{1}$ term provides an axially symmetric contribution, while the second term containing $h_{1}^{\perp}$ gives rise to the mentioned dipole pattern. If both effects are superimposed, the resulting distribution is shifted away from the center (distorted) in the $k_{\perp}$-plane.

The Boer-Mulders function can also be studied in SIDIS and therefore at the EIC. In this process it couples to the chiral-odd Collins fragmentation function $H_{1}^{\perp}$ [249] and gives rise to a $\cos 2 \phi_{h}$-modulation of the cross section. The pertinent structure function takes the generic form

$$
\begin{equation*}
F_{U U}^{\cos 2 \phi_{h}} \sim \sum_{q} e_{q}^{2}\left(h_{1}^{\perp q} \otimes H_{1}^{\perp q}+\frac{C}{Q^{2}} f_{1}^{q} \otimes D_{1}^{q}+\ldots\right) \tag{2.65}
\end{equation*}
$$

where $C$ is a kinematic factor. The second term on the right hand side of (2.65) is the so-called Cahn effect 498, 499, which is also caused by intrinsic transverse parton motion. It is a kinematic twist-4 contribution, i.e., it is suppressed by a factor $1 / Q^{2}$ relative to the first term. Theoretical estimates of this effect are still plagued by large uncertainties, mainly related to the insufficient knowledge of the transverse momentum dependence of $f_{1}^{q}$ and $D_{1}^{q}$. The explicit form of all potential additional (dynamical) twist-4 effects in this structure function is presently not known. These considerations show that a reliable extraction of the Boer-Mulders function from SIDIS requires data in a kinematic region for which the (largely unknown) higher-twist contributions can be neglected. Since $f_{1}^{q} \gg h_{1}^{\perp q}$ and $D_{1}^{q} \gg H_{1}^{\perp q}$, the suppression of the Cahn effect requires very large $Q^{2}$.

The SIDIS structure function $F_{U U}^{c o s 2 \phi_{h}}$ has already been measured by the CLAS Collaboration at JLab [500], the HERMES Collaboration at DESY [501], and the COMPASS Collaboration at CERN [502]. More precisely, typically data are shown for the relevant azimuthal asymmetry given by $F_{U U}^{\cos 2 \phi_{h}} / F_{U U}$. However, due to the limited range in $Q^{2}$ the present SIDIS data allow at most a qualitative extraction of $h_{1}^{\perp}$, as is also obvious from
a first exploratory study [367]. Moreover, the Boer-Mulders function for antiquarks is not at all constrained by the available data from SIDIS. Some information about antiquarks is available from recent Fermilab data on proton-deuteron [348] and proton-proton 349 DrellYan, though the uncertainties are again significant and not the least due to the presently large uncertainties for the Boer-Mulders function of quarks [370, 503, 504].

Even without further detailed reasoning it is clear that a quantitative knowledge about the Boer-Mulders function can only be obtained with data from new facilities. Measurements of the structure function $F_{U U}^{\cos 2 \phi_{h}}$ in the valence region in electroproduction of pions and kaons compose an important part of the upgraded JLab program on TMD studies. However, the $Q^{2}$ range obtainable with JLab12 will not be sufficient to suppress the contribution from the Cahn effect.

Only the unprecedented wide kinematic range of the EIC would provide clean measurements of the Boer-Mulders function for valence and sea quarks, and will allow for studying both, its $Q^{2}$ evolution and transition behavior from low to high $P_{h T}$.

Finally, there also exists a Boer-Mulders function for gluons, $h_{1}^{\perp g}$, describing the distribution of linearly polarized gluons in an unpolarized hadron [248, 281, 282]. In contrast to the Boer-Mulders function for quarks, $h_{1}^{\perp g}$ is T-even. See the relevant discussions in Sec. 3.

### 2.6 Overview on other TMDs

Harut Avakian, Alessandro Bacchetta, Andreas Metz, Peter Schweitzer

In previous Sections, we discussed the unpolarized TMD $f_{1}$, the Sivers distribution $f_{1 T}^{\perp}$, the transversity distribution $h_{1}$, and the Boer-Mulders distribution $h_{1}^{\perp}$. They have been given more emphasis because at the present state of our knowledge they seem to be the most attractive and promising for EIC studies.

Nevertheless, interesting physics is embodied also in all other TMDs. Only the combination of information from all TMDs will fully explore the information contained in the unintegrated quark correlator, and provide a complete picture of the parton structure of the nucleon in transverse momentum space. This wealth of information may become one of the biggest legacies of the EIC.

In this Section, we briefly discuss the leading-twist TMDs that have not been analyzed in previous Sections and some of the sub-leading twist TMDs.

(a)
quark pol.

|  |  | U | L | T |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | U | $f^{\perp}$ | $g^{\perp}$ | $\boldsymbol{e}$ | $h$ |
|  | L | $f_{L}^{\perp}$ | $g_{L}^{\perp}$ | $h_{L}$ | $e_{L}$ |
|  | T | $f_{T}, f_{T}^{\perp}$ | $\mathrm{g}_{T}, g_{T}^{\perp}$ | $h_{T}, h_{T}^{\perp}$ | $e_{T}, e_{T}^{\perp}$ |

(b)

Table 2.5. Transverse momentum dependent (a) twist-2, (b) twist-3 distribution functions. The $\mathrm{U}, \mathrm{L}, \mathrm{T}$ correspond to unpolarized, longitudinally polarized and transversely polarized nucleons (rows) and quarks (columns). Functions in boldface survive transverse momentum integration. Functions in gray cells are T-odd.

### 2.6.1 Other leading-twist TMDs

Table 2.5a summarizes the full list of leading-twist TMDs. The helicity distribution $g_{1}$, together with $f_{1}$ and $h_{1}$, survives integration over transverse momentum and has been already discussed extensively. Here we mention the importance of also studying its transverse momentum dependence. It may be possible that the transverse momentum distribution of quarks with spin antiparallel to the nucleon is different from that of quarks with spin parallel to the nucleon as suggested by lattice calculations [280] shown in Fig. [2.29] The structure function $F_{L L}$, involving the transverse-momentum dependence of $g_{1}$, is the only one where transverse-momentum resummation studies have been carried out to a level similar to $F_{U U, T}$ [372, but no extraction of the nonperturbative component has ever been attempted. The EIC will be an ideal machine to address this question.

The chiral-odd T-even TMD $h_{1 T}^{\perp}$ appears in the SIDIS structure function $F_{U T}^{\sin \left(3 \phi-\phi_{S}\right)}$. This function may be interpreted as the distribution of quarks with a polarization transverse but orthogonal to that of a transversely polarized nucleon. The popular name "pretzelosity" is due to the fact that this distribution has a quadrupole shape, vaguely reminiscent of a

Figure 2.29. Ratio between the helicity distribution and the unpolarized distribution for up quarks based on lattice QCD computations [280]: the significant $k_{\perp}$ dependence of the two curves (corresponding to two different parameterizations) suggests that quarks with different spin orientation have different transverse momentum distributions.
pretzel 411, 301. This TMD has attracted a lot of interest in the literature recently because of its possible connection with orbital angular momentum (see detailed discussion in Sec. (2.4.4). It is also interesting that, in a number of nonperturbative models, $h_{1 T}^{\perp}$ is just the difference between the quark helicity and the transversity distribution [419. Moreover, in simple spectator models of the nucleon it can be related to a particular linear combination of chiral-odd generalized parton distributions [282]. In general, $h_{1 T}^{\perp}$ involves an interference between light-cone wave function components that differ by two units of orbital angular momentum. Preliminary data from COMPASS [505] and from HERMES [506] taken with transversely polarized deuterons or protons, respectively, showed an effect compatible with zero, however, within large experimental uncertainties.

The TMDs $g_{1 T}$ and $h_{1 L}^{\perp}$ appear in the structure functions $F_{L T}^{\cos \left(\phi-\phi_{S}\right)}$ and $F_{U L}^{\sin 2 \phi}$, respectively. The chiral-even (chiral-odd) $g_{1 T}\left(h_{1 L}^{\perp}\right)$ describes longitudinally (transversely) polarized quarks in a transversely (longitudinally) polarized nucleon. Since both functions link two perpendicular spin directions, they are sometimes named "worm-gear" functions. Both functions are related to quark orbital motion inside nucleons. They represent the real part of an interference between nucleon wave functions that differ by one unit of orbital angular momentum, while the imaginary parts are related to the Sivers and Boer-Mulders functions [278, 507]. Because of this, they appear in positivity bounds together with the Sivers and Boer-Mulders function 507. They do not depend on final-state interactions and may offer cleaner insights into orbital angular momentum compared to the Sivers and Boer-Mulders functions. Interestingly, these functions are the first TMDs that have been computed on the lattice [279, 280]. The results (with the due caveats) indicate that they are sizable, $g_{1 T}^{u_{v}}>0, g_{1 T}^{d_{v}}<0$, and $g_{1 T} \approx-h_{1 L}^{\perp}$. These general findings also agree with some model calculations, see Sec. 2.4.4,

Notice that due to their chirality properties, $g_{1 T}$ couples through evolution to its analogous function for gluons (named $\Delta G_{T}$ in Ref. [281] and $g_{1 T}^{g}$ in Ref. [282]), while this is not true for $h_{1 L}^{\perp}$. This difference will be particularly relevant at the EIC, where gluons will play an important role.

By exploring QCD equations of motion, and neglecting "pure twist-3" quark-gluon correlators and current quark mass terms, one can express $g_{1 T}\left(h_{1 L}^{\perp}\right)$ in terms of $g_{1}\left(h_{1}\right)$ (see, e.g., [243, 252, 427, 508] and references therein). This is similar in spirit to the clas-
sic Wandzura-Wilczek approximation 509] for the twist-3 distribution function $g_{T}^{q}(x) \approx$ $\int_{x}^{1} \mathrm{~d} y g_{1}^{q}(y) / y$, (which is supported by the instanton QCD vacuum model [510, 511] and lattice QCD [512, 513]). At an initial stage, it may be convenient to exploit such Wandzura-Wilczek-type approximations, in order to make estimates for planned experiments [252, 508, 514]. In fact, existing data suggest that they are reasonable [508], even though at present there are no compelling grounds for supporting their validity [515, 516, 517]. In the end, these approximations should be tested and twist-3 effects should be extracted from the data, as we will also argue in the next subsection.

### 2.6.2 Subleading-twist TMDs

Eight out of the 18 structure functions providing the complete description of the SIDIS cross section are leading twist and were discussed in detail in previous sections. However, 10 structure functions are higher twist, where the underlying twist-classification follows [245]: "an observable is twist- $t$ if its effect is effectively suppressed by $(M / Q)^{t-2}$."

Higher twist functions, see Table [2.5b for a full list of twist-3 TMDs, are of interest for several reasons. Their understanding is required not only to complete the description of the SIDIS process. Besides being indispensable to correctly extract twist-2 parts from data, the knowledge of higher twists will also offer important tools to access the physics of the largely unexplored quark-gluon correlations which provide direct and unique insights into the dynamics inside hadrons, see, e.g., [518]. The EIC, which will span a large $Q$-range, will be an ideal tool to identify higher-twist effects, which fall off as powers of $1 / Q$.

Although suppressed with respect to twist-2 observables by $1 / Q$, twist- 3 observables are not small in the kinematics of fixed target experiments. Indeed, the first unambiguously measured single spin phenomena in SIDIS which triggered important theoretical developments, were the sizable longitudinal target $\left(A_{U L}^{\sin \phi}\right)$ and beam $\left(A_{L U}^{\sin \phi}\right)$ spin asymmetries observed at HERMES and JLab [519, 520, 521, 522, 523, 524]. Further data on twist-3 spin asymmetries are underway [505, 525, 526]. In unpolarized SIDIS, the sizable twist-3 effects $\left(A_{U U}^{\cos \phi}\right)$ are known since EMC [527, 528], see also recent results from JLab, HERMES and COMPASS [501, 529, 500, 530]. At high energies $A_{U U}^{\text {cos } \phi}$ can be described in perturbative QCD, and the unique possibilities of EIC could bridge [371 the gap to high energy data [531, 532, 533, 534. The understanding of the "matching" of the TMD formalism and the large- $p_{T}$ collinear description is of fundamental importance, see Sec. 2.2.5 and references therein.

The theoretical description of twist-3 observables is challenging. A good illustration of this point is that in spite of the enormous dedicated theoretical and phenomenological effort [396, 397, 465, 535, 536, 537, 538, 539, 540, 541, 542, 543, (544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, to explain the first single spin phenomena in SIDIS, $A_{U L}^{\sin \phi}$ and $A_{L U}^{\sin \phi}$, these observables are still not understood. The theoretical challenge is that presently it is not understood how to control light-cone divergences in SIDIS at $1 / Q$ order [555]. This does not necessarily mean there is no factorization, but it indicates that possibly new techniques are needed to pave the way towards a factorization proof in SIDIS at twist-3. If one assumes twist-3 TMD factorization, the phenomenological challenge is that each twist-3 observable receives contributions from several unknown twist-3 TMDs or fragmentation functions [247]. The situation simplifies in semi-inclusive jet production, a promising process to study at EIC energies, which could provide valuable complementary information on twist-3 TMDs [556].

An important process which can provide independent information on twist-3 (and, of course, also twist-2) TMDs are interference functions [451, 478, 479, 480, 476, [557, 558]. The advantage of this approach is that here collinear factorization applies, i.e. one cannot access TMDs. However, those functions which "survive" the $k_{\perp}$-integration of the quark correlator can be studied, and this includes at the twist- $3 e^{a}(x), g_{T}^{a}(x), h_{L}^{a}(x)$. These functions contribute to observables in convolution with specific interference fragmentation functions, which can be inferred from azimuthal asymmetries in $e^{+} e^{-}$annihilations 485].

There is no doubt that experimental, phenomenological and theoretical efforts to go beyond twist-2 are worth. Twist-3 functions describe multiparton distributions corresponding to the interference of higher Fock components in the hadron wave functions, and as such have no probabilistic partonic interpretations. Yet they offer fascinating insights into the nucleon structure [559. The Mellin moment $\int \mathrm{d} x x^{2} \tilde{g}_{T}^{a}(x)$ of the pure twist-3 piece in $g_{T}^{a}$ describes the transverse impulse the active quark acquires after being struck by the virtual photon due to the color Lorentz force. The Mellin moment $\int \mathrm{d} x x^{2} \tilde{e}^{a}(x)$ of the pure twist- 3 piece in $e^{a}(x)$ describes the average transverse force acting on a transversely polarized quark in an unpolarized target after interaction with the virtual photon.

Twist-3 TMDs are closely related to projections of different combinations of the collinear twist-3 correlation functions $G_{F}(x, x \prime)$ and $\tilde{G}_{F}(x, x \prime)$ discussed in Sec. [2.2.4, which are involved in the evolution equations of twist-3 collinear PDFs [560, 561, 562, 563, 564, 565, 566, and play important roles also in derivations of the evolution equations for transverse moments of TMDs [290, 291, 390, 391, 392, calculations of processes at high transverse momentum [352, or calculations of the high transverse momentum tails of TMDs [292, 295]. Ultimately, through a global study of all of these observables, one could simultaneously obtain better knowledge of twist-3 collinear functions and twist-2 TMDs, and at the same time test the validity of the formalism. Gathering as much information as one can on the quark-gluon-quark correlator is essential to reach this goal.

## Chapter 3

# Three-dimensional structure of the proton and nuclei: spatial imaging 

Convenors and chapter editors:
M. Burkardt, V. Guzey, F. Sabatié

### 3.1 Spatial imaging of sea quarks and gluons: summary

V. Guzey, F. Sabatié, M. Burkardt

The internal landscape of the nucleon and nuclei in terms of the fundamental quarks and gluons can be studied in different hard processes and can be characterized by different quantities (distributions). Hard exclusive reactions such as deeply virtual Compton scattering (DVCS) and exclusive production of mesons give an access to the aspects of the hadron structure that are encoded in generalized parton distributions (GPDs) and dipole amplitudes.

GPDs generalize the well-known form factors, distribution amplitudes and parton distributions and quantify various correlations/distributions of quarks and gluons in terms of their momentum fractions and positions in the transverse plane. Thus, GPDs provide a rigorous framework for studies of the three-dimensional parton structure of hadrons as well as many additional important aspects of the hadron structure such as the parton angular momentum and the related "spin puzzle", spin and flavor content, the role of chiral symmetry, and many more.

At the moment, our knowledge about GPDs is mostly limited to valence quark GPDs (Hermes, Compass, Jefferson Lab 6 GeV and also Jefferson Lab 12 GeV in the near future) and rather low precision data from HERA. A high-energy high-luminosity Electron-Ion Collider (EIC) will be an ideal machine for the studies of hard exclusive reactions and sea quark and gluon GPDs as summarised in table 3.1.

Table 3.1. Science Matrix for Exclusive Processes at EIC.
(i) One essential aspect of the GPD program is obtaining the transverse image of quarks and gluons in the nucleon/nucleus through the measurement of the $t$ dependence of cross sections of various exclusive processes (DVCS, production of $J / \psi, \phi, \pi, K$, etc. mesons) in a wide range of $t$. In the nucleon case, covering the interval $0 \approx|t| \leq 2 \mathrm{GeV}^{2}$ will enable one to map out the parton distributions in the transverse plane of the impact parameter $b$ down to as low as $b \approx 0.1 \mathrm{fm}$.
(ii) One area where an EIC shines is the large range in $Q^{2}$ available in the full $x_{B}$ interval. QCD evolution equations of GPDs, similarly to the PDF case, allow one to globally fit the data using flexible parameterizations of GPDs and to extract accurate and model-
independent information on GPDs. One also will use the large lever arm in $Q^{2}$ to establish the reaction mechanisms (scaling properties, higher twist effects).
(iii) Another clear advantage of an EIC is the availability of different polarizations for the lepton and proton beams that allows one to fully disentangle the various GPDs from the experimental observables. While DVCS is sensitive to singlet quark and gluon GPDs, other exclusive diffractive processes (electroproduction of $\rho, J / \psi, \phi$, etc.) and non-diffractive processes (electroproduction of $\pi^{+}, K^{+}$, etc.) will allow one to access the spin and flavor dependences of GPDs. Note that the non-diffractive processes push the requirements for high luminosity much further than DVCS or other diffractive processes.
(iv) Exclusive processes with nuclei in a collider and, subsequently, the spatial image of sea quarks and gluons in nuclei will be studied for the first time. All the processes mentioned above will benefit from the high luminosity of an EIC (of the order of $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ ) as well as excellent detection capabilities and particle identification guaranteeing exclusivity.
The contributions below describe in detail various aspects of the rich program of spatial imaging of sea quarks and gluons at an EIC. In conclusion, a high-energy high-luminosity EIC, studying various deep exclusive processes through cross sections and polarization observables, would uniquely extend and complement our knowledge of the 3D partonic structure of the nucleon/nucleus to the sea of quarks and gluons.

### 3.2 Basics of generalized parton distributions

Anatoly Radyushkin

### 3.2.1 Introduction

The fundamental physics to be accessed via the generalized parton distributions (GPDs) [274, 567, 568, 569, 570, 571, 572] is the structure of hadrons. This is a rather general statement, and we may want to have a more specific one. A classic example of such a specific case is the search for the Higgs boson (HB) performed currently at the Large Hadron Collider (LHC). The motivation for the search is that HB is supposed to be responsible for generation of masses, in particular, quark masses. However, by far, the largest part of visible mass is due to the nucleons, and out of 940 MeV of the nucleon mass, less than 30 MeV (current quark masses) may be related to HB. The remaining $97 \%$ of the nucleon mass is due to gluons - which are massless! This is a characteristic illustration of the situation in hadron physics:
i) All the relevant particles are already established, i.e., no "higgses" to find.
ii) The QCD Lagrangian is known.
iii) However, we still need to understand how QCD works, i.e., to understand hadronic structure in terms of quark and gluon fields.

Projecting quark and gluon fields $q\left(z_{1}\right), q\left(z_{2}\right), \ldots$ onto hadronic states $|p, s\rangle$ gives matrix elements:

$$
\begin{equation*}
\langle 0| \bar{q}_{\alpha}\left(z_{1}\right) q_{\beta}\left(z_{2}\right)|M(p), s\rangle \quad, \quad\langle 0| q_{\alpha}\left(z_{1}\right) q_{\beta}\left(z_{2}\right) q_{\gamma}\left(z_{3}\right)|B(p), s\rangle \tag{3.1}
\end{equation*}
$$

that can be interpreted as hadronic wave functions. In particular, in the light-cone (LC) formalism [573], a hadron is described by its Fock components in the infinite-momentum frame. For the nucleon, one can schematically write:

$$
\begin{equation*}
|P\rangle=\Psi_{q q q}\left|q\left(x_{1} P, k_{1 \perp}\right) q\left(x_{2} P, k_{2 \perp}\right) q\left(x_{3} P, k_{3 \perp}\right)\right\rangle+\Psi_{q q q G}|q q q G\rangle+\Psi_{q q q \bar{q} q}|q q q \bar{q} q\rangle+\ldots, \tag{3.2}
\end{equation*}
$$

where $x_{i}$ are momentum fractions satisfying $\sum_{i} x_{i}=1 ; k_{i \perp}$ are transverse momenta, $\sum_{i} k_{i \perp}=0 ; \Psi$ are light-cone wave functions. In principle, solving the bound-state equation $H|P\rangle=E|P\rangle$ one should get the wave function $|P\rangle$ that contains complete information about the hadron structure. In practice, however, the equation (involving an infinite number of Fock components) has not been solved yet in the realistic 4-dimensional case. Moreover, the LC wave functions are not directly accessible experimentally.

The way out of this situation is the description of hadron structure in terms of phenomenological functions. Among the "old" functions used for a long time we can list form factors, usual parton densities, and distribution amplitudes. The "new" functions, generalized parton distributions (for reviews, see [574, 575, 576, [577]), are hybrids of form factors, parton densities and distribution amplitudes. Furthermore, the "old" functions are limiting cases of the "new" ones.

### 3.2.2 Form factors

The form factors are defined through matrix elements of electromagnetic (EM) and weak currents between hadronic states. In particular, the nucleon electromagnetic form factors are given by

$$
\begin{equation*}
\left\langle p^{\prime}, s^{\prime}\right| J^{\mu}(0)|p, s\rangle=\bar{u}\left(p^{\prime}, s^{\prime}\right)\left[\gamma^{\mu} F_{1}(t)+\frac{r^{\nu} \sigma^{\mu \nu}}{2 m_{N}} F_{2}(t)\right] u(p, s), \tag{3.3}
\end{equation*}
$$

where $r=p-p^{\prime}$ is the momentum transfer and $t=r^{2}$. The electromagnetic current is given by the sum of its flavor components:

$$
\begin{equation*}
J^{\mu}(z)=\sum_{f} e_{f} \bar{\psi}_{f}(z) \gamma^{\mu} \psi_{f}(z) \tag{3.4}
\end{equation*}
$$

The nucleon helicity non-flip form factor $F_{1}(t)$ can also be written as a sum $\sum_{f} e_{f} F_{1 f}(t)$. A similar decomposition holds for the helicity flip form factor $F_{2}(t)=\sum_{f} e_{f} F_{2 f}(t)$. At $t=0$, these functions have well known limiting values. In particular, $F_{1}(t=0)=e_{N}=\sum_{f} N_{f} e_{f}$ gives total electric charge of the nucleon ( $N_{f}$ is the number of valence quarks of flavor $f$ ) and $F_{2}(t=0)=\kappa_{N}$ gives its anomalous magnetic moment. The form factors are measurable through elastic $e N$ scattering.

Figure 3.1. Elastic $e N$ scattering in the one-photon exchange approximation.

### 3.2.3 Usual parton densities

The parton densities are defined through forward matrix elements of quark/gluon fields separated by light-like distances. In particular, in the unpolarized case we have

$$
\begin{equation*}
\left.\langle p| \bar{\psi}_{a}(-z / 2) \gamma^{\mu} \psi_{a}(z / 2)|p\rangle\right|_{z^{2}=0}=2 p^{\mu} \int_{0}^{1}\left[e^{-i x(p z)} f_{a}(x)-e^{i x(p z)} f_{\bar{a}}(x)\right] d x \tag{3.5}
\end{equation*}
$$

In the local limit $z=0$, the operators in this definition coincide with the operators contributing into the non-flip form factor $F_{1}$. Since $t=0$ for the forward matrix element, we obtain the sum rule for the numbers of valence quarks:

$$
\begin{equation*}
\int_{0}^{1}\left[f_{a}(x)-f_{\bar{a}}(x)\right] d x=N_{a} . \tag{3.6}
\end{equation*}
$$

The definition of parton densities has the form of the plane wave decomposition. This observation allows one to give the momentum space interpretation: $f_{a(\bar{a})}(x)$ is the probability to find $a(\bar{a})$-quark with momentum $x p$ inside a nucleon with momentum $p$. The classic process to access the usual parton densities is deep inelastic scattering (DIS) $\gamma^{*} N \rightarrow X$.

Using the optical theorem, the $\gamma^{*} N \rightarrow X$ cross section is given by the imaginary part of the forward virtual Compton scattering amplitude. The momentum transfer $q$ is spacelike $q^{2} \equiv-Q^{2}$, and when it is sufficiently large, perturbative QCD factorization works. At the leading order, one deals with the so-called handbag diagram, see figure 3.2.

Through simple algebra, $\frac{1}{\pi} \operatorname{Im} 1 /(q+x p)^{2} \approx \delta\left(x-x_{B}\right) / 2(p q)$, one finds that DIS measures parton densities at the point $x=x_{B}$, where the parton momentum fraction equals the Bjorken variable $x_{B}=Q^{2} / 2(p q)$. Comparing parton densities to form factors, we note that the latter have a point vertex instead of a light-like separation and $p \neq p^{\prime}$.

Figure 3.2. Lowest order pQCD factorization for DIS.

### 3.2.4 Nonforward parton densities

"Hybridization" of different parton distributions is the key idea of the GPD approach. As the first step, we can combine form factors with parton densities [578] and write the flavor components $F_{1 a}(t)$ of form factors as integrals over the momentum fraction variable $x$ :

$$
\begin{equation*}
F_{1 a}(t)=\int_{0}^{1}\left[\mathcal{F}_{a}(x, t)-\mathcal{F}_{\bar{a}}(x, t)\right] d x . \tag{3.7}
\end{equation*}
$$

In the forward limit $t=0$, the new objects-nonforward parton densities $\mathcal{F}_{a(\bar{a})}(x, t)$ (NPDs) - coincide with the usual ("forward") densities:

$$
\begin{equation*}
\mathcal{F}_{a(\bar{a})}(x, t=0)=f_{a(\bar{a})}(x) . \tag{3.8}
\end{equation*}
$$

NPDs can be also treated as Fourier transforms of the impact parameter $b_{\perp}$ distributions $f\left(x, b_{\perp}\right)$ describing the variation of parton densities in the transverse plane [579, 580].

A nontrivial question is the interplay between $x$ and $t$ dependencies of $\mathcal{F}_{a(\bar{a})}(x, t)$. The simplest factorized ansatz $\mathcal{F}_{a}(x, t)=f_{a}(x) F_{1}(t)$ satisfies both the forward constraint, $\mathcal{F}_{a}(x, t=0)=f_{a}(x)$, and also the local constraint (3.7). The reality may be more complicated: light-cone wave functions with Gaussian $k_{\perp}$ dependence

$$
\begin{equation*}
\Psi\left(x_{i}, k_{i \perp}\right) \sim \exp \left[-\frac{1}{\lambda^{2}} \sum_{i} k_{i \perp}^{2} / x_{i}\right] \tag{3.9}
\end{equation*}
$$

suggest that

$$
\begin{equation*}
\mathcal{F}^{a}(x, t)=f_{a}(x) e^{\bar{x} t / 2 x \lambda^{2}} \tag{3.10}
\end{equation*}
$$

where $\bar{x} \equiv 1-x$. Taking $f_{a}(x)$ from existing parametrizations and adjusting $\lambda^{2}$ to provide the standard value of the quark intrinsic transverse momentum $\left\langle k_{\perp}^{2}\right\rangle \approx(300 \mathrm{MeV})^{2}$ gives a rather reasonable description of the proton form factor $F_{1}(t)$ in a wide range of momentum transfers $-t \sim 1-10 \mathrm{GeV}^{2}$ [578]. To comply with the Regge behavior, one may wish to change $e^{\bar{x} t / 2 x \lambda^{2}} \rightarrow x^{-\alpha^{\prime} t}$, where $\alpha^{\prime}$ is the Regge trajectory slope. The modified Regge ansatz,

$$
\begin{equation*}
\mathcal{F}^{a}(x, t)=f_{a}(x) x^{-\alpha^{\prime}(1-x) t} \tag{3.11}
\end{equation*}
$$

allows one to easily fit electromagnetic form factors for the proton and neutron 581]. A similar model was proposed in Ref. 582].

The same nonforward parton densities appear in the handbag diagrams for the wideangle real Compton scattering, see figure 3.3.

Figure 3.3. Form factor and wide-angle Compton scattering amplitude in terms of nonforward parton densities.

The handbag contribution is approximately given by the product of a new form factor, $R_{V}^{a}(t)$, and the cross section of the Compton scattering off an elementary fermion (given by Klein-Nishina expression):

$$
\begin{equation*}
\frac{d \sigma}{d t}=\left.\left[\sum_{a} e_{a}^{2} R_{V}^{a}(t)\right]^{2} \frac{d \sigma}{d t}\right|_{K N} \quad \text { with } \quad R_{V}^{a}(t)=\int_{0}^{1} \frac{\mathcal{F}^{a}(x, t)}{x} d x \tag{3.12}
\end{equation*}
$$

The predictions based on handbag dominance and NPDs [578, 583] are in much better agreement with the existing data [584] than the predictions based on two-gluon hard exchange mechanism of asymptotic perturbative QCD: the predicted cross section is too small in the latter case. The absolute normalization for predictions is settled by the form of the nonperturbative functions (NPDs in the handbag approach and nucleon distribution amplitudes in the pQCD approach) which were fixed by fitting the $F_{1}$ form factor data. Still, when there is an uncertain overall factor, it is risky to make strong statements. Remarkably, the perturbative QCD hard scattering mechanism and soft handbag mechanism give drastically different predictions for the polarization asymmetry $A_{L L}$ [583. Experiment E-99-114 performed at Jefferson Lab 584 strongly favors handbag mechanism that predicts the value close to the asymmetry for the scattering on a single quark.

### 3.2.5 Distribution amplitudes

Another example of nonperturbative functions describing the hadron structure are the distribution amplitudes (DAs). They can be interpreted as light cone wave functions integrated over transverse momentum, or as $\langle 0| \ldots|p\rangle$ matrix elements of light cone operators. In the case of the pion, we have

$$
\begin{equation*}
\left.\langle 0| \bar{\psi}_{d}(-z / 2) \gamma_{5} \gamma^{\mu} \psi_{u}(z / 2)\left|\pi^{+}(p)\right\rangle\right|_{z^{2}=0}=i p^{\mu} f_{\pi} \int_{-1}^{1} e^{-i \alpha(p z) / 2} \varphi_{\pi}(\alpha) d \alpha \tag{3.13}
\end{equation*}
$$

with $x_{1}=(1+\alpha) / 2, x_{2}=(1-\alpha) / 2$ being the fractions of the pion momentum carried by the quarks. The distribution amplitudes describe the hadrons in situations when the pQCD hard scattering approach is applicable to exclusive processes. The classic example is the $\gamma^{*} \gamma \rightarrow \pi^{0}$ transition; its amplitude is proportional to the $1 /\left(1-\alpha^{2}\right)$ moment of $\varphi_{\pi}(\alpha)$, see figure 3.4, left. The predictions for the $\gamma^{*} \gamma \rightarrow \pi^{0}$ form factor based on two competing models for the pion DA, the asymptotic $\varphi_{\pi}^{\text {as }}(\alpha)=\frac{3}{4}\left(1-\alpha^{2}\right)$ and Chernyak-Zhitnitsky DA $\varphi_{\pi}^{\mathrm{CZ}}(\alpha)=\frac{15}{4} \alpha^{2}\left(1-\alpha^{2}\right)$ differ by factor of $5 / 3$, and the hope was that this difference would allow for an experimental discrimination between them. Indeed, the comparison with CLEO and CELLO data for $Q^{2} F_{\gamma^{*} \gamma \pi^{0}}\left(Q^{2}\right)$ that extend to $Q^{2} \lesssim 10 \mathrm{GeV}^{2}$ favors DAs that are closer
to $\varphi^{\text {as }}(\alpha)$. However, recent BABAR data covering the range up to $Q^{2} \sim 40 \mathrm{GeV}^{2}$ show the increase of $Q^{2} F_{\gamma^{*} \gamma \pi^{0}}\left(Q^{2}\right)$ for $Q^{2} \gtrsim 10 \mathrm{GeV}^{2}$. To explain this increase, the scenarios were proposed in which the pion DA does not vanish at the end-points, e.g., $\varphi_{\pi}^{\text {flat }}(\alpha)=1$.

Figure 3.4. Lowest-order pQCD factorization for $\gamma^{*} \gamma \rightarrow \pi^{0}$ transition amplitude and for the pion electromagnetic form factor.

Another classic application of pQCD to exclusive processes is the pion electromagnetic form factor, see figure 3.4, right. With the asymptotic pion DA $\varphi_{\pi}^{\text {as }}(\alpha)$, the hard pQCD contribution to $F_{\pi}\left(Q^{2}\right)$ is $\left(2 \alpha_{s} / \pi\right)\left(0.7 \mathrm{GeV}^{2}\right) / Q^{2}$, which is less than $1 / 3$ of the experimental value. Taking wider DAs formally increases the size of the one-gluon-exchange contribution, but it is dominated then by the regions where the gluon virtuality is too small to be treated perturbatively. So, in this case we deal with the dominance of the competing soft mechanism which is described by nonforward parton densities, exactly in the same way as the proton form factor $F_{1}^{p}(t)$ discussed in the previous section.

### 3.2.6 Hard electroproduction processes

An attempt to use perturbative QCD to extract new information about hadronic structure is the study of deep exclusive photon [274] or meson [569, [572] electroproduction reactions. In the hard kinematics when both $Q^{2}$ and $s \equiv(p+q)^{2}$ are large while the momentum transfer $t \equiv\left(p-p^{\prime}\right)^{2}$ is small, one can use pQCD factorization which represents the amplitudes as a convolution of a perturbatively calculable short-distance amplitude and nonperturbative parton functions describing the hadron structure. The hard pQCD subprocesses in these two cases have different structure, see figure 3.5. Since the photon is a pointlike particle, the deeply virtual Compton scattering (DVCS) amplitude has the structure similar to that of the $\gamma^{*} \gamma \pi^{0}$ form factor: the pQCD hard term is of zero order in $\alpha_{s}$ (the handbag mechanism), and there is no competing soft contribution. Thus, we can expect that pQCD works from $Q^{2} \sim 2 \mathrm{GeV}^{2}$. On the other hand, the deeply virtual meson production process is similar to the pion EM form factor: the hard term has a $O\left(\alpha_{s} / \pi\right) \sim 0.1$ suppression factor. As a result, the dominance of the hard pQCD term may be postponed to $Q^{2} \sim 5-10 \mathrm{GeV}^{2}$.

Figure 3.5. Lowest-order factorization for deeply virtual photon and meson production.

One should also have in mind that the competing soft mechanism can mimic the same power-law $Q^{2}$-behavior (just like in case of pion and nucleon EM form factors). Hence, a mere observation of a "right" power-law behavior of the cross section may be insufficient to claim that pQCD is already working. One should look at other characteristics of the reaction, especially its spin properties, to make strong statements about the reaction mechanism.

### 3.2.7 Deeply virtual Compton scattering and generalized parton distributions

It is convenient to visualize DVCS in the $\gamma^{*} N$ center-of-mass frame, with the initial hadron and the virtual photon moving in opposite directions along the $z$-axis. Since the momentum transfer $t$ is small, the hadron and the real photon in the final state also move close to the $z$-axis. This means that the virtual photon momentum $q=q^{\prime}-x_{B} p$ has the component $-x_{B} p$ canceled by the momentum transfer $r$. In other words, the momentum transfer $r$ has the longitudinal component $r^{+}=x_{B} p^{+}$, where $x_{B}=Q^{2} / 2(p q)$ is the DIS Bjorken variable. One can say that DVCS has a skewed kinematics in which the final hadron has the "plus" momentum $(1-\zeta) p^{+}$that is smaller than that of the initial hadron. In the particular case of DVCS, we have $\zeta=x_{B}$.

The parton picture for DVCS has some similarity to that of DIS, with the main difference that the plus-momenta of the incoming and outgoing quarks in DVCS are not equal; they are $X p^{+}$and $(X-\zeta) p^{+}$, see figure 3.6. Another difference is that the invariant momentum transfer $t$ in DVCS is nonzero: the matrix element of partonic fields is essentially nonforward.

Thus, the nonforward parton distributions (NFPDs) $\mathcal{F}_{\zeta}(X, t)$ describing the hadronic structure in DVCS depend on $X$ (the fraction of $p^{+}$carried by the outgoing quark), $\zeta$ (the skewness parameter characterizing the difference between initial and final hadron momenta), and $t$ (the invariant momentum transfer). In the forward $r=0$ limit, we have a reduction formula

$$
\begin{equation*}
\mathcal{F}_{\zeta=0}^{a}(X, t=0)=f_{a}(X) \tag{3.14}
\end{equation*}
$$

relating NFPDs with the usual parton densities. The nontriviality of this relation is that $\mathcal{F}_{\zeta}(X, t)$ appear in the amplitude of the exclusive DVCS process, while the usual parton densities are measured from the cross section of the inclusive DIS reaction.

Another limit for NFPDs is zero skewness $\zeta=0$, where they correspond to nonforward parton densities: $\mathcal{F}_{\zeta=0}^{a}(X, t)=\mathcal{F}^{a}(X, t)$. The local limit relates NFPDs to form factors:

$$
\begin{equation*}
\int_{0}^{1} \mathcal{F}_{\zeta}^{a}(X, t) \frac{d X}{1-\zeta / 2}=F_{1}^{a}(t) \tag{3.15}
\end{equation*}
$$

The description in terms of NFPDs has the advantage of using the variables most close to those of the usual parton densities. However, the initial and final hadron momenta are not treated symmetrically in this scheme. Ji [274] proposed to use symmetric variables in which the plus-momenta of the hadrons are $(1+\xi) P^{+}$and $(1-\xi) P^{+}$, and those of the active partons are $(x+\xi) P^{+}$and $(x-\xi) P^{+}, P$ being the average momentum $P=\left(p+p^{\prime}\right) / 2$, see figure 3.6. In the simplified case of scalar fields, the GPD parametrization of the nonforward matrix element is

$$
\begin{equation*}
\langle P+r / 2| \psi(-z / 2) \psi(z / 2)|P-r / 2\rangle=\int_{-1}^{1} e^{-i x(P z)} H(x, \xi) d x+\mathcal{O}\left(z^{2}\right) . \tag{3.16}
\end{equation*}
$$

Figure 3.6. Comparison of NFPDs and OFPDs.

To take into account the spin properties of hadrons and quarks, one needs four offforward parton distributions $H, E, \tilde{H}, \widetilde{E}$, each of which is a function of $x, \xi$, and $t$. The skewness parameter $\xi \equiv r^{+} / 2 P^{+}$can be expressed in terms of the Bjorken variable, $\xi=$ $x_{B} /\left(2-x_{B}\right)$, but it does not coincide with it.

Depending on the value of $x$, each GPD has 3 distinct regions. When $\xi<x<1$, GPDs are analogous to usual quark distributions; when $-1<x<-\xi$, they are similar to antiquark distributions. In the region $-\xi<x<\xi$, the "returning" quark has a negative momentum and should be treated as an outgoing antiquark with momentum $(\xi-x) P$. The total $q \bar{q}$ pair momentum $r=2 \xi P$ is shared by the quarks in fractions $r(1+x / \xi) / 2$ and $r(1-x / \xi) / 2$. Hence, a GPD in the region $-\xi<x<\xi$ is similar to a distribution amplitude $\Phi(\alpha)$ with $\alpha=x / \xi$.

In the local limit, GPDs reduce to elastic form factors:

$$
\begin{equation*}
\sum_{a} e_{a} \int_{-1}^{1} H^{a}(x, \xi ; t) d x=F_{1}(t) \quad, \quad \sum_{a} e_{a} \int_{-1}^{1} E^{a}(x, \xi ; t) d x=F_{2}(t) \tag{3.17}
\end{equation*}
$$

The $E$ function, like $F_{2}(t)$, comes with the $r_{\mu}$ factor. Hence, it is invisible in DIS described by the forward $r=0$ Compton amplitude. However, the $t=0, \xi=0$ limit of $E$ exists:

$$
\begin{equation*}
E^{a, \bar{a}}(x, \xi=0 ; t=0) \equiv \kappa^{a, \bar{a}}(x) \tag{3.18}
\end{equation*}
$$

In particular, its integral gives the proton anomalous magnetic moment $\kappa_{p}$,

$$
\begin{equation*}
\sum_{a} e_{a} \int_{-0}^{1}\left(\kappa^{a}(x)-\kappa^{\bar{a}}(x)\right) d x=\kappa_{p} \tag{3.19}
\end{equation*}
$$

while its first moment enters Ji's sum rule for the total quark contribution $J_{q}$ to the proton spin:

$$
\begin{equation*}
J_{q}=\frac{1}{2} \sum_{a} \int_{-0}^{1} x\left[f^{a}(x)+f^{\bar{a}}(x)+\kappa^{a}(x)+\kappa^{\bar{a}}(x)\right] d x . \tag{3.20}
\end{equation*}
$$

Note that only valence quarks contribute to $\kappa_{p}$, while $J_{q}$ involves also sea quarks. Furthermore, the values of $\kappa_{p, n}$ (unlike $e_{p, n} \equiv F_{1}^{p, n}(0)$ ) strongly depend on dynamics, e.g., $\kappa_{N} \sim 1 / m_{q}$ in constituent quark models.

### 3.2.8 Double distributions

To model GPDs, two approaches are used: a direct calculation in specific dynamical models: bag model, chiral soliton model, light-cone formalism, etc., and a phenomenological construction based on the relation of GPDs to usual parton densities $f_{a}(x), \Delta f_{a}(x)$ and form factors $F_{1}(t), F_{2}(t), G_{A}(t), G_{P}(t)$. The key question in the second approach is the interplay between $x, \xi$ and $t$ dependencies of GPDs. There are not so many cases in which the pattern of the interplay is evident. One example is the function $\widetilde{E}(x, \xi, t)$ which is related to the $G_{P}(t)$ form factor and is dominated for small $t$ by the pion pole term $1 /\left(t-m_{\pi}^{2}\right)$. It is also proportional to the pion distribution amplitude $\varphi_{\pi}(\alpha)$ taken at $\alpha=x / \xi$. The construction of self-consistent models for other GPDs can be performed using an ansatz based on the formalism of double distributions (DD) [585].

The main idea behind the double distributions is a "superposition" of $P^{+}$and $r^{+}$momentum flows, i.e., the representation of the parton momentum $k^{+}=\beta P^{+}+(1+\alpha) r^{+} / 2$ as the sum of a component $\beta P^{+}$due to the average hadron momentum $P$ (flowing in the $s$-channel) and a component $(1+\alpha) r^{+} / 2$ due to the $t$-channel momentum $r$, see figure 3.7 , In the simplified case of scalar fields, the DD parametrization reads

$$
\begin{equation*}
\langle P-r / 2| \psi(-z / 2) \psi(z / 2)|P+r / 2\rangle=\int_{\Omega} F(\beta, \alpha) e^{-i \beta(P z)-i \alpha(r z) / 2} d \beta d \alpha+\mathcal{O}\left(z^{2}\right) . \tag{3.21}
\end{equation*}
$$

Thus, the double distribution $f(\beta, \alpha)$ (we consider here for simplicity the $t=0$ limit) looks like a usual parton density with respect to $\beta$ and like a distribution amplitude with respect to $\alpha$. The connection between the DD variables $\beta, \alpha$ and the GPD variables $x, \xi$ is obtained from $r^{+}=2 \xi P^{+}$, which results in the basic relation $x=\beta+\xi \alpha$. The formal connection between DDs and GPDs is

$$
\begin{equation*}
H(x, \xi)=\int_{\Omega} F(\beta, \alpha) \delta(x-\beta-\xi \alpha) d \beta d \alpha \tag{3.22}
\end{equation*}
$$

Figure 3.7. Comparison of GPD and DD descriptions.

The forward limit $\xi=0, t=0$ corresponds to $x=\beta$, and gives the relation between DDs and the usual parton densities:

$$
\begin{equation*}
\int_{-1+|\beta|}^{1-|\beta|} F_{a}(\beta, \alpha ; t=0) d \alpha=f_{a}(\beta) . \tag{3.23}
\end{equation*}
$$

The DDs live on the rhombus $|\alpha|+|\beta| \leq 1$ [denoted by $\Omega$ in (3.21) and (3.221)] and are symmetric functions of the "DA" variable $\alpha$ : $f_{a}(\beta, \alpha ; t)=f_{a}(\beta,-\alpha ; t)$ ("Munich" symmetry [586]). These restrictions suggest a factorized representation for a DD in the form of
a product of a usual parton density in the $\beta$-direction and a distribution amplitude in the $\alpha$-direction:

$$
\begin{equation*}
F(\beta, \alpha)=f(\beta) h(\beta, \alpha), h_{N}(\beta, \alpha) \sim \frac{\left[(1-|\beta|)^{2}-\alpha^{2}\right]^{N}}{(1-|\beta|)^{2 N+1}}, \int_{-1+|\beta|}^{1-|\beta|} h(\beta, \alpha) d \alpha=1 \tag{3.24}
\end{equation*}
$$

To obtain usual parton densities from DDs, one should integrate (scan) them over the vertical lines $\beta=x=$ const. To obtain the GPD $H(x, \xi)$ with nonzero $\xi$ from DDs $f(\beta, \alpha)$, one should integrate (scan) DDs along the parallel lines $\alpha=(x-\beta) / \xi$ with a $\xi$-dependent slope. One can call this process the DD-tomography. The basic feature of GPDs $H(x, \xi)$ resulting from DDs is that for $\xi=0$ they reduce to usual parton densities, and for $\xi=1$ they have a shape like a meson distribution amplitude. A more complete truth is that such a DD modeling misses terms invisible in the forward limit: meson-exchange contributions and so-called D-term, which can be interpreted as $\sigma$-exchange. The inclusion of the D-term induces nontrivial behavior in the central $|x|<\xi$ region (for details, see [587]).

### 3.2.9 GPDs and the structure of hadrons

Hadronic structure is a complicated subject, and it requires a study from many sides and in many different types of experiments. The description of specific aspects of hadronic structure is provided by several different functions: form factors, usual parton densities, distribution amplitudes. Generalized parton distributions provide a unified description: all these functions can be treated as particular or limiting cases of GPDs $H(x, \xi, t)$.

Usual parton densities $f(x)$ correspond to the case $\xi=0, t=0$. They describe a hadron in terms of probabilities $\sim|\Psi|^{2}$. However, QCD is a quantum theory: GPDs with $\xi \neq 0$ describe correlations $\sim \Psi_{1}^{*} \Psi_{2}$. Taking only the point $t=0$ corresponds to integration over impact parameters $b_{\perp}$ - information about the transverse structure is lost.

Form factors $F(t)$ contain information about the distribution of partons in the transverse plane, but $F(t)$ involve integration over momentum fraction $x$ - information about longitudinal structure is lost.

A simple "hybridization" of usual densities and form factors in terms of NPDs $\mathcal{F}(x, t)$ (GPDs with $\xi=0$ ) shows that the behavior of $F(t)$ is governed both by transverse and longitudinal distributions. GPDs provide adequate description of nonperturbative soft mechanism. They also allow to study transition from soft to hard mechanism.

Distribution amplitudes $\varphi(x)$ provide quantum-level information about the longitudinal structure of hadrons. In principle, they are accessible in exclusive processes at large momentum transfer, when hard scattering mechanism dominates. GPDs have DA-type structure in the central region $|x|<\xi$.

Generalized parton distributions $H(x, \xi, t)$ provide a 3 -dimensional picture of hadrons. GPDs also provide some novel possibilities, such as "magnetic distributions" related to the spin-flip GPD $E(x, \xi, t)$. In particular, the structure of nonforward density $E(x, \xi=0, t)$ determines the $t$-dependence of $F_{2}(t)$. Recent JLab data give $F_{2}(t) / F_{1}(t) \sim 1 / \sqrt{-t}$ rather than $1 / t$ expected in hard pQCD and many models - a puzzle waiting to be resolved. The forward reductions $\kappa^{a}(x)$ of $E(x, \xi, t)$ look as fundamental as $f^{a}(x)$ and $\Delta f^{a}(x)$ : Ji's sum rule involves $\kappa^{a}(x)$ on equal footing with $f(x)$. Magnetic properties of hadrons are strongly sensitive to dynamics providing a testing ground for models. Another novel possibility is the study of flavor-nondiagonal distributions, e.g., proton-to-neutron GPDs accessible through processes like exclusive charged pion electroproduction, proton-to- $\Lambda$ GPDs (they appear in kaon electroproduction), and proton-to- $\Delta$ GPDs - these can be related to form factors of
proton-to- $\Delta$ transition (another puzzle for hard pQCD). The GPDs for $N \rightarrow N+\operatorname{soft} \pi$ processes can be used for testing the soft pion theorems and physics of chiral symmetry breaking.

An interesting problem is the separation and flavor decomposition of GPDs. The DVCS amplitude involves all four types of GPDs, $H, E, \widetilde{H}, \widetilde{E}$, so we need to study other processes involving different combinations of GPDs. An important observation is that, in hard electroproduction of mesons, the spin nature of produced meson dictates the type of GPDs involved, e.g., for pion electroproduction, only $\widetilde{H}, \widetilde{E}$ appear, with $\widetilde{E}$ dominated by the pion pole at small $t$. This gives an access to (generalization of) polarized parton densities without polarizing the target.

In summary, the structure of hadrons is the fundamental physics to be accessed via GPDs. GPDs describe hadronic structure on the quark-gluon level and provide a threedimensional picture ("tomography") of the hadronic structure. GPDs adequately reflect the quantum-field nature of QCD (correlations, interference). They also provide new insights into spin structure of hadrons (spin-flip distributions, orbital angular momentum). GPDs are sensitive to chiral symmetry breaking effects, a fundamental property of QCD. Furthermore, GPDs unify existing ways of describing hadronic structure. The GPD formalism provides nontrivial relations between different exclusive reactions and also between exclusive and inclusive processes.

### 3.3 GPDs and transverse nucleon structure at collider energies

C. Weiss

Generalized parton distributions (GPDs) have emerged as a key concept in nucleon structure and the theory of high momentum-transfer processes in QCD. They unify the traditional notions of parton densities and elastic form factors and describe the transverse spatial distribution of quarks and gluons in a fast-moving hadron. A general introduction to GPDs and hard exclusive processes is given in section 3.2. Here we summarize the properties of GPDs at collider energies, where the parton picture can be combined with methods specific to high-energy scattering ("small-x physics"). This includes the transverse spatial structure of the nucleon at small $x$; gluon and quark imaging with hard exclusive processes at $e p$ colliders (HERA, EIC); the correspondence with the QCD dipole model and the role of transverse nucleon structure in saturation at small $x$; and the application of GPDs to high-energy $p p$ collisions with hard processes (Tevatron, LHC).

GPDs are defined as the transition matrix elements of the QCD twist- 2 operators between nucleon states of different momenta. They are functions of the longitudinal momentum fractions of the partons, $x$ and $x^{\prime}$, and the invariant momentum transfer $t$, as well as the resolution scale $Q^{2}$ (see figure 3.8a). Of particular interest is the "diagonal" limit $x=x^{\prime}$, where the momentum transfer is in the transverse direction only, $t=-|\boldsymbol{\Delta}|^{2}$, and the GPD can be regarded as the form factor of partons carrying longitudinal momentum fraction $x$. Its two-dimensional Fourier transform

$$
\begin{equation*}
f\left(x, b, Q^{2}\right) \equiv \int \frac{d^{2} \Delta}{(2 \pi)^{2}} e^{-i(\boldsymbol{\Delta} \boldsymbol{b})} \operatorname{GPD}\left(x, t=-\boldsymbol{\Delta}^{2}, Q^{2}\right) \tag{3.25}
\end{equation*}
$$

describes the transverse spatial distribution of partons with momentum fraction $x$ and thus provides a "tomographic" image of the structure of the fast-moving nucleon (see figure 3.8b) [580]. The coordinate $b$ measures the distance from the transverse center-of-mass (CM), defined as the average of the transverse positions of all constituents weighted with their longitudinal momentum fractions. In general, the removal of a parton with momentum fraction $x$ changes the position of the CM, and this effect must be taken into account in interpreting the coordinate distributions at $x \sim 1$. At $x \ll 1$ however, the contribution of the removed parton to the CM is negligible and one can think of the $b$-distributions of (3.25) as referring to a fixed transverse center of the nucleon. This considerably simplifies the spatial interpretation of GPDs at small $x$.

Figure 3.8. (a) GPD and partonic variables. (b) Transverse spatial distribution of partons. (c) QCD evolution generates small $x, x^{\prime}$ from the quasi-diagonal GPD at lower scale.

Figure 3.9. (left) Exclusive $J / \psi$ production as a probe of the gluon GPD. (right) Average transverse gluonic size of the nucleon $\left\langle b^{2}\right\rangle_{g}$ extracted from $J / \psi$ photoproduction at HERA [588, 589] and FNAL [590] (adapted from 591]). The effective scale at which the GPD is probed is $Q_{\text {eff }}^{2} \approx 3 \mathrm{GeV}^{2}$.

Hard exclusive processes require a nonzero longitudinal momentum transfer to the nucleon and probe the GPDs at $x-x^{\prime} \equiv$ $2 \xi \neq 0$, where the "skewness" is related to the Bjorken variable by $\xi=x_{B} /\left(2-x_{B}\right)$. Models or additional assumptions are generally needed to extract the diagonal GPD from the data. However, at $x_{B} \ll 1$ and sufficiently large $Q^{2}$ the "skewed" GPD can approximately be reconstructed from the diagonal limit 592, 593. In this case QCD evolution generates the GPD with $x$ and $x^{\prime}$ from configurations at a lower scale with momentum fractions $x_{0}, x_{0}^{\prime} \gg x, x^{\prime}$; because the difference of the parton momentum fractions is preserved under evolution, the lower-scale GPD is effectively evaluated in the diagonal limit $x_{0}-x_{0}^{\prime} \ll x_{0}, x_{0}^{\prime}$ (see figure 3.8k). This approximation allows one to relate the measured $t$-dependence of the differential cross sections directly to the transverse structure of the nucleon at fixed $x$.

The transverse spatial distribution of partons changes with the momentum fraction $x$ and the scale $Q^{2}$. The valence quarks and gluons at $x>0.1$ are concentrated at small transverse distances $b \ll 1 \mathrm{fm}$, as can be inferred from the nucleon axial form factor and exclusive processes at large $x$. Be-

Figure 3.10. A simulated measurement of exclusive $J / \psi$ electro-production with a mediumenergy EIC for an integrated luminosity of 100 $\mathrm{fb}^{-1}$. The expected statistical errors in the $t-$ dependence of the $J / \psi$ dilepton cross section in a fully differential measurement in $W, Q^{2}$ and $t$ are shown. The values of $x \equiv M_{J / \psi}^{2} / W^{2}$ in the bins are indicated above the curves, corresponding approximately to the $x$-values where the gluon GPD is probed. Such measurements can image the transverse distribution of gluons at $x>0.1$ and explore the unknown $t$-dependence at $|t|>1 \mathrm{GeV}^{2}$.
low $x<M_{\pi} / M_{N}$ chiral dynamics gives rise to a distinct large-distance contribution to the parton density at $b \sim 2 / M_{\pi}$ [594]. At even smaller values of $x$ the nucleon's transverse size is expected to grow as a result of Gribov diffusion in the successive parton branchings building up the small-x parton density. The transverse distribution also shrinks with increasing $Q^{2}$ as a result of DGLAP evolution [595. Overall, much interesting information on nucleon structure and non-perturbative dynamics can be obtained from the study of the transverse spatial distributions of quarks and gluons.

The transverse spatial distribution of gluons can be measured cleanly through exclusive $J / \psi$ photo- or electroproduction $\gamma^{(*)} N \rightarrow J / \psi+N$, or electroproduction of $\phi$ mesons at $Q^{2} \gtrsim 10 \mathrm{GeV}^{2}$ (see figure 3.9 a ). Measurements at HERA have confirmed the applicability of QCD factorization, with corrections for the finite size of the produced meson, and tested the universality of the gluon GPD; see 596 for a review. The data show that the nucleon's transverse gluonic radius at $x<0.01$ is substantially smaller than the transverse charge radius (see figure 3.9b). It increases only moderately with decreasing $x$, with a logarithmic slope much smaller than that of the Pomeron trajectory, $\alpha_{P}^{\prime}=0.25 \mathrm{GeV}^{-2}$, showing that Gribov diffusion is suppressed for partons with virtualities $\sim$ few $\mathrm{GeV}^{2}$. Both observations are of central importance for nucleon structure and small-x physics.

While the HERA experiments have provided basic information on the nucleon's transverse gluonic size at small $x$, many important questions remain unanswered:

- How are the gluons at $x>10^{-2}$ distributed in transverse space? Global PDF fits indicate a substantial momentum density of gluons in that $x$-range at low scales $Q^{2} \sim$ few $\mathrm{GeV}^{2}$. Knowledge of their spatial distribution would help to explain their dynamical origin, one of the key issues of nucleon structure in QCD.
- Do singlet quarks and gluons have the same transverse distribution? This can be studied by comparing the $t$-dependence of $J / \psi$ and $\phi$ with $\rho^{0}$ and $\gamma$ electroproduction. A larger radius for quarks than gluons is expected from non-perturbative effects 597.
- How are non-singlet sea quarks distributed in transverse space? The non-singlet sea at $x<0.1$ reveals non-perturbative QCD interactions (vacuum fluctuations, mesonic degrees of freedom) in the nucleon. This component is probed in exclusive $\pi, K, \rho^{+}$ or $K^{*}$ production - non-diffractive processes involving quantum number exchange.
- How does the nucleon's gluon GPD behave at $|t| \sim$ few $\mathrm{GeV}^{2}$ ? The large- $|t|$ behavior of GPDs is important not only to obtain accurate images at small $b$, but also to understand how soft Regge-like dynamics is connected to QCD at short distances.
- What is the probability for a nucleon to break up into a low-mass hadronic state ( $M_{H} \sim$ few GeV ) in an exclusive process at small $x_{B}$ ? Such "diffractive dissociation" reveals the quantum fluctuations of the nucleon's gluon density - new information going beyond the average densities described by the GPDs 598.

An EIC would enable a comprehensive program of transverse imaging of gluons and sea quarks in the nucleon. Measurements of $J / \psi$ photo- and electroproduction, as well as $\phi$ meson electroproduction at $Q^{2}>10 \mathrm{GeV}^{2}$, would cleanly map the transverse distribution of gluons, including the gluons at $x>0.1$ (see the example in figure 3.10). They could also explore the unknown $t$-dependence of the GPD at $|t|>1 \mathrm{GeV}^{2}$. Measurements of $\rho^{0}$ and $\gamma$ production (DVCS) would provide additional information on the singlet quarks. With a high-luminosity EIC, even the non-diffractive channels $\left(\pi, K, \rho^{+}, K^{*}\right)$ could be measured

Figure 3.11. (a) Dipole picture of high-energy scattering in the target rest frame. (b) Multiparton processes in high-energy $p p$ collisions.
for the first time down to $x \sim 0.01$, providing detailed information on the spatial distribution of the non-singlet sea, including its spin and flavor composition (see section 3.12).

The QCD factorization theorem for hard exclusive processes at small $x$ (figure 3.9a) is equivalent to the dipole picture of exclusive processes in the nucleon rest frame in the leading $\alpha_{s} \log Q^{2}$ approximation [599]. The scattering amplitude for a dipole of size $r$ with impact parameter $b$ is proportional to the $b$-dependent gluon density of (3.25) at a scale $Q^{2} \approx \pi^{2} / r^{2}$ (see figure 3.3a). This correspondence relates GPDs to the dipole model phenomenology of small- $x$ physics [596. In particular, the transverse spatial distribution of gluons is an essential input to studies of the unitarity limit in hard processes at small $x$ ("black-disk regime"). It defines the spatial profile of the initial conditions of non-linear QCD evolution equations leading to gluon saturation at small $x$. Detailed studies of saturation in the dipole model have used the transverse gluonic size extracted from the HERA data (see figure 3.9b) [600, 601; better knowledge of the transverse profile would help to accurately predict the $x$ and $b$-dependence of the saturation scale.

The transverse distribution of partons also plays an important role in high-energy $p p$ collisions with hard processes. It determines the probability of hard parton-parton processes as a function of the $p p$ impact parameter. Using knowledge of the transverse distribution of partons from $e p$ scattering one can explain many features of the underlying event in $p p$ collisions with hard processes [591]. In particular, one can predict the rate of multiparton processes (see figure 3.3b), which form a potentially large background to new physics events at the LHC. The enhancement of such processes beyond their geometric probability signals dynamical correlations between partons, the study of which represents a new frontier of nucleon structure.

### 3.4 How large can the distributions $E^{q}$ and $E^{g}$ be?

Markus Diehl

### 3.4.1 Positivity bounds

The generalized parton distributions $E$ for quarks and gluons play a key role in the study of nucleon structure through exclusive processes. In the following I focus on the case of zero skewness, $\xi=0$, where the physics interpretation is most intuitive and where constraints on these distributions are most easily obtained. The density of unpolarized quarks in a proton polarized along the $x$-axis is given by

$$
\begin{equation*}
q^{X}(x, \vec{b})=q\left(x, b^{2}\right)-\frac{b^{y}}{m} \frac{\partial}{\partial b^{2}} e_{q}\left(x, b^{2}\right), \tag{3.26}
\end{equation*}
$$

where $m$ is the proton mass. The quarks have impact parameter $\vec{b}$ and move in the $z$ direction with momentum fraction $x$. The term with

$$
\begin{equation*}
e_{q}\left(x, b^{2}\right)=\int \frac{d^{2} \Delta}{(2 \pi)^{2}} e^{-i \vec{b} \vec{\Delta}} E^{q}\left(x, \xi=0, t=-\vec{\Delta}^{2}\right) \tag{3.27}
\end{equation*}
$$

quantifies the transverse shift of the density due to the proton polarization. The density interpretation of (3.26) (together with its analog for longitudinal quark and proton polarization) entails a positivity bound [602]:

$$
\begin{equation*}
\frac{b^{2}}{m^{2}}\left[\frac{\partial}{\partial b^{2}} e_{q}\left(x, b^{2}\right)\right]^{2} \leq\left[q\left(x, b^{2}\right)+\Delta q\left(x, b^{2}\right)\right]\left[q\left(x, b^{2}\right)-\Delta q\left(x, b^{2}\right)\right] \tag{3.28}
\end{equation*}
$$

The theoretical status of this bound is the same as for the positivity of unpolarized parton densities and for the Soffer inequality: they hold in the parton model and are preserved by leading-order DGLAP evolution to higher scales, but they can be violated by higher-order evolution effects or at very low scales. Since so little is known about $E$, I suggest to use (3.28) as a guide, with proper caution. A consequence of (3.28) is that $\left(\partial / \partial b^{2}\right) e_{q}$ must decrease faster with $b$ than $\sqrt{q^{2}-\Delta q^{2}}$. This has immediate consequences for parameterizations: using Gaussian forms $E^{q} \propto e^{B_{e} t}$ and $\sqrt{q^{2}-\Delta q^{2}} \propto e^{B_{q} t}$ for the momentum-space distributions at $\xi=0$, one must have $B_{e}<B_{q}$, and with power laws $E^{q} \propto\left(1-t / M_{e}^{2}\right)^{-3}$ and $\sqrt{q^{2}-\Delta q^{2}} \propto\left(1-t / M_{q}^{2}\right)^{-2}$, one must have $1 / M_{e}<1 / M_{q}$, with equality of the parameters not being allowed in either case. Starting from (3.28) one can also derive a bound 602 for the integrated distribution:

$$
\begin{equation*}
e_{q}(x)=\int d^{2} b e_{q}\left(x, b^{2}\right)=E^{q}(x, \xi=0, t=0) . \tag{3.29}
\end{equation*}
$$

That bound constrains the large $x$ behavior of $e_{q}(x)$, but numerically turns out to be rather weak for $x$ below 0.5 , see e.g. 603].

Analogous definitions and bounds apply to antiquark and gluon distributions $e_{\bar{q}}$ and $e_{g}$.

### 3.4.2 Sum rules

An important constraint follows from the sum rule

$$
\begin{equation*}
\kappa_{q}=\int_{0}^{1} d x\left[e_{q}(x)-e_{\bar{q}}(x)\right] \tag{3.30}
\end{equation*}
$$

Figure 3.12. GPDs in the forward limit obtained in a phenomenological fit 582 to the nucleon form factors. The first two panels correspond to two parameter sets giving a good fit. The valence quark distributions $u_{\mathrm{val}}=u-\bar{u}$ and $d_{\mathrm{val}}=d-\bar{d}$ in the third panel are shown for comparison. All distributions are shown at the scale $\mu=2 \mathrm{GeV}$.
where $\kappa_{q}$ is the contribution of quark flavor $q$ to the anomalous magnetic moment of the proton. From the magnetic moments of proton and neutron one obtains $\kappa_{u}-\kappa_{d}=3.71$ and $\kappa_{u}+\kappa_{d}+\kappa_{s}=-0.36$. Under the reasonable assumption that $\kappa_{s}$ is small compared with $\kappa_{u}$ and $\kappa_{d}$, these numbers imply that $\kappa_{u}$ and $\kappa_{d}$ are both large but have opposite signs and largely cancel in the flavor sum. As a consequence, the functions $e_{u, \text { val }}(x)=e_{u}(x)-e_{\bar{u}}(x)$ and $e_{d, \text { val }}(x)=e_{d}(x)-e_{\bar{d}}(x)$ must be large at least in some region of $x$. This is illustrated in figure 3.12, which shows distributions obtained by fitting a model ansatz for $u$ and $d$ quark GPDs to the electromagnetic nucleon form factors [582] (neglecting strange-quark contributions). The fit suggests that $e_{u, \mathrm{val}}$ and $e_{d, \mathrm{val}}$ are of similar size as the unpolarized valence distributions, whereas $e_{u, \mathrm{val}}+e_{d, \text { val }}$ is small and poorly known, to the point that we do not know whether it has zero crossings.

The second moments of $e(x)$ appear in Ji's angular momentum sum rules,

$$
\begin{equation*}
2 J^{q}=\int_{0}^{1} d x x[q(x)+\bar{q}(x)]+\int_{0}^{1} d x x\left[e_{q}(x)+e_{\bar{q}}(x)\right], \quad 2 J^{g}=\int_{0}^{1} d x x g(x)+\int_{0}^{1} d x x e_{g}(x) \tag{3.31}
\end{equation*}
$$

where they give "nontrivial" contributions in addition to the "trivial" ones from the momentum integrals of quarks and gluons (whose values are well known). Summed over all partons, the momentum integrals add up to 1 and the angular momenta to $\frac{1}{2}$, so that

$$
\begin{equation*}
\int_{0}^{1} d x x e_{\operatorname{sing}}(x)+\int_{0}^{1} d x x e_{g}(x)=0 \tag{3.32}
\end{equation*}
$$

where $e_{\text {sing }}(x)=\sum_{q}\left[e_{q}(x)+e_{\bar{q}}(x)\right]$. Note that both (3.30) and (3.32) are exact relations in QCD, in contrast to the positivity bound (3.28). The scale dependence of $e_{g}(x)$ and $e_{\text {sing }}(x)$ is governed by coupled DGLAP equations, with the same kernels as for the unpolarized gluon and quark singlet distributions. With (3.32) one finds that to leading order in $\alpha_{s}$

$$
\begin{equation*}
\int_{0}^{1} d x x e_{g}(x, \mu)=\left(\frac{\alpha_{s}(\mu)}{\alpha_{s}\left(\mu_{0}\right)}\right)^{\gamma} \int_{0}^{1} d x x e_{g}\left(x, \mu_{0}\right) \tag{3.33}
\end{equation*}
$$

where $\gamma=50 / 81$ for $n_{f}=3$ and $56 / 75$ for $n_{f}=4$ active flavors. All numbers in the following refer to $\mu=2 \mathrm{GeV}$; the evolution of (3.33) to higher scales is rather slow.

With the distributions in 582 one finds that $\int d x x e_{\text {sing }}$ has a very small valence part $\int d x x\left[e_{u}-e_{\bar{u}}+e_{d}-e_{\bar{d}}\right]$ between -0.042 and 0.068. A similar situation is found in lattice calculations, which obtain a small contribution to $\int d x x\left[e_{u}+e_{\bar{u}}+e_{d}+e_{\bar{d}}\right]$ from connected graphs, with values between $-0.077(16)$ and $0.015(11)$ for different extrapolations to the physical quark masses 604].

Assuming that $\int d x x\left[e_{u}-e_{\bar{u}}+e_{d}-e_{\bar{d}}\right]$ is indeed small (and barring the possibility of an implausibly large $e_{s}-e_{\bar{s}}$ ) we find that the sum $\int d x x e_{g}+\int d x x e_{\text {sea }}$ of second moments must be small, where $e_{\text {sea }}=2 \sum_{q} e_{\bar{q}}$. This still leaves us with a number of possible scenarios:

1. both $e_{g}(x)$ and $e_{\text {sea }}(x)$ are small (note that this does not exclude large $e_{\bar{q}}(x)$ for individual quark flavors: only the flavor sum must be small),
2. $e_{g}(x)$ and $e_{\text {sea }}(x)$ are both large but have opposite signs,
3. both distributions are large but have nodes such that their second moments are small.

Scenario 2 is illustrated in figure 3.13, which shows two variants of model distributions proposed in 605. The absolute size of the distributions is limited by the bound (3.28) and its analogs for $e_{\bar{q}}$ and $e_{g}$, and the opposite signs of $e_{g}$ and $e_{\text {sea }}$ ensure that (3.32) can be fulfilled. We see that scenarios where both $e_{g}$ and $e_{\text {sea }}$ are large cannot be ruled out with our present knowledge. If the above model distributions are evolved to higher scales, $e_{g}$ becomes even larger and steeper at small $x$ 603].

Figure 3.13. Two variants of model distributions $e_{g}$ and $e_{\text {sing }}$ at $\mu=2 \mathrm{GeV}$ from 605]. The distributions of the quark singlet $q_{\text {sing }}=\sum_{q}(q+\bar{q})$ and the gluon are shown for comparison.

### 3.4.3 Exclusive processes

Up to now I discussed $E^{q}, E^{\bar{q}}$ and $E^{g}$ at zero skewness $\xi=0$, but in exclusive processes like DVCS and meson production $\xi$ is always nonzero. Nevertheless, experience from phenomenology and models suggests that GPDs at $\xi=0$ are closely enough related to those at $\xi \neq 0$ to serve as a guide for their overall size, see e.g. [577, 606].

Note that even the large model distributions $e_{g}$ and $e_{\text {sea }}$ in figure 3.13 result in small values for the transverse target spin asymmetry $A_{U T}$ in exclusive $\rho$ electroproduction [605]. This is in part due to cancellations in the sum over $u$ and $d$ quarks in this process (the
same distributions give a larger asymmetry for $\omega$ production). Moreover, $A_{U T}$ in exclusive meson production is proportional to $\operatorname{Im}\left(\mathcal{H} \mathcal{E}^{*}\right)$, where $\mathcal{H}$ and $\mathcal{E}$ are the scattering amplitudes associated with $H$ and $E$ distributions, respectively. Hence $A_{U T}$ is also small when both amplitudes are large but have a small relative phase. The transverse target asymmetry in DVCS is therefore of special importance, because the interference between Compton scattering and the Bethe-Heitler process is linear in $\operatorname{Im} \mathcal{E}$.

### 3.5 Imaging transverse distributions

Gerald A. Miller

### 3.5.1 Introduction

Much effort has gone into measuring electromagnetic form factors, which are related to the charge and magnetization densities within the nucleons. The influence of relativistic motion of the quarks within the nucleon causes the standard textbook interpretation of form factors as three-dimensional Fourier transforms to be wrong 607. The use of transverse densities [608, 609] avoids various difficulties by working in the infinite momentum frame and taking the spacelike momentum transfer to be in the direction transverse to that of the infinite momentum. In this case, the different momenta of the initial and final nucleon states are accommodated by using two-dimensional Fourier transforms and transverse charge and magnetization densities are constructed from density operators that are the absolute square of quark-field operators.

The transverse charge density is given by [608, 610]

$$
\begin{equation*}
\rho(b)=\int d x^{-} \rho\left(x^{-}, b\right)=\frac{1}{2 \pi} \int Q d Q J_{0}(Q b) F_{1}\left(Q^{2}\right), \tag{3.34}
\end{equation*}
$$

where $\rho\left(x^{-}, b\right)$ is the three dimensional spatial density.
The transverse charge densities are shown in [608, 609]. The interesting feature is that the central neutron charge density is negative. An interpretation of this finding based on the impact parameter distribution [580, 611 was presented in 612]. All models of these quantities are based on the Drell-Yan-West relation, which connects large values of $x$ with large values of $Q^{2}$. These models tell us that the $d$ quarks that dominate deep inelastic scattering from the neutron at large values of $x$ dominate the neutron center. It is also possible that the negatively charge pionic cloud may penetrate the center [613].

The transverse anomalous magnetization density is obtained from the matrix element of the magnetization density operator $\frac{1}{2} \vec{b} \times \vec{j}$, where $\vec{j}$ is taken in the $z$-direction:

$$
\begin{equation*}
\rho_{M}(b)=\frac{\sin ^{2} \phi}{2 M} b \int \frac{Q^{2} d Q}{2 \pi} F_{2}\left(Q^{2}\right) J_{1}(Q b) . \tag{3.35}
\end{equation*}
$$

The integral $\int d^{2} b \rho_{M}(b)$ gives the anomalous magnetic moment.

### 3.5.2 Realistic transverse images of the proton charge and magnetic densities

The word "realistic" refers to the ability to know the uncertainty in the transverse densities derived from experiment. The previously obtained transverse densities are derived from various parameterizations of the form factors. A more detailed treatment is needed to be able to extract uncertainties. The following discussion is based on the analysis 614.

The basic idea behind our approach is to use the observation that $\rho(b) \approx 0$ for $b \geq R$, where $R$ is a finite distance. Since the functions $\rho$ and $F$ are Fourier transforms, $F$ is bandlimited. We proceed in the spirit of the Nyquist-Shannon sampling theorem and expand the function $\rho$ as

$$
\begin{equation*}
\rho(b)=\sum_{n=1}^{\infty} \frac{1}{2 \pi} \frac{2}{R^{2} J_{1}\left(X_{n}\right)^{2}} F\left(Q_{n}^{2}\right) J_{0}\left(X_{n} \frac{b}{R}\right), \tag{3.36}
\end{equation*}
$$

Figure 3.14. Plot of $\rho_{D}$ (solid), 5 term approximation (red, long dash), 10 term approximation (green, medium dash) and 15 term approximation (brown, short dash). From Ref. 614].
where $X_{n}$ is the $n$-th zero of the regular cylindrical Bessel function of order $0, J_{0} ; Q_{n} \equiv$ $X_{n} / R$ and $X_{n} \approx(n+3 / 4) \pi$. Equation (3.36) defines the so-called finite radius approximation (FRA). Using, for example, $R=3 \mathrm{fm}$ and $n=10, Q_{n}^{2} \approx 4 \mathrm{GeV}^{2}$. Thus, the measurement up to $Q^{2}=4 \mathrm{GeV}^{2}$ determines the first ten terms of the expansion. As an example, let us consider the expansion (3.36) for the dipole form factor: $F_{D}\left(Q^{2}\right)=1 /\left(1+Q^{2} / \Lambda^{2}\right)^{2}$ with $\Lambda^{2}=0.71 \mathrm{GeV}^{2}$. The results shown in figure 3.14 indicate that relatively few terms suffice to give an accurate representation.

The relationship between the FRA and the usual expansion into a complete set of functions is examined in 614 where it is shown that the FRA is very accurate. The available data set consists of ep scattering up to $31 \mathrm{GeV}^{2}$ and $G_{E, M}$ are separately extracted for up to $10 \mathrm{GeV}^{2}$. The form factors $G_{E}$ and $G_{M}$ have been extracted from a global analysis of the world's cross section and polarization data, including corrections for two-photon exchange corrections [615]. The analysis is largely identical to that of 616], although additional high $Q^{2}$ form factor results [617] have been included. In addition, the slopes of $G_{E}$ and $G_{M}$ at $Q^{2}=0$ were constrained in the global fit based on a dedicated analysis of the low $Q^{2}$ data. In writing $G_{E}\left(Q^{2}\right)=1-Q^{2} R_{E}^{2} / 6$, the value of $R_{E}$ was constrained to be 0.878 fm and $R_{M}$ was constrained to be 0.860 fm . This is important in the extraction of the large scale structure of the density. The fit is given in 614.

We then use the fit and uncertainties for $G_{E}$ and $G_{M}$ to extract $F_{1}$ and $F_{2}$, treating the uncertainties in $G_{E}$ and $G_{M}$ as uncorrelated, yielding:

$$
\begin{align*}
& \left(d F_{1}\right)^{2}=\left(\frac{1}{1+\tau}\right)^{2}\left(d G_{E}\right)^{2}+\left(\frac{\tau}{1+\tau}\right)^{2}\left(d G_{M}\right)^{2}, \\
& \left(d F_{2}\right)^{2}=\left(\frac{1}{1+\tau}\right)^{2}\left(d G_{E}\right)^{2}+\left(\frac{1}{1+\tau}\right)^{2}\left(d G_{M}\right)^{2} . \tag{3.37}
\end{align*}
$$

For $Q^{2}<30 \mathrm{GeV}^{2}$, we use $d F_{1}$ above in the FRA to get $d \rho(b)$. For $Q^{2}>30 \mathrm{GeV}^{2}$, we use the FRA and take $d F_{1}= \pm \mid F_{1}$ (fit)|. This corresponds to a maximum value of $n=30$. The resulting transverse charge density is shown in figure 3.15. The proton transverse charge density is now very well known.

Our FRA technique can be exploited to image other quantities that depend on the transverse position. Suppose there is a transverse quantity $\rho^{(\lambda)}(b)$ that is a two-dimensional

Figure 3.15. (Color online) $\rho_{c h}$ (solid, blue) with error bands (short dashed, red). From Ref. 614].

Fourier transform of an experimental observable $F^{(\lambda)}\left(Q^{2}\right)$ such that

$$
\begin{equation*}
\rho^{(\lambda)}(b)=\frac{1}{2 \pi} \int Q d Q J_{\lambda}(Q b) F^{(\lambda)}\left(Q^{2}\right) . \tag{3.38}
\end{equation*}
$$

An example, discussed in detail in [614], is the magnetization density $\rho_{M}$. The index $(\lambda)$ is associated with a given number of units of the orbital angular momentum. The extraction of $\rho^{(\lambda)}(b)$ is facilitated by using the expansion

$$
\begin{equation*}
\rho^{(\lambda)}(b)=\sum_{n=1}^{\infty} \frac{2}{R^{2} J_{\lambda+1}\left(X_{\lambda, n}\right)^{2}} F^{(\lambda)}\left(Q_{\lambda, n}^{2}\right), J_{\lambda}\left(X_{\lambda, n} \frac{b}{R}\right), \tag{3.39}
\end{equation*}
$$

where $X_{\lambda, n}$ is the $n$-th zero of the Bessel function of order $\lambda ; Q_{\lambda, n}=X_{\lambda, n} / R$. The result (3.39) can be used to relate accessible kinematic ranges with transverse regions.

### 3.5.3 Summary

Much data for form factors exist and JLab12 will further improve the data set. The charge density is not a three-dimensional Fourier transform of $G_{E}$. One can interpret form factors as determining transverse charge and magnetization densities. The nucleon transverse densities are known now to high precision. The new FRA technique can be used for other quantities that depend on transverse position, in particular, for the exclusive scattering amplitudes and generalized parton distributions discussed in this chapter.

### 3.6 From transverse-momentum spectra to transverse images

Elke-Caroline Aschenauer, Markus Diehl, Salvatore Fazio

### 3.6.1 Imaging partons in the transverse plane

The principle of "parton imaging" using exclusive processes such as DVCS or hard exclusive meson production is rather simple. The key variable to measure is the transverse momentum transfer $\vec{\Delta}_{T}$ to the target proton or nucleus in the $\gamma^{*}$-target c.m. The invariant momentum transfer is then given by

$$
\begin{equation*}
t=-\frac{x^{2} m^{2}+\vec{\Delta}_{T}^{2}}{1-x} \quad \text { with } \quad x=\frac{Q^{2}+M_{V}^{2}}{Q^{2}+W^{2}} \tag{3.40}
\end{equation*}
$$

where $m$ is the target mass and $M_{V}$ the mass of the produced meson. For DVCS one should omit $M_{V}$, so that $x$ coincides with the Bjorken variable. In the limit of large $Q^{2}+M_{V}^{2}$, the $\gamma^{*} p$ scattering amplitude is a linear combination of generalized parton distributions convoluted with hard-scattering kernels. The distribution of partons in the transverse plane is obtained by a Fourier transform w.r.t. $\vec{\Delta}_{T}$ [580, 611]. In the simple case where the unpolarized quark or gluon GPDs $H^{i}$ dominate the $\gamma^{*} p$ cross section $d \sigma / d t$, the impact parameter profile is

$$
\begin{equation*}
F\left(b, x, Q^{2}\right) \propto \frac{1}{(2 \pi)^{2}} \int d^{2} \vec{\Delta}_{T} e^{-i \vec{b} \vec{\Delta}_{T}} \sqrt{\frac{d \sigma}{d t}}=\frac{1}{2 \pi} \int_{0}^{\infty} d \Delta_{T} \Delta_{T} J_{0}\left(b \Delta_{T}\right) \sqrt{\frac{d \sigma}{d t}}, \tag{3.41}
\end{equation*}
$$

where $\Delta_{T}=\left|\vec{\Delta}_{T}\right|$ and $b=|\vec{b}|$. For simplicity we drop the information from the absolute size of the cross section in this contribution and focus our attention on the normalized $b$-space profile, which satisfies $\int d^{2} b F\left(b, x, Q^{2}\right)=1$. For polarization asymmetries and for the interference term between DVCS and the Bethe-Heitler process, the extraction of the relevant $\gamma^{*} p$ amplitudes is more involved, but the principle of Fourier transforming these amplitudes w.r.t. $\vec{\Delta}_{T}$ remains the same.

In the present contribution, we estimate how accurately one can hope to determine $F\left(b, x, Q^{2}\right)$ from cross section measurements for DVCS on the proton. Firstly, $d \sigma / d t$ will have statistical and systematic errors. Secondly, the range of $\Delta_{T}$ in a measurement will be restricted both from above and from below, so that an extrapolation is required in order to perform the Fourier integral in (3.41).

### 3.6.2 Acceptance in transverse momentum

To achieve the precision discussed below for imaging partons in the impact parameter space, it is critical to integrate from the beginning the detection of the scattered proton into the detector and interaction region design. The scattered proton in exclusive reactions is characterized by carrying almost the full beam momentum and a transverse momentum $\Delta_{T}$ between several MeV and a few GeV , corresponding to very small scattering angles. Figure 3.16 shows the relation between the longitudinal momentum of the protons and their scattering angle for two different ep center-of-mass energies.

The commonly used method to detect these protons is to integrate "Roman pots" in the machine lattice. The standard technologies for such detectors are silicon strip detectors or

Figure 3.16. (Color online) The longitudinal momentum $p_{z}$ of the scattered proton in exclusive reactions vs. its scattering angle $\theta$ for an $e p$ center-of-mass energy of 15.5 GeV (left) and 145 GeV (right).
scintillating fiber detectors. The acceptance for protons with the transverse momentum in the MeV region is limited by the requirement that Roman pots must have a beam clearance distance of 10 times the beam emittance. The upper transverse acceptance is given by the apertures of the magnets that the protons have to transverse. For transverse momenta above 1 GeV , the proton can be detected in the main solenoidal detector. Details on the solutions for the eRHIC and ELIC interaction region designs are given in section 7.3,

### 3.6.3 Precision of the measurement

A detailed simulation of DVCS events is described in section 3.9. To illustrate the expected statistical accuracy of a measurement, we show $d \sigma / d t$ for a selected bin of $x$ and $Q^{2}$ in figure 3.17. The value of $y$ in this bin ranges from 0.05 to 0.14 . For bins with lower $x$ or lower $Q^{2}$, the statistical errors are smaller, except for kinematics where the $y>0.01$ cut applied in the simulation becomes relevant.

The $t$ spectrum shown in the figure 3.17 was generated with an exponential dependence $d \sigma / d t \propto \exp (B t)$ with $B=5 \mathrm{GeV}^{-2}$. An exponential fit to the generated spectrum gives $B=5.02 \mathrm{GeV}^{-2}$ with an error below $1 \%$. Data of this quality also allows one to explore possible deviations from an exponential spectrum. To this end, we have also fitted to $d \sigma / d t \propto \exp \left(B t-C t^{2}\right)$. This fit and its $1 \sigma$ error band is shown in the figure and gives $B=(4.92 \pm 0.10) \mathrm{GeV}^{-2}$ and $C=(0.079 \pm 0.076) \mathrm{GeV}^{-4}$. Although the relative uncertainty on the extra parameter $C$ is large, the term $C t^{2}$ in the exponential is small compared with $B t$ in the fitted $t$ range (as it should be for a spectrum generated with a pure exponential law). The logarithmic $t$ slope at $|t|=1.75 \mathrm{GeV}^{2}$ in this fit is $(5.20 \pm 0.18) \mathrm{GeV}^{-2}$.

We conclude at this point that with the projected luminosity available at an EIC, the $t$ spectrum for the DVCS cross section will be dominated by systematic uncertainties and not

Figure 3.17. (Color online) Generated $t$ spectrum for the DVCS cross section in a selected bin of $x$ and $Q^{2}$. The errors are statistical only and correspond to the integrated luminosity of $11.9 \mathrm{fb}^{-1}$ for $|t|<1 \mathrm{GeV}^{2}$ and to $151 \mathrm{fb}^{-1}$ for $|t|>1 \mathrm{GeV}^{2}$. The curve represents a fit explained in the text.
by statistics, even if one measures differentially in $x$ and $Q^{2}$. Systematic uncertainties, for instance due to momentum resolution, strongly depend on details of the experimental setup and have not been studied yet. We note that the normalized $b$ space profile $F\left(b, x, Q^{2}\right)$ is not affected by errors on the overall luminosity and acceptance.

### 3.6.4 Uncertainty from the extrapolation in $t$

We now estimate the uncertainty in the impact parameter profile $F(b)$ due to the lack of knowledge of the scattering amplitude for all $t$. Since the projected statistical errors are so small, we do not include them in this exercise.

For the extrapolation to large $|t|$, we assume a measured $t$-spectrum $d \sigma / d t \propto \exp (B t)$ with $B=4 \mathrm{GeV}^{-2}$ up to $|t|_{\max }=1$ or $2 \mathrm{GeV}^{2}$. Larger values of $B$ give a smaller cross section at high $|t|$ and thus a smaller extrapolation uncertainty in the Fourier integral (3.41). In turn, the statistical errors on the cross section at high $|t|$ are then larger, so that in $F(b)$ there is a tradeoff between the uncertainties from the measured $t$ spectrum and those from its extrapolation.

To estimate the extrapolation uncertainty, we adopt a strategy similar to that in 618] and assume different forms for the scattering amplitude (i.e., for $\sqrt{d \sigma / d t}$ ) at $|t|>|t|_{\max }$ :

1. an exponential $\propto \exp (B t / 2)$, labeled "exp" in figure 3.18
2. a dipole form $\propto\left(1+|t| / M^{2}\right)^{-2}$, labeled "dip",
3. a modified dipole form $\propto\left(1+0.05|t| / M^{2}\right)^{-1}\left(1+0.45|t| / M^{2}\right)^{-1}$, labeled "mod dip",
4. a modified exponential $\propto \exp \left(-D t^{2}\right)$, labeled "mod exp".

In each case we require the amplitude and its first derivative to be continuous at $|t|=|t|_{\max }$. Note that in the measured $t$ region, forms 2 to 4 would give unacceptable fits to the simulated spectrum in figure 3.17. Forms 3 and 4 should be regarded as examples for functions falling off especially slowly or especially fast and do not claim to be particularly realistic. When performing the Fourier transform (3.41), we neglect the term $x^{2} m^{2}$ in (3.40), which is justified in a large region of phase space.

In figure 3.18 we show the resulting scattering amplitude (normalized to unity at $\vec{\Delta}_{T}=$ $\overrightarrow{0}$ ) and its Fourier transform $F(b)$. We observe that the curves in $b$ space are close together in a wide region and rather quickly start to differ below a certain critical value $b_{\text {cr }}$. For $|t|_{\max }=$ $1 \mathrm{GeV}^{2}$, we find $b_{\text {cr }} \sim 0.25 \mathrm{fm}$ and an appreciable spread of $F(b)$ at lower $b$. This would be a serious limitation for studying the central region of the proton. Interesting physical effects like the variation of $F(b)$ with $x$ or $Q^{2}$ are typically expected to be only logarithmic (see, e.g., the estimates in [619]) and hence require sufficiently precise measurements. Clearly, there is a very significant gain of accuracy in impact parameter space if $|t|_{\max }$ can be raised from 1 to $2 \mathrm{GeV}^{2}$, i.e., if a scattered proton in the corresponding kinematics can be seen in the main detector. We then find $b_{\text {cr }} \sim 0.1 \mathrm{fm}$ and a small uncertainty even at $b=0$.

As an alternative scenario we assume a dipole form instead of an exponential $t$ dependence in the measured region 1 with a dipole mass $M=770 \mathrm{MeV}$ that gives the same scattering amplitude at $|t|=1 \mathrm{GeV}^{2}$ as the exponential with $B=4 \mathrm{GeV}^{-2}$. The extrapolation error is larger in the dipole scenario, but since the cross section decreases much more slowly, it can be measured out to higher values of $|t|$ before statistics becomes an issue. We recall however that a description in terms of generalized parton distributions requires $|t| \ll Q^{2}+M_{V}^{2}$. As seen in figure 3.19, a measurement up to $|t|_{\max }=3.3 \mathrm{GeV}^{2}$ in the dipole scenario gives a very precise $F(b)$ down to $b_{\text {cr }} \sim 0.1 \mathrm{fm}$. The extrapolation uncertainty at lower $b$ is larger than for $|t|_{\max }=2 \mathrm{GeV}^{2}$ in the exponential scenario.

Let us now investigate the extrapolation to small $|t|$. We assume again an exponential cross section $d \sigma / d t \propto \exp (B t)$, but now with a larger slope $B=6.6 \mathrm{GeV}^{-2}$ in order to maximize the importance of low $|t|$ in the Fourier integral. We consider either 300 MeV or 200 MeV as minimum measured values of $\Delta_{T}$, and take the following extrapolations for $\Delta_{T}$ down to zero:

1. an exponential in $t$, labeled "exp" in figure 3.20.
2. a dipole form $\propto\left(1+|t| / M^{2}\right)^{-2}$, labeled "dip",
3. a linear function in $t$, labeled "lin",
4. a monopole form $\propto\left(1+|t| / M^{2}\right)^{-1}$, labeled "mono",
5. an inverse square root $\propto\left(1+|t| / M^{2}\right)^{-1 / 2}$, labeled "sqrt".

We see in figure 3.20 that with a measurement down to $\Delta_{T}=300 \mathrm{MeV}$, one has a rapidly growing extrapolation uncertainty for $b$ above about 1.25 fm . The situation dramatically improves if one has to extrapolate only below $\Delta_{T}=200 \mathrm{MeV}$. Repeating this study with a dipole form in the measured region yields the same conclusion 621]. Whether a measurement down to even lower $\Delta_{T}$ can still improve the accuracy of $b$ space images can only be decided after an estimate of experimental uncertainties.

Let us recall the specific physics interest of the impact parameter profile of the proton at very large $b$. This is the region where the dynamics of chiral symmetry breaking should manifest itself. A description in terms of virtual pion fluctuations yields definite predictions, such as a behavior $F(b) \propto b^{-1} e^{-\kappa b}$ with $\kappa \approx 2 m_{\pi} \approx(0.7 \mathrm{fm})^{-1}$ at large $b$ 594. This translates into a small $|t|$ behavior given by the inverse square root law in point 5 (with $M^{2}=\kappa^{2}$ ). These predictions should be tested quantitatively.

[^271]

Figure 3.18. (Color online) Examples for normalized amplitudes (left) with different extrapolations to large $|t|$, together with their Fourier transforms to impact parameter space (right).

Figure 3.19. (Color online) As in figure 3.18 but with a dipole form of the amplitude up to $|t|=$ $3.3 \mathrm{GeV}^{2}$.

Figure 3.20. (Color online) As in figure 3.18, but with extrapolation to small $|t|$, i.e. small $\Delta_{T}$. The impact parameter profile $F(b)$ is multiplied with $b^{2}$ in order to make the large $b$ behavior visible.

In summary, we find that with the parameters we have assumed, neither statistics nor acceptance in $t$ will seriously limit $b$ space imaging at an EIC, with an accessible $b$ range from 0.1 fm up to 1.5 fm or larger. Detailed estimates of experimental uncertainties will be necessary to assess the limiting factors of accuracy in this endeavor.

### 3.7 GPDs from DVCS

Matthias Burkardt, Hikmat BC

### 3.7.1 Introduction

GPDs are linked to many processes and observables involving hadrons [622], but their most intuitive application is in the context of Ji's angular momentum decomposition (see section (3.4) and in three-dimensional imaging (see section (3.6). Both involve GPDs in the $\xi=0$ limit (the $\xi$-dependence drops out in the Ji sum rule). At the same time, the DVCS amplitude $\mathcal{A}_{\text {DVCS }}$ provides direct access only to GPDs along the "diagonal" $x=\xi$ (through the imaginary part of the DVCS amplitude) as well as to a convolution integral involving GPDs (through the real part of $\mathcal{A}_{\mathrm{DVCS}}$ ). In the leading order (LO) factorization, one finds

$$
\begin{align*}
\Im m \mathcal{A}_{\mathrm{DVCS}} & \longrightarrow G P D^{(+)}(\xi, \xi, t), \\
\Re e \mathcal{A}_{\mathrm{DVCS}} & \longrightarrow \int_{-1}^{1} d x \frac{G P D^{(+)}(x, \xi, t)}{x-\xi} . \tag{3.42}
\end{align*}
$$

The ' $(+)^{\prime}$ ' superscript in (3.42) emphasizes that DVCS is sensitive only charge-even (i.e., quark+antiquark) combinations of GPDs. Moreover, the accessible range in $\xi$ is limited, $\xi_{\min }<\xi<\xi_{\max }$. The lower limit $\xi_{\min }$ is defined by the DIS kinematics. The upper limit $\xi_{\text {max }}$ follows from the relation

$$
\begin{equation*}
-t=\frac{4 \xi^{2} M^{2}+\Delta_{\perp}^{2}}{1-\xi^{2}}, \tag{3.43}
\end{equation*}
$$

and the positivity of $\boldsymbol{\Delta}_{\perp}^{2}$. Thus, even in an idealized DVCS experiment (fixed $Q^{2}$ ), where angular dependencies as well as spin asymmetries have been used to disentangle different GPDs and the proton and 'neutron' targets have been used to accomplish the flavor decomposition, one can at best expect a determination of the observables in (3.42) for $\xi_{\text {min }}<\xi<\xi_{\text {max }}$. One of the key question in the context of DVCS is whether this information will allow an unambiguous and model-independent extraction of GPDs.

### 3.7.2 Constraints on GPDs: polynomiality, dispersion relations and QCD evolution

GPDs are not only constrained by DVCS, but also by DIS and form factor data. However, the form factor data constrains only charge-odd distributions and helps only in kinematical regimes where antiquark contributions are negligible. While DIS data is sensitive to charge-even distributions, there is no DIS data that would constrain the forward ( $\xi=0$, $t=0)$ limit of $E^{q}(x, \xi, t)$.

Fortunately, multiple theoretical constraints exist that will be helpful in determining GPDs from DVCS data. For example, Lorentz invariance implies the polynomiality conditions on GPDs [274, 574]:

$$
\begin{equation*}
\int_{-1}^{1} d x x^{n} G P D(x, \xi, t)=A_{n, 0}(t)+A_{n, 2}(t) \xi^{2}+\ldots+A_{n, n+1} \xi^{n+1} \tag{3.44}
\end{equation*}
$$

where the highest power $\xi^{n+1}$ is only present when $n$ is odd. These polynomiality conditions imply that the dependence of GPDs on the variables $x$ and $\xi$ cannot be independent. This imposes significant and rigorous constraints on any GPD extraction from DVCS data.

Rigorous dispersion relations exist for the DVCS amplitude $\mathcal{A}\left(\nu, t, Q^{2}\right)$ :

$$
\begin{equation*}
\Re e \mathcal{A}\left(\nu, t, Q^{2}\right)=\frac{\nu^{2}}{\pi} \int_{0}^{\infty} \frac{d \nu^{\prime 2}}{\nu^{\prime 2}} \frac{\Im m \mathcal{A}\left(\nu^{\prime}, t, Q^{2}\right)}{\nu^{\prime 2}-\nu^{2}}+\Delta\left(t, Q^{2}\right) \tag{3.45}
\end{equation*}
$$

where $\Delta\left(t, Q^{2}\right)$ is a possible subtraction that can be identified with the $D$-form factor 587. In combination with the leading order (LO) factorization (3.42), this implies for GPDs

$$
\begin{equation*}
\Re e \mathcal{A}\left(\xi, t, Q^{2}\right) \sim \int_{-1}^{1} d x \frac{G P D^{(+)}\left(x, \xi, t, Q^{2}\right)}{x-\xi}=\int_{-1}^{1} d x \frac{G P D^{(+)}\left(x, x, t, Q^{2}\right)}{x-\xi}+\Delta\left(t, Q^{2}\right) . \tag{3.46}
\end{equation*}
$$

Although its derivation from dispersion relations is more physical, (3.46) was first derived from polynomiality [574].

One of the consequences of (3.46) is that it allows to '"condense" the information from the DVCS amplitude (including the real part) into GPDs along the diagonal $x=\xi$ plus the D-form factor. However, it should be emphasized that this does not render measurements of the real part of the DVCS amplitude redundant. Indeed, measurements of $\Im m \mathcal{A}_{\text {DVCS }}$ for a given beam energy do not cover the whole region $0<\xi<1$ that enters (3.46). This implies that one can, for example, use $\Re e \mathcal{A}\left(\xi, t, Q^{2}\right)$ at fixed $Q^{2}$ to constrain $\operatorname{GPD}\left(\xi, \xi, t, Q^{2}\right)$ for the values of $\xi$ that are not accessible directly through the measurement of $\Im m \mathcal{A}\left(\xi, t, Q^{2}\right)$. In summary, a DVCS experiment at fixed $Q^{2}$ (large enough for GPD factorization to hold) should in principle allow for the determination of GPDs along the diagonal $x=\xi$ as well as the D-form factor, which (through the polynomiality condition) impose some constraints on GPDs for $x \neq \xi$.

Additional important constraints on GPDs come from their QCD evolution. The $Q^{2}$ evolution equations can be "diagonalized" by expanding GPDs in terms of Gegenbauer polynomials $C_{n}^{3 / 2}(x)$ :

$$
\begin{equation*}
G P D\left(x, \xi, t, Q^{2}\right)=\left(1-x^{2}\right) \sum_{n=0}^{\infty} C_{n}^{3 / 2}(x) \sum_{m=0(\text { even })}^{n} a_{n m}(\xi) \mathcal{C}_{n-m}\left(\xi, t, Q^{2}\right), \tag{3.47}
\end{equation*}
$$

where $a_{n m}(\xi)$ are known polynomials. The coefficients $\mathcal{C}_{k}\left(\xi, t, Q^{2}\right)$ are a priori unknown, but their $Q^{2}$ evolution is known. This allows one (in principle) to determine $\mathcal{C}_{k}\left(\xi, t, Q^{2}\right)$ model independently. For this purpose, let us consider $x=\xi$, where GPDs can be measured directly. Upon relabeling $k=n-m$, (3.47) reads

$$
\begin{equation*}
\operatorname{GPD}\left(\xi, \xi, t, Q^{2}\right)=\left(1-\xi^{2}\right) \sum_{k=0}^{\infty} \mathcal{C}_{k}\left(\xi, t, Q^{2}\right) f_{k}(\xi), \tag{3.48}
\end{equation*}
$$

where $f_{k}(\xi)=\sum_{m=0(\text { even })}^{\infty} a_{m+k, m}(\xi) C_{m+k}^{3 / 2}(\xi)$ are known functions. For any fixed $\xi$, each term in (3.48) evolves differently and, thus, a measurement over a wide range of $Q^{2}$ should allow for the determination of $\mathcal{C}_{k}\left(\xi, t, Q^{2}\right)$ as well as the GPDs for $x \neq \xi$ [via (3.47)]. At an EIC with its wide $Q^{2}$ range and high luminosity, it may be possible for the first time to carry out a model-independent extraction of GPDs. More detailed numerical studies will be required to quantify this expectation.

### 3.8 Accessing GPDs from experiment: potential of a highluminosity EIC

K. Kumerički, T. Lautenschlager, D. Müller, K. Passek-Kumerički, A. Schäfer, M. Meškauskas

### 3.8.1 Introduction

Generalized parton distributions (GPDs) [567, 568, 569] have received much attention from both the theoretical and experimental sides. This was triggered by the hope to solve the "spin puzzle" that refers to the mismatch between the quark contribution to the proton spin extracted from polarized DIS and the one given by the constituent quark model. We view the "spin puzzle" first and foremost as a quest to quantify the partonic structure of the nucleon in terms of quark and gluon angular momenta [274]. Furthermore, it has been realized that GPDs allow for a three-dimensional imaging of nucleons and nuclei 623], providing, in the zero-skewness case $(\xi=0)$, a probabilistic interpretation in terms of partonic degrees of freedom [579]. In fact, GPDs build up a whole framework for description of hadron structure [575, 576], with the "spin puzzle" being just one interesting aspect.

In phenomenology, GPDs are used for modeling elastic form factors and the description of hard exclusive leptoproduction and even photoproduction. For hard exclusive processes, factorization theorems have been proven in the collinear framework at twist-two level [572, 624. In the last decade, various hard exclusive processes have been measured by the H1 and ZEUS collaborations (DESY) in the small $x_{B}$ region and by HERMES (DESY), CLAS (JLAB), and Hall A (JLAB) in the moderate $x_{B}$ region in the fixed-target experiments.

Deeply virtual Compton scattering (DVCS) off nucleon is considered as the theoretically cleanest process offering access to GPDs. Its amplitude can be parameterized by twelve Compton form factors (CFFs) [625], which are given in terms of twist-two (including gluon transversity) and twist-three GPDs. For instance, at leading order (LO), parity-even twisttwo CFFs, $\mathcal{H}$ and $\mathcal{E}$, can be expressed through quark GPDs $H$ and $E$ :

$$
\left\{\begin{array}{c}
\mathcal{H}  \tag{3.49}\\
\mathcal{E}
\end{array}\right\}\left(x_{B}, t, \mathcal{Q}^{2}\right) \stackrel{\text { LO }}{=} \int_{-1}^{1} d x \frac{2 x}{\xi^{2}-x^{2}-i \epsilon}\left\{\begin{array}{l}
H \\
E
\end{array}\right\}\left(x, \eta=\xi, t, \mathcal{Q}^{2}\right),
$$

where both quark and anti-quark GPDs are defined in the region $x \in[-\xi, 1] ; x_{B}=$ $2 \xi /(1+\xi)$. Similar expressions can be written for twist-two parity-odd CFFs $\widetilde{\mathcal{H}}$ and $\widetilde{\mathcal{E}}$, while for other CFFs they are a bit more intricate 625]. Analogous formulae hold for the LO description of $\gamma^{*} N \rightarrow M N$ transition form factors (TFFs), measurable in deeply virtual electroproduction of mesons (DVEM). Here, in addition to GPDs, the non-perturbative meson distribution amplitude enters, which describes the transition of a quark-antiquark state into the final meson. This induces an additional uncertainty in the GPD phenomenology.

Let us briefly clarify which GPD information can be extracted from experimental measurements. Neglecting radiative and higher twist-contributions, one might view the GPD on the $\eta=x$ cross-over line as a "spectral function", which provides also the real part of the CFF via the "dispersion relation" [626, 627, 628, 629]:

$$
\begin{array}{rll}
\Im \mathrm{m} \mathcal{F}\left(x_{B}, t, \mathcal{Q}^{2}\right) & \stackrel{\mathrm{LO}}{=} \pi F\left(\xi, \xi, t, \mathcal{Q}^{2}\right), \quad F=\{H, E, \widetilde{H}, \widetilde{E}\}, \\
\Re \mathrm{e}\left\{\begin{array}{c}
\mathcal{H} \\
\mathcal{E}
\end{array}\right\}\left(x_{B}, t, \mathcal{Q}^{2}\right) & \stackrel{\mathrm{LO}}{=} \mathrm{PV} \int_{0}^{1} d x \frac{2 x}{\xi^{2}-x^{2}}\left\{\begin{array}{c}
H \\
E
\end{array}\right\}\left(x, x, t, \mathcal{Q}^{2}\right) \pm \mathcal{D}\left(t, \mathcal{Q}^{2}\right) . \tag{3.51}
\end{array}
$$

The GPD support properties ensure that (3.50) and (3.51) are in one-to-one correspondence to the perturbative formula (3.49), where the subtraction constant $\mathcal{D}$, which is related in a specific GPD representation to the so-called $D$-term [587], can be calculated from either $H$ or $E$. However, we note that the "dispersion relation" (3.51) is given in terms of partonic variables and compared to the dispersion relation formulated in physical variables it differs by power suppressed contributions. To pin down the GPD in the outer region $y \geq \eta=x$, one might employ evolution. For instance, in the non-singlet case, the change of the GPD on the cross-over line is governed by (the equation in the whole outer region is needed)

$$
\begin{equation*}
\mu^{2} \frac{d}{d \mu^{2}} F\left(x, x, t, \mu^{2}\right)=\int_{x}^{1} \frac{d y}{x} V\left(1, y / x, \alpha_{s}(\mu)\right) F\left(y, x, t, \mu^{2}\right) \tag{3.52}
\end{equation*}
$$

where $V$ is the evolution kernel [567]. Unfortunately, a large enough $\mathcal{Q}^{2}$ range is not available in fixed target experiments. Hence, we must conclude that in such measurements, essentially only the GPD on the cross-over line [thanks to (3.51), also outside of the experimentally accessible part of this line [629]] and the subtraction constant $\mathcal{D}$ can be accessed. Moments, such as those entering the spin sum rule, can only be obtained from a GPD model, fitted to data, or more generally with help of some "holographic" mapping [629]:

$$
\begin{equation*}
\left\{F\left(x, \eta=0, t, Q^{2}\right), F\left(x, \eta=x, t, Q^{2}\right)\right\} \quad \Longrightarrow \quad F\left(x, \eta, t, Q^{2}\right) . \tag{3.53}
\end{equation*}
$$

Here, $F\left(x, \eta=0, t, \mathcal{Q}^{2}\right)$ are constrained from form factor measurements and, additionally, GPDs $\widetilde{H}(H)$ by (un)polarized phenomenological PDFs. Of course, a given 'holographic' mapping holds only for a specific class of GPD models.

### 3.8.2 GPD modeling

The implementation of radiative corrections, even including LO evolution (3.52), requires to model CFFs or TFFs in terms of GPDs. This can be done in different representations, which should be finally considered as equivalent. However, for a specific purpose a particular representation may be more suitable than the others.

Neglecting positivity constraints, we model GPDs by means of a conformal SL( $2, \mathbb{R}$ ) partial wave expansion, which can be written as a Mellin-Barnes integral [630]:

$$
\begin{equation*}
F\left(x, \eta, t, \mu^{2}\right)=\frac{i}{2} \int_{c-i \infty}^{c+i \infty} d j \frac{p_{j}(x, \eta)}{\sin (\pi j)} F_{j}\left(\eta, t, \mu^{2}\right) \tag{3.54}
\end{equation*}
$$

Here, $p_{j}(x, \eta)$ are the partial waves given in terms of associated Legendre functions of the first and second kind, and the integral conformal GPD moments $F_{j}\left(\eta, t, \mu^{2}\right)$ are even polynomials in $\eta$ of order $j$ or $j+1$. Other representations of GPDs based on the $\operatorname{SL}(2, \mathbb{R})$ partial wave expansion include the so-called "dual" parameterization [631, 632, 633, 634].

In the Mellin-Barnes representation, the CFFs possess a rather convenient form, e.g., (3.49) can be rewritten in the following form [627, 635]:

$$
\begin{align*}
\left\{\begin{array}{c}
\mathcal{H} \\
\mathcal{E}
\end{array}\right\}\left(x_{B}, t, Q^{2}\right) \stackrel{\text { LO }}{=} & \frac{1}{2 i} \int_{c-i \infty}^{c+i \infty} d j \xi^{-j-1}\left[i+\tan \left(\frac{\pi j}{2}\right)\right] \\
& \times\left.\frac{2^{j+1} \Gamma(j+5 / 2)}{\Gamma(3 / 2) \Gamma(j+3)}\left\{\begin{array}{c}
H_{j} \\
E_{j}
\end{array}\right\}\left(\eta=\xi, t, Q^{2}\right)\right|_{\xi=\frac{x_{B}}{2-x_{B}}} . \tag{3.55}
\end{align*}
$$

This integral is numerically implemented in an efficient routine in two different factorization schemes, including the standard minimal subtraction ( $\overline{\mathrm{MS}}$ ) one at next-to-leading order (NLO) accuracy. Further advantages of this representation are:
(i) The conformal moments evolve autonomously at LO.
(ii) One can employ conformal symmetry to obtain next-to-next-to-leading order (NNLO) corrections to the DVCS amplitude 635, 636.
(iii) PDF and form factor constraints can be straightforwardly implemented. Namely, $F_{j}\left(\eta=0, t=0, \mu^{2}\right)$ are the Mellin moments of PDFs, $F_{j=0}$ are partonic contributions to elastic form factors, $H_{j=1}$ and $E_{j=1}$ are the energy-momentum tensor form factors, and for general $j$ one immediately makes contact to lattice measurements.

To parameterize the degrees of freedom that can be accessed in hard exclusive reactions, one can expand the conformal moments in terms of $t$-channel $\mathrm{SO}(3)$ partial waves expressed in terms of the Wigner rotation matrices $\hat{d}_{j}(\eta)\left(\hat{d}_{j}(\eta=0)=1\right)$ 637. An effective GPD model at given input scale $Q_{0}^{2}$ is provided by taking into account three partial waves,

$$
\begin{equation*}
F_{j}(\eta, t)=\hat{d}_{j}(\eta) f_{j}^{j+1}(t)+\eta^{2} \hat{d}_{j-2}(\eta) f_{j}^{j-1}(t)+\eta^{4} \hat{d}_{j-4}(\eta) f_{j}^{j-3}(t) \tag{3.56}
\end{equation*}
$$

which is valid for integral $j \geq 4$. In the simplest version of such a model, one might introduce just two additional parameters by setting the non-leading partial wave amplitudes to:

$$
\begin{equation*}
f_{j}^{j-k}(\eta, t)=s_{k} f_{j}^{j+1}(\eta, t), \quad k=2,4, \ldots . \tag{3.57}
\end{equation*}
$$

Such a model allows us to control the size of the GPD on the cross-over line and its $Q^{2}$ evolution, see fig. 3.28. A flexible parameterization of the skewness effect in the large $x$ region requires to decorate the skewness parameters $s_{k}$ with some $j$ dependence and for more convenience one might replace Wigner's rotation matrices by some effective $\mathrm{SO}(3)$ partial waves.

### 3.8.3 GPDs from hard exclusive measurements

Based on the experimental data set from the collider experiments H1 and ZEUS at DESY, the fixed target experiment HERMES at DESY, and the Hall A, CLAS, and Hall C experiments at JLAB, GPDs have been accessed from hard exclusive meson and photon electroproduction in the last few years. Favorably, DVCS enters as a subprocess into the hard photon electroproduction where its interference with the Bethe-Heitler (BH) bremsstrahlung process provides variety of handles on the real and imaginary part of twist-two and twistthree CFFs [625, 638]. However, switching from a proton to a neutron target allows only for a partial flavor separation, which is much more intricate than in DIS. On the other hand, DVEM can be used as a flavor filter, however, here one expects that both radiative 639, 640, 641 and (non-factorizable) higher-twist contributions might be rather important. The onset of the collinear description remains here an issue which should be explored.

For the DVCS process, the collinear factorization approach has been employed in a specific scheme up to NNLO in the small $x_{B}$ region 627, 635, 636]. It turns out that NLO corrections are moderate, while NNLO ones are becoming much smaller 627. Experimentally, the unpolarized DVCS cross section has been provided by the H1 and ZEUS collaborations [642, 643, 644, 645]. In the collider kinematics, the DVCS cross section is primarily given in terms of two CFFs, $\mathcal{H}$ and $\mathcal{E}$ :

$$
\begin{equation*}
\left.\frac{d \sigma^{\mathrm{DVCS}}}{d t}\left(W, t, Q^{2}\right) \approx \frac{\pi \alpha^{2}}{\mathcal{Q}^{4}} \frac{W^{2} x_{B}^{2}}{W^{2}+Q^{2}}\left[|\mathcal{H}|^{2}-\frac{t}{4 M_{p}^{2}}|\mathcal{E}|^{2}\right]\left(x_{B}, t, \mathcal{Q}^{2}\right)\right|_{x_{B} \approx \frac{Q^{2}}{W^{2}+Q^{2}}} \tag{3.58}
\end{equation*}
$$

Figure 3.21. Quark (a) and gluon (b) transverse profile function (3.59) for $Q^{2}=4 \mathrm{GeV}^{2}$ and $x=10^{-3}$ from a six parameter DVCS fit 646.

Although at a fixed scale and to LO accuracy the CFFs are given by (dominant sea) quark GPDs, evolution will induce a gluonic contribution, too. Indeed, the experimental lever arm $3 \mathrm{GeV}^{2} \lesssim Q^{2} \lesssim 80 \mathrm{GeV}^{2}$ is sufficiently large to access the gluonic GPD. In our fitting procedure, the Mellin-Barnes integral was utilized within a $\mathrm{SO}(3)$ partial wave ansatz for the conformal moments and good fits ( $\chi^{2} /$ d.o.f. $\approx 1$ ) could be obtained at LO to NNLO accuracy, exemplifying that flexible GPD models were at hand. From such fits, one can then obtain the image of quark and gluon distributions. It is illustrated in figure 3.21 that in impact space, the (normalized) transverse profiles,

$$
\begin{equation*}
\rho\left(b, x, Q^{2}\right)=\frac{\int_{-\infty}^{\infty} d^{2} \vec{\Delta} e^{i \vec{\Delta} \vec{b}} H\left(x, \eta=0, t=-\vec{\Delta}^{2}, Q^{2}\right)}{\int_{-\infty}^{\infty} d^{2} \vec{\Delta} H\left(x, \eta=0, t=-\vec{\Delta}^{2}, Q^{2}\right)}, \tag{3.59}
\end{equation*}
$$

determined for dipole and exponential $t$-dependence of $H$, mainly differ for distances larger than the disc radius of the proton, i.e., for $b>0.6 \mathrm{fm}$. Hence, the larger values of the transverse widths, $\sqrt{\left\langle\vec{b}^{2}\right\rangle}{ }_{\text {sea }} \approx 0.9 \mathrm{fm}$ and $\sqrt{\left\langle\vec{b}^{2}\right\rangle} \approx 0.8 \mathrm{fm}$ for the dipole ansatz, arise from the long-range tail of the profile function, see the solid curves in figure 3.21 For an exponential ansatz, we find slightly smaller values $\sqrt{\left\langle\vec{b}^{2}\right\rangle}$ sea $\approx 0.7 \mathrm{fm}$ and $\sqrt{\left\langle\overrightarrow{b^{2}}\right\rangle}{ }_{\mathrm{G}} \approx 0.6 \mathrm{fm}$, where the gluonic one is compatible with the analysis of $J / \psi$ production [594]. Note that the model uncertainty in the extrapolation of the GPD to $t=0$ corresponds to the uncertainty in the long-range tail. Moreover, the model uncertainty of the extrapolation into the region $-t>1 \mathrm{GeV}^{2}$ is essentially canceled in the profile (3.59) normalized at $b=0$.

We also note that at LO the gluonic GPD (as the gluonic PDF) is rather steep and radiative corrections might provide a large GPD/PDF reparameterization effect, which will be studied in more detail in the future. Our first successful LO description of DVCS within a flexible GPD model [646] is in agreement with aligned-jet model considerations 647]. We also mention that an attempt has been undertaken to access the $\mathcal{E}$ CFF from the beam charge asymmetry measurement [648], proportional to the combination $\Re \mathrm{e}\left[F_{1}(t) \mathcal{H}-\frac{t}{4 M^{2}} F_{2}(t) \mathcal{E}\right]$. Unfortunately, the size of the experimental uncertainties does not allow one to separate the $\mathcal{H}$ and $\mathcal{E}$ contributions.

An approach analogous to the one employed for DVCS [627] is also suitable for LO and NLO analysis of DVEM. Hence, one can simultaneously make use of DVCS and DVEM measurements in a global fitting procedure, which is in progress.

GPD studies were also performed for the DVCS process in the fixed target kinematics
to LO accuracy. In this region, relying on the scaling hypothesis, one might directly ask for the value of the GPDs on their cross-over line. For instance, for valence quarks we use the following generically motivated ansatz:

$$
\begin{equation*}
H^{\mathrm{val}}(x, x, t)=\frac{1.35 r}{1+x}\left(\frac{2 x}{1+x}\right)^{-\alpha(t)}\left(\frac{1-x}{1+x}\right)^{b}\left(1-\frac{1-x}{1+x} \frac{t}{M^{\mathrm{val}}}\right)^{-1} \tag{3.60}
\end{equation*}
$$

where $r=\lim _{x \rightarrow 0} H(x, x) / H(x, 0)$ is the skewness ratio; $\alpha(t)=0.43+0.85 t / \mathrm{GeV}^{2} ; b$ controls the $x \rightarrow 1$ limit and $M^{\text {val }}$ controls the residual $t$-dependence, which we set to $M^{\mathrm{val}}=0.8 \mathrm{GeV}$. For the forward limit $q(x)=H(x, 0)$, we used the LO parameterization of Alekhin [649]. The generic $(-t)^{-2}$ fall-off at large $-t$ for generalized form factors is indirectly encoded in the Regge-trajectory and the residual $t$ dependence is modeled by a monopole form with an $x$-dependent cut-off mass. The subtraction constant (3.51) is taken an a dipole form:

$$
\begin{equation*}
\mathcal{D}(t)=d\left(1-\frac{t}{M_{d}^{2}}\right)^{-2} . \tag{3.61}
\end{equation*}
$$

In a first global fit 646] to hard exclusive photon electroproduction off unpolarized proton, we took sea quark and gluon GPD models with two $\mathrm{SO}(3)$ partial waves at small $x$, reparameterized the outcome from H1 and ZEUS DVCS fits at $Q^{2}=2 \mathrm{GeV}^{2}$, and employed it in fits of fixed target data within the scaling hypothesis. To relate the CFFs with the observables, we employed the BKM formulas 625 within the 'hot-fix' convention 650 and used the Sachs parameterization for the electromagnetic form factors. Thereby, we utilized the "dispersion relation" (3.50]3.51), where the ansatz (3.60) specifies a valence-like GPD on the cross-over line. Besides the subtraction constant (3.61), we also included the parameterfree pion-pole model for the $\tilde{E}$ GPD 651 and parameterized the $\widetilde{H}$ GPD rather analogously to (3.60) with $b=3 / 2$. For the fixed target fits, we chose two data sets resulting in two fits (KM09a and KM09b). Out fit gives:

$$
\begin{array}{lllll}
\text { KM09a: } & b^{\text {sea }}=3.09, & r^{\mathrm{val}}=0.95, \quad b^{\mathrm{val}}=0.45, & d=-0.24, & M_{d}=0.5 \mathrm{GeV}, \\
\text { KM09b: } & b^{\text {sea }}=4.60, \quad r^{\mathrm{val}}=1.11, \quad b^{\mathrm{val}}=2.40, & d=-6.00, & M_{d}=1.5 \mathrm{GeV}(.3 .62)
\end{array}
$$

These values of the fit parameters are compatible with our generic expectations: the skewness effect at small $x$ should be small, i.e., $r \sim 1$, the subtraction constant should be negative [574, 652, and, according to counting rules 653], $b$ should be smaller than the corresponding $\beta$ value of the relevant PDF [646, 654].

To improve the models that we just described, we now use a hybrid technique where the sea quark and gluon GPDs are represented in terms of conformal moments, while, for convenience, the valence quarks are still modeled in momentum fraction space and within the "dispersion integral" approach. Also, the residue of the pion-pole contribution is now considered as a parameter, and the Hall A data forces a roughly three times larger value than expected from the model 651]. Optionally, we might also use the improved formulae from [655] applicable for a longitudinally polarized target. The new parameters read:

$$
\begin{array}{ll}
\text { KM10a: } & r^{\mathrm{val}}=0.88, \quad M^{\mathrm{val}}=1.5 \mathrm{GeV}, \quad b^{\mathrm{val}}=0.40, d=-1.72, \quad M_{d}=2.0 \mathrm{GeV}, \\
\text { KM10b: } & r^{\mathrm{val}}=0.81, \quad M^{\text {val }}=0.8 \mathrm{GeV}, \quad b^{\mathrm{val}}=0.77, \quad d=-5.43, \quad M_{d}=1.33 \mathrm{Ge(B.63)}
\end{array}
$$

Note that for the valence part of the $H$ GPD, these results are qualitatively compatible with those from the pure KM09 "dispersion relation" fits.

Figure 3.22. Experimental measurements for fixed target kinematics (circles) labeled by data point number $n$ : $A_{\mathrm{BS}}^{(1)}(1-18), A_{\mathrm{BC}}^{(0)}(19-36), A_{\mathrm{BC}}^{(1)}(37-54)$ from [656]; $A_{\mathrm{BS}}^{(1)}(55-66)$ and $\Sigma_{\mathrm{BS}}^{(1), w}(67-70)$ are derived from 657] and 658. Model results are from the "dispersion-relation" fits KMO9a without Hall A data 646 (squares, slightly shifted to the left) and KMO9b with the Hall A data (circles, slightly shifted to the right), hybrid model fit KM10b (triangles-up), and a hand-bag prediction GK07 from hard vector meson production (triangles-down, slightly shifted to the r.h.s.) [659].

We also performed an additional fit where we directly used the harmonics of beam spin sums and differences measured by Hall A (fit KM10). The results of our two "dispersionrelation" fits and three hybrid model fits are available as a computer program providing the four-fold cross section of polarized lepton scattering on unpolarized proton for a given kinematics, see http://calculon.phy.hr/gpd/. Unlike "dispersion-relation" fits, the hybrid model fits, where LO evolution of sea quark and gluon GPDs has been taken into account, are suitable for estimates in the small $x_{B}$ region.

In figure 3.22 we confront our fit results $\left(\chi^{2} /\right.$ d.o.f. $\approx 1$ w.r.t. the employed data sets) to experimental data: KM09a (squares), KM09b (circles), and the hybrid model fit KM10b (triangles-up) in which we now utilized the improved formulae set 655 and the Kelly form factor parameterization 660]. We also include the predictions from the GK07 model [659] (triangles-down), where we adopt the hypothesis of $H$ dominance. Qualitatively, these predictions are consistent with a $\mathrm{VGG}^{2}$ code estimate, which tends to over-estimate the BSAs [657, 656] and describes the BCAs from HERMES rather well without the $D$-term [661]. This is perhaps not astonishing, since the employed $H$ GPD model relies on Radyushkin's DD ansatz, too. We would like to emphasize that at LO, the GK07 model is in reasonable agreement with the H1 and ZEUS DVCS data $\left(\chi^{2} /\right.$ d.o.f. $\left.\approx 2\right)$, essentially thanks to the rather small and stable skewness ratio $r^{\text {sea }}$ of sea quarks.

Longitudinally polarized target data from CLAS 662 and HERMES 663 provide a handle on $\widetilde{H}$ 625, where the mean values of CFF fits 664 in the JLAB kinematics give two to three times bigger $\widetilde{H}$ contribution compared to our expectations $\left(r_{\widetilde{H}} \simeq 1, b_{\widetilde{H}} \simeq 2\right)$. These findings are one to two standard deviations away from our big $\widetilde{H}$ ad hoc scenario of the KM09b fit, which is indeed disfavored by the longitudinally polarized proton data. We like to add that with our present hybrid model a reasonable global fit, such as KM10 above, is possible. In such a fit, the Hall A data require a rather large pion pole contribution, inducing a large DVCS cross section contribution. Still, we have not included the transversal

[^272]

Figure 3.23. $\Im m \mathcal{H} / \pi$ from different strategies: our DVCS fits [dashed (solid) curve excludes (includes) Hall A data from "dispersion relation" KM09a (KM09b) 646 and hybrid KM10b (dashdotted) models], GK07 model from DVEM (dotted), seven-fold CFF fit 666, 667 with boundary conditions (squares), $\mathcal{H}, \widetilde{\mathcal{H}} \mathrm{CFF}$ fit 664 (diamonds), smeared conformal partial wave model fit 668] within $H$ GPD (circles). The triangles result from our neural network fit, cf. figure 3.24.
target data from the HERMES collaboration [661] or the neutron data from Hall A 665].
So far we did not study model uncertainties or experimental error propagation, since both tasks might be rather intricate. To illuminate this, in figure 3.23 we compare our results for $\Im m \mathcal{H}\left(x_{B}, t\right) / \pi$ with the results that do provide error estimates. The squares arise from constrained least squares fits [666, 667] at given kinematic means of HERMES and JLAB measurements on unpolarized proton, where the imaginary and real parts of twist-two CFFs are taken as parameters. The huge size of the error bars shows the limited accuracy with which $H$ can be extracted from unpolarized proton data alone 625]. A pure $H$ GPD model fit 668] (circles) to JLAB data provides much smaller errors, arising from error propagation and some estimated model uncertainties. All three of our curves are compatible with the findings [666, 667] and the $H$ GPD model analysis [668] of CLAS data. However, for Hall A kinematics, the deviation of the two predictions that are based on the $H$ dominance hypothesis (the dashed curve and circles in the right panel) are obvious and are explained by our underestimation of the cross section normalization by about $50 \%$. Moreover, the quality of fit [668, $\chi^{2} /$ d.o.f. $\sim 1.7$, might provide another indication that CLAS and Hall A data are not compatible, when this hypothesis is assumed, see, e.g., the two rightmost circles in the left panel for CLAS ( $x_{B}=0.34, t=-0.3 \mathrm{GeV}^{2}, Q^{2}=2.3$ $\left.\mathrm{GeV}^{2}\right)$ and Hall $\mathrm{A}\left(x_{\mathrm{Bj}}=0.36, t=-0.28 \mathrm{GeV}^{2}, Q^{2}=2.3 \mathrm{GeV}^{2}\right)$. While the pure $\mathcal{H}$ and $\widetilde{\mathcal{H}}$ CFF fit 664 (diamonds), including longitudinally polarized target data, is within error bars inconsistent with the $H$ dominated scenario [668] (circles), it (accidentally) reproduces our dashed curve.

Another source of uncertainties are twist-three contributions and perhaps also gluon transversity related contributions, which might be strongly affected by twist-four effects [669].

All this exemplifies that within (strong) assumptions and the present set of measurements, the propagated experimental errors cannot be taken as an estimate of GPD uncertainties. An error estimation in model fits might be based on twist-two sector projection technique [625], boundaries for the unconstrained model degrees of freedom, and error propagation in the twist-two sector. Alternatively, neural networks, already successfully used for PDF fits [47, may be an ideal tool to extract CFFs or GPDs. In figure 3.24, we present a first example in which, within the $H$-dominance hypothesis, $\mathcal{H}$ is extracted using a pro-

Figure 3.24. Neural network extraction of $\Re \mathrm{e} \mathcal{H}\left(x_{B}, t\right) / \pi$ from BCA 656] and BSA 657] data.
cedure similar to the one of 670. Here, 50 feed-forward neural nets with two hidden layers were trained using HERMES BCA [656] and CLAS BSA 657] data. Hence, only the experimental errors were propagated, which, in the absence of a model hypothesis, become large for the $t \rightarrow 0$ extrapolation.

### 3.8.4 Potential of an electron-ion collider

A high luminosity machine in the collider mode with polarized electron and proton or ion beams would be an ideal instrument to quantify QCD phenomena. It is expected that such a machine, combined with designated detectors, would allow for precise measurements of exclusive channels. Besides hard exclusive vector meson and photon electroproduction, one might address the behavior of parity-odd GPDs $\widetilde{\mathcal{H}}$ (related to polarized PDFs) and $\widetilde{\mathcal{E}}$ via the exclusive production of pions even in the small $x$ region. It is obvious from what was said above that an access of GPDs requires a large data set with small errors. In the following we would like to illustrate the potential of such a machine for DVCS studies, where we also address the GPD deconvolution problem.

Let us remind that already the isolation of CFFs is rather intricate. For a spin- $1 / 2$ target, we have four twist-two, four twist-three, and four gluon transversity-related complex valued CFFs. The photon helicity non-flip amplitudes are dominated by twist-two CFFs, the transverse-longitudinal flip amplitudes by twist-three effects, and the transverse-transverse flip ones by gluon transversity. Hence, the first, second, and third harmonics w.r.t. the azimuthal angle of the interference term are twist-two, twist-three, and gluon transversity dominated, respectively. In an ideal experiment, assuming that transverse photon helicity flip effects are negligible, cross section measurements would allow to separate the sixteen quantities that are then given in terms of twist-two and twist-three CFFs. The reader might find a more detailed discussion, based on a $1 / Q$ expansion, in 625. We also note that the definition of CFFs is convention-dependent.

In a twist-two analyzes on unpolarized, longitudinally and transversally polarized protons, one might be able to disentangle the four different twist-two CFFs via the measurement of single beam and target spin asymmetries. In figure 3.25, we illustrate that the beam spin asymmetry for a proton target (solid curves),

$$
\begin{equation*}
A_{\mathrm{BS}}^{(1)} \propto \frac{\sqrt{t_{\min }-t}}{2 M} y\left[F_{1}(t) H\left(\xi, \xi, t, Q^{2}\right)-\frac{t}{4 M^{2}} F_{2}(t) E\left(\xi, \xi, t, Q^{2}\right)+\cdots\right], \tag{3.64}
\end{equation*}
$$

Figure 3.25. KM10b model estimate for the DVCS beam spin asymmetry with a proton (solid) and neutron (dashed) target. Left panel: $A_{\mathrm{BS}}$ vs. $\phi$ for $E_{N}=250 \mathrm{GeV}, E_{e}=5 \mathrm{GeV}, x_{B}=5 \times 10^{-3}$, $Q^{2}=10 \mathrm{GeV}^{2}$, and $t=-0.2 \mathrm{GeV}^{2}$. Right panel: Amplitude $A_{\mathrm{BS}}^{(1)}$ of the first harmonic vs. $x_{\mathrm{Bj}}$ at $t=-0.2 \mathrm{GeV}^{2}$ for small $x_{B}$ (thin) $\left[E_{e}=30 \mathrm{GeV}, E_{p}=360 \mathrm{GeV}, Q^{2}=4 \mathrm{GeV}^{2}\right]$ and large $x_{B}$ (thick) $\left[E_{e}=5 \mathrm{GeV}, E_{p}=150 \mathrm{GeV}, Q^{2}=50 \mathrm{GeV}^{2}\right]$ kinematics.
might be rather sizeable over a large kinematical region in which the lepton energy loss $y$ is not too small. Here the helicity conserved CFF $\mathcal{H}$ is the dominant contribution, while $\mathcal{E}$ appears with a kinematic suppression factor $t / 4 M^{2}$, induced by the helicity flip. For a neutron target, the $\mathcal{H}$ contribution is suppressed by the accompanying Dirac form factor $F_{1}^{n}$ $\left(F_{1}^{n}(t=0)=0\right)$ and, hence, one becomes sensitive to the CFF $\mathcal{E}$. Unfortunately, one also has to worry about other non-dominant CFF contributions, indicated by the ellipsis. Note that the asymmetry for the neutron (dashed curves in figure 3.25) might be underestimated since we set in our model $E\left(x, x, t, Q^{2}\right)$ to zero.

For a longitudinally polarized target, the asymmetry

$$
\begin{equation*}
A_{\mathrm{TS}}^{\Rightarrow(1)} \propto \frac{\sqrt{t_{\mathrm{min}}-t}}{2 M}\left[F_{1}(t) \widetilde{H}\left(\xi, \xi, t, \mathcal{Q}^{2}\right)-\frac{t}{4 M^{2}} F_{2}(t) \xi \widetilde{E}\left(\xi, \xi, t, \mathcal{Q}^{2}\right)+\cdots\right] \tag{3.65}
\end{equation*}
$$

is sensitive to the GPD $\widetilde{H}$, while $\xi \widetilde{E}$ and other GPDs might contribute to some extent. Naively, one would expect that this asymmetry vanishes in the small $x_{B}$ region and might be sizeable at $x_{B} \sim 0.1$, see the left panel of figure 3.26 . Not much is known about the small $x$ behavior of $\widetilde{H}$ and it might be even accessible at smaller values of $x_{B}$, as illustrated by the $K M 09 b$ model with its big $\widetilde{H}$ contribution (solid curve, the right panel of figure 3.26 ). For a neutron target, the asymmetry becomes sensitive to the $\xi \widetilde{E}$ GPD. Note that here the factor $\xi$ is annulled by a conventional $1 / \xi$ factor in the definition of the $\widetilde{E}$ GPD.

Finally, we emphasize that a single spin asymmetry measurement with a transversally polarized target provides another handle on the helicity-flip GPDs $E$ and $\widetilde{E}$. If the target spin is perpendicular to the reaction plane, the asymmetry

$$
\begin{equation*}
A_{\mathrm{TS}}^{\Uparrow(1)} \propto \frac{t}{4 M^{2}}\left[F_{2}(t) H\left(\xi, \xi, t, \mathcal{Q}^{2}\right)-F_{1}(t) E\left(\xi, \xi, t, \mathcal{Q}^{2}\right)+\cdots\right] \tag{3.66}
\end{equation*}
$$

is dominated by a linear combination of the GPDs $H$ and $E$. In the case when the target spin is aligned with the reaction plane, the asymmetry

$$
\begin{equation*}
A_{\mathrm{TS}}^{\Downarrow(1)} \propto \frac{t}{4 M^{2}}\left[F_{2}(t) \widetilde{H}\left(\xi, \xi, t, \mathcal{Q}^{2}\right)-F_{1}(t) \xi \widetilde{E}\left(\xi, \xi, t, \mathcal{Q}^{2}\right)+\cdots\right] \tag{3.67}
\end{equation*}
$$

Figure 3.26. DVCS longitudinal target spin asymmetry vs. $\phi$ for KM09a (dashed), KM09b (solid), and KM10b hybrid (dash-dotted) models at $E_{e}=5 \mathrm{GeV}, t=-0.2 \mathrm{GeV}^{2}, \mathcal{Q}^{2}=4 \mathrm{GeV}^{2}$ within $E_{p}=150 \mathrm{GeV}, x_{\mathrm{Bj}}=0.1$ (left) and $E_{p}=350 \mathrm{GeV}, x_{\mathrm{Bj}}=0.01$ (right).

Unfortunately, compared to the single beam spin (3.64) and longitudinal target (3.65) asymmetries, the transversally ones are kinematically suppressed by an additional factor $\sim \sqrt{-t} /(2 M)$ and, for a neutron target, in addition by the Dirac form factor $F_{1}(t)$.

Although the given formulae (3.64 3.67) are rather crude, they illustrate that a measurement of single spin asymmetries would allow to access the imaginary part of the four twist-two related CFFs. However, the normalization of these asymmetries depends to some extent also on the real part of the twist-two related CFFs and the remaining eight ones. Measurements of cross section differences would allow one to eliminate the normalization uncertainty, and in combination with the harmonic analysis, one can separate to some extent twist-two, twist-three, and gluon transversity contributions. However, the extracted harmonics might also be contaminated by DVCS cross section contributions which are bilinear in the CFFs. To get rid of these admixtures, one needs cross section measurements with a positron beam. Forming differences and sums of cross section measurements with both kinds of leptons, allows one to extract the pure interference and DVCS squared terms and, thus, might allow one to quantify twist-three effects. Existing data indicate that these effects are small as expected based on kinematic factors. However, even obtaining only an upper limit is important for the determination of the systematic uncertainties of twist-two CFFs.

We also emphasize that having both kinds of lepton beams available allows one to measure the real part of CFFs. In figure 3.27, we show the beam charge asymmetry,

$$
\begin{equation*}
A_{\mathrm{BC}}^{(1)} \propto \Re \mathrm{e}\left[F_{1}(t) \mathcal{H}\left(x_{\mathrm{Bj}}, t, \mathcal{Q}^{2}\right)-\frac{t}{4 M^{2}} F_{2}(t) \mathcal{E}\left(x_{\mathrm{Bj}}, t, \mathcal{Q}^{2}\right)+\cdots\right], \tag{3.68}
\end{equation*}
$$

for an unpolarized target, which is expected to be sizeable. For a proton target, this asymmetry should possess a node in the transition from the valence to sea region(thick solid curve, right panel). In our parameterization, the real part of the $\mathcal{E}$ CFF is determined by the $\mathcal{D}$ subtraction term, which induces a sizeable asymmetry (thick dashed curve, right panel), even for a neutron target.

The large kinematical coverage of the proposed high-luminosity EIC raises the question: Can one utilize evolution, even at moderate $x_{B}$ values, to access GPDs away from their crossover line? Similarly to what has been done for the small $x_{B}$ region, we use the Mellin-Barnes integral technique to address the problem. Taking different non-leading SO(3) partial waves in the ansatz for the conformal moments (3.56[3.57), we build three different GPD models

Figure 3.27. KM10b model estimate for the DVCS beam charge asymmetry with a proton (solid) and neutron (dashed) target. Left panel: $A_{\mathrm{BC}} v s . \phi$ for $E_{N}=250 \mathrm{GeV}, E_{e}=5 \mathrm{GeV}, x_{B}=5 \times 10^{-3}$, $Q^{2}=10 \mathrm{GeV}^{2}$, and $t=-0.2 \mathrm{GeV}^{2}$. Right panel: Amplitude $A_{\mathrm{BC}}^{(1)}$ of the first harmonic vs. $x_{B}$ at $t=-0.2 \mathrm{GeV}^{2}$ for small $x_{B}$ (thin) $\left[E_{e}=30 \mathrm{GeV}, E_{p}=360 \mathrm{GeV}, Q^{2}=4 \mathrm{GeV}^{2}\right]$ and large $x_{B}$ (thick) $\left[E_{e}=5 \mathrm{GeV}, E_{p}=150 \mathrm{GeV}, Q^{2}=50 \mathrm{GeV}^{2}\right]$ kinematics.
for valence quarks that provide almost identical CFFs, see the upper left panel in figure 3.28 , They are compatible with (3.60) from the "dispersion-relation" fit KM09a (dotted curves). We note that the different model behavior at large $x_{B}$ results only in a small discrepancy for the real part of the CFF in the kinematics of interest. In the lower left panel of figure 3.28, we illustrate that for fixed $\eta$, the $x$-shape of the three GPD models looks quite differently. Compared to the minimalist model (dotted curve), a model with a negative next-to-leading partial wave (solid) decreases the size of the GPD on the cross-over line $\eta=x$ and generates an oscillating behavior in the central region. The model with an alternating-sign $\mathrm{SO}(3)$ partial wave expansion (dash-dotted) possesses more pronounced oscillation effects in the central region or even nodes. In the third model (dashed curve), the reduction on the cross-over line is reached within a next-to-next leading $\mathrm{SO}(3)$ partial wave. Note that the GPDs in the region $\eta \ll x$ are governed by the $x$-behavior of the PDF analogues. In the right panels, we demonstrate that for a large lever arm in $Q^{2}$ (e.g., $Q^{2}=50 \mathrm{GeV}^{2}$ ), the evolution effects are important in the valence quark region. However, for CFFs (the upper right panel), the discriminating power of evolution effects remains moderate even if the GPD shapes look rather different.

### 3.8.5 Conclusions and summary

With all the theoretical tools sketched above plus those which are presently under development, it is clear that our understanding of hadron structure will be revolutionized once most of the diverse asymmetries are measured with percent or permille precision (depending on the observable). At present, first steps have been undertaken to access GPDs from experimental data in the small $x_{B}$ region and in the fixed target kinematics providing us with some insight into the GPD $H$. In particular, for DVCS in the fixed target kinematics, LO model fits are compatible with least-square CFF fits and first results from neural networks (assuming $H$ dominance). The large uncertainties in extracting CFFs are mainly related to the lack of experimental data. Thus, not only the extraction of the very desired $\mathcal{E}$ playing an important role in the "spin-puzzle", but also of other CFFs, requires a comprehensive measurement of all possible observables in dedicated experiments. A further comparison

Figure 3.28. Upper left panel: The valence-like contribution (3.60) to the CFF $\mathcal{H}$ extracted with a "dispersion-relation" fit KM09a from fixed target measurements (dotted) at $t=-0.2 \mathrm{GeV}^{2}$ and $Q^{2}=2 \mathrm{GeV}^{2}$ vs. $x_{B}$ together with various models. Lower left panel: The corresponding models of the GPD $x H\left(x, \eta, t, \mathcal{Q}^{2}\right)$ together with a minimalist GPD parameterization (dotted curve) vs. $x$ at $\eta=0.2, t=-0.2 \mathrm{GeV}^{2}$, and $Q^{2}=2 \mathrm{GeV}^{2}$. The same quantities at $Q^{2}=50 \mathrm{GeV}^{2}$ are displayed in the right panels.
shows that while in the valence region the extracted quark GPDs are somewhat different, they become compatible for small $x$. The main difference lies in the gluonic sector; a more appropriate analysis requires the inclusion of radiative corrections in a global fitting procedure, which is in progress. We should also mention here that hard exclusive processes with nuclei, which at present are not extensively studied, open a new window for the partonic view of nuclei.

Imaging the partonic content of the nucleon and the phenomenological access to the proton spin sum rule from hard exclusive processes can only be reached through proper understanding of GPD models. We also point out that GPDs can also be formulated in terms of an effective nucleon (light-cone) wave function, which links GPDs to transverse momentum dependent parton distributions. The whole framework consisting of perturbative QCD, lattice simulations, and dynamical modeling is available to reveal GPDs and access the nucleon wave function. Such a unifying description can be considered as the primary goal in quantifying the partonic picture. While such a task looks rather straightforward, much effort is needed on the theoretical, phenomenological, and experimental sides, with experimental data with small uncertainties playing the key role. A high-luminosity EIC is an ideal machine that would cover a wide kinematical range and complement the planned fixed target experiments at JLab@12 GeV. Thus, besides new measurements, an EIC has a great potential to significantly improve existing data sets.
Acknowledgments. We are grateful to P. Kroll for many fruitful discussions.

### 3.9 Monte Carlo studies on DVCS with an EIC

Salvatore Fazio

### 3.9.1 Exclusive processes with a dedicated EIC detector

Our current knowledge of the role of gluons in hadronic matter comes mainly from DIS experiments of electrons off protons most notably from HERA at DESY. Although electrons only interact with electrically charged particles, and gluons carry only color charge, a highenergy electron beam can still be used as an excellent gluon microscope.

The HERA physics program of ep collisions surprisingly showed a large fraction of diffractive events contributing $10-15 \%$ to the total DIS cross-section. One of the key signatures of these "diffractive" events is an intact proton traveling at nearly beam energies, together with a gap in rapidity before some final-state particles are produced at mid-rapidity. However, the detectors (H1 and ZEUS) were not optimized for this important physics and were unable to measure the scattered proton; this was only achievable after a program of upgrades. In fact, to measure diffractive physics events, it is desirable to have very forward detectors at small angles with respect to the beam line, referred to as "Roman Pots". Other requirements are that the detector should be able to measure all processes: inclusive ( $e p \rightarrow e^{\prime} X$ ), semi-inclusive ( $e p \rightarrow e^{\prime} X+$ hadrons), and exclusive (e.g., $e p \rightarrow e^{\prime} p+J / \psi$ ) reactions. The requirements for $e p$ and $e A$ collisions are very similar, the only additional complication in $e A$ collisions arises from the need to tag the struck nucleus, or to veto events with the nucleus break-up by detecting neutrons and other breakup products with high efficiencies.

Briefly, a possible EIC detector consists (in the barrel region at mid-rapidity) of a solenoidal field with Si tracking with full rapidity coverage around the interaction point itself, followed by Cherenkov detectors for particle identification and then by both electromagnetic and hadronic calorimeters. There are further trackers and calorimeters at forward rapidities, but this time, the magnetic field is a dipole. A Roman Pots spectrometer can be installed along the beam-pipe in the direction of the outgoing proton. This is just a starting point and other technologies are under active investigation.

### 3.9.2 DVCS and GPDs: from HERA to an EIC

Measurements of observables associated with hard exclusive processes at an ep/eA collider requires substantially higher luminosities than traditional inclusive DIS because of the small cross sections and the need for differential measurements. The detectors and the interaction region have to be designed to permit full reconstruction of the final state.

In assessing the prospects for measurements of exclusive processes in ep scattering at collider energies, $W^{2} \gg 10 \mathrm{GeV}^{2}$, one needs to distinguish between "diffractive" (no exchange of quantum numbers between the target and the projectile/produced system) and "non-diffractive" processes (exchange of quantum numbers). In diffractive channels, such as $J / \psi, \rho, \phi$ production and DVCS (production of a real photon), the cross sections rapidly rise with the collision energy, $W$. At large $Q^{2}$, these processes probe the gluon GPD and/or the singlet quark GPD. In non-diffractive channels, such as $\pi^{ \pm}, \pi^{0}, \rho^{+}, K$ production, the cross sections decrease with energy. These processes at high $Q^{2}$ probe the flavor/charge/spin non-singlet quark GPDs describing the quark structure of the target.

The final state of a DVCS event, shown in figure 3.29a, contains one track and two

Figure 3.29. Diagram of the DVCS (a) and BH processes for a photon emitted from the initial (b) and final (c) lepton line.
electromagnetic clusters together with a proton scattered at a very small angle. The technique for measuring DVCS consists of first extracting a data sample of events characterized by the DVCS topology. Apart from the DVCS process, the data selection comprises also Bethe-Heitler (BH) events, a well known QED process, because DVCS and BH share the same final state. The selected sample will contain a mixture of DVCS and BH contributions. For not too large $y$ (see figure 3.31), the BH contribution is not much larger than DVCS and thus can be subtracted from the data using the MC predictions and control data samples containing BH only since at high enough $Q^{2}$ the interference contribution drops out to a good accuracy when averaging over the angle $\phi$ between the production and scattering planes.

The differential cross section as a function of $|t|$ can be parameterized by an exponential: $d \sigma / d t \propto e^{b|t|}$. The H1 Collaboration [648] measured $|t|$ from the transverse momentum distribution of the photon and studied the $b$-slope in a few bins in $Q^{2}$ and $W$. The slope $b$ seems to decrease with $Q^{2}$ up to the value expected for a hard process but it does not depend on $W$. The ZEUS Collaboration [645] performed a direct measurement of the proton final state using a Roman Pots spectrometer: the resulting $b=4.5 \pm 1.3 \pm 0.4 \mathrm{GeV}^{-2}$ at $Q^{2}=3.2 \mathrm{GeV}^{2}$ and $W=104 \mathrm{GeV}$ is consistent, within the large uncertainties due to the low acceptance of the spectrometer, with the H 1 result of $b=5.45 \pm 0.19 \pm 0.34 \mathrm{GeV}^{-2}$ at $Q^{2}=8 \mathrm{GeV}^{2}$ and $W=82 \mathrm{GeV}$ [648].

A comprehensive program of parton imaging in the nucleon would need precise measurements of $b$ for wide range of $x_{B}$ values, $10^{-4}<x_{B}<10^{-1}$; this is currently beyond the possibilities of any experiment. Building an EIC with a properly designed detector could finally make it possible - a preliminary feasibility study is reported in section 3.6.

The beam-charge asymmetry (BCA) provides an access to the real part of the DVCS amplitude through the interference between the DVCS and BH amplitudes (for illustration, we keep only the dominant $\cos (\phi)$ harmonic):

$$
\begin{equation*}
A_{C}=\frac{\frac{d \sigma^{+}}{||t|}-\frac{d \sigma^{-}}{d|t|}}{\frac{d \sigma^{+}}{d|t|}+\frac{d \sigma^{-}}{d|t|}}=p_{1} \cos (\phi) \propto 2 \mathcal{A}_{\mathrm{BH}} \frac{\Re e\left(\mathcal{A}_{\mathrm{DVCS}}\right)}{\left|\mathcal{A}_{\mathrm{DVCS}}\right|^{2}+\left|\mathcal{A}_{\mathrm{BH}}\right|^{2}} \cos (\phi) . \tag{3.69}
\end{equation*}
$$

The measurement of $A_{C}$ is complementary to the measurement of the $|t|$ distribution. The DVCS beam-charge asymmetry has been measured by the H1 648] and HERMES [671, 672] experiments.

The large rapidity acceptance and high precision tracker of the EIC detector together with its very accurate electromagnetic calorimeter and the high luminosity of the machine,
make it an ideal tool for the measurement of both the DVCS cross section differential in $|t|$ and the DVCS+BH cross section asymmetries. Specifically for the BCA, a positron beam would be required.

### 3.9.3 Monte Carlo simulations of DVCS at an EIC

The Monte Carlo generator used for our studies is MILOU 673, which simulates both the DVCS and the BH processes together with their interference term. DVCS is simulated using the framework of GPDs at next-to-leading order (NLO) accuracy, including the NLO evolution of GPDs [625]. The $t$ dependence is introduced as an exponential $d \sigma / d t \propto e^{B\left(Q^{2}\right)|t|}$, where $B\left(Q^{2}\right)$ is either a constant or can have a weak logarithmic dependence on $Q^{2}, B\left(Q^{2}\right) \sim \ln \left(Q^{2}\right)$. In the present simulation, we used the former option, $B\left(Q^{2}\right)=5 \mathrm{GeV}^{-2}$. In addition, the proton dissociation background, ep $\rightarrow e \gamma Y$, has not been included.

The DVCS and BH processes have been simulated in the following kinematic range:

- $Q^{2} \geq 1 \mathrm{GeV}^{2}$;
- $10^{-4}<x_{B}<10^{-1}$;
- $0.01<y<0.85$;
- $0.01<|t|<1 \mathrm{GeV}^{2}$.

The $Q^{2}$ and $x_{B}$ ranges correspond to the phase space achievable with an EIC; the lower $y$ limit is chosen according to the acceptance of the detector; the interval in $|t|$ relates to the acceptance of a forward proton spectrometer. The energy configuration considered for the present study is a $5-20 \mathrm{GeV}$ electron beam colliding with a 250 GeV proton beam.

Figure 3.30 shows the correlation between the scattering angle of the real photon produced in the interaction and its energy for different EIC energy configurations. For the $20 \times 250$ configuration, the photons with an energy greater than $\sim 5 \mathrm{GeV}$ are produced backward at an angle larger than 2.7 rad , corresponding to the rear end-cap calorimeter in the detector. Since for the DVCS process the electron is always scattered backward, this can lead to problems in discriminating the photon and electron clusters and makes it crucial to have an electromagnetic calorimeter with high spatial resolution and a good tracker coverage at backward rapidity to measure the electron track. Indeed, this is extremely important for the $t$ resolution in the case of a measurement performed without a Roman Pots because the four-momentum $t$ must be reconstructed, using momentum conservation, from the transverse momenta of the electron and the photon.

The fraction of BH events has been estimated using an MC sample containing both DVCS and BH processes. The samples have been normalized to the luminosity. The fraction of BH events is calculated as follows:

$$
\begin{equation*}
F_{B H}=\frac{B H_{e v t}}{B H_{e v t}+D V C S_{e v t}} . \tag{3.70}
\end{equation*}
$$

Figure 3.31 shows the fraction of BH events as a function of $y, Q^{2}$, and $|t|$. As expected, DVCS is dominant at low $y$ whereas BH dominates at higher $y$ with its fraction increasing up to $100 \%$ for $y>0.85$.

In the present study, the kinematic domain has been binned logarithmically in $1<Q^{2}<$ $100 \mathrm{GeV}^{2}$ and $10^{-4}<x_{B}<10^{-1}$. Figure 3.32 shows the distribution of the statistics per bin for the $20 \times 250$ configuration (left panel) and $5 \times 50$ configuration (right panel).

Figure 3.30. The angle of the produced real photon in a DVCS event as a function of the photon energy for different EIC energy configurations. Each plot shows also the distribution of the photon and scattered electron energies.

Figure 3.31. The fraction of BH events in the $e p \rightarrow e p \gamma$ sample as a function of $y$ (left), $Q^{2}$ (middle), and $|t|$ (right).

Figure 3.32. The distribution of the DVCS events in a logarithmically binned phase space for the $20 \times 250$ (left) and $5 \times 50$ (right) EIC beam energy configurations.

As an example of the precision that could be achieved at an EIC, figure 3.34 shows the expectations for a measurement of the DVCS ep cross section differential in $|t|, \mathrm{d} \sigma_{e p \rightarrow e p \gamma} / \mathrm{d} t$, for several bins of $x_{B}$ and $Q^{2}$. The estimated luminosity for the $20 \times 250$ configuration is $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. The integrated luminosity of the simulated events is $11.9 \mathrm{fb}^{-1}$, corresponding to approximately one month of running at $20 \times 250$ and assuming $50 \%$ operational efficiency. The $b$ slope parameter with its uncertainty is extracted for each data set via a an exponential fit $\sim e^{-b|t|}$, and its value is reported in figure 3.34 together with uncertainties.

One can see that an excellent measurement (binning over a wide range in $Q^{2}$ and $x_{B}$ ) can already be obtained with a relatively modest beam time, allowing for numerous detailed studies of the reaction mechanism ( $Q^{2}$-scaling behavior, QCD evolution) and extraction of information about the nucleon GPDs and its change with $x_{B}$. The statistical uncertainty for the differential cross section can be, at small $|t|$ values, significantly below $1 \%$, as well as the uncertainty on the extracted slope parameter, $b$. This implies that the measurement is actually limited by systematics. Thus the utilization of a high resolution spectrometer based on the Roman Pots technique becomes important for an EIC. For example, the leading proton spectrometer based on 6 Roman Pots stations equipped with silicon microstrips detectors used at ZEUS for the DVCS $d \sigma / d|t|$ measurement, allowed to measure $P_{t}$ with a resolution of 5 MeV [645] under test beam conditions which corresponded to $\Delta\left(P_{t}^{2}\right)=|\Delta t|=10^{-2} P_{t}$ for a $|t|$ measurement. A new properly designed Roman Pots spectrometer, potentially based on a radiation-hard silicon pixel technology, could reach a geometrical acceptance of about $60 \%$, with a better $P_{t}$ resolution. Since for an EIC systematics are the challenge, it is worth sacrificing the acceptance and therefore increasing the beam time for a more accurate measurement.

Figure 3.35 shows the expectations for a DVCS measurement for large- $|t|$. The data have been simulated for $1<|t|<2 \mathrm{GeV}^{2}$ in several bins of $x_{B}$ and $Q^{2}$. The luminosity of the simulated sample is $151 \mathrm{fb}^{-1}$ corresponding to approximately 52 weeks of data taking in the $20 \times 250$ configuration. One can see that even if the cross section drops drastically for large $|t|$ values, the EIC still allows for good binned measurements, but this requires
years of data taking. (For a relevant discussion, see section (3.6) In this regime, the main detector offers a much better acceptance then Roman Pots and can be used for measuring $|t|$.

A data sample containing DVCS, BH and their interference term has been simulated considering separately an electron beam (luminosity is $44 \mathrm{pb}^{-1}$ ) and a positron beam (luminosity is $47 \mathrm{pb}^{-1}$ ) and used to calculate the beam-charge asymmetry, $A_{C}$. The result is shown in figure 3.33 together with a fit in the form $A_{C}=p_{1} \cos (\phi)$ (3.69), where $p_{1}$ is a free parameter. One can see that a fair accuracy for the BCA can be obtained at an EIC for a modest integrated luminosity.

Figure 3.33. The beam-charge asymmetry $A_{C}$ as a function of the azimuthal angle $\phi$ between the production and scattering planes.

Figure 3.34. The DVCS cross section has been simulated in the range $1.0<Q^{2}<100 \mathrm{GeV}^{2}$, $10^{-4}<x_{B}<0.1$ for the $20 \times 250 \mathrm{GeV}$ energy configuration. The DVCS cross section is simulated in several bins of $x_{B}$ and $Q^{2}$ and is shown for small $|t|$ values.

Figure 3.35. The DVCS cross section has been simulated in the range $1.0<Q^{2}<100 \mathrm{GeV}^{2}$, $10^{-4}<x_{B}<0.1$ for the $20 \times 250 \mathrm{GeV}$ energy configuration. The DVCS cross is section simulated in several bins of $x_{B}$ and $Q^{2}$ and is shown for large $|t|$ values.

### 3.10 DVCS Beam Spin Asymmetries with an EIC

R. Géraud, H. Moutarde, F. Sabatié

### 3.10.1 Deeply Virtual Compton Scattering polarization observables

The photon electroproduction $e p \rightarrow e p \gamma$ can either occur by radiation along one of the electron lines (Bethe-Heitler or BH) or by emission of a real photon by the nucleon (Deeply Virtual Compton Scattering or DVCS). The total cross section as given by 625 reads:

$$
\begin{equation*}
\frac{\mathrm{d} \sigma^{e p \rightarrow e p \gamma}}{\mathrm{~d} x_{B} d y \mathrm{~d} \Delta^{2} \mathrm{~d} \phi \mathrm{~d} \varphi}=\frac{\alpha^{3} x_{B} y}{16 \pi^{2} Q^{2} \sqrt{1+\epsilon^{2}}}\left|\frac{\mathcal{T}}{e^{3}}\right|^{2}, \tag{3.71}
\end{equation*}
$$

where $\Delta$ is the 4 -momentum transfer between the initial and final proton; $Q^{2}$ the virtuality of the exchanged photon; $x_{B}$ the usual Bjorken variable; $\epsilon=2 x_{B} M / Q$ ( $M$ is the proton mass); $y$ is the fraction of the electron energy lost in the nucleon rest frame; $\phi$ is the angle between the leptonic plane $\left(e, e^{\prime}\right)$ and the photonic plane $\left(\gamma^{*}, \gamma\right)$ as shown in figure 3.36 The angle $\varphi$ is defined as the difference between $\phi$ and $\phi_{S}$, the orientation of the target spin in the case of a polarized target, shown also in figure 3.36.

Figure 3.36. Kinematics of the photon leptoproduction in the target rest frame (the Trento notations). The incoming and outgoing leptons define the scattering plane, and the outgoing photon and recoil protons define the hadronic plane. In this reference system, the azimuthal angle between the lepton and recoil proton planes is $\phi$. The angle $\phi_{S}$ defines the orientation of the target spin in the case of a polarized target (it will not be used in the present contribution).

The total amplitude $\mathcal{T}$ is the superposition of the BH and DVCS amplitudes:

$$
\begin{align*}
|\mathcal{T}|^{2} & =\left|\mathcal{T}_{\mathrm{BH}}\right|^{2}+\left|\mathcal{T}_{\mathrm{DVCS}}\right|^{2}+\mathcal{I}, \\
\mathcal{I} & =\mathcal{T}_{\mathrm{DVCS}}^{*} \mathcal{T}_{\mathrm{BH}}+\mathcal{T}_{\mathrm{DVCS}} \mathcal{T}_{\mathrm{BH}}^{*}, \tag{3.72}
\end{align*}
$$

where $\mathcal{T}_{\text {DVCS }}$ and $\mathcal{T}_{\text {BH }}$ are the amplitudes for the DVCS and Bethe-Heitler processes, and $\mathcal{I}$ denotes the interference between these amplitudes. The individual contributions to the total $e p \rightarrow e p \gamma$ cross section can be written as (up to twist- 3 contributions and corrections
in $1 / Q$ ) 625:

$$
\begin{align*}
\left|\mathcal{T}_{\mathrm{BH}}\right|^{2} & =\frac{\Gamma_{\mathrm{BH}}\left(x_{B}, Q^{2}, t\right)}{\mathcal{P}_{1}(\phi) P_{2}(\phi)}\left\{c_{0}^{\mathrm{BH}}+\sum_{n=1}^{2} c_{n}^{\mathrm{BH}} \cos (n \phi)+s_{1}^{\mathrm{BH}} \sin \phi\right\},  \tag{3.73}\\
\left|\mathcal{T}_{\mathrm{DVCS}}\right|^{2} & =\Gamma_{\mathrm{DVCS}}\left(x_{B}, Q^{2}, t\right)\left\{c_{0}^{\mathrm{DVCS}}+\sum_{n=1}^{2}\left[c_{n}^{\mathrm{DVCS}} \cos (n \phi)+s_{n}^{\mathrm{DVCS}} \sin (n \phi)\right]\right\}  \tag{3.74}\\
\mathcal{I} & \left.=\frac{\Gamma_{I}\left(x_{B}, Q^{2}, t\right)}{\mathcal{P}_{1}(\phi) P_{2}(\phi)}\right]\left\{c_{0}^{I}+\sum_{n=1}^{3}\left[c_{n}^{I} \cos (n \phi)+s_{n}^{I} \sin (n \phi)\right]\right\}, \tag{3.75}
\end{align*}
$$

where $\Gamma_{\mathrm{BH}}, \Gamma_{\mathrm{DVCS}}$ and $\Gamma_{I}$ are known kinematical prefactors. $\mathcal{P}_{1}(\phi)$ and $\mathcal{P}_{2}(\phi)$ come from the BH electron propagators and can be written as:

$$
\begin{equation*}
Q^{2} \mathcal{P}_{1}=Q^{2}+2 k \cdot \Delta, \quad Q^{2} \mathcal{P}_{2}=-2 k \cdot \Delta+\Delta^{2}, \tag{3.76}
\end{equation*}
$$

where $k$ is the 4 -momentum of the incoming lepton.
In the case of scattering on unpolarized or longitudinally polarized targets, all $\sin (n \phi)$ coefficients in (3.73(3.75) depend either on the beam helicity $\lambda$ or on the target longitudinal polarization $\Lambda$; they disappear in the unpolarized cross section.

Using a polarized beam, two separate quantities can be extracted: the difference of cross section with opposite beam helicities and the total cross section, which at leading twist can be written respectively as:

$$
\begin{align*}
d \sigma^{\rightarrow}-d \sigma^{\leftarrow} & =2 \cdot \mathcal{T}_{\mathrm{BH}} \cdot \Im m\left(\mathcal{T}_{\mathrm{DVCS}}\right), \\
d \sigma^{\rightarrow}+d \sigma^{\leftarrow} & =\left|T_{\mathrm{BH}}\right|^{2}+2 \cdot \mathcal{T}_{\mathrm{BH}} \cdot \Re e\left(\mathcal{T}_{\mathrm{DVCS}}\right)+\left|T_{\mathrm{DVCS}}\right|^{2}, \tag{3.77}
\end{align*}
$$

where the arrows correspond to the beam helicity. At low $y$, the interference term entering the total cross section is small compared to the DVCS and BH contributions, which contrasts with the case of intermediate or large $y$ where the DVCS contribution is small with respect to the interference, which itself is in general significantly smaller than the BH term. Note that the DVCS contribution to the difference of cross section only appears at higher twist.

From these two natural observables, one can write asymmetries which are experimentally easier to determine than cross sections:

$$
\begin{equation*}
A_{L U}=\frac{d \sigma^{\leftarrow}-d \sigma^{\rightarrow}}{d \sigma^{\leftarrow}+d \sigma^{\rightarrow}}, \tag{3.78}
\end{equation*}
$$

Beam spin asymmetries are mostly sensitive to the GPD $H$ and are complementary to unpolarized cross sections and beam charge asymmetry measurements presented in section 3.9.

### 3.10.2 Monte Carlo

The PROPHET package [674] was used in its Monte Carlo configuration to generate photon electroproduction pseudo-data in the EIC kinematics. We relied on the GoloskokovKroll model for GPDs 605 evaluated at NLO, integrated over the LO hard kernel to obtain Compton Form Factors $\mathcal{H}, \widetilde{\mathcal{H}}, \mathcal{E}$ and $\widetilde{\mathcal{E}}$ which are the complex counterparts of GPDs and directly relate to the DVCS amplitude at the leading order of $\alpha_{s}$ [625]. Note that $\widetilde{\mathcal{E}}$ only enters the unpolarized cross section for DVCS, but was neglected in this evaluation.

The photon electroproduction observables were evaluated using the GV package 675], which in contrast with the usual BMK formalism [625], does not make approximations of the order of $1 / Q$ in the treatment of the interference term. It was checked that the unpolarized cross sections generated by our Monte Carlo give the results simular to those shown in section [3.9, but with more realistic $b$-slopes since they were not taken as a constant but form a part of the Goloskokov-Kroll model.

### 3.10.3 Projected results

The Beam Spin Asymmetry evaluated in a typical $\left(x_{B}, Q^{2}\right)$ bin is shown in figure 3.37 The $\sin \phi$ coefficient turns out 3 to 5 times lower than that at typical lower energy and higher $x_{B}$ kinematics. Therefore, this asks for a rather large integrated luminosity. For the considered $x_{B}$ range (and lower), about three months of EIC at $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ luminosity assuming $50 \%$ operational efficiency is necessary to achieve a 10 to $15 \%$ accuracy on the extracted $\sin \phi$ coefficient, mostly linked to the imaginary part of CFF $\mathcal{H}$. For higher $x_{B}$ and $Q^{2}$ values, much larger integrated luminosities will be necessary to achieve similar statistical accuracy.

Using longitudinal and transverse target asymmetries, one will be able to obtain information on $\widetilde{H}$ and even the elusive $E$, essential for the evaluation of Ji's sum rule. Studies of these observables for the EIC are in progress using the same formalism.

Figure 3.37. Photon electroproduction Beam Spin Asymmetries for the $20 \times 250$ EIC configuration, in the typical kinematic bin: $1.58 \cdot 10^{-3}<x_{B}<2.51 \cdot 10^{-3}, 3.16<Q^{2}<5.61 \mathrm{GeV}^{2}$ for four different $t$-bins as shown on each plot. The Monte Carlo was set up as to generate 90 k events for each $t$-bin and the corresponding integrated luminosity is shown on each plot. Up to about 3 months of beam time with $50 \%$ efficiency is necessary to achieve 10 to $15 \%$ accuracy on the extracted $\sin \phi$ coefficient p0, sensitive to the imaginary part of CFF $\mathcal{H}$.

### 3.11 Hard exclusive photoproduction of Quarkonia

Peter Kroll

Photoproduction of quarkonia (e.g., $J / \Psi$ and $\Upsilon$ ) forms another class of hard exclusive processes which allow one to scrutinize the handbag approach and extract information on generalized parton distributions (GPDs). Neglecting intrinsic heavy quarks in the proton, only the gluonic subprocess $\gamma^{*} g \rightarrow M g$ (accompanied by the gluon GPDs) contributes to the scattering amplitude. A particular feature of quarkonium production is the appearance of the large mass, $m_{Q}$, of the heavy quark which provides a hard scale and allows one to treat photoproduction within a QCD factorization approach. A first leading-order calculation of quarkonium production within the handbag approach has been carried out in 676]. Recently this analysis has been improved by the inclusion of NLO corrections 6677. In these studies, a non-relativistic scenario for the description of the quarkonium state has been adopted in which the quark and antiquark share the meson's momentum equally. Hence, the quarkonium wave function is proportional to $\delta(x-1 / 2)$ and the quarkonium mass is given by $M_{Q} \simeq 2 m_{Q}$. There are other theoretical approaches to the process of interest, e.g., the dipole approach, the leading $\ln (1 / x)$ approximation or the BFKL Pomeron. Due to limitation of space these approaches will not be discussed here.

In the kinematical range of large photon-proton center-of-mass energy, $\sqrt{s} \gg M_{Q}$, and small momentum transfer, $t$, the skewness is given by

$$
\begin{equation*}
\xi=M_{Q}^{2} /(2 s) . \tag{3.79}
\end{equation*}
$$

Neglecting terms of order of $\sqrt{-t} / m_{Q}, t / 4 m^{2}$ and $\xi$, one finds the following expressions for the helicity amplitudes of the quarkonium photoproduction:

$$
\begin{align*}
\mathcal{M}_{\mu+, \mu+} & =\frac{e_{0}}{2} e_{Q} \int_{0}^{1} \frac{d x}{(x+\xi)(x-\xi+i \varepsilon)} \sum_{\lambda} \mathcal{H}_{\mu \lambda, \mu \lambda}\left[H^{g}+\lambda \widetilde{H}^{g}\right] \\
\mathcal{M}_{\mu-, \mu+} & =-e_{0} e_{Q} \frac{\sqrt{-t}}{4 m} \int_{0}^{1} \frac{d x}{(x+\xi)(x-\xi+i \varepsilon)} \sum_{\lambda} \mathcal{H}_{\mu \lambda, \mu \lambda} E^{g} \\
\mathcal{M}_{--,++} & =e_{0} e_{Q} \frac{\sqrt{-t}}{2 m} \int_{0}^{1} \frac{d x}{(x+\xi)(x-\xi+i \varepsilon)} \mathcal{H}_{--,++} H_{T}^{g} . \tag{3.80}
\end{align*}
$$

Other helicity amplitudes are zero except for those related by parity conservation to the above ones. The helicity labels $\mu$ and $\mu^{\prime}$ refer to the initial photon and final meson, respectively; the labels $\lambda$ and $\lambda^{\prime}$ refer to the initial and final gluon, respectively. The explicit helicity labels of $\mathcal{M}$ refer to the proton. In the non-relativistic scenario, the LO subprocess amplitudes read

$$
\begin{equation*}
\mathcal{H}_{\mu^{\prime} \lambda^{\prime}, \mu \lambda}=\frac{8 \pi \alpha_{s}\left(\mu_{R}\right) f_{Q}}{3 m_{Q}} \delta_{\mu^{\prime} \mu} \delta_{\lambda^{\prime} \lambda}, \tag{3.81}
\end{equation*}
$$

where $f_{Q}$ is the decay constant of the quarkonium; $\mu_{R}$ is an appropriate renormalization scale. Thus, at this level of accuracy, only the process amplitudes,

$$
\begin{equation*}
\mathcal{M}_{\mu+, \mu+}=e_{0} e_{Q} \frac{8 \pi \alpha_{s} f_{Q}}{3 m_{Q}}\left\langle H^{g}\right\rangle, \quad \mathcal{M}_{\mu-, \mu+}=-e_{0} e_{Q} \frac{8 \pi \alpha_{s} f_{Q}}{3 m_{Q}} \frac{\sqrt{-t}}{2 m}\left\langle E^{g}\right\rangle \tag{3.82}
\end{equation*}
$$

are non-zero. The terms $\langle F\rangle$ denote the convolutions of the subprocess amplitudes and GPDs. One sees that the unpolarized cross section for quarkonium production at small $t$
is only fed by $H^{g}$, while the asymmetry measured with a transversally polarized target is given by an interference term of $E^{g}$ and $H^{g}$. Other GPDs, like the chiral-odd $H_{T}^{g}$, do not contribute at this level of accuracy.

For the EIC kinematics for which $\xi<0.01$, quarkonium production is a diffractive process, i.e., the amplitudes are dominantly imaginary. Thus, essentially the GPDs are only needed at the cross-over line $x=\xi$, while the small real part may be estimated with the help of analyticity. Many methods for the construction of GPDs, e.g., the double distribution ansatz 678] or the Shuvaev transform [593], lead to GPDs which at $x=\xi$ are proportional to the usual parton distributions. In particular, for the reggeized double distribution ansatz used in [659, 679], one has

$$
\begin{equation*}
H^{g}(\xi, \xi, t)=c_{h}[2 \xi g(2 \xi)](2 \xi)^{-\alpha_{h}^{\prime} t} e^{b_{h} t} \tag{3.83}
\end{equation*}
$$

Assuming that $x g(x)=c x^{-\delta_{h}}$ at low $x$, the constant $c_{h}$ reads (with $b=2$ [678]):

$$
\begin{equation*}
c_{h}=c\left[\left(1-\delta_{h} / 5\right)\left(1-\delta_{h} / 4\right)\left(1-\delta_{h} / 3\right)\right]^{-1} . \tag{3.84}
\end{equation*}
$$

Since $\delta_{h}$ is positive, $c_{h}>c$, which implies that $H^{g}(\xi, \xi, t=0)>2 \xi g(2 \xi)$ (this is termed the skewness effect). In (3.83), a linear gluonic ('Pomeron-like') Regge trajectory is assumed:

$$
\begin{equation*}
\alpha_{h}=1+\delta_{h}+\alpha_{h}^{\prime} t . \tag{3.85}
\end{equation*}
$$

Its slope is taken from the $J / \Psi$ photoproduction data 588 ( $\left.\alpha_{h}^{\prime}=0.15 \mathrm{GeV}^{-2}\right)$, while $\delta_{h}$, the intercept minus 1 , can be fixed from the data on the cross section for electroproduction of $\rho^{0}$ and $\phi$ mesons [680] that behaves as $\sigma \propto s^{2 \delta_{h}}$. The data provide a scale-dependent intercept (see figure 3.38):

$$
\begin{equation*}
\delta_{h}(\mu)=0.1+0.06 \ln \left(\mu^{2} / \mu_{0}^{2}\right), \tag{3.86}
\end{equation*}
$$

where $\mu_{0}=2 \mathrm{GeV}$ and $\mu=Q$ for electroproduction. The scale dependence of $\delta_{h}$ is in agreement with evolution.

Figure 3.38. Left: The intercept of the gluonic trajectory shifted by one unit; the data points are from [680. Right: Various NLO gluon PDFs. The figure is from 681.

The construction of the GPD along the lines described above requires the knowledge of the gluon PDF; in figure 3.38, some recent results for it are shown. For $x$ smaller than
about $10^{-3}$, the errors of most PDFs become very large. The only exception is the CTEQ6 results [82] for which the error stays constant at the level of about $25 \%$ for $x<10^{-2}$. Since the uncertainties of the PDF are conveyed to the GPDs and, hence, to the quarkonium cross section, any prediction of the latter will suffer from huge uncertainties rendering any comparison with experiment meaningless. In order to arrive at reasonable predictions, the following remedial measure has been proposed in 659, 679]: The gluon PDF is expanded as the following series,

$$
\begin{equation*}
x g(x, \mu)=x^{-\delta_{h}(\mu)}(1-x)^{5} \sum_{i=0}^{2} c_{i}(\mu) x^{i / 2} \tag{3.87}
\end{equation*}
$$

and the expansion parameters are fitted to a given PDF for intermediate values of $x$, say, $0.003<x<0.3$, and relevant scales. The power $\delta_{h}$ is fixed at the experimental value (3.86). Applying this prescription to the NLO CTEQ6 PDF [82], one can reproduce the CTEQ6 result for $x<0.003$. Therefore, the CTEQ6 gluon PDF with its errors may be used for numerical predictions. (The same method applied to other current gluon PDFs leads, in most cases and within uncertainties, to the results for cross sections that are in a reasonable agreement with those evaluated using the CTEQ6 PDF [659].)

The calculation of the quarkonium cross section is further complicated by large NLO corrections 677, see figure 3.39. The results shown in figure 3.39 are evaluated from a GPD that is also generated from the NLO CTEQ6 PDF but under the assumption that, at the initial scale, $H^{g}$ is given by the PDF multiplied by an appropriate function of $t$. Evidently, the large NLO corrections necessitate a resummation of higher orders for a reliable prediction of the quarkonium cross section.

Figure 3.39. Left: LO and NLO predictions for the forward $J / \Psi$ photoproduction $v s . \sqrt{s}$ (the figure is from [677). Right: LO prediction using the GPD given in 679, 659, see the text. The green band indicates the uncertainty of the prediction; the data points are from [589, 588].

In order to examine the dependence of the predictions on the GPD used in the calculation, I have repeated the LO order calculation exploiting the GPD proposed in 659, 679] and whose construction is briefly described above. The result, obtained for a scale of $2 m_{Q}$ which is chosen in concord with the construction of the GPD [see (3.86)], overestimates the data but is in agreement with the experimental energy dependence. It however differs strongly from the LO result presented in 677. Similar observations can be made for photoproduction of the $\Upsilon$.

The target asymmetry for quarkonium production may give access to the GPD $E^{g}$, of which not much is known, see the discusion in section 3.4. Indeed,

$$
\begin{equation*}
A_{U T}=-\frac{\sqrt{-t}}{m} \frac{\left|\left\langle E^{g}\right\rangle\right|}{\left|\left\langle H^{g}\right\rangle\right|} \sin \phi, \tag{3.88}
\end{equation*}
$$

where $\phi$ is the relative phase between $\left\langle H^{g}\right\rangle$ and $\left\langle E^{g}\right\rangle$. Since $E^{g}$ is expected to behave similarly to $H^{g}$ at small $\xi$ but with a Regge trajectory $\alpha_{e}=1+\delta_{e}+\alpha_{e}^{\prime} t$, analyticity tells us that the relative phase is approximately given by

$$
\begin{equation*}
\phi(t)=\pi / 2\left(\alpha_{e}(t)-\alpha_{h}(t)\right) . \tag{3.89}
\end{equation*}
$$

In a soft Pomeron scenario, one would have $\alpha_{e}=\alpha_{h}$ and, hence, $A_{U T}=0$. However, the QCD evolution of the GPDs may generate differences in the trajectories and, therefore, $A_{U T}$ may be non-zero. To work this out, one needs a detailed study of the evolution of $E^{g}$, which is lacking at present. There are examples of $\alpha_{e}$ in the literature that lead to tiny asymmetries of the order of $1-2 \%$. In section 3.4, it has been proposed a parameterization of $E^{g}$ with a node at some intermediate value of $x$. In this case one may obtain a larger $A_{U T}$. However, this possibility has not yet been explored in detail.

Summary: Comparing precise data of the cross section for photoproduction of quarkonia with theoretical calculations within the handbag approach may allow for an extraction of $H^{g}$ at the cross-over line and small values of $\xi$ since the real part of the amplitude provides only small corrections to the cross section of the order of $10 \%$. This may lead to a useful constraint on $H^{g}$ and $g(x)$ at low $x$. However, in order to arrive at reliable results for $H^{g}$, the theoretical calculation should include resummed higher orders of perturbative QCD. Also, deviations from the non-relativistic scenario should be investigated and the strength of contributions from intrinsic heavy quarks estimated. Furthermore, a detailed comparison of various gluon GPDs should be made and their errors taken into account. For photoproduction of charmonium production in particular, one should be aware of possible substantial power corrections since the charm quark mass although being large enough to allow for a perturbative treatment of the subprocess, is not large enough to suppress power corrections decisively. On the other hand, for electroproduction of charmonium power corrections are likely to be smaller. In principle the target asymmetry gives an access to $E^{g}$. However, $A_{U T}$ will likely be very small except for the case when $E^{g}$ markedly differs from common parameterizations.

### 3.12 Simulations of non-diffractive exclusive processes at an EIC

## T. Horn

### 3.12.1 Introduction

Exclusive processes in $e p$ scattering at collider energies can be either "diffractive" (no exchange of quantum numbers between the target and the projectile/produced system) or "non-diffractive" (there is an exchange of quantum numbers). By measuring diffractive channels $\left(J / \Psi, \rho^{0}\right.$, or $\phi$ production) at sufficiently high $Q^{2}$, one probes the gluon GPDs and/or the singlet quark GPDs. In particular, $J / \Psi$ production probes the gluon GPD in the nucleon, and its $t$-dependence reveals the transverse spatial distribution of the gluons. Measurements of DVCS and exclusive $\rho^{0}$ production at high $Q^{2}$ provide access to the singlet quark and gluon GPDs.

Non-diffractive channels like $\pi^{+}, \pi^{0}$, or $K^{+}$production are sensitive to the flavor and spin structure of the nucleon at small $x_{B}$, which complements the information obtained from DVCS and meson production experiments in the valence region, e.g., HERMES and 6 GeV and 12 GeV JLab.

For moderate values of $x_{B}$, the proposed electron-ion collider (EIC) could reach $Q^{2}>10$ $\mathrm{GeV}^{2}$, where higher-twist contributions, which complicate the extraction of GPDs from the data, are expected to be small. Indeed, the comparison of different meson channels alone provides model-independent information about the ratio of quark spin and spatial distributions, and a comparison between, for instance, $\pi^{+}$and $K^{+}$production may allow for the studies of $\mathrm{SU}(3)$ symmetry in parton distributions.

### 3.12.2 Rate predictions

Rate predictions were made for several exclusive reaction channels using a new exclusive Monte Carlo generator. Here, we will focus on the $\pi^{+}$and $K^{+}$channels. These are the simplest systems also allowing for comparisons of non-strange and strange distributions similarly to the comparative studies of singlet quarks and gluons with diffractive exclusive channels.

Figure 3.40 shows the simulated cross section for exclusive pion and kaon production in the $5 \times 50 \mathrm{GeV}$ configuration in ep collisions $(\sqrt{s}=31.6 \mathrm{GeV})$ at a luminosity of $10^{34} \mathrm{~cm}^{-2}$ $\mathrm{s}^{-1} \sqrt[3]{3}$, and data taking for 100 days. The simulated data shown here are divided into four $Q^{2}$ bins between 10 and $45 \mathrm{GeV}^{2}$ for a bin in $x_{B}$ between 0.02 and 0.05 . Each $Q^{2}$ bin was divided into nine $-t$ bins. The simulated pion data cover a range in $-t$ up to $1 \mathrm{GeV}^{2}$ with acceptable rates for the assumed run time and luminosity for all $Q^{2}$ bins. The rates in each $Q^{2}$ bin are highest at small values of $-t$ and smallest at high values of $-t$. This makes sense as one of the features of pion production is the dominance of the "pole term" at low $-t$. Furthermore, the pion rate decreases rapidly with higher $Q^{2}$ bins as the cross sections decrease, which is a characteristic behavior of exclusive reactions. However, one should keep in mind that reaching high $Q^{2}$ is needed due to the factorization requirement for studying the transverse spatial structure of sea quarks. The kaon simulated data are presented in the same kinematic bins as the pion data. The kaon cross section is smaller than the pion

[^273]one, although it does not fall off as rapidly with increasing $-t$ for each $Q^{2}$ bin, because the kaon pole is not as dominant as the pion pole. The kaon rates are generally lower than the pion rates, but the effect is most visible in the largest $Q^{2}$ bins. For a fully differential kaon measurement, it is thus essential to have luminosities of at least $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. Given the design parameters of the medium-energy collider, this would correspond to a range in $\sqrt{s}$ between 31 and about 45 GeV .

Figure 3.40. EIC simulations for the exclusive pion and kaon electroproduction cross sections at a electron beam energy of 5 GeV and a proton beam energy of $50 \mathrm{GeV}(\sqrt{s}=31.6 \mathrm{GeV}), 100$ days running, and a luminosity of $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. The points are shown for a bin in $x_{B}$ of 0.02 to 0.05 . The four panels denote bins in $Q^{2}$ (from left to right) of $10-15 \mathrm{GeV}^{2}, 15-20 \mathrm{GeV}^{2}, 25-30 \mathrm{GeV}^{2}$, and $35-40 \mathrm{GeV}^{2}$.

The rate prediction depends to some extent on the cross section models included in the simulation. For pions, a Regge-based cross section model that describes existing data well was used 682. The model dependence of the rate prediction was estimated using a different cross section model based on an empirical parameterization of charged pion data 683. For kaons, the rate estimate was based on the empirical fits to world kaon production data. The resulting uncertainty in the simulated rates was about a factor of two.

### 3.12.3 Kinematic considerations

Measurements in exclusive reactions require, besides knowledge of the beam quantities, information of all particles in the exclusive reaction, i.e., the scattered electron, the scattered meson, and the recoil baryon. Below we will illustrate the kinematic features of exclusive reactions using the $\mathrm{H}\left(e, e^{\prime} \pi^{+}\right) \mathrm{n}$ reaction. However, the kinematic distributions shown are independent of the exclusive channel, and are thus generally applicable to all exclusive reactions (diffractive and non-diffractive).

Figure 3.41 shows the accessible phase space for exclusive reactions in $e p$ collisions for five center of mass energies 4. A cut of $Q^{2}>10 \mathrm{GeV}^{2}$ was applied to focus on the region of interest for transverse spatial structure studies. At a value of $\sqrt{s}=13.8 \mathrm{GeV}$, the meson distribution covers the angular range of about 30-40 degrees at relatively small momentum.

[^274]Up to values of $\sqrt{s}=44.7 \mathrm{GeV}$, which correspond to nearly symmetric collisions, the exclusive meson distribution spreads over a wide angular range, still at a moderate momentum. At even higher values of $\sqrt{s}$, the angular spread is reduced significantly. Indeed, the meson distribution is pushed into a relatively narrow forward cone. Furthermore, the events of interest in this narrow angular range also have very high momentum approaching the beam energy. Exclusive measurements at these large values of $\sqrt{s}$ would thus require the detection of a high energy meson over a very small angular range.

Figure 3.41. The kinematic phase space for light mesons in deep exclusive reactions for different ep collisions. A cut of $Q^{2}>10 \mathrm{GeV}^{2}$ is applied to focus on events needed for studies of transverse spatial distributions. The darker regions in the figures denote regions of the highest intensity. The center of mass energies for the medium energies are $\sqrt{s}=13.8 \mathrm{GeV}, 31.6 \mathrm{GeV}$, and 44.7 GeV , and for the high energies $\sqrt{s}=63.2 \mathrm{GeV}$ and 100 GeV . In this simulation, the direction of the electron beam is toward increasing angles.

The momentum resolution $(d p / p)$ to first order scales linearly with the momentum. The best resolution is thus achieved by keeping the laboratory momenta as low as possible for a given $\sqrt{s}$. This is achieved in symmetric, or nearly symmetric collisions. As illustrated in figures 3.41 and 3.42 such kinematics also offer the advantage that the angular distribution of the outgoing electrons and mesons covers nearly $4 \pi$, providing the best angular resolution.

Figure 3.42 shows the scattered electron distribution in deep exclusive reactions. At modest electron energies (up to about 6 GeV ) electrons predominantly scatter into the central and forward direction. Kinematically these correspond to high- $Q^{2}$ events, which are also the events of interest in studies of the transverse spatial structure of sea quarks. On the other hand, electrons at larger energies (up to the electron beam energy) scatter into the forward-electron direction. These events correspond to low- $Q^{2}$ events, which are of interest in photoproduction or heavy meson measurements.

The meson momentum distribution has a strong $Q^{2}$ dependence with the high momentum region dominated by low- $Q^{2}$ (photoproduction) events. This is illustrated in figure 3.43

Figure 3.42. The kinematic phase space for electrons in exclusive reactions at low and high $Q^{2}$ at a fixed value of $\sqrt{s}=49.0 \mathrm{GeV}$.
with a comparison of photo- and electroproduction at fixed $\sqrt{s}=22 \mathrm{GeV}$ using a cut of $Q^{2}>$ $10 \mathrm{GeV}^{2}$ to select the electroproduced light mesons. The forward scattered photoproduced mesons dominate the low $Q^{2}$ region populating a narrow angle cone with high momentum while the light mesons with $Q^{2}>10 \mathrm{GeV}^{2}$ are centered around central angles at momenta between 2 and 4 GeV . The scattered electron distribution shows the same general features as discussed above. The $t$ distribution of the recoil baryons does not change with selecting the low or high $Q^{2}$ region.

Figure 3.43. A comparison of the kinematic phase space for the scattered meson, electron, and the recoiling baryon in exclusive photo- and meson electroproduction at $\sqrt{s}=21.9 \mathrm{GeV}$. The three upper panels are dominated by photoproduction; the three lower panels focus on light meson events for studies of transverse spatial distributions.

The EIC includes the option of using higher electron energies up to 11 GeV . Figure 3.44 shows a comparison of the meson distribution at fixed values of the ion beam energy for three values of $\sqrt{s}=21.9,31.6,44.7 \mathrm{GeV}$. Here, we will focus on the distribution in the central region, which is indicated by the vertical lines. As mentioned above, the meson distribution is pushed into a narrow angular cone with an increasingly higher momentum as $\sqrt{s}$ increases. Furthermore, the average meson momentum in the central region between $\pm 30 \mathrm{deg}$ increases from $4 \mathrm{GeV} / \mathrm{c}$ to about $8 \mathrm{GeV} / \mathrm{c}$ as the electron beam energy doubles from about 5 to 10 GeV at a fixed ion beam energy. Measurements of exclusive reactions at electron beam energies of about $10 \mathrm{GeV} / \mathrm{c}$ and fixed ion beam energies would thus require the detection of high momentum mesons in the central angle region $\left( \pm 30^{\circ}\right)$.

Figure 3.44. The meson kinematic phase space for higher energies for deep exclusive reactions for different combinations of the beam electron and proton energies. The first value in the labels denotes the electron beam energy. A cut of $Q^{2}>10 \mathrm{GeV}^{2}$ is applied to focus on events needed for studies of transverse spatial distributions.

To access the physics of interest in exclusive reactions and extract information about the GPDs, one needs data binned over a sufficiently large range in $-t$ : a range of at least $0<|t|<1 \mathrm{GeV}^{2}$ is needed. In $e p$ collisions, the main challenge is that the outgoing baryons are scattered at relatively small angles, especially at low $-t$, as the resolution goes roughly as the inverse of the proton beam energy,

$$
\begin{equation*}
\frac{\delta t}{t} \sim \frac{t}{E_{p}} . \tag{3.90}
\end{equation*}
$$

Figure 3.45 illustrates the deep exclusive recoil baryon $-t$ angular resolutions for values of $\sqrt{s}=(13.8,31.6,44.7,63.2,100) \mathrm{GeV}$. The nearly symmetric collisions at lower proton beam energy provide the largest recoil baryon angular distributions of values of at least $1^{\circ}$. For asymmetric collisions, the distribution rapidly decreases to the angular distributions of less than $0.3^{\circ}$. To access the physics of interest, a better $-t$ resolution would thus be achieved with lower-energy and more symmetric kinematics.

### 3.12.4 L/T separation

Beyond studies of transverse spatial structure of sea quarks, non-diffractive processes provide the opportunity for additional studies, for instance, the tests of hard-soft QCD factorization and measurements of the pion form factor. These measurements require isolating the longitudinal part of the electroproduction cross section using the L/T separations. This

Figure 3.45. The kinematic phase space as $-t$ vs. the scattering angle of the recoil baryon in exclusive reactions for five values of $\sqrt{s}$. The first value in the labels denotes the electron beam energy. A cut of $Q^{2}>10 \mathrm{GeV}^{2}$ is applied to focus on events needed for studies of transverse spatial distributions.

Figure 3.46. The virtual photon polarization, $\epsilon$ as a function of $s$ for different combinations of the electron and proton beam energies, at fixed $Q^{2}=10 \mathrm{GeV}^{2}, x_{B}=0.1$, and $-t=0.1 \mathrm{GeV}^{2}$. At high values of $s, \epsilon \rightarrow 1$ complicating the $\mathrm{L} / \mathrm{T}$ separation.
technique requires comparing data taken at two different beam energies with sufficiently large separation of the virtual photon polarization, $\Delta \epsilon$, to control systematic uncertainties. Based on previous $\mathrm{L} / \mathrm{T}$ separations, a minimum acceptable value of $\Delta \epsilon$ is 0.1 .

Figure 3.46 shows the accessible values of $\epsilon$ as a function of $s$ at fixed values of $Q^{2}$, $x_{B}$, and $-t$. The lowest value of $\epsilon$ of about 0.8 is reached at $\sqrt{s}=14.3 \mathrm{GeV}$, increasing to near unity as $s$ increases. Beyond $\sqrt{s}=31.6 \mathrm{GeV}, \epsilon$ is effectively unity making the $\mathrm{L} / \mathrm{T}$ distributions impossible.

### 3.12.5 Summary of basic requirements for exclusive reactions

Studies of exclusive non-diffractive processes provide important information on the transverse spatial distribution of non-perturbative sea quarks. These measurements require high luminosity for fully differential measurements in $x_{B},-t$, and $Q^{2}$ as well as recoil detection for exclusivity. They require a kinematic reach in $t$ of at least up to $1 \mathrm{GeV}^{2}$ with good resolution. Our studies suggest that exclusive processes for values of $x_{B}>0.01$ have better prospects with lower-energy and more symmetric kinematics.

The following list summarizes the basic experimental requirements for studies of the transverse spatial structure of sea quarks through non-diffractive exclusive processes.
Energies

- More symmetric energies favorable in exclusive non-diffractive reactions;
- Lower energies essential for a range in $\epsilon$ for the $\mathrm{L} / \mathrm{T}$ separation.

Kinematic Reach

- Need $Q^{2}>10 \mathrm{GeV}^{2}$ (pointlike configurations);
$-x_{B}$ range between 0.001 and 0.1 overlapping with HERA and JLab 12 GeV ;
$-s$ range between 200 and $1000 \mathrm{GeV}^{2}$.
Luminosity
- Exclusive non-diffractive processes require high luminosity for low rates for fully differential measurements; - Kaons push luminosity to $>10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$.
Detection
- Need recoil detection for exclusivity;
- Range in $-t$ and resolution.

# 3.13 Partonic transverse spin in deep-inelastic exclusive experiments 

Gary R. Goldstein, Simonetta Liuti

### 3.13.1 Introduction

In this contribution, we suggest a class of deeply virtual exclusive reactions, namely pseudoscalar meson electroproduction, as a means to access chiral-odd distributions. These are described by a set of four chiral-odd GPDs which enter the matrix elements for the various terms of the cross section. We conducted an analysis using a parameterization of the GPDs that is inspired by a physically motivated picture of the nucleon as a quark-diquark system with a Regge behavior. In the chiral-even sector a quantitative parameterization can be obtained from a global fit to PDFs, nucleon form factors, and DVCS data where the masses, couplings and Regge power behavior that set the scale for the dependence on the kinematic variables, $X, \zeta, t, Q^{2}$, are determined via a recursive procedure [684].

The extension of this parameterization scheme to the chiral-odd GPDs is critical for the phenomenology of deeply virtual meson electroproduction, which was begun particularly for the $\pi^{0}$ in [685]. In the diquark spectator model, chiral-even helicity amplitudes are simply related to their chiral-odd counterparts via parity transformations. For the $d$-quark case it is only the axial diquark relations that are involved, while the $u$-quark involves the scalar contribution, as well. We thereby obtain the full set of four chiral-odd GPDs, each being linearly related to helicity amplitudes. This allows us to predict the behavior of pseudoscalar electroproduction 686].

It has now become particularly pressing to study the heavy quark components of the nucleon because of the advent of the LHC. For the types of precision measurements in the unprecedented multi- TeV CM energy regimes envisaged at the LHC it will be necessary to provide accurately determined QCD inputs. The analyses in 129 have shown how the inclusion of non perturbative charm quarks could modify the outcome of global PDF analyses. However, the situation is not clear-cut. We therefore extended our analysis to strange and charm pseudoscalar meson production [687]. We proposed that in order to refine analyses such as the one in [129], new observables need to be identified from deeply virtual meson production and spin correlation measurements. We presented preliminary results involving the following electroproduction exclusive processes: (1) $\gamma^{*} p \rightarrow J / \psi p^{\prime}$; (2) $\gamma^{*} p \rightarrow D \bar{D} p^{\prime} ;(3) \gamma^{*} p \rightarrow \bar{D} \Lambda_{c}$; (4) $\gamma^{*} p \rightarrow \eta_{C} p^{\prime}$. These processes necessitate: i) high luminosity because they are exclusive; ii) high enough $Q^{2}$ to produce the various charmed mesons, and iii) a wide kinematical range in Bjorken $x$.

Finally, a few questions have emerged concerning on one side the applicability of dispersion relations to deeply virtual exclusive processes [688], and on the other, the commonly assumed partonic picture of the ERBL region [689]. Newer deeply virtual exclusive cross section and asymmetry measurements in extended kinematical regimes will provide essential tests of the theory.

### 3.13.2 Transverse spin from pseudoscalar meson production

The basic definition of the quark-nucleon GPDs is through off-forward matrix elements of quark field correlators. Contracting with the Dirac matrices, $\gamma^{\mu}$ or $\gamma^{\mu} \gamma^{5}\left(\sigma^{\mu \nu} \gamma^{5}\right)$, and integrating over the internal quark momenta gives rise to the four chiral-even GPDs, $H, E$
or $\widetilde{H}, \widetilde{E}$, and four chiral-even GPDs, $H_{T}, E_{T}, \widetilde{H}_{T}, \widetilde{E}_{T}$ [575]. The crucial connection of the eight GPDs to spin dependent observables in DVCS and DVMP is through the helicity decomposition 575. For example,

$$
\begin{gather*}
A_{++,++}(X, \xi, t)=\frac{\sqrt{1-\xi^{2}}}{2}\left(H^{q}+\tilde{H}^{q}-\frac{\xi^{2}}{1-\xi^{2}}\left(E^{q}+\tilde{E}^{q}\right)\right),  \tag{3.91}\\
A_{++,--}(X, \xi, t)=\sqrt{1-\xi^{2}}\left(H_{T}^{q}+\frac{t_{0}-t}{4 M^{2}} \tilde{H}_{T}^{q}-\frac{\xi}{1-\xi^{2}}\left(\xi E_{T}^{q}+\tilde{E}_{T}^{q}\right)\right) . \tag{3.92}
\end{gather*}
$$

We have constructed a robust model for the GPDs, extending previous work [690 that is based on the parameterization of diquark spectators and Regge behavior at small $X$. The GPD model parameters are constrained by their relations to PDFs (at $\zeta=0, t=0$ ) and to nucleon form factors $F_{1}(t), F_{2}(t), g_{A}(t)$, and $g_{P}(t)$ through the first $x$ moments. For the chiral-odd GPDs, there are fewer constraints. In particular, $H_{T}(X, 0,0)=h_{1}(X)$ can be fit using the loose constraints in [250] since the first moment of $H_{T}(X, \xi, t)$ is the "tensor form factor", called $g_{T}(t)$. It is conjectured that the first moment of $2 \tilde{H}_{T}^{q}(X, 0,0)+E_{T}^{q}(X, 0,0)$ is a "transverse anomalous moment", $\kappa_{T}^{q}$, defined in [497].

With our ansatz, many observables can be determined in parallel with the corresponding Regge predictions. Since the initial work [685], we have undertaken a more extensive parameterization and presented several new predictions [684. In figure 3.47, we show an example corresponding to the transversely polarized proton target.

Figure 3.47. Left: Transverse spin asymmetry, $A_{U T}$, vs. $-t$ at $Q^{2}=2.3 \mathrm{GeV}^{2}$ and $x_{B}=0.36$ for different values of the tensor charge, $\delta u$, with fixed $\delta d=-0.62$. Right: Comparison of $\pi^{0}$ and $\eta_{c}$ cross sections. The range between the two lines gives an estimate of where the cross sections for the other processes will lie.

The measured cross section for $\pi^{0}$ is sizable and has large transverse $\gamma^{*}$ contributions. This indicates that the main contributions should come from chiral-odd GPDs, for which the $t$-channel decomposition is richer. In particular, because these GPDs arise from the Dirac matrices $\sigma^{\mu \nu}$, there are two series of $J^{P C}$ values for each GPD 691] corresponding to spacespace or time-space combinations $1^{--}$and $1^{+-}$. These series occur for three of the four chiral-odd GPDs, with exception of $\widetilde{E}_{T}$. We are thus led to the conclusion that chiral-odd GPDs will dominate the neutral pseudoscalar leptoproduction cross sections. This result
has interesting consequences. First, in a factorized handbag picture, these GPDs will couple to the hard part, the $\gamma^{*}+$ quark $\rightarrow \pi^{0}+$ quark, provided that $\pi^{0}$ couples through $\gamma^{5}$, which is naively twist-three, rather than the twist-two coupling $\gamma^{+} \gamma^{5}$. Second, the vector $1^{--}$and axial-vector $1^{+-}$in the $t$-channel, viewed as particles ( $\rho^{0}, \omega$ and $b_{1}^{0}, \mathrm{~h}$ ), couple primarily to the transverse virtual photon. For Reggeons, the $1^{--}$does not couple at all to the longitudinal photon, while the axial-vector $1^{+-}$does so through helicity flip 692. Guided by these observations 685], we assume that the hard part depends on whether the exchange quantum numbers are in the vector or axial-vector series, thereby introducing orbital angular momentum into the model. We use $Q^{2}$ dependent electromagnetic "transition" form factors for vector or axial-vector quantum numbers going to a pion. We calculate these using pQCD for $q+\bar{q}+\gamma^{*}\left(Q^{2}\right) \rightarrow q+\bar{q}$ and a standard $z$-dependent pion wave function, convoluted in the impact parameter representation that allows orbital excitations to be easily implemented.

With our model for the chiral-odd spin-dependent GPDs and these transition form factors, we can obtain the full range of cross sections and asymmetries in kinematic regimes that coincide with ongoing JLab experiments. (A similar emphasis on chiral-odd contributions for $\pi$ electroproduction has recently been proposed 693], although the details of that model are quite different from ours.) We are able to predict the important transverse photon contributions to the observables [685]. In figure 3.47 (left), we show one striking example of the predictions that depend on the values of the tensor charges, thereby providing a means to narrow down those important quantities. This program has been presented 684 and further details will soon appear, as the refinements of the chiral-odd parameterization are completed [686]. In figure 3.47 (right), we show the cross section, $\sigma_{T}+\epsilon \sigma_{L}$, for charmed meson production and compare it to the one for $\pi^{0}$ production 687.

In summary, through the use of physically motivated models and the new horizons provided by the EIC, a far reaching interpretation of the separate spin-dependent GPDs and thereby, a picture of the transverse structure of the nucleons will emerge. The connection of chiral-odd GPDs to the transversity structure of the nucleon is of great interest as a manifestation of quark and gluon orbital angular momentum.

### 3.14 Ways to access transversity GPDs at the EIC

B. Pire, L. Szymanowski, S. Wallon

### 3.14.1 Introduction

Transversity quark distributions in the nucleon remain among the most unknown leading twist hadronic observables. This is mostly due to their chiral-odd character which enforces their decoupling in most hard amplitudes. Generalized parton distributions (GPDs) offer a new way to access the transversity dependent quark content of the nucleon. The factorization properties of exclusive amplitudes allow in principle to extract the four chiral-odd transversity GPDs [694], $H_{T}, E_{T}, \tilde{H}_{T}, \tilde{E}_{T}$. However, one-photon or one-meson electroproduction leading twist amplitudes are insensitive to them [695, 696]. The strategy which we followed in [697, 698] is to study the leading twist contribution to exclusive processes where more mesons are present in the final state. Note that, contrarily to transversity PDFs, transversity GPDs enter the formulae for exclusive cross sections even when considering unpolarized proton target, provided one selects the polarization state of an outgoing meson.

### 3.14.2 Diffractive photoproduction of two $\rho$ mesons

We consider 697, 698], in analogy with the virtual photon exchange occurring in the deep inelastic electroproduction of a meson, the subprocess:

$$
\begin{equation*}
\mathbb{P}\left(q_{P}\right)+p\left(p_{2}\right) \rightarrow \rho_{T}\left(p_{\rho}\right)+N^{\prime}\left(p_{2^{\prime}}\right) \tag{3.93}
\end{equation*}
$$

of almost forward scattering of a virtual Pomeron (the hard scale is the virtuality $-q_{P}^{2}$ of this Pomeron) on a nucleon. This subprocess is at work in the process

$$
\begin{equation*}
\gamma_{L / T}^{(*)}(q)+p\left(p_{2}\right) \rightarrow \rho_{L, T}^{0}\left(q_{\rho}\right)+\rho_{T}\left(p_{\rho}\right)+N^{\prime}\left(p_{2^{\prime}}\right) \tag{3.94}
\end{equation*}
$$

where a real or virtual photon scatters on a proton $p$, which leads via a two-gluon exchange to the production of two vector mesons separated by a large rapidity gap and the scattered nucleon $N^{\prime}$, as shown on figure 3.48. The final state may be either $\rho^{0} \rho^{0} p$ or $\rho^{0} \rho^{+} n$. In both cases, the two-gluon exchange with the nucleon line is forbidden by charge conjugation or charge conservation and the process is thus sensitive only to quark GPDs. We consider the kinematical region where the rapidity gap between $\rho\left(p_{\rho}\right)$ and $N^{\prime}$ is much smaller than the one between $\rho\left(q_{\rho}\right)$ and $\rho\left(p_{\rho}\right)$, i.e., the energy of the $\left(\rho\left(p_{\rho}\right)+N^{\prime}\right)$ system is smaller than that of the $(\rho+\rho)$ system but is still large enough to justify our approach (in particular, it is much larger than baryonic resonance masses). Since quasi-real transverse photons are more abundant in electron-ion collisions and charged pions are most easily detected, one may specialize to the reaction:

$$
\begin{equation*}
\gamma_{T}(q)+p\left(p_{2}\right) \rightarrow \rho_{L, T}^{0}\left(q_{\rho}\right)+\rho_{T}^{0}\left(p_{\rho}\right)+p\left(p_{2^{\prime}}\right) \tag{3.95}
\end{equation*}
$$

where the initial quasi-real photon is treated as if it were real.
In this kinematical regime, the amplitude for this process is calculable consistently within the collinear factorization method, as an integral (over the longitudinal momentum fractions of the quarks) of the product of two amplitudes: the first one (the impact factor) describes the transition $\gamma^{(*)} \rightarrow \rho_{L, T}^{0}$ via a two-gluon exchange and the second one describes the subprocess $\mathbb{P}+p \rightarrow \rho_{T}^{0}+p$. The fact that the latter process is closely related to

Figure 3.48. Factorization of the process $\gamma_{T}(q)+p\left(p_{2}\right) \rightarrow \rho_{L, T}^{0}\left(q_{\rho}\right)+\rho_{T}^{+}\left(p_{\rho}\right)+n\left(p_{2^{\prime}}\right)$ in the asymmetric kinematics discussed in the text. $\mathbb{P}$ is the hard Pomeron modeled by a two-gluon exchange.
the electroproduction process $\gamma^{*} p \rightarrow \rho^{0} p$ allows us to separate its long distance dynamics expressed through the GPDs from a perturbatively calculable coefficient function. The skewness parameter $\xi$ is related in the usual way $\left(\xi \approx x_{B} /\left(2-x_{B}\right)\right)$ to the Bjorken variable defined by the Pomeron momentum $x_{B}=-q_{P}^{2} /\left(2 q_{P} \cdot p_{2}\right)$. The choice of a transversely polarized vector meson $\rho_{T}^{0}$ involves a chiral-odd distribution amplitude, which in turn selects the chiral-odd GPDs.

The resulting scattering amplitude $\mathcal{M} \gamma^{*} p \rightarrow \rho_{L}^{0} \rho_{T}^{0} p$ then receives contributions from the four chiral-odd GPDs $H_{T}, \tilde{H}_{T}, E_{T}$ and $\tilde{E}_{T}$, but only the first one does not vanish kinematically in the forward direction. Thus, assuming that the Mandelstam variable $-t=$ $-\left(p_{2}-p_{2^{\prime}}\right)^{2}$ is sufficiently small, the transversity GPD $H_{T}$ contribution dominates the amplitude of process (3.95) which reads :

$$
\begin{align*}
& \mathcal{M}^{\gamma p \rightarrow \rho_{L}^{0} \rho_{T}^{0} p}=\sin \theta 16 \pi^{2} s \alpha_{s} f_{\rho}^{T} \xi \sqrt{\frac{1-\xi}{1+\xi}} \frac{C_{F}}{N\left(p_{T}^{2}\right)^{2}} \\
& \times \int_{0}^{1} \frac{d u \phi_{\perp}(u)}{u^{2} \bar{u}^{2}} J^{\gamma \rightarrow \rho_{L}^{0}}\left(u p_{T}, \bar{u} p_{T}\right) \frac{H_{T}^{u d}(\xi(2 u-1), \xi, t)}{\sqrt{2}}, \tag{3.96}
\end{align*}
$$

where $H_{T}^{u d}=H_{T}^{u}-H_{T}^{d} ; \phi_{\perp}(u)$ is the distribution amplitude ( DA ) of the $\rho_{T}$ meson; $\theta$ is the angle between the transverse polarization vector of the target $\vec{n}$ and the polarization vector $\vec{\epsilon}_{T}$ of the produced $\rho_{T}^{0}$ meson; $\vec{\varepsilon}$ is the polarization vector of the initial photon. The impact factor reads

$$
\begin{equation*}
J^{\gamma \rightarrow \rho_{L}}\left(k_{T 1}, k_{T 2}=p_{T}-k_{T 1}\right)=-\frac{e \alpha_{s} \pi f_{\rho}^{0}}{\sqrt{2} N} \int_{0}^{1} d z(2 z-1) \phi_{\|}(z)\left(\vec{\varepsilon} \cdot \vec{Q}_{P}\right) \tag{3.97}
\end{equation*}
$$

with

$$
\begin{gathered}
\vec{Q}_{P}\left(k_{T 1}, k_{T 2}=p_{T}-k_{T 1}\right)=\frac{z \vec{p}_{T}}{z^{2} p_{T}^{2}+Q^{2} z \bar{z}+m_{q}^{2}}-\frac{\bar{z} \vec{p}_{T}}{\bar{z}^{2} p_{T}^{2}+Q^{2} z \bar{z}+m_{q}^{2}} \\
+\frac{\vec{k}_{T 1}-z \vec{p}_{T}}{\left(k_{T 1}-z p_{T}\right)^{2}+Q^{2} z \bar{z}+m_{q}^{2}}-\frac{\vec{k}_{T 1}-\bar{z} \vec{p}_{T}}{\left(k_{T 1}-\bar{z} p_{T}\right)^{2}+Q^{2} z \bar{z}+m_{q}^{2}}
\end{gathered}
$$

The scattering amplitude (3.96) receives a contribution only from the ERBL region.

### 3.14.3 Cross section estimates

To obtain an estimate of the differential cross section of this process, we need a model for the transversity GPD $H_{T}^{q}(x, \xi, t)(q=u, d)$. We proposed a simple meson-pole approach starting with the effective interaction Lagrangian,

$$
\begin{equation*}
\mathcal{L}_{\mathcal{A N N}}=\frac{g_{A N N}}{2 M} \bar{N} \sigma_{\mu \nu} \gamma_{5} \partial^{\nu} A^{\mu} N \tag{3.98}
\end{equation*}
$$

in which $g_{A N N}$ is the coupling constant determining the strength of the interaction of the axial meson $A$ with the nucleon $N$. This yields

$$
\begin{equation*}
H_{T}^{a}(x, \xi)=\frac{g_{A N N} f_{A}^{a \perp}\left(\Delta \cdot S_{T}\right)^{2}}{2 M_{N} m_{A}^{2}} \frac{\phi_{\perp}\left(\frac{x+\xi}{2 \xi}\right)}{2 \xi}, \tag{3.99}
\end{equation*}
$$

where $\Delta$ is the transverse part of the momentum transfer vector $r ; f_{A}^{a \perp}$ is related to the $A$ meson decay constant. Identifying the scalar product $\left(\Delta \cdot S_{T}\right)^{2}$ with the average of the intrinsic transverse momentum of the quarks, $\left(\Delta \cdot S_{T}\right)^{2} \rightarrow 1 / 2\left\langle k_{\perp}^{2}\right\rangle$, and the axial meson $A$ with the $b_{1}$ meson, $A=b_{1}(1235)$, we obtain our final expression for $H_{T}^{u d}$ :

$$
\begin{equation*}
H_{T}^{u d}(x, \xi, 0)=\frac{g_{b_{1} N N} f_{b_{1}}^{T}\left\langle k_{\perp}^{2}\right\rangle}{2 \sqrt{2} M_{N} m_{b_{1}}^{2}} \frac{\phi_{\perp}^{b_{1}}\left(\frac{x+\xi}{2 \xi}\right)}{2 \xi}, \tag{3.100}
\end{equation*}
$$

where $f_{b_{1}}^{T}=\sqrt{2} f_{a_{1}} / m_{b_{1}}$ with $f_{a_{1}}=(0.19 \pm 0.03) \mathrm{GeV}^{2} ; g_{b_{1} N N}=5 /(3 \sqrt{2}) g_{a_{1} N N}$ with $g_{a_{1} N N}=7.49 \pm 1.0 ;\left\langle k_{\perp}^{2}\right\rangle=(0.58-1.0) \mathrm{GeV}^{2}$. The $t$ dependence of the chiral-odd GPDs may be parameterized in the following simple way:

$$
\begin{equation*}
H_{T}^{q}(x, \xi, t)=H_{T}^{q}(x, \xi, t=0) \times \frac{C^{2}}{(t-C)^{2}} \tag{3.101}
\end{equation*}
$$

with the standard dipole form factor with $C=0.71 \mathrm{GeV}^{2}$.
In figure 3.49, we show our model estimates for the differential cross sections of photoproduction of two vector mesons (3.94), $\rho^{0}$ and transversely polarized $\rho^{+}$, with the unpolarized beam and target. Note that these cross sections depend on the $\gamma$-nucleon energy only through the variable $\xi$. The cross sections for the processes with two neutral $\rho^{0}$ mesons in the final state are two times smaller than those with $\rho^{0} \rho^{+}$.

### 3.14.4 Photoproduction at lower photon energies

Diffractive physics requires high photon energies. If low energy photon tagging may be performed at the EIC, a QCD study based solely on the collinear factorization (i.e., without any Pomeron exchange) approach may be followed, opening other interesting channels. In 699, 700, we considered the process:

$$
\begin{equation*}
\gamma(q)+p\left(p_{1}, \lambda\right) \rightarrow \pi^{+}\left(p_{\pi}\right)+\rho_{T}^{0}\left(p_{\rho}\right)+n\left(p_{2}, \lambda^{\prime}\right) \tag{3.102}
\end{equation*}
$$

on a polarized or unpolarized proton target, in the kinematical regime of large invariant mass $M_{\pi \rho}$ of the final meson pair (the hard factorization scale is now this invariant mass) and small momentum transfer $t=\left(p_{1}-p_{2}\right)^{2}$ between the initial and the final nucleons. Roughly speaking, this kinematics means a moderate-to-large, and approximately opposite, transverse momentum of each meson. The cross sections obtained are sizeable at values of

Figure 3.49. The differential cross section for the photoproduction of $\rho_{T}^{0}$ and $\rho_{T}^{+}$(left panel) and $\rho_{L}^{0}$ and $\rho_{T}^{+}$(right panel) as a function of $\xi$ for $p_{T}^{2}=2,4$, and $6 \mathrm{GeV}^{2}$. The cross sections for the processes with two neutral $\rho^{0}$ mesons in the final state are two times smaller than those with $\rho^{0} \rho^{+}$.
$s_{\gamma N}$ of the order $10-20 \mathrm{GeV}^{2}$ but decrease quickly with the photon energies. This regime is more in the range of the JLab 12 program than of EIC.

In conclusion, we stress that this approach only assumes leading twist factorization of non-perturbative quantities, such as meson DAs and chiral-odd GPDs.
Acknowledgments. We are grateful to D.Yu. Ivanov, R. Enberg and O.V. Teryaev for their contributions to the results presented here.

## Chapter 4

## Input from lattice QCD

Chapter editors:
D. Hasch, F. Yuan

### 4.1 Introduction

Philipp Hägler, Bernhard Musch, Andreas Schäfer

The focus of research at an EIC is a precise and comprehensive understanding of the quark-gluon structure and dynamics of hadrons and nuclei within the scope of traditional QCD, as well as beyond it, e.g., beyond the formalism based on collinear parton distributions. This requires the combination of input from many different fields, including lattice QCD (LQCD). In this chapter, the status of LQCD as well as the prospects for the next decade are sketched. The main tasks of LQCD is to increase precision and to extend the scope of LQCD calculations. [Both depends also significantly on progress in the understanding of perturbative QCD (pQCD).] Although working out solutions for all technical details is a formidable task, recent developments suggest that LQCD should have settled most of the open theory issues by the time the EIC starts operating.

LQCD results are by now routinely used as input for phenomenology if direct experimental information is not available. This trend will intensify when in the future ever more subtle aspects are investigated. Therefore, the EIC and a dedicated effort in LQCD have to form a strong union. If direct comparison with experiment has proven certain types of LQCD calculations to be reliable, LQCD can provide easily information which is hard to obtain experimentally, for example on moments of PDFs and GPDs and the flavour decomposition of structure functions. In this context it is, unfortunately, quite often not sufficiently appreciated that most quantities of interest calculated on the lattice can only be linked to experiment by highly non-trivial input from pQCD. Thus all three elements, experiment, LQCD and pQCD have to be combined to reach optimal results.

The two main sources of difficulty are:

- The basis of LQCD is the observation that the analytic continuation to imaginary times $x^{0} \rightarrow \mathrm{i} x^{4}$ relates quantum field theory to statistics/thermodynamics. The latter allows for a purely numerical treatment by means of Monte Carlo techniques. This analytic continuation is only simple for time-independent quantities. The quantities of this type usually studied are matrix elements of local operators (which can be evaluated at $x^{0}=0=x^{4}$ ).

$$
\begin{equation*}
\left\langle h^{\prime}\left(p^{\prime}\right)\right| \mathcal{O}(x=0)|h(p)\rangle . \tag{4.1}
\end{equation*}
$$

Here $h, h^{\prime}$ can be any hadronic state, including the QCD vacuum. One typically needs the continuum operator product expansion (OPE) to link such quantities to observables.

- Most QCD quantities of interest are scheme and scale dependent. Only in leading order (LO) this dependence can be neglected, but LO calculations are in most cases insufficient for a high precision machine like the EIC. Thus LQCD results for matrix elements of the type Eq. (4.1) have to be matched to a specific pQCD setting, typically the $\overline{M S}$ scheme at a certain scale $\mu$. This requires also a matching of renormalization effects, which are quite different in the continuum and on the lattice due to the loss of continuum symmetries (as discussed below). The lattice discretization leads to different Feynman rules, in particular the appearance of tadpole diagrams. Another concrete, simple example is the modification of the fermion propagator on the lattice,

Figure 4.1. Sketch of the different types of lattice observables. For nearly all quantities of interest for an EIC, a combination of pQCD and LQCD is needed to make contact to experiment.
which typically might read (depending on the specific lattice action)

$$
\begin{equation*}
D_{\text {Lattice }}(p)=\frac{m-\mathrm{i} a^{-1} \sum_{\mu} \gamma_{\mu} \sin \left(p_{\mu} a\right)}{m^{2}+a^{-2} \sum_{\mu} \sin ^{2}\left(p_{\mu} a\right)} \tag{4.2}
\end{equation*}
$$

Thus, renormalization factors on the lattice and in the continuum differ by finite amounts, typically of the order of a few up to 30 percent. If one aims at an overall precision of order percent, the matching of the renormalization factors between nonperturbative (i.e. all order) lattice calculations and fixed order continuum calculations has to be achieved with high precision. To achieve this for all quantities of interest is clearly one of the major challenges for theory, both LQCD and pQCD, in the next decade.

The points just discussed apply to 'indirect observables', as illustrated in the right column of Fig. 4.1. There do also exist some observables which can be compared directly, without the need for renormalization, especially hadron masses. However, these are well known experimentally, while the aim of LQCD is clearly to provide information on hitherto unknown correlators. The observables of interest at the EIC, require nearly always nonperturbative renormalization in the corresponding lattice studies.

The calculation of matrix elements like (4.1) proceeds as follows:

1. One generates a number of ensembles of gauge field configurations with the correct statistical weights. The parameters for these ensembles are chosen such that one has best control (for given computer resources) of the combined limit: lattice spacing $a \rightarrow 0$; physical lattice size $L \gg 1 / \Lambda_{Q C D}$; quark masses $m_{q} \rightarrow m_{q}($ physical $)$; large number of independent field configurations, typically $N \gg 100$.
2. One generates hadronic states using products of quark fields with the correct quantum numbers (sources), e.g., one can use for a proton $\left(C=i \gamma^{2} \gamma^{4}\right.$ is the charge conjugation matrix, $i, j, k$ run over the three color states):

$$
\begin{equation*}
\hat{B}_{\alpha}(t, \vec{p})=\sum_{\vec{x}} e^{\mathrm{i} \vec{p} \cdot \vec{x}} \epsilon_{i j k} \hat{u}_{\alpha}^{i}(x) \hat{u}_{\beta}^{j}(x)\left(C^{-1} \gamma_{5}\right)_{\beta \gamma} \hat{d}_{\gamma}^{k}(x) \tag{4.3}
\end{equation*}
$$

Propagation in Euclidean time generates real exponentials rather than phases. Consequently, when expanding into a series in the correct physical multi-particle hadronic states, propagation in Euclidean time filters out the lowest mass state for large enough times,

$$
\begin{align*}
\hat{B}(0, \vec{p})|0\rangle & =c_{0}|N\rangle+c_{1}\left|N^{\prime}\right\rangle+c_{2}|N \pi\rangle+\ldots \\
\hat{B}(t, \vec{p})|0\rangle & =c_{0} e^{-E_{N} t}|N\rangle+c_{1} e^{-E_{N^{\prime}} t}\left|N^{\prime}\right\rangle+c_{2} e^{-E_{N \pi} t}|N \pi\rangle+\ldots \\
& \sim c_{0} e^{-E_{N^{t} t}}|N\rangle \tag{4.4}
\end{align*}
$$

To improve signals and to investigate higher lying states one uses a set of sources and calculates a full correlation matrix.
3. One constructs ratios for quantities of interest in which the exponential factors cancel, e.g.,

$$
\begin{equation*}
\frac{\tilde{\Gamma}_{\alpha \beta}\left\langle B_{\beta}(t, \vec{p}) \mathcal{O} \bar{B}_{\alpha}(0, \vec{p})\right\rangle}{\Gamma_{\alpha \beta}\left\langle B_{\beta}(t, \vec{p}) \bar{B}_{\alpha}(0, \vec{p})\right\rangle} . \tag{4.5}
\end{equation*}
$$

4. Finally, one determines the relevant renormalization factors for the operator $\mathcal{O}$ nonperturbatively on the lattice and relates the lattice results to a specific pQCD scheme.

One has to appreciate that the efficient combination of experimental and LQCD results requires a good and efficient parametrization for the quantities of interest. If there exists e.g. an efficient parametrization of a specific GPD etc. in terms of just a few parameters, each result will constrain the acceptable parameter range . Thus also high quality model building is necessary.

Over the years it became clear that it is very non-trivial to derive realistic estimates, in particular of the systematic uncertainties, from the highly correlated quantities extracted from Lattice Monte Carlo data. The ultimate test revealing potentially underestimated systematic uncertainties is the comparison of certain benchmark observables with experimental measurements, in this case, EIC data. The next best option is to compare results obtained with substantially different lattice formulations. In principle, each analysis should be repeated at least once with a different action. The latter is typically done in such a way that different collaborations specialise on one specific action each.

The most critical extrapolation is the continuum limit $a \rightarrow 0$. Lattice actions violate basic symmetries of QCD (isotropy and homogeneity of space-time, chiral symmetry, isospin symmetry in the case of twisted-mass fermions ...) for finite lattice spacing. Thus the $a \rightarrow 0$ limit, which restores all symmetries, could be non-trivial. Unfortunately, $a$ can only be varied in very limited ranges because the needed CPU time is always proportional to a large power of $1 / a$. Therefore, a variety of improved lattice actions was proposed in which lattice artifacts are not proportional to $a$ but e.g. $a^{2}$. Many variants exist, all of which are well motivated in one way or the other. Substantial effort is invested to further improve such actions, and it would be very surprising if by the time an EIC starts operating also the systematic uncertainties due to the multiple extrapolation $a \rightarrow 0, L \rightarrow \infty$, $m_{q} \rightarrow m_{q}$ (physical). were not much better under control.
The purely statistical uncertainty will for sure become much smaller due to increased computer power. While the most powerful present day computers are of the Petaflop class, various initiatives aim already at Exaflop computing. In the next sections we will discuss in detail some of the physics quantities calculated on the lattice, which are especially important for the EIC.

### 4.2 Generalized form factors

Most correlators relevant for hadron structure which were determined on the lattice are related to Generalized Parton Distributions (GPDs) or Distribution Amplitudes (DAs). For GPDs the hadronic states in Eq. (4.1) are equal, $h=h^{\prime}$ but the momenta are usually different $\left(p \neq p^{\prime}\right)$. For the best known GPDs $H_{q}$ and $E_{q}$,

$$
\begin{align*}
& \left.\int \frac{d z^{-}}{2 \pi} e^{i x \bar{P}^{+} z^{-}}\left\langle P_{2}\right| \bar{q}\left(-\frac{1}{2} z\right) \gamma^{+} q\left(\frac{1}{2} z\right)\left|P_{1}\right\rangle\right|_{z^{+}=0, z_{\perp}=0} \\
= & \frac{1}{P^{+}}\left[H_{q}(x, \xi, t) \bar{N}\left(P_{2}\right) \gamma^{+} N\left(P_{1}\right)+E_{q}(x, \xi, t) \bar{N}\left(P_{2}\right) \frac{i \sigma^{+\alpha} \Delta_{\alpha}}{2 M} N\left(P_{1}\right)\right] . \tag{4.6}
\end{align*}
$$

The OPE gives moments in terms of generalized form factors $A_{n, k}(t), B_{n, k}(t), C_{n}(t)$,

$$
\begin{align*}
\int_{-1}^{1} d x x^{n-1} H(x, \xi, t) & =\sum_{\substack{k=0 \\
\text { even }}}^{n-1}(2 \xi)^{k} A_{n, k}(t)+(\mathrm{n}+1 \bmod 2)(2 \xi)^{n} C_{n}(t) \\
\int_{-1}^{1} d x x^{n-1} E(x, \xi, t) & =\sum_{\substack{k=0 \\
\text { even }}}^{n-1}(2 \xi)^{k} B_{n, k}(t)-(\mathrm{n}+1 \bmod 2)(2 \xi)^{n} C_{n}(t), \tag{4.7}
\end{align*}
$$

which can be expressed in terms of local correlators by equations like

$$
\begin{align*}
\left\langle P^{\prime}\right| \bar{q}(0) \gamma^{\left\{\mu_{\mathrm{i}}\right.} D^{\mu_{1}} \ldots \mathrm{i} D^{\left.\mu_{n}\right\}} q(0)|P\rangle & =\bar{U}\left(P^{\prime}\right)\left[\sum _ { i = 0 , e v e n } ^ { n } \left\{\gamma^{\{\mu} \Delta^{\mu_{1}} \ldots \Delta^{\mu_{i}} \bar{P}^{\mu_{i+1}} \ldots \bar{P}^{\left.\mu_{n}\right\}} A_{n+1, i}\left(\Delta^{2}\right)\right.\right. \\
& -\mathrm{i} \frac{\Delta_{\alpha} \sigma^{\alpha\{\mu} \Delta^{\mu_{1}} \ldots \Delta^{\mu_{i}} \bar{P}^{\mu_{i+1}} \ldots \bar{P}^{\left.\mu_{n}\right\}}}{2 m} B_{n+1, i}\left(\Delta^{2}\right) \\
& \left.+\left.\frac{\Delta^{\mu} \ldots \Delta^{\mu_{n}}}{m} C_{n+1,0}\left(\Delta^{2}\right)\right|_{n \text { odd }}\right] U(P) \tag{4.8}
\end{align*}
$$

where $\{\cdots\}$ denotes symmetrization and subtraction of trace terms. The fact that the sum in Eq.(4.7) extends only up to $n-1$ is called polynomiality. The proton alone has eight independent quark GPDs for each quark flavour and typically one can calculate the leading three moments with satisfactory accuracy on the lattice. Adding the gluon GPDs and repeating the analysis for all octet and decuplet baryons and octet mesons one is already speaking about several hundred quantities. In future one will also increasingly analyse hadron resonances and transition form factors, such that the lattice data base will become even richer. For each of these observables one has to analyse the renormalization properties, the quark/pion mass dependence and the finite volume dependence (within suitable versions of effective field theory/chiral perturbation theory (ChPT)). Finally one has to compare results for different lattice actions and analyse the origin of discrepancies. Obviously it is impossible to review all of this here. Rather, we refer to the comprehensive paper 604 for an example of a state of the art analysis. Fig. 4.2, taken from this paper, gives a typical example. This figure shows a number of common aspects:

1. Fluctuations are strongly suppressed for heavy quark/pion masses. This is why the statistical errors (dark blue bars) increase drastically for smalles pion masses.

Figure 4.2. The isosinglet moment $B_{20}^{u+d}(t)$ as a function of simulated pion mass and $t$ [604].

Figure 4.3. Lattice results for $J_{u}$ and $J_{d}$ compared with various models [582, 701, 605, 702 and constraints derived from experiment (colored bands)
2. The difference between the two sheets gives the variation of HBChPT fits. However, it would be safer to only use ensembles with squared pion masses below $m_{\pi}^{2} \leq 0.25 \mathrm{GeV}^{2}$, where ChPT is rather well under control, which was obviously not possible with the ensembles available for this analysis.
3. One is especially interested in the $t=0$ limit of $B_{20}$ in view of Ji's sum rule,

$$
\left\langle J_{q}^{3}\right\rangle=\frac{1}{2}\left[A_{2,0}^{q}(0)+B_{2,0}^{q}(0)\right]
$$

Already today lattice simulations give rather precise results for the total angular momentum carried by the different quark species in a nucleon, see Fig. 4.3. In future these results will further improve, e.g. due to the use of twisted boundary conditions to realize proton momenta different from the natural ones on a lattice, i.e. different from $p_{j}=\frac{2 \pi}{L} n_{j}$.

Thus, much has been done already, and much more will be done in future. Extrapolating the progress of recent years to the time an EIC will start operation it seems realistic to expect

Figure 4.4. An illustration for the transverse probability distribution of the nucleon quark distributions as a function of the transverse quark and nucleon spin direction. Figure taken from 456.
that by then pictures like Fig. 4.2 will be numerically precise and will include reliable error bands.

Another important example are the quark density distributions in the transverse plane plotted in Fig. 4.4. Their form is mainly determined by the Fourier transformations of (moments of) the GPDs.

$$
\begin{align*}
B_{n 0}^{q}\left(x, 0, b_{\perp}^{2}\right) & =\frac{1}{(2 \pi)^{2}} \int_{-1}^{1} d x x^{n-1} \int d^{2} \Delta_{\perp} e^{\mathrm{i} b_{\perp} \cdot \Delta_{\perp}} E\left(x, 0, \Delta_{\perp}^{2}\right) \\
\bar{B}_{T n 0}^{q}\left(x, 0, b_{\perp}^{2}\right) & =\frac{1}{(2 \pi)^{2}} \int_{-1}^{1} d x x^{n-1} \int d^{2} \Delta_{\perp} e^{\mathrm{i} b_{\perp} \cdot \Delta_{\perp}} \bar{E}_{T}\left(x, 0, \Delta_{\perp}^{2}\right) \tag{4.9}
\end{align*}
$$

The information on transverse structure contained in GPDs is, e.g., relevant in the following context: First LHC data show strong disagreement between observed interaction rates and predictions from event generators, see e.g. 703] for the so-called "underlying event" which denotes the whole of all medium hard reaction channels, which are completely dominated by QCD. Part of the explanation might be related to multiple-hard interactions, a class of reactions which was shown to be already relevant at the Tevatron, see [704]. In these reactions multiple hard quark-gluon interactions occur in the same proton-proton collision, which are not described by the usual inclusive factorization theorems. The correction terms have a complicated structure, see e.g. [705] and references cited there, but can be partially related to GPD profiles in the transverse coordinate plane. By combining experimental results from an EIC with improved lattice calculations it should be possible to describe these effects much more precisely than currently. In this context, as always, experimental results are crucial, because it is very difficult to judge the reliability of lattice results without being able to compare with at least some experimental facts.

A multitude of angular asymmetries and hadronic correlations, many of which include spin degrees of freedom, can be measured with a high luminosity EIC. For many of these, the microscopic reaction mechanism is not yet understood. Some of the proposals made depend crucially on the transverse hadronic structure encoded in GPDs, see e.g. [299]. One of the main missions of an EIC is to clarify both the transverse structure and the reaction mechanisms. This is a demanding task which can only be mastered with input from LQCD.

### 4.3 TMDs on the lattice

The availability of methods to study GPDs on the lattice motivates us to develop similar techniques for the calculation of TMDs [279, 280]. In contrast to other, more mature areas of lattice QCD, the present focus of TMD calculations on the lattice is on the development of methodology and on qualitative observations rather than precision. The ultimate goal is to obtain results from first principles only that can potentially be compared to experimental observations. The first step to reach this goal is to describe precisely which matrix elements need to be calculated, and how they can be regularized in the context of TMD factorization. Already at this step, the situation is much more challenging for TMDs than for moments of GPDs, where the matrix elements needed are well-known. These issues are not specific to lattice QCD, but they play a central role in the development of methods to calculate TMDs non-perturbatively.

In its basic form, the correlator that needs to be calculated is that of eq. (2.1). For our purposes, we write the trace projections $\Phi^{[\Gamma]}=\frac{1}{2} \operatorname{Tr}(\Gamma \Phi)$ of this correlator as

$$
\begin{equation*}
\Phi^{[\Gamma]}\left(x, \mathbf{k}_{\perp}\right)=\left.\frac{1}{P^{+}} \underbrace{\int \frac{d(l \cdot P)}{2 \pi} e^{-i(l \cdot P) x}}_{\mathcal{F}_{x}} \underbrace{\int \frac{d^{2} \mathbf{l}_{\perp}}{(2 \pi)^{2}} e^{i 1_{\perp} \cdot \mathbf{k}_{\perp}}}_{\mathcal{F}_{\perp}} \underbrace{\frac{1}{2}\langle P, S| \bar{q}(l) \Gamma \mathcal{W}_{\eta} q(0)|P, S\rangle}_{\widetilde{\Phi}^{[\Gamma]}(l, P, S)}\right|_{l^{+}=0} \tag{4.10}
\end{equation*}
$$

where $\Gamma$ is a Dirac matrix. The gauge $\operatorname{link} \mathcal{W}_{\eta}$ is discussed in sec. 2.4.1, and its geometry is depicted for the SIDIS process in figure 4.5 a). With the generalization of eq. (2.47) it can be written as a concatenation of straight Wilson lines $\mathcal{W}_{\eta}=V_{[l, l+\eta v]} V_{[l+\eta v, \eta v]} V_{[\eta v, 0]}$. Here $v$ is a time-like vector normalized to $v^{2}=1$. A staple shaped gauge link $\mathcal{W}_{\infty}$ extending to $\eta \rightarrow \infty$ corresponds to SIDIS, while a staple $\mathcal{W}_{-\infty}$ directed in the opposite direction corresponds to the Drell-Yan process. Beyond tree level, eq. (4.10) needs to be modified in order to take the collective effect of soft momentum gluons into account and to subtract divergences. This can be achieved, e.g., by dividing $\tilde{\Phi}^{[\Gamma]}$ by appropriate vacuum expectation values (soft factors), see, e.g., [706, 256, 257, [260, 384].

First studies of transverse momentum dependence on the lattice follow the strategy to determine matrix elements of the form $\tilde{\Phi}^{[\Gamma]}$ in eq. (4.10) directly from three-point functions. The idea of using a discrete representation of the non-local operator $\bar{q}(l) \Gamma \mathcal{W}_{\eta} q(0)$ is a novel technique and requires investigations about the properties of such extended operators on the lattice. Considering this and the ambiguities about the precise operator geometry suitable for TMD extraction, it seems reasonable to begin with a simplified setup. The following two operator geometries are under investigation:

- straight gauge link connecting the two quark fields directly, $\mathcal{W}_{0}=V_{[l, 0]}$. This simple setup yields high statistics results, but does not correspond to the situation in SIDIS or Drell-Yan. For example, non-zero time-reversal odd TMDs such as the Sivers function $f_{1 T}^{\perp}$ are forbidden by symmetry with this link geometry. However, the qualitative features of the results are interesting, especially the spin-dependence. A brief outline of findings obtained with straight links is given in sec. 4.3.1
- staple shaped gauge link of finite extent $\mathcal{W}_{\eta}$ for a spacelike choice of the direction $v$ as depicted in figure 4.5 a). Results for the SIDIS link $\mathcal{W}_{+\infty}$ and the Drell-Yan link $\mathcal{W}_{-\infty}$ can be read off if the lattice results converge to a constant for longer and longer staple extents $\eta$. Ongoing studies with this operator geometry are discussed in sec .4.3.2.

Figure 4.5. a) Staple shaped Wilson line. b) Representation of a straight Wilson line (dashed line) as a step-like product of link variables.

### 4.3.1 Straight gauge links

In lattice QCD, it is possible to determine matrix elements $\widetilde{\Phi}^{[\Gamma]}$ appearing in eq. (4.10) directly from a ratio of three- and two-point functions, provided the operator has no extent in Minkowski-time. To do this, we employ the standard methods described in sec. 4.1 Only the operator we insert is specific to our method. Operators with straight gauge links can be approximated on the lattice by a step-like product of link variables, as depicted in figure 4.5 b). At present, disconnected diagrams are neglected. Disconnected diagrams cancel in the isovector channel, i.e., in $u-d$ quark distributions.

The key element to relate the matrix elements $\widetilde{\Phi}^{[\Gamma]}$ determined on the lattice to the TMDs is a parametrization in terms of Lorentz-invariant amplitudes $\widetilde{A}_{i}\left(l^{2}, l \cdot P\right)$, similar to the parametrization in terms of amplitudes $A_{i}\left(k^{2}, k \cdot P\right)$ in ref. [243]. For straight gauge links one obtains

$$
\begin{align*}
\widetilde{\Phi}^{\left[\gamma^{\mu}\right]} & =2 P^{\mu} \tilde{A}_{2}+2 i M^{2} l^{\mu} \widetilde{A}_{3},  \tag{4.11}\\
\widetilde{\Phi}^{\left[\gamma^{\mu} \gamma^{5}\right]} & =-2 M S^{\mu} \widetilde{A}_{6}-2 i M P^{\mu}(l \cdot S) \widetilde{A}_{7}+2 M^{3} l^{\mu}(l \cdot S) \widetilde{A}_{8}, \tag{4.12}
\end{align*}
$$

To translate the amplitudes into TMDs, the Fourier transform in eq. (4.10) must be carried out. For example

$$
\begin{align*}
f_{1}\left(x, \mathbf{k}_{\perp}^{2}\right) & =2 \mathcal{F}_{\perp} \mathcal{F}_{x} \widetilde{A}_{2}\left(l^{2}, l \cdot P\right),  \tag{4.13}\\
g_{1 T}\left(x, \mathbf{k}_{\perp}^{2}\right) & =4 M^{2} \partial_{\mathbf{k}_{\perp}^{2}} \mathcal{F}_{\perp} \mathcal{F}_{x} \widetilde{A}_{7}\left(l^{2}, l \cdot P\right), \tag{4.14}
\end{align*}
$$

where the two independent Fourier transforms $\mathcal{F}_{x}$ and $\mathcal{F}_{\perp}$ are defined in eq. (4.10). On the Euclidean lattice, the matrix elements can only be evaluated in the range

$$
\begin{equation*}
l^{2} \leq 0 \quad|l \cdot P| \leq\left|\mathbf{P}_{\text {lat }}\right| \sqrt{-l^{2}} \tag{4.15}
\end{equation*}
$$

where $\mathbf{P}_{\text {lat }}$ is the three-momentum of the nucleon chosen on the lattice. As a result, data points are only available in a wedge shaped area. The opening angle of the wedge can be potentially increased by using larger lattice nucleon momenta $\mathbf{P}_{\text {lat }}$, but full coverage of the $|l|, l \cdot P$-plane can never be achieved with this method. Thus the information required to reconstruct the $x$-dependence of the distributions is not fully available; the Fourier transform $\mathcal{F}_{x}$ in eqs. (4.13)-(4.14) cannot be carried out. However, model assumptions about the

Figure 4.6. $x$-integrated density of longitudinally polarized quarks inside a nucleon polarized in the transverse $x$-direction. These results have been obtained with straight gauge links at a pion mass $m_{\pi} \approx 500 \mathrm{MeV}$ [279]. The insets display the spin polarization of the quarks and of the nucleon.
correlation of $x$ - and $\mathbf{k}_{\perp}$-dependence can be compared to the lattice data, see sec. VI of ref. [280]. Moreover, the lowest $x$-moment of TMDs can be calculated, since the required information is encoded in the data at $l \cdot P=0$. For example,

$$
\begin{align*}
f_{1}^{[1]}\left(\mathbf{k}_{\perp}^{2}\right) & \equiv \int d x f_{1}\left(x, \mathbf{k}_{\perp}^{2}\right)=\int_{0}^{1} d x\left(f_{1}\left(x, \mathbf{k}_{\perp}^{2}\right)-\bar{f}_{1}\left(x, \mathbf{k}_{\perp}^{2}\right)\right) \\
& =2 \mathcal{F}_{\perp} \widetilde{A}_{2}\left(l^{2}, 0\right), \tag{4.16}
\end{align*}
$$

where $\bar{f}_{1}$ is the unpolarized anti-quark distribution function. First results for the lowest $x$-moments $f_{1}^{[1]}, g_{1 T}^{[1]}$ and $h_{1 L}^{\perp[1]}$ using straight gauge links have been presented in Ref. [279, 280]. The calculations were carried out at a pion mass of about 500 MeV , taking advantage of existing gauge configurations from the MILC collaboration [707] and propagators from the LHP collaboration [708]. The worm gear distribution $g_{1 T}$ gives rise to dipole deformations in the $x$-integrated, $\mathbf{k}_{\perp}$-dependent density of longitudinally polarized quarks inside a transversely polarized nucleon, as shown in figure 4.6. Due to the dipole deformation, this density is not axially symmetric. The peak is clearly shifted away from the center along the axis defined by the transverse spin vector. This shift is associated with a non-zero average transverse quark momentum $\left\langle\mathbf{k}_{x}\right\rangle_{T L}$, which can be expressed in terms of a ratio of amplitudes $\widetilde{A}_{7}(0,0) / \widetilde{A}_{2}(0,0)$. The lattice computations yield $\left\langle\mathbf{k}_{x}\right\rangle_{T L}=67(5) \mathrm{MeV}$ for down quarks and $\left\langle\mathbf{k}_{x}\right\rangle_{T L}=-30(5) \mathrm{MeV}$ for up quarks (errors statistical only). Reference [709] reveals that these results are of the same sign and of quite similar magnitudes as those obtained with a light-cone constituent quark model [409, despite the unphysically large quark masses employed in the lattice calculation.

We note that the straight link results discussed above depend on two additional important ingredients: a non-perturbative renormalization condition and a Gaussian parametrization to perform the Fourier transform, see ref. [280] for details. The renormalization condition is necessary to fix the length-dependent renormalization factor $\exp (-\delta m|l|)$ due to the self-energy of the spacelike Wilson line $\mathcal{V}_{[l, 0]}$ [710, 711, 712]. At the present level of statistical precision, the parametrization of the renormalized data as Gaussian functions is very successful and acts as a provisional regulator of contributions from large $\mathbf{k}_{\perp}$. A better understanding of the operator in the transition from the short range (small $\sqrt{-l^{2}}$, corresponding to large $\mathbf{k}_{\perp}$ ) to the long range behavior may lead to a an improved parametrization of the lattice data, beyond the Gaussian assumption, and may open the possibility to make

Figure 4.7. Test calculation of a T-odd ratio of amplitudes using staple shaped links at $m_{\pi} \approx$ 800 MeV 713 .
contact with a perturbatively defined renormalization scheme.

### 4.3.2 Staple-shaped links and the Sivers function

TMDs obtained with a straight gauge link as discussed in the previous section are not strictly identical to those relevant in, e.g., SIDIS or the Drell-Yan process. Instead, a link geometry as depicted in figure 4.5 a ) is required. In particular, naively time-reversal odd TMD such as the Sivers function can only be non-vanishing once the operator structure involves another direction $v$ related to final or initial state interactions. Lattice QCD can profit from frameworks that avoid rapidity divergences by considering directions $v$ slightly off the lightlike $n^{-}$-direction [240, 241, 256, 257, 260, 384]. TMDs introduced this way follow an evolution equation in the rapidity cutoff parameter $\zeta \equiv(2 P \cdot v)^{2} /\left|v^{2}\right|$ [240, 393]. The restriction to operators $\bar{q}(l) \Gamma \mathcal{W}_{\eta} q(0)$ that have no extent in Euclidean time permits only the implementation of spacelike directions $v$ on the lattice, and furthermore limits the rapidity cutoff parameter to the range $0 \leq \zeta \leq 4\left|\mathbf{P}_{\text {lat }}\right|^{2}$, where $\mathbf{P}_{\text {lat }}$ is the selected nucleon three-momentum on the lattice. The dependence on $v$ leads to additional amplitudes $\tilde{A}_{i}$, $\tilde{B}_{i}$ in the decomposition of the correlator eq. (4.11), compare also [246]:

$$
\begin{align*}
\widetilde{\Phi}^{\left[\gamma^{\mu}\right]}= & \frac{2}{\widetilde{S}}\{ \\
& \left\{P^{\mu} \widetilde{A}_{2}+i M^{2} l^{\mu} \widetilde{A}_{3}+i M \epsilon^{\mu \nu \alpha \beta} P_{\nu} l_{\alpha} S_{\beta} \widetilde{A}_{12}+\frac{M^{2}}{(v \cdot P)} v^{\mu} \widetilde{B}_{1}\right. \\
& +\frac{M}{v \cdot P} \epsilon^{\mu \nu \alpha \beta} P_{\nu} v_{\alpha} S_{\beta} \widetilde{B}_{7}+\frac{i M^{3}}{v \cdot P} \epsilon^{\mu \nu \alpha \beta} l_{\nu} v_{\alpha} S_{\beta} \widetilde{B}_{8}  \tag{4.17}\\
& \left.-\frac{M^{3}}{v \cdot P}(l \cdot S) \epsilon^{\mu \nu \alpha \beta} P_{\nu} l_{\alpha} v_{\beta} \widetilde{B}_{9}+\frac{i M^{3}}{(v \cdot P)^{2}}(v \cdot S) \epsilon^{\mu \nu \alpha \beta} P_{\nu} l_{\alpha} v_{\beta} \widetilde{B}_{10}\right\} .
\end{align*}
$$

Here $\widetilde{S}$ generically represents a soft factor modification, as needed, e.g., in the formalism of refs. [256, 257, 260, 384]. First lattice studies are ongoing for ratios of amplitudes, in which renormalization factors and potential soft factors cancel [713, 280], similar as in the asymmetries discussed in sec. 2.2.7. Figure 4.7 shows results from a test calculation [713] of a ratio of time-reversal odd over time-reversal even amplitudes $R_{\text {odd }} \equiv\left(\widetilde{A}_{12}-\right.$ $\left.\left(M /\left|{\underset{\sim}{\mathbf{P}}}_{\text {lat }}\right|\right)^{2} \widetilde{B}_{8}\right) / \widetilde{A}_{2}$, evaluated at $l \cdot P=0,\left|\mathbf{P}_{\text {lat }}\right| \approx 0.5 \mathrm{GeV}$, for selected values of $l^{2}$. Note that $\widetilde{A}_{12}$ would correspond to the Sivers function $f_{1 T}^{\perp}$ for lightlike $v$. In the test calculation, the operator has been evaluated with staple shaped links $\mathcal{W}_{\eta}$ for a large range of extents $\eta$.

The result of the test calculation is, within statistics, an odd function of $\eta v \cdot P$, as expected for a time-reversal odd function. Moreover, we see the onset of a plateau at $|\eta v \cdot P| \gtrsim 2$. The plateau at large positive $\eta$ correspond to the SIDIS result with a $\mathcal{W}_{\infty}$ link, while the plateau at large negative $\eta$ correspond to the Drell-Yan result with the $\mathcal{W}_{-\infty}$ link. This is a promising indication that lattice estimates could be feasible for, e.g., the average transverse momentum shift due to the Sivers function given by

$$
\begin{equation*}
\left.\left\langle\mathbf{k}_{y}\right\rangle_{T U} \equiv \frac{\int d^{2} \mathbf{k}_{\perp} \mathbf{k}_{y} \Phi^{\left[\gamma^{+}\right]}}{\int d^{2} \mathbf{k}_{\perp} \Phi^{\left[\gamma^{+}\right]}}\right|_{\mathbf{S}_{\perp=(1,0)}}=M \frac{\int d x f_{1 T}^{\perp(1)}(x)}{\int d x f_{1}^{(0)}(x)}, \tag{4.18}
\end{equation*}
$$

see also [264, 444. Here $\Phi^{\left[\gamma^{+}\right]}$intuitively has an interpretation as the density of unpolarized quarks in a transversely polarized proton, and $f_{1 T}^{\perp(1)}$ and $f_{1}^{(0)}(x)$ are $\mathbf{k}_{\perp}$-moments defined as $f^{(n)}(x) \equiv \int d^{2} \mathbf{k}_{\perp}\left(\mathbf{k}_{\perp}^{2} / 2 M^{2}\right)^{n} f\left(x, \mathbf{k}_{\perp}^{2}\right)$. A generalized version of the above quantity can be formed directly from the amplitudes determined on the lattice, namely

$$
\begin{equation*}
\left\langle\mathbf{k}_{y}\right\rangle_{T U}\left(\mathcal{B}_{\perp}\right) \equiv M \frac{\int d x \tilde{f}_{1 T}^{\perp(1)}\left(x, \mathcal{B}_{\perp}^{2}\right)}{\int d x \tilde{f}_{1}\left(x, \mathcal{B}_{\perp}^{2}\right)}=-\left.M \frac{\widetilde{A}_{12}-R(\zeta) \widetilde{B}_{8}}{\widetilde{A}_{2}+R(\zeta) \widetilde{B}_{1}}\right|_{l \cdot P=0} ^{l^{2}=-\mathcal{B}_{\perp}^{2}} \tag{4.19}
\end{equation*}
$$

with $R(\zeta)=1-\sqrt{1+4 M^{2} / \zeta}$ and where $\tilde{f}_{1}$ and $\tilde{f}_{1 T}^{\perp(1)}$ are now $\mathbf{k}_{\perp}$-Fourier-transformed TMDs as they appear in eq. (2.33). Keeping the length $\mathcal{B}_{\perp}$ sufficiently large compared to the lattice spacing and correspondingly assuming renormalization properties as in continuum field theory, one finds that multiplicative renormalization factors, including Wilson line self-energies, as well as potential soft factors cancel in the ratio of amplitudes above. The extrapolation to $\mathcal{B}_{\perp}=0$, where $\left\langle\mathbf{k}_{y}\right\rangle_{T U}\left(\mathcal{B}_{\perp}\right)$ is equal to $\left\langle\mathbf{k}_{y}\right\rangle_{T U}$, will require special attention to UV divergences and cutoff effects. However, already the generalized object $\left\langle\mathbf{k}_{y}\right\rangle_{T U}\left(\mathcal{B}_{\perp}\right)$ at nonzero $\mathcal{B}_{\perp}$ may offer opportunities to compare with phenomenology, by means of an $x$-integrated version of the Bessel-weighted quantities introduced in eq. (2.33) A possible difficulty for lattice computations will be to reach large enough values $\zeta$, in the regime where evolution equations [240, 393] can be applied.

### 4.4 Spectroscopy and other physics topics

Still another approach to elucidate hadron structure is offered by lattice spectroscopy. Spectroscopy has the great advantage that it allows to avoid the subtle renormalization issues mentioned above, but the disadvantage that the deduction of information on hadron structure is less direct. A typical recent example is found in [714], see Fig. 4.8. The basic idea is that one uses a set of interpolating currents (sources) $\mathcal{O}_{i}$ with the same quantum numbers to calculate and analyse the correlation matrix as a function of separation of the time-hyper planes

$$
\begin{equation*}
C_{i j}(t)=\langle 0| \mathcal{O}_{i}(t) \mathcal{O}_{j}(0)|0\rangle \tag{4.20}
\end{equation*}
$$

and solves the generalized eigenvalue problem. One thus obtains not only the eigenvalues (masses) but also the eigenvectors in terms of the different sources. If done with care the relative overlap of the physical mass states with the different sources allows to draw conclusions about their structure. This provides information, which is often complementary to that obtained with the methods sketched above. Again for practical purposes this information is most sensitive to leading Fock-state components. While this is a very powerful method, its results must be interpreted with care. The eigenvectors of different mass states give the amplitudes with which each source contributes. All of these are forced to be orthonormal by construction. This constraint can lead to substantial artifacts if the chosen source functions span too small a function space. To avoid premature conclusions one, therefore, has to compare results obtained for different lattice actions and many different choices of sources. Presently the lattice community is still in the process of optimizing this method, but it seems already clear by now that in a few years this approach will be a standard source of many detailed information about hadron structure.

Figure 4.8. A typical example from [714]. The $1^{-}$kaon states are shown. Color coding indicates dominance of a particular charge-conjugation eigenstate

## Acknowledgments

Thanks are due to our collaborator John Negele. We are grateful to the LHP and MILC collaborations, for providing gauge configurations and propagators. We also thank Gunnar Bali, Alexei Bazavov, Vladimir Braun, Markus Diehl, Robert Edwards, Meinulf Göckeler, Alexei Prokudin, Dru Renner and David Richards for helpful discussions. Our software uses the Chroma-library [715], and we use USQCD computing resources at Jefferson Lab.

### 5.1 Chapter summary: overview and golden measurements

Alberto Accardi, Matthew Lamont and Cyrille Marquet

A basic quest of nuclear physics is the understanding of the structure of hadrons and nuclei (nucleon number $A>1$ ) in terms of QCD Lagrangian degrees of freedom, the quarks and gluons. Deviations of the nuclear quark and gluon densities from the sum of the free nucleon densities directly attest to binding effects and elucidate the QCD origin of the inter-nucleon interactions. Such deviations can arise through different mechanisms, such as a modification of the free nucleon structure, the presence of non-nucleonic degrees of freedom, and quantum-mechanical interference of the quark/gluon fields of different nucleons at small parton fractional momentum $x$ ("shadowing"), creating a fascinating landscape of many-body QCD. At even smaller $x$, the gluon density increases to the point where gluons become closely packed, leading to a strong field regime of non-linear QCD evolution called saturation. This regime is argued to have universal properties for any hadronic system, ranging from pions, to protons and nuclei, but its onset is enhanced in nuclear targets due to the superposition of the gluon field of many nucleons.

A peculiar pattern of nuclear modifications was observed in fixed-target experiments and caused much excitement; it shows suppression for $0.2<x<0.8$ ("EMC effect"), some signs of enhancement for $0.05<x<0.2$, and significant suppression (shadowing) at smaller $x$. However, such experiments were unable to reach deep into the shadowing region or probe gluons. The EIC will overcome these limitations, extend measurements to very high scales of $Q^{2}$, and determine with high precision the nuclear effects on gluon distributions. Full reconstruction of the hadronic final state also opens up for the first time the possibility of measuring charged current interactions on nuclei, and to perform a full quark flavour separation based on nuclear DIS data only. Crucially, an EIC will access much lower values of $x<0.01$ and study the onset of the saturation regime, which has never been directly probed experimentally, although tantalising (but not unequivocal) signatures have been found at the Relativistic Heavy-Ion Collider (RHIC).

Another possibility offered by nuclear targets is the study of the propagation of colour charges in nuclear matter and the space-time evolution of hadronization. The unique feature of an EIC, compared to previous fixed target experiments, is its large energy span. This allows one to experimentally boost hadronization effects completely out of the nucleus, in order to focus attention on the propagation of fast quarks and gluons, and their accompanying parton showers, through the nucleus. Thus one can use the partons as coloured probes of the soft components of the target nuclear wave function, and conversely experimentally test QCD mechanisms of parton energy loss in a known nuclear medium. At lower energies, hadronization happens partially inside the nucleus, which can then be used as a femtometer scale detector of the process. A good control of energy loss mechanisms in the partonic phase will yield unambiguous insights into the dynamics of colour confinement whereby hadrons emerge from coloured quarks and gluons.

Novel observables will be available thanks to the high energy reach, namely heavy flavours, charmonium and bottomonium, and jets, greatly expanding the experimental toolbox and sensitivity to nuclear effects, and thereby allowing a close connection to first principles calculations in QCD. The collider mode will also make it feasible to study in detail target fragmentation and its correlation to current fragmentation through multi-particle correlations, thereby expanding considerably the study of shower development and hadronization mechanisms.

### 5.1.1 Gold and silver measurements

One of the goals of the program at the INT was to identify a small number of measurements whose ability to extract novel physics is beyond question and which are feasible at an EIC. Such measurements are referred to as "golden" measurements. These are complemented by other "silver" measurements/observables, to form a broad, robust, and compelling physics program. The gold and silver measurements are summarised in Tables 5.1 and 5.2, where also their feasibility in phase-I (medium energy) and phase-II (full energy) is indicated, and further discussed below. Many more observables than can fit in this section will be available at an EIC, contributing to a very rich physics program exploring the QCD basis of nuclear physics. Many of these will be reviewed in detail in the rest of this chapter.

| Deliverables | Observables | What we learn | Phase-I | Phase-II |
| :---: | :---: | :---: | :---: | :---: |

### 5.1.2 QCD at high gluon density

The fact that we do not know the dynamics of gluons in nuclei over basically any $x$ range seems a compelling enough reason to build an EIC. The non-Abelian nature of QCD is its most distinguishing feature and controls emergent phenomena such as colour confinement, chiral symmetry breaking and the generation of the vast bulk of the visible mass in the Universe. These are, however, non-perturbative phenomena which are difficult to attack from first principles; where this is possible, such as in the case of the hadron spectrum from lattice QCD, only static aspects of the strong interactions are addressed. An EIC would allow one for the first time to experimentally probe at small $x$ dynamical non-Abelian aspects of a fundamental force of nature in a controlled setting where weak coupling methods apply. The physics in this regime is the non-perturbative physics of strong

Figure 5.1. The saturation scale, $Q \equiv Q_{s}$, and how it scales with $x$, and $A$.
colour fields; the important new feature is that the applicability of weak coupling methods allow for systematic comparisons of theory to experiment.

In addition to the intrinsic interest in this novel many-body regime of QCD, experimentally establishing and refining an effective field theory for the saturation regime - such as the Colour Glass Condensate (CGC) - as well as precisely imaging the distribution and correlations of small- $x$ partons in nuclei, besides being of intrinsic interest, would have wide-ranging applications. The universality of the saturation regime implies that such a theory would provide a microscopic basis for understanding and calculating total hadronic cross sections, with important applications to, for example, ultra-high energy cosmic ray physics, where extrapolations in energy of several orders of magnitude are required to compute their spectrum and detect possible new physics effects. In high-energy relativistic heavy-ion collisions, the release of saturated low- $x$ partons represents the starting point of the subsequent space-time evolution of the Quark-Gluon Plasma (QGP). Testing and benchmarking the underlying theory opens the prospect of a controlled, and precise, first principles calculation of such an initial state. Thereby reducing one of the largest sources of uncertainty in the interpretation of experimental observables, and the measurements of the QGP properties: an EIC would offer to the RHIC and LHC heavy-ion programs an important asset, as valuable as the one HERA provided to the LHC p+p program.

The onset of the saturation regime, when the gluon density becomes so large that further growth with energy is tamed, is characterised by the saturation scale $Q_{s}(x)$; partons with momenta below this scale overlap in transverse space, so that parton recombination and screening stops further growth in their number density. Given that parton distributions grow as $x$ decreases, and dramatically so as discovered at HERA, the saturation scale is clearly expected to grow as $x$ decreases. It is further enhanced in nuclear targets because of the overlap of the gluon fields originating from different nucleons. This is illustrated in figure 5.1. In the saturated, dense regime at small $x$, non-linear QCD dynamics becomes dominant but at the scale being set by a semi-hard $Q_{s}$ (of order 1 GeV ), calculations can be carried out by weak coupling techniques and suitable effective field theories, of which the CGC is a prime example, can be derived from first principles.

The dilute-dense separation of scales is more subtle than just described. The larger
the gluon's transverse momentum $k_{T}$, the smaller its longitudinal energy fraction $x$ needs to be to enter the saturation regime. In a scattering process, dilute partons (with $k_{T} \gg$ $\left.Q_{s}(x)\right)$ behave incoherently, whilst when the parton density is large $\left(k_{T} \lesssim Q_{s}(x)\right)$, gluons scatter coherently. Therefore, transverse momentum dependent observables will be able to uncover more details than inclusive observables, which can only access averaged saturation effects. The interplay of saturation and the transverse spatial distribution of gluons is also important; as $x$ decreases, gluon densities saturate first in the centre of the nucleus. To accommodate further growth, gluons will be pushed more and more to the periphery, so that the average gluon radius is expected to increase with decreasing $x$.

For all these reasons regarding the small- $x$ physics program in $\mathrm{e}+\mathrm{A}$ collisions, the physics deliverables of an EIC have been classified in three main categories giving access to the integrated, transverse-momentum-dependent, and impact-parameter-dependent gluons. Here, by "gluons" we mean not only the conventional single-gluon distributions but also multigluon correlations. These have often been of secondary interest, but are now recognised as essential to a full understanding of the low- $x$ regime. Indeed, except for the most inclusive observables which are subject to cancellations, consistent QCD calculations in the nonlinear regime require the knowledge of multi-gluon distributions. Integrated, transverse-momentum-dependent, and impact-parameter-dependent gluon distributions and correlations in nuclei are all unknown, and the processes we discuss below have never been measured at small $x$.

## Integrated gluons and sea-quarks

As the most basic observables from both the theory and experimental sides, the inclusive $(e+\mathrm{A} \rightarrow e+\mathrm{X})$ structure functions $F_{2}$ and $F_{L}$ stood out among other measurements, already well before the INT programme. They were the first potential golden measurements discussed; the pros and cons of these candidates to pin down the gluon and sea-quark distributions in nuclei were further reviewed during the program.
$F_{2}$ is the most inclusive observable in deep inelastic scattering. Its measurement presents no particular experimental challenge. On the theory side, it is the simplest process to calculate, along with $F_{L}$, with the fewest input assumptions. For instance, $F_{2}$ and $F_{L}$ will be the first observables for which a full NLO calculation in QCD including non-linear effects will be available. (The existing phenomenology is still based on leading-order "impact factor" computations.)

Although it is harder to extract experimentally, $F_{L}$ is a golden measurement for high density QCD because it is more directly related to the gluon distribution. Furthermore, it is more sensitive to non-linear effects than $F_{2}$. In the latter, higher-twist contributions cancel each other out delaying the onset of non-linear effects. The necessity of performing an energy scan to measure $F_{L}$ implies that the accessible $x$ range is a bit smaller than accessible with the $F_{2}$ measurement. However, the increased sensitivity to non-linear effects more than compensates for this shortcoming. Deviations of DGLAP fits of the simultaneous "singlet" dominated (at small $x$ ) evolution of $F_{2}$ and $F_{L}$ determined from EIC data should be able to quantitatively determine the onset of the saturation regime. The case for the low-energy EIC needs to be investigated more; in particular, the implementation of non-linear effects must be made more accurate, and more detailed DGLAP fits of EIC pseudo-data should be performed before establishing its sensitivity to saturation physics in the inclusive channel. One caveat discussed is that QED radiative corrections for nuclear targets can be large, and it remains to be proven that they can be controlled to the required precision. Computations
addressing the role of these radiative corrections are underway and are discussed further in the detector studies section of this report.

The charm structure functions $F_{2, L}^{c}$ were considered as silver measurements for the nonlinear regime. As in the case of $F_{L}$, these observables give more direct access to the gluon distribution relative to $F_{2}$; however due to the mass of the charm quark, they also probe higher values of $x$ and are therefore less sensitive to non-linear effects. In addition, QCD calculations with non-zero charm mass are scheme dependent, which can absorb signals of non-linear effects if not appropriately handled. However, since they can be measured precisely with a properly-designed vertex detector, charm structure functions will be a very important complementary measurement to pin down the nuclear gluon distribution throughout the $\left(x, Q^{2}\right)$ plane.

Last but not least, silver measurements in the inclusive category are those of the diffractive structure functions $F_{2}^{D}$ and $F_{L, D}$. These are sensitive to the square of the gluon distribution. As may therefore be anticipated, the strongest hints for manifestations of non-linear effects in $\mathrm{e}+\mathrm{p}$ collisions at HERA come from diffractive measurements. A striking example is the fact that the ratio of the diffractive to inclusive structure function is constant with energy, an observation not easily reconciled in a leading twist scenario. Furthermore, the leading-twist approximation does not explain the geometric scaling of the diffractive cross section. Finally, as a sign of enhanced sensitivity to non-linear effects, the DGLAP analysis of diffractive structure functions from HERA is problematic at larger values of $Q^{2}$ relative to the same for $F_{2}\left(\sim 8 \mathrm{GeV}^{2}\right.$ in the former compared to $2 \mathrm{GeV}^{2}$ in the latter). However, measurements of diffractive structure functions are relatively more difficult and the additional kinematic variables make the analyses more involved than for $F_{2, L}$.

## Transverse momentum dependent gluons and sea-quarks

The golden measurement here is that of di-hadron azimuthal correlations in $e+\mathrm{A} \rightarrow$ $e+\mathrm{h}_{1}+\mathrm{h}_{2}+\mathrm{X}$ processes. Di-hadron correlations are not only sensitive to the $k_{T}$ dependence of the gluon distribution but also to the $k_{T}$ dependence of gluon correlations. These correlations are sensitive to multi-gluon distributions for which first principles computations are only now becoming available. Precise measurements of these di-hadron correlations at an EIC would allow one to extract these multi-gluon correlations and study their non-linear evolution. Saturation effects in this channel correspond to a progressive disappearance with decreasing $x$ of the peak in the di-hadron azimuthal angle difference around $\Delta \phi=\pi$. In a leading twist picture, where there is only one hard scattering, one expects, from momentum conservation, that the peak will persist. A comparison of the heights and widths of the dihadron azimuthal distributions in $e+\mathrm{A}$ and $e+\mathrm{p}$ collisions respectively would clearly mark out such an effect experimentally. An analogous phenomenon has already been observed for di-hadrons produced at forward rapidity in $\mathrm{d}+\mathrm{Au}$ and $\mathrm{p}+\mathrm{p}$ collisions at RHIC. In that case, di-hadron production proceeds from valence quarks in the deuteron (proton) scattering on small- $x$ gluons in the target Au nucleons (proton), $q_{V}+\mathrm{Au}(\mathrm{p}) \rightarrow \mathrm{h}_{1}+\mathrm{h}_{2}+\mathrm{X}$. Lacking direct experimental control over $x$, the onset of the saturation regime is controlled by changing the centrality of the collision, the di-hadron rapidity and the transverse momenta of the produced particles. Experimentally, a striking flattening of the $\Delta \phi$ peak in $\mathrm{d}+\mathrm{Au}$ collisions is observed in central collisions, but the peak reappears in peripheral collisions or for mid-rapidity di-hadrons. Directly using a point-like electron probe, as opposed to a quark bound in a proton or deuteron, is extremely beneficial. It is experimentally much cleaner as there is no "spectator" background to subtract and the access to the exact kinematics of
the process allows for more accurate extraction of the physics than is possible at RHIC or in the future with $\mathrm{p}+\mathrm{A}$ collisions at the LHC. Because there is such a clear correspondence between the physics of this particular final state in $\mathrm{e}+\mathrm{A}$ collisions to the same in $\mathrm{p}+\mathrm{A}$ collisions, this measurement is an excellent testing ground for quantitative studies of the universality of multi-gluon correlations in $\mathrm{p}+\mathrm{A}$ and $\mathrm{e}+\mathrm{A}$ collisions.

The simplest process to extract the transverse momentum dependence of the gluon distribution is single inclusive DIS (SIDIS), $e+\mathrm{A} \rightarrow e+\mathrm{h}+\mathrm{X}$. One reason why these processes are especially interesting is that by having two momentum scales at one's disposal, it is possible to keep $Q^{2}$ large and access the saturation regime at transverse momenta $p_{T} \lesssim Q_{s}$. This way, non-perturbative effects and higher-twist contributions are suppressed, but one can nonetheless access non-linear QCD dynamics. Considering that $Q_{s}$ will not exceed a few GeV at an EIC, this helps one disentangle strong coupling effects, characterized by a fixed scale ( $\Lambda_{Q C D}$ ), from weak coupling non-linear effects more cleanly relative to inclusive observables. Furthermore, in the large $Q^{2}$ and small $x$ limits, the relation between the transverse momentum of the produced hadron $p_{T}$ and that of the small-x glue $k_{T}$ is quite direct, enabling a rather straightforward experimental probe of the gluon transverse momentum distribution. From the theoretical point of view, important connections have been established between the framework of Transverse Momentum Dependent (TMD) distributions discussed previously in this report and the CGC effective theory at small $x$. Thus SIDIS has all the pre-requisites to be considered a golden observable. It is nonetheless classified as silver because di-hadron correlations are more directly sensitive to non-linear QCD evolution.

## Transverse position dependence of gluons and sea-quarks

To pin down the transverse distribution and correlations of small- $x$ gluons, exclusive measurements are needed. The prototypical observables discussed are diffractive vector meson production (DVMP) and deeply virtual Compton scattering (DVCS). Coherent diffraction, where the nuclear target is intact, gives access to the transverse spatial distribution of the gluon density in a nucleus. Incoherent diffraction, where the nuclear target breaks up, but is separated by a rapidity gap from the projectile fragmentation region, allows one to extract, in addition, transverse plane correlations. These shed important light on the spatial picture of the partonic sub-structure of nuclei. In addition, both contribute crucial information necessary to understand the spatial gluon distributions that form the initial conditions for heavy ion collisions. $J / \Psi$ meson production off nuclei is the most widely considered exclusive channel; those of other vector mesons $\rho, \phi$ ) provide important complementary information. DVCS, though luminosity hungry, is free of the uncertainty from incomplete knowledge of vector meson wave-functions.

Coherent diffractive $J / \Psi$ production has been extensively discussed as potentially the golden measurement in this category. However, while the physics goals are golden, the technical challenges are formidable. Coherent diffraction dominates over incoherent diffraction only at rather low values of $t$. It was determined that a rejection of the target-dissociation background with at least $95 \%$ efficiency is required in order to measure the coherent cross section up to large enough momentum transfers, and a 20 MeV resolution on the momentum transfer is also needed in order to extract precise enough information in impact parameter space. While this measurement is more feasible in light nuclei, it becomes more challenging in heavier nuclei. For light nuclei, coherent diffraction could shed important light on short range nuclear forces. For larger nuclei, it is unclear at present whether what one learns is
distinguishable from the distribution of gluons obtained from the Woods-Saxon distribution of nucleons in the nucleus; the ability for coherent diffraction to distinguish between different dynamical models for large nuclei is disputed. For these reasons, it is classed as a silver measurement.

Studies of the incoherent regime of diffractive vector meson production are slowly but surely emerging. This process is a priori more sensitive to high parton densities than is coherent diffraction. This is because it is much easier to measure at large $t$, corresponding to small values of $b$, nearer the center of the nucleus where the gluon density is the largest. However, the amount of information that can be extracted from nuclear fragments is not clear, since the theoretical description of the nuclear break-up remains a challenge. The minimum requirement is to be able to identify if the nucleus breaks up into its constituent nucleons or if the nucleons themselves break-up, as the corresponding calculations require different theoretical tools. Neither experimental or theoretical works on this process are mature enough to classify it as a golden measurement. However, the effects predicted by saturation models are large and unique enough that an observation of these will be convincing evidence of this physics. Therefore, both theoretical and experimental studies of this channel should be pursued vigorously.

### 5.1.3 Parton substructure of nuclei

Nuclear deep-inelastic scattering with an EIC will provide a unique measurement of gluon and sea quark densities in the "dilute" regime at $x \gtrsim 0.01$ in a range of nuclei. While the quark densities in the region $0.05 \lesssim x \lesssim 0.6$ were studied in fixed target experiments and will be further explored at JLab with 12 GeV electron beams, the behaviour of the gluon and sea quark densities in this region is essentially unknown. An EIC will have sufficient coverage in $Q^{2}$ to extract the nuclear gluon density through the $Q^{2}$ dependence of the nuclear structure function $F_{2}^{A}$. Furthermore, direct access to gluons can be gained from the longitudinal structure function $F_{L}^{A}$ through measurements at different beam energies, or additionally, by tagging charm production.

A reliable determination of the nuclear gluon density in the dilute regime is essential for a quantitative assessment of the onset of the new QCD regime of high parton densities and non-linear gluon interactions, which will be more widely accessible at a full-energy EIC. At $x \gtrsim 0.1$, an EIC will also explore gluon anti-shadowing and EMC effects - a step that might prove as revolutionary for our understanding of nuclei as the discovery of the quark EMC effect 30 years ago. For these reasons, inclusive $F_{2, L}$ structure function measurements at larger $x$ complement those discussed for the small- $x$ regime.

As it turns out, the high luminosity envisaged for an EIC enables measurements of nuclear electromagnetic structure functions up to $x \approx 1$ competitively with, or even surpassing, what has been achieved to date in fixed target experiments. (Since the maximum $x$ in a nucleus is $A$, collider high luminosity measurements could uncover interesting physics in the Fermi regime where partons carry more more momenta than a bound nucleon.) Furthermore, the large $Q^{2}$ range and hadronic event reconstruction capabilities will also likely allow measurement of charged current structure functions, and possibly of $\gamma-Z$ interference structure functions. See the chapter on electroweak physics for further discussion. This will enable full quark flavour separation utilising only nuclear DIS data, and offer, for example, new handles on the origin of the EMC effect such as its flavour dependence. In this context, one should also mention the possibility of extracting information on particular twist four operators, which play an important role in parity violating DIS in the EMC region.

These measurements are highly interesting, important, and in some cases unique to an EIC compared to previous facilities. However, more work is needed to establish to what extent full flavour separation can be effectively carried out at an EIC; we therefore classify them as silver measurements.

Much more information on the nuclear modification of the quark/gluon structure of the proton and neutron can be gained from deep-inelastic measurements with detection of the spectator system of $(A-1)$ nucleons in the final state. In particular, measurements on deuterium with a spectator proton can measure structure functions of the bound neutron ranging from nearly on-shell to far off-shell, facilitating the extrapolation to an on-shell neutron. Measurements with a spectator neutron, which are extremely difficult with a fixed target but feasible at a collider using a zero degree calorimeter, provide completely new information on the off-shell proton structure functions, and constrain theoretical models by comparison to the well known free proton wave function. With heavier nuclear targets, one could explore the effects of parton/nucleon embedding in a complex nuclear environment. While no technical difficulty is foreseen, detailed studies of the required detectors are needed to determine the feasibility and precision of these measurements.

### 5.1.4 Parton propagation and hadronization in nuclear matter

The transition from coloured partons (quarks and gluons) to colourless hadrons - the so-called hadronization or fragmentation process - exemplifies a fundamental process in QCD which still lacks a quantitative understanding from first principles calculations. Fragmentation functions, which encode the probability that a parton fragments into a hadron, have been obtained by fitting experimental data covering large kinematic ranges and numerous hadron species. However, knowledge about the dynamics of the process remains limited and model dependent. A particular model, see figure 5.2, posits a separation of scales between a short time scale for colour neutralization due to confinement generating a colourless "pre-hadron" and a longer time scale (presumably controlled by chiral symmetry breaking), which governs the formation of hadrons. The dynamical consequences of such a model are distinguishable from other models where the separation of scales is reversed or is non-existent. Extracting these time scales would be an important step towards understanding how hadrons emerge dynamically from partons, complementing the information on properties of colour confinement extracted from lattice measurements of ground state "static" correlators.

Nuclear deep inelastic scattering (nDIS) provides a known and stable nuclear medium ("cold QCD matter") and a final state with strong experimental control on the kinematics of the hard scattering. This permits one to use nuclei as femtometer-scale detectors of the hadronization process, see figure 5.2. In fact, both the energy loss due to medium-induced gluon bremsstrahlung off a quasi-free parton and the pre-hadron re-interaction with the surrounding nucleons lead to attenuation and transverse momentum broadening of hadron yields compared to proton targets, and allow experimental access to the space-time evolution of hadronization. Theoretical models of this process can be calibrated in nDIS and then applied, for example, to the study of the Quark-Gluon Plasma ("hot QCD matter") created in high-energy nucleus-nucleus collisions.

The combination of high energy and luminosity offered by an EIC promises a truly qualitative advance in this field, compared with current and planned fixed target experiments. The large $Q^{2}$ range permits measurements in the fully calculable perturbative regime with enough leverage to determine nuclear modifications in the QCD evolution of

Figure 5.2. Parton propagation and hadronization in cold and hot nuclear matter. A scenario of possibly distinct colour neutralization $\left(t_{C N}\right)$ and hadron formation $\left(t_{F}\right)$ time scales is illustrated on the vertical time axis.
fragmentation functions; the high-luminosity permits the multidimensional binning necessary for separating the many competing effects and for detecting rare hadrons. The large $\nu$ range ( $\approx 10-1000 \mathrm{GeV}$ ) allows one to experimentally boost the hadronization process in and out of the nuclear medium, in order to isolate in-medium parton propagation effects (large $\nu$ ) and cleanly extract colour neutralization and hadron formation times (small $\nu$ ); furthermore, using the quark flavour separated nuclear PDFs expected from an EIC, one could analyze nuclear Drell-Yan data, which are free from hadronization effects, and isolate initial state parton energy loss from nuclear wave function effects, enabling a complete experimental study of colour charge interactions in cold nuclear matter. For the first time, one will be able to study hadronization of open charm and open bottom meson production in $e+A$ collisions, as well as the in-medium propagation of the associated heavy quarks: these allow one to fundamentally test high-energy QCD predictions for energy loss, and confront puzzling measurements of heavy flavour suppression in the Quark-Gluon Plasma at RHIC. Within a collider environment, one would also be able to separate target from current hadronization and cross-correlate these two, adding a new dimension to hadronization studies.

The scattered quarks and gluons, from which the final-state hadrons emerge, couple to other nuclear gluons. Good control over the colour neutralization time scale will allow one to use this internally created colour radiation to explore the structure of nuclear matter in close analogy with the well-known exploration of matter with electromagnetic radiation or electrically charged particles. Furthermore, an EIC with $\sqrt{ } s \gtrsim 30 \mathrm{GeV}$ will permit for the first time the measurement of jets and their substructure in $e+\mathrm{A}$ collisions, furnishing a novel and extensive set of observables which directly access quark energy loss and the as yet untested parton shower mechanism, fundamentally described in QCD and pervasive in applications to particle physics simulations. Jet nuclear modifications can also be directly related to the propagation of the coloured partons shower in the nuclear medium, and used to measure the cold nuclear matter transport coefficients which encode basic information on the non-perturbative soft gluon structure of the nuclei. These measurements are complementary to direct inclusive and diffractive structure functions measurements at small $x$ in accessing the high-density non-linear QCD regime, but are entirely feasible with a low-energy EIC.

The outlined parton propagation and hadronization program can for the most part be carried out in phase-I. In phase-II, we do not anticipate any qualitative new lesson will be
learned, while the increased energy and $Q^{2}$ range may prove useful, for instance, for more refined studies in the jet and heavy flavour sectors, and offering an increased reach towards small $x$ for nuclear gluon measurements via $2+1$ jet production.

In conclusion, due to the physics interest, theoretical interpretability and feasibility in phase-I, this jet and heavy quark study program as a whole was classified as a golden measurement for $e+\mathrm{A}$ collisions at an EIC, with light quark SIDIS classified as a silver measurement.

### 5.2 Review of linear and non-linear approaches in QCD at small-x

## Collinear factorization and DGLAP evolution

Anna M. Staśto
The evaluation of strong interaction cross-sections which involve hard scales is possible thanks to QCD factorization theorems. The latter are derived from first principles in QCD [716, 717] and allow the factorization of cross sections into hard scattering coefficients (computed in a perturbative expansion in the strong coupling constant) and parton densities which contain information about nonperturbative dynamics. Parton densities, due to their intrinsically non-perturbative nature, cannot be directly evaluated from first-principles lattice computations except perhaps in very limited kinematic windows. Nevertheless, their evolution with hard scale can be calculated. This is done usually using the renormalization group DGLAP equations,

$$
\begin{equation*}
\mu \frac{d}{d \mu} f_{j / h}(x, \mu)=\sum_{k} \int_{x}^{1} \frac{d z}{z} P_{j k}\left(z, \alpha_{s}(\mu)\right) f_{k / h}(x / z, \mu), \tag{5.1}
\end{equation*}
$$

with the splitting functions which have perturbative expansion in powers of the strong coupling constant $\alpha_{s}$,

$$
\begin{equation*}
P_{j k}\left(z, \alpha_{s}(\mu)\right)=\sum_{i}\left(\alpha_{s}(\mu)\right)^{i} P_{j k}^{(i)}(z) . \tag{5.2}
\end{equation*}
$$

Coefficient functions and splitting functions are known up to NNLO accuracy [4, 718, 5]. It has been found that at this order large corrections appear which are enhanced by the logarithmic terms in $1 / x$. The collinear approach suffers also from other limitations. The kinematical approximations mostly suitable for the evaluation of the inclusive observables are not sufficient for exclusive processes and can lead to large discrepancies [719].

There are also other direct indications of the breakdown of the fixed order approach. From the global fits [22, 43], it is known that the gluon density suffers from large uncertainties at the NLO level in the region of small values of $x$, and the gluon density even turns negative. Even though the gluon density is not a directly observable quantity, the aforementioned uncertainties propagate into the observable longitudinal structure function $F_{L}$. The problem is concentrated in the low $Q$ and low- $x$ region, though the uncertainties remain even at larger values of $Q$ when $x$ is decreased. A systematic study of the compatibility of the HERA deep inelastic data with DGLAP evolution has been performed in [720]. This analysis, originally based on the NNPDF1.2 analysis [681, 721], was then extended to the global NNPDF2.0 set, which includes the very precise combined HERA-I dataset as well as all the relevant hadronic data. A 'safe' region was defined as the one in which the non-DGLAP effects are expected to be negligible, and it was defined by the cut on low- $x$ and $Q$ data. A fit was then performed to the data that pass the cut and only belong to the safe region and the structure functions evaluated at different scales. It turned out that the prediction for the structure functions at low $Q^{2}$ obtained from the backward-evolution of the data above the cut exhibits a systematic downward trend. Thus the precise HERA measurements indicate that the fixed order DGLAP evolution is incompatible with the data in the low $Q^{2}$ and low $x$ region.

## Small- $x$ re-summations

Anna M. Staśto

Since the seminal works [59, 60], it is well known that observables at small $x$ receive substantial corrections due to the large logarithms $\alpha_{s} \ln 1 / x$ which need to be re-summed in this regime. The BFKL approach [59, 60] provides a framework for this summation and it is known up to next-to-leading logarithmic accuracy. The resulting evolution of the gluon Green's function provided by this framework is with respect to the $\ln 1 / x$ or rapidity variable, with the transverse momenta of the gluons being summed over all possible configurations. The evolution has the following form

$$
\begin{equation*}
G\left(Y ; \mathbf{k}, \mathbf{k}_{0}\right)=\delta^{(2)}\left(\mathbf{k}-\mathbf{k}_{0}\right)+\int d^{2} \mathbf{k}^{\prime} K\left(\mathbf{k}, \mathbf{k}^{\prime}\right) G\left(Y ; \mathbf{k}^{\prime}, \mathbf{k}_{0}\right), \tag{5.3}
\end{equation*}
$$

with the branching kernel having also the perturbative expansion

$$
\begin{equation*}
K\left(\mathbf{k}, \mathbf{k}^{\prime}\right)=\sum_{i}\left(\alpha_{s}(\mu)\right)^{i} K^{(i)}\left(\mathbf{k}, \mathbf{k}^{\prime}\right) . \tag{5.4}
\end{equation*}
$$

A solution for the gluon Green's function and therefore the resulting cross sections exhibit strong growth with the energy, the hard Pomeron, with the intercept being significantly larger than unity in the LO approximation, $\omega_{P}=1+\alpha_{s} N_{c} 4 \ln 2 / \pi$. This growth turns out to be incompatible with both the hadronic data and the data on structure functions from deep-inelastic scattering. NLL (next-to-leading-log) corrections [722, 723] turned out to be rather large numerically and point to the need for the resummation of subsequent powers of higher order corrections $\alpha_{s}^{k} \ln 1 / x$. The sizes of the various NLL corrections can be understood on physical grounds. Firstly, unlike in the DGLAP limit, the strong coupling constant is not naturally a small parameter. On top of that, the BFKL approach does not satisfy the momentum sum rule for the longi-

Figure 5.3. The intercept of the hard Pomeron extracted from the BFKL equation with fixed strong coupling in LL, NLL and re-summed cases. tudinal momentum fractions (the transverse momenta are however conserved, unlike in the collinear approach). The kinematical approximations made in the BFKL limit cannot be efficiently recovered by the truncated higher orders of the perturbative expansion.

The strategy of re-summation at small $x$ has been developed in a series of works [724, 725, 726, 727, 728. It involves the construction of the appropriate re-summed kernel of the form given by Eq. 5.4, which includes at the same time known terms in the expansion of the splitting function, Eq. 5.2. Although the details of the various approaches differ, there are common fundamental ingredients. The evolution in rapidity is subjected to kinematical constraints which originate from the requirement of the consistency of the

Figure 5.4. Left: The gluon Green's function extracted from the BFKL equation in LL and resummed cases. The coupling is running in all computations, and $\bar{k}$ denotes the scale at which the strong coupling is regularized. Right: The extracted effective splitting function from the re-summed approach: solid line. The scale was taken to be $Q=4.5 \mathrm{GeV}$. Dotted pink line indicates the LO DGLAP splitting function and the blue dashed indicates small $x$ part of the NNLO DGLAP. The dashed green line corresponds to the re-summed spliitting function from the $\omega$ expansion. The band correspond to the scale variation.
assumption about the Regge kinematics. The evolution is matched with the DGLAP evolution by including the splitting function at LO and NLO. The momentum sum rule is imposed onto the resulting re-summed splitting function. The running of the coupling is included into the evolution. Finally, matching to the NLL BFKL is performed with the suitable subtractions in order to avoid double counting. The resulting Green's function and splitting function turn out to be very stable with minimal variations across the different re-summation schemes.
c Gluon Green's function and the splitting function: In Fig. 5.3, we show the results on the intercept of the gluon Green's function in the case of the fixed strong coupling constant, obtained within the re-summation framework of [724]. The linear growth is given by the LO approximation. The NLO value of the intercept is significantly below the lowest order, and turns negative even for the intermediate values of $\alpha_{s}$. The re-summed result is between the NLO and LO, it exhibits clear growth with increasing values of the coupling constant, albeit much reduced with respect to the LO value and much closer to the phenomenology.

The rapidity dependence of the gluon Green's function is shown in Fig. 5.4 (left). The scale was chosen to be equal to $k=4.5 \mathrm{GeV}$. The reduction of the speed of growth is clear in the re-summed case. Also the scale variations are relatively small in this case.

By using the deconvolution of the integral equation, one can calculate the integrated gluon density. As a result, it is possible to solve the re-summed splitting function numerically. In this way, the perturbative and non-perturbative contributions are factorized in $Q^{2}$. In Fig. 5.4 (right), we show the results for the splitting function as a function of the momentum fraction for the re-summed case. It is compared with the results on the LO and NNLO (only small $x$ part) splitting functions. The results on the splitting function demonstrate that the small x growth is delayed to much smaller values of x (beyond HERA). The splitting function also has an interesting feature, namely that of the dip. It turns out that
this is a universal feature, present also in other schemes of re-summation. In general, it was found that the dip comes from the interplay between NNLO order and the re-summation.

Thus far, re-summation was demonstrated to give stable results for the gluon channel only. For the complete description, however, one needs to include quarks in the evolution. A matrix approach was developed which was shown to be consistent with the collinear matrix factorization of the parton densities in the singlet evolution 726. This approached enables the calculation of the anomalous dimensions matrix, which can be directly compared with the standard DGLAP matrix. It was shown that it is possible to incorporate NLLx BFKL + NLO DGLAP in this framework [726].

Conclusions and outlook: The small- $x$ regime requires a formalism which incorporates re-summation of the large terms $\alpha_{s} \ln 1 / x$. The BFKL formalism was extended to include re-summation to higher orders. This formalism includes both DGLAP NLO and BFKL NLL and higher order terms. Stability of the results was demonstrated for scale changes and model changes. There are certain universal and characteristic features which come from the solutions to the evolution equations: the rapid growth with $x$ is delayed to smaller values of $x$, and the splitting function has a minimum. A matrix model was developed which gives consistent results on the gluon Green's function and the splitting functions. For the complete framework, one needs to include the re-summed coefficient functions. Detailed fits to the data need to be performed. In this regard, the EIC will generate very important information on parton densities at small $x$, and in distinguishing small $x$ re-summation effects from higher twist saturation effects.

## Parton Saturation

## Yuri V. Kovchegov and Cyrille Marquet

The QCD description of hadrons in terms of quarks and gluons depends on the processes considered and on what part of the hadron wave function they are sensitive to. Consider a hadron moving at nearly the speed of light along the light cone direction $x^{+}$, with momentum $P^{+}$. Depending on their transverse momentum $k_{T}$ and longitudinal momentum $x P^{+}$, the virtual partons inside the hadron behave differently, reflecting the different regimes of the hadron wave function. Soft hadronic processes are mostly sensitive to the non-perturbative part of the wave function, they involve quantum fluctuations with transverse momenta of the order of $\Lambda_{Q C D} \sim 200 \mathrm{MeV}$. A hadron can then be thought of as a bound state of stronglyinteracting partons, but a QCD description of the associated dynamics is still lacking. By contrast, hard processes in hadronic collisions are sensitive to the weakly-coupled part of the wave function and resolve the partonic structure of hadrons. They probe partons with $k_{T} \gg \Lambda_{Q C D}$ whose QCD dynamics is better understood.

One can distinguish two weakly-coupling regimes in the wave function: a linear one called the hard regime, involving a small density of partons, typically with $x \lesssim 1$, in which the hadron looks like a dilute system of independent partons, and a non-linear one called the saturation regime, involving a large density of partons with $x \ll 1$, in which the hadron looks like a dense system of nevertheless weakly-interacting partons, mainly gluons (called small- $x$ gluons). The dilute-dense separation is a bit subtler than that: the larger $k_{T}$ is, the smaller $x$ needs to be to enter the saturation regime. Indeed the separation between the two regimes is characterized by a momentum scale $Q_{s}(x)$, called the saturation scale, which increases as $x$ decreases. In a scattering process, dilute partons (with $k_{T} \gg Q_{s}(x)$ ) behave
incoherently, while when the parton density is large $\left(k_{T} \lesssim Q_{s}(x)\right)$, gluons scatter coherently. The dynamics of the dilute regime is well described by the leading-twist approximation of QCD, whose hallmark is collinear factorization. As explained in the previous section, when $x$ becomes small while not yet reaching the non-linear regime, so-called small- $x$ re-summations are also needed to improve the approximation.

To describe the small- $x$ non-linear part of hadronic/nuclear wave functions in QCD, the Color Glass Condensate (CGC) effective theory was proposed. Rather than using the standard Fock-state expansion which is ineffective in dealing with numerous small-x gluons, the CGC approach employs collective degrees of freedom, static color sources at large $x$ and dynamical classical color fields at small $x$. The traditional approach to saturation physics consists of two stages, corresponding to two different levels of approximations. The first level corresponds to the classical gluon field description of nuclear wave functions and scattering cross sections. It re-sums all multiple re-scatterings in the nucleus, but lacks energy dependence. The latter is included through quantum corrections, which are re-summed by non-linear evolution equations. This constitutes the second level of approximation. We will present both stages below.

## Classical gluon fields

McLerran-Venugopalan model: Imagine a single large nucleus, which was boosted to some ultrarelativistic velocity, as shown in Fig. 5.5(left). We are interested in the dynamics of small- $x$ gluons in the wave function of this relativistic nucleus. The small- $x$ gluons interact with the whole nucleus coherently in the longitudinal direction: therefore, only the transverse plane distribution of nucleons is important for the small- $x$ wave function. As one can see from Fig. [5.5, after the boost, the nucleons, as "seen" by the small- $x$ gluons, appear to overlap with each other in the transverse plane, leading to high parton density. Large occupation numbers of color charges (partons) lead to classical gluon fields dominating the small- $x$ wave function of the nucleus. This is the essence of the McLerran-Venugopalan (MV) model [729, 730, 731]. According to the MV model, the dominant gluon field is given by the solution of the classical Yang-Mills equations $\mathcal{D}_{\mu} F^{\mu \nu}=J^{\nu}$ where the classical color current $J^{\nu}$ is generated by the valence quarks in the nucleons of the nucleus from Fig. 5.5.

Figure 5.5. Left: Large nucleus before and after an ultrarelativistic boost. Right: Unintegrated gluon distribution $\phi\left(x, k_{T}^{2}\right)$ of a large nucleus due to classical gluon fields (solid line). Dashed curve denotes the lowest-order perturbative result.

The Yang-Mills equations were solved for a single nucleus exactly [732, 733] resulting in the unintegrated gluon distribution $\phi\left(x, k_{T}^{2}\right)$ (multiplied by the phase space factor of the gluon's transverse momentum $k_{T}$ ) shown in Fig. 5.5 right as a function of $k_{T}$. (Note that in the MV model, $\phi\left(x, k_{T}^{2}\right)$ is independent of Bjorken-x.) Fig. 5.5 demonstrates the emergence
of the saturation scale $Q_{s}$. As one can see from Fig. 5.5, the majority of gluons in this classical distribution have transverse momentum $k_{T} \approx Q_{s}$. Since in this classical approximation $Q_{s}^{2} \sim A^{1 / 3}$, for a large enough nucleus, all of its small- $x$ gluons would have large transverse momenta $k_{T} \approx Q_{s} \gg \Lambda_{Q C D}$, justifying the applicability of the perturbative approach to the problem. Note that the gluon distribution slows down its growth with decreasing $k_{T}$ for $k_{T}<Q_{s}$ (from power-law of $k_{T}$ to a logarithm) and the distribution saturates.

DIS at high energy: Glauber-Mueller formula: Let us consider deep inelastic scattering (DIS) on a large nucleus. In DIS, the incoming electron emits a virtual photon, which in turn interacts with the proton or nucleus. In the rest frame of the nucleus, the interaction can be thought of as the virtual photon splitting into a quark-antiquark pair, which then interacts with the nucleus (see Fig. 5.6. left panel). Since the light cone lifetime of the $q \bar{q}$ pair is much longer than the size of the target nucleus, the total cross section for the virtual photon-nucleus scattering can be written as a convolution of the virtual photon's light cone wave function (the probability for it to split into a $q \bar{q}$ pair) with the forward scattering amplitude of a $q \bar{q}$ pair interacting with the nucleus

$$
\begin{equation*}
\sigma_{t o t}^{\gamma * A}\left(Q^{2}, x_{B j}\right)=\int \frac{d^{2} x d z}{2 \pi}\left[\Phi_{T}(\underline{x}, z)+\Phi_{L}(\underline{x}, z)\right] d^{2} b N(\underline{x}, \underline{b}, Y) \tag{5.5}
\end{equation*}
$$

with the help of the light-cone perturbation theory [734. Here the incoming photon with virtuality $Q$ splits into a quark-antiquark pair with the transverse separation $\underline{x}$ and the impact parameter (transverse position of the center of mass of the $q \bar{q}$ pair) $\underline{b}$. $Y$ is the rapidity variable given by $Y=\ln \left(s x_{T}^{2}\right) \approx \ln 1 / x_{B j}$. The square of the light cone wave function of $q \bar{q}$ fluctuations of a virtual photon is denoted by $\Phi_{T}(\underline{x}, z)$ and $\Phi_{L}(\underline{x}, z)$ for transverse and longitudinal photons correspondingly, with $z$ being the fraction of the photon's longitudinal momentum carried by the quark. At the lowest order in electromagnetic coupling ( $\alpha_{E M}$ ) $\Phi_{T}(\underline{x}, z)$ and $\Phi_{L}(\underline{x}, z)$ are given by [735, 736]

$$
\begin{gather*}
\Phi_{T}(\underline{x}, z)=\frac{2 N_{c}}{\pi} \sum_{f} \alpha_{E M}^{f}\left\{a_{f}^{2} K_{1}^{2}\left(x_{\perp} a_{f}\right)\left[z^{2}+(1-z)^{2}\right]+m_{f}^{2} K_{0}\left(x_{\perp} a_{f}\right)^{2}\right\},  \tag{5.6}\\
\Phi_{L}(\underline{x}, z)=\frac{2 N_{c}}{\pi} \sum_{f} \alpha_{E M}^{f} 4 Q^{2} z^{2}(1-z)^{2} K_{0}^{2}\left(x_{\perp} a_{f}\right) \tag{5.7}
\end{gather*}
$$

with $a_{f}^{2}=Q^{2} z(1-z)+m_{f}^{2}, x_{\perp}=|\mathbf{x}|$ and $\sum_{f}$ denoting the sum over all relevant quark flavors with quark masses denoted by $m_{f} . \alpha_{E M}^{f}=e_{f}^{2} / 4 \pi$ with $e_{f}$ the electric charge of a quark with flavor $f$.

Our first goal is to calculate the forward scattering amplitude of a quark-anti-quark dipole interacting with the nucleus, which is denoted by $N(\underline{x}, \underline{b}, Y)$ in Eq. (5.5), including all multiple re-scatterings of the dipole on the nucleons in the nucleus.To do this we need to construct a model of the target nucleus. We assume that the nucleons are dilutely distributed in the nucleus [737. There we can represent the dipole-nucleus interaction as a sequence of successive dipole-nucleon interactions, as shown in Fig. 5.6, right panel. Since each nucleon is a color singlet, the lowest order dipole-nucleon interaction in the forward amplitude from Fig. 5.6 is a two-gluon exchange. The exchanged gluon lines in Fig. 5.6 are disconnected at the top: this denotes a summation over all possible connections of these gluon lines either to the quark or to the anti-quark lines in the incoming dipole.

Figure 5.6. Left: Deep inelastic scattering in the rest frame of the target. Right: Deep inelastic scattering in the quasi-classical Glauber-Mueller approximation in $\partial_{\mu} A^{\mu}=0$ gauge.

Re-summation of the diagrams like the one in Fig. 5.6 yields [737]

$$
\begin{equation*}
N(\underline{x}, \underline{b}, Y=0)=1-\exp \left\{-\frac{x_{\perp}^{2} Q_{s}^{2}(\underline{b}) \ln \left(1 / x_{\perp} \Lambda\right)}{4}\right\} \tag{5.8}
\end{equation*}
$$

with the saturation scale defined by

$$
\begin{equation*}
Q_{s}^{2}(\underline{b}) \equiv \frac{4 \pi \alpha_{s}^{2} C_{F}}{N_{c}} \rho T(\underline{b}) \tag{5.9}
\end{equation*}
$$

Figure 5.7. The forward amplitude of the dipolenucleus scattering $N$,plotted as a function of the transverse separation between the quark and the anti-quark in a dipole ( $x_{\perp}$ ) using Eq. (5.8).

Here, $\rho$ is the density of nucleons in the nucleus ( $\rho=A /\left[(4 / 3) \pi R^{3}\right]$ for a spherical nucleus of radius $R$ with atomic number $A$ ) and $T(\underline{b})$ is the nuclear profile function equal to the length of the nuclear medium at a given impact parameter $\underline{b}$, such that $T(\underline{b})=2 \sqrt{R^{2}-\underline{b}^{2}}$ for a spherical nucleus. $\Lambda$ is an infrared cutoff. We put $Y=0$ in the argument of $N$ in Eq. (5.8) to underline that this expression does not include any small- $x$ evolution which would bring in the rapidity dependence.

Eqs. (5.8) and (5.9) allow us to determine the parameter corresponding to the re-summation of the diagrams like the one shown in Fig. 5.6. Noting that for large nuclei, the profile function scales as $T(\underline{b}) \sim$ $A^{1 / 3}$ and the nucleon density scales as $\rho \sim$ $A^{0}$, we conclude that the re-summation parameter of multiple re-scatterings is [738]: $\alpha_{s}^{2} A^{1 / 3}$. The physical meaning of the parameter $\alpha_{s}^{2} A^{1 / 3}$ is rather straightforward: at a given impact parameter the dipole interacts with $\sim A^{1 / 3}$ nucleons exchanging two gluons with each. Since the two-gluon exchange is parametrically of the order $\alpha_{s}^{2}$ we obtain $\alpha_{s}^{2} A^{1 / 3}$ as the re-summation parameter for the quasi-classical approximation.

The dipole amplitude $N$, from Eq. (5.8), is plotted (schematically) in Fig. 5.7 as a function of $x_{\perp}$. One can see that, at small $x_{\perp}, x_{\perp} \ll 1 / Q_{s}$, we have $N \sim x_{\perp}^{2}$ and the amplitude is a rising function of $x_{\perp}$. However, at large dipole sizes $x_{\perp} \gtrsim 1 / Q_{s}$, the growth stops and the amplitude levels off (saturates) at $N=1$. This regime corresponds to the black disk limit for the dipole-nucleus scattering where, for large dipoles, the nucleus appears
as a black disk. To understand that the $N=1$ regime corresponds to the black disk limit, let us note that the total dipole-nucleus scattering cross section is given by:

$$
\begin{equation*}
\sigma_{t o t}^{q \bar{q} A}=2 \int d^{2} b N(\underline{x}, \underline{b}, Y) \tag{5.10}
\end{equation*}
$$

where the integration goes over the cross sectional area of the nucleus. If $N=1$ at all impact parameters $\underline{b}$ inside the nucleus, for a spherical nucleus of radius $R$, Eq. (5.10) becomes $\sigma_{t o t}^{q \bar{q} A}=2 \bar{\pi} R^{2}$, which is a well-known formula for the cross section of a particle scattering on a black sphere [739].

The transition between the $N \sim x_{\perp}^{2}$ to $N=1$ behavior in Fig. 5.7 happens at around $x_{\perp} \sim 1 / Q_{s}$. For dipole sizes $x_{\perp} \gtrsim 1 / Q_{s}$, the amplitude $N$ saturates to a constant. This translates into the saturation of quark distribution functions in the nucleus, as was shown in [737] (as $x q+x \bar{q} \sim F_{2} \sim \sigma_{t o t}^{\gamma * A}$ ), and thus can be identified with parton saturation, justifying the name of the saturation scale.

Before we proceed, let us finally note that since $T(\underline{b}) \sim A^{1 / 3}$, the saturation scale in Eq. (5.9) scales as $Q_{s}^{2} \sim A^{1 / 3}$ with the nuclear atomic number [730, 731, 729, 737]. This implies that for a very large nucleus, the saturation scale would become very large, much larger than $\Lambda_{Q C D}$. If $Q_{s} \gg \Lambda_{Q C D}$, the transition to the black disk limit in Fig. 5.7 happens at momentum scales (corresponding to inverse dipole sizes) where the physics is perturbative and gluons are the correct degrees of freedom.

## Nonlinear evolution equations

General picture: While the classical gluon fields of the MV model exhibit many correct qualitative features of saturation physics, and give predictions about the $A$-dependence of observables which may be compared to the data, they do not lead to any rapidity/Bjorken$x$ dependence of the corresponding observables, which is essential in the data on nuclear and hadronic collisions. To include rapidity dependence, one has to calculate quantum corrections to the classical fields described above.

Figure 5.8. Nonlinear small- $x$ evolution of a hadronic or nuclear wave functions. All partons (quarks and gluons) are denoted by straight solid lines for simplicity.

The inclusion of quantum corrections is accomplished by the small- $x$ evolution equations. The first small- $x$ evolution equation was constructed before the birth of saturation physics. This is the Balitsky-Fadin-Kuraev-Lipatov (BFKL) evolution equation [60, 59]. This is a linear evolution equation, which is illustrated by the first term on the right hand side of Fig. 5.8. Consider a wave function of a high-energy nucleus or hadrons: it contains many partons, as shown on the left of Fig. 5.8. As we make one step of evolution by boosting the nucleus/hadron to higher energy, either one of the partons can split into two partons,
leading to an increase in the number of partons proportional to the number of partons $N$ at the previous step,

$$
\begin{equation*}
\frac{\partial N\left(x, k_{T}^{2}\right)}{\partial \ln (1 / x)}=\alpha_{s} K_{B F K L} \otimes N\left(x, k_{T}^{2}\right) \tag{5.11}
\end{equation*}
$$

with $K_{B F K L}$ an integral kernel. Clearly the BFKL equation (5.11) introduces a Bjorken$x /$ rapidity dependence in the observables it describes.

The main problem with the BFKL evolution is that it leads to the power-law growth of the total cross sections with energy, $\sigma_{t o t} \sim s^{\alpha_{P}-1}$, with the BFKL pomeron intercept $\alpha_{P}-1=\left(4 \alpha_{s} N_{c} \ln 2\right) / \pi>0$. Such a power-law cross section increase violates the Froissart bound, which states that the total hadronic cross section can not grow faster than $\ln ^{2} s$ at very high energies. Moreover, the power-law growth of cross sections with energy violate the black disk limit known from quantum mechanics: the high-energy total scattering cross section $\sigma_{t o t}$ of a particle on a sphere of radius $R$ is bounded by $2 \pi R^{2}$ (note the factor of 2 which is due to quantum mechanics, this is not simply a hard sphere from classical mechanics!).

We see that something has to modify Eq. (5.11) at high energy. The modification is illustrated on the far right of Fig. [5.8: at very high energies, partons may start to recombine with each other on top of the splitting. The recombination of two partons into one is proportional to the number of pairs of partons, which, in turn, scales as $N^{2}$. We end up with the following non-linear evolution equation:

$$
\begin{equation*}
\frac{\partial N\left(x, k_{T}^{2}\right)}{\partial \ln (1 / x)}=\alpha_{s} K_{B F K L} \otimes N\left(x, k_{T}^{2}\right)-\alpha_{s}\left[N\left(x, k_{T}^{2}\right)\right]^{2} . \tag{5.12}
\end{equation*}
$$

This is the Balitsky-Kovchegov (BK) evolution equation [740, 741, which is valid for QCD in the limit of large number of colors $N_{c}$. An equation of this type was originally suggested by Gribov, Levin and Ryskin [742] and by Mueller and Qiu [743, though at the time it was assumed that the quadratic term is only the first non-linear correction with higher order terms possibly appearing as well: in [740, 741 the exact form of the equation was found, and it was shown that in the large- $N_{c}$ limit, Eq. (5.12) does not have any higherorder terms in $N$. Generalization of Eq. (5.12) beyond the large- $N_{c}$ limit is accomplished by the Jalilian-Marian-Iancu-McLerran-Weigert-Leonidov-Kovner (JIMWLK) [744, 745] evolution equation, which is a functional differential equation. Both the BK and JIMWLK evolution equations will be discussed in more details later.

The physical impact of the quadratic term on the right of Eq. (5.12) is clear: it slows down the small- $x$ evolution, leading to parton saturation and to total cross sections adhering to the black disk limit. The effect of gluon mergers becomes important when the quadratic term in Eq. (5.12) becomes comparable to the linear term on the right-hand-side. This gives rise to the saturation scale $Q_{s}$, which now grows with energy (on top of its increase with $A$ ).

The Balitsky-Kovchegov equation: Let us now include the energy dependence in the dipole amplitude $N$ from Eq. (5.8). Similar to the BFKL evolution equation [59, 60, we are interested in quantum evolution in the leading longitudinal logarithmic approximation re-summing the powers of $\alpha_{s} \ln \frac{1}{x_{B j}} \sim \alpha_{s} Y$, with $Y$ the rapidity variable. Again we will be working in the rest frame of the nucleus, but this time we choose to work in the light cone gauge of the projectile $A^{+}=0$ if the dipole is moving in the light cone + direction.

Leading logs in $x$ corrections appear in the diagrams through emissions of long-lived $s$-channel gluons, as shown in Fig. [5.9. These $s$-channel gluons interact with the target

Figure 5.9. Quantum corrections to dipole-nucleus scattering.
nucleus through multiple re-scatterings. In the large- $N_{c}$ limit of QCD such diagrams can be re-summed by the BK evolution equation [740, 746, 741, 747]:

$$
\begin{align*}
\frac{\partial N\left(\underline{x}_{0}, \underline{x}_{1}, Y\right)}{\partial Y}=\frac{\alpha_{s} C_{F}}{\pi^{2}} \int d^{2} x_{2} \frac{x_{01}^{2}}{x_{20}^{2} x_{21}^{2}}\left[N\left(\underline{x}_{0}, \underline{x}_{2}, Y\right)\right. & +N\left(\underline{x}_{2}, \underline{x}_{1}, Y\right)-N\left(\underline{x}_{0}, \underline{x}_{1}, Y\right) \\
& \left.-N\left(\underline{x}_{0}, \underline{x}_{2}, Y\right) N\left(\underline{x}_{2}, \underline{x}_{1}, Y\right)\right] \tag{5.13}
\end{align*}
$$

where we have redefined the arguments of $N$ to depend on the transverse coordinates of the quark and antiquark (instead of dipole size and the impact parameter as was done in Eq. (5.8)). Here $x_{i j}=\left|\underline{x}_{i j}\right|$ and $\underline{x}_{i j}=\underline{x}_{i}-\underline{x}_{j}$.

Figure 5.10. Diagrammatic representation of the nonlinear evolution equation (5.13).
In the large- $N_{c}$ limit, gluon cascades reduce to a cascade of color dipoles. Summation of the dipole cascade is illustrated in Fig. 5.10 where the dipole cascade and its interaction with the target are denoted by a shaded oval. In one step of the evolution in energy (or rapidity) a soft gluon is emitted in the dipole. If the gluon is real, than the original dipole would be split into two dipoles, as shown in Fig. 5.10. Either one of these dipoles can interact with the nucleus with the other one not interacting, which is shown by the first term on the right hand side of Fig. 5.10 with the factor of 2 accounting for the fact that there are two dipoles in the wave function now. Alternatively, both dipoles may interact simultaneously, which is shown by the second term on the right hand side of Fig. 5.10. This term comes in with the minus sign. The emitted gluon in one step of evolution may be a virtual correction, which is not shown in Fig. 5.10: in that case, the original dipole would not split into two, it would remain the same and would interact with the target. In the end, the evolved system of dipoles interacts with the nucleus. In the large- $N_{c}$ limit, each dipole does not interact with other dipoles during the evolution which generates all the dipoles. For a large nucleus, the dipole-nucleus interaction was given above in Eq. (5.8). That result re-sums powers of $\alpha_{s}^{2} A^{1 / 3}$ : hence the BK equation re-sums powers of $\alpha_{s} Y$ and powers of $\alpha_{s}^{2} A^{1 / 3}$.

## Map of high-energy QCD

Solutions of the BK and JIMWLK evolution equations have been calculated numerically [748, 749, 750], with asymptotic limits studied analytically. The numerical solution

Figure 5.11. Left: Solutions of the BK equation at rapidities $\mathrm{Y}=0,5,15$ and 30 (curves are labeled from right to left) for the three different running coupling schemes considered in [751] Right: HERA data on the total DIS $\gamma^{*} p$ cross section plotted in [752] as a function of the scaling variable $\tau=$ $Q^{2} / Q_{s}^{2}\left(x_{B j}\right)$.
(for the BK equation with running coupling, which will be described later) is presented in Fig. 5.11751 . These plots are the same dipole amplitude $N$ plotted as a function of the dipole size labeled $r$ as was done in Fig. 5.7. In Fig. 5.11, different curves correspond to different energies/rapidities $Y$. One can clearly see that the curves tend to drift to the left with increasing energies, corresponding to increasing saturation scale with the energy/rapidity. Therefore we see that the saturation scale increases with rapidity, making the corresponding physics more perturbative.

We summarize our knowledge of high energy QCD in Fig. [5.12, in which different regimes are plotted in the $\left(Q^{2}, Y=\ln 1 / x\right)$ plane, by analogy with DIS. For hadronic and nuclear collisions one can think of typical transverse momentum $p_{T}^{2}$ of the produced particles instead of $Q^{2}$. Also rapidity $Y$ and Bjorken- $x$ variable are interchangeable. On the left of Fig. 5.12 we see the region with $Q^{2} \leq \Lambda_{Q C D}^{2}$ in which the coupling is large, $\alpha_{s} \sim 1$, and small-coupling approaches do not work. In the perturbative region, $Q^{2} \gg \Lambda_{Q C D}^{2}$, we see the standard DGLAP evolution and the linear BFKL evolution. The BFKL equation evolves gluon distributions toward small- $x$, where parton densities becomes large and parton saturation sets in. The transition to saturation is described by the non-linear BK and JIMWLK evolution equations. Most importantly, this transition happens at $Q_{s}^{2} \gg \Lambda_{Q C D}^{2}$ where the small-coupling approach is valid.

One of the most important predictions of nonlinear small-x evolution is that, at high enough rapidity, the scattering amplitude $N$ (and, consequently, DIS structure functions) would be a function of a single variable $x_{\perp} Q_{s}(Y)$, such that $N\left(x_{\perp}, Y\right)=N\left(x_{\perp} Q_{s}(Y)\right)$. This prediction is spectacularly confirmed by HERA data. Geometric scaling has been demonstrated in an analysis of the HERA DIS data [752], presenting one of the strongest arguments for the observation of saturation phenomena at HERA. These results are shown here in Fig. 5.11 from [752], where the authors combined HERA data on the total DIS $\gamma^{*} p$ cross section $\sigma_{\text {tot }}^{\gamma^{*} p}$ for $x_{B j}<0.01$ as a function of the scaling variable $\tau=Q^{2} / Q_{s}^{2}\left(x_{B j}\right)$. One can see that, amazingly enough, all the data falls on the same curve, indicating that $\sigma_{\text {tot }}^{\gamma^{*} p}$ is a function of a single variable $Q^{2} / Q_{s}^{2}\left(x_{B j}\right)$ ! This gives us the best to date experimental proof of geometric scaling. (For a similar analysis of DIS data on nuclear targets see [753].)

Figure 5.12. Map of high energy QCD in the $\left(Q^{2}, Y=\ln 1 / x\right)$ plane.

The fact that geometric scaling is a property of the solution of the BK equation was later demonstrated in 754, 755.

## Universality aspects of the Color Glass Condensate

François Gelis
The Color Glass Condensate (CGC) is an effective field theory (EFT) based on the separation of the degrees of freedom into fast frozen color sources and slow dynamical color fields [729, [731, 730]. A renormalization group equation -the JIMWLK equation [756, 757, 758, 759, 760, 761, 745, 762, 763]- ensures the independence of physical quantities with respect to the cutoff that separates the two kinds of degrees of freedom.

The fast gluons with longitudinal momentum $k^{+}>\Lambda^{+}$are frozen by Lorentz time dilation in configurations specified by a color current $J_{a}^{\mu} \equiv \delta^{\mu+} \rho^{a}$, where $\rho^{a}\left(x^{-}, x_{\perp}\right)$ is the corresponding color charge density. On the other hand, slow gluons with $k^{+}<\Lambda^{+}$are described by the usual gauge fields $A^{\mu}$ of QCD. Because of the hierarchy in $k^{+}$between these two types of degrees of freedom, they are coupled eikonaly by a term $J_{\mu} A^{\mu}$. The fast gluons thus act as sources for the fields that represent the slow gluons. Although it is frozen for the duration of a given collision, the color source density $\rho^{a}$ varies randomly event by event. The CGC provides a gauge invariant distribution $W_{\Lambda^{+}}[\rho]$, which gives the probability of a configuration $\rho$. This encodes all the correlations of the color charge density at the cutoff scale $\Lambda^{+}$, separating the fast and slow degrees of freedom. Given this statistical distribution, the expectation value of an operator at the scale $\Lambda^{+}$is given by

$$
\begin{equation*}
\langle\mathcal{O}\rangle_{\Lambda^{+}} \equiv \int[D \rho] W_{\Lambda^{+}}[\rho] \mathcal{O}[\rho], \tag{5.14}
\end{equation*}
$$

where $\mathcal{O}[\rho]$ is the expectation value of the operator for a particular configuration $\rho$ of the color sources.

The power counting of the CGC EFT is such that in the saturated regime, the sources $\rho$ are of order $g^{-1}$. Attaching an additional source to a given Feynman graph does not alter its order in $g$; the vertex where this new source attaches to the graph is compensated by the
$g^{-1}$ of the source. Thus, computing an observable at a certain order in $g^{2}$ requires the resummation of all the contributions obtained by adding extra sources to the relevant graphs. The leading order in $g^{2}$ is given by a sum of tree diagrams, which can be expressed in terms of classical solutions of the Yang-Mills equations. Moreover, for inclusive observables [764, 765], these classical fields obey a simple boundary condition: they vanish when $t \rightarrow-\infty$.

Next-to-leading order (NLO) computations in the CGC EFT involve a sum of one-loop diagrams embedded in the above classical field. To prevent double counting, momenta in loops are required to be below the cutoff $\Lambda^{+}$. This leads to a logarithmic dependence in $\Lambda^{+}$of these loop corrections. These logarithms are large if $\Lambda^{+}$is well above the typical longitudinal momentum scale of the observable considered, and must be re-summed.

For inclusive observables, the leading logarithms are universal and can be absorbed into a redefinition of the distribution $W_{\Lambda^{+}}[\rho]$ of the hard sources. The evolution of $W_{\Lambda^{+}}[\rho]$ with $\Lambda^{+}$is governed by the functional JIMWLK equation

$$
\begin{equation*}
\frac{\partial W_{\Lambda^{+}}[\rho]}{\partial \ln \left(\Lambda^{+}\right)}=-\mathcal{H}\left[\rho, \frac{\delta}{\delta \rho}\right] W_{\Lambda^{+}}[\rho] \tag{5.15}
\end{equation*}
$$

where $\mathcal{H}$ is known as the JIMWLK Hamiltonian. This operator contains up to two derivatives $\partial / \partial \rho$, and arbitrary powers in $\rho$. Its explicit expression can be found in refs. [756, 757, 758, 759, 760, 761, 745, 762, 763, 766, 767]. The derivation of the JIMWLK equation will be sketched below.

Numerical studies of JIMWLK evolution were performed in [750, 768]. An analytic, albeit formal, solution to the JIMWLK equation was constructed in 769 in the form of a path integral. Alternatively, the evolution can can be expressed as an infinite hierarchy of coupled non-linear equations for $n$-point Wilson line correlators-often called the Balitsky hierarchy [770]. In this framework, the BK equation is a mean field approximation of the JIMWLK evolution, valid in the limit of a large number of colors $N_{c} \rightarrow \infty$. Numerical studies of the JIMWLK equation [750, 768] have found only small differences with the BK equation.

Let us finally comment on the initial condition for the JIMWLK equation which is also important in understanding its derivation. The evolution should start at some cutoff value in the longitudinal momentum scale $\Lambda_{0}^{+}$at which the saturation scale is already a (semi)hard scale, say $Q_{s 0} \gtrsim 1 \mathrm{GeV}$, for perturbation theory to be applicable. The gluon distribution at the starting scale is in general non-perturbative and requires a model. A physically motivated model for the gluon distribution in a large nucleus is the McLerran-Venugopalan model [729, 731, 730]. In a large nucleus, there is a window in rapidity where evolution effects are not large but $x$ is still sufficiently small for a probe not to resolve the longitudinal extent of the nucleus. In this case, the probe "sees" a large number of color charges, proportional to $A^{1 / 3}$. These charges add up to form a higher dimensional representation of the gauge group, and can therefore be treated as classical color distributions [729, 731, 730, 771, Further, the color charge distribution $W_{\Lambda_{0}^{+}}[\rho]$ is a Gaussian distribution ${ }^{11}$ in $\rho$. The variance of this distribution -the color charge squared per unit area- is proportional to $A^{1 / 3}$ and provides a semi-hard scale that makes weak coupling computations feasible. In addition to its role in motivating the EFT and serving as the initial condition in JIMWLK evolution, the MV model allows for direct phenomenological studies in $\mathrm{p}+\mathrm{A}$ and $\mathrm{A}+\mathrm{A}$ collisions in

[^275]regimes where the values of $x$ are not so small as to require evolution.
The CGC in DIS at small $x$ : We denote $\sigma_{\text {dipole }}\left(x, \boldsymbol{r}_{\perp}\right)$ the QCD "dipole" cross-section for the quark-antiquark pair to scatter off the target. This process is shown in fig. 5.13 left, where we have assumed that the target moves in the $-z$ direction. In the leading order (LO) CGC description of DIS, the target is described, as illustrated in fig. 5.13 right, as static sources with $k^{-}>\Lambda_{0}^{-}$. The field modes do not contribute at this order.

Figure 5.13. Left: LO and NLO contributions to DIS off the CGC. Top right: sources and fields in the CGC effective theory. Bottom right: NLO correction from a layer of field modes just below the cutoff.

Employing the optical theorem, $\sigma_{\text {dipole }}\left(x, \boldsymbol{r}_{\perp}\right)$ can be expressed in terms of the forward scattering amplitude $\boldsymbol{T}\left(\boldsymbol{x}_{\perp}, \boldsymbol{y}_{\perp}\right)$ of the $q \bar{q}$ pair at LO as

$$
\begin{equation*}
\sigma_{\text {dipole }}^{\mathrm{LO}}\left(x, \boldsymbol{r}_{\perp}\right)=2 \int d^{2} \mathbf{b} \int[D \rho] W_{\Lambda_{0}^{-}}[\rho] \boldsymbol{T}_{\mathrm{LO}}\left(\boldsymbol{b}+\frac{\boldsymbol{r}_{\perp}}{2}, \boldsymbol{b}-\frac{\boldsymbol{r}_{\perp}}{2}\right), \tag{5.16}
\end{equation*}
$$

where, for a fixed configuration of the target color sources [775, (776]

$$
\begin{equation*}
\boldsymbol{T}_{\mathrm{LO}}\left(\boldsymbol{x}_{\perp}, \boldsymbol{y}_{\perp}\right)=1-\frac{1}{N_{c}} \operatorname{tr}\left(U\left(\boldsymbol{x}_{\perp}\right) U^{\dagger}\left(\boldsymbol{y}_{\perp}\right)\right), \tag{5.17}
\end{equation*}
$$

with $U\left(\boldsymbol{x}_{\perp}\right)$ a Wilson line representing the interaction between a quark and the color fields of the target, defined to be

$$
\begin{equation*}
U\left(\boldsymbol{x}_{\perp}\right)=\mathrm{T} \exp i g \int^{1 / x P^{-}} d z^{+} \mathcal{A}^{-}\left(z^{+}, \boldsymbol{x}_{\perp}\right) . \tag{5.18}
\end{equation*}
$$

In this formula, $\mathcal{A}^{-}$is the minus component of the gauge field generated (in Lorentz gauge) by the sources of the target; it is obtained by solving classical Yang-Mills equations with these sources. The upper bound $x P^{-}$(where $P^{-}$is the target longitudinal momentum) indicates that source modes with $k^{-}<x P^{-}$do not contribute to this scattering amplitude. Thus if the cutoff $\Lambda_{0}^{-}$of the CGC EFT is lower than $x P^{-}, \boldsymbol{T}_{\mathrm{LO}}$ is independent of $\Lambda_{0}^{-}$.

However, when $\Lambda_{0}^{-}$is larger than $x P^{-}$, the dipole cross-section is in fact independent of $x$ (since the CGC EFT does not have source modes near the upper bound $x P^{-}$) and depends on the unphysical parameter $\Lambda_{0}^{-}$. As we shall see now, this is related to the fact that eq. (5.16) is incomplete and receives large corrections from higher order diagrams. Consider now the NLO contributions (one of them is shown in the right panel in figure 5.13 left with gauge field modes in the slice $\Lambda_{1}^{-} \leq k^{-} \leq \Lambda_{0}^{-}$(see fig. 5.13 right). An explicit computation of the contribution of field modes in this slice gives

$$
\begin{equation*}
\delta \boldsymbol{T}_{\mathrm{NLO}}\left(\boldsymbol{x}_{\perp}, \boldsymbol{y}_{\perp}\right)=\ln \left(\frac{\Lambda_{0}^{-}}{\Lambda_{1}^{-}}\right) \mathcal{H} \boldsymbol{T}_{\mathrm{LO}}\left(\boldsymbol{x}_{\perp}, \boldsymbol{y}_{\perp}\right), \tag{5.19}
\end{equation*}
$$

where $\mathcal{H}$ is the JIMWLK Hamiltonian. All dependence on the cutoff scales is in the logarithmic prefactor alone. This Hamiltonian has two derivatives with respect to the classical field $\mathcal{A} \sim \mathcal{O}(1 / g) ; \mathcal{H} \boldsymbol{T}_{\mathrm{LO}}$ is of order $\alpha_{s} \boldsymbol{T}_{\mathrm{LO}}$ and therefore clearly an NLO contribution. However, if the new scale $\Lambda_{1}^{-}$is such that $\alpha_{s} \ln \left(\Lambda_{0}^{-} / \Lambda_{1}^{-}\right) \sim 1$, this NLO term becomes comparable in magnitude to the LO contribution. Averaging the sum of the LO and NLO contributions over the distribution of sources at the scale $\Lambda_{0}^{-}$, one obtains

$$
\begin{equation*}
\int[D \rho] W_{\Lambda_{0}^{-}}[\rho]\left(\boldsymbol{T}_{\mathrm{LO}}+\delta \boldsymbol{T}_{\mathrm{NLO}}\right)=\int[D \rho] W_{\Lambda_{1}^{-}}[\rho] \boldsymbol{T}_{\mathrm{LO}}, \tag{5.20}
\end{equation*}
$$

where $W_{\Lambda_{1}^{-}} \equiv\left(1+\ln \left(\Lambda_{0}^{-} / \Lambda_{1}^{-}\right) \mathcal{H}\right) W_{\Lambda_{0}^{-}}$. We have shown here that the NLO correction from quantum modes in the slice $\Lambda_{1}^{-} \leq k^{-} \leq \Lambda_{0}^{-}$can be absorbed in the LO term, provided we now use a CGC effective theory at $\Lambda_{1}^{-}$with the modified distribution of sources shown in eq. (5.20). In differential form, the evolution equation of the source distribution is the JIMWLK equation stated previously.

Repeating this elementary step, one progressively re-sums quantum fluctuations down to the scale $k^{-} \sim x P^{-}$. Thanks to eq. (5.20), the result of this re-summation for the dipole cross-section is formally identical to eq. (5.16), except that the source distribution is $W_{x P^{-}}$ instead of $W_{\Lambda_{0}^{-}}$. Note that if one further lowers the cutoff below $x P^{-}$, the dipole crosssection remains unchanged.

The CGC in A+A collisions: Collisions between two nuclei ("dense-dense" scattering) are complicated to handle on the surface. However, in the CGC framework, because the wave functions of the two nuclei are saturated, the collision can be treated as the collision of classical fields coupled to fast partons of each nucleus respectively described by the external current $J^{\mu}=\delta^{\mu+} \rho_{1}+\delta^{\mu-} \rho_{2}$. The source densities of fast partons $\rho_{1,2}$ are both parametrically of order $1 / g$, which implies that graphs involving multiple sources from both projectiles must be re-summed.

At leading order, inclusive observables ${ }^{2}$ depends on the retarded classical color field $\mathcal{A}^{\mu}$, which solves the Yang-Mills equations $\left[\mathcal{D}_{\mu}, \mathcal{F}^{\mu \nu}\right]=J^{\nu}$ with the boundary condition $\lim _{x^{0} \rightarrow-\infty} \mathcal{A}^{\mu}=0$. Among the observables to which this result applies is the expectation value of the energy-momentum tensor at early times after the collision. At leading order,

$$
\begin{equation*}
T_{\mathrm{LO}}^{\mu \nu}=\frac{1}{4} g^{\mu \nu} \mathcal{F}^{\lambda \sigma} \mathcal{F}_{\lambda \sigma}-\mathcal{F}^{\mu \lambda} \mathcal{F}_{\lambda}^{\nu}, \tag{5.21}
\end{equation*}
$$

where $\mathcal{F}^{\mu \nu}$ is the field strength of the classical field $\mathcal{A}^{\mu}$.
Although $\mathrm{A}+\mathrm{A}$ collisions are more complicated than $\mathrm{e}+\mathrm{A}$ or $\mathrm{p}+\mathrm{A}$ collisions, one can still factorize the leading higher order corrections into the evolved distributions $W_{\Lambda^{-}}\left[\rho_{1}\right]$ and $W_{\Lambda^{+}}\left[\rho_{2}\right]$. At the heart of this factorization is a generalization of eq. (5.19) to the case where the two projectiles are described in the CGC framework [777, 778, 779]. When one integrates out the field modes in the slices $\Lambda_{1}^{ \pm} \leq k^{ \pm} \leq \Lambda_{0}^{ \pm}$, the correction to the energy momentum tensor is

$$
\begin{equation*}
\delta T_{\mathrm{NLO}}^{\mu \nu}=\left[\ln \left(\frac{\Lambda_{0}^{-}}{\Lambda_{1}^{-}}\right) \mathcal{H}_{1}+\ln \left(\frac{\Lambda_{0}^{+}}{\Lambda_{1}^{+}}\right) \mathcal{H}_{2}\right] T_{\mathrm{LO}}^{\mu \nu} \tag{5.22}
\end{equation*}
$$

where $\mathcal{H}_{1,2}$ are the JIMWLK Hamiltonians of the two nuclei respectively. What is crucial here is the absence of mixing between the coefficients $\mathcal{H}_{1,2}$ of the logarithms of the two

[^276]projectiles; they depend only on $\rho_{1,2}$ respectively and not on the sources of the other projectile. Although the proof of this expression is somewhat involved, the absence of mixing is deeply rooted in causality. The central point is that because the duration of the collision (which scales as the inverse of the energy) is so brief, soft radiation must occur before the two nuclei are in causal contact. Thus logarithms associated with this radiation must have coefficients that do not mix the sources of the two projectiles.

Following the same procedure for eq. (5.22), as for the e+A and p+A cases, one obtains for the energy-momentum tensor in an $\mathrm{A}+\mathrm{A}$ collision the expression

$$
\begin{equation*}
\left\langle T^{\mu \nu}\right\rangle_{\mathrm{LLog}}=\int\left[D \rho_{1} D \rho_{2}\right] W_{1}\left[\rho_{1}\right] W_{2}\left[\rho_{2}\right] T_{\mathrm{LO}}^{\mu \nu} \tag{5.23}
\end{equation*}
$$

This result can be generalized to multi-point correlations of the energy-momentum tensor,

$$
\begin{equation*}
\left\langle T^{\mu_{1} \nu_{1}}\left(x_{1}\right) \cdots T^{\mu_{n} \nu_{n}}\left(x_{n}\right)\right\rangle_{\mathrm{LLog}}=\int\left[D \rho_{1} D \rho_{2}\right] W_{1}\left[\rho_{1}\right] W_{2}\left[\rho_{2}\right] T_{\mathrm{LO}}^{\mu_{1} \nu_{1}}\left(x_{1}\right) \cdots T_{\mathrm{LO}}^{\mu_{n} \nu_{n}}\left(x_{n}\right) . \tag{5.24}
\end{equation*}
$$

In this expression, all the correlations between the energy-momentum tensor at different points are from the distributions $W_{1,2}\left[\rho_{1,2}\right]$. Thus, the leading correlations are already built into the wavefunctions of the projectiles prior to the collision.

Note that the expressions in eqs. (5.23) and (5.24) are valid for proper times $\tau \sim 1 / Q_{s}$ after the heavy ion collision. Complicated final state effects, possibly driven by instabilities, are expected to bring this non-equilibrium gluonic matter into a quark-gluon plasma. Although this aspect of $\mathrm{A}+\mathrm{A}$ collisions is very different from what happens in DIS reactions, the Color Glass Condensate provides a universal description of the hadronic and nuclear wavefunctions prior to the collision in both cases, and a powerful framework to show that the logarithms of the collision energy are universal for inclusive enough observables. Thanks to this universality, measurements at small $x$ in $\mathrm{e}+\mathrm{A}$ collisions can provide valuable constraints on the distributions $W[\rho]$ for a nucleus, that can then be used in order to compute the state of the system formed at early times in A+A collisions.

## Shadowing

## Boris Z. Kopeliovich

In terms of the dipole formalism, nuclear shadowing is related to the interaction of different Fock components of the projectile particle with the nuclear target. The lowest Fock states (i.e. $\gamma^{*} \rightarrow \bar{q} q$ ) are responsible for higher twist shadowing, while higher Fock components (i.e. $\gamma^{*} \rightarrow \bar{q} q g$ ) give rise to leading twist gluon shadowing.

Quark shadowing: The magnitude of higher twist shadowing is controlled by the interplay between two fundamental quantities.
(i) The lifetime of photon fluctuations, or coherence time.

$$
\begin{equation*}
l_{c}=\frac{2 \nu}{Q^{2}+M^{2}}=\frac{P}{x_{B j} m_{N}}=P l_{c}^{\max }, \tag{5.25}
\end{equation*}
$$

where $x_{B j}=Q^{2} / 2 m_{N} \nu, M$ is the effective mass of the fluctuation, $P=\left(1+M^{2} / Q^{2}\right)^{-1}$, and $l_{c}^{\max }=1 / m_{N} x_{B j}$. The usual approximation is to assume that $M^{2} \approx Q^{2}$ since $Q^{2}$ is the only large dimensional scale available. In this case, $P=1 / 2$ and the corresponding value of $l_{c}$ is called Ioffe length of time.

Shadowing is possible only if the coherence time exceeds the mean nucleon spacing in nuclei, and shadowing saturates (for a given Fock component) if the coherence time substantially exceeds the nuclear radius.
(ii) Equally important for shadowing is the transverse separation of the $\bar{q} q$. This controls the dipole-nucleon cross section $\sigma_{\bar{q} q}^{N}(r)$, and correspondingly the total nuclear cross section 780, 781,

$$
\begin{equation*}
\left(\sigma_{\text {tot }}^{\gamma^{*} A}\right)_{l c \gg R_{A}}^{T, L}=2 \int d \alpha \int d^{2} r\left|\Psi_{\bar{q} q}^{T, L}(\varepsilon r)\right|^{2} \int d^{2} b\left[1-\exp \left(-\frac{1}{2} \sigma_{q \bar{q}}^{N}(r) T_{A}(b)\right)\right] \tag{5.26}
\end{equation*}
$$

where the perturbative light-cone distribution function for the $\bar{q} q$ has the form [782, 783],

$$
\begin{equation*}
\Psi_{\bar{q} q}^{T, L}\left(\vec{r}_{T}, \alpha\right)=\frac{\sqrt{\alpha_{e m}}}{2 \pi} \bar{\chi} \widehat{O}^{T, L} \chi K_{0}\left(\epsilon r_{T}\right) ; \tag{5.27}
\end{equation*}
$$

$\chi$ and $\bar{\chi}$ are the spinors of the quark and antiquark respectively; $K_{0}\left(\epsilon r_{T}\right)$ is the modified Bessel function; $\epsilon^{2}=\alpha(1-\alpha) Q^{2}+m_{q}^{2}$; and the operators $\widehat{O}^{T, L}$ for transversely and longitudinally polarized photons have the form,

$$
\begin{gather*}
\widehat{O}^{T}=m_{q} \vec{\sigma} \cdot \vec{e}+i(1-2 \alpha)(\vec{\sigma} \cdot \vec{n})\left(\vec{e} \cdot \vec{\nabla}_{r}\right)+(\vec{\sigma} \times \vec{e}) \cdot \vec{\nabla}_{r},  \tag{5.28}\\
\widehat{O}^{L}=2 Q \alpha(1-\alpha) \vec{\sigma} \cdot \vec{n} . \tag{5.29}
\end{gather*}
$$

Here $\vec{n}=\vec{p} / p$ is a unit vector parallel to the photon momentum; $\vec{e}$ is the polarization vector of the photon; $m_{q}$ and and $\alpha$ are the mass, and fractional light-cone momentum carried by the quark. See also eqs. (5.6) and (5.7) discussed previously.

In order to be shadowed, a $\bar{q} q$-fluctuation of the photon has to interact with a large cross section. As a result of color transparency [780, [784], small size dipoles with $r^{2} \sim$ $1 / Q^{2}$ interact only weakly and are therefore less shadowed. The dominant contribution to shadowing comes from the aligned jet configurations $(\alpha \rightarrow 0,1)$ [785] of $\bar{q} q$ pairs, which have large transverse separation, $\left\langle r^{2}\right\rangle \sim 1 /\left[Q^{2} \alpha(1-\alpha)\right]$ according to (5.27). Although the weight of such configurations is small, $1 / Q^{2}$, this is compensated by the large interaction cross section [786].

The coherence length (Eq. (5.25)) averaged over interacting $|\bar{q} q\rangle$ and $|\bar{q} q g\rangle$ fluctuations calculated in [787] is presented in Fig. 5.14. The mean values of the factor $P=l_{c} / l_{c}^{\max }$ in (5.25) are plotted for $\bar{q} q$ fluctuations of transverse and longitudinal photons, as well as for $\bar{q} q g$ fluctuations as a function of $Q^{2}$ at fixed $x_{B j}$ (left panel). We see that $\bar{q} q$ fluctuations in a longitudinal photon live about twice as long as in a transverse one. Both are different from $P=1 / 2$ corresponding to the Ioffe time. The lifetime of the higher order Fock states containing gluons is about order of magnitude shorter.

Onset of shadowing: Eq. (5.26) describing quark shadowing is valid only in the limit of $l_{c} \gg R_{A}$, i.e. at very small $x_{B j}$ where the magnitude of shadowing nearly saturates. However, all available data for DIS on nuclei are in the region of shorter coherence length, and one needs theoretical tools to describe the onset of shadowing.

The Gribov theory of inelastic shadowing [791] relates nuclear shadowing to the cross section of diffractive dissociation. In the case of a deuteron target, this approach provides a full and model independent description of shadowing. The onset of shadowing can be accurately calculated, since the phase shift $\Delta z / l_{c}$ between the impulse approximation term and the inelastic shadowing term is under control. However, a description of shadowing

Figure 5.14. Left panel: Factor $\left\langle P^{T, L}\right\rangle$ and $\left\langle P^{g}\right\rangle$ defined in (5.25) for $\bar{q} q$ fluctuations of transverse and longitudinal photons, and for $\bar{q} q g$ fluctuations, from the top to bottom. Calculations are done as a function of $Q^{2}$ at $x_{B j}=0.01$. Dotted curves correspond to perturbative wave functions and an approximate dipole cross section $\propto r_{T}^{2}$. Dashed curves rely on the realistic parameterization for the dipole cross section [788]. The solid curves show the most realistic case based on the nonperturbative wave functions. Right panel: Comparison between calculations for quark shadowing and experimental data from NMC [789, 790] for the structure functions of different nuclei relative to carbon as function of $x_{B j}$. The $Q^{2}$ range covered by the data is approximately $3 \mathrm{GeV}^{2} \leq Q^{2} \leq 17 \mathrm{GeV}^{2}$ from the lowest to the highest $x_{B j}$ bin. Solid and dashed curves are calculated with and without the real part of the light-cone potential in (5.31).
for heavy nuclei is a challenge in this approach. Indeed, only the lowest order of Gribov corrections can be calculated using data on diffraction. The higher order corrections, illustrated in Fig. 5.15a, need information unavailable from data, like the diffractive amplitudes between different excited states, $X^{*}, X^{* *}$, the attenuation of these states in the nuclear medium, etc.

a

b

Figure 5.15. a: A high order term in Gribov inelastic shadowing corrections to $F_{2}^{A}\left(x, Q^{2}\right)$; b: Dipole description based on the path integral technique, which sums up the Gribov corrections in all orders.

An alternative description with the path integral technique was proposed in [787. One should sum up over all possible trajectories of the quark and antiquark propagating through the nucleus, as is illustrated in Fig. 5.15 b. This leads to the 2-dimensional Schrödinger equation for the Green function describing propagation of a dipole with initial (final) transverse
separation $\vec{r}_{1}\left(\vec{r}_{2}\right)$ at longitudinal coordinate $z_{1}\left(z_{2}\right)$,

$$
\begin{equation*}
\left[i \frac{\partial}{\partial z_{2}}+\frac{\Delta_{\perp}\left(r_{2}\right)-\varepsilon^{2}}{2 \nu \alpha(1-\alpha)}+\frac{i}{2} \rho_{A}\left(b, z_{2}\right) \sigma_{q \bar{q}}^{N}\left(r_{2}\right)-\frac{a^{4}(\alpha) r_{2}^{2}}{2 \nu \alpha(1-\alpha)}\right] G\left(r_{2}, z_{2} \mid r_{1}, z_{1}\right)=0 \tag{5.30}
\end{equation*}
$$

The last two terms represent the imaginary and real parts of the light cone potential. The former describes the attenuation of the dipole in the nuclear medium, while the latter models the non-perturbative interactions inside the dipole. Solving this equation, one can calculate the shadowing corrections as

$$
\begin{align*}
& \left(\sigma_{\text {tot }}^{\gamma^{*} A}\right)^{T, L}=A\left(\sigma_{\text {tot }}^{\gamma^{*} N}\right)^{T, L}-\frac{1}{2} R e \int d^{2} b \int_{0}^{1} d \alpha \int_{-\infty}^{\infty} d z_{1} \int_{z_{1}}^{\infty} d z_{2} \int d^{2} r_{1} \int d^{2} r_{2}  \tag{5.31}\\
\times & {\left[\Psi_{\bar{q} q}^{T, L}\left(\varepsilon, \lambda, r_{2}\right)\right]^{*} \rho_{A}\left(b, z_{2}\right) \sigma_{q \bar{q}}^{N}\left(s, r_{2}\right) G\left(r_{2}, z_{2} \mid r_{1}, z_{1}\right) \rho_{A}\left(b, z_{1}\right) \sigma_{q \bar{q}}^{N}\left(s, r_{1}\right) \Psi_{\bar{q} q}^{T, L}\left(\varepsilon, \lambda, r_{1}\right) }
\end{align*}
$$

At $l_{c} \ll 1 / \rho \sigma$, the second term vanishes. For $l_{c} \gg R_{A}$, it saturates at the value given by Eq. (5.26). The numerical results are compared with data from the NMC experiment [789, 790] in the right panel of Fig. 5.14. The solid and dashed curves are calculated with and without the real part of the light-cone potential in (5.31). It worth emphasizing that this is a parameter-free calculation, no adjustment to nuclear data has been done. The dipole cross section was fitted to DIS data on a proton.

Note that these calculations were performed for the lowest Fock component $|\bar{q} q\rangle$ of the photon; they miss gluon shadowing related to the higher Fock states containing gluons.

Gluon shadowing: Gluon shadowing is related to specific channels of diffractive gluon radiation. In terms of Regge phenomenology, these processes correspond to the triplePomeron contribution, and can be seen in data as the large mass tail of the invariant mass distribution, $d \sigma_{d i f f} / d M_{X}^{2} \propto 1 / M_{X}^{2}$. Such an $M_{X}^{2}$-dependence is the undebatable evidence of radiation of a vector particle, i.e. a gluon.

Data show that the magnitude of diffractive gluon radiation is amazingly small. The way to see that is to express the single diffraction cross section in terms of the Pomeronproton cross section as is illustrated in the left panel of Fig. 5.16. The Pomeron can be

Figure 5.16. Left panel: The amplitude squared of diffractive excitation of the projectile proton, summed over all the excitations with invariant mass $M_{X}$, is related via the optical theorem with the total Pomeron-proton cross section at c.m. energy $M_{X}$. Right panel: The Pomeron-proton cross section extracted 792 from data on single diffraction $p p \rightarrow p X$ as function of $\mathbb{P}-p$ c.m. squared.
treated as a gluonic dipole and its cross section is expected to be about twice as big as for a $\bar{q} q$ dipole, i.e. $\sigma_{t o t}^{\mathbb{P P} p} \sim 50 \mathrm{mb}$. However, data depicted in the right panel of Fig. 5.16 show
that $\sigma_{\text {tot }}^{\mathbb{P p}}<2 \mathrm{mb}$. Such a dramatic disagreement gives a clue that diffractive gluon radiation is strongly suppressed compared with the expectation based on pQCD . This problem has been known in the Regge phenomenology as smallness of the triple-Pomeron coupling [793].

Gluon radiation can be described within the dipole approach via the propagation of a $\bar{q} q g$ dipole through the nuclear medium [794]. As the mean fractional momentum of the radiated gluon is very small, $\left\langle\alpha_{g}\right\rangle \sim 1 / \ln (s)$, one can rely on eq. (5.26) for very small $x_{B j}$, or eqs. (5.30)-(5.31) for the onset of gluon shadowing, by replacing $\sigma_{\bar{q} q}(r) \Rightarrow \sigma_{g g}(r)$. The only way to explain the observed suppression of gluon radiation is to reduce the mean size of the glue-glue dipole. This can be achieved by introducing a specifically strong nonperturbative interaction within the glue-glue dipole, which comes as the real part of the light-cone potential in eq. (5.30). Adjusting the strength of this interaction to data on diffractive gluon radiation (triple-Pomeron term) one arrives at the light-cone distribution functions in (5.26) and (5.31) with the mean glue-glue separation $r_{0} \approx 0.3 \mathrm{fm}$ [795]. This distance is smaller than the confinement radius $\sim 1 / \Lambda_{Q C D}=1 \mathrm{fm}$ and is in accord with the lattice evaluations of the $g g$ correlation radius [796], and the instanton radius [797]. There is more experimental evidence supporting the existence of a semi-hard scale in hadrons [798].

Thus, the magnitude of gluon shadowing evaluated in [795, 799] is expected to be rather small, as is depicted in Fig. 5.17. The nuclear ratio $R_{g}=G_{A}\left(x, Q^{2}\right) / A G_{N}\left(x, Q^{2}\right)$ is plotted as a function of $x_{B j}$ at $Q^{2}=4$ and $40 \mathrm{GeV}^{2}$ (left panel); and as a function of the path length in nuclear matter at $Q^{2}=4 \mathrm{GeV}^{2}$ and different values of $x_{B j}$.

Figure 5.17. Left panel: Ratio of the gluon distribution functions in nuclei (carbon, copper and lead) and nucleons versus Bjorken $x$ at $Q^{2}=4 \mathrm{GeV}^{2}$ (solid curves) and $40 \mathrm{GeV}^{2}$ (dashed curves) [795). Right panel: Nuclear ratio $R_{g}=G_{A}\left(x, Q^{2}\right) / A G_{N}\left(x, Q^{2}\right)$ for gluons as function of path length in nuclear matter, calculated in 799 at $Q^{2}=4 \mathrm{GeV}^{2}$ for several fixed values of $x$.

The path-integral approach is the most accurate method, which is valid in all regimes of gluon radiation, from incoherent to fully coherent. Nevertheless, this is still the lowest order calculation, which might be a reasonable approximation only for light nuclei, or for the onset of shadowing. The contribution of higher Fock components is still a challenge. This problem has been solved so far only in the unrealistic limit of long coherence lengths for all radiated gluons, described by the Balitsky-Kovchegov (BK) equation [740, 741. A numerical solution of this equation is quite complicated and includes lots of modelling [800]. A much simpler bootstrap equation, which only requires modelling the shape of the saturated gluon distribution, was derived in [801. It includes the self-quenching effect for gluon shadowing, and leads to a gluon distribution in nuclei which satisfies the unitarity bound 802 The results are quite similar to the numerical solutions of the BK equation 800. The magnitude of the self-quenched gluon shadowing found in 801 is similar to the above results obtained in the leading order.

## Leading-twist nuclear shadowing

## Vadim Guzey and Mark Strikman

Nuclear shadowing in hadron (photon)-nucleus scattering is the firmly established experimental phenomenon that at high energies the scattering cross section on a nuclear target is smaller than the sum of the scattering cross sections on the individual nucleons. In the nucleus rest frame, the theory of nuclear shadowing is based on the connection between nuclear shadowing and diffraction which has been established long time ago by Gribov [791]. In the derivation, the key assumption is that nuclei can be described as dilute systems of nucleons. The accuracy of the resulting theory for hadron-nucleus cross sections is very high, with the corrections at the level of a few $\%$ which reflect the small admixture of nonnucleonic degrees of freedom in nuclei and the small off-shellness of the nucleons in nuclei as compared to the soft strong interaction scale. Gribov's result can be understood 803] as a manifestation of unitarity as reflected in the Abramovsky-Gribov-Kancheli (AGK) cutting rules 804 .

The connection between shadowing and diffraction is also valid in deep inelastic scattering (DIS) with nuclei; the approach based on this connection is called the leading twist theory of nuclear shadowing [803, 805, 806, 807. In this theory, parton distribution functions (PDFs) in nuclei at small $x$ are calculated combining the unitarity relations for different cuts of the shadowing diagrams corresponding to the diffractive and inelastic final states (AGK cutting rules) with the QCD factorization theorem for hard diffraction 808 (which provides a good description of the totality of the HERA hard diffractive data). The resulting multiple scattering series for the quark nuclear PDFs is presented in fig. 5.18, where graphs $a, b$, and $c$ correspond to the interaction with one, two, and three nucleons of the target, respectively. Graph $a$ gives the impulse approximation; graphs $b$ and $c$ contribute to the shadowing correction. The interaction with $N>3$ nucleons, though not shown, is taken into account in the final expression for nuclear PDFs.

At the level of the interaction with two nucleons of a nucleus with the atomic mass number $A$, one can derive the model-independent expression for the shadowing correction to the nuclear PDF of flavor $j$ [803] (corresponding to graph $b$ of fig. [5.18):

$$
\begin{align*}
x f_{j / A}^{(b)}\left(x, Q^{2}\right) & =-8 \pi A(A-1) \Re e \frac{(1-i \eta)^{2}}{1+\eta^{2}} \int_{x}^{0.1} d x_{\mathbb{P}} \beta f_{j}^{D(4)}\left(\beta, Q^{2}, x_{\mathbb{P}}, t_{\min }\right) \\
& \times \int d^{2} \vec{b} \int_{-\infty}^{\infty} d z_{1} \int_{z_{1}}^{\infty} d z_{2} \rho_{A}\left(\vec{b}, z_{1}\right) \rho_{A}\left(\vec{b}, z_{2}\right) e^{i\left(z_{1}-z_{2}\right) x_{\mathbb{P}} m_{N}}, \tag{5.32}
\end{align*}
$$

where $f_{j}^{D(4)}$ is the diffractive parton distribution of the nucleon; $\rho_{A}$ is the nuclear matter density; $\eta$ is the ratio of the real to imaginary parts of the elementary diffractive amplitude, $\eta=\Re e A^{\text {diff }} / \Im m A^{\text {diff }} \approx 0.17$. The diffractive $\operatorname{PDF} f_{j}^{D(4)}$ depends on two light-cone fractions $x_{\mathbb{P}}=\left(M_{X}^{2}+Q^{2}\right) /\left(W^{2}+Q^{2}\right)$ and $\beta=x / x_{\mathbb{P}}$ and the invariant momentum transfer $t$, where $W$ is the invariant virtual photon-nucleon energy, $W^{2}=(q+p)^{2}$, and $M_{X}^{2}$ is the invariant mass squared of the produced intermediate diffractive state denoted as "X" in fig. 5.18. The longitudinal (collinear with the direction of the photon momentum) coordinates $z_{1}$ and $z_{2}$ and the transverse coordinate (impact parameter) $\vec{b}$ refer to the two interacting nucleons; $m_{N}$ is the nucleon mass. The $t$ dependence of $f_{j}^{D(4)}$ can be safely neglected as compared to the strong fall-off of the nuclear form-factor for $A>4$ and, as a result, $f_{j}^{D(4)}$ enters eq. (5.32) at $t_{\min } \approx-x^{2} m_{N}^{2}\left(1+M_{X}^{2} / Q^{2}\right)^{2}$ and all nucleons enter with the same impact

Figure 5.18. Multiple scattering series for nuclear quark PDFs. Graphs $a, b$, and $c$ correspond to the interaction with one, two, and three nucleons, respectively. Graph $a$ gives the impulse approximation; graphs $b$ and $c$ contribute to the shadowing correction.
parameter $\vec{b}$. Equation (5.32) satisfies the QCD evolution equations at all orders in the strong coupling constant $\alpha_{s}$.

To evaluate the contribution to nuclear shadowing of the interactions with $N \geq 3$ nucleons in fig. 5.18, one needs to invoke additional model-dependent considerations, since the interaction of a hard probe (virtual photon) with $N \geq 3$ nucleons is sensitive to fine details of the diffractive dynamics. In particular, the hard probe can be viewed as a coherent superposition of configurations which interact with the target nucleons with very different strengths. This effect of color (cross section) fluctuations is analogous to the inelastic shadowing in hadron-nucleus scattering with the important difference that the dispersion of the interaction strengths is much smaller in the hadron case than in DIS. However, the observation that $\alpha_{\mathbb{P}}(0)=1.11$ found in the analysis of hard diffraction at HERA [809] is very close to $\alpha_{P}^{\text {soft }}(0)=1.08$ in soft hadronic interactions [810] indicates that hard diffraction in DIS is dominated by large-size hadron-like (aligned jet) configurations which evolve to large $Q^{2}$ via the DGLAP evolution. (As to the point-like configurations, they give an important and increasing with $Q^{2}$ contribution to graph $a$ in fig. 5.18.)

This important observation reduces theoretical uncertainties in the treatment of the interactions with $N \geq 3$ nucleons and allows one to reliably parameterize the strength of the interaction with $N \geq 3$ nucleons by a single effective hadron-like cross section $\sigma_{\text {soft }}^{j}$. The final expression for the nuclear PDFs at a certain initial scale $Q_{0}^{2}$ reads [806, 807]:

$$
\begin{align*}
x f_{j / A}\left(x, Q_{0}^{2}\right) & =A x f_{j / N}\left(x, Q_{0}^{2}\right) \\
& -8 \pi A(A-1) \Re e \frac{(1-i \eta)^{2}}{1+\eta^{2}} \int_{x}^{0.1} d x_{\mathbb{P}} \beta f_{j}^{D(4)}\left(\beta, Q_{0}^{2}, x_{\mathbb{P}}, t_{\min }\right) \int d^{2} b \int_{-\infty}^{\infty} d z_{1} \\
& \int_{z_{1}}^{\infty} d z_{2} \rho_{A}\left(\vec{b}, z_{1}\right) \rho_{A}\left(\vec{b}, z_{2}\right) e^{i\left(z_{1}-z_{2}\right) x_{\mathbb{P}} m_{N}} e^{-\frac{A}{2}(1-i \eta) \sigma_{\text {soft }}^{j}\left(x, Q_{0}^{2}\right) \int_{z_{1}}^{z_{2}} d z^{\prime} \rho_{A}\left(\vec{b}, z^{\prime}\right)} . \tag{5.33}
\end{align*}
$$

Due to the QCD factorization theorem, these nuclear PDFs $f_{j / A}\left(x, Q^{2}\right)$ can be used to calculate many different observables at small $x$ including the nuclear structure function $F_{2 A}$ and the longitudinal structure function $F_{L}^{A}$, the charmed contributions to these structure functions $F_{2 A}^{c}$ and $F_{L}^{A(c)}$, etc.; $f_{j / A}\left(x, Q^{2}\right)$ can also be applied to the calculations of hard processes in heavy-ion collisions.

Removing the integration over $d^{2} b$ in right-hand side of eq. (5.33), one obtains the impact parameter dependent nuclear PDFs (nuclear GPDs in the $\xi=0$ limit in the impact parameter representation) 807, see Section 5.9.1.

Figure 5.19. The leading twist theory of nuclear shadowing predictions for $f_{j / A} /\left(A f_{j / N}\right)$ ( $\bar{u}$ and $c$ quarks and gluons) and $F_{2 A} /\left(A F_{2 N}\right)$ as functions of $x$ at $Q_{0}^{2}=4 \mathrm{GeV}^{2}$. The two sets of curves correspond to the two extreme scenarios of nuclear shadowing (see the text).

In our analysis 807, we used two models for the color fluctuations in the virtual photon which correspond to two models for $\sigma_{\text {soft }}^{j}$ which cover essentially all reasonable possibilities for the resulting nuclear shadowing. An example of our predictions for the gluon, $\bar{u}$ quark, $c$-quarks, and $F_{2 A}$ structure functions is presented in fig. 5.19 for the two scenarios for $\sigma_{\text {soft }}^{j}$ that we have mentioned above (labeled FGS10_H and FGS10_L). As one can see from fig. 5.19, we predict large nuclear shadowing for each singlet parton flavor with the characteristic feature that nuclear shadowing in the gluon channel is larger than that in the quark channel. The difference between the two extreme scenarios of color fluctuations (the solid and dotted curves in fig. 5.19) is less than $20 \%$ for $A \sim 200$ and much smaller for light nuclei. The spread between the solid and dotted curves is the theoretical uncertainty of our predictions. Note also that these results weakly depend on the choice of nucleon PDFs.

Accounting for the color fluctuations as done in eq. (5.33) tends to reduce the amount of nuclear shadowing as compared to the quasi-eikonal approximation used in the literature [803, 811. Also, the AGK technique allows one to calculate other quantities such as nuclear diffractive PDFs and fluctuations of multiplicity in non-diffractive DIS [803, 807, 812, both of which turn out to be sensitive to the pattern of the color fluctuations, see Section 5.4.

Our approach to nuclear shadowing assumes the applicability of the linear (in parton densities) leading-twist DGLAP approximation. Numerical studies indicate that the dominant contribution to nuclear shadowing in eq. (5.33) comes from the region of relatively large $\beta=Q^{2} /\left(M^{2}+Q^{2}\right)$ corresponding to the rapidity intervals $\leq 3$ for which the small$x$ approximation used in the BFKL-type approaches is not applicable. These approaches predict $\alpha_{\mathbb{P}}(0) \sim 1.25$, while the HERA experiments find $\alpha_{\mathbb{P}}(0) \sim 1.11 \approx \alpha_{\mathbb{P}}^{\text {soft }}(0)$ consistent with the expectations of the QCD aligned jet approximation 813 that we effectively implemented in the derivation of eq. (5.33).

## Non-perturbative approaches

## Hans J. Pirner

One of the challenges in QCD is the description and understanding of high-energy scattering on protons and nuclei. Even for high energies and large $Q^{2}$ in deep inelastic electron scattering a non-perturbative framework may be necessary. For the transverse structure function, the $q \bar{q}$ dipole in the photon can be large and the saturation scale $Q_{s}$ is small for the energies we discuss. In the following I will present the main features of such an
approach, which of course will also include the perturbative aspects.
The most important phenomenon observed in high-energy scattering is the rise of the total cross sections with increasing c.m. energy. While the rise is slow in hadronic reactions of large particles such as protons, pions, kaons, or real photons, it is steep if one small particle is involved such as an incoming virtual photon or an outgoing charmonium. This energy behavior is best seen in the proton structure function $F_{2}\left(x, Q^{2}\right)$. With increasing photon virtuality $Q^{2}$, the increase of $F_{2}\left(x, Q^{2}\right)$ towards small Bjorken $x$ becomes significantly stronger. It is tempting to test the growth of the structure function with nuclei. In the following I will summarize my work with Shoshi, Steffen and Dosch which is published in two main papers [814, 815]. For references to other work please see these two papers.

In the two-pomeron model of Donnachie and Landshoff, the energy dependence of the cross sections at high energies results from the exchange of a soft and a hard pomeron. The first dominates in hadron-hadron and $\gamma^{*} p$ reactions at low $Q^{2}$ and the second in $\gamma^{*} p$ reactions at high $Q^{2}$. The two pomerons may be related to a glueball trajectory, which is inherently non-perturbative, and a gluon ladder à la BFKL, which includes the perturbative aspects. The two-pomeron model, however, does not contain parton saturation nor unitarity effects. A model motivated by the concept of parton saturation is the one of Golec-Biernat and Wüsthoff which allows very successful fits to $\gamma^{*} p$ data, but cannot be applied to hadronhadron reactions. A successful description of dipole nucleon scattering which can be used for hadron-nucleon scattering and DIS with moderate $Q^{2}$ has been found 795 .

We have combined perturbative and non-perturbative QCD to compute high-energy reactions of hadrons and photons with special emphasis on saturation effects that manifest $S$-matrix unitarity 814. We follow the functional integral approach to high-energy scattering of Nachtmann, in which the $S$-matrix element factorizes into the universal correlation of two light-like Wegner-Wilson loops $S_{D D}$. The light-like Wegner-Wilson loops describe color dipoles given by the quark and antiquark in the meson or photon projectile and the quark and di-quark in the baryon target. This approach treats projectile and target symmetrically. $S$-matrix unitarity is respected as a consequence of a matrix cumulant expansion and the Gaussian approximation of the functional integrals. The resulting dipole cross sections do not show Glauber-like behavior with the dipole size as in the Golec-Biernat model. The loop-loop correlation function $S_{D D}$ is expressed in terms of the gauge invariant bi-local gluon field strength correlator integrated over two connected minimal surfaces. Due to the symmetric treatment of the two dipoles this formalism can explicitly investigate the dependence on the impact parameter of the two scattering partners.

The gluon field strength correlator has a non-perturbative and a perturbative component. The stochastic vacuum model of Dosch and Simonov is used for the non-perturbative low frequency background field and perturbative BFKL gluon exchange for the high frequency contributions. This combination allows us to describe long and short distance correlations in agreement with Euclidean lattice calculations of the static quark-antiquark potential with color-Coulomb behavior at short distances and confining linear rise at long distances. We have tried to model both components in AdS/QCD, but the long range looploop correlation cannot be established on a classical level, since the connecting surface in 5 dimensions breaks off at large distances 816.

Energy dependence in the loop-loop correlation function, $S_{D D}$, is introduced by hand in order to describe simultaneously the energy behavior in hadron-hadron, photon-hadron, and photon-photon reactions involving real and virtual photons as well. Motivated by the twoPomeron picture of Donnachie and Landshoff, we ascribe to the soft and hard component a weak and strong energy dependence, respectively. The parameter describing the energy
dependence of the perturbative correlation function is very large because we include multiple gluonic interactions. In ref. [814] we have considered not only the dependence of the dipole cross section on dipole size with increasing energy and the resulting $k_{t}$-saturation, but also the scattering amplitudes in impact parameter space, where the $S$-matrix unitarity imposes rigid limits on the impact parameter profiles such as the black disc limit. We present profile functions for longitudinal photon-proton scattering that provide an intuitive geometrical picture for the energy dependence of the cross sections. The profile function first becomes greyer, turns black and then increases in transverse size. Using a leading-twist NLO DGLAP relation, we estimated the impact parameter dependent gluon distribution of the proton $x G\left(x, Q^{2},\left|\vec{b}_{\perp}\right|\right)$ from the profile function for longitudinal photon-proton scattering. We have not found saturation of the profile function at HERA energies, but at higher energies, $x G\left(x, Q^{2},\left|\vec{b}_{\perp}\right|\right)$ does saturate as a manifestation of the $S$-matrix unitarity.

In the same framework, we have studied the unintegrated gluon distribution $x G\left(x, k_{t}\right)$ as a function of transverse momentum $k_{t}$ for increasing energies 815. To obtain the unintegrated gluon distribution, one uses the possibility to rewrite the non-perturbative scattering of an artificial external dipole as a superposition of perturbative contributions. In other words the string of the projectile dipole can be decomposed mathematically in a superposition of dipoles of smaller sizes, from which $x G\left(x, k_{t}\right)$ can be extracted.

The long range confining character of the non-perturbative field strength correlators determines the low $k_{t}$ behavior of the gluon structure function of the hadron as $x G\left(x, k_{t}\right) \propto$ $1 / k_{t}$. In the low momentum limit, $x G\left(x, k_{t}\right) \cdot k_{t}$ converges towards a constant independent of $x$, related to the size of the hadron. The cross-over from the non-perturbative region to the perturbative region occurs at around $k_{t}=1 \mathrm{GeV}$ at $x$-values $10^{-4}<x<10^{-2}$.

On a more fundamental level, we have analysed correlations of Wilson lines in vacuum as one approaches the light cone from space-like distances [817]. The dominant terms of the near light cone Hamiltonian for the Wilson lines define a field theory in $2+1$ dimensions. In the limit of small x , the $\mathrm{SU}(3) \mathrm{QCD}$ for Wilson lines reduces to a critical $\mathrm{Z}(3)$ theory with a diverging correlation length $\xi(x) \propto x^{-1 /\left(2 \lambda_{2}\right)}$ where the exponent $\lambda_{2}=2.52$ is obtained from the center group $\mathrm{Z}(3)$ of $\mathrm{SU}(3)$. We conjecture that the dipole wave function of the virtual photon behaves as the correlation function of Wilson lines in the vacuum. For transverse sizes smaller than the correlation size it scales like $\Psi \propto 1 /\left(x_{t}\right)^{1+n}$ with $n=0.04$ and for distances larger than the correlation length it decays exponentially which makes this region negligible. For $F_{2}$ we integrate the square of the photon wave function weighted with a dipole proton cross section of fixed size $R_{0}$ independent of x. All the energy dependence is absorbed into the photon. Because of the approximate conformality of the dipole wave function ( $n \approx 0$ ), the result depends only on $R_{0}^{2} / \xi(x)^{2} \propto R_{0}^{2} x^{1 / \lambda_{2}}$, i.e. the saturation scale varies as as $Q_{s}^{2}=Q\left(x_{o}\right)^{2}(x 0 / x)^{1 / \lambda_{2}}$. The critical index in this theory is a characteristic feature of $Z(3)$ theory i.e. the center group of $\mathrm{SU}(3)$ in an external field given by the light quarks. This is very different from the perturbative color glass condensate where $Q_{s}$ depends on the running coupling similarly to the power behaviour of BFKL.

## Estimates of higher twist in deep inelastic nucleon and nucleus scattering

Joachim Bartels, Krzysztof Golec-Biernat and Leszek Motyka

A deeper understanding of the transition region at low $Q^{2}$ and small $x$ in deep inelastic electron proton scattering has been one of the central tasks of HERA physics. It will be one of the key questions to be addressed by a future Electron Ion Collider. Approaching this transition region from the perturbative side, one expects to see the onset of corrections to the successful DGLAP description, based upon leading twist operators in QCD. The twist expansion defines a systematic approach to the short distance limit probed in deep inelastic scattering. The study of higher-twist corrections therefore provides an attractive route for investigating the region of validity of the leading twist DGLAP evolution equations.

The validity of the leading-twist QCD evolution equations is based upon the fact that, for sufficiently large $Q^{2}$ and not too small $x$, the gluons inside the proton are dilute. The DGLAP evolution equations, however, predict that, at small $x$ and low $Q^{2}$, the gluon density grows. As a result, the gluons start to interact and the gluon density eventually saturates. The onset of saturation is encoded in the saturation scale, $Q_{\text {sat }}^{2}(x)$.

The investigation of saturation is of highest importance for our understanding of QCD. Saturation can be viewed as a first step of entering the strong interaction region. While the QCD coupling constant is still small, saturation phenomena probe nonlinear dynamics of the gluon sector which plays a crucial role in many areas of strong interactions. It is expected that saturation effects in deep inelastic scattering on a nucleus are enhanced in comparison with deep inelastic scattering on a proton. In the former case, the incoming photon 'sees' the gluons of many nucleons, whereas in the case of a single nucleon, one has to go to smaller $x$ values (higher energies) in order to reach the same gluon density.

A brief discussion of the connection between saturation and the twist expansion has been given in 818]. Whereas in the GBW model [83, 819 ] there is a rather direct classification of eikonal-type exchanges of gluon ladders in terms of twist quantum numbers, in saturation models based upon the nonlinear BK-equation [85, 820] a twist decomposition is much less obvious. In the following we present some numerical estimates of higher-twist contributions, using the improved version of the GBW model 821 .

The method: The theory of higher-twist operators and their evolution equations has been outlined in 822]: in leading order, the higher-twist evolution equations are described by the nonforward DGLAP splitting functions, and there is a particular pattern of mixing between different operators of the same twist. In the same way as for leading twist, a numerical analysis of higher twists requires initial conditions for the set of evolution equations, which have to be adjusted to data. In 818 the magnitude of higher-twist corrections was evaluated in a slightly different way. Starting from the observation that within the GBW saturation model the multiple exchanges of leading-twist gluon ladders can be put into a one-toone correspondence with contributions of definite twist quantum numbers, it is possible to arrive at quantitative estimates of the leading-twist contributions and corrections due to twist $\tau=4,6, \ldots$. Details have been described in [818] and will not be repeated here.

While the analysis in [818] was performed for the case of $e+p$ scattering, it is straightforward to extend it to electron-nucleus scattering. Assuming a cylindrical nucleus with a characteristic size $R_{A} \approx A^{1 / 3} R_{p}$ (with $R_{p}$ being the proton radius), we simply replace the

Figure 5.20. Higher-twist contribution estimate for $F_{2}$ (left) and $F_{L}$ (right) of the proton.
dipole-proton cross section (eq.(42) in [818])

$$
\begin{equation*}
\sigma_{\text {dipole-proton }}=\sigma_{0}\left(1-\exp \left(-\Omega\left(x, r^{2}\right)\right)\right) \tag{5.34}
\end{equation*}
$$

by the dipole-nucleus cross section

$$
\begin{equation*}
\sigma_{\text {dipole-nucleus }}=A^{2 / 3} \sigma_{0}\left(1-\exp \left(-A^{1 / 3} \Omega\left(x, r^{2}\right)\right)\right) \tag{5.35}
\end{equation*}
$$

where $\Omega\left(x, r^{2}\right)$ is the eikonal function given in [818]. With the parameters from [818] we simply repeat the electron proton calculations for electron gold scattering, using the modified dipole cross section formula in (2).

Figure 5.21. Higher-twist contribution estimate for $F_{2}$ (left) and $F_{L}$ (right) of the gold nucleus.
Numerical results: The numerical results for $F_{2}$ and $F_{L}$ are shown in Fig. 5.20 for the proton, and Fig. 5.21 for the gold nucleus. In each figure we show, on the l.h.s in a 3dimensional view, the ratio of the higher-twist corrections and the full structure function as a fucntion of $x$ and $Q^{2}$,

$$
\begin{equation*}
\text { ratio }=\frac{F_{2, L}^{(\text {total })}-F_{2, L}^{(\tau=2)}}{F_{2, L}^{\text {(total })}} . \tag{5.36}
\end{equation*}
$$

The r.h.s. shows the projection onto the $\left(\log x, \log Q^{2}\right)$ plane: the lines belong to fixed values of the ratio (5.36). One recognizes the general trend: the corrections are getting larger when $x$ and $Q^{2}$ decrease (moving towards the lower left corner). For given $x$ and $Q^{2}$, the corrections for the longitudinal structure functions are larger than for $F_{2}$. This is a consequence of the sign structure of the corrections in $F_{L}$ and $F_{T}$ : twist four corrections to $F_{L}$ and $F_{T}$ have opposite signs, and in the analysis [818] of $F_{2}=F_{T}+F_{L}$ a strong cancellation has been found. This explains the small higher twist contribution for $F_{2}$.

One also recognizes the general trend that for gold, all corrections are larger than for the proton. Finally, the corrections to $F_{L}$ are negative and those to $F_{2}$ are mostly positive. In the case of the proton $F_{2}$ there is a change in sign in the region of very small values of $Q^{2}$ : this again is a consequence of the sign structure of the twist corrections to $F_{T}$ and $F_{L}$.

Conclusions: Our numerical analysis confirms that, in general, the structure functions $F_{L}$ are more sensitive to higher-twist corrections than $F_{2}$ which, because of the sign structure in the twist 4 corrections, seems to much better "protected" against higher twist. Also, nuclear targets are more sensitive to higher twist corrections relative to the proton. In view of these results, it seems clear that in a future electron-ion collider, the measurement of $F_{L}$ is of vital importance in the search for saturation.

## Strength of nonlinear effects in nucleons and nuclei

## Tuomas Lappi

The effects of nonlinearity and unitarity in small $x$ DIS are most clearly visible in the dipole framework. We denote $\mathcal{N}\left(x, \mathbf{b}_{T}, \mathbf{r}_{T}\right)$ the imaginary part of the scattering amplitude for a dipole of size $\mathbf{r}_{T}$ and rapidity $y=\ln (1 / x)$ to scatter off the target at impact parameter $\mathbf{b}_{T}$. The total dipole cross section is given by twice the integral of $\mathcal{N}\left(x, \mathbf{b}_{T}, \mathbf{r}_{T}\right)$ over the impact parameter. While the formal unitarity limit would be for $\mathcal{N}$ to lie between 0 and 2 , in practice the reasonable physical area is between 0 (no scattering) and 1 (complete absorption or the black disk limit). The typical value of the dipole scattering amplitude therefore serves as a good measure of the degree of nonlinearity of the scattering process.

Figure 5.22. The saturation scale in a proton and Ca and Au nuclei as a function of $b / b_{\text {med }}$, where $b_{\text {med }}$ is the median impact parameter probed in inclusive DIS at $x=0.001$ and $Q^{2}=1 \mathrm{GeV}^{2}$.

As the total cross section depends on the integral of the scattering amplitude over the impact parameter, statements about the magnitude of the scattering amplitude depend on the profile of the target in $\mathbf{b}_{T}$. The $\mathbf{b}_{T^{-}}$ depdendence for the scattering amplitude on a nucleon is, however, very much constrained by the $t$-dependence of exclusive vector meson production. Using this information, in addition to the total cross section, results in the two commonly used $\mathbf{b}_{T}$-dependent dipole amplitude parametrizations that we will use here, the IPsat and bCGC models 600, 823, 824]. They have successfully been used to describe HERA data on the inclusive cross section, exclusive vector meson production and diffractive structure functions 825 .

The saturation scale: To a first approximation the impact parameter dependence of the nuclear scattering amplitude can then be obtained by combining the nucleon one with basic knowledge of nuclear geometry in a Glauber-like treatment (see e.g. Refs. [826, 827] for details). This yields a characteristic pattern of nuclear suppression (shadowing) of the inclusive cross section, a nuclear enhancement of diffraction to small mass states and a
suppression in diffraction to large masses (small $\beta$ ) 825].
One way of quantifying the importance of nonlinear effects is to compare the value of the ( $\mathbf{b}_{T}$ and $x$-dependent) saturation scale $Q_{\mathrm{s}}^{2}$ to the virtuality $Q^{2}$ of the process. The saturation scale is defined as the inverse of the dipole size at which the scattering amplitude $\mathcal{N}$ reaches some specific value defined by convention. For $Q^{2} \gg Q_{\mathrm{s}}^{2}$ one is in the dilute limit and for $Q^{2} \sim Q_{\mathrm{s}}^{2}$ nonlinear effects become important. A naive argument of the $A$ dependence of the saturation scale for nuclei would give $Q_{\mathrm{s} A}^{2} \sim A^{1 / 3}$. The importance of a realistic impact parameter dependence for nuclei was discussed in more detail in Ref. 826], where it was found that this dependence is indeed true to a very good approximation, but the picture is more intricate than that. For the center of a nucleus vs. the center of a proton the saturation scale is suppressed by a geometrical factor $\sim 0.3 \approx R_{p}^{2} A^{2 / 3} / R_{A}^{2}$. Both a nucleon and a nucleus have a dilute edge at large impact parameters. The thickness of this edge is determined by confinement scale physics and is thus of the same order for both. The proton is, however, a much smaller object and therefore the dilute edge region is responsible for a much larger fraction of the total cross section than in a nucleus. One way to see this is to look at the saturation scale at the median impact parameter contributing to the inclusive cross DIS cross section. The value of $Q_{\mathrm{s}}^{2}\left(b_{\text {med }}\right)$ is $\sim 35 \%$ of the value at $b=0$ for a proton, but $\sim 70 \%$ for a gold nucleus (see Fig. [5.22, [826]).

Figure 5.23. Longitudinal mean scattering amplitude $\langle\mathcal{N}\rangle_{L}$ for a proton (left) and a a gold nucleus (right) with the IPsat parametrization (first row) and bCGC parametrization (second row).

The mean scattering amplitude: An alternative way of assessing the typical values of the scattering amplitude is to calculate its expectation value weighted by the cross section
of a particular process. We thus define the mean scattering amplitude as

$$
\begin{equation*}
\langle\mathcal{N}\rangle_{T, L}=\frac{\int \mathrm{d}^{2} \mathbf{r}_{T} \int_{0}^{1} \mathrm{~d} z\left|\Psi_{L, T}^{\gamma^{*}}\right|^{2} \int \mathrm{~d}^{2} \mathbf{b}_{T} \mathcal{N}^{2}\left(x, \mathbf{b}_{T}, \mathbf{r}_{T}\right)}{\int \mathrm{d}^{2} \mathbf{r}_{T} \int_{0}^{1} \mathrm{~d} z\left|\Psi_{L, T}^{\gamma^{*}}\right|^{2} \int \mathrm{~d}^{2} \mathbf{b}_{T} \mathcal{N}\left(x, \mathbf{b}_{T}, \mathbf{r}_{T}\right)} . \tag{5.37}
\end{equation*}
$$

This will yield a value between 0 and 1 for all points in the $Q^{2}, x$-plane. Note that although in principle $\langle\mathcal{N}\rangle$ varies between 0 and 1 , the maximal value for a Gaussian $\mathbf{b}_{T}$-distribution, which describes the proton very well, is only $1 / 2$. The longitudinal and transverse structure functions probe a slightly different distribution of dipole sizes $r$, with the longitudinal structure function showing a stronger $Q^{2}$-dependence. The same quantities can easily be computed also for charm quarks only.

Figure 5.24. The mean scattering amplitude $\langle\mathcal{N}\rangle_{\text {tot }}$ for the total cross section for a proton (left) and a a gold nucleus (right) with the bCGC parametrization.

Figure 5.23 shows the mean scattering amplitude probed in the longitudinal total cross section in a proton and a gold nucleus in the IPsat model. The characteristic feature of the eikonalized DGLAP-evolved gluon distribution in this parametrization is the fact that the $x$-dependence becomes faster at higher energies. The same quantity for the bCGC cross section is plotted in fig. 5.23, Here one sees the characteristic constant energy dependence $Q_{\mathrm{s}}^{2} \sim x^{-\lambda}$ in the bCGC parametrization leading to straight lines of constant $\mathcal{N}$ in a $\log -\log$ plot. The amplitude weighted by the total cross section is shown in Fig. 5.24 for the IPsat parametrization. It shows a slower $Q^{2}$-dependence than the longitudinal one, connected with the well-known fact that the longitudinal structure function is more sensitive to higher-twist effects than the total one.

In all plots for protons we have shown the kinematical limits for HERA and the EIC ( 325 GeV proton on 30 GeV electron with $y<0.9$ ) and in the nucleus plots for the EIC ( 130 A GeV nucleus on 30 GeV electron with $y<0.9$ ) and lower energy mEIC option ( $130 A \mathrm{GeV}$ nucleus on 5 GeV electron with $y<0.9$ ). The comparison between nuclei and protons is striking. In the IPsat parametrization, as is typical of DGLAP evolution, the energy dependence at the initial small $Q^{2}$-scale is very slow. Thus the lower energy of the EIC compared to HERA would be insignificant in face of the effect of using nuclei. A value of $\langle\mathcal{N}\rangle_{\text {tot }}$ of 0.3 could, for example, be reached at $Q^{2}=4 \mathrm{GeV}^{2}$ at the EIC vs. $Q^{2}=1 \mathrm{GeV}^{2}$ at HERA; much more safely in the weak coupling regime. With nuclei the EIC could, at $Q^{2}=1 \mathrm{GeV}$, reach values of $\langle\mathcal{N}\rangle_{L} \approx 0.5$ that are simply inaccessible in an ep collider at practically any energy for an approximately Gaussian proton profile.

Acknowledgments: M. Diehl came up with the idea of visualizing the strength of the nonlinear effects in the way presented here.

## Nuclear PDFs and deviations from DGLAP evolution

Alberto Accardi, Vadim Guzey and Juan Rojo

In this contribution we present a preliminary analysis which aims at determining the potential of the EIC to measure gluon shadowing and anti-shadowing and its sensitivity to saturation dynamics.

The input for this analysis is the EIC pseudo data for the inclusive DIS cross section in two scenarios, a medium energy EIC $(\sqrt{s}=$ $12,17,24,32,44 \mathrm{GeV}$, denoted by stage I) and a full energy $\operatorname{EIC}(\sqrt{s}=63,88,124 \mathrm{GeV}$, stage II), with $0.004<y<0.8$ in either case. The kinematic coverage is summarized in Fig. 5.25. The pseudo-data was generated starting from $e+p$ and $e+n$ cross sections computed using the central values of the NNPDF2.0 parton distributions [47. An integrated luminosity of $4 \mathrm{fb}^{-1}$ was assumed for all energies, and the pseudodata has been corrected for the expected statistical fluctuations. For most of the $x$ range the resulting statistical errors are negligible compared to the assumed $2 \%$ systematic error. Nuclear effects have been included in a $K$-factor approx-

Figure 5.25. Kinematical coverage of the pseudo-data included in the NNPDF analysis of the EIC e +Pb cross-sections, both for stage I and for stage II. Possible kinematical cuts relevant to the study of the onset of non-linear phenomena are also shown. imation, so that the longitudinal and transverse cross sections in ${ }^{208} \mathrm{~Pb}$ can be expressed in terms of the proton cross sections as

$$
\begin{equation*}
\sigma_{T, L}^{\mathrm{Pb}}\left(x, Q^{2}, y\right)=K_{T, L}^{\lambda}\left(x, Q^{2}, y\right) \sigma_{T, L}^{\mathrm{p}}\left(x, Q^{2}, y\right) \tag{5.38}
\end{equation*}
$$

where the label $\lambda$ sets the intensity of the assumed saturation effects, and $\lambda=1$ corresponds to the nominal saturation in the IP Non-sat model [600]. In particular, the $K$-factor in Eq. (5.38) is given by the following piece-wise expression. For small $x, x \leq 0.01$,

$$
\begin{equation*}
K_{T, L}^{\lambda}=\frac{2}{\left\langle\sigma_{q \bar{q}}\right\rangle_{T, L}} \int d^{2} b\left\langle\left(1-e^{-\lambda \frac{1}{2} A \sigma_{q \bar{q}} T_{A}(b)}\right)\right\rangle_{T, L}, \tag{5.39}
\end{equation*}
$$

where $\sigma_{q \bar{q}}$ is the dipole cross section in the IP Non-sat model (we assume for simplicity that in the EIC kinematic range there is no saturation at the proton level, and search for the nuclear medium-induced saturation); $T_{A}(b)=\int d z \rho_{A}(b, z)$, where $\rho_{A}(b, z)$ is the nuclear density normalized to unity; the brackets $\langle\ldots\rangle_{T, L}$ stand for the integration with the wave function squared of a virtual photon with transverse or longitudinal polarization, respectively. In the $0.01 \leq x \leq 0.1$ interval, we assume that $K_{T, L}^{\lambda}$ increases linearly from the value given by Eq. (5.39) at $x=0.01$ up to $K_{T, L}^{\lambda}=1$ at $x=0.1$. For $x>0.1$, we assumed that $K_{T, L}^{\lambda}$ is equal to the ratio of the nuclear to free nucleon structure functions, $F_{2 A}\left(x, Q^{2}\right) /\left[A F_{2 N}\left(x, Q^{2}\right)\right]$, which is given by the leading-order parameterization of Ref. [828]

Nuclear parton distributions are then determined by a Next-to-Leading Order QCD fit of the pseudo-data within the NNPDF framework [681, 47]. The kinematic cuts used to ensure the validity of DGLAP evolution are $Q^{2} \geq 2 \mathrm{GeV}^{2}$ and $W^{2} \geq 12.5 \mathrm{GeV}^{2}$. In this preliminary study, we consider pseudo-data for Pb targets only, and postpone discussion of the dependence of the nuclear PDFs on $A$ to a future investigation. In the collinear factorization approximation, Pb structure functions are related to Pb parton distributions in the same way as in the proton case (see Section 5.7 and Ref. [829). We also assumed for simplicity the Pb nucleus to be isoscalar, so that the structure functions depend only on three independent nuclear PDFs: the singlet quark PDF, $\Sigma^{\mathrm{Pb}}\left(x, Q^{2}\right)$, the gluon PDF $g^{\mathrm{Pb}}\left(x, Q^{2}\right)$, and the strange PDF; the latter was furthermore set to be a fixed fraction of the singlet PDF.

Now we discuss some preliminary results of the nuclear PDF fits. We show in Fig. 5.26 the singlet and the gluon PDFs at the initial scale $Q^{2}=2 \mathrm{GeV}^{2}$ obtained using only stage I data for $\mathrm{e}+\mathrm{Pb}$ collisions, and then adding the stage II data. To illustrate the accuracy that the EIC can reach in the determination of nuclear PDFs we show in Fig. 5.27 their relative uncertainties alongside those of the proton's NNPDF2.0 47] combined with those of the EPS09 nuclear modifications [40] for ${ }^{208} \mathrm{~Pb}$, which allows a comparison of the relative error bands. Since the restrictive EPS09 parametrization may underestimate the nuclear uncertainties outside the region where data is presently available, notably at $x \lesssim 0.01$, we added the relative NNPDF2.0 and EPS09 relative uncertainties linearly for a conservative estimate of the total uncertainty.

Figure 5.26. The quark singlet (left plot) and the gluon PDFs (right plot) in Pb at the initial evolution scale $Q_{0}^{2}=2 \mathrm{GeV}^{2}$, for stage I and stage I+II.

The measurement of the nuclear modifications of the gluon are one of the most important measurements at the EIC, as this quantity is essentially unknown from present data. Inclusive cross sections are sensitive to the gluon distribution both via scaling violations and, to a lesser extent, through the longitudinal structure function accessed through the proposed $\sqrt{s}=12-124 \mathrm{GeV}$ energy scan. From Fig. 5.26 we see that one can determine, with reasonable accuracy, the gluon shadowing down to $x \sim 10^{-3}$ in stage II and down to $x \sim 10^{-2}$ in stage I. The better capabilities of stage II stem both from its greater lever arm in $Q^{2}$ and its coverage of smaller values of $x$, see Fig. 5.25. In particular, the precision of the Pb gluon in Stage II at small $x$ is comparable to estimates from global proton fits. On top of this, at the EIC it will be possible to study gluon anti-shadowing, EMC and Fermi motion effects with much better accuracy than afforded by current global nuclear fits (see Sections 5.7 and 5.7 We can also see that EIC will measure accurately the sea quark shadowing, and that nuclear modifications of light quarks at large $x$ could be measured a precision similar or even better than for the proton case.

Figure 5.27. The relative uncertainty in the quark singlet (two upper panels) and the gluon PDFs in Pb (two lower panels) at the initial evolution scale $Q_{0}^{2}=2 \mathrm{GeV}^{2}$, with stage I and stage $\mathrm{I}+\mathrm{II}$ data. Results are shown on linear (left plot) and logarithmic (right plot) scales. For reference, the analogous results for the Pb PDFs using NNPDF2.0+EPS09 parametrizations are also shown.

This analysis was based on the validity of collinear factorization for nuclei, and the validity of linear DGLAP evolution in $Q^{2}$. However, at small enough $x$ and $Q^{2}$, deviations from linear fixed order DGLAP evolution are expected to appear, e.g., due to small- $x$ resummation effects 830] or gluon saturation, see Section 5.2. In heavy nuclei, the effects due to gluon saturation are boosted to higher $Q^{2}$ and $x$ by the atomic number; one then has the possibility of experimentally separating small- $x$ and saturation effects, which is not be possible with HERA $e+p$ data.

In Refs. [720, 831] a general strategy was presented to quantify potential deviations from NLO DGLAP evolution, which was then applied to proton HERA data. In a global PDF fit, deviations from DGLAP in the data can be hidden in a distortion of parton distributions; however, these can be singled out by determining undistorted PDFs from data in regions where such effects are expected to be small. In more detail, one can fit PDFs using data at large $x$ and $Q^{2}$, where DGLAP is likely to hold with high accuracy, and then evolving them down in the $Q^{2}$ region where deviations are expected to arise. DGLAP deviations can then be quantitatively determined by comparing calculations to data in this region, which were not used in the PDF determination.

This approach can be applied as well to the nuclear case. From simple theoretical arguments about the energy and $A$ dependence of the saturation scale (see Section [5.2), we expect deviations from linear evolution to appear when $Q^{2} \lesssim \bar{Q}^{2}(A \bar{x} / x)^{\frac{1}{3}}$, where $\bar{x}$ is a reference value, say $\bar{x}=10^{-3}$, and $\bar{Q}^{2}$ is the scale where DGLAP evolution at $\bar{x}$ would be broken in the proton. Note however that the $A$-dependence of the saturation scale may in fact be tamed by the leading twist nuclear shadowing, see Section 5.2. While saturation models may give an indication of the value of $\bar{Q}^{2}$, we wish to determine this scale in a model independent way as the scale at which deviations from DGLAP evolution can be detected from EIC nuclear target (pseudo-)data. The unsafe region for DGLAP evolution can also be
written as $Q^{2} \lesssim Q_{c}^{2} x^{-\frac{1}{3}}$ with $Q_{c}^{2}$ some constant setting the strength of the deviations from DGLAP. In Refs. 720,831 the range $Q_{c}^{2} \in[0.5,1.5] \mathrm{GeV}^{2}$ was considered for the proton case; in the nuclear case this range should be rescaled by a factor $A_{\mathrm{Pb}}^{1 / 3} \approx 6$. Typical values of these kinematical cuts for the Pb nucleus are shown in Fig. 5.25.

Figure 5.28. The Pb structure function $F_{2}^{\mathrm{Pb}}\left(x, Q^{2}\right)$ at $Q^{2}=3 \mathrm{GeV}^{2}$ from the analysis of the EIC stage I (left plot) and stage I+II (right plot) simulated data with $\lambda=1$, without kinematical cuts and with cuts using $Q_{c}^{2}=1.5 A_{\mathrm{Pb}}^{1 / 3} \sim 9$.

We show in Fig. 5.28 a representative result of the fits to the EIC pseudo-data after applying the cut with $\bar{Q}^{2}=1.5 A_{\mathrm{Pb}}^{1 / 3} \sim 9$, compared to the reference uncut fits to stages I and $\mathrm{I}+\mathrm{II}$ pseudo-data with $\lambda=1$. As expected when data is removed the uncertainties in the physical observables become much larger, but one can still see a systematic downwards shift in the central value, which is the signature of the departure from linear evolution [720, 831]. Note that this signal is already apparent with stage I data only, although its statistical significance might be marginal.

We plan to systematically explore the sensitivity of the EIC to non-linear dynamics using this technique, by optimizing the kinematical cuts for different values of the saturation scale used to generate the pseudo-data, exploit the interplay between the $F_{2}^{\mathrm{Pb}}$ and $F_{L}^{\mathrm{Pb}}$ structure functions, and quantitatively measuring the statistical significance of the signal. This will determine in a fairly model-independent way the smallest saturation scale that can be detected at the EIC in either stage I or stage II.

Acknowledgments: We thank F. Caola, R. Ent, S. Forte and L. Zhu for discussions and collaboration.

## Constraining the nuclear gluon distribution using inclusive observables

Victor P. Gonçalves
Data from HERA allow for a good determination of the gluon density of the proton. A much harder task has been to determine the gluon distribution of nucleons bound in a nucleus, the nuclear gluon distribution $\left(x g^{A}\left(x, Q^{2}\right)\right)$. Existing data, taken over a wide kinematic range $10^{-5} \leq x \leq 0.1$ and $0.05 \mathrm{GeV}^{2} \leq Q^{2} \leq 100 \mathrm{GeV}^{2}$, show a systematic reduction of the nuclear structure function $F_{2}^{A}\left(x, Q^{2}\right) / A$ with respect to the free nucleon structure function $F_{2}^{N}\left(x, Q^{2}\right)$. This phenomenon is known as the nuclear shadowing effect and is associated to the modification of the target parton distributions so that $x q^{A}\left(x, Q^{2}\right)<$ $A x q^{N}\left(x, Q^{2}\right)$, as expected from a superposition of $e p$ interactions. The modifications depend on the parton momentum fraction: for momentum fractions $x<0.1$ (shadowing region)
and $0.3<x<0.7$ (EMC region), a depletion is observed in the nuclear structure functions. These two regions are bridged by an enhancement known as antishadowing for $0.1<x<$ 0.3 . The experimental data for the nuclear structure function determine the behaviour of the nuclear quark distributions, while the behaviour of the nuclear gluon distribution is indirectly determined using the momentum sum rule as a constraint and/or studying the $\log Q^{2}$ slope of the ratio $F_{2}^{S n} / F_{2}^{C}$. Currently, the behaviour of $x g^{A}\left(x, Q^{2}\right)$ at small $x$ (high energy) is completely uncertain as shown in Fig. 5.29, where we present the ratio $R_{g}=x g^{A} /\left(A . x g^{N}\right)$, for $A=208$, predicted by four different groups which realize a global analysis of the nuclear experimental data using the DGLAP evolution equations in order to determine the parton densities in nuclei. In particular, the magnitude of shadowing and the presence or not of the antishadowing effe

In this contribution we study the behaviour of the nuclear longitudinal structure function $F_{L}^{A}$ and the charm structure function $F_{2}^{c, A}$ and analyse the possibility to constrain the nuclear effects present in $x g^{A}$ using these inclusive observables (For more details and references see Ref. [832]).

## $F_{L}^{A}$ and $F_{2}^{c, A}$ in the collinear formal-

 ism: The longitudinal structure function in deep inelastic scattering is one of the observables from which the gluon distribution can be unfolded. In the collinear formalism, $F_{L}$ is described in terms of the AltarelliMartinelli equation

Figure 5.29. The ratio $R_{g}=x g^{A} / A \cdot x g^{N}$ predicted by the EKS, DS, HKN and EPS parametrizations for $A=208$ and $Q^{2}=2.5 \mathrm{GeV}^{2}$.

$$
\begin{equation*}
F_{L}\left(x, Q^{2}\right)=\frac{\alpha_{s}\left(Q^{2}\right)}{2 \pi} x^{2} \int_{x}^{1} \frac{d y}{y^{3}}\left[\frac{8}{3} F_{2}\left(y, Q^{2}\right)+4 \sum_{q} e_{q}^{2}\left(1-\frac{x}{y}\right) y g\left(y, Q^{2}\right)\right] \tag{5.40}
\end{equation*}
$$

At small $x$, the second term with the gluon distribution is the dominant one. This expression can be reasonably approximated by $F_{L}\left(x, Q^{2}\right) \approx 0.3 \frac{4 \alpha_{s}}{3 \pi} x g\left(2.5 x, Q^{2}\right)$, which demonstrates the close relation between the longitudinal structure function and the gluon distribution. Therefore, we expect the longitudinal structure function to be sensitive to nuclear effects.

In order to estimate the charm contribution to the structure function we treat the charm quark as a heavy quark and estimate its contribution by fixed-order perturbation theory. This involves the computation of the boson-gluon fusion process. A $\bar{c} \bar{c}$ pair can be created by boson-gluon fusion when the squared invariant mass of the hadronic final state is $W^{2} \geq 4 m_{c}^{2}$. Since $W^{2}=\frac{Q^{2}(1-x)}{x}+M_{N}^{2}$, where $M_{N}$ is the nucleon mass, the charm production can occur well below the $Q^{2}$ threshold, $Q^{2} \approx 4 m_{c}^{2}$, at small $x$. The charm contribution to the proton/nucleus structure function, in leading order (LO), is given by

$$
\begin{equation*}
\frac{1}{x} F_{2}^{c}\left(x, Q^{2}, m_{c}^{2}\right)=2 e_{c}^{2} \frac{\alpha_{s}\left(\mu^{\prime 2}\right)}{2 \pi} \int_{a x}^{1} \frac{d y}{y} C_{g, 2}^{c}\left(\frac{x}{y}, \frac{m_{c}^{2}}{Q^{2}}\right) g\left(y, \mu^{\prime 2}\right), \tag{5.41}
\end{equation*}
$$

where $a=1+\frac{4 m_{c}^{2}}{Q^{2}}$ and the factorization scale $\mu^{\prime}$ is assumed $\mu^{\prime 2}=4 m_{c}^{2} . C_{g, 2}^{c}$ is the coefficient

Figure 5.30. Ratios $R_{g}, R_{C}$ and $R_{L}$ for the four considered nuclear parametrizations, $Q^{2}=2.5$ $\mathrm{GeV}^{2}$ and $A=208$.
function given by

$$
\begin{align*}
C_{g, 2}^{c}\left(z, \frac{m_{c}^{2}}{Q^{2}}\right) & =\frac{1}{2}\left\{\left[z^{2}+(1-z)^{2}+z(1-3 z) \frac{4 m_{c}^{2}}{Q^{2}}-z^{2} \frac{8 m_{c}^{4}}{Q^{4}}\right] \ln \frac{1+\beta}{1-\beta}\right. \\
& \left.+\beta\left[-1+8 z(1-z)-z(1-z) \frac{4 m_{c}^{2}}{Q^{2}}\right]\right\} \tag{5.42}
\end{align*}
$$

where $\beta=1-\frac{4 m_{c}^{2} z}{Q^{2}(1-z)}$ is the velocity of one of the charm quarks in the boson-gluon center-of-mass frame. Therefore, in leading order, $\mathcal{O}\left(\alpha_{s}\right), F_{2}^{c}$ is directly sensitive only to the gluon density via the well-known Bethe-Heitler process $\gamma^{*} g \rightarrow c \bar{c}$. The dominant uncertainty in the QCD calculations arises from the uncertainty in the charm quark mass. In this contribution we assume $m_{c}=1.5 \mathrm{GeV}$.

The nuclear ratios: Let us now study the behaviour of the nuclear longitudinal structure function $F_{L}^{A}$ and the charm structure function $F_{2}^{c, A}$ and analyze the possibility to constrain the nuclear effects present in $x g^{A}$ using these inclusive observables. We estimate the normalized ratios

$$
\begin{equation*}
R_{L}\left(x, Q^{2}\right)=\frac{F_{L}^{A}\left(x, Q^{2}\right)}{A F_{L}^{p}\left(x, Q^{2}\right)} \quad \text { and } \quad R_{C}\left(x, Q^{2}\right)=\frac{F_{2}^{c, A}\left(x, Q^{2}\right)}{A F_{2}^{c, p}\left(x, Q^{2}\right)} \tag{5.43}
\end{equation*}
$$

considering four distinct parametrizations for the nuclear gluon distributions and compare their behaviour with those predicted for the ratio $R_{g}=x g^{A} / A x g^{N}$.

In Fig. 5.30 we present our results. Firstly, let us discuss the small- $x$ region, $x \leq 10^{-3}$, determined by shadowing effects. We observe that $R_{L}$ practically coincides with $R_{g}$ for all parametrizations and for the two values of $Q^{2}$ considered. This suggests that shadowing effects can be easily constrained in an $e A$ collider by measuring $F_{L}$. This conclusion is, to a good extent, model independent. On the other hand, the ratio $R_{C}$ gives us an upper
bound for the magnitude of the shadowing effects. For example, if it is found that $R_{C}$ is equal to $\approx 0.6$ at $x=10^{-4}$ and $Q^{2}=2.5 \mathrm{GeV}^{2}$ the nuclear gluon distributions from DS and HKN parametrizations are very large and should be modified. Considering now the kinematical range of $x>10^{-3}$ we can analyse the correlation between the behaviour of $R_{L}$ and $R_{C}$ and the antishadowing present or not in the nuclear gluon distribution. Similarly to what is observed at small values of $x$, the behaviour of $R_{L}$ is very close to the $R_{g}$ one in the large- $x$ range. In particular, the presence of antishadowing in $x g^{A}$ directly implies an enhancement in $F_{L}^{A}$. It is almost $10 \%$ smaller in magnitude that the enhancement predicted for $x g^{A}$ by the EKS and EPS parametrizations. Inversely, if we assume the non-existence of the antishadowing in the nuclear gluon distribution at $x<10^{-1}$, as in the DS and HKN parametrizations, no enhancement will be present in $F_{L}^{A}$ in this kinematical region. Therefore, it suggests that also the antishadowing effects can be easily constrained in an $e A$ collider measuring $F_{L}$. On the other hand, in this kinematical range the behavior of $R_{C}$ is distinct of $R_{g}$ at a same $x$. However, we observe that the behavior of $R_{C}$ at $x=10^{-2}$ is directly associated to $R_{g}$ at $x=10^{-1}$. In other words, the antishadowing is shifted in $R_{C}$ by approximately one order of magnitude in $x$. For example, the large growth of $R_{g}$ predicted by the HKN parametrization at $x \geq 10^{-1}$ shown in Fig. 5.29 implies the steep behavior of $R_{C}$ at $x \geq 10^{-2}$ observed in Fig. [5.30. Consequently, by measuring $F_{2}^{c}$ it is also possible to constrain the existence and magnitude of the antishadowing effects.

## DIS in the high-energy limit at next-to-leading order

## Giovanni A. Chirilli

Nowadays,it is widely accepted that non-linear dynamics effects dominate deep inelastic lepton hadrons scattering processes (DIS) at very high-energy (Regge limit), and non-linear equations have been derived in order to describe the evolution of the structure of hadronic matter at this regime. One of these equations is the Balitsky-Kovchegov equation (BK) derived by Balitsky [770] in the Wilson lines formalism, and by Kovchegov [741, 747] in the dipole frame. The Wilson line formalism is an operator language based on the concept of factorization of the scattering amplitude in rapidity space and on the extension of the application of the Operator Product Expansion (OPE) formalism to high-energy (Regge limit). So far, the OPE formalism was known only in the Bjorken limit as an expansion in terms of local operators or in terms of light ray operators.

The relevance of the BK equation for future experiments at an Electron Ion Collider (EIC) or Large electron Hadron Collider (LeHC) can be determined by the running of the coupling constant and the evolution kernel at the next-to-leading-order (NLO) approximation (NLO corrections in power of the strong coupling constant $\alpha_{s}$ ). The argument of the coupling constant has been obtained by the authors of ref. [833, 834] where only the quark contribution has been calculated explicitly, while the gluonic part was obtained conjecturing that its contribution would follow the same pattern of the quark contribution. However, this result did not fully solve the problem of the argument of the running coupling constant due to an ambiguity of one term which is not proportional to $b=\frac{11}{3} N_{c}-\frac{2}{3} n_{f}$. The complete results of the NLO-BK kernel including the gluon contribution to the argument of the coupling constant has been obtained in [835] where it was shown that the result agrees with
the NLO Balitsky-Fadin-Kuraev-Lipatov (BFKL) kernel. The BFKL equation [836, 60] can be obtained from the BK equation by dropping out the non linear terms. Indeed, a caveat of such a linear evolution equation is the violation at very high energy of the unitarity condition which is instead preserved by the BK equation.

Conformal symmetry is a symmetry violated in QCD by the running of the coupling constant. What one would then expect from the calculation of the NLO BK-kernel is that the only source of violation of such symmetry come from the running of coupling while the rest of the kernel preserves conformal (Möbius) symmetry. However, although Wilson lines are formally conformal invariant, at one loop correction they are rapidity-divergent, and since it is not known how to regulate them in a conformally invariant way, the NLOBK kernel contains non-conformal terms (besides to the running coupling constant) as a remnant of the prescription used to cure such divergences. In order to study the source of the loss of conformal invariance, it is convenient to consider a conformally invariant theory like the $\mathcal{N}=4$ super-symmetric Yang-Mills (SYM) theory. The NLO evolution kernel obtained in this framework is also not conformally invariant 837, contrary to what one would expect from a conformal field theory. It was then shown in [837, that suitable operators for the description of processes at high-energy (Regge) theory are composite conformal (Wilson line) operators constructed order by order in perturbation theory. These operators absorb the undesired non conformal terms in the same way as counterterms are added to renormalize local composite operators in order to restore the symmetry that the bare operator lost at the level of NLO (and higher) corrections. Indeed, the NLO evolution of such composite conformal operators in QCD resolve in a running coupling part and in a conformally invariant part. In ref. [837, 838], the conformal expression for the NLO BFKL has been obtained for the first time.

In order to obtain the full NLO amplitude for DIS at high energy, one needs to calculate the coefficient function (photon impact factor) at NLO and convolute it with the NLO evolution kernel of the relative operator (the NLO BK kernel). The NLO impact factor has been calculated in ref. [839] where an analytic expression (in coordinate space) has been obtained for the first time.

High-energy operator product expansion: In the usual OPE, due to the presence of two different scales of the transverse momentum $k_{\perp}$, one introduces a factorization scale, usually denoted by $\mu$, which factorizes the amplitude of DIS processes in pertubatively calculable contributions (hard part) and in a non-pertubatively calculable ones (soft part) represented by matrix elements made of light-ray operators. The evolution of such matrix elements with respect to the renormalization point $\mu$ is the DGLAP evolution equation.

At high-energy (Regge limit), all the transverse momenta are of the same order of magnitude. Therefore, a suitable factorization scale would be the rapidity scale: one introduces rapidity $(\eta)$ which separates "fast" fields from "slow" fields. Thus, the amplitude of the process can be represented as a convolution of contributions coming from fields with rapidity $\eta<Y$ (fast fields) and contributions coming from fields with rapidity $\eta>Y$ (slow fields). As in the case of the usual OPE, the integration over the fields with rapidity $\eta<Y$ gives us the coefficient functions while the integrations over fields with rapidity $\eta>Y$ are the matrix elements of the operators. A general feature of high-energy scattering is that a fast particle moves along its straight-line classical trajectory and the only quantum effect is the eikonal phase factor acquired along this propagation path. In QCD, for the fast quark or gluon scattering off some target, this eikonal phase factor is a Wilson line - an infinite
gauge link ordered along the straight line collinear to the particle's velocity $n^{\mu}$ :

$$
\begin{equation*}
U^{\eta}\left(x_{\perp}\right)=\operatorname{Pexp}\left\{i g \int_{-\infty}^{\infty} d u n_{\mu} A^{\mu}\left(u n+x_{\perp}\right)\right\} \tag{5.44}
\end{equation*}
$$

Here, $A_{\mu}$ is the gluon field of the target, $x_{\perp}$ is the transverse position of the particle which remains unchanged throughout the collision, and the index $\eta$ labels the rapidity of the particle. Repeating the above argument for the target (moving fast in the spectator's frame) we see that particles with very different rapidities perceive each other as Wilson lines and therefore Wilson-line operators are the convenient effective degrees of freedom in high-energy QCD (for a review, see Ref. [840]). The expansion of the T product of two electromagnetic currents at high-energy (Regge limit) is then in terms of Wilson lines

$$
\begin{aligned}
& T\left\{\hat{j}_{\mu}(x) \hat{j}_{\nu}(y)\right\}=\int d^{2} z_{1} d^{2} z_{2} I_{\mu \nu}^{\mathrm{LO}}\left(x, y ; z_{1}, z_{2}\right) \hat{\mathcal{U}}\left(z_{1}, z_{2}\right) \\
& +\int d^{2} z_{1} d^{2} z_{2} d^{2} z_{3} I_{\mu \nu}^{\mathrm{NLO}}\left(x, y ; z_{1}, z_{2}, z_{3}\right)\left[\hat{\mathcal{U}}\left(z_{1}, z_{3}\right)+\hat{\mathcal{U}}\left(z_{2}, z_{3}\right)-\hat{\mathcal{U}}\left(z_{1}, z_{2}\right)-\hat{\mathcal{U}}\left(z_{1}, z_{3}\right) \hat{\mathcal{U}}\left(z_{3}, z_{2}\right)\right]
\end{aligned}
$$

where

$$
\begin{equation*}
\hat{\mathcal{U}}^{\eta}\left(x_{\perp}, y_{\perp}\right)=1-\frac{1}{N_{c}} \operatorname{Tr}\left\{\hat{U}^{\eta}\left(x_{\perp}\right) \hat{U}^{\dagger \eta}\left(y_{\perp}\right)\right\} \tag{5.45}
\end{equation*}
$$

The evolution of the Wilson line operator in eq. (5.45) is given by the BK equation [770, 741, 747,

$$
\begin{array}{r}
\frac{d}{d \eta} \hat{\mathcal{U}}(x, y)=\frac{\alpha_{s} N_{c}}{2 \pi^{2}} \int d^{2} z \frac{(x-y)^{2}}{(x-z)^{2}(z-y)^{2}}[\hat{\mathcal{U}}(x, z)+\hat{\mathcal{U}}(y, z) \\
-\hat{\mathcal{U}}(x, y)-\hat{\mathcal{U}}(x, z) \hat{\mathcal{U}}(z, y)] \tag{5.46}
\end{array}
$$

The first three terms correspond to the linear BFKL evolution equation [836, 60] and describe parton emission while the last term is responsible for parton annihilation. For sufficiently low $x_{B}$, parton emission balances parton annihilation so the partons reach the state of saturation [742, 841, 842] with the characteristic transverse momentum $Q_{s}$ growing with energy $1 / x_{B}$. The NLO evolution equation for composite Wilson line operator (preserving conformal invariance as explained in the introduction) has been calculated in [835, where one can find the full analytic expression.

In order to obtain the DIS amplitude at high-energy at the NLO, we now need the coefficient function ("impact factor") at next to leading order. Here, we present the NLO impact factor for the study of DIS in the linearized case (two gluon approximation) where the NLO BK equation reduces to the NLO BFKL equation. In this case the OPE at high energy for DIS reduces to

$$
\begin{align*}
& \frac{1}{N_{c}}(x-y)^{4} T\left\{\overline{\hat{\psi}}(x) \gamma^{\mu} \hat{\psi}(x) \overline{\hat{\psi}}(y) \gamma^{\nu} \hat{\psi}(y)\right\}  \tag{5.47}\\
& =\frac{\partial \kappa^{\alpha}}{\partial x^{\mu}} \frac{\partial \kappa^{\beta}}{\partial y^{\nu}} \int \frac{d z_{1} d z_{2}}{z_{12}^{4}} \hat{\mathcal{U}}_{a_{0}}\left(z_{1}, z_{2}\right)\left[\mathcal{I}_{\alpha \beta}^{\mathrm{LO}}\left(1+\frac{\alpha_{s}}{\pi}\right)+\mathcal{I}_{\alpha \beta}^{\mathrm{NLO}}\right]
\end{align*}
$$

where

$$
\begin{equation*}
\mathcal{I}_{\mathrm{LO}}^{\alpha \beta}\left(x, y ; z_{1}, z_{2}\right)=\mathcal{R}^{2} \frac{g^{\alpha \beta}\left(\zeta_{1} \cdot \zeta_{2}\right)-\zeta_{1}^{\alpha} \zeta_{2}^{\beta}-\zeta_{2}^{\alpha} \zeta_{1}^{\beta}}{\pi^{6}\left(\kappa \cdot \zeta_{1}\right)\left(\kappa \cdot \zeta_{2}\right)} \tag{5.48}
\end{equation*}
$$

is the LO impact factor and where we used the notation $\mathcal{R} \equiv \frac{\kappa^{2}\left(\zeta_{1} \cdot \zeta_{2}\right)}{2\left(\kappa \cdot \zeta_{1}\right)\left(\kappa \cdot \zeta_{2}\right)}$, and the conformal vectors $\kappa=\frac{\sqrt{s}}{2 x_{*}}\left(\frac{p_{1}}{s}-x^{2} p_{2}+x_{\perp}\right)-\frac{\sqrt{s}}{2 y_{*}}\left(\frac{p_{1}}{s}-y^{2} p_{2}+y_{\perp}\right), \zeta_{i}=\left(\frac{p_{1}}{s}+z_{i \perp}^{2} p_{2}+z_{i \perp}\right)$ with $x_{*}=p_{2}^{\mu} x_{\mu}=\frac{\sqrt{2}}{s} x^{+}$(s is the Mandelstam variable). The analytic expression of the NLO impact factor for DIS at high energies can be found in Ref. [839]. Note that the NLO impact factor is conformally (Möbius) invariant and is given by a linear combination of five conformal tensor structures as predicted in [843]. The next natural step would be the Fourier transformation of the result in ref. [839] (the NLO impact factor), which gives the momentum-space impact factor convenient for phenomenological applications (and available at present only as a combination of numerical and analytical expressions [844, 845, 846]).

Conclusions: We have briefly summarized the status of the NLO calculation of the structure function for DIS at high energy. The main ingredients for the full amplitude, namely the NLO BK kernel and the NLO IF, have been calculated. The main result of this analysis is that the OPE for high energy (Regge limit) is at the same status as the usual OPE in the Bjorken limit. This means that the factorization in rapidity did not break down at NLO accuracy. As an application of the factorization in rapidity, the full NLO analytic amplitude in $\mathcal{N}=4$ SYM was calculated, the NLO result for the Pomeron intercept at small $\alpha_{s}$ was confirmed, and for the first time the NLO Pomeron residue was obtained [847].

The Wilson line formalism proved to be very successful, not only in obtaining in a more efficient way many results that in the usual pertubative QCD mechanism ( pQCD ), were obtained after many years of calculations by several groups, but also to obtain some results that have not been obtained (not for lack of efforts) in the usual pQCD mechanism, like the NLO impact factor, the NLO conformal BFKL kernel and the NLO pomeron residue, and in addition to generalize these results to include the non linear effects dominant at high energies. Another example which proves the efficiency of this formalism is the calculation, in a very easy way, of the triple pomeron vertex for diffractive and non-diffractive ("fan diagrams") processes, including the subleading $N_{c}$ contributions 848.

## Running Coupling in Small-x Physics

## Yuri V. Kovchegov

Running coupling corrections have been included into BFKL/BK/JIMWLK evolution following the Brodsky-Lepage-Mackenzie (BLM) scale-setting procedure 849] in 850, 834, 833, 851, 751. The BLM prescription requires one to first re-sum the contribution of all quark bubble corrections giving powers of $\alpha_{\mu} N_{f}$, with $N_{f}$ the number of quark flavors and $\alpha_{\mu}$ the physical coupling at some arbitrary renormalization scale $\mu$. One then has to complete $N_{f}$ to the full beta-function by replacing $N_{f} \rightarrow-6 \pi \beta_{2}$ in the obtained expression. Here, $\beta_{2}=\left(11 N_{c}-2 N_{f}\right) /(12 \pi)$ is the one-loop QCD beta-function. After this, the powers of $\alpha_{\mu} \beta_{2}$ should combine into physical running couplings $\alpha_{s}\left(Q^{2}\right)=\alpha_{\mu} /\left(1+\alpha_{\mu} \beta_{2} \ln \left(Q^{2} / \mu^{2}\right)\right)$ at various momentum scales $Q$ which would follow from this calculation. The running coupling below will be written in the $\overline{\mathrm{M} S}$ renormalization scheme.

Below we will concentrate on the case of running coupling corrections to the BFKL and BK evolution equations. Running-coupling corrections to the JIMWLK equation can
be found in [834, 751]. At the moment the running coupling corrections to BK have been better explored numerically than those for JIMWLK.

Analytic result: Let us briefly summarize the results of [834, 833, 751]. The BalitskyKovchegov evolution equation with the running coupling corrections included (rcBK) reads

$$
\begin{equation*}
\frac{\partial S\left(\underline{x}_{0}, \underline{x}_{1} ; Y\right)}{\partial Y}=\mathcal{R}[S]-\mathcal{S}[S] . \tag{5.49}
\end{equation*}
$$

Here we use the $S$-matrix notation, related to the forward dipole amplitude by $S\left(\underline{x}_{0}, \underline{x}_{1} ; Y\right)=$ $1-N\left(\underline{x}_{0}, \underline{x}_{1} ; Y\right)$. The first term on the right hand side of Eq. (5.49) is referred to as the running coupling contribution, while the second term on the right hand side of Eq. (5.49) is referred to as the subtraction contribution. Separation into the two parts is arbitrary, and was done differently in 833 ] and [834, with the net sum being the same [751].

The running coupling part was calculated independently in 833] and in [834: the results of those calculations are

$$
\begin{align*}
\mathcal{R}^{\mathrm{Bal}}[S] & =\int d^{2} z \tilde{K}^{\mathrm{Bal}}\left(\underline{x}_{0}, \underline{x}_{1}, \underline{z}\right)\left[S\left(\underline{x}_{0}, \underline{z} ; Y\right) S\left(\underline{z}, \underline{x}_{1} ; Y\right)-S\left(\underline{x}_{0}, \underline{x}_{1} ; Y\right)\right]  \tag{5.50}\\
\mathcal{R}^{\mathrm{KW}}[S] & =\int d^{2} z \tilde{K}^{\mathrm{KW}}\left(\underline{x}_{0}, \underline{x}_{1}, \underline{z}\right)\left[S\left(\underline{x}_{0}, \underline{z} ; Y\right) S\left(\underline{z}, \underline{x}_{1} ; Y\right)-S\left(\underline{x}_{0}, \underline{x}_{1} ; Y\right)\right] . \tag{5.51}
\end{align*}
$$

The integral kernels in the two cases are given by

$$
\begin{equation*}
\tilde{K}^{\mathrm{Bal}}\left(\underline{r}, \underline{r}_{1}, \underline{r}_{2}\right)=\frac{N_{c} \alpha_{s}\left(r^{2}\right)}{2 \pi^{2}}\left[\frac{r^{2}}{r_{1}^{2} r_{2}^{2}}+\frac{1}{r_{1}^{2}}\left(\frac{\alpha_{s}\left(r_{1}^{2}\right)}{\alpha_{s}\left(r_{2}^{2}\right)}-1\right)+\frac{1}{r_{2}^{2}}\left(\frac{\alpha_{s}\left(r_{2}^{2}\right)}{\alpha_{s}\left(r_{1}^{2}\right)}-1\right)\right] \tag{5.52}
\end{equation*}
$$

as found in 833 and by

$$
\begin{equation*}
\tilde{K}^{\mathrm{KW}}\left(\underline{r}, \underline{r}_{1}, \underline{r}_{2}\right)=\frac{N_{c}}{2 \pi^{2}}\left[\alpha_{s}\left(r_{1}^{2}\right) \frac{1}{r_{1}^{2}}-2 \frac{\alpha_{s}\left(r_{1}^{2}\right) \alpha_{s}\left(r_{2}^{2}\right)}{\alpha_{s}\left(R^{2}\right)} \frac{r_{1} \cdot \underline{r}_{2}}{r_{1}^{2} r_{2}^{2}}+\alpha_{s}\left(r_{2}^{2}\right) \frac{1}{r_{2}^{2}}\right] \tag{5.53}
\end{equation*}
$$

as found in [834], where

$$
\begin{equation*}
R^{2}\left(\underline{r}, \underline{r}_{1}, \underline{r}_{2}\right)=r_{1} r_{2}\left(\frac{r_{2}}{r_{1}}\right)^{\frac{r_{1}^{2}+r_{2}^{2}}{r_{1}^{2}-r_{2}^{2}}-2 \frac{r_{1}^{2} r_{2}^{2}}{r_{1}-r_{2}} \frac{1}{r_{1}^{2}-r_{2}^{2}}} . \tag{5.54}
\end{equation*}
$$

One notices immediately that $\mathcal{R}^{\mathrm{Bal}}[S]$ calculated in [833] is different from $\mathcal{R}^{\mathrm{KW}}[S]$ calculated in 834 due to the difference in the kernels $\tilde{K}^{\text {Bal }}$ and $\tilde{K}^{\mathrm{KW}}$ in Eqs. (5.52) and (5.53). However that does not imply disagreement between the calculations of 833] and [834): after all, it is the full kernel on the right of Eq. (5.49), $\mathcal{R}[S]-\mathcal{S}[S]$, that needs to be compared. To do that, one has to calculate the second term on the right hand side of Eq. (5.49) (the subtraction contribution). This was done in [751, yielding

$$
\begin{align*}
\mathcal{S}[S]= & \alpha_{\mu}^{2} \int d^{2} z_{1} d^{2} z_{2} K_{(1)}\left(\underline{x}_{0}, \underline{x}_{1} ; \underline{z}_{1}, \underline{z}_{2}\right) \\
& \times\left[S\left(\underline{x}_{0}, \underline{w}, Y\right) S\left(\underline{w}, \underline{x}_{1}, Y\right)-S\left(\underline{x}_{0}, \underline{z}_{1}, Y\right) S\left(\underline{z}_{2}, \underline{x}_{1}, Y\right)\right] \tag{5.55}
\end{align*}
$$

and the re-summed BK kernel $K_{(1)}$ can be found in the original reference. Substituting $\underline{w}=\underline{z}_{1}$ (or, equivalently, $\underline{w}=\underline{z}_{2}$ ) in Eq. (55.55) yields the subtraction term $\mathcal{S}^{\text {Bal }}[S]$, which has to be subtracted from $\mathcal{R}^{\mathrm{Bal}}[S]$ calculated in [833] and given by Eq. (55.50) to obtain

Figure 5.31. Solutions of the complete (all orders in $\alpha_{s} \beta_{2}$ ) evolution equation given in Eq. (5.49) (solid lines), and of the equation with Balitsky's (dashed lines) and KW's (dashed-dotted) running coupling schemes at rapidities $Y=0,3$ and 10. Left plot uses quasi-classical McLerran-Venugopalan (MV) initial condition. The right plot employs the initial condition given by the dipole amplitude at rapidity $Y=35$ evolved using Balitsky's running coupling scheme and with $r$-dependence rescaled down such that $Q_{s}=Q_{s}^{\prime}=1 \mathrm{GeV}$.
the complete evolution equation re-summing all orders of $\alpha_{s} N_{f}$ in the kernel. Substituting $\underline{w}=\underline{z}=\alpha \underline{z}_{1}+(1-\alpha) \underline{z}_{2}$ in Eq. (5.55) yields the term $\mathcal{S}^{\mathrm{KW}}[S]$, which has to be subtracted from $\mathcal{R}^{\mathrm{KW}}[S]$ calculated in 834 and given in Eq. (5.51) again to obtain the complete evolution equation re-summing all orders of $\alpha_{s} N_{f}$ in the kernel.

Numerical Solution: The numerical solution of the running-coupling BK (rcBK) evolution just presented was performed in [751] and plotted in Fig. 5.31. One plots the runningcoupling parts from Eqs. (5.50) and (5.51) [834, 833] (dashed and dash-dotted lines correspondingly), along with the full solution (solid line). As one can see the full solution is best approximated by the Balitsky's running coupling scheme from Eq. (5.50) 833. Hence in most phenomenological applications one simply solves rcBK with Balitsky's prescription [85), 852]. Note that the rcBK solution also exhibits the property of geometric scaling [752], as was shown in [751.

Running-coupling BFKL evolution: The running-coupling BFKL equation (rcBFKL) was constructed in 851 and reads

$$
\begin{align*}
\frac{\partial \phi(k, Y)}{\partial Y}=\frac{N_{c}}{2 \pi^{2}} \int d^{2} q\{ & \frac{2}{(\boldsymbol{k}-\boldsymbol{q})^{2}} \alpha_{s}\left((\boldsymbol{k}-\boldsymbol{q})^{2} e^{-5 / 3}\right) \phi(q, Y) \\
& \left.-\frac{\boldsymbol{k}^{2}}{\boldsymbol{q}^{2}(\boldsymbol{k}-\boldsymbol{q})^{2}} \frac{\alpha_{s}\left(\boldsymbol{q}^{2} e^{-5 / 3}\right) \alpha_{s}\left((\boldsymbol{k}-\boldsymbol{q})^{2} e^{-5 / 3}\right)}{\alpha_{s}\left(\boldsymbol{k}^{2} e^{-5 / 3}\right)} \phi(k, Y)\right\}, \tag{5.56}
\end{align*}
$$

where the unintegrated gluon distribution $\phi(k, Y)$ is defined by

$$
\begin{equation*}
N\left(x_{01}, Y\right)=\int \frac{d^{2} k}{(2 \pi)^{2}}\left(1-e^{i \boldsymbol{k} \cdot \boldsymbol{x}_{01}}\right) \tilde{N}(k, Y) \tag{5.57}
\end{equation*}
$$

with

$$
\begin{equation*}
\alpha_{s}\left(k^{2}\right) \phi(k, Y)=\frac{N_{c} S_{\perp}}{(2 \pi)^{3}} k^{2} \tilde{N}(k, Y) . \tag{5.58}
\end{equation*}
$$

Here $S_{\perp}$ is the transverse area of the target. The running-coupling BFKL equation (5.56) was originally conjectured in [853, 854] by postulating the validity of the bootstrap equation for running-coupling corrections.

## Running-coupling and higher-order effects on the saturation scale

Guillaume Beuf

The DGLAP [855, 856, 857] and BFKL [858, 59, 60] equations give the evolution with kinematics of the partonic content of hadrons and nuclei in the regime where these are dilute. As these equations are linear, they can be solved analytically by using a Mellin tranform. By contrast, when the phenomenon of gluon saturation [742] is taken taken into account, the relevant evolution equations - B-JIMWLK [770, 756, 757, 759, 760, 761, 745, 762, 763] or BK [770, 741, 747] - are nonlinear, and thus cannot be solved analytically.

Nevertheless, the solutions of these nonlinear equations in the leading order (LO) approximation (where the coupling $\alpha_{s}$ is kept fixed) are well understood, by combining results from numerical simulations [859, 750,860 and analytical asymptotic expansions [755, 861, 862, 863, 864. Indeed, the BK equation belongs to a well-studied class of nonlinear equations, whose solutions develop asymptotically a universal traveling wave-front structure [865, 866], which is independent of the initial condition 3 . In the context of QCD, that traveling wavefront structure of the solution implies the geometric scaling [752] property found in the DIS data at HERA: the total virtual photon - target cross sections $\sigma_{T, L}^{\gamma^{*}}\left(Y, Q^{2}\right)$ depend on $Y$ and $Q^{2}$ essentially only through the combination $Q^{2} / Q_{s}^{2}(Y)$, because the dipole-target amplitude solution of the BK equation depends only on $r^{2} Q_{s}^{2}(Y)$ at large $Y, r$ being the dipole size. The evolution of the saturation scale $Q_{s}^{2}(Y)$ is obtained from the propagation of the wave-front. For the LO BK equation, one gets a large $Y$ expansion of the form

$$
\begin{equation*}
\log Q_{s}^{2}(Y)=a_{1} Y+a_{0} \log Y+\text { Const. }+a_{-1 / 2} Y^{-1 / 2}+\mathcal{O}\left(Y^{-1}\right) \tag{5.59}
\end{equation*}
$$

where $a_{1}, a_{0}$ and $a_{-1 / 2}$ are three known universal coefficients [864], whereas the constant term and all the ones of order $Y^{-1}$ or less do depend on the initial conditions, i.e. on the nature of the target used for the DIS. From geometric considerations, the initial $Q_{s}^{2}$ of a nucleus $A$ is enhanced by a factor $A^{1 / 3}$ with respect to that of a proton. That nuclear enhancement of $Q_{s}^{2}(Y)$ is preserved by the LO high-energy evolution, in the constant term of the expansion (5.59). Both from numerical simulations and from the expansion (5.59), one learns that the evolution of $Q_{s}^{2}(Y)$ implied by the LO BK equation is too fast to be compatible with the data for DIS and other observables, which favor $\log Q_{s}^{2}(Y) \sim \lambda Y$, with $\lambda \simeq 0.2$ or 0.3 . We are thus forced to consider higher order corrections to the BK equation.

Running vs. fixed coupling: As discussed in this section by Chirilli, the BK equation is now known at next-to-leading order (NLO) [835, 837]. However, its solutions are much less understood than the ones of the LO equation. Indeed no numerical simulations of the full NLO BK equation have been performed yet, for technical reasons, but only simulations [859, 750, 860, 751, 867 of the BK equation with LO kernel and running coupling $\alpha_{s}$, with various prescriptions used to set the scale in the coupling. By contrast, it is non-trivial to go from fixed coupling to running coupling in the analytical studies, since it leads to a different class

[^277]of wave-front solutions, for which universality of the asymptotics is not fully established. The inclusion of other NLO corrections gives however no additional difficulty. Let us first discuss the effects of running coupling only.

A priori, the running of the coupling brings the additional scale $\Lambda_{Q C D}$ into the problem, which may spoil the geometric scaling property. Indeed, there is no interval where the solutions of the running coupling BK equation show exact geometric scaling, by contrast to fixed coupling solutions, but they satisfy an approximate geometric scaling in some range. Equivalently, the wave-front in the solutions is being slowly distorted during its propagation, instead of being uniformly translated as in the fixed coupling case.

Running coupling effects turn the asymptotic behavior of the saturation scale into $\log Q_{s}^{2}(Y) \propto \sqrt{Y}$, as found in early analytical studies [742, 755, 861, 863. More precisely its large $Y$ asymptotics writes

$$
\begin{equation*}
\log \left(Q_{s}^{2}(Y) / \Lambda_{Q C D}^{2}\right)=b_{1 / 2} \sqrt{Y}+b_{1 / 6} Y^{1 / 6}+b_{0}+b_{-1 / 6} Y^{-1 / 6}+b_{-1 / 3} Y^{-1 / 3}+\mathcal{O}\left(Y^{-1 / 2}\right) \tag{5.60}
\end{equation*}
$$

where the first five terms are universal and known 4 , whereas the following ones of order $Y^{-1 / 2}$ or less are sensitive to the initial conditions. The universality of the constant term $b_{0}$ in (5.60) implies that initial conditions effects such as the nuclear $A^{1 / 3}$ enhancement of $Q_{s}^{2}$ are washed-out at high rapidity when the coupling is running, as first predicted in [869]. Numerically, it has been found [750, 860, 870] that this effect happens at very high rapidity. Hence, the nuclear enhancement of $Q_{s}^{2}$, which is one of the motivations for doing nuclear DIS at the EIC, should still be present in the kinematical range accessible at the EIC. Remarkably, the evolution of the saturation scale in the running coupling case is such that very good fits of DIS data can be performed with solutions of the running coupling BK equation [85, 820], by contrast to the fixed coupling case, without the inclusion of other NLO effects.

Other NLO effects: Apart from the contributions re-summed into the running of the coupling, there are large NLO corrections to the BK kernel, related to the large NLO corrections to the BFKL kernel [722, 723].

In a conformal gauge field theory, terms of arbitrary $\mathrm{N}^{n} \mathrm{LO}$ order from the kernel would contribute at each order of the expansion (5.59). By contrast, the running of the coupling is dynamically quenching the effect on the solutions of higher order terms in the kernel. NLO contributions start to appear at order $Y^{0}$ in (5.60), NNLO contributions at order $Y^{-1 / 2}$ and so on. Moreover, the coefficient $b_{-1 / 6}$ has been found to be NLO-independent [868]. Apart from the running of the coupling, NLO contributions thus affect mostly the normalization of $Q_{s}^{2}(Y)$ at large $Y$, via $b_{0}$, and only mildly the asymptotic $Y$-evolution of $Q_{s}^{2}(Y)$, via $b_{-1 / 3} Y^{-1 / 3}$ and further subleading terms. That property is indeed seen in numerical simulations with running coupling and a subset of other NLO contributions included 867. That result shed some light on the spectacular success of the running coupling LO BK equation to describe DIS data. There is a degeneracy in (5.60) between the contribution of $\Lambda_{Q C D}$ and $b_{0}$ to $Q_{s}^{2}(Y)$. Hence, treating $\Lambda_{Q C D}$ as a free fit parameter as in Refs. 85, 820] allows one to fit the bulk of NLO effects, without actually simulating the BK evolution with NLO kernel.

Several prescriptions [833, 834] have been proposed to split NLO corrections into contributions to the running coupling or to the kernel. Hence, BK equations with running

[^278]coupling and LO kernel obtained following different prescriptions differ formally by terms of order NLO and beyond in the kernel. In numerical simulations of such running coupling LO BK equations [751], solutions with different prescriptions differ at large $Y$ mostly by a constant rescaling of $Q_{s}^{2}(Y)$, in agreement with our previous discussion.

The problems brought by the impact-parameter dependence: Implicitly, we have discussed so far only results from studies of impact parameter independent solutions of the BK equation. The BK equation preserves unitarity at fixed impact parameter. However, its impact parameter dependent solutions violate unitarity since they violate the Froissart bound [871] on the cross-section [872, 867], due to the unphysical possibility of gluon emission at arbitrarily long range in the transverse plane. The running of the coupling reveals another problem: there is a reappearance of the diffusion into the infrared [867, which was thought to be cured by gluon saturation, from studies of impact parameter independent solutions of the BK equation. Hence, the impact parameter dependent solutions of the BK solutions are very sensitive to strongly coupled infrared physics, which is not yet implemented in the formalism. This is the most challenging open theoretical problem with regard to gluon saturation. Therefore, it is not yet clear to what extent the results about impact parameter independent solutions presented in the previous sections are reliable for realistic proton or nuclear targets.

### 5.4 Diffractive DIS ( $\mathbf{F}_{2}^{D}, \mathbf{F}_{L}^{D}$, charm contribution)

## Diffraction in $e+p$ and $e+A$ collisions

Cyrille Marquet

A non-negligible fraction of the events in DIS are diffractive, meaning that the hadronic target, of mass $M$, escapes the collision intact. As a colorless object has been exchanged in the t-channel, there is rapidity gap void of particles in the final state, between the outgoing target and the diffractive final state $X$, made up of all the other particles in the event. On top of $x$ and $Q^{2}$, two additional kinematic invariants are needed to characterize diffraction in DIS: the momentum transfer $t<0$ at the hadronic vertex, and the mass $M_{X}$ of the diffractive final state. In practice, the variable $M_{X}$ is sometimes traded for $\beta$ and the variable $x$ is traded for $x_{\mathbb{P}}$-these are defined as

$$
\begin{equation*}
\beta=\frac{Q^{2}}{Q^{2}+M_{X}^{2}-t} ; x_{\mathbb{P}}=\frac{x}{\beta}=\frac{Q^{2}+M_{X}^{2}-t}{Q^{2}+W^{2}-M^{2}} . \tag{5.61}
\end{equation*}
$$

Small values of $\beta$ refer to events with diffractive masses much bigger than the photon virtuality, while values of $\beta$ close to unity refer to the opposite situation. $x_{\mathbb{P}}$ is useful because it characterizes the size of the rapidity gap $\Delta \eta \simeq \ln \left(1 / x_{\mathbb{P}}\right)$.

There are events in which the hadronic target, instead of staying intact, may dissociate into a low-mass excited state Y, while still leaving a rapidity gap in the final state. These events are also classified as diffractive, they occur only if the mass $M_{Y}$ of the excited state is close enough to the initial mass $M$. Coherent diffraction is employed when the target scatters elastically ( $\mathrm{ep} \rightarrow \mathrm{eXp}$ ), while incoherent diffraction refers to the more general case $e p \rightarrow e X Y$ which is a sum of coherent diffraction $(Y=p)$ and target-dissociative diffraction $(\mathrm{Y} \neq \mathrm{p})$. The former dominates at low $|t|$ and the latter at large $|t|$.

While in the leading-twist approximation of QCD there is a collinear factorization theorem to compute diffractive structure functions in DIS at large $Q^{2}$, the description of hard diffraction in this framework is not as natural as for inclusive events. This is reflected in the fact that standard parton distribution functions (pdfs) are of no help to compute $F_{2}^{D}$, and one has to introduce a different set of parton distributions called diffractive pdfs (dpdfs). Therefore in the collinear factorization framework, the description of the parton content of the proton depends on whether or not the final state is diffractive. While this is successful - and should be since collinear factorization is a good approximation of QCD at large $Q^{2}$ - conceptually it is not so satisfactory as one would like to be able to describe any process with a single proton wave function.

No further conceptual advances are expected within the leading-twist approximation of QCD. There are some technical improvements that can be made, for instance it is nowadays practically impossible to extract dpdfs without assuming what is called Regge factorization: $\operatorname{dpdf}\left(x_{\mathbb{P}}, t, \beta, Q^{2}\right)=f\left(x_{\mathbb{P}}, t\right) g\left(\beta, Q^{2}\right)$. This is not satisfactory, since such a factorization is not a property of QCD. However, there is little doubt that if one could bypass this practical problem - perhaps with a larger data sample in all four directions: $Q^{2}, \beta, x_{\mathbb{P}}$ and $t$ - this approach would succeed at large $Q^{2}$.

But in fact, the purpose of an electron-ion collider is not to check whether DGLAP evolution will work at large $Q^{2}$, the goal is rather to explore what we don't know as well: the non-linear regime of QCD where collinear factorization breaks down. To be more specific, we are interested in the regime $Q^{2}<5 \mathrm{GeV}^{2}$ and $x$ as small as possible. Interestingly enough, studying the non-linear saturation regime will be easier with diffractive than with inclusive
measurements. This is so because at small $x$, diffractive processes are mostly sensitive to quantum fluctuations in the proton wave function that have a virtuality of order $Q_{s}^{2}$, instead of $Q^{2}$. As a result, power corrections (not the generic $\Lambda_{Q C D}^{2} / Q^{2}$ corrections, but rather the sub-class of them of order $Q_{s}^{2} / Q^{2}$ important at small $x$ ) are expected to come into play starting from a higher value of $Q^{2}$ in diffractive DIS, compared to inclusive DIS. In fact, there is already a hint that this is happening at HERA: collinear factorization starts to fail below about $2 \mathrm{GeV}^{2}$ in the case of $F_{2}$, while already below about $8 \mathrm{GeV}^{2}$ in the case of $F_{2}^{D}$.

The QCD description of diffractive DIS in the small- $x$ limit turns out to be much more insightful than that of the large- $Q^{2}$ limit. It is so because at small $x$, DDIS can be expressed in the Good-Walker picture (which was originally imagined for soft diffraction in hadronhadron collisions), with the benefit that, thanks to the point-like nature of the photon, the modeling part of the Good-Walker approach can be replaced by actual QCD computations. This remarkable realization of the Good-Walker picture in small-x DIS is more commonly referred to as the dipole picture: dipoles are eigenstates of high-energy scattering in QCD, and it is known how to expand the photon wave function onto the dipole basis. At the end in this approach, the parton content of the proton - both in the linear and non-linear regimes - is parametrized through the dipole cross section. As a result, diffractive structure functions also feature geometric scaling [873]. Another important fact is that at small $x$, diffraction can be entirely predicted, once the dipole cross section has been constrained with inclusive data.

In spite of the fact that this approach has been able to successfully predict $F_{2}^{D}$ at small $x$, there is still important conceptual progress to be made. For instance, the transverse impact parameter dependence of the dipole scattering amplitude is very poorly constrained. Indeed, one has been able to describe $F_{2}$ and correctly predict $F_{2}^{D}$ with two kinds of impact parameter dependences, neither of which is fully satisfactory. In a first class of dipole models, the impact parameter profile of the proton is independent of energy, yielding a dipole cross section bounded from above. In the other class of models, the black-disk regime of maximal scattering strength spreads too quickly in the transverse plane with increasing dipole size $r$, leading to a dipole cross section which diverges for large $r$. It is quite clear that the LHeC is needed to help us understand better this issue.

Finally, let us say a few important words on ep $\rightarrow$ eXY diffractive events. In past experiments, events with $Y \neq p$ have mostly been regarded as background, and model-dependent subtractions have been applied to data, yielding large normalization uncertainties. Within the kinematic reach of HERA, it has been observed that the ratio $d \sigma^{e p \rightarrow e X Y} / d \sigma^{e p \rightarrow e X p}$ is a constant independent of all kinematic variables other than $M_{Y}$ and $t$ (that ratio increases with $M_{Y}$ and $|t|$ ). Here we would like to emphazise that proton-dissociative events are also intrinsically interesting. For instance, at small $x$ the cross section difference $d \sigma^{e p \rightarrow e X Y}-d \sigma^{e p \rightarrow e X p}$ is $1 / N_{c}^{2}$ suppressed, meaning that if it were measured accurately, it would give access to details of the QCD dynamics which are untestable otherwise. The EIC provides such an opportunity.

After many fixed target experiments, it took a collider to discover diffractive events in $\mathrm{e}+\mathrm{p}$. Since no e+A collider has ever been built, diffraction in $\mathrm{e}+\mathrm{A}$ has simply never been measured. That such a deficiency exists in our knowledge of nuclear structure is compelling enough to build the EIC. Everything we would learn about DDIS off nuclei at the EIC will be new, in any kinematical domain, implying a huge discovery potential. Nevertheless, we have expectations of what diffraction off nuclei should look like, based on our current understanding of QCD. For instance, the theory of nuclear shadowing allows the
constuction of nuclear DPDFs for large $Q^{2}$ physics, while within the Color Glass Condensate framework, nuclear diffractive structure functions can be predicted at small $x$. Depending on these kinematics, different patterns of nuclear shadowing or antishadowing as a function of $\beta$ and $x_{\mathbb{P}}$ are expected. This is just one example out of many that should be checked with an e+A collider. Since the current predictions rely on rather simple models for impact parameter dependence, they need to be confronted to data, in order to, in return, improve our understanding.

Finally, there is one aspect of diffraction which is specific to nuclei that one should mention. The structure of incoherent diffraction $\mathrm{eA} \rightarrow \mathrm{eXY}$ is more complex than with a proton target, and also can teach us a lot more. In the case of a target nucleus, we expect the following qualitative changes in the $t$ dependence. First, the low- $|t|$ regime in which the nucleus scatters elastically will be dominant up to a smaller value of $|t|$ (to about $|t|=0.05 \mathrm{GeV}^{2}$ ) compared to the proton case, reflecting the larger size of the nucleus. Then, the nucleus-dissociative regime will comprise two parts: an intermediate regime in momentum transfer up to about $0.7 \mathrm{GeV}^{2}$ where the nucleus will predominantly break up into its constituents nucleons, and a large $-|t|$ regime where the nucleons inside the nucleus will also break up, implying pion production in the $Y$ system for instance. These are only qualitative expectations, it is crucial to study this aspect of diffraction quantitatively in order to complete our understanding of the structure of nuclei.

## Expectations for e+A from the CGC

## Cyrille Marquet

In this work, hard diffraction in electron-nucleus (e+A) collisions is considered within the IPsat model, 600 corresponding to the classical limit of the Color Glass Condensate approach. This effective theory of QCD at high partonic density is the most natural framework to describe the saturation phenomenon, and therefore to study e+A scattering at high energies, in particular diffractive observables. Here we shall focus on the nuclear diffractive structure function $F_{2, A}^{D}$.

Let us recall the kinematics of diffractive DIS: $\gamma^{*} A \rightarrow X A$. With a momentum transfer $t \leq 0$, the proton/nucleus gets out of the $\gamma^{*}-A$ collision intact, and is separated by a rapidity gap from the other final-state particles whose invariant mass we denote $M_{X}$. The photon virtuality is denoted $Q^{2}$, and the $\gamma^{*}-A$ total energy $W$. It is convenient to introduce the following variables: $x=Q^{2} /\left(Q^{2}+W^{2}\right), \beta=Q^{2} /\left(Q^{2}+M_{X}^{2}\right)$ and $x_{\mathbb{P}}=x / \beta$. The size of the rapidity gap is $\ln \left(1 / x_{\mathbb{P}}\right)$.

The diffractive structure function is expressed as a function of $\beta, x_{\mathbb{P}}, Q^{2}$, and $t$, and we will only consider the $t$-integrated structure function $F_{2}^{D, 3}$. While at large values of $x_{\mathbb{P}}$ and $Q^{2}$, the leading-twist collinear factorization is appropriate to describe hard diffraction off protons, this is not the case at small $x_{\mathbb{P}}$ or off nuclei, as higher twists are enhanced by $\sim\left(A / x_{\mathbb{P}}\right)^{0.3}$. In this situation, the dipole picture is better suited to address the problem. It naturally incorporates the description of both inclusive and diffractive events into a common theoretical framework: [781, 874, 875] the same dipole-nucleus scattering amplitudes, which can be computed treating the nucleus as a CGC, enter in the formulation of the inclusive and diffractive cross-sections.

Diffractive structure functions in the dipole picture: In our approach, $F_{2}^{D}=F_{T}^{q \bar{q}}+$ $F_{L}^{q \bar{q}}+F_{T}^{q \bar{q} g}$ where the different pieces correspond to transversely ( T ) or longitudinally ( L )
polarized photons dissociating into a $q \bar{q}$ or $q \bar{q} g$ final state. For instance, the $q \bar{q}$ contributions are
$x_{\mathbb{P}} F_{T}^{q \bar{q}}\left(\beta, x_{\mathbb{P}}, Q^{2}\right)=\frac{N_{c} Q^{4}}{8 \pi^{3} \beta} \sum_{f} e_{f}^{2} \int_{0}^{1} d z \Theta\left(\kappa_{f}^{2}\right) z(1-z)\left[f_{T}(z) \varepsilon_{f}^{2}(z) I_{1}\left(\kappa_{f}, \epsilon_{f}\right)+m_{f}^{2} I_{0}\left(\kappa_{f}, \epsilon_{f}\right)\right]$,
$x_{\mathbb{P}} F_{L}^{q \bar{q}}\left(\beta, x_{\mathbb{P}}, Q^{2}\right)=\frac{N_{c} Q^{6}}{8 \pi^{3} \beta} \sum_{f} e_{f}^{2} \int_{0}^{1} d z \Theta\left(\kappa_{f}^{2}\right) z(1-z) f_{L}(z) I_{0}\left(\kappa_{f}, \epsilon_{f}\right)$,
with
$\varepsilon_{f}^{2}(z)=z(1-z) Q^{2}+m_{f}^{2}, \kappa_{f}^{2}(z)=z(1-z) M_{X}^{2}-m_{f}^{2}, \quad f_{T}(z)=z^{2}+(1-z)^{2}, \quad f_{L}(z)=4 z^{2}(1-z)^{2}$.
The $x_{\mathbb{P}}$ dependence comes in the functions $I_{\lambda}$ from $N_{A}\left(r, b, x_{\mathbb{P}}\right)$, the $q \bar{q}$ dipole-nucleus scattering amplitude:

$$
\begin{equation*}
I_{\lambda}(\kappa, \epsilon)=\int d^{2} b\left[\int_{0}^{\infty} r d r J_{\lambda}(\kappa r) K_{\lambda}(\epsilon r) N_{A}\left(r, b, x_{\mathbb{P}}\right)\right]^{2} \tag{5.64}
\end{equation*}
$$

where $J_{\lambda}$ and $K_{\lambda}$ are Bessel functions. In equation (5.64), the integration variables $r$ and $b$ are the $q \bar{q}$-dipole transverse size and its impact parameter.

In principle, it is justified to neglect final states containing gluons, because these are suppressed by extra powers of $\alpha_{s}$. However, for small values of $\beta$ or large values of $Q^{2}$, the $q \bar{q}$ pair will emit soft or collinear gluons whose emissions are accomponied by large logarithms $\ln (1 / \beta)$ or $\ln \left(Q^{2}\right)$ which compensate the factors of $\alpha_{s}$. In those situations, multiple gluon emissions should be re-summed; in practice, including the $q \bar{q} g$ final state is enough to describe the HERA data. In both the small- $\beta$ and large $-Q^{2}$ limits, this can be done within the dipole picture. An implementation of the $q \bar{q} g$ contribution $F_{T}^{q \bar{q} g}$ that correctly reproduces both limits was recently proposed [876], while at large $\beta$ and small $Q^{2}$, the $q \bar{q}$ contributions in equation (5.62) dominate. The formulae that we shall use can be found in ref. [876].

The dipole-nucleus scattering amplitude: We shall use the IPsat parametrization to describe the dipole-nucleus scattering amplitude:

$$
\begin{equation*}
N_{A}(r, b, x)=1-e^{-r^{2} F(r, x) \sum_{i=1}^{A} T_{p}\left(b-b_{i}\right)}, \quad F\left(x, r^{2}\right)=\frac{\pi^{2}}{2 N_{c}} \alpha_{s}\left(\mu_{0}^{2}+\frac{C}{r^{2}}\right) x g\left(x, \mu_{0}^{2}+\frac{C}{r^{2}}\right) . \tag{5.65}
\end{equation*}
$$

This is a model of a nucleus whose nucleons interact independently. Indeed, $N_{A}$ is obtained from $A$ dipole-nucleon amplitudes $N_{p}=1-\exp \left[-r^{2} F(r, x) T_{p}(b)\right]$ assuming that the probability $1-N_{A}$ for the dipole not to interact with the nucleus is the product of the probabilities $1-N_{p}$ for the dipole not to interact with the nucleons. This assumption is not consistent with the CGC quantum evolution, which sums up nonlinear interactions between the nucleons. However, the classical limit of the dipole-CGC scattering amplitude can be thought of an initial condition (5.65). Note that in the small $r$ limit, one has $N_{A}=\sum_{i} N_{p}$, and there is no leading twist shadowing.

In (5.65), $T_{p}(b) \propto \exp \left[-b^{2} /\left(2 B_{G}\right)\right]$ is the impact parameter profile function in the proton with $\int d^{2} b T_{p}(b)=1$, and $F$ is proportional to the DGLAP evolved gluon distribution. The parameters $\mu_{0}, C$, and $B_{\mathrm{G}}$ (as well as two other parameters characterising the initial condition for the DGLAP evolution) are fit to reproduce the HERA data on the inclusive proton

Figure 5.32. Left plot: $\beta$-dependence of the different contributions to the proton diffractive structure function $F_{2, p}^{D}$. Right plot: the ratio $F_{2, A}^{D} /\left(A F_{2, p}^{D}\right)$ as a function of $\beta$ for Ca , Sn and Au nuclei. In both cases, results are for the "non breakup" case, and at $Q^{2}=5 \mathrm{GeV}^{2}$ and $x_{\mathbb{P}}=0.001$.
structure function $F_{2}$. The diffractive proton structure function $F_{2}^{D}$ is well reproduced 825] after adjusting $\alpha_{s}=0.14$ in the $q \bar{q} g$ component. Vector-meson production at HERA is also well described. 823

We introduced in (5.65) the coordinates of the individual nucleons $\left\{b_{i}\right\}$, they are distributed according to the Woods-Saxon distribution $T_{A}\left(b_{i}\right)$, which means that to compute an observable, one has to perform the following average

$$
\begin{equation*}
\langle\mathcal{O}\rangle_{N} \equiv \int\left(\prod_{i=1}^{A} d^{2} b_{i} T_{A}\left(b_{i}\right)\right) \mathcal{O}\left(\left\{b_{i}\right\}\right) . \tag{5.66}
\end{equation*}
$$

The Woods-Saxon parameters are measured from the electrical charge distribution, no additional parameters are introduced. The resulting dipole cross sections give a good agreement [826] with the small-x NMC data on the nuclear structure function $F_{2, A}$. We will use this parametrization of $N_{A}$ to predict the nuclear diffractive structure function $F_{2, A}^{D}$.

Note that performing the average at the level of the amplitude (5.66), meaning calculating $\left\langle N_{A}\right\rangle_{N}^{2}$ in (5.62), imposes that the nucleus is intact in the final state. By contrast, when performing the average at the level of the cross-section, meaning calculating $\left\langle N_{A}^{2}\right\rangle_{N}$ in (5.62), one allows the nucleus to break up into individual nucleons, which will typically happen when the momentum transfer is bigger than the inverse nuclear radius. In what follows, we shall refer to those possibilities as "non breakup" and "breakup" cases.

Nuclear enhancement and suppression of $F_{2}^{D}$ : In fig. 5.32, the $\beta$ dependence of the diffractive structure function is displayed for $Q^{2}=5 \mathrm{GeV}^{2}$ and $x_{\mathbb{P}}=0.001$. In the left plot, the hierarchy of the different contributions is analysed in the case of $F_{2, p}^{D}$. The dominant contribution is: the $q \bar{q} g$ component for values of $\beta<0.1$, the longitudinally polarized $q \bar{q}$ component for values of $\beta>0.9$, and the transversely polarized $q \bar{q}$ component for intermediate values. In the case of $F_{2, A}^{D}$, this separation is still true but the $q \bar{q}$ and $q \bar{q} g$ components behave differently as a function of $A$. The $q \bar{q}$ components are enhanced compared to $A$ times the proton diffractive structure functions while the $q \bar{q} g$ component, on the contrary, is suppressed for nuclei compared to the proton (the $Q^{2}$ and $x_{\mathbb{P}}$ dependence of these effects will be discussed shortly).

This leads to a nuclear suppression of the diffractive structure function in the small $\beta$ region, and to an enhancement at large $\beta$. This is illustrated by the right plot of fig. 5.32, where the ratio $F_{2, A}^{D} /\left(A F_{2, p}^{D}\right.$ ) is shown as a function of $\beta$ for different nuclei (for the "non

Figure 5.33. The ratios $F_{2, A}^{D, x} /\left(A F_{2, p}^{D, x}\right)$ of the different components $(x=q \bar{q} g, q \bar{q} T, q \bar{q} L)$ of the diffractive structure function for both "breakup" and "non breakup" cases. Left plot: as a function of $Q^{2}$ for $x_{\mathbb{P}}=0.001$. Right plot: as a function of $x_{\mathbb{P}}$ for $Q^{2}=5 \mathrm{GeV}^{2}$. In both cases, results are for Au nuclei and the different components are evaluated where they are dominant: at $\beta=0.1$ for $q \bar{q} g$, $\beta=0.5$ for $q \bar{q} T$ and $\beta=0.9$ for $q \bar{q} L$.
breakup" case). The net result of the different contributions is that $F_{2, A}^{D} / A$, for a large $\beta$ range down to 0.1 , is close to $F_{2, p}^{D}$, and is increasing with $A$.

In fig. 5.33, for the Au nucleus case, the ratios $F_{2, A}^{D} /\left(A F_{2, p}^{D}\right)$ of individual contributions are analyzed (for values of $\beta$ at which they are dominant). Comparisons between the "breakup" and "non breakup" cases are made, as functions of $Q^{2}$ (left plot) and $x_{\mathbb{P}}$ (right plot). For the $q \bar{q} g$ component, the nuclear suppression is almost constant (the suppression goes away slowly with $Q^{2}$ ). For the $q \bar{q}$ components, the enhancement becomes bigger with increasing $Q^{2}$ and $x_{\mathbb{P}}$. The result for the total diffractive cross-section in e +A scattering is that it decreases more slowly with increasing $Q^{2}$ or $x_{\mathbb{P}}$ compared to the e+p case. Finally, cross sections in the "non breakup" case are about $15 \%$ lower than in the "breakup" case.

Comparing with other approaches, we obtain similar features. We notice one interesting difference with the results obtained using diffractive parton distributions modified by leading twist shadowing [812]: even at large $\beta$, it is found that $F_{2, A}^{D} / A$ is suppressed compared to $F_{2, p}^{D}$ as a function of $Q^{2}$. This could be tested with measurements at a future EIC where diffraction will be an important part of a rich program. A typical nuclear enhancement of diffraction, for a Au nucleus, is a factor of $\sim 1.2$. Combining this with the typical nuclear suppression in the inclusive case $(\sim 0.8$, see 826$)$, we expect the fraction of diffractive events to be increased by a factor of $\sim 1.5$ compared to the proton, meaning 25 to $35 \%$ at the EIC.

## Expectations for diffraction e+A DIS from LT shadowing

## Vadim Guzey and Mark Strikman

The leading twist theory of nuclear shadowing (see section 5.2) that uses the connection between nuclear shadowing and diffraction [791] and allows one to predict nuclear parton distributions (PDFs) at small $x$ [803, 805, 806, 807] can also be used to predict nuclear diffractive PDFs and diffractive structure functions 812 . At small $x$ and in the nuclear target rest frame, the virtual photon interacts coherently with all nucleons of the nuclear target and the $\gamma^{*} A \rightarrow X A$ scattering amplitude is given by the sum of the multiple scattering contributions presented in Fig. 5.34. Graphs $a, b$, and $c$ correspond to the coherent
interaction with one, two, and three nucleons of the nuclear target, respectively: graph $a$ is the impulse approximation; graphs $b$ and $c$ contribute to the shadowing correction. Note that the interactions with four and more nucleons (at the amplitude level) are not shown, but they are implied. The application of the Abramovsky-Gribov-Kancheli (AGK) cutting rules [804] allows one to relate these diagrams to the corresponding diagrams for the total cross section in $\gamma^{*} A$ scattering.

Figure 5.34. The multiple scattering series for the $\gamma^{*} A \rightarrow X A$ diffractive scattering amplitude. Graph $a$ is the impulse approximation; graphs $b$ and $c$ correspond to the interaction with two and three nucleons of the nuclear target, and contribute to the shadowing correction.

Combining the Glauber-Gribov multiple scattering formalism for the $\gamma^{*} A \rightarrow X A$ scattering amplitude with the QCD factorization theorem [808], one can derive the nuclear diffractive parton distribution of flavor $j$ [807, 812]:

$$
\begin{align*}
\beta f_{j / A}^{D(3)}\left(\beta, Q_{0}^{2}, x_{\mathbb{P}}\right) & =4 \pi A^{2} \beta f_{j / N}^{D(4)}\left(\beta, Q_{0}^{2}, x_{\mathbb{P}}, t_{\min }\right) \int d^{2} b \\
& \times\left|\int_{-\infty}^{\infty} d z e^{i x_{\mathbb{P}} m_{N} z} e^{-\frac{A}{2}(1-i \eta) \sigma_{\text {soft }}^{j}\left(x, Q_{0}^{2}\right) \int_{z}^{\infty} d z^{\prime} \rho_{A}\left(b, z^{\prime}\right)} \rho_{A}(b, z)\right|^{2} \tag{5.67}
\end{align*}
$$

where the notation is the same as in eqs. (5.32) and (5.33).
While at the level of the interaction with two nucleons (graphs $a$ and $b$ in fig. 5.34) our predictions are model-independent, the contribution of the interaction with $N \geq 3$ nucleons requires additional model-dependent considerations since these interactions probe the details of the diffractive dynamics beyond what is encoded in the elementary diffractive distribution $f_{j}^{D(4)}$, as discussed in Section 5.2. Viewing the hard probe (virtual photon) as a coherent superposition of the configurations that interact with the target nucleons with very different strengths (from align-jet configurations to point-like configurations) and which are present in the virtual photon with the probability $P(\sigma)$, one immediately sees from fig. 5.34 that diffractive scattering probes all moments of the cross section (color) fluctuations of the virtual photon, $\left\langle\sigma^{n}\right\rangle \equiv \int d \sigma P(\sigma) \sigma^{n}$, up to the order $n=2 A$. One should note that coherent diffraction probes these fluctuations differently from inclusive scattering. For instance, while the shadowing correction to the deuteron's usual parton distributions is proportional to $\left\langle\sigma^{2}\right\rangle$ (i.e., it is unambiguously expressed in terms of the corresponding diffractive PDFs, see eq. 5.32 in section (5.2), the shadowing correction to the deuteron's diffractive PDFs is proportional to $\left\langle\sigma^{3}\right\rangle$ (interference of graphs $a$ and $b$ in fig. 5.34). (Note that the square of graph $b$ in fig. 5.34 proportional to $\left\langle\sigma^{4}\right\rangle$ also contributes, but its contribution is numerically very small.) As the cross section fluctuations of the virtual photon ( $\left\langle\sigma^{n}\right\rangle$ moments) are rather weakly constrained by the present data, predictions of the leading twist theory of nuclear shadowing contain unavoidable theoretical uncertainty associated with modeling of $\left\langle\sigma^{n}\right\rangle$ with $n \geq 3$. Precise measurements of the $t$ dependence of nuclear shadowing in $e D$ diffraction at an EIC will dramatically reduce this uncertainty by determining exactly these moments.

Equation (5.67) determines nuclear diffractive PDFs at a certain initial scale $Q_{0}^{2}$ $\left(Q_{0}^{2}=4 \mathrm{GeV}^{2}\right.$ in our case). As a consequence of QCD factorization [808, the subsequent $Q^{2}$ evolution is given by the DGLAP evolution equations (at fixed $x_{\mathbb{P}}$ and $t$ ). As another consequence of the QCD factorization, the same nuclear diffractive PDFs $f_{j}^{D(3)}$ enter the perturbative QCD description of many processes and observables: the diffractive structure function $F_{2 A}^{D(3)}$, the longitudinal diffractive structure function $F_{L A}^{D(3)}$, the charm structure functions $F_{2 A}^{D(3)(c)}$ and $F_{L A}^{D(3)(c)}$, and diffractive electroproduction of jets and heavy flavors.

Figure 5.35. The leading twist theory of nuclear shadowing predictions for the ratio of nuclear to nucleon gluon and $\bar{u}$ quark diffractive PDFs, $f_{j / A}^{D(3)} /\left(A f_{j / N}^{D(3)}\right)$, as a function of $\beta$ at $x_{\mathbb{P}}=10^{-3}$ and $Q_{0}^{2}=4 \mathrm{GeV}^{2}$. The two sets of curves (labeled FGS10_H and FGS10_L) correspond to the two extreme scenarios of nuclear shadowing.

As an example of our predictions for nuclear diffractive PDFs, in fig. 5.35 we present the ratio of the nuclear ( ${ }^{40} \mathrm{Ca}$ and ${ }^{208} \mathrm{~Pb}$ ) to nucleon diffractive PDFs, $f_{j / A}^{D(3)} /\left(A f_{j / N}^{D(3)}\right)$, as a function of $\beta$ at fixed $x_{\mathbb{P}}=10^{-3}$ and $Q_{0}^{2}=4 \mathrm{GeV}^{2}$. The left column of panels corresponds to the $\bar{u}$-quark distribution; the right column corresponds to the gluon distribution. The two sets of curves (labeled FGS10_H and FGS10_L) correspond to the two scenarios for the effective cross section $\sigma_{\text {soft }}^{j}$, which also determines shadowing effects as discussed in Section 5.2. As one can see from the comparison of fig. 5.35 to our predictions for the usual nuclear PDFs presented in fig. [5.19, nuclear diffractive PDFs are much more sensitive to the effect of the color fluctuations (the spread between the solid and dotted curves is much larger for $f_{j / A}^{D(3)} /\left(A f_{j / N}^{D(3)}\right)$ than for $\left.f_{j / A}\left(x, Q_{0}^{2}\right) /\left[A f_{j / N}\left(x, Q_{0}^{2}\right)\right]\right)$.

| $A /$ model | $F_{2 A, \text { incoh }}^{D(3)} / F_{2 A}^{D(3)}, x_{\mathbb{P}}=10^{-3}$ | $F_{2 A, \text { incoh }}^{D(3)} / F_{2 A}^{D(3)}, x_{\mathbb{P}}=10^{-2}$ |
| :---: | :---: | :---: |
| ${ }^{40} \mathrm{Ca}$, FGS10_H | 0.35 | 0.33 |
| ${ }^{40} \mathrm{Ca}$, FGS10_L | 0.43 | 0.38 |
| ${ }^{208} \mathrm{~Pb}$, FGS10_H | 0.12 | 0.11 |
| ${ }^{208} \mathrm{~Pb}$, FGS10_L | 0.20 | 0.16 |

Table 5.3. The leading twist theory of nuclear shadowing predictions for the ratio of the nuclear structure functions measured in incoherent and coherent diffraction in $e A$ DIS, $F_{2 A \text {,incoh }}^{D(3)} / F_{2 A}^{D(3)}$, at $x_{\mathbb{P}}=10^{-3}$ and $10^{-2}$ and $Q_{0}^{2}=4 \mathrm{GeV}^{2}$. The ratio is approximately $\beta$-independent.

The simplest observable to measure at an EIC is the diffractive structure function $F_{2 A}^{D(3)}$. Our predictions for $F_{2 A}^{D(3)} /\left(A F_{2 N}^{D(3)}\right)$ for $Q^{2} \sim$ few $\mathrm{GeV}^{2}$ are similar in shape and close in
the absolute value for ${ }^{40} \mathrm{Ca}$ and model FGS10_H to the corresponding predictions made in the framework of the color dipole model, where the main contribution originates from the aligned-jet configurations 825. (Note that at the level of the interaction with two nucleons, the expressions for the shadowing correction in our leading twist approach and in the dipole formalism are essentially the same and are unambiguously expressed in terms of $\gamma^{*}$-nucleon diffraction.) Hence, it appears that the $x_{\mathbb{P}}$ and $\beta$ dependence of coherent inclusive diffraction in $e A$ DIS at $Q^{2} \sim Q_{0}^{2}$ may not give unambiguous information on the onset of the non-linear regime of parton dynamics; to distinguish between the nonsaturation and saturation regimes one will need to study the $Q^{2}$ dependence of various diffractive observables.

In addition to inclusive coherent diffraction that we have discussed above, the leading twist theory of nuclear shadowing makes predictions for incoherent diffraction (with nuclear break-up into its constituents) in $e A$ DIS, see [807] for details. An example of our predictions for the ratio of the nuclear structure functions measured in incoherent and coherent diffraction in $e A$ DIS at $x_{\mathbb{P}}=10^{-3}$ and $x_{\mathbb{P}}=10^{-2}$ and $Q_{0}^{2}=4 \mathrm{GeV}^{2}$ is presented in table 5.3. To a good accuracy, the ratio is approximately $\beta$-independent.

## $5.5 k_{T}$-dependent gluons: SIDIS and jets

## Dijet and Dihadron production at EIC

Fabio Dominguez, Cyrille Marquet, Bowen Xiao and Feng Yuan
Dijet production at an EIC: The operator definition of the Weizsäcker-Williams (WW) gluon distribution can be written as follows [267, 283]:

$$
\begin{equation*}
x G^{(1)}\left(x, k_{\perp}\right)=2 \int \frac{d \xi^{-} d \xi_{\perp}}{(2 \pi)^{3} P^{+}} e^{i x P^{+} \xi^{-}-i k_{\perp} \cdot \xi_{\perp}}\langle P| \operatorname{Tr}\left[F^{+i}\left(\xi^{-}, \xi_{\perp}\right) \mathcal{U}^{[+\rfloor \dagger} F^{+i}(0) \mathcal{U}^{[+]}\right]|P\rangle, \tag{5.68}
\end{equation*}
$$

where the gauge $\operatorname{link} \mathcal{U}_{\xi}^{[+]}=U^{n}[0,+\infty ; 0] U^{n}\left[+\infty, \xi^{-} ; \xi_{\perp}\right]$ represents final state interactions with $U^{n}$ being the light-like Wilson line in covariant gauge. By choosing the light-cone gauge with certain boundary conditions for the gauge potential $\left(A_{\perp}\left(\zeta^{-}=\infty\right)=0\right.$ for the specific case above), we can drop out the gauge link contribution in equation (5.68) and find that this gluon distribution has the number density interpretation. Then, it can be calculated from the wave functions or the WW field of the nucleus target [729, 731, 877]. At small- $x$ for a large nucleus, it was found

$$
\begin{equation*}
x G^{(1)}\left(x, k_{\perp}\right)=\frac{S_{\perp}}{\pi^{2} \alpha_{s}} \frac{N_{c}^{2}-1}{N_{c}} \int \frac{d^{2} r_{\perp}}{(2 \pi)^{2}} \frac{e^{-i k_{\perp} \cdot r_{\perp}}}{r_{\perp}^{2}}\left(1-e^{-\frac{r_{\perp}^{2} Q_{s}^{2}}{4}}\right), \tag{5.69}
\end{equation*}
$$

where $N_{c}=3$ is the number of colors, $S_{\perp}$ is the transverse area of the target nucleus, and $Q_{s}^{2}=\frac{g^{2} N_{c}}{4 \pi} \ln \frac{1}{r_{\perp}^{2} \lambda^{2}} \int d x^{-} \mu^{2}\left(x^{-}\right)$is the gluon saturation scale with $\mu^{2}$ the color charge density in a large nuclei.

The second gluon distribution, the Fourier transform of the dipole cross section, is defined in the fundamental representation

$$
\begin{equation*}
x G^{(2)}\left(x, k_{\perp}\right)=2 \int \frac{d \xi^{-} d \xi_{\perp}}{(2 \pi)^{3} P^{+}} e^{i x P^{+} \xi^{-}-i k_{\perp} \xi_{\perp}}\langle P| \operatorname{Tr}\left[F^{+i}\left(\xi^{-}, \xi_{\perp}\right) \mathcal{U}^{[-] \dagger} F^{+i}(0) \mathcal{U}^{[+]}\right]|P\rangle \tag{5.70}
\end{equation*}
$$

where the gauge link $\mathcal{U}_{\xi}^{[-]}=U^{n}[0,-\infty ; 0] U^{n}\left[-\infty, \xi^{-} ; \xi_{\perp}\right]$ stands for initial state interactions. It has been shown in ref. [283] that the Weizsäcker-Williams gluon distribution can be directly probed in the dijet production processes in DIS while the second gluon distribution enters in the total and semi-inclusive DIS cross sections. The quark-antiquark dijet cross section in DIS can be calculated in both the CGC formalism and the TMD approach. In the CGC formalism, the photon splits into a quark-antiquark pair which subsequently undergoes multiple interactions with the nucleus (see figure 5.36 left).

After averaging over the photon's polarization and summing over the quark and antiquark colors and helicities in the splitting functions $\psi_{\alpha \beta}^{T, L \lambda}\left(p^{+}, z, r\right)$, we obtain,

$$
\begin{align*}
\frac{d \sigma^{\gamma_{T, L}^{*} A \rightarrow q \bar{q} X}}{d^{3} k_{1} d^{3} k_{2}}= & N_{c} \alpha_{e m} e_{q}^{2} \delta\left(p^{+}-k_{1}^{+}-k_{2}^{+}\right) \int \frac{\mathrm{d}^{2} x_{1}}{(2 \pi)^{2}} \frac{\mathrm{~d}^{2} x_{1}^{\prime}}{(2 \pi)^{2}} \frac{\mathrm{~d}^{2} x_{2}}{(2 \pi)^{2}} \frac{\mathrm{~d}^{2} x_{2}^{\prime}}{(2 \pi)^{2}} \\
& \times e^{-i k_{1 \perp} \cdot\left(x_{1}-x_{1}^{\prime}\right)} e^{-i k_{2 \perp} \cdot\left(x_{2}-x_{2}^{\prime}\right)} \sum_{\lambda \alpha \beta} \psi_{\alpha \beta}^{T, L \lambda}\left(x_{1}-x_{2}\right) \psi_{\alpha \beta}^{T, L \lambda *}\left(x_{1}^{\prime}-x_{2}^{\prime}\right) \\
& \times\left[1+S_{x_{g}}^{(4)}\left(x_{1}, x_{2} ; x_{2}^{\prime}, x_{1}^{\prime}\right)-S_{x_{g}}^{(2)}\left(x_{1}, x_{2}\right)-S_{x_{g}}^{(2)}\left(x_{2}^{\prime}, x_{1}^{\prime}\right)\right] \tag{5.71}
\end{align*}
$$

where $k_{1}$ and $k_{2}$ are momenta for the final state quark and antiquark, respectively. We further define $\vec{P}_{\perp}=\vec{k}_{1 \perp}-\vec{k}_{2 \perp}$ and $\vec{q}_{\perp}=\vec{k}_{1 \perp}+\vec{k}_{2 \perp}$. All transverse momenta are defined

Figure 5.36. Left: Typical diagrams contributing to the cross section in the DIS at small- $x$ limit. Right: EIC dihadron correlation function
in the center of mass frame of the virtual photon and the nucleus target. The two- and four-point functions are defined as
$S_{x_{g}}^{(2)}\left(x_{1}, x_{2}\right)=\frac{1}{N_{c}}\left\langle\operatorname{Tr} U\left(x_{1}\right) U^{\dagger}\left(x_{2}\right)\right\rangle_{x_{g}}, S_{x_{g}}^{(4)}\left(x_{1}, x_{2} ; x_{2}^{\prime}, x_{1}^{\prime}\right)=\frac{1}{N_{c}}\left\langle\operatorname{Tr} U\left(x_{1}\right) U^{\dagger}\left(x_{1}^{\prime}\right) U\left(x_{2}^{\prime}\right) U^{\dagger}\left(x_{2}\right)\right\rangle_{x_{g}}$.
The notation $\langle\ldots\rangle_{x_{g}}$ is used for the CGC average of the color charges over the nuclear wave function where $x_{g}$ is the smallest fraction of longitudinal momentum probed, and is determined by the kinematics.

In order to simplify the above result and obtain a factorized expression, we take the correlation limit of equation (5.71). For convenience, we introduce the transverse coordinate variables: $u=x_{1}-x_{2}$ and $v=z x_{1}+(1-z) x_{2}$, and similarly for the primed coordinates. The respective conjugate momenta are $\tilde{P}_{\perp}=(1-z) k_{1 \perp}-z k_{2 \perp} \approx P_{\perp}$ and $q_{\perp}$, and therefore the correlation limit $\left(\tilde{P}_{\perp} \gg q_{\perp}\right)$ can be taken by assuming $u$ and $u^{\prime}$ are small and then expanding the integrand with respect to these two variables before performing the Fourier transform. Therefore, we can obtain the following expression which agrees perfectly with the TMD approach:

$$
\begin{equation*}
\frac{d \sigma_{\mathrm{TMD}}^{\gamma_{T, L}^{*} A \rightarrow q \bar{q}+X}}{d \mathcal{P} . \mathcal{S} .}=\delta\left(x_{\gamma^{*}}-1\right) x_{g} G^{(1)}\left(x_{g}, q_{\perp}\right) H_{\gamma_{T, L}^{*} g \rightarrow q \bar{q}}, \tag{5.73}
\end{equation*}
$$

where $x_{g}$ is the momentum fraction carried by the gluon and is determined by the kinematics, $x_{\gamma^{*}}=z_{q}+z_{\bar{q}}$ with $z_{q}=z$ and $z_{\bar{q}}=1-z$ being the momentum fractions of the virtual photon carried by the quark and antiquark, respectively. The phase space factor is defined as $d \mathcal{P} . \mathcal{S}$. $=d y_{1} d y_{2} d^{2} P_{\perp} d^{2} q_{\perp}$, and $y_{1}$ and $y_{2}$ are rapidities of the two outgoing particles in the lab frame. The leading order hard partonic cross section reads

$$
\begin{equation*}
H_{\gamma_{T}^{*} g \rightarrow q \bar{q}}=\alpha_{s} \alpha_{e m} e_{q}^{2} \frac{\hat{s}^{2}+Q^{4}}{\left(\hat{s}+Q^{2}\right)^{4}}\left(\frac{\hat{u}}{\hat{t}}+\frac{\hat{t}}{\hat{u}}\right), \quad H_{\gamma_{L}^{*} g \rightarrow q \bar{q}}=\alpha_{s} \alpha_{e m} e_{q}^{2} \frac{8 \hat{s} Q^{2}}{\left(\hat{s}+Q^{2}\right)^{4}}, \tag{5.74}
\end{equation*}
$$

with the usually defined partonic Mandelstam variables $\hat{s}=P_{\perp}^{2} /(z(1-z)), \hat{t}=-\left(P_{\perp}^{2}+\right.$ $\left.\epsilon_{f}^{2}\right) /(1-z)$, and $\hat{u}=-\left(P_{\perp}^{2}+\epsilon_{f}^{2}\right) / z$ with $\epsilon_{f}^{2}=z(1-z) Q^{2}$.
di-hadron correlations in DIS: By including the $k_{t}$ dependent fragmentation functions as proposed in ref. [332, one can compute the di-hadron production cross section and the
correlation function $C\left(\phi_{12}\right)$ which is defined as follows

$$
\begin{equation*}
C\left(\phi_{12}\right)=\frac{1}{\frac{d \sigma_{\mathrm{tot} \sin 1 S}^{*}}{d z_{h 1}}} \frac{d \sigma_{\mathrm{tot}}^{\gamma^{*} A \rightarrow h_{1} h_{2}+X}}{d z_{h 1} d z_{h 2} d \phi_{12}}, \tag{5.75}
\end{equation*}
$$

where $z_{h 1}$ and $z_{h 2}$ are the longitudinal momentum fractions of two produced hadrons w.r.t. the photon momentum. $p_{1 \perp}$ and $p_{2 \perp}$ are the transverse momenta of these two back-toback hadrons and $\phi_{12}$ is the azimuthal angle between them. Thus, it is straightforward to numerically evaluate the correlation function and plot it in figure 5.36 right, where we fix $z_{h 1}=z_{h 2}=0.3, Q^{2}=4.0 \mathrm{GeV}^{2}, \sqrt{s}=100 \mathrm{GeV} . p_{1 \perp}$ and $p_{2 \perp}$ are integrated in the range $[2,3] \mathrm{GeV}$ and $[1,2] \mathrm{GeV}$, respectively. For the gluon distribution in gold nuclei, we have used a parametrization inspired by $G B W$ model. From figure 5.36, one sees the suppression of the away-side peak in nuclei due to gluon saturation.

Conclusion: First of all, we would like to compare the dijet production process in DIS to the inclusive and semi-inclusive DIS. As shown above, we derive that the dijet production cross section in DIS is proportional to the WW gluon distribution in the correlation limit. On the other hand, it is well-known that inclusive and semi-inclusive DIS involves the dipole cross section instead [878], which can be related to the second gluon distribution. This might look confusing at first sight, so let us take a closer look at equation (5.71). If one integrates over one of the outgoing momenta, say $k_{1}$, one can easily see that the corresponding coordinates in the amplitude and conjugate amplitude are identified ( $x_{1}=x_{1}^{\prime}$ ) and, therefore, the four-point function $S_{x_{g}}^{(4)}\left(x_{1}, x_{2} ; x_{2}^{\prime}, x_{1}^{\prime}\right)$ collapses to a two-point function $S_{x_{g}}^{(2)}\left(x_{2}, x_{2}^{\prime}\right)$. As a result, the SIDIS and inclusive DIS cross section only depend on two-point functions, thus they only involve the dipole gluon distribution.

Now we can see the unique feature of the dijet production process in DIS. By keeping the momenta of the quark and antiquark unintegrated, we can keep the full color structure of the four-point function which eventually leads to the WW gluon distribution in the correlation limit. Therefore, measuring the dijet production cross sections or dihadron correlations in DIS at future experimental facilities like EIC would give us a first direct and unique opportunity to probe and understand the Weizsäcker-Williams gluon distribution. Last but not least, by measuring the SIDIS and inclusive DIS cross section at EIC, one can also probe and constrain the dipole gluon distribution.

## Heavy quark production in $e+A$ collisions

## Victor P. Gonçalves

In this contribution we calculate the cross section of heavy quark production using the dipole approach and a nuclear saturation model based on the physics of the Color Glass Condensate (CGC) (For more details and references see Ref. [879]). The main input of our calculation is the dipole-nucleus cross section, $\sigma_{d A}(x, r)$, which is determined by the QCD dynamics at small $x$. In the eikonal approximation it is given by twice the impact-parameter $b$ integral of $\mathcal{N}^{A}(x, r, b)$, the forward dipole-target scattering amplitude for a dipole with size $r$ which encodes all the information about the hadronic scattering, and thus about the
nonlinear and quantum effects in the hadron wave function. In our calculations we will assume as before that the forward dipole-nucleus amplitude is given by

$$
\begin{equation*}
\mathcal{N}^{A}(x, r, b)=1-\exp \left[-\frac{1}{2} \sigma_{d p}\left(x, r^{2}\right) T_{A}(b)\right] \tag{5.76}
\end{equation*}
$$

where $\sigma_{d p}$ is the dipole-proton cross section and $T_{A}(b)$ is the nuclear profile function, which is obtained from a 3-parameter Fermi distribution for the nuclear density normalized to A. It is important to emphasize that this model describes the current experimental data on the nuclear structure function as well as includes the impact parameter dependence in the dipole nucleus cross section. For the dipole-proton cross section we will use the b-CGC model.

To estimate the magnitude of the saturation effects in heavy quark production, let us compare the CGC predictions with those associated to linear QCD dynamics. As a model for the linear regime we consider the leading logarithmic approximation for the dipole-target cross section, where $\sigma_{d A}$ is directly related to the nuclear gluon distribution $x g_{A}$ as follows

$$
\begin{equation*}
\sigma_{d A}\left(x, r^{2}\right)=\frac{\pi^{2}}{3} r^{2} \alpha_{s} x g_{A}\left(x, 10 / r^{2}\right) \tag{5.77}
\end{equation*}
$$

The use of this cross section in the formulae given below will produce results which we denote CT, from color transparency. In this limit we are disregarding multiple scatterings of the dipole with the nuclei and are assuming that the dipole interacts incoherently with the target. In what follows we consider two different models for the nuclear gluon distribution. In the first one we disregard the nuclear effects and assume that $x g_{A}\left(x, Q^{2}\right)=A \cdot x g_{N}\left(x, Q^{2}\right)$, with $x g_{N}$ being the gluon distribution in the proton and given by the GRV98 parameterization. We will refer to this model as CT. In the second model we take into account the nuclear effects in the nuclear gluon distribution as described by the EKS98 parameterization. We will call this model CT + Shad. In our calculations the charm quark mass is $m_{c}=1.5 \mathrm{GeV}$ and the bottom quark mass is $m_{b}=4.5 \mathrm{GeV}$.

Heavy quark production in the color dipole approach: Heavy quark production is usually estimated using the collinear factorization approach, where all partons involved are assumed to be on mass shell, carrying only longitudinal momenta, and their transverse momenta are neglected in the QCD matrix elements. On the other hand, in the large energy (small-x) limit, we have that the characteristic scale $\mu$ of the hard subprocess of parton scattering is much less than $\sqrt{s}$, but greater than the $\Lambda_{Q C D}$ parameter. In this limit, the effects of the finite transverse momenta of the incoming partons become important, and the factorization must be generalized, implying that the cross sections are now $k_{\perp}$-factorized into an off-shell partonic cross section and a $k_{\perp}$-unintegrated parton density function $\mathcal{F}\left(x, k_{\perp}\right)$, characterizing the $k_{\perp}$-factorization approach. Recently, an alternative approach to calculating the heavy quark production at high energies was proposed, considering the quasi-multi-Regge-kinematics (QMRK) framework. It is based on an effective theory implemented with the non-Abelian gauge-invariant action. The heavy quark production can also be calculated using the color dipole approach. This formalism can be obtained from the $k_{\perp}$-factorization approach after the Fourier transformation from the space of quark transverse momenta into the space of transverse coordinates. It is important to emphasize that this equivalence is only valid in the leading logarithmic approximation, being violated if the exact gluon kinematics is considered. A detailed discussion of the equivalence or

Figure 5.37. Transverse momentum charm spectrum (left) and bottom spectrum (right) for $Q^{2}=2$ $\mathrm{GeV}^{2}$ and different energies.
not between the dipole and the QMRK approaches still is an open question. The main advantage to use the color dipole formalism, is that it gives a simple unified picture of inclusive and diffractive processes and the saturation effects can be easily implemented in this approach.

In the color dipole approach, the heavy quark production cross section is given by

$$
\begin{align*}
\frac{d \sigma\left(\gamma^{*} A \rightarrow Q X\right)}{d^{2} p_{Q}^{\perp}} & =\frac{6 e_{Q}^{2} \alpha_{e m}}{(2 \pi)^{2}} \int d \alpha\left\{\left[m_{Q}^{2}+4 Q^{2} \alpha^{2}(1-\alpha)^{2}\right]\left[\frac{I_{0}}{p_{Q}^{\perp 2}+\epsilon^{2}}-\frac{I_{2}}{4 \epsilon}\right]\right. \\
& \left.+\left[\alpha^{2}+(1-\alpha)^{2}\right]\left[\frac{p_{Q}^{\perp} \epsilon I_{1}}{p_{Q}^{\perp 2}+\epsilon^{2}}-\frac{I_{0}}{2}+\frac{\epsilon I_{2}}{4}\right]\right\} \tag{5.78}
\end{align*}
$$

with

$$
I_{\lambda}=\int d r r J_{\lambda}\left(p_{Q}^{\perp} r\right) K_{\lambda}(\epsilon r) \sigma_{d A}(r) ; I_{2}=\int d r r^{2} J_{0}\left(p_{Q}^{\perp} r\right) K_{1}(\epsilon r) \sigma_{d A}(r)
$$

with $\lambda=0,1$, and $J_{0,1}$ and $K_{0,1}$ are Bessel functions, and $\epsilon^{2}=\alpha(1-\alpha) Q^{2}+m^{2}$.

Figure 5.38. Dependence on the photon virtuality at $p_{T}^{2}=4 \mathrm{GeV}^{2}$.
Results: In Fig. 5.37 we show the transverse momentum spectrum of charm quarks. The main purpose of this figure is to show that the predictions of the linear physics (CT +

Shad) differ from the total (i.e. bCGC) by a factor which increases with the energy $W$ and goes from $1.5(W=100 \mathrm{GeV})$ to $4(W=1400 \mathrm{GeV})$. Moreover, this difference persists for a wide momentum window. At very large $p_{T}$ we enter the deep linear regime and expect that the two curves coincide.

In Fig. 5.37 we show the transverse momentum spectrum of bottom quarks. As expected, we observe the same features of the charm distribution, except that now the nonlinear effects are weaker. Nevertheless they are still noticeable. In Fig. 5.38 we show the $Q^{2}$ dependence of the $p_{T}$ distribution at a fixed value $p_{T}=4 \mathrm{GeV}^{2}$ for different energies. The upper and lower panels show the charm and bottom distributions respectively. Here again, we observe a remarkable strength and persistence up to large virtualities of the differences between CT + Shad and bCGC.

## 5.6 b-dependent gluons: exclusive VM, DVCS

Gluon Density in e+A : KLN, CGC, DGLAP Glauber, or Neither?

William A. Horowitz

Perturbative quantum chromodynamics ( pQCD ) predicts a nontrivial expansion in the size of the nuclear wavefunction at small $x$ as the perturbative power law tails of the gluon distribution near the edge of the nucleus become important compared to the exponential dropoff due to confinement effects [871, 742, 766]. Similarly, in order to not violate unitarity, the enormous growth in the gluon parton distribution function as $x$ becomes small found via naïve application of DGLAP evolution (see [3] and references therein) must be tamed by perturbatively-calculable saturation effects [742, 766]. However it is not yet clear from a theoretical standpoint at what values of $x$ these nontrivial changes in the dominant dynamics occur [766]. Additionally a quantitative theoretical understanding of experimental heavy ion data requires a quantitative understanding of the initial geometry of a heavy ion collision. Certainly observables such as the azimuthal anisotropy of particles [880, 881, 882] are correlated with the anisotropy of the initial geometry; surprisingly the event-by-event fluctuations in the initial geometry also strongly affect these observables [883, 884. In particular the viscosity to entropy ratio $(\eta / s)$ of the quark-gluon plasma (QGP) found by comparing hydrodynamics simulations to heavy ion collision data is directly related to the eccentricity of the initial thermal quark-gluon plasma distribution that is evolved hydrodynamically. Currently the uncertainty in the initial thermal distribution due to the uncertainty in the importance of saturation effects in the initial nuclear profiles is large enough that it is not clear whether the physics of the QGP is better described by leading order weakly-coupled perturbative quantum chromodynamics (LO pQCD) or by LO strongly-coupled anti-deSitter/conformal field theory (AdS/CFT) methods [881. An experimental measurement of the spatial gluon distribution in a highly boosted nucleus, and hence the relevant physics in this kinematic range, would thus be a very interesting and important contribution to our understanding of QCD.

Exclusive vector meson production (EVMP) in e + A collisions has been proposed as a channel for just such a measurement [618, 885, 827]. In this section we will focus on the production of heavy vector mesons, in particular $J / \Psi$ mesons. To leading order, EVMP of a $J / \Psi$ meson occurs in an e + A collision when a photon emitted by the electron splits into a $c-\bar{c}$ pair which communicates with the gluon density in the highly boosted nucleus via a two gluon exchange and subsequently forms a $J / \Psi$ meson and nothing else (we will be interested here in coherent EVMP, in which case the nucleus remains intact); see figure 5.39 for a visualization of the process. It is precisely this two gluon exchange which yields a diffractive measurement of the gluon density in a nucleus.

Previous work [885 explored how modest changes in the Woods-Saxon distribution [886] of a nucleus might manifest themselves as changes in the diffractive peaks in EVMP if one assumes that the spatial distribution of gluons in a nucleus is proportional to the Glauber thickness function found from the Woods-Saxon distribution. That these modest changes do result in a visually obvious modification of the diffraction pattern motivated our further study, in which we consider whether two very different physical pictures of the gluon distribution in a highly boosted nucleus can be experimentally distinguished via EVMP: in particular we wish to compare the diffraction patterns that emerge when the gluon distribution 1) has normalization dictated by DGLAP evolution and spatial distribution
given by the Glauber thickness function and 2) is given by the KLN parameterization (see [887, 888] and references therein) of the Color Glass Condensate (CGC) (see, e.g., [766, 889] for a review). We choose to investigate these two ansätze of the gluon distribution in nuclei as they have been the dominant models used in heavy ion physics calculations to estimate the uncertainty in the viscosity to entropy ratio of the QGP produced at RHIC due to the uncertainty of the currently poorly constrained initial conditions in heavy ion collisions [880, 881].

It is worth taking a moment to comment on some common - yet confusing - terminology in the EVMP field. As mentioned above, to leading order the coherent production of a vector meson in an $\mathrm{e}+\mathrm{A}$ collision involves a two-gluon exchange between the $q-\bar{q}$ pair and the nucleus. If one assumes that all two-gluon exchanges occur independently, then one may exponentiate the single two-gluon exchange result. Making this independence assumption is often referred to in the EVMP field as using "saturation" physics because the cross section is unitarized via the exponentiation process. However this "saturation" does not refer to unitarizing the gluon distribution functions themselves. For instance in the "IP-Sat" 600] and "b-Sat" 823 models, where "Sat" is short for saturation, the $x$ evolution of the gluon PDF is effected through the use of the DGLAP equations. On the other hand, the "b-CGC" model [823] incorporates both the exponentiation of the two-gluon exchange and the CGC physics of the saturation of the gluon PDF. We note that, in principle, small- $x$ evolution effects and exponentiation effects in the dipole cross section should become appreciable simultaneously [737]. In order to (hopefully) make the presentation more clear, and to simplify some of the numerics, we will not exponentiate the two-gluon exchange; we will present results using only the leading order two-gluon exchange in which the gluon PDF is given either via DGLAP evolution or from the CGC. Any subsequent reference to "saturation" in this paper will refer to the saturation of the gluon distribution function alone.

Formalism: Following [600, 885], the diffractive production of a vector meson from a photon scattering off a target is

$$
\begin{equation*}
\frac{d \sigma}{d t}=\frac{1}{16 \pi}\left|\int d^{2} \boldsymbol{r} \int \frac{d z}{4 \pi} \int d^{2} \boldsymbol{b}\langle V \mid \gamma\rangle_{T} e^{i \boldsymbol{b} \cdot \boldsymbol{\Delta}} \frac{d \sigma_{q \bar{q}}}{d^{2} \boldsymbol{b}}\right|^{2} \tag{5.79}
\end{equation*}
$$

where $\langle V \mid \gamma\rangle_{T}$ is the overlap of the vector meson wavefunction and the transversely polarized virtual photon wavefunction - the contribution from the longitudinally polarized photon is zero as we are interested in $Q^{2}=0$ photoproduction-and we used the photon-meson overlap and Gauss-LC model for the $J / \Psi$ wavefunction from [600] ${ }^{5}$, and $\boldsymbol{\Delta}^{2}=-t$. $d \sigma_{q \bar{q}} / d^{2} \boldsymbol{b}$ is the differential cross section for the interaction of the dipole with the target; its form depends on the physics assumptions we make for the nuclear gluon distribution, as we discuss in detail below.

DGLAP Evolution in $x$, Glauber Distribution of Gluons in $b$ : If we assume that the two gluon exchange from the dipole to the nucleus occurs within an individual nucleon then

$$
\begin{equation*}
\frac{d \sigma_{q \bar{q}}}{d^{2} b}=\frac{\pi^{2}}{N_{c}} r^{2} \alpha_{s}\left(\mu^{2}\right) x g\left(x, \mu^{2}\right) T(b), \tag{5.80}
\end{equation*}
$$

[^279]

Figure 5.39. Leading order Feynman diagram for the exclusive vector meson production of a $J / \Psi$ meson.
where $r$ is the size of the dipole, $\mu=\sqrt{ }\left(\mu_{0}+C / r^{2}\right)$ is the relevant momentum scale for the dipole, $x g$ is the gluon distribution function, and

$$
\begin{equation*}
T(b)=\frac{1}{2 \pi B_{G}} e^{-b^{2} / 2 B_{G}} \tag{5.81}
\end{equation*}
$$

is the assumed spatial distribution of gluons in a nucleon. We use the MSTW parameterization of the gluon $\operatorname{PDF}$ [22]. As described in [821], $\mu_{0}$ and $C$ are free parameters; as in [821, 600, 827], we take $\mu_{0}=1 \mathrm{GeV}^{2}$ and $C=4$. From HERA data [588] the measured slope of $d \sigma / d t$ yields $B_{G} \approx 4.25 \mathrm{GeV}^{-2} 600$. Then

$$
\begin{equation*}
\frac{d \sigma^{D G L A P}}{d t}=4 \pi \sigma_{p}^{2} e^{-B_{G} t}\left|\int d b J_{0}(b \sqrt{t}) T_{A}(b)\right|^{2} \tag{5.82}
\end{equation*}
$$

where $J_{0}$ is the usual Bessel function, $T_{A}(b) \equiv \int d z \rho_{A}\left(\sqrt{b^{2}+z^{2}}\right)$, with $\int d^{2} \boldsymbol{b} T_{A}(b)=A$, is the usual thickness function, and $\rho_{A}$ is the density of the nucleus (here taken as the Woods-Saxon distribution of ${ }^{197} \mathrm{Au}$ with the usual $R=6.38 \mathrm{fm}$ and $a=0.535 \mathrm{fm}$ [890]) and

$$
\begin{equation*}
\sigma_{p} \equiv \frac{1}{4 \pi} \int d^{2} \boldsymbol{r} \int d z\langle V \mid \gamma\rangle_{T} \frac{\pi^{2}}{N_{c}} r^{2} \alpha_{s}\left(\mu^{2}\right) x g\left(x, \mu^{2}\right) \tag{5.83}
\end{equation*}
$$

CGC Distribution of Gluons in $x$ and $b$ : Alternatively we may view the nucleus as a whole and that the gluon distribution is found from the CGC. In this case

$$
\begin{equation*}
\frac{d \sigma_{q \bar{q}}}{d^{2} \boldsymbol{b}}=\frac{\pi^{2}}{N_{C}} r^{2} \alpha_{s}\left(\mu^{2}\right) x g_{A}\left(\mu^{2}, Q_{s}^{2}\right) \tag{5.84}
\end{equation*}
$$

where $x g_{A}$ is the integrated gluon distribution function related to the unintegrated gluon distribution (UGD) $\phi_{A}$ by

$$
\begin{equation*}
x g_{A}\left(\mu^{2}, Q_{s}^{2}\right)=\int d^{2} \boldsymbol{k} \phi_{A}\left(k^{2}, Q_{s}^{2}\right)=\pi \int_{0}^{k_{\max }^{2}=\mu^{2}} d k^{2} \phi_{A}\left(k^{2}, Q_{s}^{2}\right) \tag{5.85}
\end{equation*}
$$

The $x$ and $b$ dependence of the two-gluon exchange dipole scattering formula, Eq. 5.84, comes in implicitly through the $x$ and $b$ dependence of $Q_{s}^{2}$ [888,

$$
\begin{equation*}
Q_{s}^{2} \equiv \frac{2 \pi^{2}}{C_{F}} \alpha_{s}\left(Q_{s}^{2}\right) x g\left(x, Q_{s}^{2}\right) T_{A}(b) \tag{5.86}
\end{equation*}
$$

where $C_{F} \equiv\left(N_{c}^{2}-1\right) / 2 N_{c}$.
In principle one determines the UGD via the JIMWLK evolution equations or, in the large- $N_{c}$ limit, the BK evolution equations (see [766, 889$]$ and references therein). However, instead of solving the full evolution equations many heavy ion physics calculations use instead the KLN prescription of the CGC (see, e.g., [887, 888), which attempts to capture the main feature of CGC physics; in particular, the KLN UGD becomes saturated at momenta on the scale of the saturation scale $Q_{s}$. Because of its widespread use in heavy ion physics calculations and in order to simplify our own calculations we, too, will use the KLN UGD,

$$
\phi_{A}^{K L N}\left(k, Q_{s}^{2}\right)=\frac{\kappa C_{F} Q_{s}^{2}}{2 \pi^{3} \alpha_{s}\left(Q_{s}^{2}\right)} \begin{cases}\left(Q_{s}^{2}+\Lambda^{2}\right)^{-1}, & k^{2} \leq Q_{s}^{2}  \tag{5.87}\\ \left(k^{2}+\Lambda^{2}\right)^{-1}, & k^{2}>Q_{s}^{2},\end{cases}
$$

where $\kappa$ is an $O(1)$ parameter meant to represent higher order corrections to the UGD, and $\Lambda=0.2 \mathrm{GeV}$ [888.

In principle $\kappa$ is set by comparing to known experimental observables such as the measured multiplicity at midrapidity at RHIC [891, 892, 893] or LHC [894, 895] or to the diffractive cross sections for protons measured at HERA [588]. However we found that the results from the leading order multiplicity formula [887] are linearly dependent on the cutoff taken for $\alpha_{s}, \alpha_{s}^{\max }$. The KLN UGD itself, though, is not nearly as sensitive to $\alpha_{s}^{\max }$, so the multiplicity prescription does not provide a robust way of setting $\kappa$. We note in passing that the centrality dependence of the particles produced via the leading order CGC multiplicity formula using the KLN UGD's also depends on $\alpha_{s}^{\max }$. Perhaps the use of the next-to-leading order results in the UGD [896] and/or the production formula [897] will mitigate this dependence enough to make reasonable comparisons of CGC multiplicity to current data. Currently, though, there does not appear to be any quantitative estimate of the size of the dependence of the predicted CGC multiplicity as a function of centrality on $\alpha_{s}^{\max }$. $\kappa$ also cannot be set by comparing to the proton diffractive cross section as the currently available data does not probe regions of $x$ small enough such that $Q_{s}^{2}$ is a perturbative scale (at least when using the LO MSTW PDFs). In our calculations we will set $\kappa=1$.

It is important to contrast the interaction of the dipole in the KLN CGC approach taken here, in which the $q-\bar{q}$ pair interacts with the entire nucleus, and the Glauber approach, in which the pair interacts with individual nucleons. By interacting with individual nucleons the diffractive cross section for the DGLAP Glauber model picks up an extra exponential suppression in $t$ proportional to the square of the width of the nucleon, $B_{G}$.

Results: The saturation physics of the CGC has resulted in a wider and flatter gluon distribution than that from the Glauber treatment; the DGLAP growth of the small- $x$ gluon distribution - tamed by the saturation physics of the KLN CGC-leads to a significant enhancement in the cross section at $x=10^{-5}$ compared to that found using the KLN CGC gluon distribution. It is worth noting that the KLN prescription for the CGC satisfies the black disk limit.

We attempt to quantify the changes in both the nuclear gluonic width and density as a function of $x$ and note that even out to extremely small values of $x \sim 10^{-13}, b_{1 / 2}$ from the KLN CGC continues to rise sublinearly with $\log (s)$; thus the implementation of the KLN CGC used here, with the MSTW gluon PDF, satisfies the Froissart bound 871. Intriguingly this sublinear (as opposed to linear) growth in radius as a function of $\log s$ is a surprise compared to other CGC parameterizations [872]. Note the enormous growth of
the dipole cross section as $x$ decreases for the LO DGLAP-evolved gluonic density. This unitarity-violating enhancement is clearly reduced tremendously with the saturation physics of the KLN CGC.

The drastically faster increase in the gluon density from the DGLAP evolved PDF results in a cross section that increases much faster as a function of $x$ than for the KLN CGC case. As was shown in $[827]^{6}$ the incoherent cross section, in which the nucleus breaks up, begins to dominate the total diffractive cross section by $t \sim 0.02 \mathrm{GeV}^{-2}$. It is likely that the $t$ dependence of the incoherent EVMP of the two models will be different, although we do not provide a quantitative estimate here: the decrease in cross section as a function of $t$ for the DGLAP Glauber model will be enhanced by $\exp \left(-B_{G} t\right)$ due to the assumption that the heavy quark dipole interacts with individual nucleons. And in the case of coherent scattering one can discern a stronger $t$ dependence in the DGLAP Glauber results due precisely to the extra $\exp \left(-B_{G} t\right)$ factor that results from treating the nucleus as a collection of individual nucleons. More importantly, the much larger gluon density yields a particularly noticeable difference at $t=0$, where possible nuclear breakup effects are negligible.Even with the very large PDF uncertainties as $x$ decreases, there is a clear increase in the coherent diffractive cross section for the DGLAP Glauber dipole compared to the KLN CGC dipole.
Conclusions and Discussion: An enormous wealth of information on the gluonic structure of highly relativistic nuclei can be found using exclusive vector meson production. In particular we investigated the experimental signatures of the coherent scattering of a $c \bar{c}$ dipole onto a nucleus that results in an intact nucleus and a $J / \Psi$ meson in e + A collisions at eRHIC energies. We found that the diffractive cross section will readily experimentally differentiate between the two common initial highly boosted nucleus prescriptions used in heavy ion physics phenomenology: 1) the gluon density is found using DGLAP evolution and its spatial distribution is assumed to be proportional to the at-rest Glauber nuclear thickness function and 2) the gluon density and distribution is given by the KLN parameterization of the CGC. In particular there is the exciting possibility of literally watching a nucleus grow with center of mass energy as the positions in $t$ of the minima and maxima in the diffractive cross section for the saturation physics calculation depend quite strongly on $\log (x)$. On the other hand the DGLAP Glauber model yields a nucleus of constant size as a function of $x$; the positions in $t$ of the diffractive minima and maxima do not change as a function of $x$. At the same time one is determining the width of a nucleus in $\mathrm{e}+\mathrm{A}$ collisions, one will also measure the $x$ dependence of the normalization of $d \sigma / d t$. Due to the explosion of small- $x$ gluons the DGLAP Glauber approach yields a normalization that rapidly increases as a function of $x$; additionally the $t$ dependence of the DGLAP Glauber $d \sigma / d t$ is also quite strong as it is proportional to $\exp \left(-B_{G} t\right)$ due to the assumption that the $q-\bar{q}$ dipole interacts with individual nucleons. Conversely the KLN CGC dipole description does not have a strong $x$ dependence in its normalization due to its inclusion of saturation effects; similarly, the interaction of the dipole with the whole nuclear gluonic wavefunction yields a weaker $t$ dependence than is displayed by the DGLAP Glauber results.

It is clear that, at the very least, the striking difference between the $x$ dependence of the peaks and minima from the DGLAP Glauber model and the KLN CGC model are robust: these differences will persist should we use even more sophisticated models of these two physical pictures; the $x$ dependence of the peaks and minima will persist should we attempt to approximate multiple scattering within the nucleus by exponentiating the dipole cross

[^280]section, should we use a less approximate CGC calculation such as is found in 896], or should we examine the results from other vector mesons such as the $\phi$ or $\rho$. We regrettably leave the quantification of the diffractive cross section for these more sophisticated physical models and additional vector mesons for future work. Exponentiating the two-gluon exchange cross section will reduce the enormous growth in the diffractive cross section in the DGLAP Glauber picture compared to the CGC case; we suspect this reduction will not be too large, although we also leave the quantification of this reduction to future work.

Venugopalan for invaluable discussions and the INT for its hospitality and support. The author wishes to especially thank Y. Kovchegov for reading and commenting on the manuscript.

## Coherent vs incoherent diffraction

## Tuomas Lappi and Cyrille Marquet

The purpose of this section is to investigate incoherent diffraction in a simpler context than with inclusive diffraction $\gamma^{*} A \rightarrow X Y$, mainly using diffractive vector meson production $\gamma^{*} A \rightarrow V Y$, where the diffractive final state X consists of a vector meson and nothing else, $A$ stands for the target nucleus and $Y$ for the final state it may dissociate into. At high energies, the $q \bar{q}$ dipole that the virtual photon has fluctuated into, scatters off the gluonic field of the nucleus before recombining into the vector meson. While this scattering involves a color-singlet exchange, leaving a rapidity gap in the final state, the nucleus can still interact elastically ( $Y=A$, this is called coherent diffraction) or inelastically (i.e. break up, called incoherent diffraction). In this process, the momentum transfer $t$ can be determined from the meson regardless of the fate of the target, and elastic and inelastic interactions of the target can be experimentally distinguished.

Kinematically, a low invariant mass of the system $Y$ corresponds to a large rapidity gap in the final state between that system and the vector meson, and implies that the longitudinal momentum of the meson is close to that of the incoming photon. In this case, the eikonal approximation can be assumed to compute the dipole-nucleus scattering. At small values of $x=\left(Q^{2}+M_{V}^{2}\right) /\left(Q^{2}+W^{2}\right)$ where $Q^{2}$ is the photon virtuality, $M_{V}$ the vector meson mass, and $W$ the energy of the $\gamma^{*}-A$ collision, a target proton can also be considered. Indeed in that case, since partons with an energy fraction as small as $x$ are probed in the target wave function, the dipole will scatter off large gluon densities generated by the QCD evolution.

In $\mathrm{e}+\mathrm{p}$ collisions, the cross-section is maximal at minimum momentum transfer with exclusive production (or coherent diffraction) dominating. As the transfer of momentum gets larger, the role of incoherent diffraction increases and eventually it becomes dominant, typically for momenta larger that the inverse target size; the elastic contribution decreases exponentially while the inelastic contribution decreases only as a power law. It is known that saturation models describe well the exclusive cross section [600, 898, 823, 899], while the BFKL Pomeron exchange approach works well for the target-dissociation cross-section [900, 901]. In the section on proton breakup, we show that, within the Color Glass Condensate (CGC) picture of the small-x part of the hadronic wave function, both coherent and incoherent diffraction can be described in the same framework. We also explicitly calculate both contributions to the diffractive vector meson production cross-section using the

McLerran-Venugopalan (MV) model for the CGC wave function, and discuss phenomenological consequences in the context of a future electron-ion collider [902].

Diffractive dissociation is an aspect of diffraction that changes qualitatively with nuclear targets. Indeed, the structure of incoherent diffraction eA $\rightarrow$ eXY is more complex than with a proton target, and also can teach us a lot more. In the case of a target nucleus, we expect the following qualitative changes in the $t$ dependence. First, the low- $|t|$ regime in which the nucleus scatters elastically will be dominant up to a smaller value of $|t|$ (to about $|t|=0.05 \mathrm{GeV}^{2}$ ) compared to the proton case, reflecting the bigger size of the nucleus. Then, the nucleus-dissociative regime will be made of two parts: an intermediate regime in momentum transfer up to about $0.7 \mathrm{GeV}^{2}$ where the nucleus will predominantly break up into its constituents nucleons, and a large- $|t|$ regime where the nucleons inside the nucleus will also break up, implying pion production in the $Y$ system for instance. These are only qualitative expectations, it is crucial to study this aspect of diffraction quantitatively in order to complete our understanding of the structure of nuclei. The transition from the coherent to the intermediate regime is studied in the nuclear breakup section, following Ref. 827.
Proton breakup: In diffractive vector meson production, the relevant quantity is (the photon is a right mover, the CGC a left mover, and the gauge is $\mathcal{A}^{+}=0$ ):

$$
\begin{equation*}
T_{\mathbf{x y}}\left[\mathcal{A}^{-}\right]=1-\frac{1}{N_{c}} \operatorname{Tr}\left(U_{\mathbf{y}}^{\dagger} U_{\mathbf{x}}\right), \quad \text { with } U_{\mathbf{x}}\left[\mathcal{A}^{-}\right]=\mathcal{P} \exp \left(i g_{S} \int d z^{+} T^{c} \mathcal{A}_{c}^{-}\left(z^{+}, \mathbf{x}\right)\right) \tag{5.88}
\end{equation*}
$$

In terms of this object, the differential cross sections for a transversely ( T ) or longitudinally (L) polarized photon are given by (with $t=-q_{\perp}^{2}$ the momentum transfer squared)

$$
\begin{equation*}
\left.\frac{d \sigma_{T, L}}{d t}=\left.\frac{1}{4 \pi}\langle | \int d z d^{2} x d^{2} y e^{i q_{\perp} \cdot(z \mathbf{x}+(1-z) \mathbf{y})} \Psi_{T, L}(z, \mathbf{x}-\mathbf{y}) T_{\mathbf{x y}}\right|^{2}\right\rangle_{x} \tag{5.89}
\end{equation*}
$$

where $2 \Psi_{T}=\Psi_{V \mid \gamma}^{++}+\Psi_{V \mid \gamma}^{--}$and $\Psi_{L}=\Psi_{V \mid \gamma}^{00}$ with

$$
\begin{equation*}
\Psi_{V \mid \gamma}^{\lambda^{\prime} \lambda}(z, \mathbf{r})=\sum_{h \bar{h}}\left[\phi_{\lambda^{\prime}}^{h \bar{h}}(z, \mathbf{r})\right]^{*} \phi_{\lambda}^{h \bar{h}}(z, \mathbf{r}), \tag{5.90}
\end{equation*}
$$

the overlap between the photon and meson wave functions. $\lambda$ and $h$ denote polarizations and helicities while $z$ is the longitudinal momentum fraction of the photon carried by the quark and $\mathbf{x}$ and $\mathbf{y}$ are the quark and antiquark positions in the transverse plane.

The target average $\langle.\rangle_{x}$ is done with the CGC wave function squared $\left|\Phi_{x}\left[\mathcal{A}^{-}\right]\right|^{2}$ :

$$
\begin{equation*}
\langle f\rangle_{x}=\int D A^{-}\left|\Phi_{x}\left[A^{-}\right]\right|^{2} f\left[A^{-}\right] \tag{5.91}
\end{equation*}
$$

If one had imposed elastic scattering on the target side to describe the exclusive process $\gamma^{*} A \rightarrow V A$, the CGC average would be at the level of the amplitude, and the two-point function $\left\langle T_{\mathrm{xy}}\right\rangle_{x}$ inside the $|.|^{2}$ in (5.89), recovering the formula often used with dipole models.

Instead, when also including the target-dissociative part, the diffractive cross section involves the 4-point correlator $\left\langle T_{\mathbf{x y}} T_{\mathbf{u v}}\right\rangle_{x}$. In order to compute it, we must specify more about the CGC wave function. We shall use the McLerran-Venugopalan (MV) model [729, 903, 730, which is a Gaussian distribution for the color charges which generate the field $\mathcal{A}$ :

$$
\begin{equation*}
\left|\Phi_{x}\left[A^{-}\right]\right|^{2}=\exp \left(-\int d^{2} x d^{2} y d z^{+} \frac{\rho_{c}\left(z^{+}, \mathbf{x}\right) \rho_{c}\left(z^{+}, \mathbf{y}\right)}{2 \mu^{2}\left(z^{+}\right)}\right) \tag{5.92}
\end{equation*}
$$

where the color charge $\rho_{c}$ and the field $\mathcal{A}_{c}^{-}$obey the Yang-Mills equation $-\nabla^{2} \mathcal{A}_{c}^{-}\left(z^{+}, \mathbf{x}\right)=$ $g_{S} \rho_{c}\left(z^{+}, \mathbf{x}\right)$. The variance of the distribution is the transverse color charge density squared along the projectile's path $\mu^{2}\left(z^{+}\right)$, with

$$
\begin{equation*}
\left\langle\rho_{c}\left(z^{+}, \mathbf{x}\right) \rho_{d}\left(z^{\prime+}, \mathbf{y}\right)\right\rangle=\delta_{c d} \delta\left(z^{+}-z^{\prime+}\right) \delta^{(2)}(\mathbf{x}-\mathbf{y}) \mu^{2}\left(z^{+}\right) . \tag{5.93}
\end{equation*}
$$

The only parameter is the saturation momentum $Q_{s}$, with $Q_{s}^{2}$ proportional to the integrated color density squared. Note that there is no $x$ dependence in the MV model, it should be considered as an initial condition to the small- $x$ evolution.

The MV distribution is a Gaussian distribution, therefore one can compute any target average by expanding the Wilson lines in powers of $g_{S} \mathcal{A}_{c}^{-}$(see (5.88)), and then use Wick's theorem [904, 905]. The results for the 4 -point function $\left\langle T_{\mathbf{x y}} T_{\mathbf{u v}}\right\rangle$ are given in 906]. We note that, in the large $-N_{c}$ limit, one has $\left\langle T_{\mathbf{x y}} T_{\mathbf{u v}}\right\rangle=\left\langle T_{\mathbf{x y}}\right\rangle\left\langle T_{\mathbf{u v}}\right\rangle$, which means that at small $-x$, the target-dissociative part of the diffractive cross-section in suppressed at large $N_{c}$, compared to the exclusive part.

The numerical results presented below are obtained with the $x$ evolution of the saturation scale modeled as in [83]: $Q_{s}(x)=\left(x_{0} / x\right)^{\lambda / 2} \mathrm{GeV}$, with $\lambda=0.277$ and $x_{0}=4.110^{-5}$ for the case of a target proton. The collinear logarithm of $Q_{s}$ is neglected, which corresponds to exact geometric scaling [752, 907, 873]: $F(x, \mathbf{r})=F\left[\mathbf{r}^{2} Q_{s}^{2}(x)\right]$. As an illustration, the resulting cross-section for diffractive $\mathrm{J} / \Psi$ production is displayed in Fig. 5.40, and separated into its coherent and incoherent contributions. The light-cone Gaussian J/ $\Psi$ wave function [908, 909 has been used in (5.90). At small values of $|t|$ where coherent diffraction dominates, our results are in agreement with HERA data 620] (one can get a better agreement with more realistic saturation models [600, 898, 823, 899, but this is not our point). Our model indicates that for $|t|>0.7 \mathrm{GeV}^{2}$ or so (this value slightly decreases when $Q^{2}$ increases), incoherent diffraction starts to dominate. This may be the reason why the data on exclusive production stop: there is too much proton-dissociative 'background'. We observe that this part of the cross-section decreases as a power law with $|t|$, rather than exponentially as the exclusive part does.

The model discussed in this work is well adapted to describe the low- and large- $|t|$ regimes in the case of scattering off a nucleus, but not the intermediate

Figure 5.40. Diffractive $J / \Psi$ production in DIS at HERA for $W=90 \mathrm{GeV}$ and different $Q^{2}$ values. regime since the constituent nucleons are absent from the description. This problem has been addressed in a complementary setup in the case of inclusive diffraction off nuclei [826, 825], and the coherent diffraction regime was found to be dominant up to about $|t|=0.05 \mathrm{GeV}^{2}$. The vector meson production case will be addressed next. While in the proton case, both exclusive and diffractive processes can be measured, it is likely that at a future electron-ion collider, the exclusive cross section cannot
be extracted: when the momentum transfer is small enough for the nucleus to stay intact, then it will escape too close to the beam to be detectable. Therefore the diffractive physics program will rely on our understanding of incoherent diffraction.
Nuclear breakup into its constituent nucleons: To simplify our calculation, we will here use a factorized impact parameter profile for the dipole cross section in a proton

$$
\begin{equation*}
\frac{\mathrm{d} \sigma_{\mathrm{dip}}^{\mathrm{p}}}{\mathrm{~d}^{2} \mathbf{b}_{T}}\left(\mathbf{b}_{T}, \mathbf{r}_{T}, x\right)=2\left(1-S_{p}\left(\mathbf{r}_{T}, \mathbf{b}_{T}, x\right)\right)=2 T_{p}\left(\mathbf{b}_{T}\right) \mathcal{N}(r, x) \tag{5.94}
\end{equation*}
$$

where $T_{p}$ is a Gaussian profile $T_{p}\left(\mathbf{b}_{T}\right)=\exp \left(-b^{2} / 2 B_{p}\right)$. In the following we shall consider two dipole cross section parametrizations, the IIM model [84, 910, 876, for which we take take $B_{p}=5.59 \mathrm{GeV}^{-2}$, and a factorized approximation of the IPsat parametrization 600, 823, for which $B_{p}=4.0 \mathrm{GeV}^{2}$. See 827] for a discussion of the origin of these values in different fits.

To extend the dipole cross section from protons to nuclei, we will take the independent scattering approximation that is usually used in Glauber theory and write the $S$-matrix as

$$
\begin{equation*}
S_{A}\left(\mathbf{r}_{T}, \mathbf{b}_{T}, x\right)=\prod_{i=1}^{A} S_{p}\left(\mathbf{r}_{T}, \mathbf{b}_{T}-\mathbf{b}_{T i}, x\right) \tag{5.95}
\end{equation*}
$$

Here $\mathbf{b}_{T i}$ are the nucleon coordinates. This independent scattering assumption is natural in IPsat-like parametrizations or the MV-model, where $r=\left|\mathbf{r}_{T}\right|, S\left(\mathbf{r}_{T}\right) \sim$ $e^{-r^{2} Q_{\mathrm{s}}{ }^{2} / 4}$ with a saturation scale $Q_{\mathrm{s}}{ }^{2}$ proportional to the nuclear thickness $T_{A}(b)$. High energy evolution, however, introduces an anomalous dimension that leads, in the nuclear case, to what could be called leading twist shadowing. With an anomalous dimension $S \sim e^{-\left(Q_{\mathrm{s}} r\right)^{2 \gamma}}$ with $\gamma \neq 1$, a proportionality $Q_{\mathrm{s}}{ }^{2} \sim T_{A}(b)$ is not equivalent to Eq. (5.95). A solution to this problem (see also the more detailed discussion in [825]) would require a realistic impact parameter dependent solution to the BK [770, 741, 747] equation which is not yet available. We point the reader to Ref. 872, for example, for a discussion of the difficulties. These are related to the long distance Coulomb tails that, physically, are regulated at the confinement length scale that is not enforced in

Figure 5.41. The quasielastic and coherent diffractive $J / \Psi$ cross sections in gold nuclei at $Q^{2}=0$ and $x_{\mathbb{P}}=0.001$. The IPsat and IIM parametrizations are shown. We also show the result for the linearized "IPnonsat" version (used e.g. in Ref. 911) where the incoherent cross section is explicitly $A$ times that of the proton. Our approximation (5.97) is not valid for small $|t|$ and has been left out of the plot. a first principles weak coupling calculation.

The average over the positions of the nucleon in the nucleus was given in eq. (5.66). The expectation valuedefined there is equivalent to the average over nucleon configurations in a Monte Carlo Glauber calculation. We are assuming that the positions $\mathbf{b}_{T i}$ are independent, i.e. neglecting nuclear correlations that would be a subject of interest in their own right (see e.g. [912]). The coherent cross section is obtained by averaging the amplitude before
squaring it, $\left|\langle\mathcal{A}\rangle_{\mathrm{N}}\right|^{2}$, and the incoherent one is the variance $\left.\left.\langle | \mathcal{A}\right|^{2}\right\rangle_{\mathrm{N}}-\left|\langle\mathcal{A}\rangle_{\mathrm{N}}\right|^{2}$ that measures the fluctuations of the gluon density inside the nucleus. Because $\langle\mathcal{A}\rangle_{\mathrm{N}}$ is a very smooth function of $\mathbf{b}_{T}$, its Fourier transform vanishes rapidly for $\Delta \gtrsim 1 / R_{A}$. Therefore, at large $\Delta$, the quasielastic cross section is almost purely incoherent.

The cross section for quasielastic vector meson production is now expressed in terms of the dipole scattering amplitude as

$$
\begin{align*}
& \frac{\mathrm{d} \sigma^{\gamma^{*} A \rightarrow V A^{*}}}{\mathrm{~d} t}=\frac{R_{g}^{2}\left(1+\beta^{2}\right)}{16 \pi} \int \frac{\mathrm{~d} z}{4 \pi} \frac{\mathrm{~d} z^{\prime}}{4 \pi} \mathrm{~d}^{2} \mathbf{r}_{T} \mathrm{~d}^{2} \mathbf{r}_{T}^{\prime} \\
&  \tag{5.96}\\
& \left.\quad \times\left.\left[\Psi_{V}^{*} \Psi\right](r, z, Q)\left[\Psi_{V}^{*} \Psi\right]\left(r^{\prime}, z^{\prime}, Q\right)\langle | \mathcal{A}_{q \bar{q}}\right|^{2}\left(x_{\mathbb{P}}, r, r^{\prime}, \boldsymbol{\Delta}_{T}\right)\right\rangle_{\mathrm{N}}
\end{align*}
$$

where we have applied corrections for the skewedness, $R_{g}$, and the real part of the scattering amplitude (see e.g. 824) We now average the square of the dipole scattering amplitude over the nucleon coordinates, using the assumptions of Eqs. (5.95) and (5.94) and taking the large $A$ limit. We are additionally assuming that $T_{A}$ is a smooth function on the distance scale defined by $B_{p}$. Averaging the square of the amplitude gives the total quasi-elastic contribution.

Note that Eqs. (5.95) and (5.94) have enabled us to write the leading contributions as proportional to the (Gaussian) proton impact parameter profile, which can then be Fourier-transformed analytically. Giving up either of these approximations would force us to numerically Fourier-transform the "lumpy" $b$-dependence corresponding to a fixed configuration of the nucleon positions. Keeping only the terms that contribute at large $|t| \gg 1 / R_{A}^{2}$ leaves us with the expression

$$
\begin{align*}
\left|\mathcal{A}_{q \bar{q}}\right|^{2}\left(x_{\mathbb{P}}, r, r^{\prime}, \boldsymbol{\Delta}_{T}\right)=16 & \pi^{2} B_{p}^{2} A \int \\
& \quad \mathrm{~d}^{2} \mathbf{b}_{T}  \tag{5.97}\\
& \times e^{-B_{p} \boldsymbol{\Delta}_{T}^{2}} e^{-2 \pi B_{p}(A-1) T_{A}(b)\left[\mathcal{N}(r)+\mathcal{N}\left(r^{\prime}\right)\right]} \mathcal{N}(r) \mathcal{N}\left(r^{\prime}\right) T_{A}(b) .
\end{align*}
$$

Equation (5.97) has a very clear interpretation. The squared amplitude is proportional to $A$ times the squared amplitude for scattering off a proton, corresponding to the dipole scattering independently off the nucleons in a nucleus. This sum of independent scatterings is then multiplied by a nuclear attenuation factor which accounts for the requirement that the dipole must not scatter inelastically off the other $A-1$ nucleons in the target (otherwise the interaction would not be diffractive). Note that factor $4 \pi B_{p} \mathcal{N}\left(r, x_{\mathbb{P}}\right)=\sigma_{p}\left(r, x_{\mathbb{P}}\right)$ is the proton-dipole cross section for a dipole of size $r$. Thus this attenuation corresponds to the probability of a dipole with a cross section which is the average of dipoles with $r$ and $r^{\prime}$ to pass though the nucleus. A similar expression can be found in Ref. 913 for example.

The coherent cross section in our approximation is given by

$$
\begin{equation*}
\frac{\mathrm{d} \sigma^{\gamma^{*} A \rightarrow V A}}{\mathrm{~d} t}=\frac{R_{g}^{2}\left(1+\beta^{2}\right)}{16 \pi}\left|\left\langle\mathcal{A}\left(x_{\mathbb{P}}, Q^{2}, \boldsymbol{\Delta}_{T}\right)\right\rangle_{\mathrm{N}}\right|^{2} \tag{5.98}
\end{equation*}
$$

where in the large $A$ and smooth nucleus limit the amplitude is

$$
\begin{equation*}
\left\langle\mathcal{A}\left(x_{\mathbb{P}}, Q^{2}, \boldsymbol{\Delta}_{T}\right)\right\rangle_{\mathrm{N}}=\int \frac{\mathrm{d} z}{4 \pi} \mathrm{~d}^{2} \mathbf{r}_{T} \mathrm{~d}^{2} \mathbf{b}_{T} e^{-i \mathbf{b}_{T} \cdot \boldsymbol{\Delta}_{T}}\left[\Psi_{V}^{*} \Psi\right]\left(r, Q^{2}\right) 2\left[1-e^{-2 \pi B_{p} A T_{A}(b) \mathcal{N}\left(r, x_{\mathbb{P}}\right)}\right] \tag{5.99}
\end{equation*}
$$

Figure 5.41summarizes the $t$-dependence of the quasielastic and coherent cross sections. Also shown is the approximation used in [911] where nonlinear effects are left out. The most
striking result is the large suppression by a factor of $\sim 3$ of the incoherent cross section due to nonlinear effects. The incoherent and coherent curves cross saround $|t| \approx 0.05 \mathrm{GeV}^{2}$, as anticipated. With a very good detection of the nuclear breakup events, the first, even the second, diffractive dips in the coherent cross section could be measurable at the EIC, providing detailed information about the average spatial distribution of gluons inside the nucleus. For understanding the initial conditions of ultra-relativistic heavy-ion collisions what has turned out to be equally important are the fluctuations in the gluon density, which are directly measured by the incoherent part of the spectrum.

## Electroproduction of $J / \Psi$

## Boris Z. Kopeliovich

Proton target: The diffractive electro-production of charmonia and the charmoniumnucleon elastic scattering are closely related. The amplitudes of diffractive electro-production of a charmonium and elastic charmonium-proton scattering in the dipole approach have the form,

$$
\begin{align*}
\mathcal{M}_{\gamma^{*} p}\left(s, Q^{2}\right) & =\sum_{\mu, \bar{\mu}} \int_{0}^{1} d \alpha \int d^{2} r_{T} \Phi_{\Psi}^{*(\mu, \bar{\mu})}\left(\alpha, \vec{r}_{T}\right) \sigma_{q \bar{q}}\left(r_{T}, s\right) \Phi_{\gamma^{*}}^{(\mu, \bar{\mu})}\left(\alpha, \vec{r}_{T}, Q^{2}\right) ;  \tag{5.100}\\
\mathcal{M}_{\Psi p}(s) & =\sum_{\mu, \bar{\mu}} \int_{0}^{1} d \alpha \int d^{2} r_{T} \Phi_{\Psi}^{*(\mu, \bar{\mu})}\left(\alpha, \vec{r}_{T}\right) \sigma_{q \bar{q}}\left(r_{T}, s\right) \Phi_{\Psi}^{(\mu, \bar{\mu})}\left(\alpha, \vec{r}_{T}\right) \tag{5.101}
\end{align*}
$$

Here, $\mu$ and $\bar{\mu}$ are the spin indices of the $c$ and $\bar{c}$ quarks, $Q^{2}$ is the photon virtuality, $\Phi_{\gamma^{*}}\left(\alpha, r_{T}, Q^{2}\right)$ is the light-cone distribution function of the photon for a $c \bar{c}$ fluctuation of separation $r_{T}$ and relative fraction $\alpha$ of the photon light-cone momentum carried by $c$ or $\bar{c}$. Correspondingly, $\Phi_{\Psi}\left(\alpha, \vec{r}_{T}\right)$ is the light-cone wave function of $J / \Psi$, or $\Psi^{\prime}$, or $\chi$.

The wave functions of charmonia are calculated in 914 solving the Schrödinger equation with four realistic potentials, which are labelled as COR [915], BT [916], LOG [917], and POW [918. Then one should make a Lorentz boost from the charmonium rest frame to the infinite momentum frame, and to switch from 3-dimensional coordinates to the light-cone variables, $p_{T}$ and $\alpha$, which are the $c$-quark transverse and fractional longitudinal momenta respectively. This was done in 914 using the popular prescription 919 .

The important ingredient of the calculations performed in 914 (compare with [920) is the Melosh spin rotation 921 which relates the 2-dimensional spinors $\chi_{c}$ and $\chi_{\bar{c}}$, describing $c$ and $\bar{c}$ in the infinite momentum frame, to the spinors $\bar{\chi}_{c}$ and $\bar{\chi}_{\bar{c}}$ in the rest frame:

$$
\begin{equation*}
\bar{\chi}_{\mathbf{c}}=\widehat{\mathbf{R}}\left(\alpha, \tilde{\mathbf{p}}_{\mathbf{T}}\right) \chi_{\mathbf{c}}, \quad \bar{\chi}_{\overline{\mathbf{c}}}=\widehat{\mathbf{R}}\left(\mathbf{1}-\alpha,-\tilde{\mathbf{p}}_{\mathbf{T}}\right) \chi_{\overline{\mathbf{c}}}, \tag{5.102}
\end{equation*}
$$

where the matrix $R\left(\alpha, \vec{p}_{T}\right)$ has the form:

$$
\begin{equation*}
\widehat{R}\left(\alpha, \vec{p}_{T}\right)=\frac{m_{c}+\alpha M-i[\vec{\sigma} \times \vec{n}] \vec{p}_{T}}{\sqrt{\left(m_{c}+\alpha M\right)^{2}+p_{T}^{2}}} . \tag{5.103}
\end{equation*}
$$

Since the $c \bar{c}$ pair is in $S$-wave, the spatial and spin dependences in the wave function factorize, and one arrives at the following light cone wave function of the $c \bar{c}$ in the infinite momentum frame

$$
\begin{equation*}
\Phi_{\psi}^{(\mu, \bar{\mu})}\left(\alpha, \vec{p}_{T}\right)=U^{(\mu, \bar{\mu})}\left(\alpha, \vec{p}_{T}\right) \cdot \Phi_{\psi}\left(\alpha, \vec{p}_{T}\right), \tag{5.104}
\end{equation*}
$$

where

$$
\begin{equation*}
U^{(\mu, \bar{\mu})}\left(\alpha, \vec{p}_{T}\right)=\chi_{c}^{\mu \dagger} \widehat{R}^{\dagger}\left(\alpha, \vec{p}_{T}\right) \vec{\sigma} \cdot \vec{e}_{\psi} \sigma_{y} \widehat{R}^{*}\left(1-\alpha,-\vec{p}_{T}\right) \sigma_{y}^{-1} \widetilde{\chi}_{\bar{c}}^{\bar{c}} \tag{5.105}
\end{equation*}
$$

Now we can determine the light-cone wave function in the mixed longitudinal momentum - transverse coordinate representation:

$$
\begin{equation*}
\Phi_{\psi}^{(\mu, \bar{\mu})}\left(\alpha, \vec{r}_{T}\right)=\frac{1}{2 \pi} \int d^{2} p_{T} e^{-i \vec{p}_{T} \vec{r}_{T}} \Phi_{\psi}^{(\mu, \bar{\mu})}\left(\alpha, \vec{p}_{T}\right) \tag{5.106}
\end{equation*}
$$

With this wave function and with the standard distribution functions of the photon one can calculate the amplitudes in (5.100)-(5.101) and predict the cross section of $J / \Psi$ photoproduction on a proton. The results for the energy dependence are compared with HERA data (see references in (914) in Fig. 5.42, The calculation was performed in 914 with two parametrizations of the dipole cross section labelled as GBW [788] and KST [795].

We see that only BP and LOG potentials describe the data well, which, however, are not sensitive to the choice of the phenomenological dipole cross section. The $Q^{2}$ dependence of the cross section is

Figure 5.42. Integrated cross section for elastic photoproduction $\gamma p \rightarrow J / \Psi p$ with real photons ( $Q^{2}=0$ ) as a function of the energy calculated with GBW and KST dipole cross sections and for four potentials to generate $J / \Psi$ wave functions. compared to HERA data (see references in [914]) in Fig. [5.43 (left) for the LOG and BT potentials. It turns out that the effects of Melosh spin rotation have a gross impact on the cross section of elastic photoproduction $\gamma p \rightarrow J / \Psi(\psi) p$. It increases the photoproduction cross section by about $50 \%$. These effects have even more dramatic impact on the $\psi^{\prime}$, increasing the photoproduction cross section by a factor of 2-3 and eliminating the large discrepancy with data observed previously 920 .

Eventually, we are in a position to predict the charmonium-proton total cross section, which is impossible to extract directly from photoproduction data, either on protons, or nuclear targets. Indeed, neither vector dominance [922], nor Glauber model 923] can be used for data analysis. We believe that the only way is to predict the charmonium cross section within a model, which successfully describe data on photoproduction in a parameter free way. Our predictions for the energy dependent charmonium-proton total cross section are depicted in Fig. 5.43 (right) for $J / \Psi$ and $\Psi^{\prime}$.

Nuclear targets: Charmonium photoproduction on nuclei is controlled by two length scales.

$$
\begin{equation*}
l_{c}=\frac{2 \nu}{M_{c \bar{c}}^{2}+Q^{2}} \approx \frac{2 \nu}{M_{J / \Psi}^{2}+Q^{2}} ; l_{f}=\frac{2 \nu}{M_{\Psi^{\prime}}^{2}-M_{J / \Psi}^{2}} \tag{5.107}
\end{equation*}
$$

The first one is called coherence length can be interpreted as the lifetime of a $\bar{c} c$ fluctuation in the projectile photon in the nuclear rest frame. When $l_{c}$ is short compared to the mean nucleon spacing, one can treat $\bar{c} c$ production as instantaneous, with following propagation of the $\bar{c} c$ dipole through the nucleus. In the opposite limit of $l_{c} \gg R_{A}$ the $\bar{c} c$ dipole propagates and attenuates through the whole nucleus. The second scalel $l_{f}$ is the formation length,

Figure 5.43. Left: Integrated cross section for elastic photo production as a function of the photon virtuality $Q^{2}+M_{J / \Psi}$ at energy $\sqrt{s}=90 \mathrm{GeV}$. Right: Total $J / \Psi-p$ (thick curves) and $\Psi^{\prime}-p$ (thin curves) cross sections with the GBW and KST parameterizations for the dipole cross section.
which characterizes the formation of the charmonium wave function. Indeed, the produced $\bar{c} c$ dipole has a certain size and interaction cross section, but does not have any certain mass. It might be the $J / \Psi$, or its radial excitation. To disentangle between them, takes time according to the uncertainty principle.

The cross section of charmonium photo-production on nuclei is easiest to write in the limit of long $l_{c} \gg R_{A}$. In this case, the size of the $\bar{c} c$ dipoles "frozen" by Lorentz time dilation for propagation of the dipole through the nucleus. The cross sections of incoherent (the nucleus break up to fragments) and coherent (the nucleus remains intact) production have the form [923, 924 ,

$$
\begin{array}{r}
\left.\sigma_{i n c}^{\gamma_{T, L}^{*} A}\left(s, Q^{2}\right)=\int d^{2} b T_{A}(b)\left|\langle\Psi| \sigma_{\bar{c} c}\left(r_{T}, s\right) \exp \left[-\frac{1}{2} \sigma_{\overline{c c}}\left(r_{T}, s\right) T_{A}(b)\right]\right| \Psi_{c \bar{c}}^{T, L}\right\rangle\left.\right|^{2} \\
\left.\sigma_{c o h}^{\gamma_{T, L}^{*} A}\left(s, Q^{2}\right)=\int d^{2} b\left|\langle\Psi| 1-\exp \left[-\frac{1}{2} \sigma_{\bar{c} c}\left(r_{T}, s\right) T_{A}(b)\right]\right| \Psi_{c \bar{c}}^{T, L}\right\rangle\left.\right|^{2} \tag{5.109}
\end{array}
$$

where $\Psi_{\bar{c} c}^{T, L}$ are the photon wave functions given by Eq. (5.27); $\Psi\left(\vec{r}_{T}, \alpha\right)$ is the charmonium light-cone wave function calculated in the previous section. These expressions are significantly different from the Glauber model [925] and effectively include the Gribov corrections in all orders.

We define the nuclear ratios for coherent and incoherent reactions as,

$$
\begin{equation*}
R_{\Psi}^{c o h}\left(s, Q^{2}\right)=\frac{\sigma_{c o h}^{\gamma^{*} A}\left(s, Q^{2}\right)}{A \sigma^{\gamma^{*} N}\left(s, Q^{2}\right)}, \quad R_{\Psi}^{i n c}\left(s, Q^{2}\right)=\frac{\sigma_{i n c}^{\gamma^{*} A}\left(s, Q^{2}\right)}{A \sigma^{\gamma^{*} N}\left(s, Q^{2}\right)} . \tag{5.110}
\end{equation*}
$$

These ratios, calculated with Eqs. (5.108)-(5.109) for real photoproduction of $J / \Psi$ and $\Psi^{\prime}$, are depicted as a function of energy in Fig. 5.44. For coherent production, the cross section rises with $A$ nearly as $A^{4 / 3}$, so the ratio may reach a large magnitude.

One can also predict the dependence on the momentum transfer $\vec{k}_{T}$ for the charmonium electro-production on nuclei. In the case of incoherent production, this dependence is the same as for production on free nucleons. However, in coherent production, the nuclear form factor comes into play and one has

$$
\begin{equation*}
\left.\frac{d \sigma_{c o h}^{\gamma_{T, L}^{*} A}\left(s, Q^{2}\right)}{d^{2} k_{T}}=\left|\int d^{2} b e^{i \vec{k}_{T} \cdot \vec{b}}\langle\Psi| 1-\exp \left[-\frac{1}{2} \sigma_{\bar{q} q}\left(r_{T}, s\right) T_{A}(b)\right]\right| \Psi_{c \bar{c}}^{T, L}\right\rangle\left.\right|^{2} . \tag{5.111}
\end{equation*}
$$

Figure 5.44. Ratios $R_{J / \Psi}^{c o h}, R_{J / \Psi}^{i n c}, R_{\Psi^{\prime}}^{c o h}$ and $R_{\Psi^{\prime}}^{c o h}$ for coherent and incoherent production on carbon, copper and Pbas function of $\sqrt{s}$ and at $Q^{2}=0$. The solid and dashed curves refer to the GBW and KST parameterizations respectively.

We introduce the ratios the sum of $T$ and $L$ components of Eq. (5.111) to the cross section at $Q^{2}=0$ and $k_{T}=0$,

$$
\begin{equation*}
\mathcal{R}\left(s, Q^{2}, k_{T}\right)=\frac{d \sigma_{c o h}^{\gamma^{*} A}\left(s, Q^{2}\right)}{d^{2} k_{T}} /\left.\frac{d \sigma_{c o h}^{\gamma^{*} A}\left(s, Q^{2}=0\right)}{d^{2} k_{T}}\right|_{k_{T}=0} \tag{5.112}
\end{equation*}
$$

This ratio is plotted in Fig. 5.45 as a function of $k_{T}$ at $s=4000 \mathrm{GeV}^{2}$ for different virtualities of the photon. We see that the $k_{T}$ dependences are rather similar for $J / \Psi$ and $\Psi^{\prime}$. The shape of the distribution is determined mainly by the nuclear geometry (and not by the size of the (small) charmonium). The calculated curves show the familiar diffraction pattern known from elastic scattering on nuclei.

Figure 5.45. Ratios $\mathcal{R}_{J / \Psi}$ and $\mathcal{R}_{\Psi^{\prime}}$ as functions of $k_{T}$ at $s=4000 \mathrm{GeV}^{2}$ for different values of $Q$. All curves are calculated with the GBW parameterization of the dipole cross section.

It is interesting that the effects of gluon shadowing, calculated in [924], do not affect much the shape and position of the minima in $k_{T}$ dependence of the coherent cross section. However, the cross section integrated over $k_{T}$ may be significantly affected by gluon shadowing. To see the magnitude of gluon shadowing, we introduce the ratio of the cross sections calculated with and without gluon shadowing,

$$
\begin{equation*}
S_{g}\left(s, Q^{2}\right)=\frac{\sigma_{g}^{\gamma^{*} A}\left(s, Q^{2}\right)}{\sigma \gamma^{*} A\left(s, Q^{2}\right)} . \tag{5.113}
\end{equation*}
$$

for incoherent and coherent exclusive charmonium electroproduction. The predicted effects
of gluon shadowing are depicted in Fig. 5.46.
We only plot ratios for $J / \Psi$ production, because ratios for $\Psi^{\prime}$ are practically the same. All curves are calculated with the GBW parameterization of the dipole cross section. We see that the onset of gluon shadowing happens at a c.m. energy of a few tens of GeV. This is controlled by the longitudinal nuclear form factor

$$
\begin{equation*}
F_{A}\left(q_{c}^{g}, b\right)=\frac{1}{T_{A}(b)} \int_{-\infty}^{\infty} d z \rho_{A}(b, z) e^{i q_{c} z} \tag{5.114}
\end{equation*}
$$

where the longitudinal momentum transfer $q_{c}^{g}=1 / l_{c}^{g}$. For the onset of gluon shadowing, $q_{c}^{g} R_{A} \gg 1$, one can keep only the double scattering shadowing correction,

$$
\begin{equation*}
S_{g} \approx 1-\frac{1}{4} \sigma_{e f f} \int d^{2} b T_{A}^{2}(b) F_{A}^{2}\left(q_{c}^{g}, b\right) \tag{5.115}
\end{equation*}
$$

where $\sigma_{\text {eff }}$ is the effective cross section which depends on the dynamics of interaction of the $\bar{q} q g$ fluctuation with a nucleon.

It was found in 787] that the coherence length for gluon shadowing is rather short, $l_{c}^{g} \approx\left(10 x m_{N}\right)^{-1}$, where Bjorken $x$ in our case should be an effective one, $x=\left(Q^{2}+\right.$ $\left.M_{\Psi}^{2}\right) / 2 m_{N} \nu$. The onset of shadowing according to (5.114) and (5.115) should be expected at $q_{c}^{2} \sim 3 /\left(R_{A}^{c h}\right)^{2}$ corresponding to $s_{g} \sim$ $10 m_{N} R_{A}^{c h}\left(Q^{2}+M_{\Psi}^{2}\right) / \sqrt{3}$, where $\left(R_{A}^{c h}\right)^{2}$ is the mean culated with and without gluon shadowing for incoherent and coherent square of the nuclear $J / \Psi$ production..
charge radius. This esti-
mate is in a good agreement with Fig. 5.46. Remarkably, the onset of shadowing is delayed with rising nuclear radii and $Q^{2}$. This follows directly from Eq. (5.115) and the fact that the formfactor is a steeper falling function of $R_{A}$ for heavy than for light nuclei, provided that $q_{c}^{G} R_{A} \gg 1$.

At medium energies, the effects of finite coherence length, $l_{c} \sim R_{A}$ become important. They increase the incoherent and suppress coherent cross sections of charmonium electroproduction. One can find the details of the corresponding calculations in 924 .

## Exclusive processes in $e+A$ collisions

Victor P. Gonçalves
Exclusive processes in deep inelastic scattering (DIS) have appeared as key reactions to trigger the generic mechanism of diffractive scattering. In particular, diffractive vector meson production and deeply virtual Compton scattering (DVCS) have been extensively
studied at HERA and provide a valuable probe of the QCD dynamics at high energies. The cross sections for exclusive processes in DIS are proportional to the square of the scattering amplitude, which makes them strongly sensitive to the underlying QCD dynamics.

In this contribution, we present our estimate for the coherent and incoherent cross sections for exclusive $\rho, J / \Psi$, and $\phi$ production as well as for nuclear DVCS, making use of the numerical solution of the Balitsky-Kovchegov equation including running coupling corrections in order to estimate the contribution of the saturation physics to exclusive processes (For more details and references see Refs. [926, 927).

Exclusive production: In the color dipole approach, exclusive production $\gamma^{*} A \rightarrow E Y$ $(E=\rho, \phi, J / \Psi$ or $\gamma)$ in electron-nucleus interactions at high energies $\left(l_{c} \gg R_{A}\right)$ is given by

$$
\begin{equation*}
\sigma^{c o h}\left(\gamma^{*} A \rightarrow E A\right)=\int d^{2} b\left\langle\mathcal{N}^{A}(x, r, b)\right\rangle^{2} \tag{5.116}
\end{equation*}
$$

where

$$
\begin{equation*}
\langle\mathcal{N}\rangle=\int d^{2} r \int d z \Psi_{E}^{*}(r, z) \mathcal{N}^{A}(x, r, b) \Psi_{\gamma^{*}}\left(r, z, Q^{2}\right) \tag{5.117}
\end{equation*}
$$

and $\mathcal{N}^{A}(x, r, b)$, defined in eq. (5.76), is the forward dipole-target scattering amplitude for a dipole with size $r$ and impact parameter $b$. We will assume that $\sigma_{d p}$ in eq. (5.76) is given by the bCGC saturation model or the solution of the running coupling BK equation.

On the other hand, if the nucleus scatters inelastically, i.e. breaks up $(Y=X)$, the process is called incoherent production. In this case, one sums over all final states of the target nucleus, except those that contain particle production. The $t$ slope is the same as in the case of a nucleon target. Therefore we have

$$
\begin{equation*}
\sigma^{i n c}\left(\gamma^{*} A \rightarrow E X\right)=\frac{|\mathcal{I} m \mathcal{A}(s, t=0)|^{2}}{16 \pi B_{E}} \tag{5.118}
\end{equation*}
$$

where at high energies $\left(l_{c} \gg R_{A}\right)$ :

$$
\begin{equation*}
|\mathcal{I} m \mathcal{A}|^{2}=\int d^{2} b T_{A}(b)\left|\Psi_{E}^{*}(r, z) \sigma_{d p} \exp \left[-\frac{1}{2} \sigma_{d p} T_{A}(b)\right] \Psi_{\gamma^{*}}\left(r, z, Q^{2}\right)\right|^{2} \tag{5.119}
\end{equation*}
$$

and $\sigma_{d p}$ is the dipole-proton cross section. In the incoherent case, the $q \bar{q}$ pair attenuates with a constant absorption cross section, as in the Glauber model, except that the whole exponential is averaged rather than just the cross section in the exponent. The coherent and incoherent cross sections depend differently on $t$. At small $-t\left(-t R_{A}^{2} / 3 \ll 1\right)$ coherent production dominates, with the signature being a sharp forward diffraction peak. On the other hand, incoherent production will dominate at large- $t\left(-t R_{A}^{2} / 3 \gg 1\right)$, with the $t$ dependence being to a good accuracy the same as in the production off free nucleons.

In Eqs. (5.117) and (5.119) the functions $\Psi^{\gamma}(z, r)$ and $\Psi^{E}(z, r)$ are the light-cone wavefunctions of the photon and the exclusive final state, respectively. The variable $r$ defines the relative transverse separation of the pair (dipole) and $z(1-z)$ is the longitudinal momentum fraction of the quark (antiquark). In the dipole formalism, the light-cone wavefunctions $\Psi(z, r)$ in the mixed representation $(r, z)$ are obtained through a two dimensional Fourier transform of the momentum space light-cone wavefunctions $\Psi(z, k)$. The photon wavefunctions are well known in the literature. For the meson wavefunction, we considered the Gauss-LC model. In the DVCS case, as one has a real photon in the final state, only

Figure 5.47. Energy dependence of the coherent (left) and incoherent (right) cross sections for different final states and $Q^{2}=1 \mathrm{GeV}^{2}$.
the transversely polarized overlap function contributes to the cross section. Summed over the quark helicities, for a given quark flavour $f$, it is given by,

$$
\begin{equation*}
\left(\Psi_{\gamma}^{*} \Psi\right)_{T}^{f}=\frac{N_{c} \alpha_{\mathrm{em}} e_{f}^{2}}{2 \pi^{2}}\left\{\left[z^{2}+\bar{z}^{2}\right] \varepsilon_{1} K_{1}\left(\varepsilon_{1} r\right) \varepsilon_{2} K_{1}\left(\varepsilon_{2} r\right)+m_{f}^{2} K_{0}\left(\varepsilon_{1} r\right) K_{0}\left(\varepsilon_{2} r\right)\right\} \tag{5.120}
\end{equation*}
$$

where we have defined the quantities $\varepsilon_{1,2}^{2}=z \bar{z} Q_{1,2}^{2}+m_{f}^{2}$ and $\bar{z}=(1-z)$. Accordingly, the photon virtualities are $Q_{1}^{2}=Q^{2}$ (incoming virtual photon) and $Q_{2}^{2}=0$ (outgoing real photon).
Results: In Fig. 5.47 left, we show the coherent production cross section as a function of the photon-target c.m.s energy, $W$, for a fixed photon virtuality $Q^{2}=1 \mathrm{GeV}^{2}$. Fig. 5.47 right is the exact analogue for the corresponding incoherent cross sections. Each one of the panels shows the results obtained for one specific final state. In each figure, the two upper (lower) curves show the results for a $\mathrm{Pb}(\mathrm{Ca})$ target. In all figures, the dashed (solid) lines are obtained with the bCGC (rcBK) dipole-proton cross section. At low $W$, the bCGC and rcBK production cross sections are indistinguishable from one another because the dipole cross sections tend to coincide. These latter have been tuned to fit DIS data, which are taken in this kinematical region. Another expected feature is the observed decrease of the cross sections with increasing vector meson masses, which comes from the wave functions. Differences are expected to appear at higher energies, where we enter the lower $x$ (extrapolation) region. In all cases we see that the results obtained with the rcBK cross section are larger than those obtained with the bCGC one. This is related to the fact that the numerical solutions of the BK equation tend to reach the unitarity limit later. Due to this fact, the results obtained with the rcBK dipole cross section grow faster with energy than those obtained with the bCGC one. Another feature is that the differences between bCGC and rcBK are larger for heavier vector mesons. Comparing the results shown in Fig. 5.47 we verify the dominance of the coherent production with a small contribution coming from incoherent processes.

## Constraining the $\rho$ wavefunction

Jeffrey R. Forshaw and Ruben Sandapen

In the dipole model [735, 928, the imaginary part of the amplitude for diffractive $\rho$ production is written as [899]

$$
\begin{equation*}
\Im m \mathcal{A}_{\lambda}\left(s, t ; Q^{2}\right)=\sum_{h, \bar{h}} \int \mathrm{~d}^{2} \mathbf{r} \mathrm{~d} z \Psi_{h, \bar{h}}^{\gamma^{*}, \lambda}\left(r, z ; Q^{2}\right) \Psi_{h, \bar{h}}^{\rho, \lambda}(r, z)^{*} e^{-i z \mathbf{r} \cdot \boldsymbol{\Delta}} \mathcal{N}(x, \mathbf{r}, \boldsymbol{\Delta}) \tag{5.121}
\end{equation*}
$$

where $t=-|\boldsymbol{\Delta}|^{2}$. In a standard notation [929, 899, 898, $\Psi_{h, \bar{h}}^{\gamma^{*}, \lambda}$ and $\Psi_{h, \bar{h}}^{\rho, \lambda}$ are the light-cone wavefunctions of the photon and the $\rho$ meson respectively while $\mathcal{N}(x, \mathbf{r}, \boldsymbol{\Delta})$ is the imaginary part of the dipole-proton elastic scattering amplitude. The energy dependence of the latter is via the dimensionless variable $x$, taken here to be $x=\left(Q^{2}+4 m_{f}^{2}\right) /\left(Q^{2}+s\right)$ where $m_{f}$ is a phenomenological light quark mass 7 Setting $t=0$ in equation (5.121), we obtain the forward amplitude used in reference [929]:

$$
\begin{equation*}
\left.\Im m \mathcal{A}_{\lambda}\left(s, t ; Q^{2}\right)\right|_{t=0}=s \sum_{h, \bar{h}} \int \mathrm{~d}^{2} \mathbf{r} \mathrm{~d} z \Psi_{h, \bar{h}}^{\gamma, \lambda}\left(r, z ; Q^{2}\right) \hat{\sigma}(x, r) \Psi_{h, \bar{h}}^{\rho, \lambda}(r, z)^{*} \tag{5.122}
\end{equation*}
$$

where we have used the optical theorem to introduce the dipole cross-section $\hat{\sigma}(x, r)=$ $\mathcal{N}(x, r, \mathbf{0}) / s$. Note that since the momentum transfer $\boldsymbol{\Delta}$ is Fourier conjugate to the impact parameter $\mathbf{b}$, the dipole cross-section at a given energy is simply the $b$-integrated dipoleproton scattering amplitude:

$$
\begin{equation*}
\hat{\sigma}(x, r)=\frac{1}{s} \int \mathrm{~d}^{2} \mathbf{b} \mathcal{N}(x, r, \mathbf{b}) \tag{5.123}
\end{equation*}
$$

This dipole cross-section can be extracted from the $F_{2}$ data since

$$
\begin{equation*}
F_{2}\left(x, Q^{2}\right) \propto \int \mathrm{d}^{2} \mathbf{r} \mathrm{~d} z\left|\Psi_{\gamma^{*}}\left(r, z ; Q^{2}\right)\right|^{2} \hat{\sigma}(x, r) \tag{5.124}
\end{equation*}
$$

and the photon's light-cone wavefunctions are known in QED, at least for large $Q^{2}$. The $F_{2}$-constrained dipole cross-section can then be used to predict the imaginary part of the forward amplitude for diffractive $\rho$ production and thus the forward differential cross-section,

$$
\begin{equation*}
\left.\frac{d \sigma_{\lambda}}{d t}\right|_{t=0}=\frac{1}{16 \pi}\left(\Im m \mathcal{A}_{\lambda}(s, 0)\right)^{2}\left(1+\beta_{\lambda}^{2}\right), \tag{5.125}
\end{equation*}
$$

where $\beta_{\lambda}$ is the ratio of real to imaginary parts of the amplitude and is computed as in reference 929 . The $t$-dependence can be assumed to be the exponential dependence as suggested by experiment 930:

$$
\begin{equation*}
\frac{d \sigma_{\lambda}}{d t}=\left.\frac{d \sigma_{\lambda}}{d t}\right|_{t=0} \times \exp (-B|t|), \quad B=N\left(14.0\left(\frac{1 \mathrm{GeV}^{2}}{Q^{2}+M_{\rho}^{2}}\right)^{0.2}+1\right) \tag{5.126}
\end{equation*}
$$

with $N=0.55 \mathrm{GeV}^{-2}$. After integrating over $t$, we can compute the total cross-section $\sigma=\sigma_{L}+\epsilon \sigma_{T}$ which is measured at HERA. 8

[^281]Presently, several dipole models [931, 824, 910, 821, 823] are able to fit the current HERA $F_{2}$ data and there is evidence that the data prefer those incorporating some form of saturation [932]. We can use the $F_{2}$-constrained dipole cross-section in order to extract the $\rho$ light-cone wavefunction using the current precise HERA data [930, 680]. This has recently been performed in reference [929] using the Regge-inspired FSSat dipole model 931 and we shall report the results of this work here. In addition, we repeat the analysis using two alternative models [910, 824, 823] both based on the original Colour Glass Condensate (CGC) model [84. They differ from the original CGC model by including the contribution of charm quarks when fitting to the $F_{2}$ data. Furthermore in one of them 910, 824, the anomalous dimension $\gamma_{s}$ is treated as an additional free parameter instead of being fixed to its LO BFKL value of 0.63 . We shall refer to these models as CGC[0.74] and CGC[0.63] models where the number in the square brackets stands for the fitted and fixed value of the anomalous dimension respectively. For both models, we use the set of fitted parameters given in reference [824]. All three models, i.e FSSat, CGC[0.63] and CGC[0.74] account for saturation although in a $b$ - (or equivalently $t$-) independent way. Indeed, at a given energy, the dipole cross-section is equal to the forward dipole-proton amplitude or to the $b$-integrated dipole proton amplitude given by equation (5.123). Finally, all three dipole models we consider here give a good description of the diffractive structure function data [876, 933].

## Boosted Gaussian predictions

BG fits

| Dipole model | $\chi^{2} /$ data point |
| :---: | :---: |
| FSSat | $310 / 75$ |
| CGC[0.74] | $262 / 75$ |
| CGC[0.63] | $401 / 75$ |

| Model | $\chi^{2} /$ d.o.f |
| :---: | :---: |
| FSSat [929] | $82 / 72$ |
| CGC[0.74] | $64 / 72$ |
| CGC[0.63] | $83 / 72$ |

## Improved fits

| Model | $\chi^{2} /$ d.o.f |
| :---: | :---: |
| FSSat [929] | $68 / 70$ |
| CGC[0.63] | $67 / 70$ |

Table 5.4. Left: Predictions of the $\chi^{2} /$ data point using the BG wavefunction. Center: $\chi^{2} /$ d.o.f obtained when fitting $R_{\lambda}$ and $b_{\lambda}$ to the leptonic decay width and HERA data. Right: $\chi^{2} /$ d.o.f obtained when fitting $b_{\lambda}, R_{\lambda} c_{T}, d_{T}$ the leptonic decay width and HERA data.

Fitting the HERA data: Previous work [898, 899, 824] has shown that a reasonable assumption for the scalar part of the light-cone wavefunction for the $\rho$ is of the form

$$
\begin{align*}
\phi_{\lambda}^{\mathrm{BG}}(r, z)= & \mathcal{N}_{\lambda} 4[z(1-z)]^{b_{\lambda}} \sqrt{2 \pi R_{\lambda}^{2}} \exp \left(\frac{m_{f}^{2} R_{\lambda}^{2}}{2}\right) \exp \left(-\frac{m_{f}^{2} R_{\lambda}^{2}}{8[z(1-z)]^{b_{\lambda}}}\right)  \tag{5.127}\\
& \times \exp \left(-\frac{2[z(1-z)]^{b_{\lambda}} r^{2}}{R_{\lambda}^{2}}\right)
\end{align*}
$$

and is referred to as the 'Boosted Gaussian' (BG). This wavefunction is a simplified version of that proposed originally by Nemchik, Nikolaev, Predazzi and Zakharov 934]. In the original BG wavefunction, $b_{\lambda}=1$ while the parameters $R_{\lambda}$ and $\mathcal{N}_{\lambda}$ are fixed by the leptonic decay width constraint and the wavefunction normalization conditions [929]. However, when the BG wavefunction is used in conjunction with either the FSSat model or any of the CGC models, none of them is able to give a good quantitative agreement with the current HERA $\rho$-production data. This is illustrated by the large $\chi^{2}$ values in table 5.4, the situation is

## Best fit parameters

|  | $R_{L}^{2}$ | $R_{T}^{2}$ | $b_{L}$ | $b_{T}$ | $c_{T}$ | $d_{T}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| FSSat [929] | 26.76 | 27.52 | 0.5665 | 0.7468 | 0.3317 | 1.310 |
| CGC[0.63] | 27.31 | 31.92 | 0.5522 | 0.7289 | 1.6927 | 2.1457 |
| CGC[0.74] | 26.67 | 21.30 | 0.5697 | 0.7929 | 0 | 0 |

Table 5.5. Best fit parameters for each dipole model.
considerably improved by fitting $R_{\lambda}$ and $b_{\lambda}$ to the leptonic decay width and HERA data (we fit to the same data set and with the same cuts as in reference 929).

For the FSSat and CGC[0.63] models, we can further improve the quality of the fit by allowing for additional end-point enhancement in the transverse wave-function, i.e. using a scalar wave-function of the form

$$
\begin{equation*}
\phi_{T}(r, z)=\phi_{T}^{\mathrm{BG}}(r, z) \times\left[1+c_{T} \xi^{2}+d_{T} \xi^{4}\right] \tag{5.128}
\end{equation*}
$$

where $\xi=2 z-1$. The results are shown in table 5.4.

Figure 5.48. Best fits to the HERA (left) and ZEUS (right) total cross-section data. CGC[0.74]: solid; FSSat: dotted; CGC[0.63]: dashed.

The best fits obtained with each dipole model are compared to the HERA data in figures 5.48 and 5.49, The corresponding fitted parameters are given in table 5.5 Note that we achieve a lower $\chi^{2} /$ d.o.f $=0.89$ with $\operatorname{CGC}[0.74]$ than with $\mathrm{CGC}[0.63]$ and FSS at for which we obtain $\chi^{2} /$ d.o.f $=0.96$ and $\chi^{2} /$ d.o.f $=0.97$ respectively. Compared to the FSSat and CGC[0.63] fits, note that no additional enhancement in the transverse wavefunction is required in the CGC[0.74] fit. Nevertheless the extracted wavefunction still exhibits enhancement compared to the old BG wavefunction. The extracted light-cone wavefunctions are shown in figure 5.50 left.

Distribution Amplitudes: The leading twist-2 Distribution Amplitude (DA) reads 929]:

$$
\begin{equation*}
\varphi(z, \mu) \sim\left(1-\mathrm{e}^{-\mu^{2} / \Delta(z)^{2}}\right) \mathrm{e}^{-m_{f}^{2} / \Delta(z)^{2}}[z(1-z)]^{b_{L}} \tag{5.129}
\end{equation*}
$$

Figure 5.49. Best fits to the $\sigma_{L} / \sigma_{T}$ data. The H1 data are at $W=75 \mathrm{GeV}$ while the ZEUS data are at $W=90 \mathrm{GeV}$. CGC[0.74]: solid; FSSat: dotted; CGC[0.63]: dashed.

Figure 5.50. Left and center: The longitudinal and transverse light-cone wavefunctions squared at $r=0$. (CGC[0.74]: solid; FSSat: dotted; CGC[0.63]: dashed.) Right: The extracted leading twist-2 DAs at $\mu=1 \mathrm{GeV}$ compared to the DA of reference 935 also at 1 GeV (long-dashed) and the asymptotic DA (dot-dashed).
where $\Delta(z)^{2}=8[z(1-z)]^{b_{L}} / R_{L}^{2}$. This leading twist DA is only sensitive to the longitudinal wavefunction and, as illustrated in figure 5.50 right, we expect little variation in the predictions using the different dipole models. To compare with existing theoretical predictions for the DA, we compute moments:

$$
\begin{equation*}
\left\langle\xi^{n}\right\rangle_{\mu}=\int_{0}^{1} \mathrm{~d} z \xi^{n} \varphi(z, \mu) \tag{5.130}
\end{equation*}
$$

where by convention [929] $\int_{0}^{1} \mathrm{~d} z \varphi(z, \mu)=1$. In reference 929, we noted that our DA is very slowly varying with $\mu$ for $\mu>1 \mathrm{GeV}$, i.e our parameterization neglects the perturbatively known $\mu$-dependence of the DA. This statement remains true if we use the CGC[0.63] or CGC[0.74] instead of the FSSat model.

Our results are compared with the existing predictions in table 5.6. The moments obtained with our best fit, i.e with the CGC[0.74] model, are very similar to those obtained with FSSat model or the CGC[0.63]. In all cases, the results are in very good agreement with expectations based on QCD sum rules and the lattice. Finally, in figure 5.50 right, we compare our DAs with that predicted by Ball and Braun [935], at a scale $\mu=1 \mathrm{GeV}$. The agreement is reasonable given that in reference [935], the expansion in Gegenbauer polynomials is truncated at low order, which is presumably responsible for the local minimum at $z=1 / 2$. Certainly, all 4 distributions are broader than the asymptotic prediction $\sim 6 z(1-z)$.

Conclusions: We have used the current HERA data on diffractive $\rho$ production to extract

Moments of the leading twist DA at the scale $\mu$

information on the $\rho$ light-cone wavefunction. We find that the corresponding leading twist- 2 DA is broader than the asymptotic shape and agrees very well with the expectations of QCD sum rules and the lattice. We also find that the data prefer a transverse wavefunction with end-point enhancement although the degree of such an enhancement is model-dependent.

### 5.7 Nuclear effects across the $x-Q^{2}$ plane: quarks and gluons

## Introduction

Rodolfo Sassot, Marco Stratmann, Pia Zurita

In spite of the remarkable phenomenological success of QCD as the theory of strong interactions, a detailed understanding of the role of quark and gluon degrees of freedom in nuclear matter is still lacking and poses great challenges for the theory. Ever since the discovery that quark and gluons in bound nucleons exhibit momentum distributions different from those measured in free or loosely bound nucleons [941], the precise determination of nuclear parton distribution functions (nPDF) has attracted growing attention, driving both increasingly accurate and comprehensive nuclear structure functions measurements 942 ] and a more refined theoretical understanding of the underlying physics.

The precise knowledge of nPDFs is not only required for a deeper understanding of the mechanisms associated with nuclear binding from a QCD improved parton model perspective, but is also a crucial input for the theoretical interpretation and analyses of a wide variety of ongoing and future high energy physics experiments, such as, for instance, heavy ion collisions at BNL-RHIC [943], proton-nucleus collisions to be performed at the CERN-LHC [944, or neutrino-nucleus interactions in long baseline neutrino experiments [945. Consequently, the kinematic range and the accuracy at which nPDFs are known has evolved into a key issue in many areas of hadronic and particle physics.

The standard description of DIS processes off nuclear targets is customarily done in terms of the hard scale $Q$ set by the virtuality of the exchanged photon and a scaling variable $x_{A} \equiv Q^{2} /\left(2 p_{A} \cdot q\right)$, analogous to the Bjorken variable used in DIS off nucleons. Here, $p_{A}$ is the target nucleus momentum, and, consequently, $x_{A}$ is kinematically restricted to $0<x_{A}<1$, just like the standard Bjorken variable. Alternatively, one can define another scaling variable $x_{B} \equiv A x_{A}$, where $A$ is the number of the nucleons in the nucleus. Under the assumption that the nucleus momentum $p_{A}$ is evenly distributed between the nucleons $p_{N}=p_{A} / A$, this variable resembles the Bjorken variable corresponding to the scattering off free nucleons, $x_{B} \equiv Q^{2} /\left(2 p_{N} \cdot q\right)$. However, in the context of nuclear scattering, it spans the interval $0<x_{B}<A$ by definition, reflecting the fact that a parton may in principle carry more than the average nucleon momentum.

In a naive picture, parton distributions in a nucleus are simply given by the incoherent sum of the parton distributions in the $Z$ protons and $(A-Z)$ neutrons that constitute the nucleus. In that case, the ratios between the structure functions or cross sections of two iso-scalar nuclei (with the same proportion of protons and neutrons, such as carbon and deuteron) should be just proportional to the ratio of their respective number of nucleons (or to unity if we normalize the structure functions by the number of nucleons $A$ ).

If we take into account Fermi motion effects, one would expect that in the larger nuclei, the cross section extends up to larger $x_{B}$, so the rates should typically grow to larger than unity at high $x_{B}$. What the EMC experiment found was that in addition to this motion effect, there was a significant and quite unexpected drop in the rates between approximately $x_{B} \approx 0.3$ and $x_{B} \approx 0.7$. In fig, 5.51, we show a precise measurement that illustrates both effects. which was recently performed at JLab [946 Later on, it was found that the situation was even worse for the naive picture outlined above, because at lower $x_{B}$ values, the rates showed non-trivial patterns of suppression and enhancement. These effects are called shadowing and anti-shadowing, respectively. The phenomenon has been measured at

Figure 5.51. Left: EMC effect and Fermi motion as measured at JLab 946. Right: The experimental results of Ref. 947] are illustrated for a gold target. The solid line is the result from Ref. [948] for the usual EMC effect and the dashed and dashed-dotted lines are respectively the EMC effects in the $F_{2}^{W^{+}}$and $F_{2}^{W^{-}}$structure functions. In both panels, $x \equiv x_{B}$ as defined in the text.
different $Q^{2}$ and persists at higher $Q^{2}$ but with a dependence specific for each $x_{B}$ region.
After more than 30 years of experimental and theoretical studies, a standard picture of nuclear modifications of structure functions and parton densities has not yet emerged. This is a clear target for detailed studies at the EIC, which have a large potential to qualitatively improve the current situation.

## The EMC effect at an EIC

Ian C. Cloët

The EMC effect has an immediate parton model interpretation, which is that the valence quarks in nuclei carry a smaller momentum fraction than the valence quarks in a free nucleon. There have been numerous attempts to explain the EMC effect, for example nuclear structure 949, nuclear pion enhancement [950, dynamical rescaling and inter-nucleon color conductivity [951, 952, 953], point like configurations [954] and the medium modifications to the bound nucleons [955, 956, 957, 958]. However, after more than a quarter of a century since the original EMC experiment, there is still no universally accepted explanation of the EMC effect. Therefore, it appears likely that to gain a deeper insight into the origins of the EMC effect we require new experimental information that is not accessed in traditional DIS.

An electron ion collier (EIC) provides excellent opportunities to access different aspects of the EMC effect, which are not as accessible with traditional fixed target experiments. A standout example is $W$-production via the DIS processes

$$
\begin{aligned}
& \ell^{-}+A \longrightarrow W^{-}+\nu_{\ell}+A \longrightarrow \nu_{\ell}+X, \\
& \ell^{+}+A \longrightarrow W^{+}+\bar{\nu}_{\ell}+A \longrightarrow \bar{\nu}_{\ell}+X .
\end{aligned}
$$

The extraction of the target structure functions from these reactions is possible at an EIC because of the unique ability to reconstruct the final state and therefore avoid the need to directly determine the outgoing momentum of the neutrino or anti-neutrino. The parton model expressions for the $F_{2}$ structure functions that characterize these processes are [959]

$$
\begin{align*}
& F_{2 A}^{W^{+}}(x)=\bar{u}_{A}(x)+d_{A}(x)+s_{A}(x)+\bar{c}_{A}(x),  \tag{5.131}\\
& F_{2 A}^{W^{-}}(x)=u_{A}(x)+\bar{d}_{A}(x)+\bar{s}_{A}(x)+c_{A}(x), \tag{5.132}
\end{align*}
$$

where $u_{A}(x), \bar{u}_{A}, \ldots$ are the various quark distributions of the target. In the valence quark region these $W^{ \pm}$structure functions are completely dominated by quark distributions of a single flavour, and hence a measurement of these structure functions provides direct access to the flavour decomposition of the nuclear parton distributions functions in this region. The flavour dependence of the EMC effect can then be determined, which will provide extremely important new information on the nature of this important phenomena.

The EMC effect ratio can be defined as

$$
\begin{equation*}
R^{i}=\frac{F_{2 A}^{i}}{Z F_{2 p}^{i}+N F_{2 n}^{i}}, \quad \text { where } \quad i \in \gamma, W^{ \pm} \tag{5.133}
\end{equation*}
$$

and $F_{2 p}^{i}, F_{2 n}^{i}, F_{2 A}^{i}$ are respectively the proton, neutron and nuclear structure functions. The atomic number of the nucleus is labelled by $Z, N$ is the neutron number. Using the nuclear quark distribution results from Ref. [948, we can construct the usual EMC effect associated with the exchange of a virtual photon and also the EMC effect in the $W^{ \pm}$ structure functions. These results are illustrate in Fig. 5.51 for an Au nucleus.

Therefore, measurements of $F_{2 A}^{W^{ \pm}}(x)$ for various nuclei, for example $\mathrm{C}, \mathrm{Fe}, \mathrm{Au}$ and Pb would provide important new information on the flavour dependence of the EMC effect, which in ref. [948 is predicted to be large for nuclei like Pb and Au . It is also claimed that a significant part of the NuTeV anomaly may also be explained by this isovector EMC effect 948 . Therefore, these measurements present an excellent opportunity for an EIC and will undoubtedly help us understand the origins of the EMC effect, which is essential if we are to ever have a QCD based description of nuclei.

## Nuclear gluons

## Hans J. Pirner

Historically, the very accurate NMC measurements of DIS on Tin and Carbon nuclei has allowed one to extract the gluon distribution from the scaling violation in $F_{2}(A)$. This has been done by Gousset and myself 960 for the first time. That analysis shows an enhancement of $10 \%$ i.e. antishadowing for $x \approx 0.1$ and the same amount of shadowing, namely also $10 \%$ at $x \approx 0.01$. A high experimental accuracy is demanded, therefore only a trend could be established. The asymptotic calculation of heavy charmonium production on nuclei is often proposed as another method to extract the nuclear gluon distribution based on the gluon-gluon fusion process. As shown in various papers by Kopeliovich this production is more complicated, especially for $J / \Psi$, because of initial and final state effects. Measurements of the gluon distribution would give an experimental window on the importance of gluonic effects in nuclear binding. Very little is known about the role of gauge fields in nuclei.

To gain insight on gluons in bound nucleons system, we have studied an abelian QED model 961 where the nucleon is replaced by an atom and the nucleus by a molecule, i.e., we have analysed the structure function of the photon in the $\mathrm{H}_{2}$-molecule and compared it with the structure function in the $H$-atom. The electron orbits of the hydrogen atoms in the molecule are polarized and modified by the electron exchange interaction leading to a suppression of photons at small $x$. At the momentum corresponding to the relative distance of the two protons, a small antishadowing peak is visible 961. In analogy, gluon antishadowing in the region $x=0.1$ may indicate the distance $\Delta r \approx 2 \mathrm{fm}$ between the centers of the nucleons which act as color sources of common gluon fields between nucleons.

A covalent binding of quarks may manifest itself as a density dependent lack of long range gluons at $x<0.1$ similarily to the deformation of the photon cloud in the hydrogen molecule. In addition, in non-Abelian QCD, one expects at small $x$ that the gluons from different nucleons overlap and merge. Both of these effects have also an interpretation in the nuclear rest frame in terms of the absorption of various partonic components in the wave function of the photon.

During the last ten years, the available data have been used to extract nuclear parton distributions and evolve them to high $Q^{2}$, as reviewed below. In a careful analysis one has to respect the large errors of the starting distribution at low $Q^{2}$ for the nuclear gluon distributions and also the larger $x$ region has to be included correctly - at least the fact that the nuclear gluon distribution [962] is more strongly affected by Fermi-motion of the nucleons than the quark distribution, since it has a stronger decrease at large $x$. Enhancement of the nuclear gluon distribution sets in already at $x=0.5$ which may be of importance for charmonium production at JLab 962 .

## Global fits of nuclear PDFs: current status

## Rodolfo Sassot, Marco Stratmann, Pia Zurita

From the point of view of perturbative $\mathrm{QCD}(\mathrm{pQCD})$, the extraction of nPDF can be performed in close analogy to what is routinely done for free nucleons: they are considered as non-perturbative inputs, to be inferred from data, whose relation to the measured observables and their energy scale dependence can be computed order by order in perturbation theory. Although one cannot discard potentially larger higher-twist or power corrections than in the case of free nucleons, or non-linear nuclear recombination effects, standard QCD factorization and universality of nPDFs are found to hold to a very good approximation in the kinematical range covered by present experiments.

At variance with PDFs for free nucleons, which, driven by the demand for increasingly precise predictions of the standard model, obtained an impressive degree of accuracy and refinement, extractions of $n P D F s$ are done at a considerably lower level of sophistication. Not only the number, variety, kinematical coverage, and precision of nuclear data are much more limited, but the precise parameterization of nPDFs is also much more involved as it depends not only on the energy scale $Q$ and the parton's momentum fraction $x$, but also on the size of the nucleus characterized by the atomic number $A$. In the following, we present a brief summary of the current status of nPDFs and outline limitations in the analyses imposed by the data available so far.

Thanks to its variable beam energy, the possibility to run with different nuclei, and the envisioned large luminosities, an EIC will add invaluable novel information on nPDFs from studies of the inclusive structure functions $F_{2, L}$. It will extend the kinematic range toward lower values of $x$ as well as higher scales of $Q$, allowing precise determination of the gluon distribution from scaling violations of $F_{2}$, permit the flavour separation of the quark sea and the study the onset of non-linear saturation effects at small $x$ (see Section 5.3), which eventually spoil the factorized pQCD approach.

Status of Nuclear Parton Densities. From the point of view of pQCD and a factorized approach, the description of nuclear DIS can be viewed as follows. In a DIS processes off a nuclear target, we also have a hard momentum scale $Q$ that allows one to factorize the measured cross section into a point-like partonic cross section and non-perturbative parton

Figure 5.52. Quality of the fit to nuclear DIS and Drell-Yan data; taken from Ref. 40.
densities, characteristic of partons seen in that nucleus. These "effective" parton densities factorize and encode all the non-perturbative information, including the details about the nuclear structure, and every mechanism, interaction, or effect we can imagine. Since the hard partonic cross sections are just the same as those appearing in the factorization for free nucleons, the nuclear parton densities will evolve with scale in the same way as ordinary parton densities. For similar reasons, the approach could be extended to higher orders. What is clearly not obvious within this line of reasoning is why, or how, one could split the non-perturbative effective nuclear parton density into a piece containing only the effects related to quarks and gluons belonging to single nucleon from those related to the nucleons bound in the nuclei. No field theoretical tool gives us a precise prescription of how to achieve this. It is important to keep in mind that even in lepton-nucleon scattering standard PDFs are not just naive probability densities; they are non-trivial, though perfectly well defined, objects which depend on the choice of factorization scheme and contain other ingredients such as gauge links.

What can be done, of course, is to follow a program of global QCD analyses completely analogous to the one carried out for PDFs, i.e., to extract the nPDFs and their $A$ dependence from data. In doing so one can explore if the basic properties of factorization and universality still hold in a nuclear environment. The first QCD extractions of nPDFs defined in this way were done at the end of the 90 's by two pioneering groups who performed leading order (LO) analyses of nuclear DIS data (EKS98, HKM01) [963, 828, 964 .

When introducing nPDFs, the usual approach was to propose a very simple relation between the parton distribution of a proton bound in the nucleus, $f_{i}^{A}$, and those for free protons $f_{i}$,

$$
\begin{equation*}
f_{i}^{A}\left(x_{B}, Q_{0}^{2}\right)=R_{i}\left(x_{B}, Q_{0}^{2}, A, Z\right) f_{i}\left(x_{B}, Q_{0}^{2}\right), \tag{5.134}
\end{equation*}
$$

in terms of a multiplicative nuclear correction factor $R_{i}\left(x_{B}, Q^{2}, A, Z\right)$, specific to a given
nucleus $(A, Z)$, parton flavor $i$, and initial energy scale $Q_{0}^{2}$. Such a description is convenient since the ratio $R_{i}\left(x_{B}, Q^{2}, A, Z\right)$ compares directly the parton densities with and without nuclear effects, and is closely related to the most common nuclear DIS observables, which are the ratios between the nuclear and deuterium structure functions. In Ref. [39] the alternative to relate nPDFs to standard PDFs by means of a convolution was introduced. The convolution approach implements straightforwardly effects related to rescalings or shifts in the parton's momentum fraction due to interactions with the nuclear medium. In addition, convolution integrals are the most natural language for parton dynamics beyond the LO and allow for the straightforward application of the Mellin transform techniques, convenient for a numerical fast and accurate computation of the scale dependence of PDFs and relevant cross section estimates.

Following the developments for standard PDFs, nPDFs analyses subsequently incorporated various improvements such as a consistent next-to-leading order (NLO) framework (nDS) [39, a thorough uncertainty analysis (HKN04 LO) 965, and periodical updates of the different sets in order to incorporate new data (EKPS07 LO) [966], up to NLO accuracy (HKN07 NLO, EPS09 NLO) [38, 40]. In the latest sets 40, 36] particular attention has been paid to the possible impact of $\mathrm{d}+\mathrm{Au}$ collision data from RHIC and neutrino DIS data on the global fits. A typical comparison to nuclear DIS and Drell-Yan data is shown in Fig. 5.52,

It is worth noticing that the inclusion of $d+A u$ data in nPDF fits, although neglecting any nuclear modifications in the hadronization process, leads to significantly larger gluon shadowing and antishadowing, as has been pointed out in [40]. The same data, however, can be described with much more moderate nuclear gluon PDFs, but including medium modified nFFs [967, see Section 5.10.

Figure 5.53. Comparison to neutrino data; taken from Ref. 968.
Regarding the impact of neutrino data, Schienbein et al. [36] claim that within their analysis it is not possible to reproduce simultaneously the trend of the data coming from electromagnetic nuclear DIS and some observables derived from neutrino DIS measurements. Of course, these conclusions are reached under rather stringent assumptions such as a very specific parameterization for nuclear effects and those implicit in the derivation of the neutrino DIS rates to deuteron, which have not been actually measured yet. On the other hand, using the EPS09 analysis and neutrino DIS data, Paukkunen and Salgado [968] find

Figure 5.54. Comparison between different sets of nPDFs from 969 .
no traces of such tension, besides some energy dependent fluctuations in the NuTeV data. A typical comparison to neutrino data is given in Fig. 5.53.

Different recent extractions of nPDFs are shown in Fig. 55.54. A general shortcoming of all present fits is that independent nuclear modification factors can be determined only for gluons, valence, and sea quarks without distinguishing different quark flavors. Also, present fixed-target data do not constrain nPDFs below about $x_{B} \simeq 0.01$, and the curves shown at smaller values of $x_{B}$ are mere extrapolations. Uncertainties on nPDFs are large, in particular for the nuclear gluon distribution. There is clearly a need for more precise data covering also the small $x_{B}$ region.

Conclusions. In the last few years, our knowledge of the way that both parton densities and fragmentation probabilities are modified in a nuclear environment have improved significantly. Different studies performed so far have clearly demonstrated that pQCD factorization and universality are extremely good approximations within the precision and kinematic range of the available data. Although the uncertainties and differences between different QCD global analysis are still large, the availability of more data for different processes, and their subsequent inclusion in the analyses will certainly help to reduce them further. Ultimately, the EIC will be required for precise quantitative studies and to explore the small $x_{B}$ regime where novel non-linear recombination and saturation phenomena are expected. A preliminary study of the capabilities of the EIC in these respects has been presented in Section 5.3 the EIC has the potential to determine gluon and quark nPDFs to a precision comparable to the nucleon PDFs down to $x \sim 10^{-3}$, and indeed to detect saturation effects as a deviation from DGLAP linear evolution.

## HKN nuclear parton distribution functions

## Shunzo Kumano

The Hirai, Kumano and Nagai (HKN) nuclear PDFs [965, 38] are determined by a global analysis of world data on charged-lepton DIS and Drell-Yan processes with nuclear targets. Since the PDFs of the nucleon are relatively well determined, it is appropriate to
parametrize the $n P D F s$ at the initial $Q_{0}^{2}=1 \mathrm{GeV}^{2}$ using Eq. (5.134) and

$$
\begin{equation*}
R_{i}\left(x_{B}, Q_{0}^{2}, A, Z\right)=1+\left(1-\frac{1}{A^{\alpha}}\right) \frac{a_{i}+b_{i} x+c_{i} x^{2}+d_{i} x^{3}}{(1-x)^{\beta_{i}}} \tag{5.135}
\end{equation*}
$$

The determined $u_{v}, \bar{q}$, and $g$ nPDFs from the HKN07 analysis [38] are shown for the calcium nucleus in Fig. 5.55 at $Q^{2}=1 \mathrm{GeV}^{2}$. LO and NLO results are shown with uncertainty bands, showing that nPDFs are determined more accurately at NLO. We obtain $\chi_{\text {min }}^{2} /$ d.o.f. $=1.35$ and 1.21 for the LO and NLO fits, respectively.

The valence-quark modifications are well determined because of accurate measurements on the $F_{2}$ ratios at medium $x$. The small- $x$ region is fixed by the baryon-number and charge conservations together with the modifications in the medium- and large- $x$ regions. The antiquark modifications are also determined well at small $x$ due to measurements on $F_{2}$ shadowing, and they are also fixed at $x \sim 0.1$ because of Fermilab Drell-Yan measurements. However, the region at $x>0.2$ is not determined at all. The E906/SeaQuest collaboration is currently measuring this medium- $x$ region, and there is also a possibility to measure this region with an experiment at J-PARC. In the near future, the uncertainty bands should be significantly reduced for the antiquark.

The gluon distribution has the largest uncertainties since it contributes to the $F_{2}$ and Drell-Yan ratios only as higher-order effects, and the $Q^{2}$ dependence of $F_{2}^{A} / F_{2}^{A^{\prime}}$ is not measured accurately on nuclear targets, which makes it difficult to pin down the gluon modifications measured by scaling violations of $F_{2}$. The small- $x$ nPDFs are dominated by huge gluon distributions, so that it is essential to determine them accurately for new discoveries by high-energy heavyion experiments. Therefore, it is important to mea-

Figure 5.55. Determined nuclear modifications in Ca 38. sure the $Q^{2}$ dependence of $F_{2}^{A} / F_{2}^{A^{\prime}}$ at EIC for determining nuclear gluon distributions.

In HKN07, the nPDFs are also investigated for the deuteron. In obtaining the "nucleonic" PDFs, deuteron data are used after crude nuclear corrections. Since the current PDFs could possibly contain nuclear effects, appropriate nuclear corrections should be applied in future for excluding such effects. Our codes for calculating the nPDFs and their uncertainties are available at the web site 970. The technical details are explained in Refs. [965, 38] and within the subroutine.

### 5.8 Color transparency

## Color transparency phenomena

B. Z. Kopeliovich

The nuclear medium is more transparent for colorless hadronic wave packets than predicted by the Glauber model. One can treat this phenomenon either in the hadronic basis as a result of Gribov's inelastic corrections [791], or in QCD as a result of color screening [780], an effect called color transparency (CT). Although the two approaches are complementary, the latter interpretation is more intuitive and straightforward. Indeed, a point-like colorless object cannot interact with external color fields, therefore its cross section vanishes as $\sigma(r) \propto r^{2}$ when $r \rightarrow 0$ [780]. When a colorless wave packet propagates through a nucleus, the fluctuations with small size have an enhanced survival probability which leads to a non-exponential attenuation $\propto 1 / L$ [780, where $L$ is the path length in nuclear matter.

Diffractive electro-production of vector mesons off nuclei is affected by shadowing and absorption which are different phenomena. Final state absorption of the produced meson exists even in the classical probabilistic approach which relates nuclear suppression to the survival probability $W(z, b)$ of the vector meson produced at the point with longitudinal coordinate $z$ and impact parameter $\vec{b}$,

$$
\begin{equation*}
W(z, b)=\exp \left[-\sigma_{i n}^{V N} \int_{z}^{\infty} d z^{\prime} \rho_{A}\left(b, z^{\prime}\right)\right] \tag{5.136}
\end{equation*}
$$

where $\rho_{A}(b, z)$ is the nuclear density and $\sigma_{i n}^{V N}$ is the inelastic $V N$ cross section. Shadowing, is also known to cause nuclear suppression. In contrast to final state absorption, it is a pure quantum-mechanical effect which results from destructive interference of the amplitudes for which the interaction takes place on different bound nucleons. It can be interpreted as a competition between the different nucleons participating in the reaction: since the total probability cannot exceed one, each participating nucleon diminishes the chances of others to contribute to the process. The interplay between absorption and shadowing is controlled by the two time scales introduced for the case of charmonium in eq. (5.107). They are defined similarly for other hadrons.

In the low-energy limit of short $l_{c}<l_{f} \ll R_{A}$ (shorter than the mean nucleon spacing $\sim 2 \mathrm{fm}$ ) only final state absorption matters. The ratio of the quasielastic $\gamma^{*} A \rightarrow V X$ and $\gamma^{*} N \rightarrow V X$ cross sections reads,

$$
\begin{equation*}
\left.R_{\text {inc }}\right|_{l_{c}, l_{f} \ll R_{A}} \equiv \frac{\sigma_{V}^{\gamma^{*} A}}{A \sigma_{V}^{\gamma^{*} N}}=\frac{1}{A} \int d^{2} b \int_{-\infty}^{\infty} d z \rho_{A}(b, z) \exp \left[-\sigma_{i n}^{V N} \int_{z}^{\infty} d z^{\prime} \rho_{A}\left(b, z^{\prime}\right)\right] \tag{5.137}
\end{equation*}
$$

In the limit of long $l_{c} \gg R_{A}$, it takes a different form; in the Glauber approximation,

$$
\begin{equation*}
\left.R_{i n c}\right|_{l_{c} \gg R_{A}}=\int d^{2} b T_{A}(b) \exp \left[-\sigma_{i n}^{V N} T_{A}(b)\right], \tag{5.138}
\end{equation*}
$$

One can see that the $V$ meson attenuates along the whole nucleus thickness in Eq. (5.138), but only along roughly half of that length in Eq. (5.137). The exact expression beyond VDM which interpolates between the two regimes (5.137) and (5.138) can be found in 925 .

Figure 5.56. Comparison of the dipolea pproach with E665 data 971 for nuclear effect in electroproduction of $\rho$-mesons. Left panel: $Q^{2}$ - dependence of nuclear transparency for lead and calcium. Solid and dashed curves show the results of using the Green function approach and the "frozen" approximation respectively. Right panel: $Q^{2}$-dependence of the total cross section ratio $R_{c o h}(A / C)=12 \sigma_{c o h} / A \sigma_{c o h}$.

The effects of color transparency lead to deviation from this expression. These effects, which can be understood as Gribov inelastic corrections lead to equation (5.108), which should be used to study the effects of color transparency.

Light-cone distribution functions for the photons and vector mesons. In what follows, we rely on the dipole description and need to know the distribution functions for the photon and vector mesons. To be self-consistent, we should use the same light-cone potential for describing both. In equation (5.30) for the Green function, we chose the real part of the potential of the $\bar{q} q$ dipole as in Refs. [795, (913). Solving Eq. (5.30) for the Green function with this potential and assuming similar spin structures for the vector mesons and photons, one can obtain an explicit formula for the vector meson light-cone wave function [913], depending on a "width" and a "quark mass" phenomenological parameters that were fitted to data in 934 .
Cross section on a proton. Now we are in a position to calculate the forward electroproduction diffractive amplitudes, which have the following form, The forward scattering amplitude $\left.\mathcal{M}_{\gamma^{*} N \rightarrow V N}^{T, L}\left(s, Q^{2}\right)\right|_{t=0}$ can be extracted from eq. (5.100) discussed previously. These amplitudes are normalized as $\left|\mathcal{M}^{T, L}\right|^{2}=16 \pi d \sigma_{N}^{T, L} /\left.d t\right|_{t=0}$. In what follows we calculate the cross sections $\sigma=\sigma^{T}+\epsilon \sigma^{L}$ assuming that the photon polarization is $\epsilon=1$.

For HERA data, the normalization of the cross section and its energy and $Q^{2}$ dependence are remarkably well reproduced, see [913]. This is important, since the absolute normalization is usually much more difficult to reproduce than nuclear effects, which we switch to in the nest section.

As a cross-check for the choice of the $\rho^{0}$ wave function, we also calculated the total $\rho^{0}$ nucleon cross section, which is usually expected to be roughly similar to the pion-nucleon cross section $\sigma_{\text {tot }}^{\pi N} \sim 25 \mathrm{mb}$. For the dipole cross section, we adopt the KST parameterization [795], which has been used above, and is designed to describe low- $Q^{2}$ data. Then, at $\nu=100 \mathrm{GeV}$, we obtain $\sigma_{t o t}^{\rho N}=27 \mathrm{mb}$ which is quite a reasonable number.
Diffractive electroproduction on nuclei. In the high energy regime of $l_{c} \gg R_{A}$ one can rely on Eq. (5.111) for incoherent electroproduction of $\rho$-mesons (with different quark mass and meson wave function). As a manifestation of color transparency, the nuclear ratio, also called nuclear transparency, $\operatorname{Tr}_{A}^{i n c} \equiv R_{\text {inc }}$ defined in (5.110), was predicted in 972 to rise as

Figure 5.57. Nuclear transparency for incoherent and coherent electroproduction of $\rho^{0}$ on nitrogen and lead as function of energy. Solid and dashed curves correspond to calculations with and without gluon shadowing, respectively. Left two panels: Incoherent production at $Q^{2}=0,1,3,5,10 \mathrm{GeV}^{2}$. Right two panels: Coherent production at $Q^{2}=0,3,10 \mathrm{GeV}^{2}$.
function of $Q^{2}$. Indeed, the mean size of the $\bar{q} q$ component of the virtual photon decreases qith $Q^{2}$, so the nucleus becomes more transparent. The results of the E665 experiment at Fermilab 971 depicted in Fig. 5.56 are in a good accord with the predicted behavior. The calculations performed in the "frozen" approximation ( $l_{c} \gg R_{A}$ ) are presented with dashed curves. The more realistic results including finiteness of $l_{c}$ and $l_{f}$ are plotted by solid curves. While the "frozen" approximation is rather accurate for incoherent production, the deviation from its expectation for coherent process at the energy of the E665 experiment is significant.

The predicted energy dependence of the nuclear ratios in incoherent and coherent $\rho$ production on nitrogen and lead are depicted in Fig. 5.57. As was expected, the nucleus becomes more opaque with energy for incoherent production. This happens because when the hadronic fluctuations of the virtual photon live longer, they propagate through the whole nucleus and attenuate more. On the other hand, in incoherent production the phase shifts between the amplitudes of $\rho$ production on different nucleons must me very small in order the nucleus remained intact. This is why the nuclear ratio depicted in the bottom part of Fig. 5.57 is so suppressed at low energies.

At high energies, such as at an EIC, gluon shadowing causes an additional nuclear suppression of $\rho$ production. This correction is calculated as was described in Sect. 5.2 and the final results are plotted in Fig. 5.57 by solid curves. As was expected, the effect of gluon shadowing is not significant.

## From color transparency to color opacity

## Mark Strikman

Color transparency (CT) phenomena play several roles. They probe both the high energy dynamics of the strong interaction and the minimal small size components of the hadrons. In the case when some of the produced particles have energies smaller than 10 GeV in the nucleus rest frame, these processes could be also used to study the space-time evolution of small wave packets - a question relevant for interpretation of heavy-ion collisions. They also provide an important link to the hard QCD black disk regime - the regime of strong absorption for the processes which at lower energies exhibit the CT regime, and determine the kinematics where factorization can be applied to generalized parton distribution studies.

The basic feature of CT is the suppression of the interaction of small size color singlet
configurations: for a dipole of transverse size $d$, perturbative QCD gives

$$
\begin{equation*}
\sigma\left(d, x_{N}\right)=\frac{\pi^{2}}{3} \alpha_{s}\left(Q_{e f f}^{2}\right) d^{2}\left[x_{N} G_{N}\left(x_{N}, Q_{e f f}^{2}\right)+2 / 3 x_{N} S_{N}\left(x_{N}, Q_{e f f}^{2}\right)\right] \tag{5.139}
\end{equation*}
$$

where $Q_{e f f}^{2} \propto 1 / d^{2}, x_{N}=Q_{e f f}^{2} / W^{2}$, and the second term is due to the contribution of quark exchanges which is important for intermediate energies 973]. There are two critical requirements for CT phenomena: squeezing, the selection of small size configurations, and freezing, the selection of high enough energies to allow the squeezed configuration to live long enough.

At high energies, one can select CT processes by selecting special final states: for example, the diffraction of a pion into two high $p_{t}$ jets, or a small initial state $\gamma_{L}^{*}$ such as in the exclusive production of mesons. QCD factorization theorems [572, 973] were proven for these processes based on the CT property of QCD. The space time picture of these processes in the nucleus rest frame is as follows: long before the target, the projectile pion or virtual photon fluctuates into a $q \bar{q}$ configuration with transverse separation $d$, which elastically scatters off the target with an amplitude which for $t=0$ is given by Eq. (5.139) (up to small corrections due to different off shellness of the $q \bar{q}$ pair in the initial and final states), followed by the transformation of the pair into two jets or a vector meson. With a slight simplification, the amplitude for dijet diffractive production can be written as

$$
\begin{equation*}
A(\pi N \rightarrow 2 \mathrm{jets}+N)\left(z, p_{t}, t=0\right) \propto \int d^{2} d \psi_{\pi}^{q \bar{q}}(d, z) \sigma_{q \bar{q}-N(A)}(d, s) e^{i p_{t} d} \tag{5.140}
\end{equation*}
$$

where $z$ is the light-cone fraction of the pion momentum carried by a quark, and $\psi_{\pi}^{q \bar{q}}(z, d) \propto$ $z(1-z)_{d \rightarrow 0}$ is the quark-antiquark Fock component of the meson light cone wave function. The presence of the plane-wave factor in the final state leads to an expectation of an earlier onset of scaling than in the case of the vector meson production, where the vector meson wave function appears instead. CT was observed in the pion diffraction into two jets [974, confirming predictions in [975. The HERA data on exclusive vector meson production are also well described.

## Investigations at an EIC

Studies at an EIC will require investigations of different exclusive meson production channels as a function of $x, Q^{2}$. In the CT limit and $-t \geq 0.1 \mathrm{GeV}^{2}$, where coherence effects are negligible, one expects

$$
\begin{equation*}
\sigma_{\gamma_{L}^{L} A \rightarrow " m e s o n " A^{*}}^{i n c o h}(t)=Z \sigma_{\gamma_{L}^{*} p \rightarrow " \text { meson" } N}(t)+N \sigma_{\gamma_{L}^{*} n \rightarrow " \text { meson" } N}(t) \tag{5.141}
\end{equation*}
$$

In EIC kinematics, the coherence length is $\gg 2 R_{A}$ so deviations from the CT prediction could be due to leading twist effects - leading twist shadowing, and higher twist effects of multiple interactions of the $q \bar{q}$ pair with the target nucleus. There are two distinctive regimes: $x \geq 0.03$ where nuclear PDFs are practically linear in A, and $x \leq 0.01$ where a significant LT shadowing of nPDFs is expected (see discussion in section 5.2).
The $x \geq 0.03$ region. Multiple interactions should reduce the cross section. At an EIC, it would be possible to perform a scan as a function of $Q^{2}$. For low $Q^{2}$ and especially for $\sigma_{T}$, one expects a hadron-like regime in which absorption is strong and $\sigma_{\gamma_{L}^{2} A \rightarrow " \text { meson" } A^{*}}^{i n c o h}(t) \propto A^{1 / 3}$. With an increase of $Q^{2}$, one expects a transition from soft dynamics with Gribov-Glauber type screening to the CT regime without significant LT gluon shadowing. In the case of $J / \psi$
production, one expects the CT regime already at low $Q^{2}$ while for the light mesons, the onset of CT can be much slower as essential transverse sizes of the $q \bar{q}$ pair decrease rather slowly with $Q^{2}$ as manifested in the slow convergence of the t-slope of $\rho$-meson production to the t-slope of $J / \psi$ production with increasing $Q^{2}$ [976].
The $x \leq 0.01$ region. In this regime, one expects large shadowing due to the LT mechanisms both for the incoherent and coherent contribution in which case 977, perturbative color opacity is given by

$$
\begin{equation*}
\frac{d \sigma_{\gamma_{L} A \rightarrow V A}}{d t} / \frac{d \sigma_{\gamma_{L} N \rightarrow V N}}{d t}=G_{A}^{2}\left(x, Q_{e f f}^{2}\right) / G_{N}^{2}\left(x, Q_{e f f}^{2}\right) \cdot F_{A}^{2}(t) \tag{5.142}
\end{equation*}
$$

where $F_{A}(t)$ is the nucleus form factor. Typical results for the expected suppression effect are given in Fig. 5.58. Note here that effective $Q^{2}$, which enters in Eq.5.142, is much smaller than $Q^{2}$ in the electro-production of light vector mesons. For example, in the case of the $\rho$ meson, $Q_{e f f}^{2} \sim 3 \mathrm{GeV}^{2}$ for $Q^{2} \sim 10 \mathrm{GeV}^{2}$. For $J / \psi$ photo-production, $Q_{e f f}^{2} \sim 3 \div 4 \mathrm{GeV}^{2}$ and grows slowly with $Q^{2}$ [978. Hence, for the top EIC energies, one expects a reduction in the coherent $J / \psi$ photo/electro production of at least a factor of two. Numerically, the LT shadowing mechanism leads to a larger screening effect for the interaction of the small dipoles than the HT dipole eikonal models (cf. [976]).

The incoherent cross section, $\sigma_{i n c o h}$, is shadowed somewhat more strongly than the coherent cross section, $\sigma_{c o h}$. The effect grows with the increasing strength of the elementary interaction. As a result, the ratio $B_{\gamma^{*} N \rightarrow " V}^{-1}{ }^{\prime \prime} N \cdot \sigma_{i n c o h} / \sigma_{\text {coh }}$ of incoherent and coherent cross sections integrated over $t$ and divided by the slope of the elementary cross section is expected to decrease slowly with decreasing $x$ at fixed $Q^{2}$ (cf. Fig. 43 in [979]). For example, for $B=4 \mathrm{GeV}^{-2}, R \equiv \sigma_{\text {incoh }} / \sigma_{c o h}$ changes from $R \approx 0.3$ in the impulse approximation limit to $R \approx 0.18$ in the regime of strong absorption (strength of dipole interaction of the order $\left.\sigma_{t o t}(\pi N)\right)$. Simultaneous measurements of coherent and incoherent diffraction will allow the testing of the underlying dynamics in greater detail.

Note that it will be feasible to measure the coherent cross section at $t \sim 0$ due to the very steep $t$ dependence of coherent peak and the ability to kill most of the incoherent diffraction experimentally. At the same time, measurements of the $t$ dependence of coherent diffraction beyond the first minimum are unlikely (except for the lightest nuclei like ${ }^{4} H e$ ) due to the dominance of processes of the nuclear excitations for $-t \geq-t_{1}$. (Measurements of very soft photons at rather large opening angles are required 980 .) Note that the cross section of inelastic diffraction with production of hadrons in the nucleus fragmentation region is comparable to that of quasi-elastic diffraction. Studies of the t-dependence of the meson production and/or hadron production in the nucleus fragmentation regionare required to separate these two processes.
Testing the onset of the black disk regime. The study of vector meson production provides a fine probe to test the onset of high density color opacity regime where the LT approximation breaks down - the black disk regime in which interactions of small dipoles with heavy nuclei become completely absorptive. In this limit, one can derive a model independent prediction for the cross section of the vector meson production [981]:

$$
\begin{equation*}
\frac{d \sigma^{\gamma_{T}^{*}}+A \rightarrow V+A}{d t}=\frac{M_{V}^{2}}{Q^{2}} \frac{d \sigma_{L}^{\gamma_{L}^{*}+A \rightarrow V+A}}{d t}=\frac{\left(2 \pi R_{A}^{2}\right)^{2}}{16 \pi} \frac{3 \Gamma_{V} M_{V}^{3}}{\alpha\left(M_{V}^{2}+Q^{2}\right)^{2}} \frac{4\left|J_{1}\left(\sqrt{-t} R_{A}\right)\right|^{2}}{-t R_{A}^{2}} \tag{5.143}
\end{equation*}
$$

where $\Gamma_{V}$ is the electronic decay width $V \rightarrow e^{+} e^{-}, \alpha$ is the fine-structure constant. Eq. (5.143) corresponds to a drastically different result: a factor of $Q^{4}$ slower $Q^{2}$ dependence of the cross section than the LT result.

Figure 5.58. Leading twist shadowing effect for coherent vector meson production off Ca and Pb . Bands reflect the range of predictions given by the FGS10_L and FGS10_H parametrizations of the gluon LT shadowing.

Figure 5.59. Examples of $2 \rightarrow 3$ processes probing (a) nucleon GPDs and large angle $\gamma^{*}(q \bar{q}) \rightarrow$ $\pi \pi(\pi \rho)$ scattering; (b) photon GPDs and large angle nucleon $(q \bar{q}) \rightarrow \pi N$ scattering, (c) nucleon $\rightarrow$ meson GPD and large angle $\gamma^{*}(q q q) \rightarrow \rightarrow \pi N$ scattering.

Other directions of studies. Recently, a number of novel processes were suggested to check the interplay between CT and color opacity phenomena as well as to use CT to understand the dynamics of various elementary processes.

1. It was demonstrated that it is possible to trace small dipoles through the center of the nucleus by selecting large $t \mathrm{VM}$ production with rapidity gap $\gamma^{*} A \rightarrow V+g a p+Y$ for $x_{g}=-t /\left(-t+M_{Y}^{2}\right) 982$.
2. It was suggested that amplitudes of high energy $2 \rightarrow 3$ branching processes: $a+b \rightarrow$ $c+d+e$, where $t=\left(p_{b}-p_{e}\right)^{2}$ is small, $t^{\prime}=\left(p_{a}-p_{c}\right)^{2}, s^{\prime}=\left(p_{c}+p_{e} d\right)^{2}$ are large, and $t^{\prime} / s^{\prime}=$ const can be written in a factorized form as a convolution of different nucleon quark GPDs and hard $2 \rightarrow 2$ amplitudes [983]. Several examples of such processes are depicted in Fig. 5.59, In the case of the ep collider one would be able to study both the nucleon GPDs and GPDs of the real (virtual photon). Also, it will be possible to study large angle $\gamma\left(\gamma^{*}\right)+(q \bar{q}) \rightarrow$ meson $_{1}+$ meson $_{2}$ and $\gamma\left(\gamma^{*}\right)+(q q q) \rightarrow$ meson + baryon reactions.
3. Embedding these processes in nuclei, for example by studying the process $\gamma+A \rightarrow$ $\pi^{+} \pi^{+} A^{*}$, will make it possible to determine at what $p_{T}$ of the pions CT sets in and hence determine minimal $p_{T}$ for which these processes could be used to study various quark GPDs. The nuclear transparency for these processes is very sensitive
to the size of the meson $\bar{q}$ configurations 984. Hence it may be possible to determine the characteristic transverse size of the $q \bar{q}$ dipole involved in the hard process using Eq. (5.139). Also, by studying the transparency as a function of $s$ for fixed $s^{\prime}, t$ and $t^{\prime}$, one could measure in great detail the rate and the pattern of the space time evolution of small $q \bar{q}$ wave packets.

### 5.9 Nuclear GPDs and TMDs

### 5.9.1 Nuclear quark and gluon GPDs

Vadim Guzey, Mark Strikman

Generalized parton distributions (GPDs) parameterize the response of hadronic targets (nucleon, nucleus) when probed by hard probes in exclusive reactions. The QCD factorization theorems state that GPDs are universal distributions that can be accessed in a wide range of hard exclusive processes: deeply virtual Compton scattering (DVCS) 624, electroproduction of mesons by longitudinal virtual photons [572], time-like Compton scattering, etc. GPDs are fundamental and rigorously-defined quantities that encode information on: (i) the distributions and correlations of partons in hadrons that is much richer than that contained in usual diagonal parton distributions and elastic form factors (in a certain sense, GPDs provide three-dimensional parton imaging), (ii) parton total angular momentum (thus, GPDs are believed to help resolve the so-called proton spin crisis), etc. For the detailed discussion of GPDs, see section 3.1 on "Imaging QCD Matter"

While what has been said above holds true for any hadronic target, nuclear GPDs are also interesting in their own right:
(i) Nuclear GPDs give access to both proton and neutron GPDs [985, 986, 987, 988, 989 . Incoherent reactions (with nuclear break-up) can be used to study quasi-free neutron GPDs 990.
(ii) Traditional nuclear effects-off-diagonal EMC effect 991, 992], nuclear shadowing and antishadowing [993, 994, 807]-have been predicted to be more prominent than in the diagonal case.
(iii) Nuclear GPDs may be a good tool to study not well-established/controversial and novel nuclear effects such as the medium modifications of bound nucleon GPDs 992, 995 and presence of non-nucleonic degrees of freedom 996].

Medium $x_{B}>0.05$
The cleanest way to study GPDs is deeply virtual Compton scattering (DVCS), $\gamma^{*}+A \rightarrow$ $\gamma+A^{\prime}$. Nuclear DVCS is more complex and versatile than that with the free proton because the nuclear target, $A$, can have various spins (the number of GPDs increases with the spin of the target) and many different final states, $A^{\prime}$, can be produced ( $A^{\prime}=A, A^{*}, A+\pi, A-1+N$, etc.). In the situation when the final nuclear state cannot be detected, one can sum over all final states $A^{\prime}$ assuming their completeness and obtain for the nuclear DVCS cross section [988]:

$$
\begin{equation*}
\sigma_{\mathrm{DVCS}}=A(A-1) \sigma_{\mathrm{DVCS}}^{\mathrm{coh}}+A \sigma_{\mathrm{DVCS}}^{N} . \tag{5.144}
\end{equation*}
$$

In this expression, the first term is the coherent-dominated contribution (without nuclear break-up or excitation) which is proportional to the nuclear form factor squared, $F_{A}^{2}$, and significant only at the small momentum transfer $t$. The second term is the incoherent contribution whose $t$ dependence is governed by that of the nucleon GPDs; this term dominates at large $t$.

Similarly to Eq. (5.144), the expressions interpolating between the coherent and incoherent regimes can also be derived for the interference between DVCS and Bethe-Heitler
(BH) amplitudes and BH cross section. For instance, the coherent-dominated contribution to the interference between DVCS and BH amplitudes scales as $Z(A-1)$ and that to the BH cross section scales as $Z(Z-1)(Z$ is the nuclear charge). Therefore, one immediately and model-independently predicts the enhancement of the ratio of the nuclear to free proton DVCS beam-spin asymmetries at small $t, A_{\mathrm{LU}}^{A} / A_{\mathrm{LU}}^{p} \sim(A-1) /(Z-1)$ [987, 988]. At large $t$, the cross section is dominated by the incoherent contribution, no nuclear enhancement is expected, and $A_{\mathrm{LU}}^{A} / A_{\mathrm{LU}}^{p} \sim 1$ (in fact, the neutron contribution somewhat suppresses the ratio and makes $A_{\mathrm{LU}}^{A} / A_{\mathrm{LU}}^{p}<1$ [989]). While the HERMES analysis of nuclear DVCS with ${ }^{4} \mathrm{He},{ }^{14} \mathrm{~N},{ }^{20} \mathrm{Ne},{ }^{84} \mathrm{Kr}$, and ${ }^{132} \mathrm{Xe}$ targets supports that $A_{\mathrm{LU}}^{A} / A_{\mathrm{LU}}^{p} \sim 1$ at large $t$ and $A$-independent at all $t$, it finds that at small $t, A_{\mathrm{LU}}^{A} / A_{\mathrm{LU}}^{p}=0.91 \pm 0.19$ [672].

Quark nuclear GPDs in the kinematic region of the off-diagonal EMC effect, $0.1<$ $x_{B}<0.3$, will be constrained with high precision by the analysis CLAS data on DVCS on ${ }^{4}$ He 997. The experiment measured purely coherent nuclear DVCS (the recoiled nucleus was detected using the BoNuS spectator tagger) and also DVCS on a quasi-free proton. The latter will probe possible nuclear medium modifications of the bound proton quark GPDs [995]. Gluon GPDs in nuclei can be accessed best in hard exclusive production of heavy vector mesons. For instance, coherent $J / \psi$ production for $x_{B}>0.1$ can be used to learn about the off-diagonal EMC effect in the gluon channel. The incoherent production of $J / \psi$ can be used to probe medium modifications of the gluon GPD of the bound nucleon.

The EIC will be the only other accelerator beside JLab 12 GeV to study GPDs in $e+A$ collisions, and will contribute considerably to their knowledge. In particular, it will access sea quark and gluon distributions, which are hard to measure at 6 GeV due to the limited $x$ and $Q^{2}$ range, and open dedicated channels like $J / \Psi$ diffreactive production.

## Small $x_{B}<0.05$ : leading twist shadowing and exclusive diffraction

The EIC will open the way to experimental measurements of nuclear GPDs at small $x_{B}$, where nuclear shadowing is known to occur for PDFs. The leading twist theory of nuclear shadowing (see section 5.2) allows one also to predict the impact parameter dependence of nuclear PDFs [807, 803, 805, 806]. The resulting impact parameter dependent nuclear PDFs, $f_{j / A}\left(x, Q^{2}, b\right)$ are the corresponding nuclear generalized parton distributions (GPDs) in the $\xi \rightarrow 0$ limit and in impact parameter space [994], $f_{j / A}\left(x, Q^{2}, b\right)=H_{A}^{j}\left(x, \xi=0, b, Q^{2}\right)$, where the latter GPD depends in general on two light-cone fractions $x$ and $\xi ; \xi$ is fixed by the external kinematics, $\xi=x_{B} /\left(2-x_{B}\right)$, where $x_{B}$ is the standard Bjorken $x$. The number of GPDs depends on the spin of the target; we shall consider only spinless targets characterized by one twist-two chirally-even GPD $H^{j}$ ( $j$ is the parton flavor).

Using the predictions of the leading twist theory of nuclear shadowing for the impact parameter dependence of nuclear PDFs (Eq. (5.33)) and the connection of these to GPDs, one can obtain the nuclear GPD $H_{A}^{j}$ at small $x$ in the $\xi=0$ limit. The final result for the GPDs in the momentum space is

$$
\begin{align*}
H_{A}^{j}(x, \xi & \left.=0, t, Q^{2}\right)=A F_{A}(t) f_{j / N}\left(x, Q^{2}\right) \\
& -\frac{A(A-1)}{2} 16 \pi \Re e\left\{\frac{(1-i \eta)^{2}}{1+\eta^{2}} \int d^{2} b e^{i \vec{\Delta}_{\perp} \cdot \vec{b}} \int_{\infty}^{\infty} d z_{1} \int_{z_{1}}^{\infty} d z_{2} \int_{x}^{0.1} d x_{\mathbb{P}} \rho_{A}\left(b, z_{1}\right)\right. \\
& \left.\times \rho_{A}\left(b, z_{2}\right) e^{i m_{N} x_{\mathbb{P}}\left(z_{1}-z_{2}\right)} e^{-\frac{A}{2}(1-i \eta) \sigma_{\text {soft }}^{j}\left(x, Q^{2}\right) \int_{z_{1}}^{z_{2}} d z^{\prime} \rho_{A}\left(b, z^{\prime}\right)} \frac{1}{x_{\mathbb{P}}} f_{j}^{D(4)}\left(\beta, Q^{2}, x_{\mathbb{P}}, t_{\min }\right)\right\}, \tag{5.145}
\end{align*}
$$

Figure 5.60. The ratio of the gluon and $\bar{u}$-quark $H_{A}^{j}(x, \xi=0, t) /\left[A F_{A}(t) f_{j / N}\left(x, Q^{2}\right)\right]$ for ${ }^{208} \mathrm{~Pb}$ as a function of $x$ for different values of $t$. All curves correspond to $Q^{2}=4 \mathrm{GeV}^{2}$ and model FGS10_H.
where the notation is the same as in eqs. (5.32) and (5.33).
Fig. 5.60 presents our predictions for the ratio $H_{A}^{j}\left(x, \xi=0, t, Q^{2}\right) /\left[A F_{A}(t) f_{j / N}\left(x, Q^{2}\right)\right]$ for ${ }^{208} \mathrm{~Pb}$ as a function of $x$ for different values of $t$. The left panel corresponds to the ratio of the $\bar{u}$-quark distributions; the right panel corresponds to the gluon distributions. All curves correspond to $Q^{2}=4 \mathrm{GeV}^{2}$ and model FGS10_H (see details in section 5.2). Since the $t$ dependence of the shadowing correction to $H_{A}^{j}(x, \xi=0, t)$ (second term in Eq. (5.145)) is somewhat slower than that of the impulse approximation (the first term), the effect of nuclear shadowing increases as $|t|$ is increased, as expected.

Experimental observables measured in hard exclusive processes such as, e.g., $\gamma^{*}+A \rightarrow$ $\gamma(J / \Psi, \rho, \ldots)+A$, probe the GPD $H_{A}^{j}\left(x, \xi, t, Q^{2}\right)$ integrated over the entire region of the light-cone variable $x, 0 \leq x \leq 1$. However, at high energies (small $\xi$ or $x_{B}$ ), the situation simplifies: the predominantly imaginary $\gamma^{*}+A \rightarrow \gamma(J / \Psi, \rho, \ldots)+A$ scattering amplitudes are expressed solely in terms of the GPDs at the $x=\xi$ cross-over line, $H_{A}^{j}\left(\xi, \xi, t, Q^{2}\right)$ (to the leading order in the strong coupling constant $\alpha_{s}$ ). In addition, it was shown in 592 that at high energies and in the leading logarithmic approximation (LLA), GPDs at an input scale $Q_{0}^{2} \sim$ few $\mathrm{GeV}^{2}$ can be approximated well by the usual parton distributions, i.e., it is safe to neglect the effect of the skewness $\xi$. Therefore, for instance, for the imaginary part of the coherent nuclear deeply virtual Compton scattering (DVCS) amplitude ( $\gamma^{*}+A \rightarrow \gamma+A$ ), we have at the leading order in $\alpha_{s}$ :

$$
\begin{align*}
\Im m \mathcal{A}_{\mathrm{DVCS}}\left(\xi, t, Q^{2}\right) & =-\pi \sum_{q} e_{q}^{2}\left[H_{A}^{q}\left(\xi, \xi, t, Q^{2}\right)+H_{A}^{\bar{q}}\left(\xi, \xi, t, Q^{2}\right)\right] \\
& \approx-\pi \sum_{q} e_{q}^{2}\left[H_{A}^{q}\left(\xi, \xi=0, t, Q^{2}\right)+H_{A}^{\bar{q}}\left(\xi, \xi=0, t, Q^{2}\right)\right] \tag{5.146}
\end{align*}
$$

where $e_{q}$ are the quark charges; $H_{A}^{q}\left(\xi, \xi=0, t, Q^{2}\right)$ are given by Eq. (5.145).
The cleanest way to access GPDs is via DVCS. At the photon level, the $\gamma^{*}+A \rightarrow \gamma+A$ cross section reads, (see, e.g., 625):

$$
\begin{equation*}
\frac{d \sigma_{\mathrm{DVCS}}}{d t}=\frac{\pi \alpha_{\mathrm{em}}^{2} x^{2}\left(1-\xi^{2}\right)}{Q^{4} \sqrt{1+\epsilon^{2}}}\left|\Im m \mathcal{A}_{\mathrm{DVCS}}\left(\xi, t, Q^{2}\right)\right|^{2} \tag{5.147}
\end{equation*}
$$

where $\alpha_{\mathrm{em}}$ is the fine-structure constant; $\epsilon^{2}=4 x^{2} m_{N}^{2} / Q^{2} ; \Im m \mathcal{A}_{\mathrm{DVCS}}$ is given by Eq. (5.146).
The DVCS process interferes and competes with the purely electromagnetic BetheHeitler ( BH ) process. The BH cross section at the photon level can be written in the

Figure 5.61. The DVCS (solid curves) and Bethe-Heitler (dot-dashed curves) cross sections for ${ }^{208} \mathrm{~Pb}$ at $Q^{2}=4 \mathrm{GeV}^{2}$. Left panel: $t$-integrated cross sections vs. $x$. The four BH curves correspond, from left to right, to $\sqrt{s}=(32,44,66,90) \mathrm{GeV}$. Middle panel: differential cross sections vs. $|t|$ at fixed $x=5 \times 10^{-3}$; the BH curve corresponds to $\sqrt{s}=32 \mathrm{GeV}$. Right panel: beam-spin asymmetry $A_{L U}$.
following form 625]:

$$
\begin{equation*}
\frac{d \sigma_{\mathrm{BH}}}{d t}=\frac{\pi \alpha_{\mathrm{em}}^{2}}{4 Q^{2} t(1+\epsilon)^{5 / 2}\left(1-y-y^{2} / 2\right)} \int_{0}^{2 \pi} \frac{d \phi}{2 \pi} \frac{1}{\mathcal{P}_{1}(\phi) \mathcal{P}_{2}(\phi)}\left|\mathcal{A}_{\mathrm{BH}}\left(\xi, t, Q^{2}, \phi\right)\right|^{2} \tag{5.148}
\end{equation*}
$$

where $y=\left(q \cdot P_{A}\right) /\left(k \cdot P_{A}\right)=Q^{2} /(x s)$ ( $k$ is the incoming lepton momentum, $q$ is the momentum of the virtual photon, $P_{A}$ is the momentum of the incoming nucleus, $s$ is the total invariant energy squared); $\phi$ is the angle between the lepton and hadron scattering planes; $\mathcal{P}_{1}(\phi)$ and $\mathcal{P}_{2}(\phi)$ are proportional to the lepton propagators; $\left|\mathcal{A}_{\mathrm{BH}}\left(\xi, t, Q^{2}\right)\right|^{2}$ is the BH amplitude squared. The expressions for $\mathcal{P}_{1,2}(\phi)$ and $\left|\mathcal{A}_{\mathrm{BH}}\left(\xi, t, Q^{2}\right)\right|^{2}$ can be found in 625]. Note that $\left|\mathcal{A}_{\mathrm{BH}}\left(\xi, t, Q^{2}\right)\right|^{2}$ is proportional to the nuclear electric form factor squared $\left(\left|F_{A}(t)\right|^{2}\right)$ and the nucleus charge squared $\left(Z^{2}\right)$.

Integrating the differential cross sections in Eqs. (5.147) and (5.148) over $t$, one obtains the corresponding $t$-integrated cross section $\sigma_{\mathrm{DVCS}(\mathrm{BH})}$ between $t_{\min } \approx-x^{2} m_{N}^{2}$ and $t_{\max }=$ $-1 \mathrm{GeV}^{2}$ :

In fig, 5.61 we present our predictions for a ${ }^{208} \mathrm{~Pb}$ target: in the left plot, the DVCS and BH cross sections at $Q^{2}=4 \mathrm{GeV}^{2}$, in the middle plot the differential cross sections as a function of $|t|$ at fixed $x=5 \times 10^{-3}$, and in the right plot the $A_{L U}$ asymmetry.

In the considered kinematics, the $t$-integrated BH cross section is much larger than the DVCS cross section for $x<10^{-2}$ due to the dramatic enhancement of the BH cross section at small $t \approx t_{\text {min }}$ by the factor $1 / t$, see Eq. (5.148). Therefore, in order to extract a small DVCS signal on the background of the dominant BH contribution for such $x$, one needs to consider the observable differential in $t$. The $t$ dependence of the DVCS and BH differential cross sections has the characteristic shape of the nuclear form factor squared, with distinct minima and maxima. However, the minima of the DVCS cross section are slightly shifted towards smaller $t$ : this is the effect of the leading twist nuclear shadowing in quark nuclear GPDs. The small shift of the minima toward smaller $t$ can be interpreted as an increase of the transverse size of the distributions of quarks in nuclei. One can enhance the effect by using lighter nuclei (e.g., ${ }^{4} \mathrm{He}$ and ${ }^{12} \mathrm{C}$ ) or by considering observables sensitive to the interference between the BH and DVCS amplitudes. For instance, the DVCS beam-spin asymmetry at $A_{\mathrm{LU}}\left(\phi=90^{\circ}\right)$, dramatically oscillates as a function of $|t|$ [994], and the sole reason for these oscillations is the leading twist nuclear shadowing.

Another possibility to study nuclear shadowing in DVCS is offered by processes with nuclear break-up. In this case, the nuclear modification (suppression due to shadowing) of the DVCS break-up cross section (as compared to the impulse approximation) is as large-or even bigger - as that for the coherent case. At the same time, in the impulse approximation,
the relative contribution of the DVCS and BH cross sections is enhanced by $A / Z$ compared to the ep case. It allows one to observe the DVCS signal on the large BH background down to much smaller $x$ than in the ep case, see the discussion in section 3.1.

The leading twist theory of nuclear shadowing allows one also to make predictions for certain observables in exclusive electroproduction of heavy vector mesons $(J / \psi, \Upsilon)$ with nuclear targets which probe the nuclear gluon distribution, with a pattern similar to that discussed for small- $x$ nuclear DVCS 807. See the discussion by M.Strikman in Section 5.8.

### 5.9.2 Nuclear TMDs

Jian-Hua Gao, Zuo-tang Liang, Xin-Nian Wang, Jian Zhou
Transverse momentum dependent distributions (TMDs) were discussed extensively for nucleons earlier in this report. TMDs play an important role in studying final/initial state multiple re-scattering effects in nuclei. Indeed, the leading power nuclear effect comes from the gauge link appearing in the nuclear TMDs, in which the re-scattering effect is encoded.

The extraction of the TMDs from high energy scattering data relies on TMD factorization theorems, established in the $e^{+} e^{-}$annihilation process 241 and semi-inclusive deepinelastic (SIDIS) lepton-nucleon scattering [256]. It is not so clear whether TMD factorization still holds in SIDIS off a large nucleus target. In our recent work [998], we simply assume that it does. Correspondingly, one can introduce leading power unpolarized nuclear TMDs. For simplicity, we restrict our discussion to the light cone gauge, $A^{+}=0$ [263], where

$$
\begin{equation*}
f_{q}^{A}\left(x, \vec{k}_{\perp}\right)=\int \frac{d y^{-}}{2 \pi} \frac{d^{2} y_{\perp}}{(2 \pi)^{2}} e^{i x p^{+} y^{-}-i \vec{k}_{\perp} \cdot \vec{y}_{\perp}}\langle A| \bar{\psi}\left(0, \overrightarrow{0}_{\perp}\right) \frac{\gamma^{+}}{2} \mathcal{L}_{\perp}(0, y) \psi\left(y^{-}, \vec{y}_{\perp}\right)|A\rangle \tag{5.149}
\end{equation*}
$$

and the transverse gauge link is $\mathcal{L}_{\perp} \equiv P \exp \left[-i g \int_{\overrightarrow{0}_{\perp}}^{\vec{y}_{\perp}} d \vec{\xi}_{\perp} \cdot \vec{A}_{\perp}\left(\infty, \vec{\xi}_{\perp}\right)\right]$. This gauge link is not only crucial to ensure the gauge invariance of the TMD parton distribution functions, but also leads to physical consequences such as single-spin asymmetries in SIDIS and the Drell-Yan process in $e+p$ collisions [251, 261, 262]. For DIS off a nucleus target, it should also contain information on the quark transverse momentum broadening due to multiple scattering inside the nucleus 998 .

In the study of either cold or hot nuclear matter, parton transverse momentum broadening plays a crucial role in unraveling the medium properties. One important parameter that controls parton energy loss is the parton transport parameter $\hat{q}$, i.e., the transverse momentum broadening squared per unit of propagation length [999. Therefore, the calculation and measurement of the jet transport parameter is an important step toward understanding the intrinsic properties of the QCD medium. Much effort has been devoted to the study of transverse momentum broadening in high energy collisions within different approaches [999, 1000, 1001, 1002, 1003, 1004, 1005, 1006.

In this contribution, we start from the matrix element definition of the nuclear TMD and identify the gauge link as the main source of leading nuclear effects. The broadened distribution has a Gaussian form, as found in earlier studies [1005], and suppresses the azimuthal asymmetry in SIDIS off nuclear targets. This in turns gives direct experimental access to the cold nuclear matter transport coefficient $\hat{q}$, and offers a way to determine the relative magnitude of the intrinsic transverse momentum in various nucleon TMDs.
Nuclear TMDs and nucleon TMDs. The effect of final state interactions that lead to transverse momentum broadening can be encoded in the gauge link. In fact, the nuclear
dependent part of the quark TMD can be isolated from the gauge link so that the nuclear TMD can be expressed as a convolution of the Gaussian broadening and the nucleon TMD. Assuming a weakly bound nucleon, neglecting the correlation between different nucleons, and keeping only the matrix elements with nuclear enhancement one obtains the nuclear TMD,

$$
\begin{equation*}
f_{q}^{A}\left(x, \vec{k}_{\perp}\right)=\frac{A}{\pi \Delta_{2 F}} \int d^{2} \ell_{\perp} e^{-\left(\vec{k}_{\perp}-\vec{\ell}_{\perp}\right)^{2} / \Delta_{2 F}} f_{q}^{N}\left(x, \vec{\ell}_{\perp}\right), \tag{5.150}
\end{equation*}
$$

as a convolution of the nucleon TMD and a Gaussian with a width $\Delta_{2 F}$ given by the total transverse momentum broadening squared,

$$
\begin{equation*}
\Delta_{2 F}=\frac{1}{A f_{q}^{N}(x)} \int d^{2} k_{\perp} k_{\perp}^{2}\left[f_{q}^{A}\left(x, \vec{k}_{\perp}\right)-f_{q}^{N}\left(x, \vec{k}_{\perp}\right)\right]=\int d \xi_{N}^{-} \hat{q}_{F}\left(\xi_{N}\right) \tag{5.151}
\end{equation*}
$$

where the quark transport parameter $\hat{q}_{F}\left(\xi_{N}\right)$ is defined as

$$
\begin{equation*}
\hat{q}_{F}\left(\xi_{N}\right)=-\frac{g^{2}}{2 N_{c}} \rho_{N}^{A}\left(\xi_{N}\right) \int \frac{d \xi^{-}}{2 p^{+}}\langle N| F_{+\sigma}(0) F_{+}^{\sigma}\left(\xi^{-}\right)|N\rangle=\frac{2 \pi^{2} \alpha_{s}}{N_{c}} \rho_{N}^{A}\left(\xi_{N}\right)\left[x f_{N}^{g}(x)\right]_{x=0}, \tag{5.152}
\end{equation*}
$$

with $\rho_{N}^{A}\left(\xi_{N}\right)$ is the spatial nucleon density inside the nucleus and $f_{g}^{N}(x)$ is the gluon distribution function in a nucleon. Eq. (5.150) is our main result.

Nuclear dependence of azimuthal asymmetry in SIDIS. One can generalize the above approach to the nuclear modification of higher twist TMD parton distributions. The case of twist-3 and twist-4 TMDs [243, 247, 1007, which account for the $\cos \phi$ and $\cos 2 \phi$ azimuthal asymmetries in SIDIS, has been recently investigated in Ref. [1008, 1009]. Here we review the nuclear dependent $\cos \phi$ azimuthal asymmetry in the two kinematic regions: at small transverse momentum $P_{h \perp} \sim \Lambda_{Q C D}$ and intermediate transverse momentum $\Lambda_{Q C D} \ll P_{h \perp} \ll Q$, where $Q$ is the virtual photon momentum. The central ingredient of the treatment in Ref. 1008 is the relation between the nucleon twist-3 TMDs and nuclear ones. If we look at jet production in SIDIS, the azimuthal asymmetry is solely determined by one twist-3 TMD distribution $f^{\perp}\left(x, k_{\perp}\right)$. The ratio of the asymmetry between SIDIS off nucleons and nuclei is,

$$
\begin{equation*}
\frac{\langle\cos \phi\rangle_{e A}}{\langle\cos \phi\rangle_{e N}}=\frac{f_{\perp}^{A}\left(x, k_{\perp}\right) / f^{A}\left(x, k_{\perp}\right)}{f_{\perp}^{N}\left(x, k_{\perp}\right) / f^{N}\left(x, k_{\perp}\right)} \tag{5.153}
\end{equation*}
$$

The ratio depends on how the twist-3 TMD distributions $f_{\perp}^{A}$ is enhanced/suppressed due to the stronger final state interaction taking place inside a nucleus. Following the same approach applied to the twist-2 TMD distribution, we relate the function $f_{\perp}^{A}$ to $f_{\perp}^{N}$,

$$
\begin{equation*}
f_{\perp}^{A}\left(x, k_{\perp}\right) \approx \frac{A}{\pi \Delta_{2 F}} \int d^{2} \ell_{\perp} \frac{\left(\vec{k}_{\perp} \cdot \vec{\ell}_{\perp}\right)}{\vec{k}_{\perp}^{2}} e^{-\left(\vec{k}_{\perp}-\vec{\ell}_{\perp}\right)^{2} / \Delta_{2 F}} f_{\perp}^{N}\left(x, \ell_{\perp}\right) \tag{5.154}
\end{equation*}
$$

Given the TMDs $f^{N}\left(x, k_{\perp}\right)$ and $f_{\perp}^{N}\left(x, k_{\perp}\right)$, one will be able to calculate the ratio (5.154). To illustrate the nuclear dependence of the asymmetry qualitatively, we consider an ansatz of the Gaussian distributions in $k_{\perp}$ for both TMDs,

$$
\begin{equation*}
f^{N}\left(x, k_{\perp}\right)=\frac{1}{\pi \alpha} f_{q}^{N}(x) e^{-k_{\perp}^{2} / \alpha}, \quad f_{\perp}^{N}\left(x, k_{\perp}\right)=\frac{1}{\pi \beta} f_{q \perp}^{N}(x) e^{-k_{\perp}^{2} / \beta} . \tag{5.155}
\end{equation*}
$$

As shown in Fig. 5.62, the azimuthal asymmetry is suppressed in $e+A$ SIDIS as compared to that in $e+N$ SIDIS. Note also that the suppression pattern as a function of $k_{\perp}$ is sensitive to the relative magnitude of the intrinsic transverse momentum in the nucleon TMDs.

Figure 5.62. Ratio $\frac{\langle\cos \phi\rangle_{e A}}{\langle\cos \phi\rangle_{e N}}$ as a function of $\Delta_{2 F}$ for different $k_{\perp}$ and the relative width $\beta / \alpha$.

Now let us discuss the asymmetry at intermediate transverse momentum. The fact that TMDs are perturbatively calculable when $p_{\perp} \gg \Lambda_{Q C D}$ or $k_{\perp} \gg \Lambda_{Q C D}$ allows us to reduce the theoretical uncertainty, since the twist-3 TMDs are poorly known so far. In the parton model, the azimuthal asymmetry for hadron production in SIDIS can be expressed as a convolution of a few TMD distributions and TMD fragmentation functions [243, 247]. It turns out that fragmentation functions $H_{1}^{\perp}$ and $\tilde{H}$ are power suppressed compared to $\tilde{D}_{\perp}$ and $D$ at large $p_{\perp}$ [292, 296, 297]. Therefore, at intermediate transverse momentum, the leading power terms are proportional to $f_{1} \tilde{D}_{\perp}$ and $f_{\perp} D$. In the current fragmentation region, where $p_{\perp}$ is large, we make a collinear expansion around $p_{\perp}=q_{\perp}$ in terms of the power $k_{\perp} / q_{\perp}$ and keep the quadratic terms $k_{\perp}^{2} / q_{\perp}^{2}$ in order to extract the nuclear dependent contributions. After carrying out the integrals over $p_{\perp}$, we find the nuclear dependent azimuthal asymmetry is related to the term $D(z) \int \frac{k_{\perp}^{2}}{q_{\perp}^{2}} f_{1}\left(x, k_{\perp}\right) d^{2} k_{\perp}$. Therefore, the difference of the $\cos \phi_{h}$ azimuthal asymmetry is proportional to the transverse momentum broadening.

$$
\begin{equation*}
\left\langle\cos \phi_{h}\right\rangle_{e A}-\left\langle\cos \phi_{h}\right\rangle_{e N} \propto \int \frac{k_{\perp}^{2}}{q_{\perp}^{2}}\left[f_{1}^{A}\left(x, k_{\perp}\right)-f_{1}^{N}\left(x, k_{\perp}\right)\right]=\frac{\Delta_{2 F}}{q_{\perp}^{2}} \tag{5.156}
\end{equation*}
$$

Conclusions. In summary, we can get a direct handle on the crucial transport parameter $\hat{q}$, which descrcibed the properties of the QCD medium, by measuring the nuclear dependent azimuthal asymmetry at intermediate transverse momentum. Conversely, the target nucleus can be used as a filter to study nucleon TMDs, e.g., to determine the relative magnitude of the intrinsic transverse momentum of $f^{N}$ and $f_{\perp}^{N}$.

Acknowledgments: J.Z. thanks A. Metz and M. Diehl for helpful discussion.

### 5.10 Current fragmentation

## Introduction and the role of $e+A$ collisions

Raphaël Dupré and Alberto Accardi
The fragmentation process, by which hard partons turn into hadrons, is only partly known due to its non perturbative nature. Fragmentation functions, which encode the probability that a parton fragments into a hadron, have been obtained by fitting experimental data covering large kinematic ranges and numerous hadron species, see Section 5.10. However, knowledge about the dynamics of hadronization remains fragmentary: this process has been studied in a number of model calculations, but lacks a first-principles description in QCD. One possible scenario for the hadronization process is sketched in figure 5.63 as an example for DIS. At LO the virtual photon strikes a quark, which then propagates quasifreely emitting gluons; after a time called production time, the quark neutralizes its color and gluon emission stops. The quark becomes a pre-hadron, which will eventually form a hadron at the formation time. In fact, a color string connects the struck quark to its nucleon, and hadrons can be formed all along this string, but we focus our attention on the hadron that contains the struck parton. In nuclear DIS, the hadronization process happens at least in part in the target nucleus (cold nuclear matter). Thus the quark is subject to energy loss by medium-induced gluon brehmsstrahlung, and the prehadron (as well as the hadron) can have inelastic interactions with the surrounding nucleons, leading to attenuation and broadening of the produced particle spectra. The relative weight of one mechanism compared to the other is determined by the magnitude of the color neutralization time. For full reviews, see Refs. [1010, 1011, 1012]. Alternative scenarios are also feasible and final states in nuclear DIS (nDIS) can help untangle these from the scenario outlined here to provide genuine insight into the hadronization process.

Figure 5.63. A model sketch of the hadronization process.
These nuclear effects are both an opportunity for a first principles study hadronization and nuclear properties as well as important benchmarks for reducing existing uncertainties in many nuclear measurements. For example, in neutrino experiments, nuclei are used to maximize the cross section and the kinematics are reconstructed from the hadronic final state. Therefore, a poor knowledge of hadron attenuation leads to a tangible systematic error. In heavy-ion collisions, hadrons are produced in hot and expanding nuclear matter, whose properties can be measured, among other methods, by the modifications of highenergy particle spectra compared to proton-proton and proton-nucleus collisions. It is clear that the details and the time scales of the hadronization process can profoundly modify the interpration of the data, see Fig. 5.2,

The role of $e+A$ collisions. Nuclear deep inelatic scattering provides a known and stable
cold nuclear medium and a low-multiplicity final state with strong experimental control on the kinematics of the hard scattering. This permits one to use nuclei as femtometer-scale detectors and study the time scales of the hadronization process and calibrate theoretical models for parton energy loss and prehadronic scattering, that can then be applied, for instance, to the study of the QGP, see Figure 5.2, Initial state parton energy loss can furthermore be studied in isolation from hadronization in Drell-Yan lepton pair production in $p+A$ collisions, where however it can be masked by nuclear modification of the target wave function such as antishadowing and the EMC effect. So, an interplay of nuclear DIS and nuclear Drell-Yan can help isolate hadronization effects on one hand, and on the other to clarify the differences in quark and anti-quark antishadowing. Perhaps more interestingly, the study of hadronization in nuclear DIS can give direct information about the gluon structure of the nuclei. For example, one can link energy loss and transverse momentum broadening to the gluon density [1013] or more directly to the saturation scale [801]. In models like GiBUU [1014, focussing on hadron absorption, access to the pre-hadron evolution and its color transparency evolution is possible. All these physical interpretation of the data are model dependent and based on very different assumptions about the relative importance of the interaction mechanisms, therefore they are fragile and need to be carefully validated and calibrated with precise data.

The typical observables used to explore hadronization in nuclear DIS are the multiplicity ratio and the transverse momentum broadening, in both cases they are comparison of deuterium with heavier nuclei. The multiplicity ratio, representing the production rate of a hadron $h$ in a nuclear target $A$ compared to Deuterium, is defined as

$$
\begin{equation*}
R_{A}^{h}\left(Q^{2}, \nu, z_{h}, p_{T}^{2}\right)=\frac{N_{A}^{h}\left(Q^{2}, \nu, z_{h}, p_{T}^{2}\right) / N_{A}^{e}\left(Q^{2}, \nu\right)}{N_{D}^{h}\left(Q^{2}, \nu, z_{h}, p_{T}^{2}\right) / N_{D}^{e}\left(Q^{2}, \nu\right)} \tag{5.157}
\end{equation*}
$$

with $N_{t}^{e}$ and $N_{t}^{h}$ respectively the number of electrons and the number of semi-inclusive hadrons $h .1-R_{A}^{h}$ is the attenuation of hadron production in a nucleus of atomic mass $A$. This ratio minimizes the influence of nuclear PDF modifications, which have been shown to cancel to a large degree up to NLO. The hadron transverse momentum broadening, representing the increase of transverse momentum in a nuclear target A compared to Deuterium, is defined by $\Delta\left\langle p_{T}^{2}\right\rangle=\left\langle p_{T}^{2}\right\rangle_{A}-\left\langle p_{T}^{2}\right\rangle_{D}$, with $\left\langle p_{T}^{2}\right\rangle_{t}$ the average hadron transverse momentum measured in a nucleus. When integrated over a large kinematic range, these observables they are dominated by the geometry of the nuclei and do not discriminate well between the models. One needs to also consider more differential observables, including a multi-dimensional analysis of $R_{M}$ and $\Delta\left\langle p_{T}^{2}\right\rangle$, and hadron-hadron and photon-hadron correlations.

Another possibility is to use experimental settings in which we can isolate the involved processes. In the case of EIC, the high energy boost imparted to the struck quark in events with large $\nu$ can increase dramatically the production length, which leads to prehadron production far outside the nuclei and an experimental isolation of pure parton energy loss effects. Since the pre-hadron production time is expected to roughly be inversely proportional to the mass squared of the hadron, measuring attenuation and $p_{T}$-broadening of many meson and baryon species, together with the large $\nu$ leverage afforded by the EIC, will give another important handle in the exploration of the hadronization mechanism. New features will be availabe at the EIC, the high rate for heavy flavor production ( $D$ and $B$ mesons) will allow the measurement of heavy quark energy loss. Finally, jet production, will open the possibility to study the dynamics of parton showers and the detailed transport properties of cold nuclear matter using specific jet observables.

Overview of theoretical models. Three processes are typically included in theoretical descriptions of in-medium hadronization: quark energy loss, pre-hadron absorption and modified fragmentation functions. The models in the literature are usually based on one or two of those and neglect the others. In this section we will discuss a few examples to give an idea of the abundant existing literature; for a detailed review, including models specific to heavy-ion collision experiments, see Ref. [1010].

Pure quark energy loss models assume a very long production time and are typically used to describe hadron suppression in the hot nuclear matter produced in heavy-ion collision. In a few cases they have been applied to nDIS data as well [1015, 1016 permitting a common interpretation of hadron suppression in cold and hot nuclear matter. In these models, hadron suppression is due to the lower energy of the quark when it fragments, so that hadrons are produced in lower number and at lower energy. The differences in the models depend on the way calculations of medium-induced gluon radiation are performed, on the modeling of the medium, and on assumptions about its coupling to the hard parton.

Typically, parton energy loss is determined by the transport coefficient $\hat{q}$, which is defined as the transverse momentum square transfered to a quark after propagating through a length of nuclear matter and is a characteristic property of that matter. It is expected to be much larger in a Quark-Gluon Plasma than in the nucleus of a nDIS experiment, which is what is observed from the analysis of experimental data from RHIC and HERMES [1015, 1016, 1017, 1018. The $\hat{q}$ transport coefficient is directly related to the observed broadening of the $p_{T}$ distribution of hadrons in nDIS; it follows that the main challenge for these pure energy loss models is to make a coherent picture of both multiplicity ratios and hadron $p_{T}$ broadening. In particular, for some of the models, the $\hat{q}$ extracted from multiplicity ratios is larger by an order of magnitude than what one would estimate from the hadron transverse momentum broadening. This has led some authors 1019 to the conclusion that quark energy loss is not enough to explain the observed nuclear effects; nevertheless, the variation between theoretical models is still too big for a definitive statement.

The GiBUU model [1014] is an absorption model based on Boltzmann equation including only hadronic and pre-hadronic interactions, see Section 5.10. It assumes short productions times obtained from the Lund string model and neglects gluon brehmstralung from the partonic stage. It can describe very well well most of the hadron multiplicity ratios measured at HERMES and EMC using a linear growth of the pre-hadron cross section between production time and formation time. Other pure absorption models [1020, 1021, 1022] are also successful in describing hadron attenuation. However, the transverse momentum broadening remains a challenge for this kind of models; some progress within GiBUU has been presented during the meeting by Kai Gallmeister.

To resolve the problems of the previous "pure" models, Kopeliovich et al. [1019] describe hadronization including both quark energy loss and hadron absorption. In their model, the transverse momentum broadening is linked to quark energy loss and the multiplicity ratio suppression is explained by hadron absorption, therefore the two processes can be independently quantified. This model describes HERMES data to a large extent, and highlights the fact several processes are involved and need to be disentangled.

Recently, HERMES data have also been described by assuming factorization and universality to hold at the nuclear level not only for parton distributions but also for fragmentation functions, and a set of nuclear Fragmentation Functions have been fitted to experimental data using both $e+A$ interactions and $d+A u$ collisions at RHIC. In this case, no dynamical assumption is made of the physical mechanism for nuclear modifications of hadron production; this information is subsumed into the non-perturbative nuclear FFs-see Section

Figure 5.64. Multiplicity ratio of positively charged hadrons (left) and negatively charged hadrons (right) from the HERMES experiment [1029]
5.10

A number of other models exist using different variants of the discussed mechanisms, and most of them are able to describe the existing data to a good extent: no consensus is reached yet on which mechanisms are dominant, and indeed this is the main motivation for future precise measurements of hadronization at Jefferson Lab [1023], which will be completed by the time EIC starts its operations, and will help settle some of the issues related to early time color dynamics and interaction in cold nuclear matter.
Previous mesurements and open questions. Unidentified charged hadron multiplicity ratios in nuclei were measured in numerous lepton facilities, the earlier results were by Osborne et al. [1024] at SLAC, Hand et al. 1025] and the E665 collaboration [1026] at FNAL, and the European Muon Collaboration [1027, 1028 at CERN. Those measurements revealed a general picture: hadron suppression is stronger at low $\nu$ and high $z$. On the opposite side, at low $z$, an increase of the number of hadron is observed.

In the more recent data from the HERMES collaboration [1029, 1030] several hadrons are studied individually (Fig. 5.64), and new observables such as transverse momentum broadening (figures 5.67 and 5.68) and two hadrons multiplicity ratios 1031 are measured. Because of their improved precision and the large number of hadron species, these data provide us today with a much more detailed picture, which leads to new questions. The behavior of the kaons, for example, is very interesting: $\mathrm{K}^{+}$are less suppressed than pions, but $\mathrm{K}^{-}$have the same behavior as pions (figure 5.64). This difference is not reproduced by existing models, showing that the relatively simple phenomenological models utilized so far cannot fully describe the data. Furthermore, the introduction by HERMES of precise and flavor dependent $\Delta p_{T}^{2}$ measurement [1030] has revealed another strange behavior: the $p_{T}$ broadening of $K^{+}$is larger than for the pion (Figure 5.67 right). This seems to indicate more interaction for kaons, and yet they are less suppressed. To solve this apparent incongruity, one may have to consider models based on different processes involved at different
stages of hadronization, like in Reference [1019], reinforcing the indications coming from kaon suppression. Furthemore, no model is able to describe the $z$ dependence of the $p_{T}$ broadening, highlighting once again the need for a more detailed theoretical understanding of hadronization. Finally, proton observables are very different from anti-protons (figure 5.64), and no model is yet able to reproduce them correctly, although few attempts have been made [1014, 1032]. At the low energies of HERMES, part of the problem may be due to protons coming from the target fragmentation region, which is interesting in its own right. The collider geometry and the large energy range of EIC will permit to experimentally separate clearly target and current fragmentation, allowing to address hadronization in either region. Indeed developing a consistent picture within a given model for both current and target fragmentation would be a great theoretical progress.

To complete the review of existing data, we should mention the preliminary results on pion and kaon production from the CLAS collaboration at Jefferson Lab, where electrons up to 5 GeV scatter on fixed targets ranging from Carbon to Lead [1033, 1034].

## Studying hadronization at an EIC

## Raphaël Dupré and Alberto Accardi

The experimental study of the hadronization process using nDIS is well established; however the high energy available at the EIC creates novel opportunities. The main interest in going at higher energy is to ensure that hadron formation occurs outside of the nuclei, in order to isolate in-medium parton interactions and energy loss. Furthemore, an EIC will permit, for the first time in $e+A$ collisions, the study of hadronization of the open charm and eventually open bottom mesons. Recent results from RHIC [1035, 1036] are showing unexpected results for open charm and bottom suppression in $A+A$ collisions, and several contrasting explainations have already been suggested, with more detailed experiments planned at RHIC. However, due to the intricated interplay of the many variables in $A+A$ collisions and to the poorly known nature of the Quark-Gluon Plasma partons, the $e+A$ input seems necessary to confirm any interpretation. Also, the considerable energy leverage offered by an EIC is a chance to map precisely the $Q^{2}$ evolution of parton energy loss, and determine possible nuclear modifications of DGLAP evolution. The high luminosity will also facilitate the study of two particle correlations (such as hadron-hadron or photon-hadron) over a wide energy range, largely improving recent HERMES measurements, and complementing the low-energy measurements planned at CLAS. Finally, high energy permits access to jets, which give an opportunity to use new observables with improved sensitivity to quark energy loss and the medium modification of fragmentation functions, see Section 5.11. They also facilitate a detailed determination of the cold nuclear matter transport coefficients, which encode basic information on the non perturbative gluonic structure of the nuclei and can be calculated from first principles, e.g., in lattice QCD [1037].

To illustrate the possibilities offered by EIC, we show projections done using the PYTHIA Monte-Carlo generator to evaluate cross sections at $s=200$ or $1000 \mathrm{GeV}^{2}$, and $L=$ $200 \mathrm{fb}^{-1}$. We apply a series of cuts on the generated events to ensure the DIS nature of the interaction $\left(Q^{2}>1 \mathrm{GeV}^{2}\right.$ and $\left.W^{2}>4 \mathrm{GeV}^{2}\right)$, to limit radiative corrections ( $y<0.85$ ), to insure that we can detect the scattered electron $(y>0.1)$ and to limit di-parton production in the hard scattering of the virtual photon $\left(x_{B j}>0.1\right)$. Finally we assume an acceptance of $50 \%$ for pions, eta meson and kaons, and, an acceptance of $2 \%$ for heavy mesons. The acceptance is set low for heavy mesons to account for the small number of decay channels

Figure 5.65. Multiplicity ratio in function of z for various $\nu$ bins. Full points are data from HERMES [1029, empty are projections for statistical errors at the EIC, at arbitrary vertical position. The left panel shows EIC measurements at $s=200 \mathrm{GeV}^{2}$, for 2 different $\nu$ cuts $(20<\nu<30 \mathrm{GeV}$ and $50<\nu<70 \mathrm{GeV}$ ); the right panel at $s=1000 \mathrm{GeV}^{2}$ with $100<\nu<130 \mathrm{GeV}$.
that can be effectively detected. EIC observables are plotted on arbitrary vertical scales, and include statistical errors only.

An EIC is the perfect tool for precise measurement of quark energy loss and transverse momentum broadening. One may object that at the higher EIC energies, because of the large $\nu \gtrsim 150 \mathrm{GeV}$, the relative effect on the quark momentum is too little to produce an appreciable hadron attenuation. This is true at least for the pions, as shown by EMC data. However, attenuation may in fact disappear at a yet higher value of $\nu$ for large $z$ or for heavier particles, because of reduced production times, or for large $Q^{2}$, because of a faster evolution in virtuality as discussed in Section 5.11. Anyway, because of the EIC kinematic flexibility, interesting multiplicity ratios can be measured. For example, Figure 5.65 shows projections for light and heavy flavors, which would shed light on the heavy quarks at RHIC, where they unexpectedly display a similar suppression compared to their light counterparts. It is also interesting to compare mesons of different mass but the same valence quark contents, such as $\pi^{0}$ vs. $\eta$, and $K^{0}$ vs $\Phi$. Figure 5.66 shows projections for the former case compared to calculations in a pure energy loss or pure prehadron absorption scenario. The sensitivity of such measurement to the hadronization time scales is obvious.

Changing observables, measurements of the hadron transverse momentum broadening permit getting around the small values of hadron attenuation at large energies. Indeed the $p_{T}$ broadening to first approximation is independent of $\nu$, and even very little effects can be experimentally observed; moreover, the induced transverse momentum has a theoretical interpretation in terms of transport coefficients. However, one should keep in mind that $\Delta\left\langle p_{T}^{2}\right\rangle$ of pions or other hadrons is not a direct measurement of $\hat{q}$, which is the parton transverse momentum broadening, and that it is essential to use dependences in $\nu$ and $z$ to make a model independent extraction of $\hat{q}$. One may also access $\hat{q}$ through nuclear modifications of hadron azimuthal asymmetries, see Section 5.9.2. The importance of this topic, especially in the scope of other EIC measurements, is enhanced by the connection between $\hat{q}$ and the saturation scale 801, enabling an independent large- $x$ measurement of the latter, complementary to the more traditional small- $x$ measurements discussed in Section 5.2, An EIC will not only allow one to make those measurements with pions but

Figure 5.66. Multiplicity ratio for $\pi^{0}$ and $\eta$ mesons compared to pure energy loss and pure prehadron absorption computations.

Figure 5.67. Transverse momentum broadening in function of z (left) and A (right), empty triangles and star are projections for EIC at $s=1000 \mathrm{GeV}^{2}$, full points are HERMES data.
also, and uniquely compared to previous $\mathrm{e}+\mathrm{A}$ facilities, with heavy mesons (see figures 5.67).

The $Q^{2}$ evolution of hadron attenuation is not clearly understood: HERMES data indicate a small rise of the transverse momentum broadening, but the $Q^{2}$ coverage is not large enough to make a definite statement. An EIC can do a far better job as shown in figure 5.68 and provide a unique probe to detect any modification of the DGLAP evolution in nuclear medium.

The scaling of the hadronization times and the quark energy loss with the mass of quarks is an important question that can be used to reveal pQCD effects in parton energy loss and non perturbative effects in hadronization [1038, 1039. Many measurements to explore this at the EIC are possible, as the figures in this section illustrate.

To achieve the discussed measurement the key experimental requirement are good particle ID in general; for heavy flavors one needs in particular a very good vertex detector resolution, which needs to be of the order of few tens of micrometer, and high luminosity to reach a statistical precision allowing unambigous theoretical interpretations. Having a $\nu$ range covering low values for studies of hadronization and large values for studies of parton propagation and energy loss will require energies spanning $s=200-1000 \mathrm{GeV}^{2}$. The

Figure 5.68. Multiplicity ratio (left) and transverse momentum broadening (right) in function of $Q^{2}$, empty markers are projections for EIC at $s=200 \mathrm{GeV}^{2}$ (triangles) and at $s=1000 \mathrm{GeV}^{2}$ (circles), full markers are HERMES data.
lowest required energy can be increased provided measurements of $y<0.1$ can be achieved for SIDIS observables.

Finally, the high energy of an EIC provides the chance, for the first time in $e+A$ collisions, to study hadronization through jet observables. Jets are a new and independent way to access transport coefficient $\hat{q}$ and confirm other measurements, to explore in detail the medium induced gluon radiation and transport properties of cold nuclear matter, and to study the conversion of the parton shower into hadrons, see Section 5.11.

## Hadronization in $e+A$ collisions within GiBUU

## Kai Gallmeister and Ulrich Mosel

The study of the interaction of hadrons, produced by elementary probes in a nucleus, with the surrounding nuclear medium can help to investigate important topics, such as color transparency and hadronization time scales. We investigate this by means of the semiclassical GiBUU transport code 1040, which not only allows for the absorption of newly formed hadrons, but also for elastic and inelastic scattering as well as for side feeding through coupled channel effects. A study of parton interactions in cold, ordinary nuclear matter of known properties is important to disentangle effects of the interaction of partons from those of the medium in which they move.

We summarize here the main features of our model, for details see [1014]. The model relies on a factorization of hadron production into the primary interaction process of the lepton with a nucleon, essentially taken to be the free one, followed by an interaction of the produced hadrons with nucleons. We have modeled the prehadronic interactions such that the description is applicable at all energy regimes and describes the transition from high to low energies correctly. For the first step, we use the PYTHIA model that has been proven to very successfully describe hadron production, also at the low values of $Q^{2}$ and $\nu$ treated in our studies. This model contains not only string fragmentation but also direct interaction processes such as diffraction and vector-meson dominance. In this first step, we take nuclear effects such as Fermi motion, Pauli blocking and nuclear shadowing into account [1041. The relevant production and formation times 1014 are obtained directly from PYTHIA [1042. In the second step we introduce prehadronic interactions between

Figure 5.69. Nuclear modification factor for charged hadrons. Experimental data are shown for HERMES at 27 GeV and for EMC at $100-280 \mathrm{GeV}$. The cross section scenarios are (from left to right): constant, linear and quadratic increase with time after production.
the production and the formation time and the full hadronic interactions after the hadron has been formed.

The actual time dependence of the prehadronic interactions presents an interesting problem in QCD. Dokshitzer et al. 1043 have pointed out that QCD and quantum mechanics lead to a time-dependence somewhere between linear and quadratic. We also note that a linear behavior has been used by Farrar et al. [1044] in their study of quasi-exclusive processes. In our calculations, we work with different time-dependence scenarios, among them a constant, lowered pre-hadronic cross section, a linearly rising one, and a quadratically rising one. In addition, we study a variant of the latter two, where the cross section for leading hadrons, i.e., hadrons that contain quarks of the original target nucleon, starts from a pedestal value $\sim 1 / Q^{2}$, thus taking into account possible effects of color transparency.

Fig. 5.69 shows a comparison of these various model assumptions to HERMES and EMC data on unidentified charged hadron attenuation. A good description of both data sets simultanousely is obtained only with a linear time dependence of the cross sections. Furthermore, a nearly perfect agreement is observed in HERMES data for pions, kaons, and protons, which

Figure 5.70. The average formation time of different particles divided by $\nu$ as a function of $\nu$ for several experimental setups. give the attenuation $R_{M}$ as a function of energy transfer $\nu$, relative energy $z_{h}=E_{h} / \nu$, momentum transfer $Q^{2}$ and the squared transverse momentum $p_{T}^{2}$ [1029. The rise of $R_{M}$ with $\nu$ is mainly an acceptance effect, as we have shown in [1041], whereas the weaker rise of $R_{M}$ with $Q^{2}$ reflects the pedestal value $\sim 1 / Q^{2}$ of the pre-hadronic cross sections.

In Fig. 5.70 we show the average formation time for different particle species as a function of the boson energy $\nu$. One realizes a smooth transition from CLAS at 5 GeV up to EMC at 280 GeV for all particle species. One observes a somehow larger formation time for pions than for the heavier particles. Nevertheless, this effect, being somewhere on a $50 \%$
level, is much smaller than mass ratios would suggest: $m_{N} / m_{\pi} \sim 7$. Thus, recalling the basic boost relation, $t_{h}=\gamma_{h} \tau_{h}=\left(E_{h} / m_{h}\right) \tau_{h}$, the factor $\tau_{h}$ and the factor $m_{h}$ in the nominator/denominator cancel each other. We therefore conclude that, within our model, the formation time of a hadron in its rest frame is proportional to its mass, $\tau_{f} \propto m_{H}$, contrary to common assumptions of a constant formation time for all hadron species, which can also be obtained from uncertainty principle considerations [1038, 1010].

Figure 5.71. The hadron attenuation for different hadron species within several $Q^{2}$ bins as function of $z$ (left panel) and $\nu$ (for $z>0.2$, right panel) for a collider setup $(3+30) \mathrm{GeV}$.

Hadron Attenuation at an EIC: Strong $Q^{2}$ Dependence. One may now look at hadron attenuation at an EIC. Fig. 5.71shows the expected attenuation for different hadron species within several $Q^{2}$ bins as functions of $\nu$ and $z$ for a very low energy collider setup $(3+30) \mathrm{GeV}$, which is close to former EMC conditions. One observes a large $Q^{2}$ dependence: while for low $Q^{2}$ values, the attenuation of all hadron species decreases to approx. 0.5 at $z \rightarrow 1$, the attenuation is only approx. 0.8 for $Q^{2}>4 \mathrm{GeV}^{2}$. This is also shown in Fig. 5.71, where the same attenuation is shown, but now as a function of $Q^{2}$ and integrated over all $\nu$ and $z>0.2$ values. It is worthwhile mentioning that there is nearly no $\nu$ dependence for all $Q^{2}$ bins visible in our calculations.
Hadron Attenuation at an EIC: $\boldsymbol{\pi}^{0}$ vs. $\boldsymbol{\eta}$. As already shown in Fig. 5.71, some differences in the resulting attenuation ratio show up for different hadron species. In Section 5.10, it has been suggested that a comparison of $\eta$ and $\pi^{0}$ attenuation ratios will distinguish between energy-loss models and absorption models. In Fig. 5.72 we show our results for the attenuation of these two particle species. Both attenuation signals are close to each other, but show stronger absorption for $\pi^{0}$ than for $\eta$ mesons, in which case the discriminatory power would weaken. In Fig. 5.72 we also show the hadronic interaction cross section of pions and eta mesons with nucleons. For laboratory momenta larger than 2 GeV , these are nearly identical. Thus differences in the attenuation are due to formation time effects.

## A global fit of nuclear fragmentation functions

## Rodolfo Sassot, Marco Stratmann, Pia Zurita

Similarly to modifications of PDFs in nuclei, the production of hadrons in the finalstate is known to be affected when occurring in a nuclear environment. For example,

Figure 5.72. Left panel: The hadron attenuation for $\pi^{0}$ and $\eta$ mesons for a collider setup of $3+30$ GeV. Right panel: The hadronic interaction cross section of $\pi^{0}$ and $\eta$ mesons with nucleons at rest as a function of the meson momentum.
semi-inclusive deep-inelastic scattering (SIDIS) off large nuclear targets shows significant differences as compared to hadron production off light nuclei or proton targets, as reviewd in Section 5.10.

The past few years have seen a significant improvement in the pQCD description of hadron production processes, and, more specifically, in the precise determination of vacuum fragmentation functions (FFs), including estimates of their uncertainties [74. FFs carry the details of the non-perturbative hadronization process, factorized from the hard scattering cross section in the same way as for PDFs. The most important result of these studies is that the standard pQCD framework not only reproduces data on electron-positron annihilation into hadrons, but it describes with remarkable precision also other processes like semiinclusive deep-inelastic scattering and hadron production in proton-proton collisions. It is then quite natural to ask if pQCD factorization can be also generalized to final-state nuclear effects, i.e., to introduce medium modified or nuclear fragmentation functions ( nFFs ), and to assess how good such an approximation works or to determine where and why it breaks down. From theoretical considerations alone, the answer is, however, not obvious since on the one hand, interactions with the nuclear medium may spoil the requirements of the factorization theorems, but, on the other hand, any estimates of possible factorization breaking effects are strongly model dependent.

Within the factorization ansatz, nFFs should contain (factorize) all the non-perturbative details related to hadronization in a nuclear environment, would be exchangeable from one process to another (universal), and would allow for QCD estimates at any given order in perturbation theory in a well defined and unified framework. These features can be explicitly tested using data from an increasing but still limited number of experiments that have performed precise measurements of hadron production off nuclear targets, for instance, in SIDIS by HERMES [1029] or in deuteron-gold collisions studied at RHIC [1045, 1046]. Both type of processes are compatible with a universal nuclear modification of the hadronization mechanism in the currently accessible kinematic regime. The inclusion of next-to-leading order QCD corrections and the possibility to use different observables have been proven to be crucial for an accurate parametrization of nFFs 967.

In addition to the primary goal of testing the factorization properties of nFFs and to constrain them from different data sets in a consistent theoretical framework (for further comparison with the different model estimates), a thorough analysis of nFFs also serves as a baseline for ongoing studies of hadron production processes in heavy-ion collisions performed at RHIC and the LHC [1047. In the following, we present a brief summary

Figure 5.73. Quality of the nFF fit to nuclear SIDIS data from HERMES.
of the first global fit of nFFs and outline limitations in the analysis imposed by the data available so far.
Medium Modified Fragmentation Functions. Even though nuclear effects in the hadronization process have been known to be significant for quite some time, only recent experiments have become precise enough and selective from a kinematical point of view to allow for more detailed and quantitative studies. Specifically, the HERMES collaboration has performed a series of measurements of pion, kaon and proton attenuation on different nuclear targets as a function of the hadron momentum fraction $z$ and the photon virtuality $Q^{2}$, which both are used to characterize fragmentation functions, as well as the virtual photon energy $\nu$, that can be related to the nucleon momentum fraction $x$ carried by initial-state parton, see Fig. 5.64,

Single-inclusive identified hadron yields obtained in $d+A u$ collisions at mid-rapidity at BNL-RHIC, which show a characteristic nuclear suppression and enhancement pattern as a function of the hadron transverse momentum $p_{T}$, are another source of information on nuclear modification effects in the hadronization process. These measurements are often

Figure 5.74. Comparison of medium modified and standard FFs.
seen as "control experiments" associated with the heavy-ion program at RHIC to explore the properties of nuclear matter under extreme conditions. However, in view of the evidence for strong medium induced effects in the fragmentation process found in SIDIS, $d+A u$ data are also of particular relevance for extracting nFFs and testing the assumed factorization and universality properties.

To perform global nFF fits, it was proposed in Ref. [967] to relate the medium modified fragmentations to the standard ones in a convolution approach with a very simple ansatz for the weight functions. The fits gives a very good description of the full kinematic dependence of the HERMES data as can be seen in Fig. 5.73 while an approach which ignores all finalstate nuclear effects clearly fails. The same set of nFFs that account for nuclear modification in SIDIS also reproduce the main features of the $d+A u$ data from RHIC. The peculiar $p_{T}$ dependence of the effects is found to come from an interplay between quark and gluon fragmentation as a function of $p_{T}$ in the hadron production cross section. It is interesting to notice that there seems to be no visible conflict between the standard $Q^{2}$ dependence assumed for the nFFs and the data. In this respect, there have been many interesting suggestions and model dependent calculations at the LO level, motivating the use of medium modified evolution equations. However, in the range of $Q^{2}$ covered by present SIDIS and $d+A u$ data, there is no evidence for any significant departure from standard time-like evolution equations [1048, 1049, 1050, 1051].

The pattern of medium induced modifications is rather different for quarks and for gluons, see Fig. 5.74. The dominant role of quark fragmentation in SIDIS leads to a suppression, i.e., $R_{q}^{\pi}<1$, increasing with nuclear size $A$ as dictated by the pattern of hadron attenuation found experimentally. The enhancement of hadrons observed in $d+A u$ collisions for $p_{T} \approx 10 \mathrm{GeV}$, along with the dominant role of gluon fragmentation at low values of $p_{T}$ explains that $R_{g}^{\pi}>1$ for $z \rightarrow 0.2$. Below $z \simeq 0.2$, where all the data used in the fit have very limited or no constraining power, both quark and gluon nFFs drop rapidly. For the time being, the behavior in this region could easily be an artifact of the currently assumed functional form for the parameterization. The extended $Q^{2}$ range of EIC will allow one to accurately test the factorization assumption for nFFs , which is at the basis of the presented approach to nuclear modfications of hadron production.

## Heavy quarks and quarkonia in a nuclear environment

## B. Z. Kopeliovich

Time dependence of vacuum radiation. The color field of a quark originating from a hard reaction (DIS, high- $p_{T}, e^{+} e^{-}$, etc.) is stripped off, i.e., such a quark is lacking a color field up to transverse frequencies $q \lesssim Q$, and starts regenerating its field by radiating gluons, i.e., forming a jet. This can be described by means of an expansion of the initial "bare" quark over the Fock states containing a physical quark and different number of physical gluons with different momenta. Originally, this is a coherent wave packet equivalent to a single bare quark $|q\rangle$. However, different components have different invariant masses and they start gaining relative phase shifts as a function of time. As a result, the wave packet is losing coherence and gluons are radiated in accordance with their coherence times. The required time is to the jet energy, since the radiation time (or length) depends on the gluon energy and transverse momentum $k$ (relative to the jet axis),

$$
\begin{equation*}
l_{c}=\frac{2 E}{M_{q g}^{2}-m_{q}^{2}}=\frac{2 E x(1-x)}{k^{2}+x^{2} m_{q}^{2}} . \tag{5.158}
\end{equation*}
$$

Here, $x$ is the fractional light-cone momentum of the radiated gluon; $m_{q}$ is the quark mass; $M_{q g}^{2}=m_{q}^{2} /(1-x)+k^{2} / x(1-x)$ is the invariant mass squared of the quark and radiated gluon.

One can trace how much energy is radiated over the path length $L$ by the gluons which have lost coherence during this time interval [1052, 1019, 1053, 1054, 1055,

$$
\begin{equation*}
\Delta E(L)=E \int_{\Lambda^{2}}^{Q^{2}} d k^{2} \int_{0}^{1} d x x \frac{d n_{g}}{d x d k^{2}} \Theta\left(L-l_{c}\right) \tag{5.159}
\end{equation*}
$$

where $Q \sim p_{T}$ is the initial quark virtuality; the infra-red cutoff is fixed at $\Lambda=0.2 \mathrm{GeV}$. The radiation spectrum reads

$$
\begin{equation*}
\frac{d n_{g}}{d x d k^{2}}=\frac{2 \alpha_{s}\left(k^{2}\right)}{3 \pi x} \frac{k^{2}\left[1+(1-x)^{2}\right]}{\left[k^{2}+x^{2} m_{q}^{2}\right]^{2}} \tag{5.160}
\end{equation*}
$$

where $\alpha_{s}\left(k^{2}\right)$ is the running QCD coupling, which is regularized at low scale by the substitution: $k^{2} \Rightarrow k^{2}+k_{0}^{2}$ with $k_{0}^{2}=0.5 \mathrm{GeV}^{2}$. In the case of heavy quark the $k$-distribution Eq. (5.160) peaks at $k^{2} \approx x^{2} m_{q}^{2}$, corresponding to the polar angle (in the small angle approximation) $\theta=k / x E=m_{q} / E$. This is known as the dead cone effect [1056, 1057].

The step function in Eq. (5.159) creates another dead cone [1055): since the quark is lacking a gluon field, no gluon can be radiated unless its transverse momentum is sufficiently high, $k^{2}>2 E x(1-x) / L-x^{2} m_{q}^{2}$. This bound relaxes with the rise of $L$ until it reaches $k^{2} \sim x^{2} m_{q}^{2}$, characterizing the heavy quark dead cone at $L_{q}=E(1-x) / x m_{q}^{2}$. The radiation of such a "naked" quark has its own dead cone controlled by its virtuality $Q^{2} \gg m_{q}^{2}$, and is much wider than the one related to the quark mass. Therefore, there is no mass dependence of the radiation until the quark virtuality cools down to $Q^{2} \Rightarrow Q^{2}(L) \sim m_{q}^{2}$. At the early stage of hadronization, when $Q^{2}(L) \gg m_{q}^{2}$, all quarks radiate equally, and the results of [1057] for a reduced energy loss of heavy quarks should be applied with a precaution. The numerical results demonstrating this behavior are depicted in Fig. 5.75,

One can see that a substantial difference between the radiation of energy by charm and light quarks onsets at rather large distances, above 10 fm . However the $b$-quark radiation is suppressed already at a short distance, less than one fermi. Moreover, it completely regenerates the color field already at a distance of the order of 1 fm

Figure 5.75. Left panel: Vacuum energy loss by light $\left(m_{q}=0\right)$, charm ( $m_{c}=1.5 \mathrm{GeV}$ ) and bottom ( $m_{b}=4.5 \mathrm{GeV}$ ) quarks with $E=15 \mathrm{GeV}$ and virtuality $Q \sim E$ as function of path length. Right panel: The same, but for energies 20 (three upper curves) and 10 GeV (three bottom curves), and zoomed in at short path lengths. and does not radiate any more. Of course, this $b$-quark still may have a medium induced radiation, which is very weak according to 1057 . Notice that the interference between vacuum and induced radiations is absent because they occur on different time scales.
Production and formation length. One should clearly distinguish between the production time scales for a colorless dipole (pre-hadron) and the final hadron. The former signals color neutralization, which stops the intensive energy loss caused by vacuum radiation following the hard process, while the latter is a much longer time taken by the dipole to gain the needed hadronic mass, i.e. to develop the hadron wave function. While the former is proportional to $1-z_{h}$ and contracts at large fractional momentum $z_{h}$ of the hadron, the latter keeps rising proportionally to $z_{h}$. These two time scales are frequently mixed up. The shortness of the production lengths at large $z_{h}$ is dictated by energy conservation. Indeed, a parton originating from a hard reaction intensively radiates, losing energy. This cannot last long, otherwise the parton energy will drop below the energy of the detected hadron. Only the creation of a colorless pre-hadron, which does not radiate gluons any more, can stop the dissipation of energy. Energy conservation thus imposes a restriction on the color neutralization time [1058], $l_{p} \leq \frac{E_{q}}{\langle d E / d z\rangle}\left(1-z_{h}\right)$, which must vanish at $z_{h} \rightarrow 1$. One should also distinguish between the mean hadronization time of a jet, whose energy is shared between many hadrons, and specific events containing a leading hadron with $z_{h} \rightarrow 1$. The production of such a hadron in a jet is a small probability fluctuation, usually associated with large rapidity gap events. The space-time development of such an unusual jet is different from the usual averaged jet. It is illustrated in Fig. 5.76. Notice that one should not mix up the production time with the time scale evaluated in [1059], Eq. (2), which is just the well known coherence time. This is not the time of duration of hadronization which we are interested in. If hadronization were lasting as long as the coherence time, energy conservation would be broken. Besides, a pre-hadron does not have any certain mass, since according to the uncertainty relation it takes time, called formation time, to resolve between the ground and excited states, which have certain masses. Therefore, one cannot evaluate the production time of a pre-hadron relying on the mass of the hadron.

Since the produced pre-hadron strongly attenuates in the nuclear medium, the position of the color neutralization point is crucial for the resulting nuclear suppression. Notice

Figure 5.76. The two-step process of leading hadron production. On the production length $l_{p}$ the quark is hadronizing experiencing multiple interactions broadening its transverse momentum and inducing an extra energy loss. Eventually, the quark color is neutralized by picking up an antiquark. The produced color dipole (pre-hadron) is attenuating in the medium and developing the hadron wave function over the formation path length $l_{f}$.
that such a picture of space-time development of hadronization is classical. In quantum mechanics one cannot say with certainly whether the pre-hadron is produced inside or outside the medium: the inside-outside interference term is significant 1060 .
Heavy flavored hadrons. The production length distribution calculated for light quarks [1052, 1019, 1054 should be similar to that for charm quarks, which have a similar vacuum radiation during the first several fermi. However, a bottom quark, according to Fig. 5.75. dissipates considerably less energy, moreover, its vacuum radiation ceases at the distance of about 1 fm , because the quark completely restores its color field. Of course, confinement does not allow a colored quark, even with a restored field, to propagate freely. It keeps losing energy via nonperturbative mechanisms [1054, like in the string (flux tube) model. Surprisingly, nonperturbative dynamics is more involved into hadronization of heavy compared with light quarks. However, one should remember that this is true only for jets which end up producing leading hadrons with $z_{h} \rightarrow 1$.

A high-energy heavy quark always escapes from the medium and produces an open flavor hadron with no suppression. Therefore, a break-up of a light-heavy dipole propagating in a medium should not lead to a suppression, unless the fractional momentum $z_{h}$ of the detected hadron is fixed at a large value. In such a case, break up of the dipole ignites continuation of vacuum energy loss, which slows down the quark to smaller values of $z_{h}$. This is why a quark should stop radiating at a distance $l \sim l_{p}$ and produce a colorless dipole, which then survives through the medium.

It is interesting that the produced heavy-light, $c-q$ or $b-q$ dipoles expand their sizes faster than a light $\bar{q} q$ dipole. This happens because of the very asymmetric sharing of the longitudinal momentum in such dipoles. Minimizing the energy denominator one gets the fractional momentum carried by the light quark, $\alpha \sim \frac{m_{q}}{m_{Q}}$, which indeed is very small, about 0.1 for charm and 0.03 for bottom. Then according to [1055, 1061, the dipole size is evolving with time as $r_{T}^{2}(t)=\frac{2 t}{\alpha(1-\alpha) E}+r_{0}^{2}$, where $r_{0}$ is the initial dipole separation: the $b-q$ dipole is expanding much faster than $\bar{q} q$.

Conclusions. The hadronization of charm and bottom quarks ends up at a short distance $l_{p}$ with production of a colorless dipole which is strongly absorbed by the medium. This may explain why both of them are strongly suppressed in $A+A$ collisions. Studies of light vs. heavy meson productions at the EIC will clearly be able to validate the discussed effects.

### 5.11 Jets

## Jets, in-medium parton propagation and nuclear gluons

Alberto Accardi, Matthew A. C. Lamont, Gregory Soyez
Preliminary results from the SLAC E665 fixed target experiment have demonstrated jet production in $e+A$ collisions at $s \approx 1000 \mathrm{GeV}^{2}$ [1062, 1063]. Thus, the start of the jet study programme should be feasible in a Phase-I EIC. This can be confirmed by further simulations, required to study the capabilities in a collider experiment as opposed to a fixed-target experiment like E665.

As will be discussed in detail in the next 2 contributions, the nuclear modification of $1+1$ jet production, i.e., 1 jet from current fragmentation and 1 from target fragmentation, is of great interest to study parton propagation through cold nuclear matter, in order to extract cold nuclear transport coefficients, and probing soft gluons in nuclei. In addition, the nucleus can be used as a femtometer-scale detector of the evolution of parton showers, allowing to test their perturbative descriptions (e.g., $k_{T}$-ordering $v s$. rapidity ordering) and Monte-Carlo implementations, which are used pervasively in all fields of high-energy physics to analyze experimental data.

The case of $2+1$ jets is also interesting. Indeed, the cross section for this prcess reads

$$
\begin{equation*}
\frac{\mathrm{d}^{2} \sigma_{2+1}}{\mathrm{~d} x_{p} \mathrm{~d} Q^{2}}=A_{q}\left(x_{p}, Q^{2}\right) q_{A}\left(x_{p}, Q^{2}\right)+A_{g}\left(x_{p}, Q^{2}\right) g_{A}\left(x_{p}, Q^{2}\right) \tag{5.161}
\end{equation*}
$$

where the two terms correspond to the quark-initiated and gluon-initiated processes respectively, and the coefficients $A_{q}$ and $A_{g}$ are matrix elements that can be computed at given order in perturbation theory. Unlike the $1+1$ case which is dominated by quark initiated processes, the $2+1$ cross section is now also sensitive to nuclear gluons, and offers yet another way to measure them.

Since the outgoing jets have to travel in the medium, the coefficients $A_{q}$ and $A_{g}$ will be affected by in-medium propagation. We shall assume here that the measurements of $1+1$ jet cross-sections allow to control in medium quark jets, hence $A_{q}$. Then, by tagging or vetoing gluon jets in $2+1$ events one can study, respectively, gluon jets in-medium propagation and the nuclear gluon distributions. In Fig. 5.77, we show the expected kinematic reach of the gluon measurements for a phase-I and phase-II EIC, and for various cuts on the jet transverse momentum $p_{T}$. Details can be found in [1064. Detailed simulations are planned to study the feasibility and physics reach of these jet studies.

## Monte-Carlo for hard jets in $\mathrm{e}+\mathrm{A}$ collisions

## A. Majumder

The production and modification of hard jets produced in lepton nucleus collisions is considered. The assumption of factorization of the hard scattering cross section from the structure functions and final fragmentation function allow one to compute the final medium modified fragmentation function in both cold nuclear matter and in a hot Quark-GluonPlasma (QGP) in an identical formalism. This allows for both a cross check of the basic energy loss formalism used in these reactions, and a comparative study of the partonic sub-structure of these different phases of QCD matter. Detailed descriptions are provided

Figure 5.77. Left: Parton-level processes that contribute (a) to the $1+1$ and (b,c) $2+1$ jet crosssection. Middle and Center: Accessible kinematic range in $x_{p}$ and $Q^{2}$ for the $2+1$ jets scenario. The accessible region is plotted for different energies $E$ of the electron beam and hadron beam energy $E_{p}=100 \mathrm{GeV}$, corresponding to a phase-I and phase-II EIC, for different jet transverse momentum cuts $p_{T}>p_{T, \text { min }}$ at fixed jet energy cut $E_{c u t}$.
via a Monte-Carlo simulation of such calculations. We compare the results of analytical calculations in these two regimes and present preliminary Monte-Carlo simulations for jets produced in deep-inelastic collisions.
Introduction to in-medium DGLAP. Collision processes which involve a hard scale can be factorized into separate probabilities of hard and soft processes which are convoluted via a single dimensionless variable [716]. For example, for the case of single hadron inclusive production in deep-inelastic-scattering (DIS), the differential cross section may be expressed as,

$$
\begin{equation*}
\frac{d \sigma}{d z}=\int d x G\left(x, Q^{2}\right) \otimes \frac{d \hat{\sigma}}{d Q^{2}} \otimes D\left(z, Q^{2}\right) \tag{5.162}
\end{equation*}
$$

where, $G\left(x, Q^{2}\right)$ represents the parton distribution function, $\frac{d \hat{\sigma}}{d Q^{2}}$ represents the electron quark scattering cross section via single photon exchange. $D\left(z, Q^{2}\right)$ represents the fragmentation function to produce a hadron with a momentum $z \nu$ from the fragmentation of the outgoing quark jet. The structure functions and fragmentation functions are defined and factorized from the hard cross sections at a given scale $\mu^{2}$ which, in this case, is chosen to be equal to the hard scale of the process $Q^{2}$. They only need to be measured at a single scale, and the change of these functions with scale is given by the DGLAP evolution equations 856. For fragmentation functions, these equations read

$$
\begin{equation*}
\frac{\partial D\left(z, Q^{2}\right)}{\partial \ln Q^{2}}=\frac{\alpha_{S}}{2 \pi} \int \frac{d y}{y} P(y) D\left(\frac{z}{y}, Q^{2}\right), \tag{5.163}
\end{equation*}
$$

where, $P(y)$ is the gluon splitting function and represents the probability for a quark to radiate a gluon and retain a fraction $y$ of its light cone momentum.

In the case of DIS on a large nucleus, one may simply include the entire effect of the medium by including a length dependent multiplicative factor to the gluon splitting function [1065], which accounts for the fact that the radiated gluon will scatter in the medium influencing its radiation amplitude, i.e., $P(y) \rightarrow P(y) K\left(y, q^{-}, L^{-}, Q^{2}\right)$. The medium dependent factor given as [1066],

$$
\begin{equation*}
K\left(y, q^{-}, L^{-}, Q^{2}\right)=\int_{0}^{L^{-}} d \zeta^{-} \frac{\hat{q}}{Q^{2}}\left[2-2 \cos \left(\frac{Q^{2} \zeta^{-}}{2 p^{+} q^{-} y(1-y)}\right)\right] \tag{5.164}
\end{equation*}
$$

Figure 5.78. Left: A comparison of the results of an analytic DGLAP evolution calculation and a Monte-Carlo shower calculation for the same choice of input parameters. Right: Results of a set of Monte-Carlo simulations of a jet propagating through a 4 fm brick.

In the equation above, $L^{-}$is the maximum possible length traversed in the medium in the course of one emission. In an evolution equation, the formation time of the final radiation is chosen to be larger than the maximum medium length. This restricts the length to be no larger than $q^{-} / Q_{\min }^{2}$, where $Q_{\text {min }}$ is the minimum allowed virtuality on exit from the medium. In an analytic solution to the DGLAP equation, one requires an input fragmentation function. The most unambiguous input is to use the known vacuum fragmentation function at the scale $Q_{\min }^{2}$ where we have stipulated that the jet has emerged from the medium. This is then evolved in $Q^{2}$ up to the hard scale of the process using the medium modified evolution equation which includes the kernel of Eq. (5.164).

Results from such an in-medium DGLAP evolution are plotted in Fig. 5.78. The input distribution in vacuum is taken from KKP at an input scale of $\mu_{i n}^{2}=1 \mathrm{GeV}^{2}$ and evolved up to $Q^{2}$. Its ratio to the KKP fragmentation at the scale $Q^{2}$ is plotted as the green dashed line in Fig. 5.78, Note that our numerical implementation of the DGLAP equation is different from that of KKP and so for comparison, we plot the ratio of the vacuum evolved fragmentation function in our implementation versus that in the KKP where both calculations start from the same input distribution i.e. the KKP function at the scale $\mu_{i n}^{2}$, and are compared at the higher scale of $Q^{2}$. The ratio is plotted as the magenta curve in Fig. 5.78, While over the range of $z$ considered, the curve is close to unity, it may deviate by up to $20 \%$ at lower values of $z$.

The solid blue line in Fig. 5.78 represents the ratio of the medium modified fragmentation function to the vacuum fragmentation function, where both numerator and denominator are calculated using the same numerical routine (for the vacuum FF we simply use $\hat{q}=0$ ). This ratio can be approximately compared to the ratio of hadron yields in DIS experiments. It should be pointed out that in all the calculations reported in this article, the medium is assumed to be static and uniform with a fixed length. This fixed length is travelled by each jet. Realistic geometries will be considered in the future.
Monte-Carlo implementation. In any realistic calculation of jet modification in an extended medium a variety of approximations need to be made. For example, in the inmedium DGLAP evolution equations reported in the previous sections, we assumed that
the entirety of the parton shower exits the medium and fragments in vacuum. This is obviously not the case. In reality, a large portion of the shower is trapped in the medium and does not undergo vacuum fragmentation. Such effects cannot be treated in a DGLAP setup where the input is the final vacuum fragmentation. Note that such effects may be included with a position dependent input fragmentation function. However, such input is always ambiguous and the computation of the evolution of a position, energy and obviously $z$-dependent fragmentation functions are prohibitively numerically intensive.

The obvious solution to this is to use a Monte-Carlo jet routine. Unlike analytic inmedium DGLAP calculations which evolve upwards, numerical Monte-Carlo routines evolve downwards in virtuality. As such, they are a more natural calculation which reconstructs the shower forwards in time. One starts with the original produced hard virtual parton and then constructs the Sudakov factor

$$
\begin{equation*}
\Delta\left(Q^{2}, \mu^{2}\right)=\exp \left[-\frac{\alpha_{S}}{2 \pi} \int_{\mu^{2}}^{Q^{2}} \frac{d q^{2}}{q^{2}} \int d y P(y)\left\{1+K\left(y^{-}, q^{-}, L^{-}, q^{2}\right)\right\}\right] \tag{5.165}
\end{equation*}
$$

which yields the probability of no resolvable emission between $Q^{2}$ and $\mu^{2}$ and uses this to numerically estimate the probability of the initial parton being produced with a maximum virtuality of $\mu^{2}$. One then samples the splitting function to estimate the probability that the produced partons have fractions $y$ and $1-y$ of the parent parton. Unlike the case of the vacuum Sudakov factor, the equation above also contains in addition the medium dependent kernel $K$ defined in Eq. (5.164). This means that at each point, the shower may undergo either a vacuum split or a medium induced split. It also clearly demonstrates how the probability of splitting increases in the medium. At each point, we estimate the location of the parton based on its formation time, which may be easily obtained from its virtuality and its energy.

This showering routine is repeated to obtain partons with lower and lower virtuality. We terminate the shower when the virtuality of the parton reaches $\Lambda_{0}=1 \mathrm{GeV}$. If at this point the parton is found outside the medium, then it is convoluted with a vacuum fragmentation function. If it is found inside the medium then it is removed from the final shower. We point out again that the medium in all these calculations is not a real nucleus, but rather a static brick. Once the shower is calculated in the medium, it is then repeated in vacuum. Thus, both numerator and denominator of the ratio of fragmentation functions are calculated by an identical routine.

Using this implementation we may repeat our calculations in the HERMES-like systematics of Fig. 5.78, The results of the Monte-Carlo is represented by the solid black line. We should mention in passing that the fragmentation function used in the Monte-Carlo calculation is BKK while that in the DGLAP is KKP. We note that the ratio of fragmentation functions are rather similar. The Monte-Carlo results are for the most part below the DGLAP calculation. This is because of the mechanism by which we can systematically remove the partons which fragment in the medium, which can only be done in the MC calculation. The excess at lower $z$ is partially due to the use of a different fragmentation function and partially due to some of these partons having a long formation time.

Having tested the Monte-Carlo calculation in HERMES-like systematics ( $E=20 \mathrm{GeV}$ and $Q^{2}=3 \mathrm{GeV}^{2}$ ), we apply the MC calculation to the EIC-like systematics ( $E=25,35,50$ GeV and $Q^{2}=100 \mathrm{GeV}^{2}$ ). First off, we note that even with the larger energies there is a considerable amount of suppression. This is due to the larger $Q^{2}$ of the produced jet. Such jets tend to shower a lot and thus end up being considerably affected by the medium. This
goes beyond what is known at HERMES that increasing the energy reduces the observed suppression. We also find a kind of universal suppression at large $z$ which is independent of energy. This kind of universal suppression was also noted in the DGLAP calculations performed for comparison with the HERMES data. In the earlier DGLAP calculations, the reason for the scaling was due to the vanishing of the real part of the evolution equation, leaving the same virtual corrections for different energies. It is difficult to state at this point if the scaling observed in the Monte-Carlo calculations is due to a similar reason, i.e., the vanishing of the real part of the equivalent DGLAP calculation.

If the results reported here are verified by a future EIC, this would represent an interesting observation: to find an almost $50 \%$ suppression in the large $z$ yield even for 50 GeV jets. Such high $Q^{2}$ jets should be describable using perturbation theory over a large part of their lifetime and would thus yield deep probes of the medium through which they propagate. This would allow for a much clearer understanding of the gluonic structure of nucleons inside nuclei. It would also greatly facilitate our understanding of how jets are modified in a dense extended environment, which would allow for more refined probes of matter produced in heavy-ion collisions.

## Jet evolution in hot and cold matter

## Hans J. Pirner

We will discuss jet propagation in hot matter first before addressing jet propagation in the "cold" matter of electron-nucleus collisions. A common interpretation of the large pion attenuation in $\mathrm{Au}+\mathrm{Au}$ collisions at RHIC is parton energy loss, where hadronization occurs outside of the hot zone and is not affected by the medium. There is no doubt that gluon radiation plays an important role for the energy loss and the parton evolution at RHIC and the LHC. The respective virtualities of partons are around $Q=20 \mathrm{GeV}$ and $Q=100 \mathrm{GeV}$. In our modeling of jet evolution [1067, 1068] the parton shower is treated together with the propagation of the parton in the medium which is more realistic because of the relevant time scales. A typical shower at RHIC lasts about $\tau_{\text {evo }}=2 \mathrm{fm}$. The non-perturbative part of hadronization involves the decay of the resonances at the pre-confinement scale $Q_{0}=1-2 \mathrm{GeV}$ into $3-4$ pions. The lifetime of the plasma can be estimated at $\tau_{c}=3.3 \mathrm{fm}$. Comparing the two time estimates, we see that at the end of the evolution at RHIC, resonances interact with hadronic resonance matter. This process can be described by a hadronic theory with cross sections slightly larger than hadronic cross sections in vacuum. Because of these large cross sections, absorptive effects play a decisive role in the observed suppression of hadrons in RHIC experiments. We have advocated two scenarios. Scenario 1 uses the conservative radiative energy loss obtained from QCD and includes pre-hadron formation and resonance absorption. Scenario 2 neglects the resonance phase but tunes up the energy loss parameter to fit the data.

In more detail, our model [1067] works as follows: The parton produced in a hard process radiates successively to reduce its virtuality and become on mass-shell. This parton shower is modified by scattering in the medium. As both terms enter the same equation, one cannot separate scattering and radiation. This equation includes truly radiative energy loss, but without coherence. Quark fragmentation at RHIC and gluon fragmentation at the LHC should give the essential results. The indices on the fragmentation functions and the splitting functions can then be dropped and the formalism becomes simpler. For the in-medium fragmentation function $D^{m}\left(x, Q^{2}\right)$ we include into the DGLAP evolution the
scattering term $S\left(x, Q^{2}\right)$.

$$
\begin{equation*}
\frac{\partial D^{m}\left(x, Q^{2}\right)}{\partial \ln Q^{2}}=\frac{\alpha_{s}\left(Q^{2}\right)}{2 \pi} \int_{x}^{1} \frac{\mathrm{~d} z}{z} P(z) D^{m}\left(\frac{x}{z}, Q^{2}\right)+S\left(x, Q^{2}\right) \tag{5.166}
\end{equation*}
$$

with

$$
\begin{equation*}
S\left(x, Q^{2}\right) \simeq f \frac{n_{g} \sigma\left\langle q_{\perp}^{2}\right\rangle}{2 m_{s} Q^{2}}\left(D\left(x, Q^{2}\right)+x \frac{\partial D}{\partial x}\left(x, Q^{2}\right)\right) \tag{5.167}
\end{equation*}
$$

The quantity appearing in the scattering term is the jet transport parameter $\hat{q} \simeq \bar{n} \bar{\sigma}\left\langle q_{\perp}^{2}\right\rangle$, which describes the mean acquired transverse momentum of the parton per unit length.

To allow a direct fit of experimental data with only parton energy loss, we introduce a possible enhancement factor $f$ in the scattering term. The scattering term is most relevant at small virtualities $Q \simeq Q_{0}$ and consequently we have used the scale $Q_{0}$ in $\alpha_{s}$ to arrive at an upper boundary for $\hat{q}$. More explicitly, these expressions give $\hat{q}=0.5 \mathrm{GeV}^{2} / \mathrm{fm}$ for a temperature of $T=0.3 \mathrm{GeV}$ for RHIC and $\hat{q}=5.2 \mathrm{GeV}^{2} / \mathrm{fm}$ for $T=0.5 \mathrm{GeV}$ corresponding to the LHC. As shown in ref. 1067 we can fit the RHIC data including prehadron absorption in the final state resonance gas. The prediction for LHC gives $R_{A A} \approx 0.4$. If we use an enhancement factor $f=8$ which is beyond any higher order QCD correction, the measurement of hadrons with high transverse momentum would be totally suppressed at the LHC.

Let us now discuss jets in cold matter resulting from DIS on nuclei. Electron scattering on a target at intermediate Bjorken $x$ can be treated along similar lines as the DGLAP evolution of the quark jet in the cold medium, whereas electron-nucleus scattering at low $x$, in principle necessitates the evolution of the quark and antiquark produced from photongluon fusion. It is not clear whether the cascades from the two reaction products behave independently when they propagate through the target. In the Ariadne model, two strings result from the quark and antiquark produced by photon-gluon fusion. The first string connects the antiquark with the quark which emitted the gluon. The second string combines the quark with the remnant di-quark of the proton. Due to the aligned jet configuration, one of the two strings only contains a few low momentum particles and perhaps may be neglected in the first approximation. The evolution equation outlined above can then be applied to jet propagation in cold matter, and applications to an EIC are planned. Scattering partners of the quark are nucleons and the quantity $<\sigma q_{\perp}^{2}>$ can be derived from the dipole cross section on nucleons. The resulting transport parameter at HERMES energies is very small $\hat{q}=0.035 \mathrm{GeV}^{2} / \mathrm{fm}$ and has been tested in hadronic broadening of the produced hadrons [1069]. For a high energy machine with an electron-nucleon energy $E_{c m}=100 \mathrm{GeV}$ the transport parameter will be larger due to the increasing dipole cross section, we estimate that the transport parameter will increase to about $\hat{q}=0.1 \mathrm{GeV}^{2} / \mathrm{fm}$. So effects should well be observable, but smaller than at RHIC.

### 5.12 Target fragmentation

## Fragmentation of nuclei - a critical tool for novel QCD phenomena

Mark Strikman

The main focus of the discussions on quark propagation through the nucleus has been on current fragmentation processes, e.g., the suppression of the leading hadron spectrum, $p_{t}$ broadening and jet propagation in nuclear matter. So far, very little attention has been paid to nuclear fragmentation in DIS. To some extent, this is due to the lack of experimental data as such measurements are very challenging. However, while nuclear effects in the current fragmentation region decrease with increasing $Q^{2}$ at fixed $x$, the nuclear effects in the fragmentation region persist in this limit, and are likely to depend on $x$. They may help address a number of important questions:

- Are color tubes formed in propagation of quarks through nuclear media?
- How different are the propagations of gluons and quarks through the nuclear media?
- How different are the propagations of quark and dipole?

To visualize these questions, it is convenient to consider the process in the nuclear rest frame and distinguish three kinematic regions: (a) For $x \geq 0.1$, a quark is knocked out (or a gluon if we consider for example a leading di-jet or charm production in DIS), (b) for $0.1>x \geq 1 /\left(2 R_{A} m_{N}\right)$ the virtual photon converts to a $q \bar{q}$ pair inside a heavy nucleus, and (c) for $x<1 / 2 R_{A} m_{N}, \gamma^{*} \rightarrow q \bar{q}$ transition occurs predominantly before the target, see Fig. 5.79

In the case of of $x>0.1$ and large $Q^{2}$ corresponding to the knock out of a quark, a color triplet $q q$ system is left inside the nucleus and it is typically moving along the virtual photon momentum direction with a relatively small velocity. The knocked out quark fragments into partons/hadrons at longitudinal distances $y \geq 2 p_{q} / \Delta m^{2} \gg R_{A}$, where $\Delta m^{2} \sim 1 \mathrm{GeV}^{2}$ can be estimated based on the current DIS data [1014]. It is similar to that for color transparency processes. As a result, the leading hadron spectrum at large $Q^{2}$ approaches the universal limit given by pQCD. This pattern is consistent with the experimental data. Different to the naive expectations of the parton model, an A-dependent $p_{t}$ broadening in present in this limit. Naively the hadrons produced in the fragmentation of the quark are formed at distances given by $y \geq 2 p_{h} / \Delta m^{2}$, so that there should be a depletion in the spectrum at $p_{h}^{\text {crit }} \sim \Delta m^{2} R_{A} / 2$ followed by an enhancement at rapidities close to the nuclear rapidity (hadron pileup). Since for heavy nuclei $p_{h}^{\text {crit }} \sim 10 \div 20 \mathrm{GeV} / \mathrm{c}$, one would expect a strong deformation of the hadron spectrum with a large increase of multiplicity for $\left|y-y_{A}\right| \leq 2 \div 3$ for $A \sim 200$. In particular, it would be manifested in the strong break up of the heavy

Figure 5.79. Space-time picture of DIS in the nucleus rest frame for different x

Figure 5.80. Left: Coulomb exchanges may lead to formation of extended spatial regions where color is not screened. Right: The E665 data 1070 for the soft neutron multiplicity compared with the calculation of 1071.
nuclei which is associated with emission of many soft neutrons. One should also expect an increase of the multiplicity of soft neutrons with an increase of $p_{t}$ of the leading hadron, since large $p_{t}$ selects events with extra Coulomb exchanges which are more likely for longer quark paths inside the nucleus and should result in a larger number of wounded nucleons. These may also lead to the creation of large unscreened color regions in the nucleus - see Fig.5.80. An open question is how these expectations could be affected by a high degree of coherence in the emission of the partons in pQCD. Such a coherence may lead to strong screening effects in the formation of the final state and in particular a reduction of $\Delta m^{2}$ away from the current fragmentation region. Also, if the color tube is very narrow, a chance that the tube intersects with other nucleons maybe significantly reduced.

For intermediate $x \sim 0.05$, the virtual photon also penetrates any point in the nucleus but it can hit either quark or antiquark, so in principle, by studying the properties of the leading hadron one can compare the structure of the final state interaction for the removal of quark and antiquark which maybe different, for example since $\bar{q}$ can belong to a color singlet $q \bar{q}$ cluster.

For small $x \leq 0.03$, the virtual photon predominantly transforms into a $q \bar{q}$ pair before the target nucleus. In the aligned jet model one would expect that the number of wounded nucleons would be given by $A \sigma(e N) / \sigma(e p)$ with the hadrons formed at the similar distances as in the large $x$ case. Hence naively one would expect that many nucleons will be wounded in a heavy nucleus, leading to a strong excitation of the nucleus which is known to be associated with multiple neutron emission, and emission of protons with momenta of $\geq 300$ $\mathrm{MeV} / \mathrm{c}$, see also Section 5.12.

The process of neutron emission in DIS off Pb was studied by the E665 collaboration at FNAL for average $x \sim 0.05$ and $Q^{2} \sim$ few $\mathrm{GeV}^{2} 1070$. The results of the measurement are compared the theoretical calculation of [1071] in Fig. 5.80. Calculations using a Monte Carlo event generator tuned to reproduce the neutron emission in the proton-nucleus scattering reproduces both the neutron multiplicity and the neutron momentum distribution, provided only recoil nucleons with energy smaller than 1 GeV are allowed to interact in the nucleus. Taken at face value, this suggests a very strong reduction of the final state interactions at large energies which is consistent with the trend of the E665 data to have a smaller neutron multiplicity for larger $\nu$.

At very small $x$ and moderate $Q^{2}$, one may reach the black disk regime. In this regime, the leading hadron spectrum is reduced and the pQCD factorization for the parton fragmen-
tation breaks down in a gross way [981, see also Section 5.8. In this limit, the selection of events with enhanced activity in the nuclear fragmentation region should lead to reduction of the forward spectrum: this would provide a clear signal for a new regime, since no such correlation is possible in the leading-twist pQCD regime.

In summary, hadron production in the nuclear fragmentation region is very sensitive to the dynamics of space-time evolution of the triplet and octet color tubes as well as of color dipoles. This is one of the unexplored frontiers where the collider kinematics will allow a qualitative improvements in the data, and likely lead to the discovery of a series of new regularities. This may include a much higher degree of coherence in the fragmentation (hinted at by the E665 data) than suggested by the current models. Understanding of the fragmentation dynamics will be also of great help for understanding the dynamics in the nuclear fragmentation region in heavy ion collisions, where high density quark-gluon systems may be produced.

## In-medium hadronization and EMC effects in nuclear SIDIS

C. Ciofi degli Atti, L. P. Kaptari, B. Z. Kopeliovich, and C. B. Mezzetti

The SIDIS process $A\left(e, e^{\prime}(A-1)\right) X$ in which, instead of the leading hadron, a nucleus ( $A-1$ ) in the ground or in low excitation states is detected in coincidence with the scattered electron, can provide new information about the mechanism of hadronization and the origin of the EMC effect [1072, 1073, 1074, 1075, 1076]. Two main advantages of the new SIDIS process over the classical SIDIS [1010] and inclusive $A\left(e, e^{\prime}\right) X$ scattering [1077] are worth mentioning here. Firstly, it can provide a new insight into the space-time development of hadronization at the early stage, which can be probed only by placing additional scattering centers at microscopic distances, i.e. by using nuclear targets. By detecting a jet produced on a nuclear target, one can get information about its time development, but in a rather indirect and complicated way, since cascading inside the nuclear medium essentially modifies the observables. Measuring the recoil nucleus supplies additional and cleaner information about the dynamics of hadronization; in particular, this process is free of the uncertainties caused by cascading, and the survival probability of the recoil nucleus is extremely sensitive to the multiparticle components of the jet [1072. Secondly, a proper ratio of the cross sections on a nucleus $A$ taken at different values of the Bjorken scaling variable $x_{B j}$ provides information on the nucleon structure functions in the medium, $F_{2}^{N / A}$. Several experimental projects to investigate the new process at 12 GeV have been proposed thanks to the development of proper recoil detectors [1078], and the experiment on Deuteron targets has already been performed [1079].

The basic ingredients of the theoretical calculation are the nuclear momentum distributions, the nucleon structure function $F_{2}^{N / A}$ in the medium, and the effective cross section of interaction between the hadronizing nucleon debris and the spectator nucleons. This last reads 1072

$$
\begin{equation*}
\sigma_{e f f}\left(z, x_{B j}, Q^{2}\right) \equiv \sigma_{e f f}(z)=\sigma_{t o t}^{N N}+\sigma_{t o t}^{\pi N}\left[n_{M}(z)+n_{G}(z)\right] \tag{5.168}
\end{equation*}
$$

where $\sigma_{\text {tot }}^{N N}$ and $\sigma_{\text {tot }}^{\pi N}$ are the total nucleon-nucleon $(N N)$ and pion-nucleon $(\pi N)$ cross sections, and the $Q^{2}$ - and $x_{B j}$-dependent quantities $n_{M}(z)$ and $n_{G}(z)$ denote the pion multiplicities due to the breaking of the color string and to gluon radiation, respectively. Their explicit form directly follows from the hadronization mechanism proposed in Ref. [1080], leading to a satisfactory description of the grey track production in DIS off nuclei [1032].

Figure 5.81. Top panels: the distorted momentum distributions $n_{0}$ with $\theta=\widehat{\theta_{\mathbf{P}_{A-1} \mathbf{q}}}$ and $p \equiv\left|\mathbf{P}_{A-1}\right|$ for ${ }^{3} \mathrm{He}$ and ${ }^{40} \mathrm{Ca}$. Bottom panels: The ratio $R\left(A, A^{\prime}\right)$ of Eq. 5.171 with $A=2$, and $A^{\prime}={ }^{3} \mathrm{He}$ or ${ }^{40} \mathrm{Ca}$.

The cross section of the $A\left(e, e^{\prime}(A-1)\right) X$ process [1072, 1074] schematically reads

$$
\begin{equation*}
\frac{d \sigma^{A, F S I}}{d x_{B j} d Q^{2} d \mathbf{P}_{A-1}}=F_{2}^{N / A}\left(x_{A}, Q^{2}, k^{2}\right) \otimes n_{0}^{A, F S I}\left(\mathbf{P}_{A-1}\right) \tag{5.169}
\end{equation*}
$$

where $x_{A}=x_{B j} / z_{1}^{(A)}, z_{1}^{(A)}=\left(M_{A} k \cdot q\right) /\left(m_{N} P_{A} \cdot q\right), k$ is the four-momentum of the bound nucleon and $P_{A}$ of the target nucleus. In this equation, $n_{0}^{A, F S I}\left(\mathbf{P}_{A-1}\right)$ is the distorted momentum distribution of the bound nucleon after final state interaction (FSI) with the debris nucleon ( $\mathbf{k}_{1}=-\mathbf{P}_{A-1}$ in Plane Wave Impulse Approximation):

$$
\begin{equation*}
\left.n_{0}^{A, F S I}\left(\mathbf{P}_{A-1}\right)=\frac{1}{2 J_{A}+1} \sum_{\mathcal{M}_{A}, \mathcal{M}_{A-1}}\left|\int d \mathbf{r}_{1}^{\prime} e^{i \mathbf{P}_{A-1} \mathbf{r}_{1}^{\prime}}\left\langle\Psi_{J_{A-1}, \mathcal{M}_{A-1}}^{0}\right| S_{F S I}^{X N}\right| \Psi_{J_{A}, \mathcal{M}_{A}}^{0}\right\rangle\left.\right|^{2}(5 \tag{5.170}
\end{equation*}
$$

where $S_{F S I}^{X N}$ is the debris-nucleon eikonal scattering $S$-matrix which differs from the Glauber form because of the $z$ dependence of $\sigma_{e f f}$ [1081]. The results of some calculations are presented in what follows, using for Deuteron and ${ }^{3} \mathrm{He}$ realistic wave functions [1082] corresponding to the AV18 interaction [1083], and for heavy nuclei single particle mean field wave functions. A good agreement between our parameter-free calculation [1076] and the experimental data for $2 H\left(e, e^{\prime} p\right) X$ around $\theta \simeq 90^{\circ}$ is exhibited.

The distorted momentum distributions of ${ }^{3} \mathrm{He}$ and ${ }^{40} \mathrm{Ca}$ at kinematics more appropriate for an EIC are shown in Fig. 5.81, As already pointed out, the FSI is governed by the details of $\sigma_{e f f}$ and strongly affects the survival probability of $(A-1)$, as it can be seen by comparing the results for ${ }^{3} \mathrm{He}$ and ${ }^{40} \mathrm{Ca}$. Let us denote the cross section (5.169) by $\sigma^{A, F S I}$. Then, if our description is correct, the ratio of cross sections on different nuclei,

$$
\begin{equation*}
R\left(A, A^{\prime}, \mathbf{P}_{A-1}\right)=\frac{\sigma^{A, \exp }\left(x_{B j}, Q^{2},\left|\mathbf{P}_{A-1}\right|, z_{1}^{(A)}, y_{A}\right)}{\sigma^{A^{\prime}, \exp }\left(x_{B j}, Q^{2},\left|\mathbf{P}_{A-1}\right|, z_{1}^{\left(A^{\prime}\right)}, y_{A^{\prime}}\right)} \rightarrow \frac{n_{0}^{(A, F S I)}\left(\mathbf{P}_{A-1}\right)}{n_{0}^{\left(A^{\prime}, F S I\right)}\left(\mathbf{P}_{A-1}\right)} \tag{5.171}
\end{equation*}
$$

should be governed only by the FSI, as shown in Fig. 5.81.

Figure 5.82. The ratio $R\left(x_{B j}, x_{B j}\right)$ of Eq. (5.172) for the process ${ }^{3} H e\left(e, e^{\prime} d\right) X$ and ${ }^{40} C a\left(e, e^{\prime 39} K\right) X$ calculated with different nucleon structure functions: i) free structure function; ii) off mass-shell (xrescaling) structure function; iii) with suppression of point-like configurations (PLC) in the medium depending upon the nucleon virtuality 1084$]\left(P_{A-1} \equiv\left|\mathbf{P}_{A-1}\right|\right)$.

In order to tag bound nucleon structure functions, whose nuclear modification is one of the causes of the EMC effect, one has to get rid of the distorted nucleon momentum distributions and other nuclear structure effects. This can be achieved by considering the ratio of the cross sections on a nucleus $A$ measured at two different values of the Bjorken scaling variable, $x_{B j}$ and $x_{B j}^{\prime}$, leaving unchanged all other quantities in the two cross sections, i.e., the ratio

$$
\begin{equation*}
R\left(x_{B j}, x_{B j}^{\prime},\left|\mathbf{P}_{A-1}\right|\right)=\frac{\sigma^{A, \exp }\left(x_{B j}, Q^{2},\left|\mathbf{P}_{A-1}\right|, z_{1}^{(A)}, y_{A}\right)}{\sigma^{A, \exp }\left(x_{B j}^{\prime}, Q^{2},\left|\mathbf{P}_{A-1}\right|, z_{1}^{(A)}, y_{A}\right)} \approx \frac{F_{2}^{N / A}\left(x_{A}, Q^{2}, k^{2}\right)}{F_{2}^{N / A}\left(x_{A}^{\prime}, Q^{2}, k^{2}\right)} \tag{5.172}
\end{equation*}
$$

which depends only upon the nucleon structure function $F_{2}^{N / A}$. Calculations of the ratio (5.172) have been performed [1076] using three different structure functions, namely, the free one, giving no EMC effect, and two medium dependent structure functions, yielding only a few percent difference in the inclusive cross section. It can be seen from Fig. 5.82 that the discrimination of different models of the medium dependence of $F_{2}^{N / A}\left(x_{A}, Q^{2}, k^{2}\right)$ can indeed be achieved, especially at large $P_{A-1} \equiv\left|\mathbf{P}_{A-1}\right|$.

In conclusion, from what shown here and in the original papers [1073, 1072, 1074, 1075, 1076 it appears that the SIDIS process $A\left(e, e^{\prime}(A-\right.$ 1)) $X$, with detection of a complex nucleus $(A-$ 1), would be extremely useful to clarify the origin of the EMC effect and to study the early stage of hadronization at short formation times. At EIC kinematics (large $Q^{2}$ and $W_{X}^{2}$ ), the

Figure 5.83. The production cross section of neutrons with low momenta for different longitudinal production points, normalized to the corresponding number of events. (The calculations are preliminary.) theoretical assumptions underlying Eqs.(55.168)(5.170) are expected to be of higher validity than at lower energy. The problem remains as to whether experiments of the kind we are discussing, i.e. the detection of low-momentum light nuclei at specific angles, could be performed at an Electron Ion Collider. We have calculated the process ${ }^{3} \mathrm{He}\left(e, e^{\prime} d\right) X$ at various EIC kinematics and found that, e.g. at $Q^{2} \simeq 30 \mathrm{GeV}^{2}$ and $x_{B j} \simeq 0.7$, when the Deuteron is emitted at about $90^{\circ}$ in the target
rest frame, this corresponds to about $1^{0}$ in the direction of the incident nucleus in the collider CM frame.

## Proving the microscopic origin of nuclear forces

## Mark Strikman

An important task for the EIC is to probe nuclear forces on the microscopic level using hard probes. Before describing some of the possible avenues for EIC research, it is worth summarising what is already known from the analyses of the experimental studies of the nuclear pdfs.

- The quark distributions at large $x$ are suppressed as compared to the naive expectations based on the picture of the nucleus built of nucleons with internal parton distributions coinciding with the free nucleon pdfs, the so called EMC effect - for a review see e.g. [942. However, the EMC effect modification of the nucleon pdfs remains small - $\leq 2 \%$ for $x \leq 0.5$ after one takes into account the Coulomb field contribution into the wave function of the heavy nuclei and uses the proper scaling variable $x_{A}=A Q^{2} / 2 q_{0} M_{A}$ for the comparison of the nuclear cross sections [1085]. The modification of the nucleon pdfs strongly grows with $x$ at $x>0.5$ reaching $\sim 10 \%$ at $x=0.6$.
- The $A$-dependence of the EMC effect at large $x$ indicates that the main contribution to the EMC effect is due to scattering off the short-range correlations (SRC) in nuclei.
- Experiments at JLab confirm approximate $A$-independence of the momentum distribution of nucleons in the short-range correlations, though the absolute probability is a factor of $\sim 5$ larger in heavy nuclei than in the deuteron, for a recent review see [1086.
- The measurements of the antiquark distributions in nuclei were performed using the Drell-Yan process. No enhancement of the $\bar{q}_{A} / \bar{q}_{N}$ ratio was observed for $x \sim 0.1$ where the models of nuclear forces with dynamic pion fields predicted $10 \div 20 \%$.
- Application of the baryon and momentum sum rules indicate that the valence quarks and gluons are enhanced in nuclei at $x \sim 0.1$ [1087, 828].

The region of $x \sim 0.1$ is especially interesting for the purposes of studying the QCD origin of the nuclear forces since it corresponds to the Ioffe distances $\sim 1 / 2 x m_{N} \sim 1 \mathrm{fm}$, characteristic of more medium and short-distance nuclear forces. The regularities listed above suggest that meson exchanges which lead to the enhancement of the sea quark distributions are less important than it is suggested in the meson models of the nuclear forces, while quark and gluon interchanges between nearby nucleons play a significant role. The inclusive measurements at the EIC will directly measure $V_{A} / V_{N}, G_{A} / G_{N}$ for $x \sim 0.1$.

A new tool which will be available at the EIC is exclusive hard processes for which the QCD factorization theorem has been proven for the processes $\gamma_{L}+T \rightarrow V M+T^{\prime}$ for the Bjorken limit and the mass of the final system $T^{\prime}$ being fixed [572]. We will focus on the processes with deuteron target since in this case it is easier to select scattering off the compact proton - neutron configurations and measure a complete final state. The rational here is that the structure of the SRC in nuclei is approximately the same while using a
heavier target, say ${ }^{4} \mathrm{He}$ would increase the impulse approximation interaction rate by a factor of $\sim 3$ only (due to a higher probability of SRCs in ${ }^{4} \mathrm{He}$ ). However this apparent gain will be compensated to a large extent by the final state absorption/distortions and multistep processes significantly complicating the interpretation of the observations.

The first question one can address is whether the quark and gluon transverse distributions in bound nucleon are the same. The simplest possible processes are break up of the deuteron

$$
\begin{equation*}
\gamma+{ }^{2} H \rightarrow J / \psi+p+n . \tag{5.173}
\end{equation*}
$$

and

$$
\begin{equation*}
\gamma_{L}^{*}+{ }^{2} H \rightarrow \rho^{-}+p+p . \tag{5.174}
\end{equation*}
$$

which probe gluon and quark transverse distributions.
The exclusivity of the process could be tested by measuring $p_{t}\left(N_{1}\right)+p_{t}\left(N_{2}\right)+p_{t}(V M)=$ 0 . To avoid an ambiguity which of the nucleons was interacting via the hard process $\gamma^{*}+N \rightarrow V M+N$, one needs to select transverse momenta of the vector meson $\geq 600 \div$ $700 \mathrm{MeV} / \mathrm{c}$ with momentum of the nucleon $N_{1}$ in approximately the opposite direction. For the spectator to belong to the SRC one needs to ensure that it has a large momentum in the deuteron rest frame $\geq 0.3 \mathrm{GeV} / \mathrm{c}$. It could be either mostly longitudinal or have a transverse component sufficiently deviating from the direction opposite to $p_{t}(V M)$.

The measurement involves studying the dependence of the ratio of the cross section of the reaction (5.173), (5.174) and elementary reaction

$$
R\left(p_{s} p\right)=\frac{\frac{d \sigma\left(\gamma^{*}+{ }^{2} H \rightarrow N N+V M\right)}{d W_{\gamma N} d Q^{2} d t, d p_{s p}}}{\frac{d \sigma\left(\gamma^{*}+N \rightarrow N+V M\right)}{d W_{\gamma N} d Q^{2} d t}}
$$

on the momentum transfer to the vector meson $-t \approx-p_{t}(V M)^{2}$ for fixed values of $p_{s p}$. Deviations of the t -dependence from a constant (which can be calculated in the two nucleon approximation) would signal the change of the size of the bound nucleon. The theoretical expectation is that such effects are proportional to the nucleon "off-shellness" so they should rapidly increase with increasing $p_{s p}$, roughly $\propto p_{s p}^{2}$ [1088, 1084]. It is worth noting that nucleon deformation along and transverse to the direction between the nucleons may differ (like in the case of polarization of the atoms in the molecules). Hence a nontrivial dependence of $R\left(p_{s} p\right)$ on the angle between $p_{s p}$ and $p_{t}(V M)$ is possible (such a dependence is absent if the deformation depends only on the virtuality). It would be possible to study the dependence of $R\left(p_{s} p\right)$ on $x$ (for photoproduction of $J / \psi$ on $m_{J / \psi}^{2} / W^{2}$ probing how the nucleon deformation depends on $x$ of the gluon in the bound nucleon wave function.

Another possible direction for studies is probing directly the pion exchange mechanism using exclusive hard processes - for example $\gamma+{ }^{2} H \rightarrow J / \psi+\pi^{-}+p p$ with transverse momenta of $J / \psi$ and $\pi^{-}$back to back and large deuteron rest frame momenta of both protons (to ensure that the process occurs off the SRC).

The discussed class of the reactions is well suited also for looking for non-nucleonic baryonic components in the SRCs (six quarks, $\Delta \Delta, \ldots$ ). For example one can study the process $\gamma+{ }^{2} H \rightarrow J / \psi+\Delta^{++}+\Delta^{-}$where transverse momenta of $J / \psi$ and one of $\Delta$ 's are back to back. The advantage of this reaction as compared to medium energy processes is the absence of a non-vacuum exchange in t -channel.

## Slow neutrons and final-state interaction length

Kai Gallmeister, Ulrich Mosel

With collider kinematics, it is very instructive to look at "slow" nucleons of energy less than 10 GeV , considered slow with respect to the (fast) target nucleon [1071], see also Section [5.12. Performing some exploratory simulations within the GiBUU framework (see Section (5.10) we are confronted with a lot of complications. In Fig. 5.83 we show some distributions of slow neutrons as a function of energy for different production points in the longitudinal axis, normalized to the corresponding number of scattered electrons. This result is to be considered as preliminary, since we learned that we need a more accurate treatment of Pauli-blocking and binding effects in the few MeV region. In addition, we need to take into account the production of slow nucleons via evaporation and fragmentation. This work is currently in progress by inclusion of a multi-fragmentation framework (SMM) [1089] and correcting for effects of the large energy gap between initial interaction and fragmenting nucleons.

It has been proposed by Ciofi degli Atti and coworkers in many papers (see Section 5.12) that the interaction cross section of the jet particles within a SIDIS event with the debris of the target nucleus shows interesting formation length dependencies. We see a large potential for our GiBUU model to study all these questions.

### 5.13 Bose-Einstein correlations at an electron-ion collider

Gerald P. Gilfoyle

QCD directs the formation of hadrons from quarks and gluons in hard scattering. However, our understanding of this process is ad hoc; there is no full, QCD-based theory to explain hadronization and fragmentation. To probe these processes, we propose to take advantage of an iconic quantum mechanical effect, the symmetrization of the wave function required for bosons. Particles formed near one another will have overlapping wave functions and the interference of the wave functions produces correlations in the intensity and momentum dependence of the final particles. These Bose-Einstein Correlations (BEC) (or the Hanbury-Brown Twiss effect) are examples of intensity interferometry and can be used to study the space-time extent of the source of the particles and/or learn about the dynamics of their formation. They have been used to investigate hot nuclear matter, but there are only a few cases where $e+A$ interactions have been studied. That work revealed that BECs can be used to study the QCD string in hard scattering and our simulations show we will be able to make precise measurements of the BEC source size at an EIC.

Bose-Einstein Correlations arise when two identical bosons are detected and their joint wave function $\left|p_{1} p_{2}\right\rangle$ ( $p_{i}$ is the particle 4 -momentum) must be symmetric under particle exchange. In other words, when the two bosons are detected from different points in spacetime, the observer cannot distinguish the origin of each particle so their amplitudes must add. This requirement gives rise to interference terms in the intensity that do not exist for non-identical particles. In fact, for identical fermions there would an anti-correlation between the particles. The BEC in energy-momentum space is related to the extent of the source in its spatial dimensions and the correlation function can be written as

$$
\begin{equation*}
R\left(Q_{12}\right)=\frac{d N / d Q_{12}}{d N_{\text {ref }} / d Q_{12}} \tag{5.175}
\end{equation*}
$$

where $Q_{12}=\sqrt{-\left(p_{1}-p_{2}\right)^{2}}$ is the Lorentz-invariant momentum difference between the identical bosons and $N_{\text {ref }}$ is a reference spectrum constructed with no BECs. The correlation function is often parameterized as

$$
\begin{equation*}
R\left(Q_{12}\right)=\alpha\left(1+\lambda \Omega\left(Q_{12} r_{12}\right)\right)\left(1+\beta Q_{12}\right) . \tag{5.176}
\end{equation*}
$$

In static models of particle sources, $\Omega\left(Q_{12} r_{12}\right)$ can be interpreted as the Fourier transform of the spatial distribution of the emission region of bosons with overlapping wave functions and is characterized by the size parameter $r_{12}$ of the source. It is typically treated as a Gaussian $\left(e^{-Q_{12}^{2} r_{12}^{2}}\right)$ or an exponential $\left(e^{-Q_{12} r_{12}}\right)$. The parameter $\lambda$ measures the coherence of the source, $\alpha$ is a normalization factor, and $\beta$ accounts for long range correlations.
Existing measurements. There is a long history of the study of BECs in particle and nuclear physics going back to 1960 when two-pion correlations were measured in $p \bar{p}$ collisions [1091. They have been used to study geometric properties in $e+p$ reactions [1090], the space-time extent of hot nuclear matter in $A u+A u$ collisions [1092, 1093], and the dynamical properties of hadrons extracted from $A u+A u$ collisions [1094]. Figure 5.84 shows the two-pion correlation function from Ref. [1090] for $e+p$ reactions measured at the DESY collider for an electron momentum $p_{e}=27.6 \mathrm{GeV}$ and proton momenta $p_{p}=-820 \mathrm{GeV}$ and $p_{p}=-920 \mathrm{GeV}$. It shows several of the important features seen in many correlation functions. There is a clear correlation that is maximal at $Q_{12}=0$ and drops rapidly to unity

Figure 5.84. Left: the measured Bose-Einstein correlation function, $R\left(Q_{12}\right)$, together with Gaussian and exponential fits 1090. The error bars show the statistical uncertainties. The data points included in the fit are marked with the circles. The other points are excluded from the fit because the correlation is dominated by resonance effects. Right: Pythia simulation of $\pi^{+} \pi^{+}$Bose-Einstein correlations (BEC) at Electron-Ion Collider kinematics. The BEC parameters were taken from Ref. [1090. The Lund fragmentation model was used.
and below with increasing momentum difference. The height of the correlation function at $Q_{12}=0$ measures the coherence in the source. At moderate $Q_{12}$ the correlation drops below one, reflecting the usual practice of requiring the integral of the entire correlation function to go to one. There is a steady rise in $R$ at larger $Q_{12}$ due to long-range effects. Recall the denominator Eq. (5.175); It should be free of the correlations arising from Bose-Einstein statistics, but will not be free of all correlations: momentum conservation will push $R$ up at large $Q_{12}$. The width of the peak at $Q_{12}=0$ reflects the size of the source of the two bosons, i.e. large width in momentum space implies a small spatial source. The width of $R$ in Fig. 5.84 corresponds to $r_{12} \approx 0.9 \mathrm{fm}$ for an exponential fit and is largely independent of $Q^{2}$, the square of the four-momentum transfer.
BECs at an EIC. Measurements with the CLAS detector of a different type of correlations (i.e., two protons) have been performed on nuclear targets. Some of the results are shown in the left-hand panel of Fig. 5.85 (1095). The figure shows the effects on the source size $r_{r m s}$ (extracted from the correlation) of the average pair momentum $\left(p=\left|\vec{p}_{1}+\vec{p}_{2}\right| / 2\right)$ and the nuclear size on the correlation function. At low average pair momentum $r_{r m s}$ increases for the heavier nuclei and approaches the nuclear size; implying the possible dominance of proton rescattering. The density of the source was extracted in Ref. [1095] and found to be about 2-3 times the nuclear density in helium. In the right-hand panel of Fig. 5.85 we show preliminary results on $\pi^{+} \pi^{+}$pairs on several nuclear targets [1099]. Below $Q_{12} \approx$ $0.15 \mathrm{GeV} / \mathrm{c}$ the correlations from all nuclei rise to a large positive correlation. Above $Q_{12} \approx 0.15 \mathrm{GeV} / \mathrm{c}$ the correlation functions overlap one another within the statistical uncertainty.

Measurement of Bose-Einstein correlations at an EIC will provide a new portal to studies of cold, high-density nuclear matter and the process of hadronization. The ground-state properties of nuclei are now well understood. Ab initio calculations of the nuclear ground state are successful for nuclei up to $A=8$ and higher [1100, 1101] and lattice QCD calculations continue to make progress toward a fundamental understanding of the nucleon

Figure 5.85. Left panel: The size parameter $r_{r m s}$ as a function of the mean pair momentum $p=$ $\left|\vec{p}_{1}+\vec{p}_{2}\right| / 2$ is shown for different nuclear targets [1095]. Data from Refs [1096, 1097, 1098, are shown which correspond to $e-{ }^{16} \mathrm{O}$ interactions at initial energy of 5 GeV and $Q^{2}<0.1(\mathrm{GeV} / \mathrm{c})^{2}$ are shown for comparison. Right panel: Preliminary correlation functions for $\pi^{+} \pi^{+}$from the CLAS detector at Jefferson Lab [1099.
[1102]. However, the high-momentum components of the nuclear ground state are only now being revealed. These high-momentum nucleons are often paired with another, nearby neutron or proton forming regions of cold, dense nuclear matter. Short-range correlations have shown the importance of high-density components and the influence of the tensor force [1103, 1104]. The results of Ref. [1095] (left-hand panel of Fig. 5.85) demonstrated the use of correlations to extract density information. Measurements at an EIC could also help us to understand neutron stars [1105] and the EMC effect [1106].
Simulations. We have simulated Bose-Einstein correlations for $\pi^{+} \pi^{+}$pairs at the kinematics of an Electron-Ion Collider to investigate the feasibility of measuring BECs at an EIC. For our starting point we used the results for $\pi^{+} \pi^{+}$correlations from ep reactions at DESY that are shown in Fig. 5.84 [1090]. That measurement covered the range $Q^{2}=4-8000(\mathrm{GeV} / \mathrm{c})^{2}$ and there was limited $Q^{2}$ dependence in the BEC parameters they extracted. It is reasonable to believe those parameters may also apply to the EIC kinematics. We chose the $\pi^{+} \pi^{+}$ channel because we expect them to be abundant and there is data from other experiments that enable us to make comparisons. We took advantage of several existing tools to perform the simulations. The Pythia program [81] was used to generate events with either Lund string model or independent fragmentation. The code also includes a feature to simulate Bose-Einstein correlations [1107, 1108]. The algorithm for the BECs starts with the usual fragmentation simulation and then pairs of identical particles (i.e. $\left.\pi^{+} \pi^{+}\right)$are selected. For these pairs the relative 4-momentum $Q_{12}$ is modified according to the desired parameterization (see discussion of Eq. (5.176) above) with the constraint that the total 3-momentum of the pair remains the same in the center-of-mass (CM). The overall effect of applying the algorithm is to preserve momentum conservation, but reduce the energy. To compensate for the energy reduction, the CM momentum vectors are then rescaled.

As a consistency check, we compared the simulated correlation function $R$ for $\pi^{+} \pi^{+}$ pairs with the measurements from DESY shown in Fig. 5.84. The simulated correlation was weaker than the measured one, $R\left(Q_{12}=0\right)=1.2$ (simulated) versus $R\left(Q_{12}=0\right)=1.38$ (measured), and not as wide, but still experimentally significant. Since we are studying the possibility of observing BECs, the parameters from Ref. 1090 will provide a more

Figure 5.86. Longitudinal and transverse ( $L T$ ) correlation functions calculated with Pythia. The left-hand panel shows the correlations functions using the Ref. 1090 parameters. The other two panels show a comparison between those results and ones from a calculation with a smaller source size $r_{12}$.
conservative (and safer) test. We also simulated the BECs at the same kinematics as the preliminary results shown in the right-hand panel of Fig. 5.85 ( $p_{e}=5 \mathrm{GeV}$ and fixed target). Here we found the simulated correlation disappeared entirely. The multiplicity of the events generated by Pythia dropped significantly at these kinematics reflecting the limitations of the code at these lower energies.

At EIC kinematics ( $p_{e}=11 \mathrm{GeV} / \mathrm{c}$, $p_{i o n}=-60 \mathrm{GeV} / \mathrm{c}, \sqrt{s}=51 \mathrm{GeV}$ ), we used the BEC parameters from ZEUS [1090]. Since the EIC will run at energies lower than at HERA, but above the current ones at Jefferson Lab, our estimates of the BECs are again conservative ones. Our simulation of $R$ at EIC kinematics is shown in the right panel of Fig. [5.84. There is, like in the Ref. [1090] data, a sizable correlation at $Q_{12}=0$, a decrease in $R$ with width $\approx 0.2 \mathrm{GeV} / \mathrm{c}$, a dip below unity (recall discussion of Fig. 5.84) and then the data approach one at high $Q_{12}$. The Lund model was used here for the fragmentation and a calculation using the independent fragmentation model in Pythia yielded similar results. This result shows we can expect sizable correlation functions at the EIC.

One of the possible effects we may see at an EIC is the stretching of the QCD color string at high $Q^{2}$ and/or changes in the string tension (recall Ref. [1109]). The fragmentation region may not be spherical as observed in Ref. [1109, but may have different sizes in the longitudinal and transverse directions. Such a difference was measured in Ref. 1090 where the longitudinal radius was $0.26 \pm 0.03 \mathrm{fm}$ bigger than the transverse one. To search for such an effect in our simulation requires a different approach to extracting $R$. We worked in the longitudinal Center-of-Mass System (LCMS), where the longitudinal components of the pair momentum add to zero and extracted the transverse and longitudinal 3-momentum differences $\Delta p$. Our initial results are shown in the left-hand panel of Fig. 5.86. The transverse (red, filled circles) and longitudinal (blue, open circles) produce the characteristic shapes seen above for $R$, but with significant quantitative differences between the two. The transverse correlation is about twice the longitudinal one at $Q_{12}=0$ and the widths are similar. The large difference between the correlation functions suggests this may be a useful tool for studying space-time properties of the emission source. To delve deeper into this question, we considered the sensitivity of the $L T$ distributions to changes in the size parameter in the BEC parameterization. The middle and right-hand panels in Fig. 5.86 show a comparison of the same $L T$ correlation functions shown in the left-hand panel with ones calculated with a smaller size parameter $\left(r_{12}=0.73 \mathrm{fm}\right.$ versus $r_{12}=0.93 \mathrm{fm}$
from Ref. [1090). The smaller radius amplifies the shape of the correlation functions (the maximum at $Q_{12}=0$ increases and the dip at $Q_{12} \approx 0.6 \mathrm{GeV} / \mathrm{c}$ is deeper. We can clearly separate the two distributions within the Monte Carlo statistics shown here. We expect the statistical uncertainties for an EIC measurement to be better than the Monte Carlo statistical uncertainties shown here. The cross sections for these reactions (from Pythia) multiplied by the EIC luminosity suggest a production rate of $10^{5} \mathrm{~Hz}$. We also fitted the correlation functions with Eq. (5.176) and obtained uncertainties on the size parameter $r_{12}$ less than 0.15 fm which is comparable to the precision of the results in Ref. [1090]. Thus, we will be able to discriminate between different size parameters at least at the 0.2 fm level. Conclusions. Bose-Einstein correlations will be an important tool at an Electron-Ion Collider for studying high-density nuclear matter, the dynamics of the QCD string in hard scattering, and to gain a deeper understanding of fragmentation and hadronization. Our simulations have shown us that we can expect large (20\%) effects in the correlation function at small $Q_{12}$. The longitudinal-transverse correlations are sensitive to the size parameter to a fraction of a fm . Finally, the large $\pi^{+} \pi^{+}$BECs observed at JLab that are not reproduced in our simulations hold the promise of new physics to be uncovered with the EIC.

## $5.14 \mathrm{e}+\mathrm{A}$ Monte Carlo simulation tools

### 5.14.1 A Monte Carlo Generator for Diffractive Events in e+A Collisions

Tobias Toll and Thomas Ullrich

While there is a rich set of Monte Carlo (MC) event generators for $e+p$ collisions available (e.g. PYTHIA6 [110], HERWIG++ [1111, LEPTO [91], PEPSI [155], RAPGAP [1112], ARIADNE [1113], CASCADE [1114, SHERPA [1115]), the situation for eA collisions is less favorable. The exception is DPMJET [1116 which attempts to describe deep-inelastic $e \mathrm{~A}$ events but does not include the rich physics accessible via diffractive events.

In strong interactions, diffractive events can be interpreted as resulting from scattering via the exchange of a pomeron that carries the quantum numbers of the vacuum, as discussed in 5.4. It was a surprise to see that a large fraction (approximately $15 \%$ ) of all $e+p$ events at HERA were diffractive. Calculations predict this fraction to be even larger in $e+\mathrm{A}$ collisions at EIC where the large nuclei remain intact $\sim 25-30 \%$ of the time (e.g. [826, 825]). In fact diffractive events are considered the most sensitive means of studying saturation since the dipole scattering amplitude is proportional to the square of the gluon momentum distribution $x g\left(x, Q^{2}\right)$. Another fascinating aspect of the study of diffractive events at an EIC is that that it would allow us to measure the intensity and the spatial distribution of the strong field that binds the nucleus together [885].

For all the above measurements the most important process to study is the production of exclusive diffractive vector mesons, such as $J / \Psi, \phi$, and $\rho$ mesons, as well as Deeply Virtual Compton Scattering (DVCS) photons. These processes give very clean final states, consisting of the scattered electron and nucleus and one extra particle: a vector meson or a real photon. This is a process which is dominated by small momentum fractions $x<10^{-2}$. $J / \Psi$ production is particularly well suited for studies of the spatial gluon distribution inside nuclei due to its well known wave function, narrow decay width, and its large branching ratio for electromagnetic decays $J / \Psi \rightarrow e^{+}+e^{-}\left(\right.$or $\left.\mu^{+}+\mu^{-}\right)$.

The measurement of exclusive vector meson production in diffractive events will be one of the key measurements at an EIC. Therefore these processes has been the starting point in our efforts to realise a new multi-purpose MC generator.
The Dipole Model: The dipole model is an important tool in investigations of diffractive processes and for the purpose of applying it to $e+$ A collisions, we needed an impact parameter dependent model as starting-point. Two known models fulfil this requirement: bSat (or IPSat) 823] and bCGC [823, 824]. They are the underlying building blocks used in the generator. In what follows, we will concentrate on the bSat model and not discuss the technical details of the generator but focus on how the dipole models are applied with emphasis on the extension to $e+$ A collisions.

The parameters of the dipole models described below have been tuned to inclusive HERA data, and they describe a wide variety of HERA measurements exceptionally well [823, 824].

The Dipole Model in $e+p$ : The production of exclusive vector mesons and DVCS photons at small $x$ for ep collisions, $e+p \rightarrow e^{\prime}+p^{\prime}+V / \gamma$, in the dipole model has been extensively studied [823, 824]. Here the virtual photon splits into a quark-antiquark dipole which interacts with the target diffractively via one or many two-gluon pomeron exchanges

Figure 5.87. (a) shows the dipole cross-section for various impact parameters as a function of dipole size in the bSat model. (b) and (c) depict the wave overlap functions for $J / \Psi$ and $\rho$ mesons respectively as a function of $r$ for various $Q^{2}$ for transversely polarized photons (from [823]).
(see Fig. 3.14). The amplitude for this process is

$$
\begin{equation*}
\mathcal{A}_{T, L}^{\gamma^{*} p \rightarrow V p}(x, Q, \boldsymbol{\Delta})=i \int \mathrm{~d}^{2} \mathbf{r} \int \frac{\mathrm{~d} z}{4 \pi} \int \mathrm{~d}^{2} \mathbf{b}\left(\Psi_{V}^{*} \Psi\right)(r, z) e^{-i \mathbf{b} \cdot \boldsymbol{\Delta}} \frac{\mathrm{~d} \sigma_{q \bar{q}}^{(p)}}{\mathrm{d}^{2} \mathbf{b}}(x, r, \mathbf{b}) \tag{5.177}
\end{equation*}
$$

Here $T$ and $L$ represent the transverse and longitudinal polarizations of the virtual photon, $r$ is the size of the dipole, $z$ the energy fraction of the photon taken by the quark, $\Delta=\sqrt{-t}$ is the transverse part of the four-momentum difference of the outgoing and incoming proton, and $\mathbf{b}$ is the impact parameter of the dipole. The wave function of the produced vector meson or real photon is $\Psi_{V}$ while that of the incoming photon that splits into the dipole is $\Psi$.

In the bSat model the dipole cross-section in terms of the dipole scattering amplitude $\mathcal{N}^{(p)}(x, r, \mathbf{b})$ is

$$
\begin{equation*}
\frac{\mathrm{d} \sigma_{q \overline{\mathrm{q}}}^{(p)}}{\mathrm{d}^{2} \mathbf{b}} \equiv 2 \mathcal{N}^{(p)}(x, r, \mathbf{b})=2\left[1-\exp \left(-\frac{\pi^{2}}{2 N_{C}} r^{2} \alpha_{S}\left(\mu^{2}\right) x g\left(x, \mu^{2}\right) T(b)\right)\right] \tag{5.178}
\end{equation*}
$$

where $\mu^{2}=4 / r^{2}+\mu_{0}^{2}$ and $\mu_{0}^{2}$ is a cut-off scale in the DGLAP evolution of the gluons $g\left(x, \mu^{2}\right)$. The nucleon shape function $T^{(p)}(b)=1 /\left(2 \pi B_{G}\right) \exp \left(-b^{2} /\left(2 B_{G}\right)\right)$. The parameter $B_{G}$ is determined through fits to HERA data 823 ]. We use $B_{G}=4 \mathrm{GeV}^{-2}$. It should be noted that bSat is a model of multiple two-gluon exchanges and does not contain any gluon-gluon recombinations. It is however, by construction, a model that obeys unitarity, so in this respect it is a saturation model.

Figure 5.87(a) shows the dipole cross-section as a function of $r$ for different impact parameters. Figure 5.87(b) and (c) depict the wave overlap, $\left(\Psi_{V}^{*} \Psi\right)(r, z)$, for $J / \Psi(\mathrm{b})$ and $\rho$ mesons (c) 823] used in Eq. 5.177. It should be noted that the $J / \psi$ is not necessarily the best suited vector meson for probing saturation effects. Studying saturation implies probing large dipole radii $r \gtrsim 2 \mathrm{GeV}^{-1}(0.4 \mathrm{fm})$. However, the wave overlap with the $J / \Psi$ vanishes almost entirely for these dipole sizes. The lighter vector mesons $\rho$ and $\phi$ certainly appear more suited in this case. Unfortunately the wave functions of the lighter vector mesons are less well known than that of the $J / \Psi$ increasing the uncertainties in model-data
comparisons. This can be overcome in the future by improving our knowledge of the light vector meson wave functions.
Phenomenological Corrections to the Cross-Section: In the derivation of the dipole amplitude (eq. (5.177)) only the real part of the $S$-matrix is taken into account, making the amplitude purely imaginary. The real part of the amplitude can be included by multiplying the cross-section by a factor $\left(1+\beta^{2}\right)$, where $\beta$ is the ratio of real to imaginary part of the amplitude. It is calculated using

$$
\begin{equation*}
\beta=\tan \left(\lambda \frac{\pi}{2}\right), \quad \text { where } \lambda \equiv \frac{\partial \ln \left(\mathcal{A}_{T, L}^{\gamma * p \rightarrow V p}(x, Q, \Delta)\right)}{\partial \ln (1 / x)} \tag{5.179}
\end{equation*}
$$

Also, the two gluons interacting in each event do not carry the same momentum fraction $x$. In the leading $\ln (1 / x)$ limit, this skewedness effect disappears, but can still be accounted for by a factor $R_{g}(\lambda)$, where $R_{g}(\lambda)=2^{2 \lambda+3} \Gamma(\lambda+5 / 2) / \Gamma(\lambda+4) / \sqrt{\pi}$.
$R_{g}$ is multiplied to the gluon distribution $x g\left(x, \mu^{2}\right)$ and $\lambda$ is defined as the derivative of $\ln \left(x g\left(x, \mu^{2}\right)\right)$ with respect to $\ln (1 / x)$. It should be noted that while the correction of the real part of the amplitude is on firm theoretical footing, the skewedness correction should be viewed as a purely phenomenological correction. Also, the correction variable $\lambda$ is only well behaving for small values of $x<10^{-2}$. The combined magnitude of both corrections is $x$ dependent and is typically of the order of $10-60 \%$.

Extending the Dipole Model from $e+p$ to $e+A$ : When going from $+e p$ to $e+\mathrm{A}$ scattering we will use the independent scattering approximation (see also eq. (5.95)),

$$
\begin{equation*}
1-\mathcal{N}^{(A)}=\prod_{i=1}^{A}\left(1-\mathcal{N}^{(p)}\left(x, r,\left|\mathbf{b}-\mathbf{b}_{i}\right|\right)\right) \tag{5.180}
\end{equation*}
$$

where $\mathbf{b}_{i}$ is the position of each nucleon in the nucleus. Here, these positions are generated according to the Wood-Saxon potential. Combining equations (5.178) and (5.180) the bSat dipole cross-section for $e+\mathrm{A}$ becomes:

$$
\begin{equation*}
\frac{\mathrm{d} \sigma_{q \bar{q}}^{(A)}}{\mathrm{d}^{2} \mathbf{b}}(x, r, \mathbf{b}, \Omega)=2\left[1-\exp \left(-\frac{\pi^{2}}{2 N_{C}} r^{2} \alpha_{S}\left(\mu^{2}\right) x g\left(x, \mu^{2}\right) \sum_{i=1}^{A} T^{(p)}\left(\mathbf{b}-\mathbf{b}_{i}\right)\right)\right] \tag{5.181}
\end{equation*}
$$

At small gluon momentum fractions, $x<10^{-2}$, the dipole interacts coherently with large volumes of the nucleus. Therefore the configuration of nucleons in the nucleus is not an observable. To obtain the total cross-section, these nucleon configurations have to be averaged over:

$$
\begin{equation*}
\left.\frac{\mathrm{d} \sigma_{\text {total }}}{\mathrm{d} t}=\left.\frac{1}{16 \pi}\langle | \mathcal{A}\left(x, Q^{2}, t, \Omega\right)\right|^{2}\right\rangle_{\Omega} \tag{5.182}
\end{equation*}
$$

where $\Omega$ denotes nucleon configurations.
One defines two different kinds of diffractive events in $e A$ : coherent and incoherent. In incoherent diffractive processes the nucleus breaks up into two or more color neutral fragments, something not possible in diffractive $e p$. If the nucleus stays intact the diffractive processes are coherent. In the Good-Walker picture [1117] (also found in [885]) the incoherent cross-section is proportional to the variance of the amplitude with respect to the initial nucleon configurations $\Omega$ of the nucleus:

$$
\begin{equation*}
\left.\frac{\mathrm{d} \sigma_{\text {incoherent }}}{\mathrm{d} t}=\frac{1}{16 \pi}\left(\left.\langle | \mathcal{A}\left(x, Q^{2}, t, \Omega\right)\right|^{2}\right\rangle_{\Omega}-\left|\left\langle\mathcal{A}\left(x, Q^{2}, t, \Omega\right)\right\rangle_{\Omega}\right|^{2}\right) \tag{5.183}
\end{equation*}
$$

where the first term on the R.H.S is the total cross-section and the second term is the coherent part of the cross-section.
The Generator: The Monte Carlo event generator is implemented in C++ through a set of modular classes. A rich set of input parameters let the user select beam energy and species (A), wave function model, dipole model, kinematic range and the final state particle to study: $\rho, \pi, J / \Psi$, or $\gamma$ (DVCS). Internally, the variables $t, Q^{2}$, and $W^{2}$ are generated following a probability density function (pdf). From these three variables, the complete final state consisting of the scattered electron, the scattered proton or nucleus, and the produced vector meson or photon can be unambiguously calculated.

Generating Events for ep: The variables are generated from a probability density function which for $e p$ is

$$
\begin{equation*}
\operatorname{pdf}\left(Q^{2}, W^{2}, t\right)=\frac{\partial^{3} \sigma_{\mathrm{tot}}}{\partial Q^{2} \partial W^{2} \partial t}=\frac{1}{16 \pi} \sum_{T, L} f_{T, L}^{\gamma^{*}}\left(Q^{2}, W^{2}\right)\left|\mathcal{A}_{T, L}^{\gamma^{*} p \rightarrow V p}\left(W^{2}, Q^{2}, t\right)\right|^{2} \tag{5.184}
\end{equation*}
$$

where $f_{T, L}^{\gamma^{*}}$ is the photon flux for transversely and longitudinally polarized photons. The user may also choose to include the corrections for the real part of the amplitude and/or the skewedness effect as described above.
Generating Events for $e \mathbf{A}$, the MC-Glauber Approach: For $e \mathrm{~A}$ the pdf is

$$
\begin{equation*}
\left.\frac{\partial^{3} \sigma_{\text {total }}}{\partial Q^{2} \partial W^{2} \partial t}\left(Q^{2}, W^{2}, t\right)=\left.\frac{1}{16 \pi} \sum_{T, L} f_{T, L}^{\gamma^{*}}\left(Q^{2}, W^{2}\right)\langle | \mathcal{A}_{T, L}^{\gamma^{*} A \rightarrow V A}\left(Q^{2}, W^{2}, t, \Omega\right)\right|^{2}\right\rangle_{\Omega} \tag{5.185}
\end{equation*}
$$

Here the average of an observable $\mathcal{O}$ with respect to the initial nucleon configurations $\Omega$ is defined as $\langle\mathcal{O}\rangle_{\Omega} \equiv \frac{1}{C_{\max }} \sum_{j=1}^{C_{\text {max }}} \mathcal{O}\left(\Omega_{j}\right)$, where a number of $C_{\text {max }}$ configurations $\Omega_{j}$ are generated and summed over. This sum will converge to the true average for large $C_{\max }$. We call this way of performing the average the MC-Glauber approach. It should be noticed that this method of averaging the initial nucleon configurations is different than in previous publications, e.g. in 826] and 885].

For each event, the coherent part of the cross-section is calculated simultaneously with the total cross-section, by averaging the amplitude before squaring it. It is then decided probabilistically that the nucleus breaks up if

$$
\begin{equation*}
\left(\frac{\partial^{3} \sigma_{\text {total }}}{\partial Q^{2} \partial W^{2} \partial t}-\frac{\partial^{3} \sigma_{\text {coherent }}}{\partial Q^{2} \partial W^{2} \partial t}\right) / \frac{\partial^{3} \sigma_{\text {total }}}{\partial Q^{2} \partial W^{2} \partial t}>R \tag{5.186}
\end{equation*}
$$

where $R$ is a random number from a uniform distribution on $[0-1]$. When this happens, the final state does not contain a scattered nucleus but rather the decay products resulting from the break-up of the nucleus.
Generating Events for $e \mathbf{A}$, the Optical Approach: A simpler and faster way of doing the average over the initial nucleon configurations is what we call the optical approach. Here the average is done implicitly in the dipole cross-section which becomes 826

$$
\begin{equation*}
\left\langle\frac{\mathrm{d} \sigma_{q \bar{q}}^{A}}{\mathrm{~d}^{2} \mathbf{b}}\right\rangle_{\Omega, \text { Optical }}=2\left[1-\left(1-\frac{T_{A}(\mathbf{b})}{2} \sigma_{q \bar{q}}(x, r)\right)^{A}\right] \tag{5.187}
\end{equation*}
$$

For processing speed reasons we approximate the integrated dipole cross-section using the GBW model 819]:

$$
\begin{equation*}
\sigma_{q \bar{q}}^{\mathrm{GBW}}(x, r)=\sigma_{0}\left(1-\exp \left(-\frac{r^{2} Q_{s}^{2}(x)}{4}\right)\right) \tag{5.188}
\end{equation*}
$$

Figure 5.88. Left plot. The coherent part of the cross-section as a function of $|t|$ for electron-gold scattering at $Q^{2}=10^{-4} \mathrm{GeV}^{2}$ and $x_{p}=0.006$ averaged over $40,80,160$ and 500 configurations respectively. Right plot. The total, coherent, and incoherent cross-sections as a function of $|t|$ for $e \mathrm{Au}$ scattering at $Q^{2}=10^{-4} \mathrm{GeV}^{2}$ and $x_{p}=0.006$ averaged over 500 configurations.
where $Q_{s}^{2}(x)=\left(x_{0} / x\right)^{\lambda}$. Here, $\sigma_{0}=23.9 \mathrm{mb}, \lambda=0.287$ and $x_{0}=1.1 \cdot 10^{-4}$ [823]. $T_{A}$ is the projection of the Woods-Saxon potential in the transverse plane. This approximation is valid for large nuclei. In the optical approach, only the coherent part of the cross-section can be calculated, since it gives the average of the amplitude, but not of the amplitude squared. It is implemented in the program as a fast alternative to the more accurate but CPU-time intensive MC-Glauber approach.
Results: In the following we only show results from the $e+\mathrm{A}$ part of the generator. In Figure 5.88, the coherent part of the crosssection for $e+\mathrm{A} \Rightarrow e^{\prime}+\mathrm{A}^{\prime}+J / \Psi$ is shown as a function of $|t|$, with $Q^{2}=10^{-4} \mathrm{GeV}^{2}$ and $x_{p}=0.006$. The nucleus used is gold with $\mathrm{A}=197$. The cross-section is calculated for different numbers of averaged nucleon configurations $C_{\text {max }}$. The target is probed by the dipole at a scale $\Delta$ which means that at large $|t|$ the cross-section is much more sensitive to smaller variations in the positions of the nucleons than it is for small $|t|$. Therefore, for small $|t|$, the sum over configurations converges quickly, while for larger $|t|$, more configurations are needed for the sum to converge. As indicated in Fig. 5.88 approximately 100 configurations are needed to describe $e \mathrm{~A}$ scatterings up to $|t| \approx 0.2 \mathrm{GeV}^{2}$. In Figure 5.88 the total

Figure 5.89. The coherent part of the cross-section of $e+\mathrm{A} \rightarrow e^{\prime}+\mathrm{A}^{\prime}+J / \Psi$ for two different distributions of the initial nucleon configurations: WoodsSaxon and KLN (from [1118]). cross-section and the incoherent part of the cross-section are shown as averaged over 500 nuclear configurations. The $t$-slope of the incoherent cross-section is close to $6 \mathrm{GeV}^{-2}$. This is a bit steeper than is found in [827, where the impact parameter dependence was factorized out in the dipole cross-section and therefore the $t$-slope $=B_{G}=4 \mathrm{GeV}^{-2}$.

In order to measure the spatial distribution of gluons inside the nucleus, the coherent cross-section has to be well measured as a function of $t$. The inverse Fourier transformation
of this will then give the transverse spatial dependence of the amplitude. To do this the position of the several coherent maxima in the $t$-distribution have to be measured accurately.

Experimentally, this requires the suppression of the large incoherent fraction, which is of course also of great interest in itself [825]. Coherent and incoherent processes can be separated by detecting the nuclear-breakup, i.e., detecting the nuclear fragments. While this is experimentally straight forward in fixed target experiments it is rather challenging at an EIC since the charged fragments are transported along the ion beam line. The most promising approach is the measurement of emitted neutrons via zero-degree-calorimeters, a technique used extensively at RHIC. Preliminary studies using de-excitation models (e.g. Gemini $++[1119$ and SMM [1120]) and a realistic layout of an EIC interaction region showed that rejection factors of larger than $10^{5}$ can be achieved.

In Fig. 5.88, the nucleon configurations have been explicitly generated according to the Woods-Saxon configuration. Fig. 5.89 shows the same Woods-Saxon distribution in the optical approach compared with a KLN distribution motivated by the CGC as discussed in [1118]. It can be seen that the difference when using different initial nucleon distributions within the nucleus is considerable and easily measurable by an EIC. It also demonstrates the flexibility of the generator in adapting different models at all stages of the generation process.
Summary and Outlook: A new event generator for the generation of diffractive events in $e p$ and $e \mathrm{~A}$ collisions has been implemented based on an impact parameter dependent dipole model. It describes the coherent and incoherent contributions to the cross-sections. In its current version it is limited to the production of exclusive vector mesons and DVCS photons. We intend to include more general diffractive processes in the same framework, $e+p / \mathrm{A} \rightarrow e^{\prime}+p^{\prime} / \mathrm{A}^{\prime}+X$ where $X$ is a general final state consisting of two or more hadrons. When completed it will be the first diffractive event generator for $e \mathrm{~A}$ collisions with a broad range of processes relevant for the physics of a future EIC.

Acknowledgments: The authors would like to thank the INT for their hospitality and support. Also many thanks to G. Beuf, M. Diehl, A. Dumitru, W. Horowitz, H. Kowalski, T. Lappi, and R. Venugopalan for many helpful discussions.

### 5.14.2 Parton propagation and hadronization simulations: overview

## Alberto Accardi

The "Parton Propagation and Fragmentation" working group is currently working on several Monte Carlo simulations to address hadronization in the cold nuclear medium. More information, references and links are available on the PPF working group wiki [1121].

- PyQM. The "Pythia Quenching Model" is an energy-loss simulation based on Pythia, see Section 5.14.3. The partons created in the hard scattering are allowed to lose energy according to the Salgado-Wiedemann quenching weights, and then fed into the Lund string fragmentation Pythia module. The goal is to determine if the Lund string fragmentation leads to observable differences compared to using Fragmentation Functions to describe leading hadron attenuation (as implemented e.g. in PQM, see below), and to provide a simulation for a broader range of hadron flavors.
- Q-Pythia extension to DIS. Q-Pythia is an energy loss simulation by Armesto, Cunqueiro and Salgado based on medium-modified DGLAP evolution equations. Cur-
rently, only energy loss in the QGP is implemented, and we are working on implementing energy loss in the cold nuclear target. Pursuing this simulation is likely to have a very big pay-off: it will allow to study jet nuclear modifications, the effects of medium modified DGLAP evolution on hadron observables, and compare this to the BDMPS energy loss formalism in the integrated PQM simulation, and the implementation of the Higher-Twist energy loss formalism. Comparison to simulations done with Q-Herwig, would also allow one to gauge the effects of cluster vs. Lund string hadronization.
- PQM. The "Parton Quenching Model" is a simulation by Dainese, Loizides and Paic, which uses Pythia as a parton level generator, and then applies the SalgadoWiedemann quenching weights to determine the parton energy loss before using Fragmentation Functions to determine single hadron attenuation. It has been integrated in Q-Pythia by C. Loizides.
- PyQM integration. It will be interesting to integrate PyQM in Q-Pythia, to provide a direct comparison between hadronization performed according to the Lund string model and using Fragmentation Functions.
- Higher-Twist energy loss. The Higher-Twist energy loss formalism has recently been extended to include a resummation of all higher-twist contributions, and inmplemented in a Monte-Carlo simulation, see Section 5.11,
- GiBUU. This is (among other things) a simulation of nuclear modifications of hadron production in DIS based on the Lund string model and BUU coupled-channel transport equation for the (pre)hadrons, and completely neglects energy loss, see Section 5.10. It has been extensively tested on HERMES and EMC data, and is ready to use at the EIC energy. It will be interesting to implement the few variations in the space-time prehadron production schemes available on the market and investigate possible observable differences. Inclusion of target fragmentation is currently in progress in the multi-fragmentation framework (SMM) 1089 and correcting for effects of the large energy gap between initial interaction and fragmenting nucleons.

### 5.14.3 PyQM: a pure energy loss Monte-Carlo simulation

## Raphaël Dupré and Alberto Accardi

Pure quark energy loss models are widely used to describe jet quenching in relativistic heavy ion collisions (RHIC), however most of the calculations were never applied to the nDIS experiments, which are usually at lower energy, making any comparison difficult. EIC is the chance to have data of both processes at similar kinematic, in this context it is natural to develop PyQM, a pure energy-loss Monte-Carlo simulation for nDIS based on the Salgado-Wiedemann quenching weights formalism [1122] widely used to analyze RHIC data. This simulation will be utilized as a tool to evaluate the future EIC capabilities concerning quark energy loss measurement; since it also provides rate estimates and the kinematics of particles to detect, this information will be used to discuss the relevance and interest of various observables and the accelerator and detector requirements to access them.

The PyQM Monte-Carlo simulation is based on PYTHIA [81] for the DIS interaction and the fragmentation process, which is described by the Lund string model. Between the intial hard scattering and string fragmentation, we apply quark energy loss on the struck
parton, using a nuclear density profile [1123] to estimate the quantity of matter the quark has to go through, and the Salgado-Wiedmann quenching weights [1124] to calculate the energy loss itself. To account for the geometry of the nuclei, we follow Ref. [1125], and pick randomly the interaction point according to the nuclear density distribution; the thickness of the nuclear matter seen by the parton is then given by $R=\frac{2 \bar{\omega}_{C}^{2}(\vec{b}, y)}{\int_{y}^{\infty} d z \hat{q}_{A}(\vec{b}, z)}$ with $y$ the position along the propagation direction with its origin at the interaction point, and $\vec{b}$ the transverse position of the y axis relative to the center of the nucleus. The characteristic energy $\omega_{C}$, and the local transport coefficient $\hat{q}$ are given by

$$
\begin{equation*}
\omega_{C}(\vec{b}, y)=\int_{y}^{\infty} d z(z-y) \hat{q}_{A}(\vec{b}, z) \quad \hat{q}_{A}(\vec{b}, y)=\frac{\hat{q}_{0}}{\rho_{0}} \rho_{A}(\vec{b}, y) \tag{5.189}
\end{equation*}
$$

Then the only free parameter for the quenching weights, and indeed for the whole simulation, is $\hat{q}_{0}$, the transport coefficient at the center of the nucleus. This is found to be $\hat{q}_{0}=0.6 \mathrm{GeV}^{2}$ $\mathrm{fm}^{-1}$ from a fit of the HERMES data [1029] (figure 5.90), in agreement with the analytic calculations of [1125, 1010]. A full description of the results of this simulation compared to HERMES would be beyond the scope of this presentation; here we note that its results are satisfactory for the multiplicity ratio, but require a seemingly too large $\hat{q}$ compared to HERMES data on pion $p_{T}$-broadening. We are currently working on an implementation of $p_{T}$-broadening in our simulation, which, puzzingly, appears instead to produce the right amount of integrated $p_{T}$ broadening as a function of $A$. This issue is directly linked to the quenching weight calculation and work is in progress to better understand it.

Figure 5.90. Multiplicity ratio of positive pions from HERMES [1029 (points) compared to the PyQM pure energy loss simulation (lines).

### 5.15 Connections to other fields

### 5.15.1 Gluon Tomography in Nuclei - The Heavy Ion Collision Initial State

William A. Horowitz

The main purpose of colliding large nuclei is the creation and study of the quark-gluon plasma (QGP), the deconfined state of QCD matter at high temperatures ( $T \sim 200 \mathrm{MeV}$ ) and low baryon chemical potential $(\mu \sim 0)$. Measuring the properties of the QGP is interesting as it is a known phase of the strong force, one of the four known forces in Nature. The QGP is fascinating from a theoretical standpoint as there exists the possibility of experimentally measuring the emergent many-body properties of the non-linear, nonAbelian QCD field theory. It was hoped that the collision of large, ultra-relativistic nuclei in a heavy-ion collision (HIC) might provide an experimental window with which to observe the properties of the QGP, and it appears that just such a novel phase of matter has been created at RHIC [1126, 1127, 1128, 1129, 1130].

But what are the properties of this QGP that has been created? Qualitatively: is the medium strongly or weakly coupled; what are its relevant degrees of freedom; does viscous relativistic hydrodynamics describe the bulk physics of the QGP; does either pQCD or the phenomenological string theory methods of the AdS/CFT correspondence or neither describe the physics of either the bulk medium or the high momentum probes of the medium? Quantitatively: what is the viscosity of the medium; what are the values of its transport coefficients? Is the QGP at RHIC the most perfect fluid created by mankind? The difficulty faced when trying to answer these questions is that a heavy-ion collision is an incredibly complex event. It is useful to think about a HIC, as currently best understood, as a series of separate stages: 1) $t=-\infty$, the time before overlap, when the nuclei are boosted to 200 GeV per nucleon at RHIC; 2) $t=0$, the actual collision of the nuclei and creation of large chromodynamic fields; 3 ) $0 \lesssim t \lesssim 1 \mathrm{fm} / \mathrm{c}$, the initial large chromodynamic fields rapidly thermalize; 4) $1 \lesssim t \lesssim 3 \mathrm{fm} / \mathrm{c}$, evolution as a QGP; 5) $3 \lesssim t \lesssim 4 \mathrm{fm} / \mathrm{c}$, hadronization; 6) 4 $\mathrm{fm} / \mathrm{c} \lesssim t \rightarrow \infty$, evolution as a hadron gas. A cartoon of a typical central heavy ion collision is shown in figure 5.91.

Figure 5.91. Cartoon of the stages of a heavy ion collision. Timescales are approximate.
As one can see, the system is in the QGP phase for only a brief period of its entire spacetime evolution! These times are important to understand not only because they are interesting in their own right-What are the non-linear evolution effects on the color charge density of highly boosted nuclei? How do very large chromodynamic fields thermalize so rapidly? How does hadronization occur? -but also because the interpretation of experimental observables associated with the QGP is sensitive to the details of the physics of the other stages of a HIC. Any new means of experimentally extending our understanding of these other stages would provide a qualitative leap forward in our understanding of the

Figure 5.92. (a) Initial spatial anisotropy evolves into momentum anisotropy in non-central heavy ion collisions. Hydrodynamics aims to quantitatively model this process to gain information on the medium and its properties. (b) Comparison of data and theoretical predictions using viscous relativistic hydrodynamics for $v_{2}^{h}\left(N_{\text {part }}\right)$ (left) and $v_{2}^{h}\left(p_{T}\right)$ (right). Viscous hydrodynamics predictions use Glauber-like initial conditions (top) or a simplified implementation of color glass condensate (CGC) physics (bottom). Note the $100 \%$ difference in extracted $\eta / s$ from the two naive geometry models. figures adapted from [1131, 881].

QGP created at RHIC. Of particular importance are the initial conditions of a heavy-ion collision, from $t=-\infty$ to $t \sim 1 \mathrm{fm} / \mathrm{c}$, from the time before the collision up through thermalization. An electron-ion collider that probes gluons at $x \sim 10^{-3}$ could provide precisely this qualitatively new physics understanding of the initial conditions.

The two most striking discoveries of the RHIC heavy-ion program so far are perfect fluidity and jet suppression. The naive interpretation of the measured flow of low momentum particles is that the QGP is a strongly coupled fluid whose properties are described by AdS/CFT; the naive interpretation of the measured jet suppression is that the QGP is a weakly coupled plasma whose properties are described by pQCD. These two interpretations are both mutually exclusive and highly dependent upon the initial conditions of HIC.
Hydrodynamics. The stunning success of ideal relativistic hydrodynamics at RHIC as compared to its failure in lower energy machines [1132, 1133, 880, led to the proclamation of the creation of a perfect fluid at RHIC [1134, 1135, 1136, In HIC particle spectra are often conveniently reported as

$$
\begin{equation*}
\frac{d N^{h}}{d p_{T}}\left(p_{T}, \phi, N_{\text {part }}\right)=\frac{d N^{h}}{d p_{T}}\left(p_{T}, N_{\text {part }}\right)\left(1+2 v_{2}^{h}\left(p_{T}, N_{\text {part }}\right) \cos 2 \phi+\ldots\right), \tag{5.190}
\end{equation*}
$$

where $\phi$ is the angle of the observed particle with respect to the semiminor axis of the overlap region; see figure 5.92 (a). As pictured in figure 5.92 (a) the $v_{2}^{h}$ develops from pressure gradients that build up as a result of the spatial anisotropy created in the initial overlap of the two nuclei.

The nearly ideal fluid flow as surmised from hydrodynamics is exciting because the extracted value of $\eta / s$, the shear viscosity to entropy ratio, is smaller than for any other known substance [1137. From a theoretical standpoint, this nearly ideal flow is a huge success for string phenomenology: the lower bound for $\eta / s$ in a strongly-coupled liquid as computed using the AdS/CFT correspondence is $1 / 4 \pi$, in natural units. This value of $1 / 4 \pi \simeq 0.1$ should be compared to the naive estimate from $\mathrm{pQCD}, \eta / s \sim 1$. Conservative

Figure 5.93. (a) A plot of the early success of pQCD energy loss calculations in describing $R_{A A}\left(p_{T}\right)$, Eq. 5.191 (b) Cartoon of the energy loss from a high- $p_{T}$ parton in the QGP medium. The longer the pathlength $L$ the greater the energy loss: the spatial anisotropy manifests as a suppression anisotropy, which is represented by $v_{2}^{h}$. (c) pQCD ( $\Delta E \sim L^{2}$ ) energy loss significantly underpredicts the anisotropy while AdS/CFT $\left(\Delta E \sim L^{3}\right)$ loss is consistent. The simultaneous description of $R_{A A}$ and $v_{2}$ seems to require both $L^{3}$ energy loss and a CGC-like initial state. figures adapted from 1140, 884.
estimates of the extracted value of $\eta / s$ from comparison between theoretical calculations and experimental data yield $\eta / s \sim 0.1-0.5$ [1137]. Hydrodynamics is a set of partial differential equations: initial conditions, for which hydrodynamics can tell us nothing, must be supplied. Figure 5.92 (b), in which a $2+1 D$ viscous hydrodynamics calculation is compared with data, shows the at least factor of 2 uncertainty in the extracted value of $\eta / s$ that arises from the poorly constrained mean value of the initial geometry. The uncertainty from fluctuations [1138], in which hot and cold spots appear in the initial conditions, might also be very large [1139]. This very large range of $\eta / s$ means that one cannot definitively claim that the medium is better understood as strongly coupled and near the lower bound set by AdS/CFT or weakly coupled, with pQCD providing a good physical description.
High-pT Physics. Originally, high- $p_{T}$ particles were hoped to provide a tomographic probe of the QGP medium produced at RHIC. Jet tomography, then, would provide a means, independent of hydrodynamics, for determining many medium properties; most important, jet tomography could be a tool to investigate the initial geometry of the HIC. While early work showed great promise, see figure 5.93 (a), there are several observables for which the perturbative energy loss calculations do not provide a good description of the data (see, e.g., figure 5.93 (c)). There is currently not much theoretical control over the inmedium energy loss experienced by high- $p_{T}$ partons: different assumptions about the best physics approximations have yielded very different energy loss calculations (see, e.g., [1141, (1011), and all these calculations suffer from large, mostly unquantified uncertainties due to simplifying mathematical approximations [1142]. Nevertheless, qualitatively fascinating discoveries can be made from high- $p_{T}$ observables. In particular, one may compare the results of strong coupling calculations derived using the AdS/CFT correspondence to those derived using traditional pQCD methods; in this way, energy loss holds out the possibility of rigorously investigating, independent of hydrodynamics, whether RHIC creates a stronglycoupled perfect fluid or a weakly-coupled plasma.

High-energy particle spectra are often reported as normalized by the $p+p$ spectrum multiplied by $N_{\text {coll }}\left(N_{\text {part }}\right)$, where $N_{\text {coll }}\left(N_{\text {part }}\right)$ is the expected number of $p+p$-like hard
collisions in an $A+A$ collision with a given number of participants:

$$
\begin{equation*}
R_{A A}^{h}\left(p_{T}, \phi, N_{\text {part }}\right)=\frac{d N_{A A}^{h}}{d p_{T}}\left(p_{T}, \phi\right) / N_{\text {coll }}\left(N_{\text {part }}\right) \frac{d N_{p p}^{h}}{d p_{T}}\left(p_{T}\right), \tag{5.191}
\end{equation*}
$$

where $h$ is the measured hadron species and $\phi$ is the same angle as was defined in the discussion of hydrodynamics. This ratio is also often reported as a Fourier expansion, with $v_{2}^{h}$ again representing twice the first Fourier coefficient (the same $v_{2}^{h}$ as in hydrodynamics). However the physical understanding of the origin of the high- $p_{T} v_{2}^{h}$ is very different from the hydrodynamics physics which dominates the generation of the low- $p_{T} v_{2}^{h}$. For high$p_{T}$ observables, $v_{2}^{h}$ comes from high $-p_{T}$ partons traversing a medium asymmetric from the initial geometry: less energy loss occurs for partons traveling the short direction of the almond-shaped overlap region compared to those partons that travel the long direction. A cartoon of this physical picture is shown in figure 5.93 (b). The size of $v_{2}^{h}$ is then an entangled measure of the geometry of the medium and the pathlength dependence of the energy loss mechanism: perturbative elastic energy loss, which goes as $L^{1}$, produces less $v_{2}^{h}$ for a given geometry than perturbative inelastic energy loss, which goes as $L^{2}$, which produces less $v_{2}^{h}$ than strong-coupling energy loss, which, for light partons, goes as $L^{3}$ and as $\exp (-L)$ for heavy partons. $v_{2}^{h}$ is of particular interest because it was recently measured out to $p_{T} \sim 13 \mathrm{GeV}$, well beyond momentum scales where hadronization effects might be important. That the observed $v_{2}^{h}$ is significantly larger than that predicted by perturbative methods, shown in figure 5.93 (c), is perhaps the best high- $p_{T}$ experimental evidence that $\mathrm{AdS} / \mathrm{CFT}$, as opposed to pQCD, is the best approximation to the relevant physics at RHIC.

As the theoretical prediction of high- $p_{T} v_{2}^{h}$ comes directly from the azimuthal anisotropy of the QGP medium, knowledge and constraint of the initial geometry is crucially important for a rigorous scientific conclusion to be made: the sharper the produced medium the larger the $v_{2}^{h}$, regardless of energy loss mechanism. As one can see from figure 5.93, there are reasonable initial conditions for which no known energy loss calculation describes the data. And just as in hydrodynamics, fluctuations may play an important, even outsized, role.
Measuring the Initial State. From the above discussion it is clear that knowledge of the initial conditions at RHIC is crucial for interpreting the experimental data. The density of the charged and neutral matter density of nuclei at rest is well understood from diffraction pattern experiments (see, e.g., [1143]). Knowledge of the rest frame density of protons and neutrons in nuclei has been used extensively in estimating the initial matter density created in HIC. Matter production in HIC, though, depends on the distribution of quarks and, especially, gluons in the nuclear wavefunction. Below some value of Bjorken $x$ that is not yet precisely known, non-Abelian, non-linear QCD evolution effects become important. The (mostly) gluonic initial state medium at midrapidity at RHIC consists of particles of $x \sim p_{T} / \sqrt{ } s \sim 10^{-3}$, which is at the order of magnitude for which small- $x$ physics likely becomes relevant. Unfortunately the theory of small-x physics in $A+A$ collisions is very complicated, and current knowledge is incomplete. Additionally, the aforementioned theoretical calculations of $v_{2}^{h}$ are in fact most sensitive to the the quantitative shape of the edge of the initial nuclear overlap in HIC; it is just in this region that many of the theoretical tools developed for small-x physics study break down. It turns out, though, that through careful measurements, diffraction patterns may be measured at an electronion collider using deeply-virtual Compton scattering and vector meson production. These diffraction patterns, in turn, may be inverted to constrain the initial gluon and quark densities of the highly boosted nuclei. Fortuitously, these experimental measurements give
the most sensitive determination of these densities at the edge of the nucleus, the region of the overlap which hydrodynamics and energy loss calculations are most sensitive to.

### 5.15.2 Constraining initial conditions in $\mathrm{A}+\mathrm{A}$ collisions

Adrian Dumitru

Understanding small- $x$ gluon production in the initial state of relativistic $\mathrm{A}+\mathrm{A}$ collisions constrains the amount of additional entropy produced via "final-state" interactions such as parton thermalization / QGP formation [1144 and its subsequent hydrodynamic expansion. If these processes provide a significant contribution, then that should presumably show in the centrality dependence of the multiplicity in the final state: final state interactions should be much more prevalent for a head-on collision of two large nuclei than for a grazing shot or $\mathrm{p}+\mathrm{A}$ or (minimum bias) $\mathrm{p}+\mathrm{p}$ collisions. It is therefore very important to test models for initial particle production over a broad range of centralities - perhaps down to the level of $\mathrm{p}+\mathrm{p}$ collisions - in order to constrain entropy production due to thermalization and viscous hydrodynamic expansion (1145.

To compute the number of small- $x$ gluons released from the wavefunctions of the colliding nuclei, one frequently employs the $k_{\perp}$-factorization formalism [742, 1146],

$$
\begin{align*}
& \frac{d N}{d^{2} \mathbf{r}_{\perp} d y}=\mathcal{N} \frac{N_{c}}{N_{c}^{2}-1} \int \frac{d^{2} p_{\perp}}{p_{\perp}^{2}} \int^{p_{\perp}} d^{2} k_{\perp} \alpha_{s}\left(Q^{2}\right) \\
& \quad \times \phi_{A}\left(x_{1}, \frac{\left(\mathbf{p}_{\perp}+\mathbf{k}_{\perp}\right)^{2}}{4} ; \mathbf{r}_{\perp}\right) \phi_{B}\left(x_{2}, \frac{\left(\mathbf{p}_{\perp}-\mathbf{k}_{\perp}\right)^{2}}{4} ; \mathbf{r}_{\perp}\right), \tag{5.192}
\end{align*}
$$

where $N_{c}=3$ is the number of colors, and $p_{\perp}, y$ are the transverse momentum and the rapidity of the produced gluons, respectively. $x_{1,2}=p_{\perp} \exp ( \pm y) / \sqrt{s_{N N}}$ denote the lightcone momentum fractions of the colliding gluon ladders, $\sqrt{s_{N N}}$ is the collision energy, and typically one chooses $Q^{2}=\max \left(\left(\mathbf{p}_{\perp}+\mathbf{k}_{\perp}\right)^{2},\left(\mathbf{p}_{\perp}-\mathbf{k}_{\perp}\right)^{2}\right) / 4$. The normalization factor $\mathcal{N}$ can be fixed from peripheral collisions, where final-state interactions should be suppressed. It effectively also absorbs NLO corrections and the contribution from sea (anti-)quarks. The unintegrated gluon distribution $\phi$ is related to the dipole scattering amplitude in the adjoint representation, $N_{G}$, through a Fourier transform [1147]:

$$
\begin{equation*}
\phi\left(x, k_{\perp}^{2} ; \mathbf{r}_{\perp}\right)=\frac{C_{F}}{\alpha_{s}\left(k_{\perp}\right)(2 \pi)^{3}} \int d^{2} \mathbf{s}_{\perp} e^{-i \mathbf{k}_{\perp} \cdot \mathbf{s}_{\perp}} \nabla_{\mathbf{s}_{\perp}}^{2} N_{G}\left(x, s_{\perp} ; \mathbf{r}_{\perp}\right) . \tag{5.193}
\end{equation*}
$$

The multiplicity in heavy-ion collisions. Figure 5.94 (left) shows the centrality dependence of particle production for heavy-ion collisions at 200 GeV and 2760 GeV , respectively, obtained by integrating eq. (5.192) over the transverse overlap of the colliding nuclei. The unintegrated gluon distributions are solutions of the local (impact parameter independent) Balitsky-Kovchegov (BK) equation with running-coupling corrections according to the Balitsky prescription [751]. The impact parameter dependence is due entirely to the initial condition where it has been assumed that essentially $Q_{s}^{2}\left(x_{0} ; \mathbf{r}_{\perp}\right)=Q_{0}^{2} \sigma_{0} T_{A}\left(\mathbf{r}_{\perp}\right)$ increases in proportion to the thickness of the nucleus ( $Q_{0}$ and $\sigma_{0}$ denote constant scales; for details see ref. [896). Neglecting the impact parameter dependence of the dipole scattering amplitude $N_{G}$ in a nucleon relies on the scale separation $R_{A} \gg R_{N} \gg Q_{s}^{-1}$ where $R_{A}$ is the size of the overlap region in the collision 1150 .

Figure 5.94. Left: Centrality dependence of the multiplicity at 200 GeV and 2760 GeV , respectively, from $k_{\perp}$ factorization with running-coupling BK unintegrated gluon distributions (see [896] for details). PHOBOS data: 891] $(\mathrm{Au}+\mathrm{Au})$, 1148 , $(\mathrm{Cu}+\mathrm{Cu})$; ALICE data from ref. 894]. Right: $v_{2} / \varepsilon$ versus the transverse particle density [1149] $v_{2} / \varepsilon_{\mathrm{CGC}}$ has been scaled by $1 / 2$ for better visibility.

Apparently, the model calculation describes both the centrality and the energy dependence of particle production fairly well. If so, this constrains final-state entropy production and correlates the thermalization time and the shear viscosity to entropy density ratio: extremely rapid thermalization and/or $\eta / s \gtrsim 0.3$ would be excluded by stringent entropy production bounds [1145].

Several caveats remain. As already mentioned above, the absolute normalization of the gluon density at small $x$ (alternatively, the factor $\mathcal{N}$ in the $k_{\perp}$ factorization formula) can be fixed in practice only from very peripheral $\mathrm{A}+\mathrm{A}$ or $\mathrm{p}+\mathrm{p}$ collision: 9 . For $\mathrm{p}+\mathrm{p}$ collisions, however, the impact parameter dependence of the dipole scattering amplitude over distance scales $\sim R_{N}$ can not be neglected, see for example ref. [1151.

Furthermore, it may be important to consider in more detail the structure of running coupling corrections to the $k_{\perp}$-factorization formula (5.192) [897] and the effect of a full NLO treatment of BK evolution. Indeed, if such corrections modify the centrality dependence of particle production in $\mathrm{A}+\mathrm{A}$ collisions then they will also affect entropy production constraints and thus the fundamental understanding of the thermalization processes and time scales as well as estimates of the shear viscosity of thermal QCD.
The eccentricity in heavy-ion collisions. Other quantities of relevance for the interpretation of heavy-ion collisions exhibit even greater sensitivity to the actual distribution of produced gluons in the transverse $\mathbf{r}_{\perp}$ plane than its integral $d N / d y$. A collision of two heavy ions at non-zero impact parameter, neglecting fluctuations of the local density of participant nucleons, leads to a momentum asymmetry called "elliptic flow", $v_{2} \sim\langle\cos 2 \phi\rangle$, as described in section 5.15.1. In the absence of any scales (such as the freeze-out temperature $T_{f}$, the phase transition temperature $T_{c}$, or a non-vanishing mean free path $\lambda$ ), hydrodynamics predicts that $v_{2}$ is proportional to the eccentricity $\varepsilon$ of the overlap area [1152], $\varepsilon=\left\langle y^{2}-x^{2}\right\rangle /\left\langle y^{2}+x^{2}\right\rangle$. The average is taken with respect to the distribution of produced gluons in the transverse $x-y$ plane. Clearly, $\varepsilon$ involves large cancellations of the contributions of gluons produced near the center $r_{\perp} \sim 0$ of the overlap zone and so is more sensitive to particle production in the periphery.

A simple geometry based initial condition assumes that by analogy to the Glauber model for soft particle production $d N / d y d^{2} r_{\perp} \sim \rho_{\text {part }}^{\text {ave }}\left(r_{\perp}\right) \equiv\left(\rho_{\text {part }}^{A}\left(r_{\perp}\right)+\rho_{\text {part }}^{B}\left(r_{\perp}\right)\right) / 2$, where $\rho_{\text {part }}^{i}$

[^282]is the density of participants of nucleus $i$ per unit transverse area. High-density QCD (the "Color-Glass Condensate") predicts a somewhat different distribution of gluons in the transverse plane, corresponding to a higher eccentricity $\varepsilon$. In particular, in the " $\mathrm{p}+\mathrm{A}$ limit" when one of the nuclei is very dense while the other is dilute, the number of produced particles is proportional only to the density of the dilute collision partner, whose partons add up linearly. Hence, in the reaction plane, $d N / d y d^{2} r_{\perp} \sim \min \left(Q_{s, A}^{2}, Q_{s, B}^{2}\right) \sim \min \left(\rho_{\text {part }}^{A}, \rho_{\text {part }}^{B}\right)$ drops more rapidly as one moves towards the edge of the overlap zone than $d N / d y d^{2} r_{\perp} \sim$ $\rho_{\text {part }}^{\text {ave }} 1153$. Thus, a higher eccentricity is a generic effect due to a dense target or projectile. Specific numerical estimates rely on an accurate determination of the unintegrated gluon distribution, however. Ref. [896] finds that the energy dependence of $\varepsilon$ from RHIC to LHC is very weak.

Figure 5.94 (right) shows the elliptic flow $v_{2}$ measured in heavy-ion collisions at RHIC scaled by the eccentricity $\varepsilon$ of the overlap zone 1149 . As already mentioned above, in the absence of any scales such as a non-zero mean free path, $v_{2} / \varepsilon$ would be independent of the transverse density of particles. Indeed, if the $v_{2}$ data is scaled by the eccentricity obtained from a CGC model implementation then the required breaking of scale invariance is lower than for purely geometry based (Glauber-like) initial conditions. Actual solutions of viscous hydrodynamics (for $v_{2}$ ) appear to confirm this simple observation in that the slope of $v_{2} / \varepsilon$ versus transverse density is sensitive to the distribution of produced particles [1154.

More recent studies attempt to understand also the relation of higher moments of anisotropic flow $v_{n}$ to corresponding moments of the initial eccentricity $\varepsilon_{n}-$ such as the "triangularity" [1155, 1156, 1157, 883, 1158, which is non-zero because of fluctuations of the large- $x$ sources in the transverse impact parameter plane before the collision. A quantitative interpretation of the "response" $v_{n}$ of the Quark-Gluon Plasma medium to the initial geometry will also rely on a good understanding of particle production in high-energy QCD.

### 5.15.3 Particle production at low- $x$ and gluon saturation: from $p+A$ to $e+A$

## Kirill Tuchin

In the beginning of the RHIC era, the $p(d)+A$ program was perceived as merely a useful baseline reference for the heavy-ion program. It very soon turned out that due to a wise choice of colliding energy, RHIC probes the transition region to a new QCD regime of gluon saturation. While the first hints of gluon saturation were observed in DIS experiments at HERA, it is fair to say that gluon saturation was discovered in $d A$ collisions at RHIC. At present, as we are heading toward the era of EIC, it is important to review what we have learned at RHIC and how it can be used to optimize the EIC program. The purpose of this section is to review phenomenological studies of gluon saturation at RHIC.

The reason why $p A$ and $e A$ high energy physics programs are closely related is provided by the Pomerantchuk theorem, which states that all high energy scattering processes are mediated by the exchange of a collective gluon state - known as a Pomeron - that has vacuum quantum numbers. For this reason, inclusive processes in both programs share many similarities in the low $x$ region. The main distinction arises from the difference in the characteristic scales of the projectile: in protons it is a soft scale $\Lambda$, while in virtual photons, it is the photon virtuality $Q^{2}$, which depends on the electron kinematics. A possibility to control the $Q^{2}$ is a great advantage of DIS. In particular, it allows one to study the total cross sections/structure functions. However, in practice, the requirement to keep $x$ low
significantly restricts the range of $Q^{2}$, s available for low $x$ studies.
The relation between $p A$ and $e A$ scattering at low- $x$ becomes particularly apparent in the framework of the dipole model [737]. In the dipole model, the cross section for $e A \rightarrow X$ or $p A \rightarrow X$ scattering, where $X$ is an arbitrary final state, can be represented as

$$
\begin{equation*}
d \sigma_{p\left(\gamma^{*}\right)+A \rightarrow X}=\int d^{2} r_{\perp} \Phi^{p\left(\gamma^{*}\right)}\left(r_{\perp}\right) d \sigma_{\mathfrak{D}+A \rightarrow X}\left(r_{\perp}\right) \tag{5.194}
\end{equation*}
$$

where $\mathfrak{d}$ stands for color dipole (letter $d$ is reserved for deuteron) of size $r_{\perp}$ in the transverse plane. Eq. (5.194) is based on the separation of scales: the interaction length $\ell_{i} \sim R_{A}$ (in the target rest frame) is much smaller than the coherence length $\ell_{c}=\gamma / M_{N}$, where $\gamma \gg 1$ is the Lorentz factor and $M_{N}$ is the nucleon mass. $\Phi^{p\left(\gamma^{*}\right)}\left(r_{\perp}\right)$ is the light-cone "wave function" describing the Fourier decomposition of a projectile into dipoles; it can be calculated in QED (for $\gamma^{*}$ ), or modeled (for proton), see e.g. [1159, 1160. The main theoretical concern in low $x p A / e A$ scattering is calculation of the dipole-nucleus cross section, which is universal for both processes. With this observation in mind, we are going to consider some of the $p A$ processes at RHIC that are of relevance for low- $x$ physics at EIC.
Inclusive hadron production: $p+A \rightarrow h+X$. The cornerstone for phenomenological applications of the Color Glass Condensate (CGC), which is the theory of gluon saturation, is the factorization theorem proved in [1147, where the cross section was derived that resums all leading logarithmic contributions $\alpha_{s} \ln (1 / x) \sim 1$ (LLA) for a heavy nucleus in the quasi-classical limit $\alpha_{s}^{2} A^{1 / 3} \sim 1$. A similar result was reported in [1161, 1162, 1163]. One does not expect that any of the hard perturbative QCD (hpQCD) factorizations apply in this case because higher twist interactions of valence quarks and gluons give contributions of order unity. Nevertheless, despite the fact that individual diagrams break factorization in covariant and light-cone gauges, the final re-summed expression can be cast in the $k_{T}$-factorized form. Unlike in hpQCD, the physical quantity that is factorized - the unintegrated gluon distribution $\varphi\left(x, Q^{2}\right)$ - can be calculated perturbatively owing to the existence of a hard scale $Q_{s} \gg \Lambda_{\mathrm{QCD}}$. Another surprising fact is that contrary to naive expectations, $\varphi\left(x, Q^{2}\right)$ is related not to the momentum space Fourier-image of the nucleus gluon-field correlation function $\left\langle A_{\perp}\left(0_{\perp}\right) \cdot A_{\perp}\left(x_{\perp}\right)\right\rangle$, but rather to the Fourier-image of $\nabla_{r}^{2} N\left(r_{\perp}, b_{\perp}, y\right)$, where $N\left(r_{\perp}, b_{\perp}, y\right)$ is the imaginary part of the forward elastic scattering amplitude of a color dipole of size $r_{\perp}$ at impact parameter $b_{\perp}$ and rapidity $y=\ln (1 / x)$ in the heavy nucleus. Although the inclusive gluon production in $p A$ collisions is the only known case were $k_{T}$-factorization holds, factorization of the multipoles in the transverse coordinate space is a general feature of the low- $x$ cross sections. It must be stressed that this multipole factorization does not imply hpQCD factorizations ( $k_{T}$ or collinear ones) and neither opposite is generally true.

The $k_{T}$-factorization formula derived in [1147] led to successful phenomenology of inclusive hadron production in $d A$ collisions at RHIC, where the suppression of hadrons at forward rapidities and Cronin enhancement at mid-rapidity were qualitatively predicted [1164, 1165] and then quantitatively described in the CGC framework [1166, 1167, 1168]. The production of valence quarks in the forward direction gives an important contribution to inclusive hadron production at large- $x$ of the proton and was discussed in [1169, 1170, 1171].

By integrating the gluon spectrum over $p_{\perp}$, one arrives at the total hadron yield as a function of rapidity $y$. It is rather weakly dependent on the details of the gluon distributions. Therefore, a simple model suggested in [1172] is able to describe inclusive hadron yield with remarkable accuracy.

Open charm (beauty) production: $\boldsymbol{p}+\boldsymbol{A} \rightarrow \boldsymbol{D}+\boldsymbol{X}$. The production of heavy quarks in $p A$ collisions at low- $x$ was calculated in [1173, 905, 1174]. One expects that the hpQCD factorization is applicable if the saturation momentum is much smaller than the quark mass $m$ [1175]. At RHIC, $Q_{s} \sim m$ for charm and bottom, hence factorization is broken in both cases. Indeed, analysis of [1176] indicates that semi-classical calculations of 905 disagree with $k_{T}$-factorization by about $10 \%$ at the $t$-channel gluon transverse momenta around $m$. hpQCD factorization is restored in the kinematic region where the operator product expansion is applicable, i.e. at transverse momenta much higher than the saturation momentum.

The phenomenology of open heavy quark production at RHIC was developed in [1177], where it was found that the production pattern of heavy quarks is qualitatively similar to that of light quarks and gluons, although the magnitude of nuclear effects (Cronin and suppression) slowly decrease with increasing quark mass. These qualitative features are in good agreement with preliminary data.
Inclusive production of $J / \Psi: p+A \rightarrow J / \Psi+X$. In addition to the scales $\ell_{i}$ and $\ell_{c}$ mentioned earlier, the production of a charmonium state is characterized by another scale: formation length $\ell_{f}=\gamma / \Delta M$, where $\Delta M$ is its binding energy. The key theory observation is strong ordering of the scales at high energies: $\ell_{i} \ll \ell_{c} \ll \ell_{f}$ [977, 1178]. Consequently, we can distinguish three stages of $J / \Psi$ production. (i) $g^{*} \rightarrow c \bar{c}$ described by the light-cone amplitude $\psi^{g}\left(k_{\perp}, z\right)$ often referred to as gluon's light-cone wave function, (ii) interaction of the gluon or the $c \bar{c}$ with the target depending on whether the splitting has occurred after or before the interaction, and (iii) formation of charmonium wave function. Unlike stages (i) and (ii), which can be described using perturbation theory owing to the weakness of the strong interaction at the $J / \Psi$-mass scale, stage (iii) is non-perturbative because $\Delta M \ll M$. This, however, does not preclude us from using perturbation theory for calculating the $J / \Psi$ production cross section, since the fragmentation process is independent of energy and atomic weight $\left(\ell_{f} \gg R_{A}\right)$. In other words, fragmentation happens in the vacuum long after any interaction with the target.

Thus, the problem of calculating the $J / \Psi$ production cross-section reduces to the calculation of the cross section of $\mathfrak{d}+A \rightarrow\left[c \bar{c}\left(1^{--}\right)\right]+X$ dipole-nucleus scattering. This calculation was done in [1179, 1180. Note, that interaction depends on the quantum state of the $c \bar{c}$ pair, which must be in the $1^{--}$color singlet state. Therefore, only those higher twist contributions may be taken into account that lead to this quantum state, and which are also enhanced by $\alpha_{s}^{2} A^{1 / 3} \sim 1$. At the lowest order in $\alpha_{s}$, the projectile gluon in the proton wave-function has two interaction possibilities: (i) leading twist processes $g+g \rightarrow J / \Psi+g$, which is of order $\mathcal{O}\left(\alpha_{s}^{5} A^{1 / 3}\right)$ and (ii) higher twist process $g+g+g \rightarrow J / \psi$ (initial gluons come from different nucleons), which is of the order $\mathcal{O}\left(\alpha_{s}^{6} A^{2 / 3}\right)$. Since $\alpha_{s}^{2} A^{1 / 3} \sim 1$, the higher twist mechanism (ii) is parametrically enhanced. Notice, that this leading contribution explicitly breaks $k_{T}$-factorization as it is proportional to $x G\left(x_{1}\right)\left[x G\left(x_{2}\right)\right]^{2}$. Results reported in [1179, 1180] show strong coherence effects consistent with expectations of CGC theory.
Electromagnetic probes. The main advantage of electromagnetic probes, such as photons and dileptons, is that they are directly observable without an intermediate hadronization process, in contrast to quarks and gluons. Therefore, they are a cleaner probe of low$x$ nuclear matter. Their disadvantage is a low production rate due to the smallness of electromagnetic coupling. Prompt photon production in $p A$ collisions was considered in [1181] through the process $q A \rightarrow \gamma q X$. The production of di-leptons in a similar process $q A \rightarrow l^{+} l^{-} q X$ was addressed in [1182, 1183, 1184]. At higher energies, gluons become
much more abundant than quarks in the central rapidity region which implies that photon (dilepton) production will go via the process $g^{*} A \rightarrow q \bar{q} X \gamma\left(l^{+} l^{-}\right)$. It is suppressed by $\alpha_{s}$ but enhanced by a positive power of energy. There have been no detailed phenomenological studies of electromagnetic probes in $p A$ collisions at RHIC.
Double inclusive hadron production and correlations. Azimuthal correlations are an important tool to investigate properties of QCD at low $x$. In 1185 it was proposed that azimuthal correlations of hadrons produced at large rapidity separation $(\Delta y \gg 1)$ may be depleted due to a quasi-classical nature of the saturated gluon fields. Unfortunately, accurate theoretical calculations in the region of large but finite $\Delta y$ are challenging as they must involve complicated NLO BFKL effects. Important progress has been made in the investigation of azimuthal correlations at smaller $\Delta y$.

It has been suggested that correlations at small $\Delta y$ in the forward direction can be effectively used to study gluon saturation [1186], where the forward direction corresponds to low- $x$ of the nucleus where saturation effects are strongest. Theory predicts that back-toback correlations are suppressed due to gluon saturation. Phenomenological models based on the CGC were suggested in [1186, (1187] and [1188] and rely on different approximations. An approach of [1186, 1187] is based on the dipole model [737] in which double inclusive gluon [1189], quark-anti-quark [1173, 905, [1174] and valence quark-gluon [1186] cross sections were calculated. Another approach [1188] is based on an approximate $k_{T}$-factorization and relies on calculating double-inclusive production based on NLO BFKL [1190, 1191 .

Both models give a reasonable quantitative description of experimental data. However, in order to use azimuthal correlations to study low- $x$ physics in the most effective way, work remains to be done to reconcile the existing approaches and reduce model-dependencies in calculations. Measurements of forward azimuthal correlations in $e A$ will have a clear advantage over that in $p A$ due to much better theoretical control of the projectile current. Diffraction. One of the most sensitive probes of low- $x$ QCD is diffraction. This is because scattering in the high energy limit of QCD is mediated by the same collective gluon state (Pomeron) as the diffractive scattering. Saturation effects on diffractive processes in $p A$ collisions were investigated in [1159, 1192, 1193, 1160, 1194 where the main focus was on diffractive hadron production. (In [1195, 1196 this work was extended to DIS).

In diffraction on nuclear targets, it is important to distinguish two processes: coherent and incoherent diffraction, depending on the final state of the target. Coherent diffractive hadron production in $p A$ collisions is a process $p+A \rightarrow X+h+[L R G]+A$, where $[L R G]$ stands for Large Rapidity Gap. Coherent diffractive production exhibits a much stronger dependence on energy and atomic number than the corresponding inclusive process. Indeed, the diffractive amplitude is proportional to the square of the inelastic one. At asymptotically high energies, coherent diffractive events are expected to constitute up to a half of the total cross section, the other half being all inelastic processes. Therefore, coherent diffraction is a powerful tool for studying the low- $x$ dynamics of QCD.

In all phenomenological applications of the CGC formalism, one usually relies on the mean-field approximations in which only the lowest order Green's functions are relevant. Although corrections to the mean-field approximation, i.e. quantum fluctuations about the classical solution, are assumed to be small in $p A$ collisions at RHIC, their detailed phenomenological study is absent. An observable that is directly sensitive to quantum fluctuations is incoherent diffraction: $p+A \rightarrow X+h+[L R G]+A^{*}$, where $A^{*}$ denotes excited nucleus that subsequently decays into a system of colorless protons, neutrons and nuclei debris. Incoherent diffraction measures fluctuations of the nuclear color field. Calculations show that unlike the nuclear modification factor for coherent diffractive gluon production,
the nuclear modification factor for incoherent diffraction is not expected to exhibit a significant rapidity and energy dependence [1194]. Therefore, the two diffractive processes can in principle be experimentally distinguished and yield unique information about low- $x$ QCD. Unfortunately, the study of diffraction in $p A$ collisions at RHIC is a virgin subject in part due to technical difficulties associated with measurements at very small forward angles.
Instead of a summary. Studying particle production in DIS at low $x$ has two main advantages: (i) one has much better theoretical understanding of the forward kinematic region owing to the weakness of the QED coupling and (ii) new kinematic regions open up for investigation depending on values of momentum scales $Q^{2}, k_{\perp}^{2}$ and $Q_{s}^{2}$, where $Q^{2}$ is photon virtuality, $Q_{s}^{2}$ is saturation scale and $k_{\perp}$ is transverse momentum of produced hadron.

### 5.15.4 Small-x dynamics in ultraperipheral heavy ion collisions at the LHC

Mark Strikman

Experiments at HERA have demonstrated that reactions with quasi real photons provide an effective tool of probing pQCD which complements studies of DIS processes. In the near future it will be possible to extend these studies to ultra-high energy photon - nucleus collisions via the study of ultra-periperal collisions (UPCs) of heavy ions (protons and ions) at the LHC. The feasibility and the possible reach of these investigations was explored in a five year long study undertaken by the collaboration of theorists and experimentalists. The results of the study were published as a volume of Physics Reports [979]. Due to the high energy of the colliding nuclei and very good acceptance of the CMS and ATLAS detectors at large rapidities, UPCs at the LHC allows to study a wide range of the processes sensitive to the small-x dynamics for $W_{\gamma N} \leq 1-2 \mathrm{TeV}$. This would extend the $x$ range probed at HERA down by at least by a factor of ten. A further advantage

Figure 5.95. The kinematic range in which UPCs at the LHC can probe gluons in protons and nuclei in quarkonium, di-jet and di-hadron production. For comparison, the kinematic ranges for $J / \psi$ at RHIC, $F_{2}^{A}$ and $\sigma_{L}^{A}$ at eRHIC and $Z^{0}$ hadroproduction at the LHC are also shown. for the search for non-linear effects will be the use of the nuclear targets.

The kinematic range for which studies of several processes of interest will be feasible is presented in figure 5.95 (taken from [979]) as a function of $x$ and $Q$ which is the typical gluon virtuality which, as the transverse momentum of the jet or leading pion, sets the scale for dijet and $\pi \pi$ production respectively. The typical gluon virtuality scale for exclusive quarkonium photoproduction is shown for $J / \psi$ and $\Upsilon$. Below we list some of the directions of the planned studies.

Dijet production. Dijet production in the discussed kinematic range is dominated by photon - gluon fusion. Estimates of the counting rates including cuts due to the acceptance of the CMS detector were performed in [1197]. It was found that measurements of the nuclear gluon pdfs will be feasible down to $x \sim 10^{-4}$ via study of several channels: dijet, charm, beauty jets, providing a number of cross checks. Use of the zero degree calorimeters (ZDCs) will also allow the separation of diffractive events and hence measure the nuclear gluon diffractive pdfs in the same kinematics. Hence, it will be possible to test a prediction of the leading twist theory of nuclear shadowing that the probability of the gluon induced coherent diffraction at large $p_{T}$ and small $x$ should be of the order $10-15 \%$ [812].

The cutoff $p_{t}($ jet $) \geq 6-8 \mathrm{GeV} / \mathrm{c}$ (necessary for selecting dijet production) reduces non-linear effects in dijet production. The parameter which governs non-linear effects is $R_{N L}=C_{F}^{2} \alpha_{s}(Q) x G_{T}\left(x, Q^{2}\right) / \pi r_{T}^{2} Q^{2}$, where $C_{F}^{2}$ is the Casimir operator, equal to $4 / 3$ for $q \bar{q}$ and 3 for $g g$, and $r_{T}$ is the transverse area of the target. For the smallest $x, p_{T}$ corner, $R_{N L}$ for the UPC processes $R_{N L}$ is about the same as for $F_{2 A}\left(x, Q^{2} \sim 2-4 \mathrm{GeV}^{2}\right)$ for the lowest $x$ which could be reached at the EIC.

It will be also possible to reach larger $R_{N L}$ at smaller virtualities and $x \sim 10^{-4}$ using leading pion production in the central detectors $|y| \leq 2.4$ - see dashed area in figure 5.95, This is a kinematics similar to the production of two forward pions in $\mathrm{d}+\mathrm{Au}$ collisions at RHIC. Within the mechanism of fractional energy losses [981, 1198, one expects a strong suppression of the two pion yield as compared to the single pion yield which would allow one to perform clean tests of the onset of the black disk regime ( BDR ).

Another sensitive probe of the onset of BDR would be exclusive diffractive production of two jets in the process $\gamma+\mathrm{A} \rightarrow 2$ jets +A . In the case of light quark jets, this process is strongly suppressed in the pQCD regime, while it is a dominant contribution to the diffraction mechanism in the BDR 981 .

The interaction of small dipoles with nuclear media. In the leading twist approximation, the suppression of onium coherent production is given by the square of the ratio of the gluon densities in the nucleus and the proton gluon pdfs. It will be feasible to investigate the suppression of coherent $J / \psi, \Upsilon$ production in nucleus-nucleus collisions down to $x \sim m_{\text {onium }} / 2\left(E_{A} / A\right)$ corresponding to production at the central rapidities. At rapidities away from zero, photons of smaller energies dominate in the production of $J / \psi$, making it very difficult to probe smaller x for virtualities $\sim 3 \mathrm{GeV}^{2}$ characteristic for $J / \psi$ coherent photoproduction. However, the use of incoherent diffractive onium production appears to solve this problem as one can use production of soft neutrons to determine which of the nuclei emitted a photon and which was involved in the strong interaction [979]. As a result, there is a potential for probing $J / \psi$ production down to $x \sim 10^{-6}$, see figure 5.95.

A complementary method of tracking a small dipole through the nuclear media will be provided by the $J / \psi$ production in the $-t \geq$ few $\mathrm{GeV}^{2}$ process $\gamma+A \rightarrow J / \psi+$ rapidity gap +Y [982]. It is possible in this case to select the kinematics where $x_{g}$ of the gluon involved in the hard process is $x_{g} \geq 0.01$. In this case, scattering at central impact parameters dominates and one can probe the propagation of a small dipole through $\sim 10 \mathrm{fm}$ of the nuclear media up to $W_{\gamma N} \sim 1 \mathrm{TeV}$.

In conclusion, it appears that UPC studies to be performed at the LHC in the next few years will allow for the search of several signals of the onset of the BDR. However, it will not be possible to perform a precision scan of the range of moderate $Q^{2}$ sensitive to the transition between non-linear and linear regimes in the $x$ range to be covered by the EIC. Hence the UPC - LHC and EIC programs will nicely complement each other.

### 6.1 Electroweak physics at the EIC

Krishna Kumar, Yingchuan Li, William J. Marciano

### 6.1.1 Introduction

The $S U(3)_{C} \times S U(2)_{L} \times U(1)_{Y}$ standard model of particle physics has been extremely successful in describing strong and electroweak interactions. Its unbroken gauge symmetry, $S U(3)_{C}$ or Quantum Chromodynamics (QCD), taken on its own, represents a "perfect theory"' with no arbitrary free parameter. Nevertheless, it beautifully encompasses all the basics of strong interactions: quark confinement, chiral symmetry breaking, asymptotic freedom, etc. The electroweak sector is potentially much more mutable. In addition to its, as yet, undiscovered Higgs scalar remnant of $S U(2)_{L} \times U(1)_{Y}$ symmetry breaking, it contains many arbitrary free masses, couplings and mixing angles. They are accommodated but not understood at a deep level. Questions such as: why parity violation, why 3 generations of quarks and leptons? etc suggest that simplifying principles must await future new discoveries. However, precision measurements and searches for rare phenomena still have important roles to play. They have the capability of indirectly probing scales of physics beyond collider facilities and expanding the horizons of electroweak physics.

The EIC is being proposed mainly for the study of strong interactions but also has a unique ability to measure parity violating structure functions involving $W^{ \pm}$and $Z$ boson mediated interactions. The high energy and luminosity combined with polarized electrons and protons as well as a variety of heavy ion targets will provide a wealth of data in an area never explored before.

Two EIC capabilities for electroweak measurements, outlined in table 6.1, are: 1) Precision measurements of the weak mixing angle over a broad range in $Q^{2}$ and 2) Searches for $e \rightarrow \tau$ flavor changing conversion. For the former, we show how parity violating, right-left, deep-inelastic polarized $e p$ and $e d$ asymmetries can be used to precisely determine the running $\sin ^{2} \theta_{W}(Q)$ as a function of $Q^{2}$. The comparison of those measurements with precision values obtained from other lower energy or Z-pole studies can be used to find hints of "new physics". Alternatively, the overall World average of $\sin ^{2} \theta_{W}$ can be compared with precisely determined quantities such as $\alpha_{E M}, G_{F}, m_{Z}$, and $m_{W}$ to test the SM at the quantum loop level and probe "new physics" effects. In the case of $e-\tau$ conversion, the $e p \rightarrow \tau X$ reaction is examined, including isolation cuts and $\tau$ identification. First estimates suggest that backgrounds are under control and the high luminosity goals of the EIC allow the search of reactions well beyond HERA sensitivities.

| Deliverables | Observables | What we learn | Phase I | Phase II |
| :---: | :---: | :---: | :---: | :---: |
| Weak mixing | Parity violating | physics behind EW | good precision | high precision |
| angle | asymmetries in <br> $e p$ - and $e d$-DIS | symmetry breaking <br> \& BSM physics | over limited <br> range of scales | over wide range <br> of scales |
| e- $\tau$ conversion | ep $\rightarrow \tau, \mathrm{X}$ | flavour violation <br> induced by BSM <br> physics | challenging | very promising |

Table 6.1. Science Matrix for Electroweak physics at an EIC.

# 6.2 The weak mixing angle via polarized electron scattering asymmetries 

Krishna Kumar, Yingchuan Li, William J. Marciano, Seamus Riordan

### 6.2.1 Introduction

The nature of spontaneous gauge symmetry breaking implies that the masses and couplings of weak gauge bosons $W$ and $Z$ are related by natural lowest order relations $\sin ^{2} \theta_{W}^{0}=e_{0}^{2} / g_{0}^{2}=1-m_{W}^{0}{ }^{2} / m_{Z}^{0}$. The weak mixing angle plays a central role in those correlations. In the context of the Standard Model (SM) as a complete stand alone theory, the renormalized weak mixing angle is related to the other precisely measured quantities

$$
\begin{align*}
\alpha^{-1} & =137.03599959(40)  \tag{6.1}\\
G_{\mu} & =1.1663788(7) \times 10^{-5} \mathrm{GeV}^{-2} \\
m_{Z} & =91.1871(21) \mathrm{GeV}
\end{align*}
$$

via

$$
\begin{equation*}
\sin ^{2} 2 \theta_{W}\left(m_{Z}\right)_{\overline{M S}}=\frac{4 \pi \alpha}{\sqrt{2} G_{\mu} m_{Z}^{2}\left[1-\Delta \hat{r}\left(m_{t}, m_{H}\right)\right]} \tag{6.2}
\end{equation*}
$$

where $\Delta \hat{r}$ denotes loop corrections that depend on the top quark and Higgs masses while the renormalized weak mixing angle is defined by modified minimal subtraction $\overline{M S}$ [1199, 1200. The value of $\sin ^{2} 2 \theta_{W}\left(m_{Z}\right) \overline{M S}$ can be determined from parity violating asymmetries and other weak interaction measurements. A comparison of the parameters in equation 6.2 at a high level of precision was used in the past to constrain the top quark mass (before its discovery) and more recently, to provide an upper bound on the Higgs boson mass, the missing particle of the SM. After the Higgs mass is directly measured, equation 6.2 will be used to probe for "new physics" effects at the tree or loop level.

Incorporating $m_{W}=80.398(25) \mathrm{GeV}$ via

$$
\begin{equation*}
\sin ^{2} \theta_{W}\left(m_{Z}\right)_{\overline{M S}}=\frac{\pi \alpha}{\sqrt{2} G_{\mu} m_{W}^{2}\left[1-\Delta r\left(m_{Z}\right)_{\overline{M S}}-0.0085 S-\mathcal{O}(1) m_{W}^{2} / m_{W^{*}}^{2}\right]}, \tag{6.3}
\end{equation*}
$$

with $\Delta r\left(m_{Z}\right)_{\overline{M S}}=0.0696(2)$ representing loop corrections insensitive to $m_{t}$ and $m_{H}$, one has another handle on "new physics" parameters such as $S$ [1201, 1202, a measure of possible new heavy chiral doublets such as a 4 th generation, or $m_{W^{*}}$, the scale of possible Kaluza-Klein excitations.

The most precise determinations of $\sin ^{2} \theta_{W}$ come from two measurements at SLAC [1203] and CERN 1204

$$
\begin{array}{ll}
\sin ^{2} \theta_{W}\left(m_{Z}\right)_{\overline{M S}} & =0.23070(26) \quad(\text { SLAC })  \tag{6.4}\\
\sin ^{2} \theta_{W}\left(m_{Z}\right)_{\overline{M S}} & =0.23193(29) \quad(\text { CERN }),
\end{array}
$$

with both extracting $\sin ^{2} \theta_{W}$ at the Z pole and carrying an error of roughly $0.1 \%$ level. Unfortunately, they disagree by about 3 sigma and therefore, individually provide completely different implications for the Higgs mass and possible "new physics". For example, the SLAC left-right asymmetry result weighs heavily in the leptonic Z pole average which indicates a Higgs mass of

$$
\begin{equation*}
m_{H} \approx 50_{-23}^{+34} \mathrm{GeV} \tag{6.5}
\end{equation*}
$$

Figure 6.1. The past, currently running, and future experiments on extracting $\sin ^{2} \theta_{W}(Q)$.
with the center value significantly below the LEP II direct search limit [3]

$$
\begin{equation*}
m_{H}>114 \mathrm{GeV}(95 \% \mathrm{C} . \mathrm{L} .) . \tag{6.6}
\end{equation*}
$$

On the other hand, the LEP $Z \rightarrow b \bar{b}$ forward-backward asymmetry weights heavily in the hadronic Z pole average which implies a rather heavy Higgs [1205]

$$
\begin{equation*}
m_{H} \approx 480_{-230}^{+350} \mathrm{GeV} \tag{6.7}
\end{equation*}
$$

The often quoted bound $m_{H}<150 \mathrm{GeV}$ results mainly from the Z-pole world average $\sin ^{2} \theta_{W}\left(m_{Z}\right)_{\overline{M S}}=0.23125(16)$. Is the world average correct? We may have to wait and see what the LHC tells us.

In addition to experiments at the Z pole, several precision measurements of $\sin ^{2} \theta_{W}$ have been carried out at lower $Q^{2}$, including atomic parity violation [1206], polarized Moller scattering [1207, and deep-inelastic neutrino scattering [1208], but with uncertainties about an order of magnitude larger, i.e. $\mathcal{O}(1 \%)$. Together all such measurements play an important role in constraining "new physics" appendages to the SM, such as heavy $Z$ ' bosons of $\mathcal{O}(1$ TeV ) and are useful for demonstrating the running of $\sin ^{2} \theta_{W}(Q)$, due to $\gamma-Z$ loop mixing, at about the 6 sigma level.

It is highly desirable to have other experimental extractions of $\sin ^{2} \theta_{W}$ with a precision roughly comparable to Z pole measurements, given the $3 \sigma$ discrepancy between the two best values. Fortunately, several new measurements are in progress or planned at Jefferson lab, including $Q_{\text {weak }}$ using elastic ep scattering [1209] ( $\pm 0.0008$ ), polarized Moller scattering [1210] ( $\pm 0.00025$ ), and SOLID using polarized ed-DIS ( $\pm 0.0006$ ), which aim to extract $\sin ^{2} \theta_{W}$ at low $Q^{2}$ in very high luminosity fixed target experiments. Their projected uncertainties are shown in figure 6.1.

Here, we focus on the feasibility of measuring $\sin ^{2} \theta_{W}$ at high $Q^{2}$ using an Electron-Ion Collider (EIC). Since the center of mass energy of the EIC is expected to be much higher than
fixed target experiments, parity violating asymmetries are larger and, therefore, potentially more sensitive to weak interaction effects. In addition, the EIC enables one to extract $\sin ^{2} \theta_{W}(Q)$ and demonstrate its evolution over a wide range of $Q^{2}$. Those measurements will test the predicted running of $\sin ^{2} \theta_{W}\left(Q^{2}\right)$, improve the world average $\sin ^{2} \theta_{W}\left(m_{Z}\right)_{\overline{M S}}$, and test for "new physics" such as $Z^{\prime}$ bosons via comparison with Z-pole and low $Q^{2}$ results. We demonstrate those capabilities for an EIC with integrated luminosity of $200 \mathrm{fb}^{-1}, \sqrt{s} \approx 140$ GeV and electron (as well as perhaps hadron) polarization. A statistical determination of $\sin ^{2} \theta_{W}\left(Q^{2}\right)$ to about $\pm 0.25 \%$ is found for a range of $Q^{2}$ with overall precision roughly equal to the best Z-pole and proposed polarized $e^{-} e^{-}$measurements.

### 6.2.2 Extracting $\sin ^{2} \theta_{W}$ from parity-violating right-left polarization asymmetries

Various parity violating asymmetries in $e p$ - and $e d$ (deuteron)-DIS can be obtained from ratios of differences and sums of cross-sections with opposite polarizations

$$
\begin{align*}
& d \bar{\sigma}\left(P_{e}, P_{p, d}\right)-d \bar{\sigma}\left(-P_{e},-P_{p, d}\right) \propto  \tag{6.8}\\
& \frac{1}{2} \Sigma_{i} f_{i}(x)\left\{\left(P_{e}+\tilde{f}_{i}(x) P_{p, d}\right)\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)\right. \\
& \left.\quad+\left(P_{e}-\tilde{f}_{i}(x) P_{p, d}\right)\left(d \sigma_{R L}^{i}-d \sigma_{L R}^{i}\right)\right\}
\end{align*}
$$

and

$$
\begin{align*}
& d \bar{\sigma}\left(P_{e}, P_{p, d}\right)+d \bar{\sigma}\left(-P_{e},-P_{p, d}\right) \propto  \tag{6.9}\\
& \frac{1}{2} \Sigma_{i} f_{i}(x)\left\{\left(1+\tilde{f}_{i}(x) P_{e} P_{p, d}\right)\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)\right. \\
& \left.\quad+\left(1-\tilde{f}_{i}(x) P_{e} P_{p, d}\right)\left(d \sigma_{R L}^{i}+d \sigma_{L R}^{i}\right)\right\}
\end{align*}
$$

where $P_{e}$ and $P_{p, d}$ are longitudinal polarizations of the electron and proton (deuteron) beams. The $\alpha$ and $\beta$ in $d \sigma_{\alpha \beta}^{i}(\alpha, \beta=R, L)$ label polarizations of the electron and quark of type $i$, respectively. The $f_{i}(x)$ is the unpolarized parton distribution function and

$$
\begin{equation*}
\tilde{f}_{i}(x) \equiv \Delta f_{i}(x) / f_{i}(x) \tag{6.10}
\end{equation*}
$$

is the ratio of polarized and unpolarized parton distribution function. The quantity $\tilde{f}_{i}(x) P_{p, d}$ can be viewed as the effective quark longitudinal polarization in a polarized proton (deuteron).

The polarized electron-quark cross-sections are proportional to 1211

$$
\begin{align*}
d \sigma_{R R}^{i} & \propto\left(\frac{Q_{R e}^{\gamma} Q_{R i}^{\gamma}}{Q^{2}}+\frac{Q_{R e}^{Z} Q_{R i}^{Z}}{Q^{2}+M_{Z}^{2}}\right)^{2} \\
d \sigma_{L L}^{i} & \propto\left(\frac{Q_{L e}^{\gamma} Q_{L i}^{\gamma}}{Q^{2}}+\frac{Q_{L e}^{Z} Q_{L i}^{Z}}{Q^{2}+M_{Z}^{2}}\right)^{2} \\
d \sigma_{R L}^{i} & \propto\left(\frac{Q_{R e}^{\gamma} Q_{L i}^{\gamma}}{Q^{2}}+\frac{Q_{R e}^{Z} Q_{L i}^{Z}}{Q^{2}+M_{Z}^{2}}\right)^{2}(1-y)^{2} \\
d \sigma_{L R}^{i} & \propto\left(\frac{Q_{L e}^{\gamma} Q_{R i}^{\gamma}}{Q^{2}}+\frac{Q_{L e}^{Z} Q_{R i}^{Z}}{Q^{2}+M_{Z}^{2}}\right)^{2}(1-y)^{2} \tag{6.11}
\end{align*}
$$

Left-handed and right-handed couplings of electrons and quarks to the photon are the same

$$
\begin{equation*}
Q_{L}^{\gamma}=Q_{R}^{\gamma} \equiv Q^{\gamma} \tag{6.12}
\end{equation*}
$$

while those to the $Z$ are different (giving rise to parity violation)

$$
\begin{align*}
Q_{L}^{Z} & =\frac{e}{\sin \theta_{W} \cos \theta_{W}}\left(T_{3 L}-Q^{\gamma} \sin ^{2} \theta_{W}\right) \\
Q_{R}^{Z} & =\frac{e}{\sin \theta_{W} \cos \theta_{W}}\left(-Q^{\gamma} \sin ^{2} \theta_{W}\right) \tag{6.13}
\end{align*}
$$

with

$$
\begin{align*}
& Q_{u}^{\gamma}=\frac{2}{3}, Q_{d}^{\gamma}=-\frac{1}{3}, Q_{e}^{\gamma}=-1, \\
& T_{3 L}^{u}=\frac{1}{2}, T_{3 L}^{d}=T_{3 L}^{e}=-\frac{1}{2} . \tag{6.14}
\end{align*}
$$

For an ep collider, there are two single-polarization parity violating right-left asymmetries

$$
\begin{align*}
A_{e p}^{e} & \equiv \frac{d \bar{\sigma}\left(P_{e}, P_{p}=0\right)-d \bar{\sigma}\left(-P_{e}, P_{p}=0\right)}{d \bar{\sigma}\left(P_{e}, P_{p}=0\right)+d \bar{\sigma}\left(-P_{e}, P_{p}=0\right)}  \tag{6.15}\\
& =P_{e} \frac{\Sigma_{i} f_{i}(x)\left[\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)+\left(d \sigma_{R L}^{i}-d \sigma_{L R}^{i}\right)\right]}{\Sigma_{i} f_{i}(x)\left[\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)+\left(d \sigma_{R L}^{i}+d \sigma_{L R}^{i}\right)\right]}
\end{align*}
$$

and

$$
\begin{align*}
A_{e p}^{p} & \equiv \frac{d \bar{\sigma}\left(P_{e}=0, P_{p}\right)-d \bar{\sigma}\left(P_{e}=0,-P_{p}\right)}{d \bar{\sigma}\left(P_{e}=0, P_{p}\right)+d \bar{\sigma}\left(P_{e}=0,-P_{p}\right)}  \tag{6.16}\\
& =P_{p} \frac{\Sigma_{i} \Delta f_{i}(x)\left[\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)-\left(d \sigma_{R L}^{i}-d \sigma_{L R}^{i}\right)\right]}{\sum_{i} f_{i}(x)\left[\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)+\left(d \sigma_{R L}^{i}+d \sigma_{L R}^{i}\right)\right]}
\end{align*}
$$

with electron and proton separately polarized.
These asymmetries are simplified for an ed collider since the deuteron is an iso-singlet. Restricting to the large $x$ region ( $x>0.2$ ), the anti-quark contributions can be neglected. To first approximation, the parton distributions of $u$ and $d$ quark are the same (up to charge symmetry violation effects) in the deuteron and can thus be factored out of the sum over quark flavors. They then cancel in the asymmetries

$$
\begin{align*}
\left.A_{e d}^{e}\right|_{x>0.2} & \equiv \frac{d \bar{\sigma}\left(P_{e}, P_{d}=0\right)-d \bar{\sigma}\left(-P_{e}, P_{d}=0\right)}{d \bar{\sigma}\left(P_{e}, P_{d}=0\right)+d \bar{\sigma}\left(-P_{e}, P_{d}=0\right)}  \tag{6.17}\\
& =P_{e} \frac{\Sigma_{i}\left[\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)+\left(d \sigma_{R L}^{i}-d \sigma_{L R}^{i}\right)\right]}{\sum_{i}\left[\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)+\left(d \sigma_{R L}^{i}+d \sigma_{L R}^{i}\right)\right]}
\end{align*}
$$

and

$$
\begin{align*}
\left.A_{e d}^{d}\right|_{x>0.2} & \equiv \frac{d \bar{\sigma}\left(P_{e}=0, P_{d}\right)-d \bar{\sigma}\left(P_{e}=0,-P_{d}\right)}{d \bar{\sigma}\left(P_{e}=0, P_{d}\right)+d \bar{\sigma}\left(P_{e}=0,-P_{d}\right)}  \tag{6.18}\\
& =\tilde{f}^{D} P_{d} \frac{\Sigma_{i}\left[\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)-\left(d \sigma_{R L}^{i}-d \sigma_{L R}^{i}\right)\right]}{\Sigma_{i}\left[\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)+\left(d \sigma_{R L}^{i}+d \sigma_{L R}^{i}\right)\right]} .
\end{align*}
$$

Figure 6.2. The right-left asymmetries $A_{e p}^{e}$ and $A_{e d}^{e}$ as functions of $Q$ for $e p$ - and $e d$ - DIS at $\sqrt{s}=140$ GeV with polarized electron $\left(P_{e}=0.8\right)$.

This leads to some simplification in the case of the single-polarization asymmetry $A_{e d}^{e}(x)$ for the $e d$ collider over $A_{e p}^{e}(x)$ for the $e p$ collider. Both $A_{e p}^{e}(x)$ and $A_{e d}^{e}(x)$ are proportional to electron polarization $P_{e}$ and thus carry smaller uncertainties than asymmetries $A_{e p}^{p}(x)$ and $A_{e d}^{d}(x)$ which are proportional to the hadron polarization $P_{p, d}$ which has a larger uncertainty. In fact, the single-polarization asymmetries $A_{e p}^{p}(x)$ and $A_{e d}^{d}(x)$ with a hadron beam polarized would hardly play any role for the purpose of measuring $\sin ^{2} \theta_{W}$ to high precision due to the large uncertainty in $P_{p, d}$ expected to be $\mathcal{O}( \pm 5 \%)$. Instead, hadron polarization (or quark polarization) may be precisely determined from the asymmetries.

The double-polarization asymmetries

$$
\begin{align*}
& A_{e p, e d}^{e p, e d} \equiv \frac{d \bar{\sigma}\left(P_{e}, P_{p, d}\right)-d \bar{\sigma}\left(-P_{e},-P_{p, d}\right)}{d \bar{\sigma}\left(P_{e}, P_{p, d}\right)+d \bar{\sigma}\left(-P_{e},-P_{p, d}\right)}  \tag{6.19}\\
= & \frac{\Sigma_{i} f_{i}(x)\left\{\left(P_{e}+\tilde{f}_{i}(x) P_{p, d}\right)\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)+\left(P_{e}-\tilde{f}_{i}(x) P_{p, d}\right)\left(d \sigma_{R L}^{i}-d \sigma_{L R}^{i}\right)\right\}}{\Sigma_{i} f_{i}(x)\left\{\left(1+\tilde{f}_{i}(x) P_{e} P_{p, d}\right)\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)+\left(1-\tilde{f}_{i}(x) P_{e} P_{p, d}\right)\left(d \sigma_{R L}^{i}+d \sigma_{L R}^{i}\right)\right\}}
\end{align*}
$$

for both $e p$ and ed collider running depend on hadron polarization; however, there are circumstances for which the asymmetry can be simplified and carry a reduced uncertainty. First, the $d \sigma_{R L, L R}$ are proportional to $(1-y)^{2}$ and thus suppressed in the kinematic region $y \rightarrow 1$. Second, the double-polarization asymmetry can be further simplified for a ed collider at large $x$. As a result, the asymmetry

$$
\begin{equation*}
\left.A_{e d}^{e d}\right|_{y \rightarrow 1, x>0.2} \approx P_{\text {eff. }} \frac{\Sigma_{i}\left(d \sigma_{R R}^{i}-d \sigma_{L L}^{i}\right)}{\Sigma_{i}\left(d \sigma_{R R}^{i}+d \sigma_{L L}^{i}\right)} \tag{6.20}
\end{equation*}
$$

is proportional to the effective polarization

$$
\begin{equation*}
P_{\text {eff. }} \equiv \frac{P_{e}+\tilde{f}(x) P_{d}}{1+\tilde{f}(x) P_{e} P_{d}} \tag{6.21}
\end{equation*}
$$

which carries a reduced fractional uncertainty.
From the above discussion, it is clear that with regard to precision $\sin ^{2} \theta_{W}$ measurements, the most useful asymmetries are the two single-polarization asymmetries $A_{e p}^{e}$ and $A_{e d}^{e}$ with only the electron polarized for $e p$ and $e d$ collisions, respectively, and the double-polarization

Figure 6.3. The figure of merit of measuring the asymmetries $A_{e p}^{e}$ and $A_{e d}^{e}$ at an $e p$ and $e d$ collider with $\sqrt{s}=140 \mathrm{GeV}$ and polarized electron $\left(P_{e}=0.8\right)$, integrated luminosity of $200 \mathrm{fb}^{-1}$, for bin size of 10 GeV . A cut of $x>0.2$ is imposed for ed collisions.
asymmetry $A_{e d}^{e d}$ for the $e d$ collision, since they carry the smallest systematic polarization errors.

In general, the high energy EIC gains some advantage over experiments at low energy. For example, the error from higher $1 / Q^{2}$ twist effects should be negligible at high $Q$. In addition, since the uncertainty from parton distributions largely cancel in $A_{e d}^{e}$, the major source of systematic error comes from the polarization of electron beam $P_{e}$ which is expected to carry an uncertainty of roughly $\pm 0.5 \%$. This leads to an uncertainty of $\pm 0.5 \%$ in the single-polarization asymmetries $A_{e p, e d}^{e}$ and roughly $\pm 0.25 \%$ in $\sin ^{2} \theta_{W}$. One possible way to obtain some leverage on extracting $\sin ^{2} \theta_{W}$ with further reduced systematic error is to make use of the $y$ dependence to extract the term proportional to the vector coupling $g_{V}^{e} \propto 1-4 \sin ^{2} \theta_{W}$ of electrons to the $Z$ boson. It is well known that this coupling is very sensitive to $\sin ^{2} \theta_{W}$. An accuracy of $1 \%$ of the asymmetry proportional to this coupling determines $\sin ^{2} \theta_{W}$ at the $0.1 \%$ level. This may help with the systematic precision but unlikely with the statistical one since the latter would decrease in extracting various pieces from the $y$ dependence. To assess the statistic error in measuring $\sin ^{2} \theta_{W}$, we carry out a Monte Carlo simulation for polarized ep- and ed- DIS at $\sqrt{s}=140 \mathrm{GeV}$ as an example. We use the parton distribution functions of CTEQ6L 82]. We have included $u$ and $d$ quark and anti-quark contributions. For ed-DIS, a cut of $x>0.2$ is imposed to suppress the anti-quark contribution as needed to simplify the asymmetry in equation 6.17. We show the asymmetries $A_{e p}^{e}$ and $A_{e d}^{e}$ for $e p$ and $e d$ collider with polarized electron $\left(P_{e}=0.8\right)$ in figure 6.2. The asymmetries grow with $Q$ and reach $14 \%$ and $17 \%$ for $Q \approx 70 \mathrm{GeV}$, for ep and ed collisions, respectively.

Based on these polarized cross-sections, one can further obtain the statistical figure of merit (F.O.M.) $A^{2} N /\left(1-A^{2}\right) \approx A^{2} N$ for measuring the asymmetry and the statistical errors for a given luminosity. In figure 6.3, we show the figure of merit for $e p$ and $e d$ collisions with integrated luminosity of $200 \mathrm{fb}^{-1}$ as function of $Q$, with bin size of 10 GeV .

The corresponding statistical errors, $\Delta A / A \approx\left(A^{2} N\right)^{-1 / 2}$, are shown in figure 6.4 for $e p$ and $e d$ colliders. For an ed collider, the energy of the deuteron beam is shared by the proton and neutron, thus effectively the CM energy for e-nucleon is reduced from 140 GeV to roughly 100 GeV . For both $e p$ and ed collider, with 10 GeV bin, the statistical error is about $\pm 0.5 \%$ for $Q$ between 10 and 50 GeV . For $Q>50$ and $Q<10 \mathrm{GeV}$ region, the statistical error is significantly higher. However, a smaller error is achievable for $Q>50$

Figure 6.4. The statistical error expected for the asymmetries $A_{e p}^{e}$ and $A_{e d}^{e}$ for $e p$ and $e d$ collider at $\sqrt{s}=140 \mathrm{GeV}$ with polarized electron $\left(P_{e}=0.8\right)$, and with luminosity of $200 \mathrm{fb}^{-1}$, for bin size of 10 GeV . A cut of $x>0.2$ is imposed for $e d$ collider. The statistical error for $\sin ^{2} \theta_{W}(Q)$ is roughly $1 / 2$ the percentage error on $A_{e p}^{e}$ or $A_{e d}^{e}$.

GeV region if a larger bin is used. Overall, the error in extracting $\sin ^{2} \theta_{W}$ is roughly half of the error in the asymmetry. Therefore, the statistical error in extracting $\sin ^{2} \theta_{W}$ for most of the $Q$ region between a few GeV and Z-pole is below $\pm 0.25 \%$ level.

### 6.2.3 Conclusions

The advantage of measuring $\sin ^{2} \theta_{W}$ at a polarized EIC lies in its high $Q^{2}$, which enhances the parity violating asymmetry, reduces some of the uncertainty from higher twist effects, and most importantly enables one to extract $\sin ^{2} \theta_{W}$ over a wide range of $Q$ from a few GeV to $Q \approx m_{Z}$. We demonstrated the capability of measuring $\sin ^{2} \theta_{W}$ for an EIC with integrated luminosity of $200 \mathrm{fb}^{-1}, \sqrt{s} \approx 140 \mathrm{GeV}$ and electron (as well as perhaps hadron) polarization. A statistical determination of $\sin ^{2} \theta_{W}\left(Q^{2}\right)$ to about $\pm 0.25 \%$ is found for most of the region of $Q$ with overall precision roughly equal to the best Z-pole measurements. In figure 6.1, we have plotted values of $\sin ^{2} \theta_{W}(Q)$ obtained from past, ongoing and planned as well a possible EIC measurements. The running of $\sin ^{2} \theta_{W}(Q)$ is based on ref. 1212, 1213. The error bar for EIC measurements only represents the statistical error based on figure 6.4. A combination of all the measurements of $\sin ^{2} \theta_{W}$ at various scales will play very important roles in revealing the physics behind EWSB and other "new physics".

### 6.3.1 Introduction and Motivation

Every conservation law in the Standard Model (SM) is anticipated to have a symmetry associated with it. We have no knowledge of a symmetry that asserts Lepton Flavor Conservation in the Standard Model (SM) of particle physics and yet its (direct) violation has never been seen. Although discovery of neutrino oscillations [1214, 1215] indicates that charged Lepton Flavor Violation (LFV) processes such as $\mu \rightarrow e \gamma$ should be allowed (within the SM), its rate is expected to be very small $\left(\operatorname{BR}(\mu \rightarrow e \gamma)<10^{-54}\right)$ due to the very small values of the neutrino masses. This level of sensitivity is beyond the reach of any present or planned experiment. However, many models of physics Beyond the SM (BSM) predict rates of charged lepton flavor violation significantly higher than those within the SM, some of them even within the reach of present or planned experiments. LFV hence becomes a very attractive process for experimental discovery of physics beyond the Standard Model.

Many searches for specific reactions which violate lepton flavor have been performed. The most sensitive include searches for $\mu+N \rightarrow e+N$ using low energy muons (from the SINDRUM II collaboration [1216]), the muon decay $\mu \rightarrow e \gamma$ (MEGA collaboration [1217, [1218]), and decays of kaons ( 1219 ). The limits from these processes, though extremely precise, are all sensitive to $e \leftrightarrow \mu$ transitions (abbreviated $\operatorname{LFV}(1,2)$ ) and not to $e \leftrightarrow \tau$ transitions (LFV(1,3)). Also, each of these processes involve specific quark flavors: in some, only the 1st generation quarks participate; in others the same quark flavor must couple to the initial and final leptons, or strange quarks must participate. These stringent bounds are related to the opportunities for such searches afforded by specific experimental apparatuses. None of these searches involved the $\tau$ lepton either in the initial or in the final state. Since a general model with lepton flavor violation may involve a $\tau$ lepton and also initial and final state quarks of different flavors (not necessarily including strange quarks), the above measurements would be blind to such LFV mechanisms. Existing best limits on $e \leftrightarrow \tau$ conversion come from the BaBar Collaboration $(\tau \rightarrow e \gamma)$ 1220 and the BELLE Collaboration $(\tau \rightarrow 3 e)$ [1221. These are notably worse than the limits on $e \leftrightarrow \mu$ by several orders of magnitude. LFV searches at proposed future experiments would further improve limits on $e \leftrightarrow \mu$ transitions.

The search for LFV involving $\tau$ leptons has been performed by the high energy lepton - hadron collider experiments H1 and ZEUS. The LFV process could proceed via exchange of a leptoquark (LQ), a color triplet boson - scalar or vector - with both lepton and baryon quantum numbers which appears naturally in many extensions of the SM such as GUTs, supersymmetry, compositeness, and technicolor (for a concise review of LFV in several such models, see [1222]). The most recent limits on the search for $e p \rightarrow \mu X$ and $e p \rightarrow \tau X$ were set by the H1 collaboration using HERA collisions at 320 GeV center-of-mass energy and an integrated luminosity of $0.5 \mathrm{fb}^{-1}$. They did not find any evidence for lepton flavor violation [1223, 1224], and in turn they put limits on the mass and couplings of the leptoquarks in the Buchmüller-Rückl-Wyler (BRW) effective model 1225 .

A high energy, high luminosity electron-proton/ion collider (EIC) is being considered by the US nuclear science community with a variable center-of-mass energy of $50 \rightarrow 160$ GeV and with $100-1000$ times the accumulated luminosity of HERA over a comparable operation time, see sections 7.1 and 7.2 . In a recent study [1226] it has been argued that a

90 GeV center-of-mass e-p collider with $10 \mathrm{fb}^{-1}$ of integrated luminosity could set a limit on leptoquark coupling-over-mass ratios that would surpass the current best limits from HERA experiments. The study also shows that the proposed EIC could compete or surpass the updated leptoquark limits from $\tau \rightarrow e \gamma$ for a subset of quark flavor diagonal couplings. Lastly, the authors found that although $e \rightarrow \tau$ LFV is indeed severely suppressed, $e \rightarrow \tau$ transition could still exist within the reach of the EIC, under certain situations [1226]. The present study of search for leptoquarks at the EIC was motivated by these exciting possibilities.

For completeness, we studied leptoquark couplings with first, second and third generation leptons ( $e \rightarrow e, \mu, \tau$ ) in our simulations, although the main focus of this study was the $e \rightarrow \tau$ transition. We comment here on all three.

1. Leptoquark decays to first generation leptons lead to final states similar to those in SM deep inelastic scattering (DIS) neutral current (NC, ep $\rightarrow e X$ ) and charged current $(\mathrm{CC}, e p \rightarrow \nu X)$ interactions. These processes contribute as backgrounds by mimicking the final state signature of the signal events, and hence are indistinguishable. Other SM backgrounds arise from photo-production $\gamma p \rightarrow X$, lepton-pair production (ep $\rightarrow$ $e l^{+} l^{-} X$ ), and W production ( $e p \rightarrow e W X$ ). We simulate them and study the angular correlations of the final states and the missing momentum spectra in cases where neutrinos are involved in the final state. Possibilities of misidentification of events due to detector inefficiencies will be commented upon in section 6.3.7,
2. Leptoquark decays with a $\mu$ in the final state give a back-to-back muon and hadronic system event characteristic in the transverse plane. Since muons typically deposit a very small fraction of their energy in a calorimeter, in real experiments, such events are characterized by a large missing calorimetric transverse momentum. Additionally, such muons are typically required to be isolated, well separated from the hadronic jets or tracks in such an event. Such selections strongly suppress the NC component of the SM backgrounds, which mainly arise from muon-pair production and muonic decays of W bosons. See details in [1223, 1224].
3. The $1 \rightarrow 3$ transition, ep $\rightarrow \tau X$, is the principle focus of this study; it is studied using three $\tau$ decay channels: electronic, muonic and hadronic. Electronic decays $\tau \rightarrow e \nu_{e} \nu_{\tau}$ have a topology similar to high $Q^{2} \mathrm{NC}$ events, except for missing transverse momentum due to the escaping neutrinos, which can be exploited to reduce this background. Muonic decays $\tau \rightarrow \mu \nu_{\mu} \nu_{\tau}$ result in similar final states as the electronic decay of $\tau$ and hence a similar criteria for their selection is used. Hadronic decays of $\tau$ lead to a high transverse momentum, narrow jet resulting in a signal topology of a di-jet event with no leptons. These events can be selected using various well known algorithms to identify and separate the $\tau$-jet from other hadronic jets in NC DIS and photoproduction events.

Many of the above mentioned strategies require detailed detector simulation of the response. This is not done in the present study. However, we studied the event topologies of the SM processes and the leptoquark events through simulations with beam energies and detector acceptance guidelines suggested on the INT website [131. The differences in event topologies generated by $p_{T}^{\text {miss }}$ (the missing transverse momentum) and the angle $\phi$ (between the $\tau$-jet and the missing transverse momentum vector) present in SM and LQ events with final state neutrinos were studied. We ask in this study: are they different enough to be
distinguishable from one another at the EIC energies, and for what range of leptoquark couplings and masses could the LFV LQ events be differentiated from a SM event at the EIC.

This report proceeds as follows. In section 6.3.2, the leptoquark framework is introduced and the findings of [1226] are summarized and updated to reflect recent developments regarding higher EIC integrated luminosities and the proposed reach of Super-B experimental searches for $\tau \rightarrow e \gamma$. Section 6.3.3 discusses the possibility of $e \rightarrow \tau$ searches at the EIC in the broader context of an effective operator framework. Concluding remarks for the theoretical analysis are presented in section 6.3.4. An experimental analysis begins with section 6.3.5 in which we present the SM process generation and its study for the above correlations. In section 6.3.6 we detail the MC generator study for the leptoquark and study some of its parameters (leptoquark mass dependence and the coupling strength dependence) on the observable missing $p_{T}$ and $\phi$ spectra. In section 6.3.7 we compare some of the selected spectra from SM and the leptoquark and show potentially how leptoquarks may be identified at a future EIC. We then conclude with a comment on the limitations of this study and a brief plan for the near future.

### 6.3.2 Theory I: Leptoquark Framework

We begin our study of $e \rightarrow \tau$ conversion at the EIC by assuming a leptoquark framework. Leptoquarks (abbreviated LQs) are particles coupling to leptons and quarks which arise in models such as Pati-Salam color- $S U(4)$ and $S U(5)$ GUTs. Leptoquarks provide a useful framework for an initial analysis of $e \rightarrow \tau$ conversion because they allow for the conversion process to occur at tree level, as described further below, and so larger cross sections may be expected relative to other models which induce LFV through loop effects. Additionally, searches for leptoquark-induced $e \rightarrow \tau$ were performed at HERA, and so direct comparisons can be made between limits from HERA and potential limits from the EIC.

The class of particles which may be described as "leptoquarks" have a variety of properties: spin 0 or 1 ; fermion number $F=3 B+L=0$ or $\pm 2 ; S U(2)_{L}$ singlet, doublet, or triplet representations; and chiral couplings to $L$ - or $R$-handed leptons. We use the Buchmüller-Rückl-Wyler (BRW) parameterization of LQs 1225. In this parameterization, there are 14 different LQs encompassing all allowed combinations of the listed properties; their interactions with quarks and leptons are given by the renormalizable SM gauge-invariant Lagrangian in equation (6.22).

$$
\begin{align*}
\mathcal{L}_{L Q}= & \mathcal{L}_{F=0}+\mathcal{L}_{|F|=2} \\
\mathcal{L}_{F=0}= & h_{1 / 2}^{L} \bar{u}_{R} \ell_{L} S_{1 / 2}^{L}+h_{1 / 2}^{R} \bar{q}_{L} \epsilon e_{R} S_{1 / 2}^{R}+\tilde{h}_{1 / 2}^{L} \bar{d}_{R} \ell_{L} \tilde{S}_{1 / 2}^{L} \\
& \quad+h_{0}^{L} \bar{q}_{L} \gamma_{\mu} \ell_{L} V_{0}^{L^{\mu}}+h_{0}^{R} \bar{d}_{R} \gamma_{\mu} e_{R} V_{0}^{R \mu}+\tilde{h}_{0}^{R} \bar{u}_{R} \gamma_{\mu} e_{R} \tilde{V}_{0}^{R \mu} \\
& \quad+h_{1}^{L} \bar{q}_{L} \gamma_{\mu} \vec{\tau} \ell_{L} \vec{V}_{1}^{L \mu}+\text { h.c. }  \tag{6.22}\\
\mathcal{L}_{|F|=2}= & g_{0}^{L} \bar{q}_{L}^{c} \epsilon \ell_{L} S_{0}^{L}+g_{0}^{R} \bar{u}_{R}^{c} e_{R} S_{0}^{R}+\tilde{g}_{0}^{R} \bar{d}_{R}^{c} e_{R} \tilde{S}_{0}^{R}+g_{1}^{L} \bar{q}_{L}^{c} \epsilon \vec{\tau} \ell_{L} \vec{S}_{1}^{L} \\
& \quad+g_{1 / 2}^{L} \bar{d}_{R}^{c} \gamma_{\mu} \ell_{L} V_{1 / 2}^{L \mu}+g_{1 / 2}^{R} \bar{q}_{L}^{c} \gamma_{\mu} e_{R} V_{1 / 2}^{R \mu} \\
& \quad+\tilde{g}_{1 / 2}^{L} \bar{u}_{R}^{c} \gamma_{\mu} \ell_{L} \tilde{V}_{1 / 2}^{L \mu}+\text { h.c. }
\end{align*}
$$

In equation (6.22), $q_{L}$ and $\ell_{L}$ are the $S U(2)_{L}$ doublet quarks and leptons, $u_{R}, d_{R}, e_{R}$ are the $S U(2)_{L}$ singlet quarks and charged lepton, $\epsilon$ is the $S U(2)_{L}$ antisymmetric tensor $\left(\epsilon_{12}=-\epsilon_{21}=+1\right), \vec{\tau}=\left(\tau_{1}, \tau_{2}, \tau_{3}\right)$ are the Pauli matrices, and the charge conjugated fermion
is defined as $\psi^{c} \equiv C \bar{\psi}^{T}=i \gamma_{2} \gamma_{0} \bar{\psi}^{T}$ in the Dirac basis for the $\gamma$ matrices. Color, $S U(2)_{L}$, and flavor (generation) indices have been suppressed. We follow the notation used in the recent literature where spin-0 leptoquarks are $S$ and spin-1 are $V$, the subscript indicates the $S U(2)_{L}$ quantum number ( 0 for a singlet, $1 / 2$ for a doublet, 1 for a triplet), the superscript $L, R$ indicates the chirality of the lepton coupling to the leptoquark, and a tilde ( ${ }^{( }$) is used to distinguish between leptoquarks which have different hypercharges but are otherwise identical. The dimensionless coupling constants $g$ and $h$ (which we assume to be real) carry the same lepton chirality and $S U(2)_{L}$ labels as their associated leptoquarks. Lepton flavor violating processes mediated by LQs arise if the couplings - which are matrices in flavor space - have non-zero off-diagonal elements.

The $e \rightarrow \tau$ conversion process mediated by LQs is shown at the partonic level in the Feynman diagrams in figure 6.5. For simplicity, the couplings $g$ and $h$ in equation (6.22) have been replaced by $\lambda_{i j}$ where the first index corresponds to the lepton generation and the second index the quark generation. The cross section for the deep inelastic scattering conversion process $e^{-}+p \rightarrow \tau^{-}+X$ mediated by a single leptoquark is calculated using the Feynman rules derived from the Lagrangian of equation (6.22) and convoluting the partonic subprocess with the appropriate parton distribution functions for the initial state quark or antiquark. In the high mass approximation, where the LQ mass is much larger than the center-of-mass energy and all fermion masses are neglected, the momentum dependence of the LQ propagator can be neglected, effectively shrinking the propagator to a four fermion contact interaction. The cross section is then given by [1227]

$$
\begin{align*}
\sigma_{F=0}= & \sum_{\alpha, \beta} \frac{s}{32 \pi}\left[\frac{\lambda_{1 \alpha} \lambda_{3 \beta}}{M_{L Q}^{2}}\right]^{2}\left\{\int d x d y x \bar{q}_{\alpha}(x, x s) f(y)\right. \\
& \left.+\int d x d y x q_{\beta}(x,-u) g(y)\right\}, \\
\sigma_{|F|=2}=\sum_{\alpha, \beta} \frac{s}{32 \pi} & {\left[\frac{\lambda_{1 \alpha} \lambda_{3 \beta}}{M_{L Q}^{2}}\right]^{2}\left\{\int d x d y x q_{\alpha}(x, x s) f(y)\right.}  \tag{6.23}\\
& \left.+\int d x d y x \bar{q}_{\beta}(x,-u) g(y)\right\} .
\end{align*}
$$

The functions $f$ and $g$ are defined differently for scalar and vector leptoquarks:

$$
f(y)=\left\{\begin{array}{cc}
1 / 2 & (\text { scalar })  \tag{6.24}\\
2(1-y)^{2} & (\text { vector })
\end{array} \quad, g(y)=\left\{\begin{array}{cc}
(1-y)^{2} / 2 & \text { (scalar) } \\
2 & \text { (vector) }
\end{array} .\right.\right.
$$

The parton distribution functions for the quarks and antiquarks are $q\left(x, Q^{2}\right)$ and $\bar{q}\left(x, Q^{2}\right)$, respectively, evaluated at momentum fraction $x$ and energy scale $Q^{2}$. Also, $u=x s(y-1)$ and both $x$ and $y$ are integrated from 0 to 1 . As equation (6.23) shows, in the high mass approximation the unknown leptoquark couplings and masses appear in the cross section as the ratio $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$.

In the $e^{ \pm} p$ collisions at HERA, no $e \rightarrow \tau$ conversion events were observed. Limits on the LQ ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ were set by both the ZEUS [1228] and H1 [1224] collaborations. In our analysis, we determine how the EIC might improve on these limits set by ZEUS and H1 by answering the question, to what values of the ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ would the EIC be sensitive? As with the ZEUS and H1 analyses, we consider all combinations of the quark

Figure 6.5. Feynman diagrams showing the leptoquark-mediated $e \rightarrow \tau$ conversion process. $\alpha$ and $\beta$ are the quark generation indices.
generations $\alpha$ and $\beta$ (excluding the top quark) for all 14 BRW leptoquarks. It is assumed that one of the BRW LQs dominates the cross section and the LQs in $S U(2)_{L}$ multiplets are degenerate in mass. Full results of this analysis can be found in [1226]; in this report, we summarize the results and discuss a few representative examples.

With $1000 \mathrm{fb}^{-1}$ of integrated luminosity (attainable within a reasonable length of time at a high luminosity machine such as the EIC), the EIC would in principle be sensitive to $e \rightarrow \tau$ conversion cross sections at a level of 0.001 fb 1 This would yield on the order of one $e \rightarrow \tau$ conversion events (not accounting for backgrounds, $\tau$ reconstruction efficiency, etc.). Using this number for the cross section, and assuming a center-of-mass energy $\sqrt{s}=90 \mathrm{GeV}$, the LQ ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ can be calculated from equation (6.23). Generally, for nearly all leptoquarks and combinations of quark generations $\alpha$ and $\beta$, the EIC could probe values of the ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ that are smaller than the HERA limits by a factor between 10 and 200. This is demonstrated for the LQ $S_{0}^{R}$ in figures 6.6 and 6.7 where the cross sections for the different quark generation combinations $(\alpha \beta)$ are plotted as a function of the number $z$, defined to be the LQ ratio $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ scaled by the corresponding HERA limit. For example, the cross section for first generation initial and final state quarks (the red line in figure (6.6) is equal to 0.001 fb at $z \simeq 0.05$. This means that the EIC could improve the HERA limit on the ratio $\lambda_{11} \lambda_{31} / M_{L Q}^{2}$ for the leptoquark $S_{0}^{R}$ by as much as a factor of 20 ; or, if such a leptoquark exists and has properties such that $\lambda_{11} \lambda_{31} / M_{L Q}^{2}$ is between 0.05 and 1 times the HERA limit, this LQ could induce a number of $e \rightarrow \tau$ conversion events sufficiently large enough to be observed at the EIC.

Also shown in figure 6.6 are the values of the LQ ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ (again scaled by the HERA limits) to which future Super-B experiments may be sensitive ${ }^{2}$; these are indicated

[^283]

Figure 6.6. The $e \rightarrow \tau$ cross section for the leptoquark $S_{0}^{R}$ plotted as a function of $z$, defined to be the ratio $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ scaled by the HERA limit. A cross section of 0.001 fb , corresponding to order 1 events with $1000 \mathrm{fb}^{-1}$ integrated luminosity, is indicated with a gray dashed line. The cross section is plotted for the different quark generation combinations, $(\alpha \beta)$. Shown here are the quark flavor-diagonal contributions with $\alpha=\beta$. The vertical dashed lines indicate the range of these ratios to which the Super-B experiments may be maximally sensitive from $\tau \rightarrow e \gamma$ searches.

Figure 6.7. As for figure 6.6] but shown here are the quark flavor-off-diagonal contributions with $\alpha \neq \beta$. No $\tau \rightarrow e \gamma$ limits exist in this case.

Figure 6.8. Feynman diagrams showing the leptoquark loops contributing to the $\tau \rightarrow e \gamma^{*}$ process.
with vertical dashed lines in the figure. The scalar leptoquarks can contribute to the $\tau \rightarrow e \gamma$ decay through loop diagrams shown in figure $\left[6.83^{3}\right.$ Limits on the LQ ratios are derived as follows. The amplitude for the process $\tau \rightarrow e \gamma^{*}$ has the general form [1229]

$$
\begin{align*}
& \mathcal{M}_{\tau \rightarrow e \gamma^{*}}=e \epsilon^{* \nu} \bar{u}_{e}\left(p^{\prime}\right)\left[\left(q^{2} \gamma_{\nu}-q_{\nu}(q \cdot \gamma)\right)\left(A_{1}^{L} P_{L}+A_{1}^{R} P_{R}\right)\right. \\
&\left.+i m_{\tau} q^{\alpha} \sigma_{\nu \alpha}\left(A_{2}^{L} P_{L}+A_{2}^{R} P_{R}\right)\right] u_{\tau}(p), \tag{6.25}
\end{align*}
$$

where the $A_{1} \mathrm{~s}$ and $A_{2}$ s are model-dependent factors. For a real photon, $q^{2}=0$, and so $|\mathcal{M}|^{2}$ depends only on the factors $A_{2}^{L, R}$. Then, the $\tau$ decay rate ratio is given by

$$
\begin{equation*}
R(\tau \rightarrow e \gamma) \equiv \frac{\Gamma\left(\tau^{-} \rightarrow e^{-} \gamma\right)}{\Gamma\left(\tau^{-} \rightarrow e^{-} \bar{\nu}_{e} \nu_{\tau}\right)}=\frac{48 \pi^{3} \alpha_{E M}}{G_{\mu}^{2}}\left(\left|A_{2}^{L}\right|^{2}+\left|A_{2}^{R}\right|^{2}\right) . \tag{6.26}
\end{equation*}
$$

Recent work by the BABAR collaboration [1220] has set a $90 \%$ C.L. limit $\Gamma(\tau \rightarrow e \gamma) / \Gamma_{\text {total }} \leq$ $3.3 \times 10^{-8}$. The current consensus is that future Super-B experiments will be able to improve this limit by a single order of magnitude, and so we take $R \leq 1.85 \times 10^{-8}$. The coefficients $A_{2}^{L}$ and $A_{2}^{R}$ can be determined for each scalar leptoquark by computing the amplitude for the $\tau \rightarrow e \gamma$ loop diagrams and picking out terms proportional to the magnetic moment operator $q^{\alpha} \sigma_{\nu \alpha}$. When neglecting the lepton masses and expanding in powers of $m_{q}^{2} / M_{L Q}^{2}$, at zeroth order the $A_{2}$ s will depend on a sum over $\alpha$ of the ratios $\lambda_{1 \alpha} \lambda_{3 \alpha} / M_{L Q}^{2}$ (here, $\alpha=\beta$ since there is only one quark present in the loop). Thus, the experimental limit on $R$ determines a range of upper limits on the LQ ratios: the stronger upper limit is set by assuming all three quark generations contribute to the $A_{2}$ coefficients equally, while the weaker upper limit assumes only a single quark generation contributes to the $A_{2}$ coefficients. Both upper limits on $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ (again scaled by the HERA limit) are indicated by vertical dashed lines for each quark generation in figure 6.6.

As figure 6.6 shows for the $S_{0}^{R}$ LQ, the EIC could potentially surpass upper limits on the LQ ratios derived from an improved Super-B factory $\tau \rightarrow$ er limit. For the other scalar leptoquarks, it is generally true that the EIC would be competitive with or surpass the future limits from Super-B factories. The EIC also has two additional advantages over $\tau \rightarrow e \gamma$ searches. First, $\tau \rightarrow e \gamma$ only constrains those leptoquark ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$ for which $\alpha=\beta$, while the EIC can probe all combinations of quark generations. Second, it is possible for the LQ-induced $\tau \rightarrow e \gamma$ to be suppressed relative to $e \rightarrow \tau$ conversion: the first non-zero contribution to the $A_{2}$ coefficient may be proportional to $m_{q}^{2} / M_{L Q}^{2} \ll 1$ because of a cancellation of electric charges in the zeroth order term. Under these circumstances, the $\tau \rightarrow e \gamma$ yields relatively weak upper bounds on the LQ ratios. This occurs for the scalar leptoquark $\tilde{S}_{1 / 2}^{L}$.

Finally, we discuss the impact of $\operatorname{LFV}(1,2)$ searches on the leptoquark limits. As in the case of the effective operators below, a priori there is nothing in the BRW leptoquark parameterization that relates the LQ couplings to second generation leptons to LQ couplings to third generation leptons. Therefore, experimental limits on $\mu \rightarrow e$ conversion, $\mu \rightarrow e \gamma$, and $\mu \rightarrow 3 e$ do not necessarily affect the expected size of the cross sections expected for leptoquark-mediated $e \rightarrow \tau$ conversion at the EIC. Only by considering a specific model with an additional symmetry does a connection between LQ-induced $\operatorname{LFV}(1,2)$ and $\operatorname{LFV}(1,3)$ exist. An example is the $S U(5)$ GUT studied in [1230, 1231]. The leptoquark present in this model has the same spin and gauge group quantum numbers as the BRW leptoquark $\tilde{S}_{1 / 2}^{L}$.

[^284]

Figure 6.9. Feynman diagrams showing the contributions of the magnetic moment $\left(\mathcal{O}_{\sigma L, R}\right)$, four lepton $\left(\mathcal{O}_{\ell L, R}\right)$, and four fermion $\left(\mathcal{O}_{\ell q}\right)$ operators to the $e \rightarrow \tau$ conversion process.

As mentioned above, this particular LQ evades limits from $\tau \rightarrow e \gamma$ as well as $\mu \rightarrow e \gamma$ for the same reason. Additionally, the $S U(5)$ symmetry implies that the leptoquark couplings are proportional to the neutrino mixing angles and squared mass differences, and the stringent experimental bounds on $\mu \rightarrow e$ conversion further constrain the LQ couplings. Imposing all of these limits, the LQ couplings can still yield an $e \rightarrow \tau$ conversion cross section within reach of the EIC with $1000 \mathrm{fb}^{-1}$ integrated luminosity (for details, see [1231, [1226]). In particular, the $e^{-}+p \rightarrow \tau^{-}+X$ cross section is dominated by the partonic subprocess $e+d \rightarrow \tau+b$, implying that a $\tau$ plus a $b$-jet may be a unique experimental signatature of this particular $S U(5)$ GUT at the EIC.

### 6.3.3 Theory II: Effective Operators

We now examine the $e \rightarrow \tau$ conversion process at the EIC from the perspective of model-independent effective operators. A complete list of $S U(3)_{C} \times S U(2)_{L} \times U(1)_{Y}$ gaugeinvariant dimension- 5 and -6 operators built from the SM field content can be found in [1232] (for an updated list, see [1233]). There are three classes of operators which can contribute to $e \rightarrow \tau$ conversion and are of particular interest [1234, 1235]:

1. magnetic moment operators (written here after electroweak symmetry breaking)

$$
\begin{equation*}
\mathcal{O}_{\sigma L}=i m_{j} \bar{\ell}_{L i} \sigma^{\mu \nu} \ell_{R j} F_{\mu \nu}+\text { h.c. } ; \tag{6.27}
\end{equation*}
$$

2. four lepton operators

$$
\begin{equation*}
\mathcal{O}_{\ell L}=\bar{\ell}_{L i} \ell_{L j}^{C} \bar{\ell}_{L k}^{C} \ell_{L m} ; \tag{6.28}
\end{equation*}
$$

3. four fermion (two quark, two lepton) operators

$$
\begin{equation*}
\mathcal{O}_{\ell q}=\bar{\ell}_{i} \Gamma_{\ell} \ell_{j} \bar{q} \Gamma_{q} q \tag{6.29}
\end{equation*}
$$

We use indices $i, j, k, l$ to indicate the lepton generations and suppress the gauge group indices; the superscript ${ }^{C}$ indicates charge conjugation. Note that analogous operators with right-handed fields can also be constructed. These operators can contribute to the deep inelastic electron-to-tau conversion process, as shown in figure 6.9,

The leptonic current for the photon exchange diagrams in figure 6.9 (left and middle) has a general parameterization similar to the $\tau \rightarrow e \gamma$ amplitude in equation (6.25):

$$
\begin{align*}
j^{\mu}= & \bar{u}_{e}\left[\left(q^{2} \gamma^{\mu}-q^{\mu}(q \cdot \gamma)\right)\left(A_{1}^{L} P_{L}+A_{1}^{R} P_{R}\right)\right.  \tag{6.30}\\
& \left.+i m_{\tau} q_{\nu} \sigma^{\mu \nu}\left(A_{2}^{L} P_{L}+A_{2}^{R} P_{R}\right)\right] u_{\tau}
\end{align*}
$$

| $\tau \rightarrow 3 e$ | $\Gamma\left(\tau^{-} \rightarrow e^{-} e^{+} e^{-}\right) / \Gamma_{\text {total }}<3.6 \times 10^{-8}$ |
| :--- | :--- |
| $\tau \rightarrow e \mu \mu$ | $\Gamma\left(\tau^{-} \rightarrow e^{-} \mu^{+} \mu^{-}\right) / \Gamma_{\text {total }}<3.7 \times 10^{-8}$ |
| $\tau \rightarrow \mu e e$ | $\Gamma\left(\tau^{-} \rightarrow \mu^{-} e^{+} e^{-}\right) / \Gamma_{\text {total }}<2.7 \times 10^{-8}$ |
| $\tau \rightarrow 3 \mu$ | $\Gamma\left(\tau^{-} \rightarrow \mu^{-} \mu^{+} \mu^{-}\right) / \Gamma_{\text {total }}<3.2 \times 10^{-8}$ |
| $\tau \rightarrow e \gamma$ | $\Gamma\left(\tau^{-} \rightarrow e^{-} \gamma\right) / \Gamma_{\text {total }}<3.3 \times 10^{-8}$ |
| $\tau \rightarrow \mu \gamma$ | $\Gamma\left(\tau^{-} \rightarrow \mu^{-} \gamma\right) / \Gamma_{\text {total }}<4.4 \times 10^{-8}$ |

Table 6.2. All limits are taken from [3] and are at a $90 \%$ C.L.
The two structures in this current are the charge radius term, $q^{2} \gamma^{\mu}-q^{\mu}(q \cdot \gamma)$, with $A_{1}^{L, R}$ coefficients, and the magnetic moment term, $i m_{\tau} q_{\nu} \sigma^{\mu \nu}$, with $A_{2}^{L, R}$ coefficients. The loop diagram (middle) in figure 6.9 which contains the four fermion and four lepton operators contributes to the charge radius term of the leptonic current, and so the Wilson coefficients of the operators $\mathcal{O}_{\ell L, R}$ and $\mathcal{O}_{\ell q}$ appear in the coefficients $A_{1}^{L, R}$. These contributions are loop-suppressed but receive potentially large logarithmic enhancements which go like $\ln \left(\Lambda_{L F V}^{2} / m^{2}\right)$ (where $m$ is the mass of the quark or lepton in the loop and $\Lambda_{L F V}$ is the scale at which new degrees of freedom that induce LFV are no longer integrated out of the theory) [1234. The left photon exchange diagram in figure 6.9 containing the magnetic moment operator implies that the $A_{2}^{L, R}$ factors in the leptonic current depend on the Wilson coefficients of the $\mathcal{O}_{\sigma L, R}$ operators. These effective operators also are loop suppressed since they appear in the effective theory when heavy particles in loop diagrams (e.g., the leptoquarks in figure (6.8) are integrated out of the full theory.

The four fermion operator in figure 6.9 (right), similar to the Fermi theory for weak interactions, is a contact interaction that arises when a massive propagator is integrated out of the full theory at external momentum scales much smaller than the propagator's mass. This operator contributes to $e \rightarrow \tau$ conversion at tree level. Its cross section is expected to be larger than the cross sections from the other diagrams and operators discussed above (assuming the Wilson coefficients for all of the operators in equations (6.27)-(6.29) are all roughly the same order).

Limits on the magnetic moment and four lepton operator coefficients can be determined directly from relevant $\tau$ decay limits, some of which are listed in table 6.2, The smallness of the limits on these $\tau$ decays, in conjunction with loop suppression factors, ensures that the contributions of the $\mathcal{O}_{\sigma L, R}, \mathcal{O}_{\ell L, R}$ coefficients to the leptonic current in equation (6.30) are negligible. Therefore, as stated previously, it is expected that the greatest contributions to $e \rightarrow \tau$ conversion will come from the four fermion operators $\mathcal{O}_{\ell q}$, while photon exchange contributions will be negligibly small. Limits on the four fermion operators' coefficients can be determined from the limits on the leptoquark ratios $\lambda_{1 \alpha} \lambda_{3 \beta} / M_{L Q}^{2}$. The 14 leptoquarks in the BRW parameterization correspond to 7 of the four fermion operators listed in [1232], as shown in table 6.3 (though the correspondence is not one-to-one). Hence the leptoquark limits set by direct $e \rightarrow \tau$ searches at HERA as well as the rare process searches cited by the HERA analyses [1228, such as $\tau \rightarrow \pi e$ and decays of $B$ and $K$ mesons, allow limits to be set on the four fermion operator coefficients.

We conclude our discussion of the effective operators by noting that searches for $\mu \rightarrow e$ conversion, $\mu \rightarrow e \gamma$, and $\mu \rightarrow 3 e$ bound the coefficients of the operators in (6.27)-(6.29) which mix first and second generation leptons. However, a priori, limits on such LFV(1,2)

Table 6.3. List of four fermion operators. For the operator names, we follow the notation of 1232 . In the middle column, we maintain the same notation as in equation (6.22). The right column lists the leptoquarks from which these operators are obtained upon integrating out the LQs. Some operators are a linear combination of different LQs which are enclosed in parentheses.
operators do not constrain the $\operatorname{LFV}(1,3)$ operators relevant for $e \rightarrow \tau$ conversion. Only by assuming the existence of an additional symmetry or a particular underlying model can the two sets of operators be related. One example of such an additional symmetry is the theory of minimal flavor violation (MFV) in the lepton sector [1236]. Under the assumptions of MFV, the breaking of the lepton flavor symmetry group $S U(3)_{L} \times S U(3)_{E}$ (for the left-handed doublets and the right-handed charged leptons) arises solely from the charged lepton and neutrino mass matrices 4 As a result, all higher-dimensional lepton flavor violating operators constructed from the lepton bilinears $\bar{\ell}_{L}^{i} \Gamma \ell_{L}^{j}, \bar{e}_{R}^{i} \Gamma \ell_{L}^{j}$, and $\bar{e}_{R}^{i} \Gamma e_{R}^{j}$ are suppressed by one or more powers of lepton masses and/or neutrino mixing parameters. This is true even of the four fermion type operators. Under the MFV hypothesis, the $e \rightarrow \tau$ conversion cross section is unobservably small; it is probable that any observation of $e \rightarrow \tau$ conversion at the EIC would therefore rule out the MFV hypothesis.

### 6.3.4 Theory III: Conclusions and Future Work

The theoretical analysis of the $e \rightarrow \tau$ DIS process presented in 1226 and section 6.3.2 shows that leptoquarks provide a framework in which $e \rightarrow \tau$ conversion searches at the EIC are feasible. Present leptoquark limits are not prohibitive, and the EIC would be competitive with future Super-B experiments ( $\tau \rightarrow e \gamma$ searches) on similar time scales, for several reasons: the EIC would have high luminosity and be sensitive to small cross sections; the EIC like HERA can set limits for all combinations of quark generations while $\tau \rightarrow e \gamma$ is more limited in this region; and the EIC could probe leptoquarks which may evade $\tau \rightarrow e \gamma$ searches.

Limits from $\operatorname{LFV}(1,2)$ searches may or may not be relevant for leptoquarks. While the BRW framework implies no connection between $\operatorname{LFV}(1,2)$ limits and $\operatorname{LFV}(1,3)$ processes, in general it is presumed that leptoquarks will arise from physics at the high scale which does in fact constrain $\operatorname{LFV}(1,3)$ processes given the current stronger limits on $\operatorname{LFV}(1,2)$ processes. However, at least one model, the $S U(5)$ GUT discussed above, exists in which

[^285]limits from $\operatorname{LFV}(1,2)$ searches $(\mu \rightarrow e$ conversion, $\mu \rightarrow e \gamma), \tau \rightarrow e \gamma$ searches, and the neutrino sector can be implemented and still allow for observable $e \rightarrow \tau$ conversion cross sections at the EIC.

An estimation of $e \rightarrow \tau$ cross sections using model-independent effective operators and present limits on $L F V$ processes suggests that the best hope for observing $e \rightarrow \tau$ conversion at the EIC is with models which give rise to four fermion operators through tree level processes at low energies. Four lepton and magnetic moment operators are generally too suppressed to give rise to large enough $e \rightarrow \tau$ cross sections via photon exchange, especially when the relevant limits (e.g., $\tau \rightarrow 3 e, \tau \rightarrow e \gamma$ ) are imposed on the operator coefficients. Limits from additional LFV $(1,2)$ searches like $\mu \rightarrow e$ conversion and $\mu \rightarrow e \gamma$ can be applied to the effective operator analysis if an additional symmetry such as MFV is imposed. MFV results in a suppression of all the LFV operators, including the four fermion operators, and hence negligibly small $e \rightarrow \tau$ cross sections.

There are several theoretical topics worthy of further attention for the $e \rightarrow \tau$ EIC search. First is the study of leptoquarks and $\operatorname{LFV}(1,3)$ flavor structure at LHC. While studies of LQ searches at the LHC have been performed in the past (as an example, see [1237]), such work has focused only on first generation fermions coupling to leptoquarks and has not considered LFV leptoquark final states. Further work is required to determine the extent to which the EIC and the LHC may provide complementary probes of the leptoquark flavor violating parameter space.

An additional topic which merits further study is a broader analysis of model-dependent $e \rightarrow \tau$ searches at the EIC. Non-leptoquark models or symmetries may give promising results for the $e \rightarrow \tau$ conversion process. For example, R-parity violating supersymmetry allows for tree level $e \rightarrow \tau$ conversion mediated by squarks; this suggests that large cross sections perhaps may be expected. Furthermore, depending on the models which give rise to the effective operators discussed above, there may be large log enhancements in the charge radius contribution to photon exchange $e \rightarrow \tau$ which could overcome the limits on the four lepton operators.

Finally, we observe that many experiments have over many years placed limits on a wide variety of flavor-violating processes. Many of these experiments constrain the leptoquark parameter space, as analyzed in [1238. Updated limits from experimental searches for other flavor-violating processes may exist and still need to be considered in analyzing the potential of the EIC (and LHC) to search for LQ-mediated LFV events. Such limits may also be relevant for non-LQ scenarios. Improved limits from ongoing and future experiments searching for $\operatorname{LFV}(1,2)$ processes also need to be included, depending on the context for the $e \rightarrow \tau$ analysis.

This concludes the discussion of the theoretical analysis of leptoquark-induced $e \rightarrow \tau$ conversion in deep-inelastic scattering at the EIC. The analysis so far has been optimistic and disregarded important experimental considerations that would impact a search for $e \rightarrow \tau$ events. The next several sections address the questions of SM backgrounds and $\tau$ detection.

### 6.3.5 Experiment I: Standard Model Backgrounds \& the Analysis Strategy

In this section, we discuss the main SM processes that could mimic the $\operatorname{LFV}(1,3)$ signal at the EIC. In the SM, ep scattering is caused by the exchange of an electroweak gauge boson between the electron and a quark inside the proton. Photon exchange dominates when
the momentum transfer $Q$ is low, but the amplitude of weak gauge bosons becomes more important as $\left|Q^{2}\right|$ approaches $M_{W^{ \pm}}^{2}$ and $M_{Z^{0}}^{2}$. Standard Model NC and CC DIS processes are shown in figure 6.10. The EIC acceptance from the beampipe $\left(0.1^{\circ}<\theta<179.9^{\circ}\right)$ restricts all EIC kinematics to $Q^{2}>0.01 \mathrm{GeV}^{2}$ [1239]. This cut was implemented in the SM simulations at low momentum transfer. However, we focused our SM background analysis on events with very high $Q^{2}$ since a cut of $Q^{2}>1000 \mathrm{GeV}^{2}$ was used in all simulations involving leptoquarks (given the range of LQ masses chosen, see table 6.6).

Figure 6.10. NC and CC DIS diagrams.
Ignoring rare processes, the final state $\tau$ in the $\operatorname{LFV}(1,3)$ event can decay in three different ways: electronic channel, muonic channel, and hadronic channel. Like previous searches done at HERA [1223, 1224, we consider five different SM events whose final states could be misidentified with a decaying $\tau$ : NC DIS, CC DIS, photoproduction, lepton-pair production, and real W boson production.

SM processes lead to final state particles that could be misidentified as our candidate $\tau$. In other words, they produce particles that leave tracks in the detector that look like the leptons or hadrons produced in a $\tau$ decay. However, the geometry of the SM events and the $\operatorname{LFV}(1,3)$ events do differ. Indeed, the identified $\tau$ lepton in an $e p \rightarrow \tau X$ conversion must be back-to-back in azimuth with the hadronic sector $X$. In addition, the angular distribution in the $\theta$ direction of the decay products of scalar LQs, vector LQs, and SM DIS background will differ because their corresponding cross sections have a different $y$ dependence 5 By inspecting equations (6.23) and (6.24) we can see that in the s-channel (see figure 6.5) vector LQs are distributed according to $d \sigma / d y \propto(1-y)^{2}$, whereas scalar LQs decay isotropically (flat $d \sigma / d y$ distribution) in their rest frame (and vice-versa in the u-channel). In contrast, NC DIS events have $d \sigma / d y \propto y^{-1 / 2}$, and this difference between LQ and SM $y$ spectra could be exploited to identify background DIS events 1240 .

At the detector level, the events in all channels at the EIC must be accepted by a trigger for a large imbalance in the transverse energy flow. The energy flow summation runs over all energy deposits in the calorimeters and missing transverse momentum is associated to the neutrinos that escape the detector without any energy deposit. In this initial analysis, the missing transverse momentum $p_{T}^{\text {miss }}$ is defined as:

$$
\begin{equation*}
p_{T}^{m i s s}=\sqrt{\left(\sum P_{x, i}\right)^{2}+\left(\sum P_{y, i}\right)^{2}} \tag{6.31}
\end{equation*}
$$

where $i$ runs over all final state particles in an event, excluding all neutrinos.
PYTHIA 6.4.23 is used to generate all SM events with the CTEQ 5L parametrization

[^286]of the parton distribution functions of the proton 1241 . Initial and final state radiation are included. No GEANT simulation of the EIC detector has been used. Two different energies are chosen for the ep MC simulations: $20 \times 325 \mathrm{GeV}$ with $\sqrt{s}=161.25 \mathrm{GeV}$ and $10 \times 250 \mathrm{GeV}$ with $\sqrt{s}=100.01 \mathrm{GeV}$. Although not directly relevant for the conclusions of this topological study, we allowed ourselves the possibility of gathering a total integrated luminosity of $1000 \mathrm{fb}^{-1}$ as suggested on this workshop's web page [1239].

## Standard Model Event Generation

NC DIS: $(e p \rightarrow e X)$
NC DIS events are mediated by a photon or a $Z^{0}$ boson, and the final state includes an electron. The final state event topology of the tau electronic decay $\left(\tau \rightarrow e \nu_{e} \nu_{\tau}\right)$ is therefore very similar to that of high $Q^{2}$ NC DIS. By energy-momentum conservation the $\sum\left(E-P_{z}\right)$ distribution for NC DIS events is peaked at $2 E_{0}$, where $E_{0}$ is the electron beam energy (10 or 20 GeV ). We can also select NC events by implementing an upper and lower cut to the quantity $\sum\left(E-P_{z}\right)$ measured. In contrast, the $\tau$ decay exhibits a large missing transverse momentum due to the neutrinos in the decay.

CC DIS: $(e p \rightarrow \nu X)$
CC DIS events are mediated by a $W^{ \pm}$boson and are characterized by high missing transverse momentum $p_{T}^{m i s s}$ and higher $Q^{2}$.

Photoproduction: $(\gamma p \rightarrow X)$
Events from photoproduction processes occur in the low $Q^{2}$ limit and may contribute to the final selection if a narrow hadronic jet fakes the tau signature or is misidentified as an electron. For $\gamma p$ events simulated with PYTHIA, the photon can be either direct (point-like) or resolved (VMD and GVMD/anomalous). A photon is assumed to be direct (point-like) when it can only interact in processes which explicitly contain the incoming photon [81], such as $f_{i} \gamma \rightarrow f_{i} g$. A photon is considered to be resolved when it interacts through its constituent quarks and gluons. Each photoproduction subprocess leads to a different event structure and has a cross section that depends strongly on the virtuality of the photon. For high virtualities (high $Q^{2}$ ), DIS events dominate, and the photon is very virtual $\left(\gamma^{*}\right)$. For very low $Q^{2}$, however, the photon can be treated as real and can have a partonic structure that can interact in different ways with the proton's quark (e.g., resolved photoproduction).

However, the LFV processes were simulated with a $Q^{2}>1000 \mathrm{GeV}^{2}$ cut and hence the SM photoproduction background will automatically be reduced to zero. As table 6.4 below suggests, most of the background that concerns us is therefore in the DIS region where the photon is very virtual.

## Lepton-pair Production: $\left(e p \rightarrow e l^{+} l^{-} X\right)$

Lepton-pair production events contribute to the background because they may lead to high momentum leptons in the final state. An analysis of the event geometry is required to avoid misidentifying the three pencil-like tracks in the tau decay with the tracks left

| Subprocess | \% of tot. events, $Q^{2}>0.01$ | \% of tot. events, $Q^{2}>1000$ |
| :---: | :---: | :---: |
| VMD | 61.56 | 0 |
| Direct | 11.28 | 0 |
| Anomalous | 9.05 | 0 |
| DIS $\left(\gamma^{*} q \rightarrow q\right)$ | 18.11 | 100 |

Table 6.4. Event statistics for photoproduction/DIS subprocesses simulated at $20 \times 325 \mathrm{GeV}$ with $Q^{2}>0.01 \mathrm{GeV}^{2}$ and $Q^{2}>1000 \mathrm{GeV}^{2}$.
by $l^{+}, l^{-}$and $X$ when the scattered electron is missed. The background samples include $e^{+} e^{-}, \tau^{+} \tau^{-}$and $\mu^{+} \mu^{-}$production. The simulation of these processes was not included in this analysis due to its very low cross section given the chosen EIC energy range. However, they can be included in the future using a better suited generator with improved efficiency compared to PYTHIA.

## W Production: $(e p \rightarrow e W X)$

Real W boson production leads to final states with isolated leptons with high transverse momentum. The simulated W production samples include hadronic W decays (which can fake a tau decay) and leptonic ( $\left.l \bar{\nu}_{l}\right)$ decays that contribute to the missing transverse momentum and could potentially produce a non-LFV $\tau$. However, the cross section of this process $\left(2.449 \times 10^{-13} \mathrm{mb}\right.$ for $10 \times 250$ and $5.343 \times 10^{-11} \mathrm{mb}$ for $\left.20 \times 325\right)$ at EIC energies and luminosities is negligible.

## Results

Figures 6.11 and 6.12 include all SM processes. Shown are the $p_{T}^{m i s s}$ and acoplanarity $\Delta \phi_{\text {miss- }}$ jet found in events due to missing neutrinos. The plots are made for two different beam energy combinations (top and bottom). It is apparent that beam energies do not matter, the plots are very similar. Two different $Q^{2}$ conditions were studied: left and right, which isolate predominantly high and low $Q^{2}$ events, respectively. With no $Q^{2}$ cut, the event sample is dominated by low $Q^{2}$ photo-production background. If a cut of $Q^{2}>1000 \mathrm{GeV}^{2}$ is made the EW-physics (W) events become apparent. Figure 6.12 shows the acoplanarity $\Delta \phi_{\text {miss- }}$ jet , the angle between the reconstructed $\tau$-jet direction and the missing momentum direction (presumably the neutrinos in the primary collision) for the two different energies and virtualities. The figures also reveal that the shapes of the curves are very similar for the two different center-of-mass energies.

The particles in table 6.3.5 are primarily produced from the decays of hadrons in the hadronic sector $X$; e.g., $\tau \mathrm{s}$ can be produced from $D_{s}$ meson decay, but also include leptons from the processes mentioned above. The low $P_{T}$ suggests that these background particles can be partially avoided by restricting the kinematics phase space to high $Q^{2}$ and high transverse momentum.

Figure 6.11. $p_{T}^{m i s s}$ at $10 \times 250$ and $20 \times 325 \mathrm{GeV}$ with low $Q^{2}$ and $Q^{2}>1000 \mathrm{GeV}^{2}$.

Figure 6.12. Acoplanarity $\Delta \phi_{\text {miss }-\tau \text { jet }}$ at $10 \times 250$ and $20 \times 325 \mathrm{GeV}$ with low $Q^{2}$ and $Q^{2}>1000$ $\mathrm{GeV}^{2}$.

### 6.3.6 Experiment II: Leptoquark Simulation Study

## Type of Leptoquark Studied: Parameter Space

In this work we present the distribution of $p_{T}^{\text {miss }}$ generated from a LFV signal Monte Carlo sample of the leptoquark $\tilde{S}_{1 / 2}^{L} \frac{6}{6}$ The mass of the leptoquark is determined from the ratios $z \equiv \frac{\lambda_{i} \lambda_{j}}{M^{2}}$. The smallest value of the these ratios 1242 which the EIC will potentially probe are listed in table6.6. The LFV signal Monte Carlo events were generated using a LQ generator called "LQGENEP" [1243]. LQGENEP is a LQ generator for electron/positronproton scattering which simulates processes involving LQ production and exchange using the BRW [1225] effective model. The generator is interfaced with the PYTHIA event generator. The value of $\lambda_{i}=\lambda_{j}=0.3$ is taken throughout this study. The values of $\lambda$ are correlated with $z$ through their relation to the mass of the leptoquarks, $M_{L Q}$.

Table 6.6. The initial and final quark flavors $\left(q_{i} q_{j}\right)$ in the subprocess $e q_{i} \rightarrow \tau q_{j}$, the ratio $z$ and the mass of the LQ for $\lambda_{i}=\lambda_{j}=0.3$.

## Leptoquark Event Characterization

Electron-to-tau events were generated using the LFV generator LQGENEP for two EIC energies, namely, $10 \times 250 \mathrm{GeV}$ and $20 \times 325 \mathrm{GeV}$, in ep scattering. These events were restricted to sub-processes with a specific intermediary BRW LQ, $\tilde{S}_{1 / 2}^{L}$. The kinematic region was restricted to $Q^{2}>1000 \mathrm{GeV}^{2}$ and $y>0.1$.

## Electronic \& muonic $\tau$ decays

The leptonic decays of the tau, $\tau \rightarrow e \bar{\nu}_{e} \nu_{\tau}, \mu \bar{\nu}_{\mu} \nu_{\tau}$, were studied. Background for these events is present from SM neutral current events in ep DIS. The $p_{T}^{m i s s}$ distribution for $10 \times 250$ and $20 \times 325$ are shown in figure 6.3 .6 (left) and (right), respectively. The plots shown are for electron final states. The muon final state plots are identical. The different panels indicate the $p_{T}^{\text {miss }}$ spectrum for each combination of quarks $i, j$ involved. The $p_{T}^{\text {miss }}$ spectrum is wider at higher center-of-mass energies, but otherwise the spectra are generally similar.

Figure 6.13. Missing transverse momentum in the electronic $\tau$ decay channel in the ep scattering with 10 x 250 (left) and $20 \times 325$ (right) energies and the ratios, $z$, from table 6.6 for $\left(q_{i} q_{j}\right) \equiv 13,22,23,31,32$ and 33. The lepton-quark couplings are $\lambda_{i}=\lambda_{j}=0.3$.

## Hadronic $\tau$ decays

The hadronic decay of high- $P_{T} \tau$ leptons results in a characteristic narrow "pencillike" jet with three pions. The event $e p \rightarrow \tau X$ would look like a a di-jet event with one narrow and one wide/high multiplicity jet. The jet associated with the $\tau$ decay is narrow. Thus one narrow and one wide jet in a di-jet event is a potential candidate for the signal. Various standard algorithms are used to identify such events [1224]. We did not simulate the detector response - this is a topic for a future detector study - but we studied the event characteristics and topology for such events.

The $p_{T}^{\text {miss }}$ distribution for 10x250 and 20x325 are shown in figure 6.3.6 (left) and (right), respectively. Also plotted is the acoplanarity, $\Delta \phi_{\text {miss }-\tau j e t}$, between the $\tau$-jet and the missing transverse momentum. $\Delta \phi_{\text {miss- }- \text { jet }}$ for the EIC energies $10 x 250$ and 20 x 325 , shown in figure 6.3 .6 (left) and (right) respectively. Figure 6.3 .6 shows the same results as previous two figures but with an additional requirement of $\Delta \phi_{\text {miss- } j \text { jet }}$ below $20^{\circ}$. A small $\Delta \phi_{\text {miss- }}$ jet requirement means that the missing transverse momentum in the event, in the form of a $\tau$ neutrino, is aligned with the $\tau$ jet. These should be the events in which the $\tau$ decayed with neutrinos in the final state.

### 6.3.7 Experiment III: Concluding Remarks

We have studied the topological differences between events in the SM and a BRWleptoquark extension of the SM. Leptoquark searches in electron-hadron machines are sensitive to the ratio of the product of coupling constant to the square of the leptoquark mass. Motivated by recent theoretical expectations first presented in [1226] and summarized above in section 6.3.2, we have studied this for a range of leptoquark masses. While we studied the topologies of leptoquark-mediated transitions between the electron and all three generations of charged leptons, we limit our comments to the $\operatorname{LFV}(1,3)$ transition, for now.

Figure 6.14. Missing transverse momentum in the hadronic $\tau$ decay channel in the ep scattering with $10 \times 250$ (left) and $20 \times 325$ (right) energies and the ratios, $z$, from table 6.6 for $\left(q_{i} q_{j}\right) \equiv 13,22,23,31,32$ and 33. The lepton-quark couplings are $\lambda_{i}=\lambda_{j}=0.3$.

Figure 6.15. Figure 6.16. The acoplanarity, $\Delta \phi_{\text {miss- }-j e t}$, between the $\tau-j e t$ and the missing transverse momentum in the hadronic $\tau$ decay channel in the ep scattering with $10 \times 250$ (left) and $20 \times 325$ (right) energies respectively and the ratios, $z$, from table 6.6 for $\left(q_{i} q_{j}\right) \equiv 13,22,23,31,32$ and 33 . The lepton-quark couplings are $\lambda_{i}=\lambda_{j}=0.3 . \Delta \phi_{m i s s-\tau j e t}$ is required to be below $20^{\circ}$.

## Observations

The topological features of a SM event that produces a $\tau$ lepton which decays and an event in which a $\tau$ is created as a decay of a leptoquark are distinct in two different variables routinely studied in colliders. They are: 1) $p_{T}^{\text {miss }}$ spectrum, transverse missing momentum in such an event, and 2) $\Delta \phi_{\text {miss- }}$ jet , defined as the transverse angle $\phi$ between the $\tau$ created in the event and the vector direction of missing momentum.

As shown in figure 6.17, the $p_{T}^{\text {miss }}$ spectrum is extremely narrow for SM events with final state leptonic or hadronic decays of the $\tau$ created in the collisions. This implies that the neutrinos released in the decay of the SM-produced $\tau$ are boosted in the direction of the $\tau$ and hardly any noticeable transverse momentum is lost. In contrast, the $\tau$ produced in a leptoquark decay tends to have a larger spread in the $p_{T}^{\text {miss }}$ spectrum. These general features of the $p_{T}^{m i s s}$ spectra do not depend on the center-of-mass of the collision: the top histograms in figure 6.17 correspond to 100 GeV center-of-mass energy, while on the bottom they correspond to 160 GeV . Note that these plots are not normalized amongst themselves.

Figure 6.18 shows the acoplanarity plots, the angle between the $\tau$-jet in the event and the missing momentum vector reconstructed in the transverse plane using all other observable hadronic and leptonic activity (whether part of a jet or not). The left plots at each center-of-mass energy are unnormalized acoplanarity distributions showing that the SM events are distributed widely over the $\phi$ range, while the leptoquark-produced $\tau$ jets are narrowly peaked at $180^{\circ}$. If a proximity requirement cut of $20^{\circ}$ is made - meaning that the missing neutrinos were very close in $\phi$ angle with the direction of the generated $\tau$ - the distribution switches sides, indicating two categories of such events (the plots on the right of figure). Again, the top two histograms are for 100 GeV center-of-mass energy and the bottom are for 160 GeV . They show no differences based on these center-of-mass energies. This feature by itself will be less deterministic of the event topology of the leptoquarks, but we expect (as was done in previous searches [1223]) the $p_{T}^{\text {miss }}$ spectrum and the acoplanarity distributions together will be utilized in a maximum likelihood or neural network analysis to search for excesses seen in future EIC events.

Figure 6.17. SM and LQ (both hadronic and electronic channels) $p_{T}^{m i s s}$ at $10 \times 250$ and $20 \times 325 \mathrm{GeV}$ with $Q^{2}>1000 \mathrm{GeV}^{2}$. These plots are not normalized amongst themselves.

Figure 6.18. Acoplanarity $\Delta \phi_{\text {miss }, \tau \text { jet }}$ at $10 \times 250$ and $20 \times 325 \mathrm{GeV}$ with $Q^{2}>1000 \mathrm{GeV}^{2}$. The two plots in the right side have a $\Delta \phi<20^{\circ}$ cut implemented on the LQ simulation. In this case, the LQ preserves the quark flavor: $\left(q_{i}=1 q_{j}=1\right)$. These plots are not normalized amongst themselves.

## Outlook

The study we performed is only a beginning. The estimates made in the theoretical motivation in section 6.3.2 and [1226 assume a $100 \%$ efficiency of final state leptonic and hadronic decay reconstruction of the $\tau$ created in the final state. The experimental publications [1223, 1224 indicate that their detailed simulation of the H 1 detector resulted in a range of $7 \%$ to $15 \%$ in the reconstruction efficiency of the $\tau$ in those final states. BELLE and BaBar detectors have reported higher efficiencies reaching about $20 \%$. It is reasonable to assume that a future EIC detector may be able to achieve at least that. Assuming this we note that the luminosity requirements stated in section 6.3.2 and [1226] for the EIC to probe $e \rightarrow \tau$ cross sections at the level stated are an underestimate by about 10-to- 5 times. This means at 90 GeV center-of-mass, the stated $10 \mathrm{fb}^{-1}$ could be as high as 100 or as low as $50 \mathrm{fb}^{-1}$.

The studies we performed were based on HERA studies in which the collision energies were about 300 GeV in the center-of-mass frame. The efficiencies of some cuts and selection criteria would certainly be better at those energies than at the EIC 100 and 160 GeV center-of-mass energies, so the cut efficiencies may not transfer exactly as it has been assumed in these estimates. However, it is not unreasonable to assume that a similar but equally (if not more) efficient set of cuts and analysis techniques may be eventually found for this search at the future EIC.

The group now formed hopes to continue these studies with detailed detector simulation as it will become available in near future.

### 7.1.1 Introduction

In this paper, we describe a future electron-ion collider (EIC), based on the existing Relativistic Heavy Ion Collider (RHIC) hadron facility, with two intersecting superconducting rings, each 3.8 km in circumference [1244]. The replacement cost of the RHIC facility is about two billion US dollars, and the eRHIC will fully take advantage and utilize this investment. We plan adding a polarized $5-30 \mathrm{GeV}$ electron beam to collide with variety of species in the existing RHIC accelerator complex, from polarized protons with a top energy of 325 GeV , to heavy fully-stripped ions with energies up to $130 \mathrm{GeV} / u$.

Brookhavens innovative design, (figure 1), is based on one of RHICs hadron rings and a multi-pass energy-recovery linac (ERL). Using the ERL as the electron accelerator assures high luminosity in the $10^{33}-10^{34} \mathrm{~cm}^{-2} \sec ^{-1}$ range, and for the natural staging of eRHIC, with the ERL located inside the RHIC tunnel. eRHIC will provide electron-hadron collisions in up to three interaction regions. We detail eRHICs performance in subsection 7.1.2,

Since the first paper on eRHIC in 2000, its design has undergone several iterations. Initially, the main eRHIC option (the so-called ring-ring, RR, design) was based on an electron ring, with the linac-ring (LR) option as a backup. In 2004, we published the detailed "eRHIC 0th-Order Design Report" including a cost-estimate for the RR design [1245]. After detailed studies, we found that an LR eRHIC has about a 10 -fold higher luminosity than the RR. Since 2007, the LR, with its natural staging strategy and full transparency for polarized electrons, became the main choice for eRHIC. In 2009, we completed technical studies of the design and dynamics for MeRHIC with 3-pass 4-GeV ERL. We learned much from this evaluation, completed a bottom-up cost estimate for this $\$ 350 \mathrm{M}$ machine, but then shelved the design.

In the same year, we turned again to considering the cost-effective, all-in-tunnel sixpass ERL for our design of the high-luminosity eRHIC (figure 7.1). In it, electrons from the polarized pre-injector will be accelerated to their top energy by passing six times through two SRF linacs. After colliding with the hadron beam in up to three detectors, the e-beam will be decelerated by the same linacs and dumped. The six-pass magnetic system with small-gap magnets [1246] will be installed from the start. We will stage the electron energy from 5 GeV to 30 GeV stepwise by increasing the lengths of the SRF linacs.

We considered several IR designs for eRHIC. The latest one, with a 10 mrad crossing angle and $\beta^{*}=5 \mathrm{~cm}$, takes advantage of newly commissioned $N b_{3} S n$ quadrupoles [1247]. Subsection 7.1.3 details the eRHIC lattice and the IR layout.

The current eRHIC design focuses on electron-hadron collisions. If justified by the EIC physics, we will add a 30 GeV polarized positron ring with full energy-injection from the

Figure 7.1. (a) Layout of the ERL-based, all-in-RHIC-tunnel, $30 \mathrm{GeV} \times 325 \mathrm{GeV}$ high-energy high-luminosity eRHIC. (b) Location of eRHICs six recirculation arcs in the RHIC tunnel.
eRHIC ERL. This addition to the eRHIC facility provides for positron-hadron collisions, but at a significantly lower luminosity than those attainable in the electron-hadron mode.

As a novel high-luminosity EIC, eRHIC faces many technical challenges, such as generating 50 mA of polarized electron current. eRHIC also will employ coherent electron cooling (CeC) 1248 for the hadron beams. Staff at BNL, JLab, and MIT are pursuing vigorously an R\&D program for resolving addressing these obstacles. In collaboration with Jlab, BNL plans experimentally to demonstrate CeC at the RHIC. We discuss the structure and the status of the eRHIC R\&D in subsection 7.1.4.

### 7.1.2 Main eRHIC parameters

eRHIC is designed to collide electron beams with energies from 5 - to $30-\mathrm{GeV} 1$ with hadrons, viz., either with heavy ions with energies from $50-$ to $130-\mathrm{GeV}$ per nucleon, or with polarized protons with energies between $100-$ and $325-\mathrm{GeV}$. Accordingly, eRHIC will cover the C.M. energy range from $44.7-$ to $197.5-\mathrm{GeV}$ for polarized e-p, and from 31.6- to $125-\mathrm{GeV}$ for electron heavy-ion-collisions.

Several physics and practical considerations influenced our choice of beam parameters for eRHIC. Some of these limitations, such as the intensity of the hadron beam, the space charge and beam-beam tune shift limits for hadrons, come from experimental observations at RHIC or other hadron colliders. Some of them, for example $\beta^{*}=5 \mathrm{~cm}$ for hadrons, are at the limits of current accelerator technology, while others are derived either from practical or cost considerations. For example, from considering the operational costs, we limit the electron beam's power loss for synchrotron radiation to about 7 MW , corresponding to a 50 mA beam current at 20 GeV . Above 20 GeV , the electron beam's current will decrease in inverse proportion to the fourth power of energy, and will be restricted to about 10 mA at an energy of 30 GeV . It means that the luminosity of eRHIC operating with 30 GeV electrons will be a $1 / 5$ th of that with 20 GeV .

[^288]Since the ERL provides fresh electron bunches at every collision, the electron beam can be strongly abused, i.e., it can be heavily distorted during a collision. The only known effect that might cause a serious problem is the so-called kink instability. The ways of suppressing it within range of parameters accessible by eRHIC is well-understood [1249] and it no longer presents a problem.

We list below some of our assumed limits and parameters:

1. Bunch-intensity limits:
a. For protons: $210^{11}$
b. For Au ions: $1.210^{9}$
2. Electron-current limits:
a. Polarized current: 50 mA
b. Un-polarized current: 250 mA
3. Minimum $\beta^{*}=5 \mathrm{~cm}$ for all species
4. Space-charge tune shift for hadrons: $\leq 0.035$
5. Proton (ion) beam-beam parameter: $\leq 0.015$
6. Bunch length (with coherent electron-cooling):
a. Protons: 8.3 cm at energies below $250 \mathrm{GeV}, 4.9 \mathrm{~cm}$ at 325 GeV
b. Au ions: 8.3 cm in all energy ranges
7. Synchrotron radiation intensity limit is defined as that of a 50 mA beam at 20 GeV
8. Collision rep-rate $\leq 50 \mathrm{MHz}$.

The limitations on luminosity resulting from various considerations are involved. The main trend is that eRHIC's luminosity does not depend on the electron beam's energy (below 20 GeV ) and reaches its maximum at the hadron beam's highest energy. We mentioned the exception for energies of electrons above 20 GeV . The top eRHIC performance for various species is shown in table 7.1,

Table 7.2 lists the luminosity of a polarized electron-proton collision for a set of electronand proton-energies. Table 7.3 contains this information for a polarized electron beam colliding with Au ions, while tables 7.4 and 7.5 provide data for the case of unpolarized electrons.

An additional major parameter describing eRHIC's overall performance is its expected average luminosity. Since the plans for eRHIC are to use coherent electron cooling to control the parameters of hadron beam, its lifetime will be affected only by scattering on residual gas, and by burn-off in collisions with electrons. Hence, the hadron beam's luminosity lifetime could be as long as a few days, and, in the most likely scenario, the average delivered luminosity will be determine by the reliability of RHIC systems. Hence we anticipate that the average luminosity will be $\sim 70 \%$ of that listed in the tables.

### 7.1.3 The eRHIC interaction region

The current high-luminosity eRHIC IR design incorporates a 10 mrad crab-crossing scheme; thus, hadrons traverse the detector at a 10 mrad horizontal angle, while electrons go straight through. Figure 7.2 plots this scheme. The hadron beam is focused to $\beta^{*}=5 \mathrm{~cm}$ by a special triplet wherein the first magnet is a combined function magnet ( 1.6 m long with 2.23 T magnetic fields and a - $109 \mathrm{~T} / \mathrm{m}$ gradient). It has two functions; it focuses the hadron beam while bending it 4 mrad . Two other quadrupoles do not bend the hadron beam but serve only for focusing. Importantly, all three magnets provide zero magnetic fields along the electron beam's trajectory. Quadrupoles for this IR require very high gradients, and can be built only with modern superconducting technology [1247, 1250]

Figure 7.2. Layout of the right side of eRHIC IR from the IP to the RHIC arc. The spin rotator is the first element of existing RHIC lattice remaining in place in this IR design.

This configuration guaranties the absence of harmful high-energy X-rays from synchrotron radiation. Furthermore, the electron beam is brought into the collision via a 130 meter long merging system (figure 7.3). The radiation from regular bending magnets would be absorbed. The last 60 meters of the merging system use only soft bends: downwards magnets have strength of 84 Gs ( for 30 GeV beam ) and the final part of the bend used only 24 Gs magnetic field. Only 1.9 W of soft radiation from the later magnets would propagate through the detector.

One important factor in the IR design with low $\beta^{*}=5 \mathrm{~cm}$ is that the chromatism of the hadron optics in the IR should be controlled, which is reflected in the maximum $\beta$-function of the final focusing quadrupoles. Figure 7.4a shows the designed $\beta$ - and dispersion-functions for the hadron beam. The values of the $\beta$-function are kept under 2 km , and the chromaticity held at the level typical for RHIC operations with $\beta^{*} \sim 1 \mathrm{~m}$. We are starting full-fledged tracking of hadron beams in RHIC, including characterizing beam-beam effects and all known nonlinearities of RHIC magnets: we do not anticipate any serious chromatic effects originating from our IR design.

Figure 7.3. (a) Vertical trajectory of 30 GeV electron beam merging over 130 meters into the IP. (b) Spectra of the radiation from various part of the merger. Only 1.9 W of soft X-ray radiation will propagate through the detector; the absorbers intercept the rest of it.

Furthermore, we introduced the bending field in the first quadrupole for the hadrons thereby to separate the hadrons from the neutrons. Physicists considering processes of interest for EIC science requested our installing this configuration. Since the electrons are used only once, the optics for them is much less constrained. Hence, it does not present any technical- or scientific-challenges, and so we omit its description here.

Finally, beam-beam effects play important roles in eRHIC's performance. While we will control these effects on the hadron beam, i.e., we will limit the total tune shift for hadrons to about 0.015 , the electron beam is used only once and it will be strongly disrupted during its single collision with the hadron beam. Consequently, the electrons are strongly focused by the hadron beam (pinch effects), and the e-beam emittance grows by about a factor of two (disruption) during the collision. These effects, illustrated in figure 7.5, do not represent a serious problem, but will be carefully studied and taken into account in designing the optics and the aperture .

More details on the lattice and IR design are given in reference 1251 .

### 7.1.4 eRHIC R\&D

The list of the needed accelerator R\&D on eRHIC is quite extensive, ranging from the 50 mA CW polarized source [1252, 1253, 1254] to Coherent Electron Cooling [1248]. It includes designing and testing multiple aspects of SRF ERL technology in BNL's R\&D ERL (1255.

Coherent Electron Cooling (figure 7.6) promises to cool both ion beams by an order of magnitude (both transversely and longitudinally) in under half an hour. Traditional stochastic or electron cooling techniques could not satisfy this demand. Being a novel unverified technique, CeC will be tested in a proof-of-principle experiment at RHIC in a collaboration between scientists from BNL, JLab, and TechX [1256.

Another important R\&D effort, supported by an LDRD grant, focuses on designing and prototyping small-gap magnets and vacuum chamber for cost-effective eRHIC arcs [1246]. In addition to their energy efficiency and inexpensiveness, small-gap magnets assure
a very high gradient as room-temperature quadrupole magnets. Figure 7.7 shows two such prototypes; they were carefully tested and their fields were mapped using high-precision magnetic measurements. While the quality of their dipole field is close to satisfying our requirements, the quadrupole prototype was not manufactured to our specifications. We will continue this study, making new prototypes using various manufacturers and techniques.

Figure 7.6. Possible layout of RHIC CeC system cooling for both the yellow and blue beams.

Figure 7.7. (a) A prototype of eRHIC quadrupole with 1 cm gap; (b) Assembled prototype of eRHIC dipole magnet with 5 mm gap.

Another part of our R\&D encompasses testing the RHIC in the various modes that will be required for eRHIC's operation.

### 7.1.5 Conclusions and Acknowledgements

We are making steady progress in designing the high-energy, high-luminosity electronion collider eRHIC and plan to continue our R\&D projects and studies of various effects and processes. So far, we have not encountered a problem in our proposal that we cannot resolve. Being an ERL-based collider, eRHIC offers a natural staging of the electron beam's energy from 5-6 to 30 GeV . During this year, we will complete our cost estimate of all eRHIC stages.

### 7.2 A Polarized Medium-Energy Electron-Ion Collider at JLab

B. Terzić, Y. Zhang, S. Abeyratne, S. Ahmed, A. Bogacz, P. Chevtsov, Ya. Derbenev, B. Erdelyi, A. Hutton, A. Kondratenko, G. Krafft, R. Li, S. Manikonda, F. Marhauser, V. Morozov, P. N. Ostrumov, F. Pilat, R. Rimmer, T. Satogata, H. Sayed, M. Spata, M. Sullivan, H. Wang, B. Yunn

The conceptual design of MEIC, a polarized ring-ring electron-ion collider based on CEBAF, has been continuously optimized for best supporting the nuclear science program. MEIC covers a medium CM energy region up to 65 GeV (for 6 T superconducting dipole magnets) and achieves a luminosity of above $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ for one high-luminosity and one full-acceptance detectors. The unique compact figure- 8 shaped collider rings, designed to accommodate 3 to 11 GeV electrons and up to 96 GeV protons or 48 (38) $\mathrm{GeV} / \mathrm{u}$ for light (heavy) ions ( 128 GeV protons or $64(51) \mathrm{GeV} / \mathrm{u}$ light (heavy) ions for 8 T superconducting magnet), provide a great advantage for delivering and preserving high polarization of ion beams (including polarized deuterons) for collisions at multiple interaction points. The design is upgradable to accommodate 20 GeV electrons and about 250 GeV proton energies at a late stage, with luminosities up to $10^{35} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. The present focus of the Jefferson Lab accelerator team is to develop a coherent machine design that integrates all of the design features that have been explored over recent years, based upon state-of-the-art performance criteria. Various collider components including ion linac and boosters, spin rotators, and interaction regions have been designed and integrated into a unified design. These advances will be discussed in detail.

### 7.2.1 Introduction

Over the last decade, Jefferson Lab has been developing a conceptual design of an electron-ion collider for future nuclear physics research. This facility, fully utilizing the 12 GeV upgraded CEBAF, will provide collisions between polarized electrons and polarized light ions or unpolarized light to heavy ions up to lead over a wide CM energy range at multiple interaction points (IPs). Requirements of the science programs drive the design efforts to focus on achieving ultra-high luminosity $\left(10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}\right.$ or above) per detector, and high polarization (over $80 \%$ ) for both electron and light ion beams.

Our primary design focus at the present time is a Medium-energy Electron-Ion Collider (MEIC), with a CM energy up to 65 GeV , which covers electron energy up to 11 GeV , proton energy up to 96 GeV and ion energy up to 48 GeV per nucleon. It is considered as an optimal compromise between science, technology and project cost. We also maintain a well-defined upgrade capability to higher energies, ELIC, which can reach up to 20 GeV electron energy, and 250 GeV proton energy or 100 GeV /u heavy ion energies (typically, for heavy ions the proton number is about $40 \%$ of the atomic mass number). In both instances, high luminosity and high polarization remain the main design drivers.

The present MEIC design features a traditional ring-ring collider with a high luminosity at a level of $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ per detector, over up to three IPs, by taking full advantage of an electron beam from the upgraded 12 GeV CEBAF recirculated SRF linac. As a design concept, the high luminosity of MEIC is attained by utilizing high bunch repetition rate, crab-crossing colliding electron and ion beams with short bunch length and small transverse
emittances, and strong final focusing at collision points. Our choice of this luminosity concept was motivated by the remarkable success of two electron-positron colliders at KEK and SLAC B-factories, which had reached luminosities over $2 \times 10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. In a way, Jefferson Lab is poised to replicate the same success in a collider involving hadron beams. The new concept requires the colliding ion beams of MEIC to be very different from all existing or previously operated hadron colliders in terms of bunch intensity (very small), bunch length (very short), transverse emittances (very small) and repetition frequency (very high), while, at the same time, it pushes the final focusing parameter $\beta^{*}$ to be much smaller than what has been achieved in hadron colliders. To support such a conceptual design, extensive R\&D programs have been established at Jefferson Lab, supplemented by several external collaborations.

As a design strategy, we are taking a conservative technical position by limiting many MEIC design parameters within or close to the present state-of-the-art in order to minimize technical uncertainty. This conservative technical design will form a baseline for future design optimization guided by the evolution of the science program, technology innovations and $R \& D$ advances.

### 7.2.2 Baseline Design

The MEIC main parameters are summarized in table 7.2 .2 for a design point of 60 GeV proton and 5 GeV electron. Figure 7.8 presents luminosities as a function of CM energy for both proton and ions. In deriving this set of design parameters, we have imposed certain limits on several key machine or beam parameters in order to reduce technical risk and the accelerator R\&D challenges and to improve robustness of the design. These limits, based on largely previous lepton and hadron collider experiences and state-of-art of accelerator technologies, are:

- Average current of the stored beams are up to 1 A for protons/ions and 3 A for electrons,
- Electron synchrotron radiation power density is less than $20 \mathrm{~kW} / \mathrm{m}$,
- Peak bending field of ion superconducting dipole is no larger than 6 T ,
- The maximum betatron value at the beam extension area near an IP is no larger than 2.5 km ,
- Frequency of accelerating RF cavity in the electron ring is less than 1 GHz .

Also, different nuclear programs usually require different detector acceptances and arrangement of interaction regions (IR). While such detector requirements are still in a formation stage, we have considered two different types of IR designs, one for a full-acceptance detector (with 0.5 to 179.5 degree solid angular acceptance before the ion final focusing magnets, and the apertures of the latter sufficient to allow particles with angles up to 0.5 degrees to go through the bore of the magnet for downstream detection), the other for a high-luminosity detector. The key difference of the IR designs is a space between the collision point and the location of the first final focusing quad, and values of these distances for the two detectors are 7 m and 4.5 m respectively for ion beams, while the space for electron beams can be as low as 3 m for both cases. The relatively short distance of 4.5 m enables a further reduction of the final focusing $\beta^{*}$ to 8 mm , thus resulting in a more than a factor two increase of luminosity for that detector configuration as shown in table 7.2.2.

| Quantity | Unit | $p^{-}$beam | $e$ beam |
| :--- | :---: | :---: | :---: |
| Beam energy | GeV | 60 | 5 |
| Collision frequency | MHz | 749 |  |
| Particles per bunch | $10^{10}$ | 0.416 | 2.5 |
| Beam current | A | 0.5 | 3 |
| Polarization | $\%$ | $>70$ | $\sim 80$ |
| Energy spread | $10^{-3}$ | 0.3 | 0.71 |
| RMS bunch length | mm | 10 | 7.5 |
| Horiz. emit. (norm.) | $\mu \mathrm{m}$ | 0.35 | 53.5 |
| Vertical emit. (norm.) | $\mu \mathrm{m}$ | 0.07 | 10.7 |
| Horizontal $\beta^{*}$ | cm | $10(4)$ | $10(4)$ |
| Vertical $\beta^{*}$ | cm | $2(0.8)$ | $2(0.8)$ |
| Vertical beam-beam tuneshift |  | 0.015 | 0.03 |
| Laslett tuneshift |  | 0.06 | small |
| Distance from IP to 1 ${ }^{\text {st }}$ final focusing quad | m | $7(4.5)$ | 3.5 |
| Luminosity per IP | $10^{33} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ | $5.6(14.2)$ |  |

Table 7.6. MEIC design parameters for the full-acceptance detector. Values for the high-luminosity detector are given in parentheses.

The MEIC design calls for the construction of a green-field ion accelerator complex and two collider rings, one for electrons and the other for medium energy ions, as shown in figure 7.9. There are four crossing points of these figure-8 collider rings which will accommodate three detectors, at least two of which are available for medium-energy collisions, and the other for low-energy collisions with ions stored in a large booster. As presently envisaged, the two collider rings of identical circumferences are vertically stacked and the ion beams are transported into the plane of the electron ring via a vertical chicane, where horizontal crab crossings were used to collide the two beams at the collision points.

Figure 7.8. MEIC and its high-energy upgrade ELIC in CM energy-luminosity space.
The ion complex consists of ion sources, a 200 MeV SRF linac, a 3 GeV pre-booster and a large booster with energy up to 20 GeV . The ion beams are formed and accelerated in multiple stages in the low-energy ion complex, and are then filled into the collider ring for further acceleration to the colliding energy and stored for collision. A large figure-8 ring, also drawn in Fig. 7.9 (in grey), accommodates high-energy ion beams in a future energy upgrade. In that case, the compact medium-energy collider ring will act as another large booster. On the electron side, a 12 GeV upgraded CEBAF SRF linac will serve as a
full-energy injector into the electron collider ring, which could also be operated in a top-off mode in order to maintain high beam current. It is possible to continue the fixed target program for the CEBAF whenever there is a need, since each filling of the electron ring is very short.

The MEICs figure-8 shape in all
 rings is an optimal solution to preserve full polarization of light ion beams by avoiding spin resonances during acceleration in multiple booster and collider rings. It is also the only practical way to accelerate polarized deuterons and to arrange for longitudinal spin polarization at IP. The figure-8 layout allows for energy independence of the spin tune, as well as the transverse polarization of deuterons.

An essential component of every version of Jefferson Lab electron-ion collider design is an electron cooling facility, which is required for reducing ion beam transverse emittance and along with strong RF bunching, shortening the bunch length to 1 cm .

### 7.2.3 Ion Complex

Being primarily a lepton lab, Jefferson Lab does not have an ion complex at this time. This is usually considered a disadvantage to the Jefferson
Figure 7.9. Layout and side view of the MEIC and cross-section of tunnel. Lab electron-ion collider design effort, since a new ion complex is usually more expensive than a new electron complex. However, a green-field ion complex provides an excellent opportunity for applying new concepts and accelerator technologies which have been developed, tested and perfected over the last half century. Therefore, the MEICs ion complex could, in principle, be built to be far superior to the existing or legacy hadron facilities, thereby offsetting the relatively high project cost.

The main design goal of MEIC ion complex is to create and accelerate polarized or un-polarized ion beams with appropriate time, spatial and phase space structure matching the electron beam in order to implement the new luminosity concept. It is important to note that, while, on the one hand, the MEIC design requires bunch length and transverse emittances order of magnitude smaller than that of the conventional ion beams, on the other hand, due to a high bunch repetition rate, the MEIC ion bunch intensity is unusually low (at $4 \times 10^{9}$ ), approximately 50 times smaller than RHIC ion beam, thereby drastically easing the process of forming such ion beams and intensity dependent collective beam instabilities.

The MEIC ion complex is shown in figure 7.9 Its layout also characterizes the scheme of
ion beam acceleration and formation. The ions, coming out from the polarized or unpolarized sources, will be accelerated step-by-step to the colliding energy in the following major machine components: a 200 MeV SRF linac, a 3 GeV pre-booster, a 20 GeV large booster and finally a medium-energy collider ring of 20 to 60 GeV . All rings are in figure- 8 shape for the benefit of ion polarization. We will present a brief description on each component in the rest of this section. The pre-booster is also an accumulator ring, accepting and stacking ions ( 0.5 to 1 A average current) from a SRF linac in a multi-turn injection with assistance of a conventional DC electron cooling (except the case of $\mathrm{H}^{-} / \mathrm{D}^{-}$for which a phase space paint technique will be used). The accumulated ion beam in the pre-booster will become a coasting beam and will be re-bunched later in the medium-energy collider ring in order to decouple the RF frequencies in the linac and collider rings, as well as to suppress space charge tune-shift at low-energy stage.

## Ion Sources

The MEIC ion sources will rely on existing and mature technologies. We will have an Atomic Beam Polarized Ion Source (ABPIS) with Resonant Charge Exchange ionization for producing polarized light ions $\mathrm{H}^{+} / \mathrm{D}^{+}$and ${ }^{3} \mathrm{He}^{++}$. For unpolarized light to heavy ions, we will utilize Electron-Beam Ion Source (EBIS) which is current in operation at BNL. It is a realistic extrapolation, given future $R \& D$, that an ABPIS should be able to deliver 10 mA polarized $\mathrm{H}^{+} / \mathrm{D}^{+}$pulses at 5 Hz repetition frequency, over a 0.5 ms pulse length with a polarization better than $90 \%$. An EBIS, on the other, hand is expected to generate unpolarized ${ }^{208} \mathrm{~Pb}^{30+}$ pulses also at 5 Hz repetition rate and about 1.6 mA averaged current over a much shorter pulse length of 10 to $40 \mu \mathrm{~s}$. Alternatively, an Electron Cyclotron Resonance Source (ECR) can generate heavy ion beams with similar averaged currents, but 10 to 50 times longer pulse lengths, resulting in a factor of 10 or more pulse charges. In all of these instances, the present ion source technologies should be able to meet the requirement of the MEIC.

## Ion Linac

A technical design of an advanced SRF ion linac, originally developed at Argonne National Laboratory as a heavy-ion driver accelerator for Rare Isotope Beam Facility, has been adopted for the MEIC proposal. This $150-\mathrm{m}-\mathrm{long}$ linac, as shown in figure 7.10, is very effective in accelerating a wide variety of polarized and unpolarized ions from $\mathrm{H}(285 \mathrm{MeV})$ to ${ }^{208} \mathrm{~Pb}^{67+}(100 \mathrm{MeV} / \mathrm{u})$. Economic acceleration of lead ions up to $100 \mathrm{MeV} / \mathrm{u}$ requires a stripper with an optimal stripping energy of $13 \mathrm{MeV} / \mathrm{u}$. The stripping efficiency of ${ }^{208} \mathrm{~Pb}$ ion beam to the most abundant charge state $67+$ is $21 \%$.

Figure 7.10. Schematic drawing of MEIC SRF linac conceptual design.

## Pre-Booster/Accumulator Ring

The pre-booster ring, as shown in figure 7.11 is an essential component of the ion accelerator complex, which accepts beam pulses of any ions from the ion linac and, after accumulation and/or acceleration, transfers the beam to the subsequent large booster for further acceleration. The exact mechanisms of pre-booster operation depend on the ion species, relying on either combined longitudinal and transverse paint technique for $\mathrm{H}^{-} / \mathrm{D}^{-}$or conventional DC electron cooling for lead or other heavy metals during multiturn injection from the SRF linac. One important design consideration of the pre-booster is sufficiently high transition gamma, such that the ions never cross the transition energy during acceleration in order to prevent associated particle loss. In addition, the betatron motion working point should be carefully chosen such that the tune footprint does not cross low-order resonances.

| Length | Crossing angle | Max. beam size | $\gamma$ for 3 GeV particles | Transition $\gamma$ | Mom. compaction |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 234 m | 75 deg | 2.3 cm | 4.22 | 5 | 0.04 |

Table 7.7. Parameters for the pre-booster ring.

Figure 7.11. A figure-8 shaped pre-booster ring.

## Large Booster

The MEIC large booster shares the same tunnel as the electron and ion collider ring. It accelerates protons from 3 GeV to 12 to 20 GeV before sending them to the medium-energy collider ring. The extraction energy will be determined in the further design optimization. The boosters can handle all ion species. However, the energy will be affected by the ratio of charge and mass of the ion species. In principle, higher extraction energy is preferred. The key design requirements are that the ring must be also a figure- 8 shape, its magnetic lattice should be built by warm magnets and a crossing of the transition energy must be avoided. It should be pointed out that the large booster will be also used as a low-energy collider ring for collision energies in the region of 5 to 20 GeV per nucleon over only one detector. Special insertions such as an interaction region and an electron cooling facility must be inserted or added to meet such physics demand.

### 7.2.4 Collider Rings

Figure 7.12 shows a scaled layout of the electron and ion collider rings. When designing the optics of the electron and ion collider rings, the following geometric constraints must be taken into account:

- Figure- 8 shape, and four intersection points in two straights,
- Two short $(20 \mathrm{~m})$ straights in the middle of the two arcs for two Siberian snakes,
- A 60 m Universal Spin Rotator consisting of two solenoids and two sets of arc bending dipoles on each end of two electron arcs,
- Layouts of the interaction regions must match for both electron and ion rings,
- Footprints of the two collider rings must be very close so that they can be housed in one tunnel,
- The ion ring circumference must be equal to the big boosters length and be an integer multiple of the pre-boosters length for the purpose of RF matching.
The circumferences of the electron and ion rings are about 1340 m . The circumferences can be modified by adjusting length of straights, crossing angle and arc radii. The figure- 8 crossing angle is $60^{\circ}$. The electron and ion rings IPs coincide. The maximum separation of the electron and ion beam lines in the design is less than 4 m , which can be further reduced to be within the required limits once the optics design concept is finalized. The parameters of the electron ring and optics design are summarized in table 7.8,

Figure 7.12. Layout of the electron and ion collider rings.

| Arc's net bend | Crossing angle | Arc length | Arc avg. radius | straight length | circumference |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 240 deg | 60 deg | 405.75 m | 96.86 m | 264.46 m | 1340.41 m |

Table 7.8. Parameters for the collider ring.

### 7.2.5 Interaction Region

## Detector

The primary detector of the MEIC will be unique in its ability to provide almost full acceptance for the produced particles of electron-ion collisions. To accomplish this, a high
level of integration with the interaction region of the accelerator is required. The central detector will be built around a solenoid barrel, providing tracking, particle identification, and calorimetry for all particles, and two end-caps focusing on the detection of electrons and hadrons respectively. See section 7.3 for further discussion.

## Crab Crossing

With a 749 MHz bunch repetition rate for both colliding beams of MEIC, the bunch spacing is about 40 cm . A crab crossing of the colliding beams provides a simple way to separate quickly the two colliding beams near an IP to avoid undesired parasitic collisions. In the present MEIC IR design, the horizontal crabbing angle is 50 mrad . There are two ways currently under consideration to tilt the orientation of the electron or ion bunches in horizontal plane by a half crab crossing angle in order to restore head-on collisions. The first approach is placing crab cavities on each side of an IP. Such approach has been proved recently at KEK-B factory, which led to a record-high luminosity. It has been estimated that we need approximately 1.26 and 16.2 MV integrated transverse kicking voltage for 5 GeV electron and 60 GeV protons respectively. While a KEK-type squashed crab cavity should be readily adopted for the MEIC electron ring, the ion ring needs a set of such KEK crab cavities to achieve the design goal. At Jefferson Lab, a new type of crab cavity, which is more compact and promises much higher field, has been recently conceptually designed using transverse electromagnetic field (TEM), as another candidate of crab cavities for the MEIC. An alternative approach is dispersive crabbing, in which tilting of a bunch is achieved through purposely leaking the horizontal dispersion in the normal accelerating RF cavities.

## Interaction Region Design

As mentioned earlier, the two collider rings of MEIC are stacked vertically. In an early version of the IR design, the electron beam was vertically bent into a crab crossing, while the ion ring remains in a plane. Such design layout was abounded due to several problems: (i) bending electrons will generate excessive synchrotron radiation near an IP, which, consequently, interferes with the detector and degrades the background; (ii) the synchrotron radiation and quantum excitations in a beam extension area (betatron values are still very large) could enlarge the electron beam emittance by an order of magnitude; (iii) polarization decrease caused by vertical bend could be also very significant. The present MEIC IR design now requires the ions to undergo a vertical excursion to facilitate a horizontal crab crossing at an IP. For a 50 mrad crab crossing angle, the required bending field of the dipoles is quite modest for our ion energy range.

A typical magnet lattice layout of the MEIC interaction region is illustrated in figure 7.42. At a medium-energy region, the ion beams are modestly asymmetric in two transverse dimensions, as a result of balance of electron cooling and intra-beam scatterings. For instance, the emittance aspect ratio of a 60 GeV proton bunch is about 5. For such modestly flat beams, a final focusing quad doublet is a good choice.

For the MEIC IR design with a 2 cm or less $\beta^{*}$, chromatic aberration of the final focusing quads is one important issue that special attention must be paid. The chromaticity, defined as a ratio of betatron tune shift and momentum spread, could be as high as 110 per IR. A dedicated chromaticity compensation block, consisting of a set of sextupoles, will be inserted in the beam extension area on both sides of an IR to mitigate the problem. The initial studies indicate that, with proper values of these sextupoles, the chromaticity can be
reduced dramatically to single digits. Particle tracking simulations for dynamic aperture are currently underway.

### 7.2.6 Electron Cooling

Cooling of the ion beam is essential to achieve high luminosity in MEIC. At low energy, DC electron cooling is employed to help stacking of the ions in the pre-booster. At the collider ring, we rely on a concept of staged cooling of bunched ion beams of medium energies. Electron cooling is first called in the injection energy for reduction of the area that the ion beam occupies in the 6D phase space. After ions are accelerated to the collision energy, electron cooling will be utilized again for conditioning the beam to the design values. And most importantly, electron cooling will be continued during the collision mode to suppress the intra-beam scattering induced beam heating and emittance growth. Shortening the bunch length (down to 1 cm or less) that results from electron-cooling of the ion beam captured in a high voltage SRF field, in particular, it is critical for the high luminosity in MEIC, since it facilitates two important advances: an extreme focusing of the colliding beams and implementation of crab crossing at the IPs for achieving the highest bunch collision rate (up to 1.5 GHz ) and luminosity.

A schematic drawing of the MEIC ERL based electron cooler is shown in figure 7.13 , Two technologies, namely, energy recovery linac (ERL) and circulator ring, play critical roles to the success of this facility. A high-charge electron bunch from a photo-cathode is accelerated in a SRF ERL linac to required energy 10 to 50 MeV and then sent to a specially designed circulator cooler ring, with optics matching the cooling channel for cooling of a proton or ion bunch. The photo-injector and SRF linac ensure a high quality of the injected cooling bunch. An individual bunch circulates a large number of revolutions (up to a few hundred) in the ring before its quality is degraded by intra- and inter-beam scatterings, after which it returns to the same SRF linac for energy recovery. The recovered energy will be used for accelerating a new electron bunch. This circulator ring reduces the average current from a photo-cathode by a factor equal to the number of recirculation. Therefore, it provides a near-perfect solution for two bottlenecks of the facility: the high current and high power of the cooling electron beam. For example, a $3 \mathrm{~A}, 50 \mathrm{MV}$ (e.g. 150 MW of power) cooling beam can effectively be provided by $30 \mathrm{~mA}, 2 \mathrm{MV}$ (e.g 60 kW of active beam power) from the electron injector.

### 7.2.7 R\&D

For an advanced accelerator design like MEIC, there are many R\&D issues needed to be completed to solidify the design. We have identified a list of critical R\&D issues: electron cooling of the bunch ion beams at medium energy; crab crossing and crab cavity; polarization life time and spin tracking; beam-beam effects; non-linear collective beam effects and feedback systems; interaction region design and dynamic aperture, etc. The Jefferson Lab accelerator team and its collaborators are currently working on each of these issues. The details of the ongoing research are reported in a number of publications: overall design [1257, 1258], lattice design [1259, 1260], ion complex [1261, 1262, beam-beam simulations [1263, 1264], crab cavity [1265], electron cloud [1266], beam instabilities [1267], and others. For brevity, here we only highlight one topic from our R\&D list - beam-beam simulations.

Beam-beam interactions present a key limitation to collider performance, because they may lead to appreciable emittance growth of colliding beams and rapid reduction of lumi-

Figure 7.13. Schematic of electron cooling for the MEIC.
nosity. Such nonlinear collective beam effects can pose a significant design challenge when the machine parameters are pushed into a new regime. In order to lend credibility to the conceptual design, we use computer simulations to examine beam-beam instabilities, to optimize and explore limits of machine parameters.

A first phase of the beam-beam simulations of MEIC at Jefferson Lab, featuring a simplified model with linear transfer map, head-on collisions, and perfect chromaticity correction, has been already carried out for the current medium-energy configuration [1263, 1264, 1268] using the state-of-the-art beam collision code BeamBeam3D [1269]. These studies established that both designs were safely away from coherent beam-beam instabilities.

Furthermore, we use an evolutionary (genetic) algorithm [1270, 1271 to search for the optimal working point in the tune space, and demonstrated that such an approach is orders of magnitude more efficient than the simple tune scans [1272]. Figure 7.14 illustrates how the evolutionary algorithm successfully navigates the 4D betatron tune space ( 2 tunes for each beam) to find a (near-)optimal working point for which the luminosity exceeds the design luminosity by about $30 \%$.

### 7.2.8 Summary

The MEIC is the future of nuclear physics at Jefferson Lab. It is optimized to collide a wide variety of polarized light ions and unpolarized heavy ions with polarized electrons. It covers an energy range matched to the science program proposed by the Jefferson Lab nuclear physics community ( $\sim 4200 \mathrm{GeV}^{2}$ ), with luminosity exceeding $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. An upgrade path to higher energies $\left(250 \times 20 \mathrm{GeV}^{2}\right)$ has been developed and should provide luminosity of close to $10^{35} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$. The design is based on a figure- 8 ring for optimum polarization, and an ion beam with high repetition rate, small emittances and short bunch lengths.

We reported on the status of the design for the MEIC at Jefferson Lab. Our design is both mature, having addressed all the required aspects of the design in the various level of detail, and flexible, being able to accommodate revisions in design specifications and advances in accelerator $R \& D$. We have identified the critical accelerator R\&D topics for the MEIC, and are presently working on them.

Figure 7.14. MEIC beam-beam simulation with Evolutionary algorithm. Green line represents the design luminosity. The simulation locates a (near-)optimal working point within only 320 simulations (blue x ).

## Acknowledgment

We would like to thank members of the Jefferson Lab EIC nuclear science study group as well as the CEBAF user community for working with us on developing the MEIC design. In particular, we are grateful to Rolf Ent for coordinating the collaboration between the accelerator and nuclear physics groups, Alberto Accardi for generating Figure 7.14, Pawel Nadel-Turonski and Tanja Horn for their contributions on detector and interaction region design.

# 7.3 Kinematics and detector designs for the different EIC machine designs 

E.C. Aschenauer, R. Ent, T. Horn, P. Nadel-Turonski, H. Spiesberger

### 7.3.1 Kinematics and Requirements for an EIC Detector

The physics program of an EIC imposes several challenges on the design of a detector, and more globally, the extended interaction region, as it spans a wide range in center-of-mass energy, different combinations of both beam energy and particle species, and several different physics processes. The various physics processes encompass inclusive measurements $\left(e p / A \rightarrow e^{\prime}+X\right)$, which require detection of the scattered lepton and/or the full scattered hadronic debris with high precision; semi-inclusive processes ( $e p / A \rightarrow e^{\prime}+h+X$ ), which require detection in coincidence with the scattered lepton of at least one (current or target region) hadron; and exclusive processes ( $e p / A \rightarrow e^{\prime}+N^{\prime} / A^{\prime}+\gamma / m$ ), which require detection of all particles in the reaction. The following figures in this section demonstrate the differences in particle kinematics of some representative examples of these reaction types, as well as differing beam energy combinations. For these plots, the directions of the beams are defined as for HERA at DESY: the hadron beam is in the positive z direction $\left(0^{\circ}\right)$ and the lepton beam is in the negative z-direction $\left(180^{\circ}\right)$. The upper panel of fig. 7.15 illustrates that the lower $\mathrm{Q}^{2}$ is, the closer the momentum of the scattered lepton is to the original lepton beam energy. For all lepton-hadron beam energy combinations (indicated by the panel in each of the plots), the scattered lepton goes in the direction of the original lepton beam for low $Q^{2}$ and more and more into a central detector acceptance for higher $Q^{2}$. For a fixed hadron beam energy the lepton scattering angle becomes smaller at a fixed $\mathrm{Q}^{2}$ with increasing lepton energy.

Fig. 7.16 shows the $\mathrm{x}-\mathrm{Q}^{2}$ plane for two different center-of-mass energies. In general, the correlation between $x$ and $Q^{2}$ for a collider environment is weaker than for fixed target experiments. Nonetheless, it becomes stronger for small scattering angles or corresponding small inelasticity $y$, and momentum and scattering angle resolution for the scattered lepton become an issue, at HERA roughly at $y=0.1$. To circumvent this problem, HERA reconstructed the lepton kinematics from the hadronic final state using the Jacquet-Blondel method [1273, 1274], and has reached successful measurements down to $y$ of 0.005 . The main reason why this hadronic method renders better resolution at low $y$ follows from the equation $y_{J B}=E-P_{z}^{\text {had }} / 2 E_{e}$, where $E-P_{z}^{\text {had }}$ is the sum over the energy minus the longitudinal momentum of all hadronic final-state particles and $E_{e}$ is the electron beam energy. This quantity has no degradation of resolution for $y<0.1$ as compared to the electron method, where $y_{e}=1-\left(1-\cos \theta_{e}\right) E_{e}^{\prime} / 2 E_{e}$. This is directly correlated to the relative resolutions for both quantities: $\Delta y_{J B} / y_{J B} \sim$ constant and $\Delta y_{e} / y_{e} \sim 1 / y_{e}$.

Typically, one can obtain for a given center-of-mass energy squared roughly a decade of $Q^{2}$ reach at fixed $x$ when using only an electron method to determine lepton kinematics, and roughly two decades when including the hadronic method. If only using the electron method, one can increase the range in accessible $Q^{2}$ by lowering the center-of-mass energy, as can be seen from comparing the two panels of fig. 7.16. This may become relevant for some semi-inclusive and exclusive processes. The advantages and disadvantages of this solution are discussed in the two machine-specific detector sections of this section.

In general, one would like to access as large a range in $Q^{2}$ at fixed $x$ as possible for a given beam energy combination, and reach as low $y_{J B}$ as possible. This requirement

Figure 7.15. $\mathrm{Q}^{2}$ vs. momentum (upper panel) and $\mathrm{Q}^{2}$ vs. scattering angle (lower panel) of the scattered lepton in the laboratory frame. The following cuts have been applied in both figures: $\mathrm{Q}^{2}>0.1 \mathrm{GeV}^{2}, 0.01<\mathrm{y}<0.95$. The lepton-hadron beam energy combinations are indicated by the panel in each individual plots
directly implies two important considerations for the detector design:

- good hadronic coverage in the forward direction
- low noise and/or good noise suppression algorithms in the hadronic calorimeter to allow for hadron detection down to 0.5 GeV . More detailed detector simulations are needed to confirm these requirements.

Figure 7.16. The $\mathrm{x}-\mathrm{Q}^{2}$ plane for center-of-mass energy 45 GeV (left) and 140 GeV (right). The black lines indicate different $y$-cuts placed on the scattered lepton kinematics.

It is important to point out that the reconstruction of the event kinematics from the hadronic final state is also important in suppressing events with radiation of a real or virtual photon from the incoming or outgoing lepton (radiative corrections); for details please see section 7.3.2.

One should keep in mind that there are additional complications at low $y$ for the measurement of asymmetries and/or polarized cross sections, to for example extract the helicitydependent parton distributions. A depolarization factor, defined in [1275] as:

$$
\begin{equation*}
D=\frac{y\left[\left(1+\gamma^{2} y / 2\right)(2-y)-2 y^{2} m_{e}^{2} / Q^{2}\right]}{y^{2}\left(1-2 m_{e}^{2} / Q^{2}\right)\left(1+\gamma^{2}\right)+2(1+R)\left(1-y-\gamma^{2} y^{2} / 4\right)} \tag{7.1}
\end{equation*}
$$

is needed to correct the measured helicity-dependent asymmetries $\left(A_{\|}\right)$. The depolarization factor corrects for the polarization transfer from the lepton to the virtual photon, and is small at low $y$. This reduces the effective polarized luminosity and increases the uncertainties of the measured polarized quantities at low y $\left(\delta A_{1}=\delta A_{\|} / D\right)$. Therefore, the $x-Q^{2}$-plane of precision polarized cross section measurements will be reduced as compared to unpolarized ones, for fixed center-of-mass energy.

Fig. 7.17 shows the momentum versus scattering angle distributions in the laboratory frame for pions originating from semi-inclusive reactions, for different lepton and proton beam energy combinations. For lower lepton energies, pions are scattered more in the forward (ion) direction. For fixed low lepton energy of 5 GeV , this pattern remains more or less constant as a function of proton energy. With increasing lepton beam energy, the hadrons increasingly populate the central region of the detector, and at the highest lepton energies, hadrons are even largely produced going backward (i.e. in the lepton beam direction). The kinematic distributions for kaons and protons, applying the same cuts as for pions, are essentially identical to those of the pions. The distributions for semi-inclusive events in electron nucleus collisions may be slightly altered due to nuclear modification effects, but the global features will remain.

Figure 7.17. Momentum vs. scattering angle in the laboratory frames for pions from non-exclusive reactions. The following cuts have been applied: $\mathrm{Q}^{2}>1 \mathrm{GeV}^{2}, 0.01<\mathrm{y}<0.95$ and $0.1<\mathrm{z}<0.9$

Fig. 7.17 also indicates a shift of the momentum range of pions towards higher momenta in the central-angle region for higher lepton energy, to typical momenta of about $10 \mathrm{GeV} / \mathrm{c}$, which has implications for the required particle identification (PID). To be able to identify the different hadron types over a wide momentum and angular range an EIC detector needs to have detectors capable of good PID in the forward, central and backward direction. For the higher hadron momenta, typically in the forward ion direction and also in the backward direction for higher lepton beam energies, the most viable detector technology is a RingImaging Cherenkov (RICH) detector with dual-radiators. In the central detector region a combination of high resolution time-of-flight (ToF) detectors (preferentially with timing resolutions $\delta \mathrm{t} \sim 10 \mathrm{ps}$ ), a DIRC, or a proximity focusing Aerogel RICH may be adequate detector technologies.

For certain kinematics, the hadrons (both charged and neutral) will be produced in the backward ion direction (see fig. 7.18) and need to be disentangled from the scattered leptons. The kinematic region in rapidity $\eta$, over which hadrons and photons need to be suppressed with respect to electrons, shifts to more negative rapidity with increasing center-of-mass energy. This can be cross-correlated with the angular and momentum patterns for scattered leptons of fig. 7.15] For the lower center-of-mass combination, electron, photon and charged hadron rates are roughly comparable at $1 \mathrm{GeV} / \mathrm{c}$ total momentum and $\eta=$ -3 . For the higher center-of-mass energy, electron rates are a factor of $10-100$ smaller than photon and charged hadron rates, and comparable again at a $10 \mathrm{GeV} / \mathrm{c}$ total momentum.

This adds another requirement to the detector: good electron identification. The kinematic region in rapidity $\eta$ over which hadrons and also photons need to be suppressed, typically by a factor of $10-100$, shifts to more negative rapidity with increasing center-
of-mass energy. Measuring the ratio of the lepton energy and momentum, $\mathrm{E}_{e}^{\prime} / \mathrm{p}_{e}^{\prime}$, typically gives a reduction factor of $\sim 100$ for hadrons. This requires the availability of both tracking detectors (to determine momentum) and electromagnetic calorimetry (to determine energy) over the same rapidity coverage. This availability also immediately suppresses the misidentification of photons in the lepton sample, by requiring that a track must point to the electromagnetic cluster. Of course, the availability of good tracking detectors over similar coverage as electromagnetic calorimetry similarly aids in $y$ resolution at low y from a lepton method only (see earlier), as the angular as well as the momentum resolution for trackers are much better than for electromagnetic calorimeters. The hadron suppression can be further improved by adding a Cherenkov detector to the electromagnetic calorimetry. Combining the electromagnetic calorimeter response and the response of Cherenkov detectors may especially help in the region of low-momentum scattered leptons, about 1 $\mathrm{GeV} / \mathrm{c}$. Other detector technologies, such as transition radiation detectors, may provide another factor 100 hadron suppression for lepton momenta greater than $4 \mathrm{GeV} / \mathrm{c}$.

An additional advantage of a collider detector over a fixed target experiment is the large coverage in transverse momentum. This is especially important for measurements linking the perturbative high-transverse momentum $p_{T}$ region to the region of small transverse momentum, $p_{T} \sim \Lambda_{Q C D}$, where single-spin asymmetries as functions of $p_{T}, x, Q^{2}, z$ and $\phi$ are the prime observable to extract TMDs - Transverse Momentum Dependent Parton Distributions (see chapter (2), like the Sivers function. Fig. 7.19 shows the coverage in hadron $\mathrm{p}_{T}$ measured with respect to the virtual photon vs. $z=E_{h} / \nu$ assuming an angular acceptance of a detector $0.5^{\circ}<\theta<179.5^{\circ}$. One can see that for all beam energy combinations a large range in transverse momentum is achievable. In general, such physics does not drive the most forward (or backward) detector requirements, leaving ample phase space in transverse momentum with respect to the virtual-photon direction - typically more central.

There is specific interest in detecting events with heavy quarks (charm or bottom). To measure the inclusive structure functions, $\mathrm{F}_{2}^{c}, \mathrm{~F}_{L}^{c}$, and $\mathrm{F}_{2}^{B}$ for heavy quarks, it is sufficient to tag the charm and the bottom quark content via the detection of additional leptons (electron, positron, muons) to the scattered lepton. The leptons from charmed mesons can be identified via a displaced vertex of the second lepton ( $<\tau>\sim 150 \mu \mathrm{~m}$ ). This can be achieved by integrating a high-resolution vertex detector into the detector design. For measurements of the charmed (bottom) fragmentation functions, or to study medium modifications of heavy quarks in the nuclear environment, at least one of the charmed (bottom) mesons must be completely reconstructed to have access to the kinematics of the parton. This requires, in addition to measuring the displaced vertex, good particle identification to reconstruct the meson via its hadronic decay products, e.g. $D_{0} \rightarrow K^{ \pm}+\pi^{\mp}$.

Fig. 7.20 (upper panel) shows the momentum versus scattering angle distributions for pions following from an exclusive reaction with a $\rho^{0}$ vector meson production $\left(Q^{2}>1.0\right.$ $\mathrm{GeV}^{2}$ ), in the laboratory frame and for different beam energy combinations. As in fig. 7.17, two familiar patterns arise. For increasing lepton beam energy, the pion distribution goes from being more peaked in the forward-angle direction to a distribution with both a peak in the forward and backward ion direction, and the momentum in the forwardion direction is slightly reduced. Most of the forward-ion direction pions in fig. 7.20 are correlated with lower- $Q^{2}$ processes, though possibly of less interest for these processes. If one would use a $Q^{2}>10 \mathrm{GeV}^{2}$ cutoff in these exclusive processes, only a peak in the backward-ion direction would remain and in that sense, lower lepton energies correspond to lower hadron momenta on average and reduced particle identification requirements. The distributions for kaons from exclusive $\phi$-mesons production as well as for muons/electrons

Figure 7.18. The number of photons and hadrons as well as the number of scattered leptons in a rapidity bin vs momentum having 5 GeV leptons colliding with 100 GeV protons and 20 GeV leptons colliding with 250 GeV protons. No kinematic cuts are applied.

Figure 7.19. Transverse momentum vs. z for pions applying the following cuts $\mathrm{Q}^{2}>1 \mathrm{GeV}^{2}, 0.01<$ $\mathrm{y}<0.95,0.5^{\circ}<\theta<179.5^{\circ}$ and $\mathrm{p}>1 \mathrm{GeV}$. A momentum cut is applied to simulate the threshold of potential particle-identification-detectors.
from exclusive $J / \psi$ production look very similar, see lower panel of fig. 7.20. The most challenging constraints on the detector design for exclusive reactions compared to semiinclusive reactions is, however, not given by the hadrons originating from vector mesons, but from the detection of the exclusive hadronic state remaining.

As one specific example of an exclusive reaction, deeply virtual compton scattering (DVCS) was chosen, fig. 7.21 (top) shows the energy versus scattering angle distributions of photons in the laboratory frame, for different beam energy combinations. A cut of $\mathrm{Q}^{2}>$ $1 \mathrm{GeV}^{2}$ is assumed, although larger values of $\mathrm{Q}^{2}$ may be required. Lower lepton energies show a more symmetric distribution, and higher lepton energies are more backward-ion angle peaked. The distributions show relatively homogeneous distributions of the DVCS photons from forward to backward, with a small preference for the backward direction. The latter is true for all lepton-hadron beam energy combination.

Fig. 7.21 (bottom) correlates the distribution of the photon angle and the electron scattering angle in the laboratory frame, for different beam-energy combinations. With increasing lepton beam energy, the photon and scattered lepton tend towards the same detector hemisphere. Following fig. 7.21 (top), electromagnetic calorimetry is required over the entire rapidity range of the detector. Fig. 7.21 (bottom) illustrates that tracking and electromagnetic calorimetry capabilities covering similar rapidity range will greatly aid the separation of the photon and lepton, reducing a difficulty encountered by the ZEUS collaboration in their DVCS event reconstruction.

For exclusive reactions in general, with DVCS as the example above, it is extremely important to ensure that the remaining nucleon (or the nucleus) remains intact during the

Figure 7.20. Upper Panel: Momentum vs. scattering angle in the laboratory frames for pions following from exclusive $\rho^{0}$ vector meson production. The following cuts are applied: $\mathrm{Q}^{2}>1.0$ $\mathrm{GeV}^{2}, 0.01<\mathrm{y}<0.95$.
Lower Panel: Momentum vs. scattering angle in the laboratory frames for muons following from exclusive $\mathrm{J} / \psi$ vector meson production. No cuts on $\mathrm{Q}^{2}$ have been applied as a hard scale for the process is given by the $\mathrm{J} / \psi$ mass.

Figure 7.21. Upper panel: Energy vs. scattering angle in the laboratory frame for photons from DVCS. The following cuts have been applied: $\mathrm{Q}^{2}>1.0 \mathrm{GeV}^{2}, 0.01<\mathrm{y}<0.95$ and $\mathrm{E}_{\gamma}>1$. GeV . Lower Panel: The scattering angle in the laboratory frame of the photon vs. that of the scattered lepton for DVCS events. The following cuts have been applied: $\mathrm{Q}^{2}>1.0 \mathrm{GeV}^{2}, 0.01<\mathrm{y}<0.95$ and $\mathrm{E}_{\gamma}>1 . \mathrm{GeV}$
scattering process. Hence, one has to ensure exclusivity by measuring all products. Fig. 7.22 illustrates the kinematic requirements for the DVCS case, showing the scattered proton momentum versus its scattering angle for three different beam energy combinations. In general, for exclusive reactions one wishes to map the four-momentum transfer (or Mandelstam variable) t to the hadronic system, and then obtain an image by a Fourier transform, at relatively low t of up to $1-2 \mathrm{GeV}$. The angle of the recoiling hadronic system is directly correlated with $t$ and the proton energy $E_{p}$, as $\sqrt{t} / E_{p}$. As can be seen in fig. 7.22, the proton scattering angle requirements indeed linearly (and inversely) scale with proton energy.

Even at a proton energy of 50 GeV , the proton scattering angles only range to about $1-2^{\circ}$. At proton energies of 250 GeV , this number is reduced to one fifth. In all cases, one obtains small to extremely small scattering angles, extending to or completely within the $0.5^{\circ}$ angular detector cutoff often used above. Because of this, the detection of these protons, or more general recoil baryons, is extremely dependent on the exact interaction region design and will therefore be discussed in more detail in the machine-dependent part of this chapter.

Figure 7.22. Scattered proton momentum vs. scattering angle in the laboratory frames for DVCS events with different beam energy combinations. The following cuts have been applied: $1 \mathrm{GeV}^{2}<$ $\mathrm{Q}^{2}<100 \mathrm{GeV}^{2}, 10^{-5}<\mathrm{x}<0.7$ and $0<\mathrm{t}<2 \mathrm{GeV}^{2}$.

Detection of the intact nucleus following an exclusive reaction in eA collisions is even more complicated. The binding energy in heavy nuclei is of the order 8 MeV per nucleon. In general, the smallest measurable outgoing angle of heavy scattered or fragmented nuclei, $\theta_{\text {min }}$, is limited by the beam angular divergence and the requirement to have a $\sim 10 \sigma$ clearance of any detector element (often 'Roman pots') from the beam. For a beam divergence of say 0.1 mrad and an ion beam of $100 \mathrm{GeV} / \mathrm{u}$, the transverse momentum required in the nuclear breakup to be beyond the so-called machine 'beam-stay-clear' area of $\sim 10 \sigma$ is 100

MeV , well beyond the 8 MeV (or so) needed for a single nucleon. This would assume that the transverse momentum is equal to the excitation energy of the nucleus.

The diffractive slope at $\mathrm{t}=0$ depends on the size of the nucleus. Fig. 5.88 shows, for small $t \sim 1 / R_{A}^{2}$, a very steep t dependence, $\sim \exp \left(-t R_{A}^{2} / 3\right)$, and then several diffractive $\operatorname{minima}\left(R_{A}=(1.12 \mathrm{fm}) A^{1 / 3}-(0.86 \mathrm{fm}) A^{-1 / 3}\right.$, for details see [1276]). The incoherent background starts to dominate at $t$ values at which the coherent cross section has fallen to $1 / e$. These $t$ values can be estimated by $\exp \left(-|t| B_{0} A^{2 / 3}\right)=1 / A$, with $B_{0}=(1.12 f m)^{2 / 3}$. These values of $t$ are much smaller than the $t$ value corresponding to the first minimum in the coherent cross section and the $t$-values corresponding to the smallest measurable outgoing angle of scattered heavy nuclei. Therefore the strategy to ensure exclusive production on a nucleus is to veto nuclear breakup, by detecting the neutrons from incoherent events.

Another possibility can be to require a rapidity gap between the hadron beam and the produced jet, (vector) meson or real photon (where all events represent the sum of elastic and incoherent events). The left panel of fig. 7.23 shows the rapidity distribution of the most forward particle in deep-inelastic scattering (blue filled distribution) and diffractive events (unfilled histogram), respectively, for a 5 GeV electron and a 100 GeV proton beam energy combination. The 100 GeV is here chosen to mimic the $100 \mathrm{GeV} / \mathrm{u}$ ion beam. The right panel of fig. 7.23 shows the efficiency and purity for diffractive events to DIS events (1:1) as function of rapidity, varying the lepton beam energy while keeping the hadron beam energy fixed. If one requires 4 units of rapidity between the hadron beam and a produced jet, vector meson or real photon, an efficiency of above $60 \%$ and a purity close to $100 \%$ for diffractive events would be obtained. A detector with wide rapidity coverage is essential for

Figure 7.23. Left: Rapidity distribution of DIS and diffractive events for the most forward particle (MFP) in the event. Right: Efficiency and Purity for diffractive events with respect to DIS events (1:1) as a function of the detector rapidity coverage and the center-of-mass energy.
such events.

### 7.3.2 Radiative Corrections

The radiation of real and virtual photons leads to large additional contributions to the observable cross section of electron scattering at high energies. Precision measurements of the nucleon structure require a good understanding of these radiative corrections. For neutral-current lepton nucleon scattering, a gauge-invariant classification into leptonic, hadronic and interference contributions can be obtained from Feynman diagrams. The Feynman diagrams for leptonic corrections are shown in fig. 7.24, Leptonic corrections dominate and strongly affect the experimental determination of kinematic variables.

Usually, the cross section is measured as a function of $Q^{2}$ and Bjorken-x, $x_{B}$, defined as

$$
\begin{equation*}
Q^{2}=-\left(l-l^{\prime}\right)^{2}, \quad x_{B}=\frac{Q^{2}}{2 P \cdot\left(l-l^{\prime}\right)}, \tag{7.2}
\end{equation*}
$$

where $l$ and $l^{\prime}$ denote the 4 -momenta of the incoming and outgoing lepton, respectively, and $P$ is the 4 momentum of the incoming nucleon. The true values of these variables seen by the nucleon when a photon with 4 -momentum $k$ is radiated are, however, given by (see fig.)

$$
\begin{equation*}
\tilde{Q}^{2}=-\left(l-l^{\prime}-k\right)^{2}, \quad \tilde{x}_{B}=\frac{\tilde{Q}^{2}}{2 P \cdot\left(l-l^{\prime}-k\right)} . \tag{7.3}
\end{equation*}
$$

If the photon momentum is large and balancing the transverse momentum of the scattered lepton, $\tilde{Q}^{2}$ can be shifted to small values, leading to an enhancement of the radiative corrections. This effect is similar to the radiative tail of a resonance.

Kinematics of leptonic radiation.

Figure 7.24. Feynman diagrams for leptonic radiation in lepton-quark scattering.
The effect of radiation of photons from the lepton can be described with the help of radiator functions $\tilde{R}_{i}\left(l, l^{\prime}, k\right)$. There is one $\tilde{R}_{i}$ for every structure function $F_{i}, i=2, L$. The radiator functions comprise both real radiation from the initial and the final state as well as the contribution from vertex and self-energy diagrams. Using $\tilde{x}_{B}$ and $\tilde{Q}^{2}$ from equation (7.3) to parametrize the integration over the phase space of emitted photons, one can express the observed structure functions as convolutions,

$$
\begin{equation*}
F_{i}^{\mathrm{obs}}\left(x_{B}, Q^{2}\right)=\int \mathrm{d} \tilde{x}_{B} \mathrm{~d} \tilde{Q}^{2} R_{i}\left(x_{B}, Q^{2}, \tilde{x}_{B}, \tilde{Q}^{2}\right) F_{i}^{\mathrm{true}}\left(\tilde{x}_{B}, \tilde{Q}^{2}\right) \tag{7.4}
\end{equation*}
$$

The integration limits are determined by the energy allowed for the radiated photon which, in the photon-nucleon center-of-mass frame, is given by

$$
\begin{equation*}
E_{\gamma}^{\max }=\sqrt{\frac{1-x_{B}}{x_{B}} Q^{2}} \tag{7.5}
\end{equation*}
$$

Radiative corrections are, therefore, large at large $Q^{2}$ and small $x_{B}$. In contrast, at small $Q^{2}$ and large $x_{B}$, the phase space for photon emission is restricted and negative virtual corrections dominate.

From equation (7.4) it is obvious that the determination of the true structure functions $F_{i}^{\text {true }}\left(\tilde{x}_{B}, \tilde{Q}^{2}\right)$ requires unfolding, a procedure which is in general only possible in an iterative way and with reasonably chosen assumptions about the starting values. Moreover, the observed structure functions depend on the way in which the kinematic variables are measured. For example, if the momentum of the hadronic final state, $p_{X}$, could be measured, $\tilde{x}_{B}$ and $\tilde{Q}^{2}$ would be known. In practice this will be difficult to achieve; however, any information about the hadronic final state could contribute to a narrowing down of the phase space available for photon emission, thereby reducing the size of radiative corrections.

The radiator functions are dominated by peaks in the angular distribution for the collinear radiation of photons from the initial state (ISR) or from the final state (FSR). At high energies, it is a good approximation to assume that photon radiation can be described by a simple rescaling of the lepton momentum, $l \rightarrow z l$ for ISR and $l^{\prime} \rightarrow l^{\prime} / z$ for FSR. The radiator function in the collinear approximation takes the simple, universal form

$$
\begin{equation*}
R_{\text {coll }}=\frac{\alpha}{2 \pi} \log \frac{Q^{2}}{m_{e}^{2}}\left(\frac{1+z^{2}}{1-z}\right)_{+} \tag{7.6}
\end{equation*}
$$

so that the cross section is obtained from

$$
\begin{equation*}
\mathrm{d} \sigma_{\mathrm{ISR}}=\int \frac{\mathrm{d} z}{z} R_{\mathrm{coll}}(z) \mathrm{d} \sigma_{\mathrm{Born}}\left(l^{\mu} \rightarrow z l^{\mu}\right) \tag{7.7}
\end{equation*}
$$

(and similarly for FSR). The potentially large $\operatorname{logarithm} \log Q^{2} / m_{e}^{2}$ may reach the order of $10 \%$ at large $Q^{2}$.

As an example, we show numerical results for electron proton scattering at two typical sets of beam energies: $E_{e}=5 \mathrm{GeV}$ with $E_{p}=50 \mathrm{GeV}$ (left panel of fig. 7.25) and $E_{e}=30$ GeV with $E_{p}=325 \mathrm{GeV}$ (right panel). The figures show the correction factor

$$
\begin{equation*}
r_{c}(y)=\frac{\mathrm{d} \sigma /\left.\mathrm{d} y\right|_{O(\alpha)}}{\mathrm{d} \sigma /\left.\mathrm{d} y\right|_{B o r n}}-1 \tag{7.8}
\end{equation*}
$$

where $y=Q^{2} / Q_{\max }^{2}, Q_{\max }^{2}=x_{B} S, S=2 l \cdot P$. The different curves correspond to different ranges of $x_{B}$ : at the lower center-of-mass energy (left panel of fig. 7.25, from the bottom up): $0.1<x_{B}<0.4,10^{-2}<x_{B}<10^{-1}$ and $10^{-3}<x_{B}<10^{-2}$; at the higher center-ofmass energy (right panel, again from the bottom up): $0.1<x_{B}<0.4,10^{-2}<x_{B}<10^{-1}$, $10^{-3}<x_{B}<10^{-2}, 10^{-4}<x_{B}<10^{-3}$, and $10^{-5}<x_{B}<10^{-4}$. The general features following from the preceding discussion are clearly visible: corrections are large at large $y$ and small $x_{B}$, while corrections become negative at large $x_{B}$ and small $y$.

Lacking a full Monte Carlo event simulation for scattering with heavy nuclei at present, we have studied the influence of a simple cut on the invariant mass of the hadronic final state. Imposing the condition $W_{\text {had }}>1.4 \mathrm{GeV}$ would remove the elastic tail and the contribution

Figure 7.25. $y$-dependence of the leptonic radiative correction factor for electron proton scattering with different beam energies and in different $x_{B}$ ranges. Left: $E_{e}=5 \mathrm{GeV}, E_{p}=30 \mathrm{GeV}$ and the curves from the bottom up correspond to $0.1<x_{B}<0.4,10^{-2}<x_{B}<10^{-1}, 10^{-3}<x_{B}<10^{-2}$; Right: $E_{e}=30 \mathrm{GeV}, E_{p}=325 \mathrm{GeV}$ and $0.1<x_{B}<0.4,10^{-2}<x_{B}<10^{-1}, 10^{-3}<x_{B}<10^{-2}$, $10^{-4}<x_{B}<10^{-3}, 10^{-5}<x_{B}<10^{-4}$ (full and dashed lines alternating for better visibility).

Figure 7.26. Influence of a cut on the mass of the hadronic final state on the leptonic radiative correction factor for a proton target in different $x_{B}$ ranges and beam energies as indicated in the figures. Dashed curves are without a cut, full curves are obtained after a cut of $W_{\text {had }}>1.4 \mathrm{GeV}$.
from low-lying resonances. A similar effect can be achieved cutting on $E-p_{z}$ from the Jacquet-Blondel method. The effect of such a naive cut is shown in fig. 7.26. The reduction of the radiative corrections is considerable at largest $y$ and at small $x_{B}$, but probably not yet sufficient at larger values of $x_{B}$. From similar studies for electron-nucleus scattering at HERA [1277, 1278, 1274, one can expect to obtain a much stronger reduction of radiative corrections, if more refined prescriptions for the measurement of kinematic variables are found.

Figure 7.27. Left: Radiative corrections for electron scattering off a Au nucleus at $5 \times 130 \mathrm{GeV}^{2}$ beam energies, $10^{-3}<x_{B}<10^{-2}, Q^{2}>1 \mathrm{GeV}^{2}, W_{\text {had }}>1.4 \mathrm{GeV}$ with different models for nuclear PDFs: EPS09 (full curve), EPS08 (dash-dotted line), EKS98 (dashed line) and HKN (dotted line). Right: Radiative corrections for different nuclei with CTEQ61M PDFs modified by the EPS09 prescription. Beam energies and kinematic range as in the left figure. From the bottom up: proton, ${ }^{4} \mathrm{He},{ }^{56} \mathrm{Fe}$, ${ }^{197} \mathrm{Au}$.

Since the determination of the true structure functions requires an iterative unfolding procedure, it is important to show that the radiative corrections do not depend too strongly on the assumed input structure functions. In fig. 7.27a we show the correction factor $r_{c}(y)$ as defined above for the case of electron scattering off an ${ }^{197} \mathrm{Au}$ nucleus, assuming different parameterizations of parton distribution functions corrected for nuclear effects, as available in the literature [38, 828, 1279, 40]. Although differences at the level of $10 \%$ are visible, one can still observe a similar overall behavior of radiative corrections. Finally, in fig. 7.27b, we show results for scattering off different nuclei, again supporting the assumption that a common unfolding procedure would allow one to obtain the true structure functions.

Corrections due to the emission of photons from the hadrons, or quarks in the deep inelastic regime, require a careful separation into contributions which should be considered as a part of the hadron structure (leading to an electromagnetic contribution to scaling violations [1280]) and contributions which can, in principle, be related to the observation of direct photons radiated from quarks. The interference of radiation from the lepton and the quark is small [1277]. In certain phase space regions one may expect higher than one-photon corrections to be important. For example, soft-photon exponentiation will be necessary at small $y$ and large $x_{B}$. The procedure is well-known and straightforward. Finally, multi-
photon radiation may become important at large $y$ and small $x_{B}$. In this case, the collinear approximation is sufficient to reach a precision at the level of one percent [1281].

### 7.3.3 Detector Design for eRHIC

The BNL design of an EIC allows for collisions at three interaction regions: one at IP-12 with a new dedicated EIC detector, and at IP-6 and IP-8 with the current RHIC detectors STAR and PHENIX. In the following, first the design considerations for a dedicated EIC detector are described and then the capabilities of PHENIX and STAR for ep / eA collisions are discussed.

## A dedicated EIC detector

Combining all the requirements described in section 7.3 .1 and in the physics chapters before, a schematic view of the emerging dedicated eRHIC detector is shown in fig. 7.28, As already discussed, it is important to have equal rapidity coverage for tracking and

Figure 7.28. A schematic view of a dedicated EIC detector. Details of the GEANT-3 model can be found at https://wiki.bnl.gov/eic/index.php/Detector_Design.
electromagnetic calorimetry. This will provide good electron identification and give better momentum and angular resolutions at low inelasticity $y$ than with an electro-magnetic calorimeter alone.

The significant progress in the last decade in the development of Monolithic Active Pixel Sensors (MAPS), in which the active detector, analog signal shaping, and digital conversion take place in a single silicon chip (i.e. on a single substrate; see [1282 and references therein), provides a unique opportunity for a $\mu$-vertex detector for an eRHIC detector. These devices, built using CMOS technology, use an epitaxial layer as the active sensing element. Ionization deposited in the epitaxial layer is collected by $\mathrm{N}+$ wells embedded in
the epitaxial layer. The "pixel" pitch is determined by the location of the N wells so there is no need for actual segmentation of the detector as is done with traditional hybrid pixel detectors. As a result, CMOS pixel detectors can be built with high segmentation, limited primarily by the space required for additional shaping and digital conversion elements. The key advantage of CMOS MAPS detectors is the reduced material required for the detector and the (on substrate) on-detector electronics. Such detectors have been fabricated and extensively tested (see e.g. [1283]) with thicknesses of about $50 \mu \mathrm{~m}$, corresponding to $0.05 \%$ of a radiation length.

For tracking at larger radii, there are several possibilities which need to be investigated first through Monte Carlo studies for position resolution and material budget, and later through R\&D and building prototypes. The two most prominent options for the barrel tracker are a TPC and a cylindrical GEM-Tracker. For large radii, forward tracking GEMTrackers are the most likely option. The projected rates for a luminosity of $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$ range, depending on the center-of-mass energy, between 300 and 600 kHz , with an average of 6 to 8 charged tracks per event. These numbers do not impose strong constraints on the technology for a tracker.

Due to the momentum range to be covered, the only solution for PID in the forward direction is a dual radiator RICH, combining either Aerogel with a gas radiator like $\mathrm{C}_{4} \mathrm{~F}_{10}$ or $\mathrm{C}_{4} \mathrm{~F}_{8} \mathrm{O}$ if $\mathrm{C}_{4} \mathrm{~F}_{10}$ is no longer available, or combining the gas radiator with a liquid radiator like $\mathrm{C}_{6} \mathrm{~F}_{14}$.

In the barrel part of the detector several solutions are possible, as the momenta of the majority of the hadrons to be identified are between 0.5 GeV and 5 GeV . The technologies available in this momentum range are high resolution ToF detectors ( $\mathrm{t} \sim 10 \mathrm{ps}$ ), a DIRC or a proximity focusing Aerogel RICH.

For the electromagnetic calorimetry in the forward and backward direction, a solution based on $\mathrm{PbWO}_{4}$ crystals would be optimal. The advantages of such a calorimeter would be a small Molière radius of 2 cm and a factor of two better energy resolution and higher radiation hardness than, for example, lead-glass. To increase the separation of photons and $\pi^{0}$ s to high momenta and to improve the matching of charged tracks to the electromagnetic cluster, it would be an advantage to add, in front of all calorimetry, a high resolution pre-shower. We follow for the barrel part of the detector the concept of very compact electromagnetic calorimetry (CEMCal). A key feature is to have at least one preshower layer with 1-2 radiation lengths of tungsten and silicon strip layers (possibly with two spatial projections) to allow separation of single photons from $\pi^{0}$ to up $p_{T} \approx 50 \mathrm{GeV}$, as well as enhanced electron-identification. A straw-man design could have silicon strips with $\Delta \eta=0.0005$ and $\Delta \phi=0.1$. The back section for full electromagnetic energy capture could be, for cost effectiveness and good uniformity, an accordion Lead-Scintillator Design, which would provide gain uniformity and the ability to calibrate the device. A tungsten- and silicon-strip-based pre-shower would also be a good solution for the forward and backward electromagnetic calorimetry.

To achieve the physics program as described in earlier sections, it is extremely important to integrate the detector design into the interaction region design of the collider. As already described, particularly challenging is the detection of forward-going scattered protons from exclusive reactions, as well as of decay neutrons from the breakup of heavy ions in nondiffractive reactions. Previous experience of electron colliders (SLAC, KEK B-factories) and HERA, an electron-proton collider, indicated difficulties with synchrotron radiation coming from bending the electron beam close to the interaction region (IR). The newest large improvements in luminosity at KEK in Japan, by introducing crab cavities, show
that colliding heavy ions or protons with electrons could be obtained without bending the electrons close to the IR, but that it is possible to use the crossing angle between the two beams without losing luminosity. This is the path chosen in the eRHIC design: a 10 mrad crossing angle between the protons or heavy ions during collisions with electrons. This choice removes potential problems for the detector induced by synchrotron radiation. To obtain luminosities higher than $10^{34} \mathrm{~cm}^{-2} \mathrm{~s}^{-1}$, very strong focusing close to the IR is required to have the smallest beam sizes at the interaction point. A small beam size is only possible if the beam emittance is also very small. The focusing triplets are 4.5 meters away from the interaction point (IP). The strong focusing quadrupoles induce very large chromaticities. The current eRHIC design has its highest values of the amplitude betatron functions of the same size as the present operating conditions of the RHIC collider. In addition the design allows a correction of the first, second and third order chromaticities by using sextupoles at the triplets as well as 180 degrees away from the quadrupoles source (as shown in fig. 7.29).

Figure 7.29. The Beta-function along the eRHIC hadron ring.
While the above accomplishes a small-emittance electron beam, the ions and protons need to be cooled by coherent electron cooling to have small emittance. The eRHIC interaction region design relies on the existence of small emittance beams with a longitudinal RMS of 5 cm , resulting in $\beta^{*}=5 \mathrm{~cm}$. Strong focusing is obtained by three high-gradient quadrupole magnets using recent results from the LHC quadrupole magnet upgrade program (reaching gradients of $200 \mathrm{~T} / \mathrm{m}$ at 120 mm aperture). To ensure the previously described requirements from physics are met, four major requirements need to be fulfilled: high luminosity ( $>100$ times that of HERA), the ability to detect neutrons, measurement of the scattered proton from exclusive reactions (i.e. DVCS) and the detection of low-momentum
protons ( $\mathrm{p} \sim \mathrm{p}_{0} / 2.5$ ) from heavy-ion breakup. The eRHIC IR design fulfills all these requirements: the first magnet in the high focusing quadrupole triplet is a combined function magnet producing a 4 mrad bending angle of the ion/proton beam (see fig. 7.30). The 120 mm diameter aperture of the last quadrupole magnet allows detection of neutrons with a solid angle of $\pm 4 \mathrm{mrad}$, as well as the scattered proton from exclusive reactions, i.e. DVCS, up to a solid angle of $\sim 9 \mathrm{mrad}$. The electrons are transported to the interaction point through the heavy ion/proton triplets, seeing zero magnetic field as shown in fig. 7.30 .

Figure 7.30. Combined-function magnet of the hadron beam high focusing quadrupole triplet.
Fig. 7.31 shows the current eRHIC interaction region design in the direction of the outgoing hadron beam. The other side of the IR is mirror symmetric for the incoming hadron beam. For the outgoing lepton beam we are currently investigating how to best integrate a low scattering-angle lepton tagger. Such a tagger is critical for any low $Q^{2}$ physics, like elastic $J / \psi$ production in eA collisions (see section 5.14).

Figure 7.31. Schematic view of the eRHIC interaction region design in the direction of the outgoing hadron beam.

The scattered proton from DVCS events were tracked through this design and beam optics using HECTOR [1284. The DVCS events have been generated with MILOU, a MC
code dedicated to DVCS [673. From fig. 7.32 it is clear that protons from DVCS events can be measured in 'Roman Pots' after the high-focusing quadrupole triplet with a high detection efficiency for hadron beam energies starting from 100 GeV (as example are shown the results for 50 GeV and 250 GeV ). More studies are needed to determine the momentum and angular resolution that can be achieved depending on the 'Roman Pot' design.

As pointed out previously, equally challenging is the detection of the breakup neutrons from heavy ions to veto incoherent events. The nuclear breakup of Au nuclei depending on the excitation energy $\mathrm{E}^{*}$ was simulated using the Monte Carlo generator GEMINI++ [1285] and SMM [1286]. The MC simulation showed that whenever the nucleus breaks up there will be at least one neutron emitted. At very low excitation energies there is the possibility that only a photon is emitted, while the nucleus remains intact. The possibility of detecting these photons still needs to be investigated. Fig. 7.33 shows the angular distribution of the breakup neutrons for three different excitation energies. The aperture of 120 mm diameter of the last quadrupole magnet allows detection of neutrons with a solid angle of $\pm 4 \mathrm{mrad}$, which is indicated by the simulations to be sufficient.

Fig. 7.34 shows the detection inefficiency for these neutrons for three different excitation energies as function of the maximal aperture of the last magnet. For apertures discussed for the IR design the inefficiencies are $10^{-2}$ or much lower for all excitation energies. This assumes a $100 \%$-efficient zero degree calorimeter (ZDC). The critical question is: to suppress incoherent events at high $t$ in eA collisions, can the detection inefficiencies be controlled on the $10^{-3}$ to the $10^{-4}$ level?

There are many detector, interaction region and machine parameters still to be worked out in detail, but one of the hardest questions for an EIC will be to estimate the limiting factors for the systematic uncertainties. Due to the high luminosity, many inclusive and semi-inclusive physics observables will be systematics-limited after a relatively short time of data taking, assuming a $50 \%$ operations efficiency. This requires great care to be taken to consider the possible systematic limitations from the beginning and to integrate solutions to minimize them into the design. Only some of the possible limiting systematic effects that will need to be addressed with great care in the design are listed here. Their impact on key physics observables still needs to be studied.

- Absolute luminosity measurements between different beam energy combinations. This is extremely important for measurements like the structure function $\mathrm{F}_{L}$.
- Relative luminosity measurements between bunches with different bunch helicities, i.e. ,,++---+ and +- . Here it will be important to investigate whether Bremsstrahlung can be used for this measurement, as the Bremsstrahlung cross section has a term that is dependent on polarization.
- The measurements of the absolute hadron and electron beam polarization. To date the best precision in the measurement of lepton beam polarization at high energies in a collider was obtained during HERA-I running with $1.6 \%$ [1287. At RHIC the best hadron polarization measurement achieved to date is $\sim 5 \%$ [1288, 1289, 1290] for a polarized proton beam. For high energy polarized ${ }^{3} \mathrm{He}$ beams, $\mathrm{R} \& \mathrm{D}$ is needed to determine how to measure an absolute polarization.

Figure 7.32. Row-1: Spatial distribution of the scattered protons from DVCS events at 20 m from the IP for 2 different beam energy combinations. Row-2: As Row-1, applying the aperture limitations due to the magnets. Row-3: As Row-2, applying the limitations due to the $10 \sigma$ beam clearance and the acceptance of 'Roman Pots' as currently used by pp2pp at STAR. Row-4: Comparison of the $p_{T}$ spectrum of generated protons (black), those accepted by the quadrupole aperture (blue) and those detected in the 'Roman Pots' (red).

Figure 7.33. The angular distribution of neutrons from the breakup of a Au nucleus depending on the excitation energy.

Figure 7.34. The inefficiency to detect the neutrons from the breakup of a Au-nucleus as function of the maximal aperture of the last magnet for different excitation energies.

## ePHENIX

PHENIX is one of the two large dedicated RHIC detectors, located at IP-8. The PHENIX detector consists of two muon spectrometer arms and two central arms sitting in a 1 tesla solenoid. Over the years the detector has been upgraded to the configuration shown in fig. 7.35, Fig. 7.35 and the upper plot of fig. 7.36 show clearly that PHENIX

Figure 7.35. A schematic view of the current (2011) configuration of the PHENIX detector.
in its current configuration has only a very small acceptance $(|\eta|<0.35)$ for the scattered lepton. This makes the current PHENIX detector basically not usable for DIS physics.

For the RHIC decadal plan covering the period 2010-2020, PHENIX has proposed a major upgrade of the current detector [1291]. The decadal plan outlines an exciting program

Figure 7.36. Rapidity coverage of the current PHENIX detector compared to the strawman new PHENIX detector. The central barrel detector covers $|\eta|<1.0$; the forward detector has tracking coverage for $-4<\eta<-1$, with full EMCal and HCAL coverage for $-4.0<\eta<-2.0-(-1.5)$ with the exact range dependent on the final design configuration

Figure 7.37. Schematic drawing of the new PHENIX detector.
in heavy ion and spin physics in polarized pp collisions, focused on an investigation of the interplay between perturbative and nonperturbative physics in QCD and on the relative importance of strong and weak coupling. The physics aims have been translated into an extensive set of required physics observables to answer the key scientific questions, leading to the design of the new PHENIX detector. The upgrade plan involves replacing the PHENIX central magnet with a new compact solenoid. The limited aperture provided by the outer central arm detectors would be replaced with a compact EMCal and a Hadronic Calorimeter covering two units in pseudorapidity and full azimuth, complemented by the existing VTX and FVTX inner silicon tracking. Two additional tracking layers would be added. We highlight that the large acceptance and excellent detector capability is combined with high rate and bandwidth. The limited forward coverage of the current PHENIX detector does not allow one to adequately address the questions driving the nucleon structure and cold nuclear matter community, nor does it provide any capabilities for $\mathrm{e}+\mathrm{p}$ or $\mathrm{e}+\mathrm{A}$ collisions. Hence, an upgrade is being considered where one muon arm would be replaced by a new largeacceptance forward spectrometer with excellent PID for hadrons, electrons, and photons and full jet reconstruction capability. The modified detector layout is shown schematically in fig. 7.37. The increase in overall acceptance is shown in the lower part of fig. 7.36. The new compact barrel component at midrapidity is designed for excellent jet reconstruction and PID for photons, electrons, and $\pi^{0}$ in $\mathrm{p}+\mathrm{p}$, proton-nucleus, through central nucleusnucleus collisions. The forward upgrade design is driven by nucleon structure physics and cold nuclear matter physics. Such a forward spectrometer added to PHENIX would not only allow measurements of the single spin asymmetry at forward rapidity to test the QCD prediction that the Sivers function in Drell-Yan and SIDIS is opposite, but would also allow the unique possibility to detect the scattered lepton in $\mathrm{e}+\mathrm{p} / \mathrm{e}+\mathrm{A}$ collisions in the era of an eRHIC to virtualities $\mathrm{Q}^{2}>0.1 \mathrm{GeV}^{2}$. To realize these physics goals it is necessary to upgrade significantly the current PHENIX detector to a detector with high acceptance at forward rapidity $1<\eta<4.0$.

The strawman design for the central barrel has already been described. The forward detectors of the strawman design consist of a RICH, a preshower, an EMCal, an HCal, and additional tracking detectors to provide good momentum definition of the particles going forward. This combination of detectors is motivated by both Drell-Yan and e+p/e+A physics to emphasize the detection of electrons with high efficiency and purity.

It must be stressed again that the PHENIX detector upgrades as discussed above are driven by $\mathrm{p}+\mathrm{p}, \mathrm{p}+\mathrm{A}, \mathrm{A}+\mathrm{A}$ physics. But, comparing the requirements for the physics program at an EIC as described in section 7.3.1, it becomes clear that this detector upgrade also provides opportunities to carry out an $\mathrm{e}+\mathrm{p}$ and $\mathrm{e}+\mathrm{A}$ physics program, referred to as ePHENIX. The upgraded PHENIX is well suited for

- Inclusive e+p physics to measure polarized and unpolarized structure functions.
- Inclusive $\mathrm{e}+\mathrm{A}$ physics to measure unpolarized structure functions and derive nuclear parton distribution functions (nPDFs).
- e+p / e+A physics involving charm and bottom
- Elastic diffractive physics, i.e. elastic vector meson production and deeply virtual Compton scattering. These measurements require the addition of 'Roman pot' detectors.
nearly independent of the center-of-mass energy and lepton and hadron beam combination. Unfortunately due to the limited PID capabilities of the ePHENIX design, most of the SIDIS physics program for an EIC will not be possible.

There are still several open question on the detailed performance of the upgraded PHENIX detector in ep / eA collisions, which need to be studied in the next months. Some examples are given below. Of course, some of these concerns can easily be solved by addressing them by design changes.

- How can ePHENIX be integrated in the current IR design of eRHIC?
- What does the current material budget do to the momentum and angular resolution of the scattered lepton?
- Does the current compact solenoid provide enough bending power to achieve sufficient momentum resolution for the scattered lepton at low $\mathrm{Q}^{2}$ ?
- How can a luminosity measurement for ep/eA collisions be integrated in the design?
- Are the currently planned electromagnetic calorimeter designs suited in energy resolution to separate leptons from hadrons via $E / p$, and to get the required resolution for the DVCS photon?

## eSTAR

STAR is the other of the two large dedicated RHIC detectors, located at IP-6. Fig. 7.38 shows STAR in the configuration anticipated in 2014.

The unique strength of STAR (solenoidal tracker at RHIC) [1292] is its large, uniform acceptance capable of measuring and identifying a substantial fraction of the particles produced in heavy ion collisions. The heart of STAR is its main tracking device: a TPC, covering full azimuthal angle and $\pm 1.5$ units of pseudo-rapidity. $\mathrm{A} \mathrm{dE} / \mathrm{dx}$ resolution of $\sim$ $8 \%$ can be achieved by requiring the tracks of charged particles to have at least 20 out of a maximum of 45 hits in the TPC. Detailed descriptions of the TPC and its electronics system have been presented in [1293, 1294. The TPC sits in a 0.5 tesla solenoid, surrounded by electromagnetic calorimetry (EMC Barrel, EMC End Cap, FMS) covering $-1<\eta<4$, muon identification (MTD) covering $-1<\eta<1$ and a high-resolution time of flight system (MRPC ToF Barrel) covering $-1<\eta<1$. The tracking in STAR will be further improved by 2014 by adding a forward GEM tracker (FGT) covering $1<\eta<2$ and a high-resolution silicon detector (HFT) covering $-1<\eta<1$. The HFT gives the possibility to separate events with charmed mesons from those with beauty mesons through the detection of the displaced vertex for charmed mesons. Identification in the lepton sector will be enhanced with the Muon Telescope Detector (MTD), which will tag muons for $-1<\eta<1$. This will enable dilepton studies in the $\mu-\mu$ and $e-\mu$ channels, with a focus on separating the Upsilon states and constraining charm backgrounds to the thermal continuum in intermediate mass dileptons. Another unique feature of STAR is the 'Roman Pots' around the main detector; their main focus is to detect protons from elastic diffractive events in pp collisions.

In addition to large coverage in tracking and electromagnetic calorimetry, STAR has good particle identification capabilities. For stable charged hadrons, the TPC provides $\pi / \mathrm{K}(\pi+\mathrm{K} / \mathrm{p})$ identification to $\mathrm{p}_{T} \sim 0.7(1.1) \mathrm{GeV} / \mathrm{c}$ by the measurement of ionization energy loss ( $\mathrm{dE} / \mathrm{dx}$ ). The STAR PID capability is further enhanced by the TOF system with a time resolution of $<100 \mathrm{ps}$, which is able to identify $\pi / \mathrm{K}(\pi+\mathrm{K} / \mathrm{p})$ to $\mathrm{p}_{T} \sim 1.6$ (3.0)

Figure 7.38. Schematic drawing of the STAR detector in 2014.

Figure 7.39. Left: $1 / \beta$ vs. momentum for $\pi^{ \pm}, K^{ \pm}$, and $(p \bar{p})$ from $200 \mathrm{GeV} \mathrm{d}+\mathrm{Au}$ collisions. Separation between pions and kaons (kaons and protons) is achieved up to $\mathrm{p}_{T} \sim 1.6$ (3.0) $\mathrm{GeV} / \mathrm{c}$. The insert shows $m^{2}=p^{2}\left(1 / \beta^{2}-1\right)$ for $1.2<p_{T}<1.4 \mathrm{GeV} / \mathrm{c}$. Right: Distribution of $\log _{10}(d E / d x)$ as a function of $\log _{10}(p)$ for electrons, pions, kaons and (anti-)protons. The units of $d E / d x$ and momentum $(p)$ are $\mathrm{keV} / \mathrm{cm}$ and $\mathrm{GeV} / \mathrm{c}$, respectively. The color bands denote the $\pm 1 \sigma d E / d x$ resolution.
$\mathrm{GeV} / \mathrm{c}$, as demonstrated in the left panel of fig. 7.39, In addition, with the relativistic rise of $\mathrm{dE} / \mathrm{dx}$ from charged hadrons traversing the TPC at intermediate/high $\mathrm{p}_{T}(>3 \mathrm{GeV} / \mathrm{c})$ and diminished yields of electrons and kaons at this $\mathrm{p}_{T}$ range, pions and protons can be identified up to very high $\mathrm{p}_{T}(\sim 10 \mathrm{GeV} / \mathrm{c})$ in $\mathrm{p}+\mathrm{p}, \mathrm{p}+\mathrm{A}$ and $\mathrm{A}+\mathrm{A}$ collisions (see right panel fig. 7.39).

STAR has, like PHENIX, provided a decadal plan outlining the physics program for $\mathrm{pp}, \mathrm{dA}$ and AA collisions in the next 10 years [1295]. Contrary to PHENIX, the STAR upgrade plans are much more moderate and focus on forward rapidity $(2<|\eta|<4)$. On the side of the STAR detector at which the FMS is situated, the plan is to improve charged particle tracking by adding more tracking planes to the FGT to cover rapidities $2.5<\eta<4$. To improve lepton/hadron and $\gamma / \pi^{0}$ discrimination, as well as baryon/meson separation, a RICH detector and a preshower detector will be added in front of the FMS. The addition of a hadronic calorimeter behind the FMS will further improve the lepton/hadron separation, as well as give the possibility of measuring the energy due to neutral particles in jet reconstruction. The motivation for this upgrade is, like in the case of the PHENIX forward upgrade, transverse spin physics in pp collisions (Sivers asymmetry in Drell Yan) and the study of cold nuclear matter, i.e. parton saturation at small $x$.

The upgrade in rapidity $-4<|\eta|<-1$ is driven solely towards improving the detection capabilities of STAR for the scattered lepton in ep/eA collisions during the era of eRHIC. Currently, proposals include the addition of tracking and electromagnetic calorimetry as well as an additional ToF for PID. For tracking, it is proposed to combine high-resolution with electron identification by for example integrating a Cherenkov detector in the tracking detector.

Combining all these upgrades in fig. 7.40 shows that STAR will have very good acceptance for both the scattered lepton and for the hadrons produced by the current jet at the first stage of eRHIC, with 5 GeV electron beams colliding with proton beams with energies as high as 325 GeV . From these figures it is also obvious that the upgrade at negative rapidity is essential to provide good coverage for the scattered lepton below $\mathrm{Q}^{2}$ of $10 \mathrm{GeV}^{2}$.

Figure 7.40. Kinematic coverage of the STAR detector in the ( $\mathrm{x}, \mathrm{Q}^{2}$ ) plane. Left: electron. Right: struck quark. The electron beam energy is 5 GeV , and the nucleus beam energy is $100 \mathrm{GeV} / \mathrm{u}$. Lines of constant laboratory energy of the electron and the struck quark are shown.

The list of questions which need to be answered is very similar to that listed in the ePHENIX section, and many further detailed simulations must be performed to understand in detail the performance of STAR for ep/eA collisions. However from the first studies it is
clear that eSTAR will be able to make key measurements such as:

- Inclusive e+p physics to measure polarized and unpolarized structure functions.
- Inclusive $\mathrm{e}+\mathrm{A}$ physics to measure unpolarized structure functions and derive nuclear parton distribution functions (nPDFs).
- Elastic diffractive physics, i.e. elastic vector meson production and deeply virtual Compton scattering. Here the great advantage is that eSTAR already possesses 'Roman pot' detectors.
- The good particle ID capabilities also open the possibility of studying many of the semi-inclusive observables in ep/eA collisions, i.e. to do a flavour separation of the quark polarizations to understand both the helicity structure and the transverse spin structure (via Sivers and Collins functions) of the proton.

### 7.3.4 Detector Design for MEIC/ELIC

The Jefferson Lab design of an EIC is based on a novel figure-8 ring-ring design optimized for polarization preservation. The initial version of this EIC is termed the Medium-Energy EIC, or MEIC, which is upgradable to a higher-energy version termed Electron Ion Collider, or ELIC. The MEIC/ELIC will have minimal impact on continued operation of the Jefferson Lab (JLab) 12 GeV fixed-target program.

The ring-ring design of the MEIC/ELIC allows simultaneous operation at high luminosity of multiple detectors located at different interaction points (IPs). Due to the nature of the figure-8, four IPs are foreseen with different functions. The MEIC detector/interaction region has concentrated on maximizing acceptance for deep exclusive processes and processes associated with very-forward going particles, which are the most challenging from the detector point of view. This section will describe the baseline full-acceptance detector in more detail, where it is understood that the various MEIC/ELIC interaction points can house detectors employing different technologies and having a slightly different physics focus.

Given that the detailed design of various subsystems does not have to be frozen for another decade or so, and dedicated pre-R\&D projects are only now under way, the focus of the JLab effort has been on formulating requirements, identifying and addressing critical design issues, and integrating the detector with the interaction region of the accelerator. A tentative detector configuration with estimates based on realistic projections has been adopted, however, to provide users with input for simulations.

## The Medium-energy EIC (MEIC)

The current effort is geared towards the MEIC, for which the guiding principle has been based upon science motivation and design choices close to present state-of-the-art whenever possible. The exception to the latter is the ion beam properties, which have been established for electron-positron colliders but fundamentally depend on electron cooling for proton/ion beams. The fundamental choice for the MEIC design has been to assume short bunches, each carrying a small charge, and to achieve the requirements for the proton beam quality assume extrapolations from conventional electron cooling that have been successfully employed at Fermilab, albeit at modest proton energies. Extending this technology may be incremental, rather than transformational in nature.

While ELIC would have a circumference of about 3 km , and support proton energies up to 250 GeV (as well as heavy ions up to $100 \mathrm{GeV} / \mathrm{A}$ ), and electrons post-accelerated up to about 20 GeV , the MEIC would be somewhat smaller than the 1.4 km of the CEBAF accelerator, from which it would inject electron or positron beams between 3 and 11 GeV . The maximum proton energy would be around 100 GeV (or $40 \mathrm{GeV} / \mathrm{A}$ for heavy ions), but the often quoted design point for which performance parameters are being worked out in detail, is 60 GeV . The choice of a mid-range energy for these studies is primarily based on two considerations. On the accelerator side, a proton energy of 60 GeV is a somewhat more conservative value for which one could anticipate the performance projections for the electron cooling to become valid at an early stage of operations. On the physics side, a range of measurements, for instance related to the 3D structure of the nucleon, place strong demands on the resolution in $t$ and the luminosity at modest values of proton energy, corresponding to $s \sim 2000 \mathrm{GeV}^{2}$.

To further illustrate the importance of a mid-range energy for detailed imaging studies through exclusive reactions, we come back to the kinematics associated with these processes, but for a cut in $Q^{2}>10 \mathrm{GeV}^{2}$, a likely must for the valid partonic interpretation of such studies. If one implies a $Q^{2}>10 \mathrm{GeV}^{2}$ cutoff in such exclusive processes, the kinematic patterns of earlier fig. 7.20 drastically change. The upper panels of fig. 7.41 shows how the momentum distribution of mesons associated with exclusive pseudoscalar meson production change with lepton and proton energy. Compared to fig. 7.20, the peak in the forward-ion direction has disappeared completely. Lower lepton energies also push towards lower hadron momenta in the central-angle region, and thus reduced particle identification requirements. The bottom panels of fig. 7.41 show one of the most challenging constraints on the detector and interaction region design for exclusive reactions from the need for detection of the exclusive hadronic state remaining in the exclusive process. The figures show the direct correlation between $t$ and proton energy, scaling like $1 / E_{p}$, and shows the remaining baryonic state goes very much in the forward-ion direction, but far less so (and with lower momenta) for lower proton energies, which are thus much easier to peel off from any beam-stay-clear area. Even more, assuming a fixed resolution in $t$, there are obvious benefits of lower proton energies for imaging. Of course, any high-energy ELIC would in turn greatly benefit from the experience gained from the construction and operation of the MEIC.

While maintaining a future upgrade path to the high-energy ELIC is important and always folded into the MEIC design, emphasis has been placed on ensuring that ELIC will not simply supersede the MEIC, but rather provide a complementary capability. The MEIC is thus designed to excel in the kinematic range that it will cover (i.e., on one hand having an overlap with JLab 12 GeV , and on the other with HERA data with $y<0.3$ ). Overlap in science goals is in part achieved by various accelerator features. Perhaps one of the most prominent is the figure- 8 shape, which could allow storage of polarized deuterium beams. By tagging the spectator proton in the small-angle ion spectrometer (discussed below), this will allow to carry out measurements on quasi-free (polarized) neutrons. A high luminosity over a broad kinematic range will make it possible to accumulate sufficient statistics for multiple beam energy settings. The capability to vary the beam energies is essential for some measurements (e.g., $F_{L}$ ), but also makes it possible to optimize the data taking by reducing reliance on data taken at extreme values of $y$, where the systematic uncertainties grow. This can be achieved by having a lepton beam energy that can be varied continuously, and a series of closely spaced discrete ion beam energies. In the MEIC, the latter can be accomplished by changing the number of stored ion bunches by one, and the bunch separation distance accordingly - a scheme facilitated by the high bunch repetition

Figure 7.41. The momentum distribution of the exclusive hadronic final state as a function of the scattering angle for three different center of mass energies, $\sqrt{s}=31.6,44.7,100 \mathrm{GeV}$ (upper three panels), and the $t$ distribution as a function of scattering angle of the recoiling baryon in exclusive reactions for proton beam energies $E_{p}=50 \mathrm{GeV}$ and 250 GeV (lower two panels). A cut of $Q^{2}>10$ $\mathrm{GeV}^{2}$ is applied to select the kinematic range of interest for exclusive processes. For lower center of mass energies, the momentum distribution tends towards more central scattering angles and covers lower momenta. The angle of the recoiling hadronic system is directly and inversely correlated with the proton energy. It thus decreases with increasing proton energy. For instance, as shown here, the baryon scattering angle ranges to about $1-2^{\circ}$ at a proton energy of 50 GeV and is reduced to one fifth of that as the proton energy increases to 250 GeV .
frequency. Independently varying beam energies also makes it possible to choose the most suitable lab kinematics at a certain value of $s$, potentially improving acceptance, resolution, and particle identification for the reaction of interest (see also fig. 7.41).

Having small, short ion bunches with a high bunch repetition frequency also facilitates the use of SRF crab crossing cavities, which were originally developed for KEKB to allow beams collide at an angle without significant loss of luminosity. In the context of an EIC, these were pioneered in the ELIC design, and the possibility of creating a significant crossing angle (at least 50 mrad ) became early on a key feature of the small-angle detection for the MEIC (see section 7.3.4).

## Detector Placement and Backgrounds

The figure-8 ring can support two IPs per straight section, one of which will be a "highluminosity" IP with the full crossing angle. In order to minimize backgrounds, the two high-luminosity IPs will be located close to where the ion beam exits the arc, and far away from the arc where the lepton beam exits. The latter helps to decrease synchrotron radiation (and the secondary neutron flux) at the IP, which is anyway already reduced due to the use of crab crossing (with the ion beam, not the electron beam, making the horizontal bend correction). The synchrotron background is reduced even further by lowering the strength of the last arc dipoles. The short distance between the ion arc and IP suppresses detector backgrounds from interactions of the beam with residual gas in the beam pipe by providing a smaller "target" with line-of-sight to the detector. A shorter section of the beamline is also easier to bake and keep at at ultra-high vacuum. A comparison with HERA, also taking into account the lower $p-p$ (and $p-A$ ) cross section and lower hadron multiplicity at the 100 GeV , suggests that the hadronic background will be about an order of magnitude lower in the MEIC at comparable vacuum and ion beam current, leaving a lot of headroom to increase the latter. Due to the bends associated with the horizontal crossing, the secondary IPs on each straight section will not have a line-of-sight along the full straight section, but there this is less of an issue since they are intended to either have diagnostics equipment (e.g., polarimetry), or special detectors which are less sensitive to backgrounds or intended to operate at lower beam currents.

## Detector and Interaction Region Layout

A global outline of the fully integrated MEIC detector and interaction region is given in fig. 7.42, We will in the subsequent subsections go in more detail over the central detector region, defined as the region of the detectors operating within the solenoid, the electron and ion endcaps, and the strategy to accomplish a full-acceptance detector. The latter has two ingredients, a relatively simple approach to incorporate low- $Q^{2}$ electron detection and a more challenging solution to measure forward and ultra-forward (in the ion direction) going hadronic or nuclear fragments. Here, we make critical use of various ingredients of the MEIC detector/interaction region design: i) the 50 mrad crossing angle; ii) the range of proton energies; iii) a small 1-2 Tm dipole field to allow measurement down to $0.5^{\circ}$ before the ion final focusing magnets; iv) ion final focusing magnets with apertures sufficient for particles with angles up to at least $0.5^{\circ}$; and v) a large 20 Tm dipole field much more downstream to peel off spectator particle and allow for very small-angle detection.

The strategy will be that various detector elements, amongst which zero degree calorimeters for neutron detection and various small-angle detectors, will be placed in the region

Figure 7.42. Interaction region and central detector layout, and its placement in the general integrated detector and interaction region. The central detector includes endcaps in both the electron and ion direction.
between the ion final focusing quads and the 20 Tm dipole field, and also beyond this 20 Tm dipole field. This then results in an essentially $100 \%$ full acceptance detector. The electron beam traverses the center region of the solenoid, while the proton/ion beam traverses at the crab crossing angle. This choice minimizes any electron steering and synchrotron radiation. Note that the 50 mr crab crossing angle also facilitates the small-diameter electron final focusing quads to be moved in to 3.5 meter distance of the interaction point. The lower electron beam energies and hence lower-field requirements for the electron beam allows the construction of relatively small-sized quadrupoles, much simplifying the electron optics design.

## Central Detector

To fulfill the requirement of hermeticity, the central detector will be built around a solenoid magnet (with a length of about 5 m ). Due to the asymmetric beam energies, the interaction point (IP) will be slightly offset towards the electron side $(2 \mathrm{~m}+3 \mathrm{~m})$. This will allow more distance for the tracking of high-momentum hadrons produced at small angles, and a larger bore angle for efficient detection of the scattered beam leptons.

The characteristics of the solenoid are guided by the desire to optimize the tracking resolution, which at central angles scales like $\Delta p / p \sim \sigma p / B R^{2}$, where $\sigma$ is the position resolution, $p$ the particle momentum, $B$ the magnetic field, and $R$ the radius of the central tracker. At forward angles, however, the resolution depends on the scattering angle, but is independent of $R$ as the particle leaves the cylindrical central tracking system from the front side (see the left panel of fig. (7.43). The resolution will then deteriorate rapidly given the lack of transverse field along the central axis of a solenoid. This will later be remedied
by adding a small dipole field, as high ion energies boost the outgoing hadrons to high momenta at forward angles and one wishes to optimize resolutions also in the forward-ion direction. To obtain a roughly better than $1 \%$ momentum resolution for central angles and particles in the $5-10 \mathrm{GeV} / \mathrm{c}$ momentum range, a field $B$ in the 2-4 T range seems highly desirable. This high field requirement suggests a magnet with a reasonably small diameter, preferably not larger than about 4 m , putting radial space at a premium. Of course, a smaller diameter has the advantage of simplifying the magnet design, with the additional advantage of reducing detector cost (which scale with the radius for the barrel calorimeter and roughly as the radius squared for the endcaps). An alternate solution may be to increase the space for tracking in the central solenoid while reducing the required solenoid field, as illustrated in the right panel of fig. 7.43, Here, the resolution improvement for pions with $10 \mathrm{GeV} / \mathrm{c}$ momentum and a scattering angle of $90^{\circ}$ is shown as a function of the tracking length and solenoidal field. Thus, there is strong incentive to reduce the space requirements for particle identification detectors within the central solenoid as much as possible, to use available space for tracking, or reduce the solenoid diameter.

Figure 7.43. (left) The resolution as a function of lab angle for a particle (pion) momentum of 5 $\mathrm{GeV} / \mathrm{c}$ in a 4 T ideal solenoidal field and with a cylindrical tracker of radius 1.25 m ; (right) The resolution as function of solenoidal field strength and tracker radius for a particle (pion) momentum of $10 \mathrm{GeV} / \mathrm{c}$ and a scattering angle of $90^{\circ}$.

The central detector would contain a tracker, particle identification, and calorimetry. A three layer configuration of the central tracker was suggested at the JLab EIC detector workshop (June 4-5, 2010)2. The first layer would consist of a low-mass vertex tracker with sufficient resolution to separate primary and secondary vertices in charm production. The middle layer would be a Time-Projection Chamber (TPC) with GEM-based readout, and the outer layer would be a cylindrical GEM tracker. The position resolution of the TPC would be about $50 \mu \mathrm{~m}$, which is a factor two improvement over the inner drift chambers of CLAS12. In conjunction with the outer GEM layer, it should provide adequate $(r, \theta, \phi)$ in-

[^289]formation. Ongoing R\&D for vertex and micropattern detectors (including GEMs), suggest that such a high-performance tracker could be built for the EIC detector. Nevertheless, a radius of at least 1 m would be required.

Particle identification in the central detector is the most open design question. At low momenta, $\mathrm{dE} / \mathrm{dx}$ (in the TPC) or TOF can be helpful. With precise timing, the momentum range of the latter could be extended somewhat (although this would require a comparable uncertainty on the track length determination in order to get a good $t_{0}$ ). The most challenging requirement is, however, for a radially compact detector providing $\pi / K$ identification over a sufficiently wide momentum range. Taking up 8 cm of radial space, a BaBar-type DIRC could satisfy this condition, providing $3 \sigma \pi / K$ separation up to $4 \mathrm{GeV} / \mathrm{c}$, e/ $\pi$ separation close to $1 \mathrm{GeV} / \mathrm{c}$, and p/K separation up to $7 \mathrm{GeV} / \mathrm{c}$. An aerogel barrel RICH could provide almost comparable performance. Neither is sufficient for the exclusive (GPD) or semi-inclusive (TMD) programs. The current baseline design thus includes a Low-Threshold Cherenkov Counter (LTCC) with $C_{4} F_{10}$ or $C_{4} F_{8} O$ gas in addition to the DIRC. This would provide $e / \pi$ separation between 1 and $3 \mathrm{GeV} / \mathrm{c}$, and $\pi / K$ separation from 4 to $9 \mathrm{GeV} / \mathrm{c}$, but at a price of $50-70 \mathrm{~cm}$ of radial space. Adding $C_{4} F_{10}$ to a barrel RICH would increase the radius by at least $80-90 \mathrm{~cm}$, although a RICH could extend the momentum coverage to $14 \mathrm{GeV} / \mathrm{c}$. Ultimately the allocation of radial space to PID and tracking is a matter of priorities, and with multiple detectors one could easily imagine that these would offer complementary capabilities. On the other hand, if one could improve the $\theta_{c}$ resolution for a DIRC by about a factor of two, its $3 \sigma \pi / K$ separation could be extended to about $6 \mathrm{GeV} / \mathrm{c}$, with the upper limits for the other particle species shifting accordingly, eliminating the need for the gas Cherenkov. Given the size of the EIC detector, an all-crystal electromagnetic calorimeter would be financially expensive and only needed in critical regions. Tungsten powder / scintillating fiber or other technologies may provide a more affordable alternative for the barrel without an excessive loss of resolution. If needed, the return yoke of the solenoid magnet can be used as part of a hadronic calorimeter, and as an absorber for muon detection (along the lines of CMS).

## Detector Endcaps

The electron side endcap would face requirements quite similar to those of CLAS12, and it is natural to adopt a similar design. Due to the offset of the IP, lower particle momenta, and simpler small-angle detection (see section 7.3.4), the electron side is not nearly as crowded as the ion one. For lepton detection at small polar angles ( $\theta$ ), the main priority of the tracking would be to provide good $\theta$ resolution, as this directly impacts the reconstruction of the event kinematics. The inner part of the endcap tracker should thus be an extension of the vertex tracker, using semiconductor detectors. At larger angles, the requirements are not as demanding and the choice of technology is not as crucial. It could include planar GEMs or even cheaper drift chambers with a small cell size. Given the generous space constraints, a final tracking region could be added outside of the solenoid itself to improve tracking performance. Lepton identification will also use an electromagnetic calorimeter and a High-Threshold Cherenkov Counter (HTCC) with $C F_{4}$ gas or equivalent. The light can be collected by mirrors, producing a cost-effective readout. In this endcap region, hadron identification will be partially provided by a TOF detector, for which the endcap is more suitable than the barrel due to the longer flight path. The $\pi / K$ identification range, again in the electron endcap region, could be extended through the use of a LowTheshold Cherenkov Counter (LTCC) with $C_{4} F_{8} O$ gas or equivalent, possibly operating
slightly above atmospheric pressure to lower the pion detection threshold. Of course, to push $\pi / K$ identification to larger momenta, $\sim 10 \mathrm{GeV} / \mathrm{c}$, a RICH detector may need to be considered, but there does not seem to be a compelling need in this electron endcap region for the MEIC. Given the space available on the electron side, there is no strong requirement for a compact electromagnetic calorimeter. Since the momentum resolution from tracking deteriorates at small angles, where also the rates go up, the ideal configuration would involve an inner circle of high-resolution, radiation-hard crystals, and a more budget-friendly outer part. Both could be covered by the same pre-shower calorimeter.

The ion side endcap would have to deal with hadrons with a wide range of momenta, some approaching that of the ion beam. The forward tracking would thus greatly benefit from good position resolution (e.g., planar GEMs), at least on par with the $50 \mu \mathrm{~m}$ of the TPC. The smallest angles can be covered by semiconductor detectors as on the electron side. Of course, a good position resolution will also put significant demands on the detector alignment and field knowledge. The most important feature of the forward tracker, however, is related to the ion beam crossing angle with respect to the electron beam. In addition to being a key component of the small-angle detection, this turns the tracking resolution into a 2D problem. Whereas the momentum resolution in a solenoidal field deteriorates rapidly at small angles with respect to the axis, the hadron scattering angle is essentially defined with respect to the ion beam line. Given that the proton/ion beam traverses the solenoid at a 50 mr (crab crossing) angle, so already encounters some transverse magnetic field component, hadrons scattered away from the electron beam will end up in a part of the detector with better momentum resolution than those scattered towards the electron beam. Taking the 2D character of the problem into account, and the significant 50 mr beam crossing angle, the spot of poor resolution will be moved into the periphery covering and only a small range in the azimuthal angle $\phi$ will be affected. For most processes, all particle tracks will remain in the zone of good resolution. In contrast, if the crossing angle is small, all particle tracks at very forward angles will suffer from poor momentum resolution, as shown in the right panel of fig. 7.43 ,

To identify particles of various species over the full momentum range, one would ideally want to use several radiators. A typical combination could include aerogel (perhaps with more than one index of refraction), $C_{4} F_{10}$ or equivalent gas, and $C F_{4}$. This would make some kind of RICH detector an attractive option, in particular if the endcap radius was not too large. Still, there are several possible approaches which eventually will need to be studied in detail. One could, for instance, imagine a dual radiator gas RICH combined with a disk DIRC (as in PANDA), with the latter providing $\pi / K$ identification up to about $4 \mathrm{GeV} / \mathrm{c}$. Having the longest flight path from the IP, the ion endcap is also where one could achieve the best results with high-resolution TOF (perhaps even integrated with the readout of the RICH). Regardless of technical solution, the total thickness of the stack of PID detectors is assumed not to exceed 1.5 m . Calorimetry in the ion endcap will include both electromagnetic and hadronic parts. The main focus of the former will be to study various reaction products rather than the scattered lepton. However, the same resolution arguments apply as for the electron endcap, and a solution with an inner high-resolution circle, and a more cost-effective outer part makes sense here as well. The magnetic enclosure of the endcap can, as in the case of the return yoke of the central detector, be integrated with a hadronic calorimeter, and serve as an absorber for muon detection.

## Small-angle Detection

The design for the full-acceptance detector envisions small-angle detection on both sides of the central detector. The naming convention used here will be that the "ion side" or "ion endcap" refers to the side of the outgoing ion and incoming electron beam. The "electron side" refers to the other one.

Figure 7.44. Forward ion detection with 50 mrad crossing angle for the full-acceptance detector. Note that the distance to the final focusing quadrupoles are located 7 m from the IP.

On the ion side, the detection will be performed in three stages as illustrated in fig. 7.44. The first stage is the endcap (discussed in section 7.3.4), which will cover all angles down to the acceptance of the forward spectrometer. This in turn has two stages, one upstream of the ion Final Focus Quadrupoles (FFQs), covering down to $0.5^{\circ}$, and one downstream covering up to at least $0.5^{\circ}$. The former will use a 1-2 Tm dipole to augment the solenoid in the range where the resolution is poor. The magnet will be about 1 m long and cover the distance to the electron beam (corresponding to the horizontal crossing angle of 50 mrad ), and about twice that in the other directions, for a total acceptance of 150 mrad in the horizontal and 200 mrad in the vertical plane. An important feature of the magnet design is to ensure that the electron beam line stays field free. The dipole will have trackers at the entrance and exit, and a calorimeter covering the ring-shaped area in front of the first ion FFQ. For neutrons, the primary goal of this calorimeter is to have good angular resolution. This intermediate stage is essential for providing good coverage and resolution in $-t$, and to investigate target fragmentation. The former is of particular importance for the study of exclusive processes, essential for the 3D imaging of the nucleon, requiring detection of the recoil baryon. Since $t \sim \theta_{p}^{2} E_{p}^{2}$, the $t$-resolution depends on the angular resolution that can be achieved. With a 50 GeV proton beam, a $-t$ of $1 \mathrm{GeV}^{2}$ corresponds to about 27 mrad (see fig. (7.41). With an angular resolution of 1 mrad , the intermediate detection stage would be able to cover $-t$ up to $2 \mathrm{GeV}^{2}$ with a resolution of about $40-50 \mathrm{MeV}^{2}$ a value that would scale with angular resolution of the inner silicon forward tracker. Recoil baryons with larger values of $-t$ would be detected in the endcap. At higher ion beam energies the $t$-acceptance of the dipole increases, but the resolution deteriorates rapidly (due to the $E_{p}^{2}$ factor). Going to lower ion energies, the opposite is true.

The last stage is the ultra-forward detection that is crucial for the tagging of spectator protons in deuterium, as well as other recoil baryons/nuclei. The design is heavily integrated with the accelerator (see fig. 7.45), using two key features. One is, again, the horizontal crossing angle for the ion beam, which needs to be "corrected" some distance downstream of the interaction point (IP). For a 50 mrad crossing angle, this corresponds to a bend of close to 100 mrad , and the required 20 Tm dipole(s) can also serve as a dedicated forward spectrometer, using the long drift space beyond for detection of both charged and neutral

Figure 7.45. The integration of particle detection in the accelerator.
particles. The other feature is a beam optics requiring low quadrupole gradients, allowing large aperture magnets. In the current design, the maximum quad gradient is less than 65 $\mathrm{T} / \mathrm{m}$. With a 10 cm aperture, this creates a 6.5 T peak field (simply the product of the aperture radius and gradient), which the magnet design should be able to support if larger peak fields were acceptable, the apertures would increase accordingly. The gradients are further arranged so that they drop off faster than the distance from the IP to that specific location, allowing the apertures to become correspondingly larger, and thereby making sure that no bottlenecks are created. This defines a geometrical acceptance through the ion final-focusing quads (FFQs) of 10 mrad , or well beyond $0.5^{\circ}$, on each side of the beam ( 20 mrad in total). To focus the 250 GeV beams in ELIC, the maximum quadrupole gradients would have to be 2.5 times larger than for the 100 GeV of the MEIC, and the apertures reduced accordingly.

The acceptance for charged particles depends on both the polar and azimuthal angles (since quads focus in one plane and defocus in the other), as well as their momentum. This can be optimized by placing a dipole spectrometer relatively close to the FFQs. To give a numerical example, a 100 mrad bend to a deuterium beam would equate to a 200 mrad bend for a spectator proton. Over a drift space of 10 m (a relatively modest distance), the spectator proton would acquire a transverse separation of 1 m from the main beam. For heavy nuclei $(\mathrm{A} / \mathrm{Z}=2.5)$ with a negligible scattering angle at close to the beam momentum, this would increase to 1.5 m , while fragments with other $\mathrm{A} / \mathrm{Z}$ ratios would be lined up in between (in particular, $\mathrm{N}=\mathrm{Z}$ would be at 25 cm , while neutron rich fragments would be deflected to the other side). Ions scattered at zero degrees and having $98 \%$ of the beam momentum would be 2 cm from the beam after 10 m of drift. Due to the large deflection
in a well known field (including the few preceding elements), the momentum resolution of the spectrometer would be excellent. Since no position measurements would be possible within the beam-stay-clear area, the angular resolution would depend on the knowledge of the optics between the IP and detection point. The reconstruction of the angle would be aided by the scattered particles quickly exiting the beam-stay-clear area after having passed the spectrometer, with multi-point tracking to be applied in the drift region. Nevertheless, some some low-momentum particles scattered at large angles will not make it all the way to the dipole spectrometer. To detect these particles, some ad hoc detectors ("Roman pots") may be placed along the way, although an interesting idea currently under investigation is to have a small-diameter compensating solenoid between the FFQs and the 20 Tm dipole. In addition to its benefits for the accelerator, such a magnet could help in tracking charged particles that do not reach the final spectrometer dipole.

The low- $Q^{2}$ tagger on the electron side will complement the electron detection in the central detector and electron side endcap. Since the electron quad gradients required for 11 GeV beams are very small compared with what is needed for 100 GeV protons, one can make the apertures very large without being constrained by peak fields (the different apertures on the incoming and outgoing sides do not affect the optics). The optimal transition point from the calorimeter to tagger coverage will ultimately be determined by physics simulations. The quads would be followed by a dipole spectrometer with sufficient drift space ( 8 m in the current layout) to detect leptons with a significant fraction of the beam energy.

## Beam Helicity Reversals

The electron and ion beam polarimetry has been given a special "interaction region" in the MEIC/ELIC design, in part due to the often large amount of space needed for Compton polarimetry. With the anticipated work in systematic understanding of Compton polarimetry in both JLab Halls A and C, and further plans to cross-calibrate this with atomic beam Moller polarimetry for a future demanding parity-violating Moller experiment, electron beam polarization determination through Compton polarimetry may well achieve sub- $0.5 \%$ uncertainties. Ion beam polarimetry remains more complicated, although efforts to reduce uncertainties are underway and possibilities are studied in elastic and inelastic electron-proton scattering experiments in situ.

The MEIC design will need both fast electron spin helicity reversal or flip for double-spin experiments and a program of deep-inelastic parity-violating experiments, and fast ion-spin flip for single-nucleon spin asymmetry experiments. The latter can also be an alternate method for double-spin experiments. The MEIC design, with its 750 MHz bunch trains, does not assume bunch-to-bunch spin flips, but also does not need it. A helicity-reversal frequency of 0.1 Hz will be at about the level needed for experiments.

For double-spin experiments, it is to first order equivalent to perform fast helicity reversals of electron or ions. The choice is a question of detailed precision, as shown later. For single-spin asymmetry experiments, these techniques are however totally different, and can not replace each other. Single-electron spin asymmetry (flipping electrons only) is mostly useful for parity violation experiments, while single-nucleon spin asymmetry (flipping ions) is mostly useful for nucleon transverse-spin and other TMD experiments. Both type of experiments are routinely performed at JLab, and both will become an important part of the EIC science program.

The rate of the required helicity flips is closely related to the systematic understanding of the precision. Typically, although already very difficult, one can control the systematic
uncertainties between two helicity states to about $1 \%$. To further reduce this asymmetry, to a level of $10^{-8}$ for the case of typical parity-violating experiments at JLab, or to a level of $10^{-5}$ for transverse-spin experiments, one has to provide a suppression faction of $10^{-6}$ (for electron spin flip) or $10^{-3}$ (for ion spin flip) by fast spin flip techniques. The suppression factor by such fast helicity reversal is proportional to $1 / \sqrt{N}$, where $N$ is the number of pairs of spin flip. If we assume a typical single-nucleon spin asymmetry experiment of 3 months of continuous running (assuming one can keep control of the systematic uncertainties between the two helicity states at the $1 \%$ level for the full period), one needs to accumulate $10^{6}$ pairs to reach a suppression of 1000 , or about 8 flips per minute. This is the root of the present 0.1 Hz beam helicity reversal assumption mentioned above.

#### Abstract

This article presents the physics case for a new high-energy, ultra-high statistics neutrino scattering experiment, NuSOnG (Neutrino Scattering on Glass). This experiment uses a Tevatron-based neutrino beam to obtain over an order of magnitude higher statistics than presently available for the purely weak processes $\nu_{\mu}+e^{-} \rightarrow \nu_{\mu}+e^{-}$and $\nu_{\mu}+e^{-} \rightarrow \nu_{e}+\mu^{-}$. A sample of Deep Inelastic Scattering events which is over two orders of magnitude larger than past samples will also be obtained. As a result, NuSOnG will be unique among present and planned experiments for its ability to probe neutrino couplings to Beyond the Standard Model physics. Many Beyond Standard Model theories physics predict a rich hierarchy of TeV -scale new states that can correct neutrino cross-sections, through modifications of $Z \nu \nu$ couplings, tree-level exchanges of new particles such as $Z^{\prime}$ s, or through loop-level oblique corrections to gauge boson propagators. These corrections are generic in theories of extra dimensions, extended gauge symmetries, supersymmetry, and more. The sensitivity of NuSOnG to this new physics extends beyond 5 TeV mass scales. This article reviews these physics opportunities.

## I. INTRODUCTION

Exploring for new physics at the "Terascale" - energy scales of $\sim 1 \mathrm{TeV}$ and beyond - is the highest priority for particle physics. A new, high energy, high statistics neutrino scattering experiment running at the Tevatron at Fermi National Accelerator Laboratory can look beyond the Standard Model at Terascale energies by making precision electroweak measurements, direct searches for novel phenomena, and precision QCD studies. In this article we limit the discussion to precision electroweak measurements; QCD studies and their impact on the precision measurements are explored in ref. [1, 2]. The ideas developed in this article were proposed within the context of an expression of interest for a new neutrino ex-
periment, NuSOnG (Neutrino Scattering On Glass) [1].
A unique and important measurement of the NuSOnG physics program is the ratio of neutral current (NC) and charged current (CC) neutrino-electron scattering, which probes new physics. The leading order Feynman diagrams for these processes are shown in Fig. 1. The NC process, $\nu_{\mu}+e^{-} \rightarrow \nu_{\mu}+e^{-}$, called "elastic scattering" or ES, provides the sensitivity to the Terascale physics. This process can explore new physics signatures in the neutrino sector which are not open to other, presently planned experiments. The CC process, called "inverse muon decay" or IMD, $\nu_{\mu}+e^{-} \rightarrow \nu_{e}+\mu^{-}$, is well understood in the Standard Model due to precision measurement of muon decay [3]. Since the data samples are collected with the same beam, target and detector at

FIG. 1: Left: "elastic scattering" (ES). Right:"Inverse Muon Decay" (IMD).
the same time, the ratio of ES to IMD events cancels many systematic errors while maintaining a strong sensitivity to the physics of interest. Our measurement goal of the ES to IMD ratio is a $0.7 \%$ error, adding systematic and statistical errors in quadrature. The high sensitivity which we propose arises from the combined high energy and high intensity of the NuSOnG design, leading to event samples more than an order of magnitude higher than past experiments.

Normalizing the ES to the IMD events represents an important step forward from past ES measurements, which have normalized neutrino-mode ES measurements to the antineutrino mode, $\bar{\nu}_{\mu}+e^{-} \rightarrow \bar{\nu}_{\mu}+e^{-}$[4, 5]. The improvement is in both the experimental and the theoretical aspects of the measurement. First, the flux contributing to IMD and $\nu \mathrm{ES}$ is identical, whereas neutrino and antineutrino fluxes are never identical and so require corrections. Second, the ratio of $\nu \mathrm{ES}$ to $\bar{\nu} \mathrm{ES}$ cancels sensitivity to Beyond Standard Model (BSM) physics effects from the NC to CC coupling ratio, $\rho$, which are among the primary physics goals of the NuSOnG measurement. In contrast, there is no such cancellation in the ES to IMD ratio.

The design of this experiment, described in Sec. II, is driven both by requiring sufficient statistics to make precision neutrino-electron scattering measurements and by the need for a neutrino flux which does not extend below the IMD threshold. The threshold for IMD events is

$$
\begin{equation*}
E_{\nu} \geq E_{\mu} \geq \frac{m_{\mu}^{2}}{2 m_{e}}=10.9 \mathrm{GeV} \tag{1}
\end{equation*}
$$

where we have dropped the small $m_{e}^{2}$ term for simplicity. The functional form above threshold, shown in Fig. 2, is given by $\left(1-m_{\mu}^{2} / E_{c m}^{2}\right)^{2}$, where $E_{c m}$ is the center of mass energy. Thus a high energy neutrino beam is required to obtain a high statistics sample of these events. The flux design should provide a lower limit on the beam energy of about 30 GeV , still well above the IMD threshold.

Sec. III describes the Standard Model Physics of neutrino electroweak scattering, for both electron and quark targets. In this section, the value of the normalization of the ES to IMD events is further explored. The very high statistics will also permit an electroweak measurement using the deep inelastic scattering (DIS) data sample from NuSOnG, via the "Paschos Wolfenstein method"

FIG. 2: Threshold factor for the IMD cross section, as a function of neutrino energy.
(PW) 6. The best electroweak measurement using DIS events to date comes from the NuTeV experiment, which has observed an anomaly. The status of this result is reviewed below. Making conservative assumptions concerning systematic improvements over NuTeV , our measurement goal using this technique is a $0.4 \%$ error on $\sin ^{2} \theta_{W}$, adding statistical and systematic errors in quadrature.

In Sec. IV, we discuss NuSOnG's potential to discover or constrain new physics through indirect probes, by making precision measurements of SM processes to look for deviations from SM predictions. We first frame the issue by considering in turn several model-independent parameterizations of possible new physics and asking what constraints will be imposed on new physics in the event NuSOnG agrees with the SM. (1) Oblique correction parameters describe the effects of heavy new states in vector boson loops. (2) New states may induce higherdimensional effective operators involving neutrinos. Finally, (3) new states may modify the couplings of the gauge bosons to neutrinos and leptons, including possibly violating lepton universality. In each case we consider the ability of NuSOnG to detect or constrain these types of deviations from the SM.

In Sec. V. we examine specific models for new physics. We begin by presenting the sensitivity to a set of new physics models. In particular, we consider

- typical $Z^{\prime}$ models,
- non-degenerate leptoquark models,
- R-parity violating SUSY models,
- extended Higgs models.

The models were selected because they are often used as benchmarks in the literature. While this list is not exhaustive, it serves to illustrate the possibilities. For each case, we consider how NuSOnG compares to other measurements and note the unique contributions. We end this section by approaching the question from the opposite view, asking: how could the results from NuSOnG clarify the underlying physics model, should evidence of new physics emerge from LHC in the near future?

FIG. 3: The assumed energy-weighted flux, from the NuTeV Experiment [7, in neutrino mode (left) and antineutrino mode (right). Black: muon neutrino, red: muon antineutrino, blue: electron neutrino and antineutrino flux.

Two further studies which can be performed by NuSOnG are QCD measurements and direct searches. The very large ( $\sim 600$ million event) DIS sample will allow the opportunity for precision studies of QCD. There are many interesting measurements which can be made in their own right and which are important to NuSOnG's Terascale physics program. The very high flux will also permits direct searches for new physics. Those which complement the physics discussed in this paper include:

- non-unitarity in the light neutrino mixing matrix;
- wrong-sign inverse muon decay (WSIMD), $\bar{\nu}_{\mu}+$ $e^{-} \rightarrow \mu^{-}+\bar{\nu}_{e} ;$
- decays of neutrissimos, i.e., moderately-heavy neutral-heavy-leptons, with masses above 45 GeV .

For more information on these studies, see refs. [1, 2,

## II. CONCEPTUAL DESIGN FOR THE EXPERIMENT

In order to discuss the physics case for a new high energy, high statistics experiment, one must specify certain design parameters for the beam and detector. The beam and detector should marry the best aspects of NuTeV [7], the highest energy neutrino experiment, and Charm II [9, the experiment with the largest ES sample to date. The plan presented here is not optimized, but provides a basis for discussion. The final design of the NuSOnG detector will be based on these concepts, and is still under development.

In this section, we present, but do not justify, the design choices. Later in this article, we discuss the reasoning for the choices, particularly in Secs. IIIC and IIID.

We will assume a beam design based on the one used by the NuTeV experiment [7], which is the most recent high energy neutrino experiment. This experiment used 800 GeV protons on target. The beam flux, shown in Fig. 3. is ideal for the physics case for several reasons. There is essentially no flux below 30 GeV , hence all neutrinos
are well above the IMD threshold. It is sign-selected: in neutrino mode, $98.2 \%$ of neutrino interactions were due to $\pi^{+}$and $K^{+}$secondaries, while in antineutrino mode $97.3 \%$ came from $\pi^{-}$and $K^{-}$. The "wrong sign" content was very low, with a $0.03 \%$ antineutrino contamination in neutrino mode and $0.4 \%$ neutrino contamination in antineutrino mode. The electron-flavor content was $1.8 \%$ in neutrino mode and $2.3 \%$ in antineutrino mode. The major source of these neutrinos is $K_{e 3}^{ \pm}$decay, representing $1.7 \%$ of the total flux in neutrino mode, and $1.6 \%$ in antineutrino mode.

Redesign of the beamline for NuSOnG is expected to lead to modest changes in these ratios. For example, if the decay pipe length is 1.5 km rather than 440 m , as in NuTeV , the $\pi / K$ ratio increases by $20 \%$ and the fractional $\nu_{e}$ content is reduced.

With respect to Tevatron running conditions, we will assume that twenty times more protons on target (POT) per year can be produced for NuSOnG compared to NuTeV . This is achieved through three times higher intensity per pulse (or "ping"). Nearly an order of magnitude more pulses per spill are provided. Our studies assume $4 \times 10^{19} \mathrm{POT} /$ year, with 5 years of running. Preliminary studies supporting these goals are provided in ref. 8].

The event rates quoted below are consistent with $1.5 \times 10^{20}$ protons on target in neutrino running and $0.5 \times 10^{20}$ protons on target in antineutrino running. The choice to emphasize neutrino running is driven by obtaining high statistics ES, which has a higher cross section for neutrino scatters, and to use the IMD for normalization this process only occurs in neutrino scattering. The Standard Model forbids an IMD signal in antineutrino mode. However, some antineutrino running is required for the physics described in the following sections, especially the PW electroweak measurement.

The beam from such a design is highly forward directed. NuTeV was designed so that $90 \%$ of the neutrinos from pion decay were contained within the detector face, where the detector was located at 1 km . For NuSOnG, which will use a 5 m detector, $\sim 90 \%$ of the neutrinos from pion decay are contained at $\sim 3 \mathrm{~km}$.

The optimal detector is a fine-grained calorimeter for electromagnetic shower reconstruction followed by a toroid muon spectrometer. This allows excellent reconstruction of the energy of the outgoing lepton from charged current events. We employ a Charm II style design [9, which uses a glass target calorimeter followed by a toroid. We assume one inch glass panels with active detectors interspersed for energy and position measurement. Glass provides an optimal choice of density, low enough to allow electromagnetic showers to be well sampled, but high enough that the detector length does not compromise acceptance for large angle muons by the toroid. Approximately $10 \%$ of the glass will be doped with scintillator to allow for background studies, as discussed in Sec. IIID.

The design introduces four identical sub-detectors of

| 600 M | $\nu_{\mu}$ CC Deep Inelastic Scattering |
| :---: | :---: |
| 190 M | $\nu_{\mu}$ NC Deep Inelastic Scattering |
| 75 k | $\nu_{\mu}$ electron NC elastic scatters (ES) |
| 700 k | $\nu_{\mu}$ electron CC quasi-elastic scatters (IMD) |
| 33 M | $\bar{\nu}_{\mu}$ CC Deep Inelastic Scattering |
| 12 M | $\bar{\nu}_{\mu}$ NC Deep Inelastic Scattering |
| 7 k | $\bar{\nu}_{\mu}$ electron NC elastic scatters (ES) |
| 0 k | $\bar{\nu}_{\mu}$ electron CC quasi-elastic scatters (WSIMD) |

TABLE I: Rates assumed for this paper. NC indicates "neutral current" and CC indicates "charged current."
this glass-calorimeter and toroid design, each a total of 29 m in length (including the toroid). Between each subdetector is a 15 m decay region for direct searches for new physics. The total fiducial volume is 3 ktons.

The NuSOnG run plan, for reasons discussed in Sec. IIIB and IIIC, concentrates on running in neutrino mode. This design will yield the rates shown in Table $\mathbb{I}$. These rates, before cuts, are assumed throughout the rest of the discussion. We can compare this sample to past experiments. The present highest statistics sample for $\nu_{\mu}$ and $\bar{\nu}_{\mu}$ ES is from CHARM II, with $2677 \pm 82$ events in neutrino mode and $2752 \pm 88$ events in antineutrino mode [5]. Thus the proposed experiment will have a factor of $30(2.5)$ more $\nu(\bar{\nu})$-electron events. As an example, after cuts, the first method of analysis described in Sec. IIID retains $63 \%$ of the $\nu$ sample. For deep inelastic scattering, 600 M and 190 M events are expected in neutrino and antineutrino modes, respectively. After minimal cuts to isolate DIS events [10], NuTeV had 1.62M DIS (NC+CC) events in neutrino mode and 0.35 M in antineutrino mode; thus NuSOnG has orders of magnitude more events.

The detector will incorporate several specialized regions. A region of fine vertex-tracking facilitates measurements of the strange sea relevant for the electroweak analysis, as described in ref. [2]. Two possibilities are under consideration: an emulsion detector or a silicon detector of the style of NOMAD-STAR [11]. Both are compact and easily accommodated. For further QCD studies, it will also be useful to intersperse alternative target materials: $\mathrm{C}, \mathrm{Al}, \mathrm{Fe}$, and $\mathrm{Pb}[2]$.

## III. ELECTROWEAK MEASUREMENTS IN NEUTRINO SCATTERING

Neutrino neutral current (NC) scattering is an ideal probe for new physics. An experiment like NuSOnG is unique in its ability to test the NC couplings by studying scattering of neutrinos from both electrons and quarks. A deviation from the Standard Model predictions in both the electron and quark measurements would present a compelling case for new physics.

The exchange of the $Z$ boson between the neutrino $\nu$
and fermion $f$ leads to the effective interaction:

$$
\begin{align*}
\mathcal{L}=-\sqrt{2} G_{F}[ & \left.\bar{\nu} \gamma_{\mu}\left(g_{V}^{\nu}-g_{A}^{\nu} \gamma_{5}\right) \nu\right]\left[\bar{f} \gamma^{\mu}\left(g_{V}^{f}-g_{A}^{f} \gamma_{5}\right) f\right] \\
=-\sqrt{2} G_{F}[ & \left.g_{L}^{\nu} \bar{\nu} \gamma_{\mu}\left(1-\gamma_{5}\right) \nu+g_{R}^{\nu} \bar{\nu} \gamma_{\mu}\left(1+\gamma_{5}\right) \nu\right] \\
& \times\left[g_{L}^{f} \bar{f} \gamma^{\mu}\left(1-\gamma_{5}\right) f+g_{R}^{f} \bar{f} \gamma^{\mu}\left(1+\gamma_{5}\right) f\right] \tag{2}
\end{align*}
$$

where the Standard Model values of the couplings are:

$$
\begin{align*}
g_{L}^{\nu} & =\sqrt{\rho}\left(+\frac{1}{2}\right) \\
g_{R}^{\nu} & =0 \\
g_{L}^{f} & =\sqrt{\rho}\left(I_{3}^{f}-Q^{f} \sin ^{2} \theta_{W}\right) \\
g_{R}^{f} & =\sqrt{\rho}\left(-Q^{f} \sin ^{2} \theta_{W}\right), \tag{3}
\end{align*}
$$

or equivalently,

$$
\begin{align*}
g_{V}^{\nu} & =g_{L}^{\nu}+g_{R}^{\nu}=\sqrt{\rho}\left(+\frac{1}{2}\right) \\
g_{A}^{\nu} & =g_{L}^{\nu}-g_{R}^{\nu}=\sqrt{\rho}\left(+\frac{1}{2}\right) \\
g_{V}^{f} & =g_{L}^{f}+g_{R}^{f}=\sqrt{\rho}\left(I_{3}^{f}-2 Q^{f} \sin ^{2} \theta_{W}\right) \\
g_{A}^{f} & =g_{L}^{f}-g_{R}^{f}=\sqrt{\rho}\left(I_{3}^{f}\right) \tag{4}
\end{align*}
$$

Here, $I_{3}^{f}$ and $Q^{f}$ are the weak isospin and electromagnetic charge of fermion $f$, respectively. In these formulas, $\rho$ is the relative coupling strength of the neutral to charged current interactions ( $\rho=1$ at tree level in the Standard Model). The weak mixing parameter, $\sin ^{2} \theta_{W}$, is related (at tree level) to $G_{F}, M_{Z}$ and $\alpha$ by

$$
\begin{equation*}
\sin ^{2} 2 \theta_{W}=\frac{4 \pi \alpha}{\sqrt{2} G_{F} M_{Z}^{2}} \tag{5}
\end{equation*}
$$

## A. Neutrino Electron Elastic Scattering

The differential cross section for $\nu_{\mu}$ and $\bar{\nu}_{\mu}$ ES, defined using the coupling constants described above, is:

$$
\begin{align*}
\frac{d \sigma}{d T}=\frac{2 G_{F}^{2} m_{e}}{\pi}[ & \left(g_{L}^{\nu} g_{V}^{e} \pm g_{L}^{\nu} g_{A}^{e}\right)^{2} \\
& +\left(g_{L}^{\nu} g_{V}^{e} \mp g_{L}^{\nu} g_{A}^{e}\right)^{2}\left(1-\frac{T}{E_{\nu}}\right)^{2} \\
& \left.-\left\{\left(g_{L}^{\nu} g_{V}^{e}\right)^{2}-\left(g_{L}^{\nu} g_{A}^{e}\right)^{2}\right\} \frac{m_{e} T}{E_{\nu}^{2}}\right] . \tag{6}
\end{align*}
$$

The upper and lower signs correspond to the neutrino and anti-neutrino cases, respectively. In this equation, $E_{\nu}$ is the incident $\nu_{\mu}$ energy and $T$ is the electron recoil kinetic energy.

More often in the literature, the cross section is defined in terms of the parameters $\left(g_{V}^{\nu e}, g_{A}^{\nu e}\right)$, which are defined as

$$
g_{V}^{\nu e} \equiv\left(2 g_{L}^{\nu} g_{V}^{e}\right)=\rho\left(-\frac{1}{2}+2 \sin ^{2} \theta_{W}\right)
$$

$$
\begin{equation*}
g_{A}^{\nu e} \equiv\left(2 g_{L}^{\nu} g_{A}^{e}\right)=\rho\left(-\frac{1}{2}\right) \tag{7}
\end{equation*}
$$

In terms of these parameters, we can write:

$$
\begin{align*}
\frac{d \sigma}{d T}= & \frac{G_{F}^{2} m_{e}}{2 \pi}\left[\left(g_{V}^{\nu e} \pm g_{A}^{\nu e}\right)^{2}\right. \\
& +\left(g_{V}^{\nu e} \mp g_{A}^{\nu e}\right)^{2}\left(1-\frac{T}{E_{\nu}}\right)^{2} \\
& \left.-\left\{\left(g_{V}^{\nu e}\right)^{2}-\left(g_{A}^{\nu e}\right)^{2}\right\} \frac{m_{e} T}{E_{\nu}^{2}}\right] . \tag{8}
\end{align*}
$$

When $m_{e} \ll E_{\nu}$, as is the case in NuSOnG, the third term in these expressions can be neglected. If we introduce the variable $y=T / E_{\nu}$, then

$$
\begin{equation*}
\frac{d \sigma}{d y}=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi}\left[\left(g_{V}^{\nu e} \pm g_{A}^{\nu e}\right)^{2}+\left(g_{V}^{\nu e} \mp g_{A}^{\nu e}\right)^{2}(1-y)^{2}\right] \tag{9}
\end{equation*}
$$

Integrating, we obtain the total cross sections which are

$$
\begin{equation*}
\sigma=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi}\left[\left(g_{V}^{\nu e} \pm g_{A}^{\nu e}\right)^{2}+\frac{1}{3}\left(g_{V}^{\nu e} \mp g_{A}^{\nu e}\right)^{2}\right] \tag{10}
\end{equation*}
$$

Note that

$$
\begin{align*}
\left(g_{V}^{\nu e}+g_{A}^{\nu e}\right)^{2} & =\rho^{2}\left(-1+2 \sin ^{2} \theta_{W}\right)^{2} \\
& =\rho^{2}\left(1-4 \sin ^{2} \theta_{W}+4 \sin ^{4} \theta_{W}\right) \\
\left(g_{V}^{\nu e}-g_{A}^{\nu e}\right)^{2} & =\rho^{2}\left(2 \sin ^{2} \theta_{W}\right)^{2} \\
& =\rho^{2}\left(4 \sin ^{4} \theta_{W}\right) \tag{11}
\end{align*}
$$

Therefore,

$$
\begin{align*}
& \sigma\left(\nu_{\mu} e\right)=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi} \rho^{2}\left[1-4 \sin ^{2} \theta_{W}+\frac{16}{3} \sin ^{4} \theta_{W}\right] \\
& \sigma\left(\bar{\nu}_{\mu} e\right)=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi} \frac{\rho^{2}}{3}\left[1-4 \sin ^{2} \theta_{W}+16 \sin ^{4} \theta_{W}\right] \tag{12}
\end{align*}
$$

The ratio of the integrated cross sections for neutrino to antineutrino electron ES is

$$
\begin{equation*}
R_{\nu / \bar{\nu}}=\frac{\sigma\left(\nu_{\mu} e\right)}{\left.\sigma^{( } \bar{\nu}_{\mu} e\right)}=3 \frac{1-4 \sin ^{2} \theta_{W}+\frac{16}{3} \sin ^{4} \theta_{W}}{1-4 \sin ^{2} \theta_{W}+16 \sin ^{4} \theta_{W}} \tag{13}
\end{equation*}
$$

Fig. 4 (top) shows the results for $\sin ^{2} \theta_{W}$ from many past experiments which have used this " $\nu / \bar{\nu} \mathrm{ES}$ ratio."

In the ratio, $R_{\nu / \bar{\nu}}$, the dependence on $\rho$ canceled. This directly extracts $\sin ^{2} \theta_{W}$. The relationship between the error on the ratio and the error on $\sin ^{2} \theta_{W}$, which for convenience we abbreviate as $z$, is:

$$
\begin{align*}
\delta z= & \left(\frac{32 z-12}{16 z^{2}-4 z+1}+\right. \\
& \left.\frac{448 z^{2}-144 z-512 z^{3}+12}{48 z^{2}-8 z-128 z^{3}+256 z^{4}+1}\right)^{-1} \delta R_{\nu / \bar{\nu}} \\
= & -0.103 \delta R_{\nu / \bar{\nu}}  \tag{14}\\
\delta z / z= & -0.575 \delta R_{\nu / \bar{\nu}} / R_{\nu / \bar{\nu}} \tag{15}
\end{align*}
$$

FIG. 4: Measurements of $\sin ^{2} \theta_{W}$ from past experiments. Top: neutrino-electron elastic scattering experiments. Bottom: neutrino DIS experiments. All DIS results are adjusted to the same charm mass (relevant for experiments not using the PW method). The Standard Model value, indicated by the line, is 0.2227 [12].
for $z=0.2227$ (or $R_{\nu / \bar{\nu}}=1.242$ ). Roughly, the fractional error on $\sin ^{2} \theta_{W}$ is $60 \%$ of the fractional error on $R_{\nu / \bar{\nu}}$.

## B. A New Technique: Normalization Through IMD

An experiment such as NuSOnG can make independent measurements of the electroweak parameters for both $\nu_{\mu}$ and $\bar{\nu}_{\mu}$-electron scattering. We can achieve this via ratios or by direct extraction of the cross section. In the case of $\nu_{\mu}$-electron scattering, we will use the ratio of the number of events in neutrino-electron elastic scattering to inverse muon decay:

$$
\begin{equation*}
\frac{N\left(\nu_{\mu} e^{-} \rightarrow \nu_{\mu} e^{-}\right)}{N\left(\nu_{\mu} e^{-} \rightarrow \mu^{-} \nu_{e}\right)}=\frac{\sigma_{N C}^{\nu e} \times \Phi^{\nu}}{\sigma^{I M D} \times \Phi^{\nu}} \tag{16}
\end{equation*}
$$

Because the cross section for IMD events is well determined by the Standard Model, this ratio should have low errors and will isolate the EW parameters from NC scattering. In the discussion below, we will assume that the systematic error on this ratio is $0.5 \%$.

In the case of $\bar{\nu}_{\mu}$ data, the absolute normalization is more complex because there is no equivalent process to inverse muon decay (since there are no positrons in the detector). One can use the fact that, for low exchange energy (or "nu") in Deep Inelastic Scattering,

FIG. 5: Kinematic distributions for IMD events from incident neutrino energy between 100 and 200 GeV . Left: $y$ distribution; right: $\theta_{\mu}$ distribution. Black: distribution of events before cuts; Red: distribution after cuts for analysis method 1 (see Sec. III D.
the cross sections in neutrino and antineutrino scattering approach the same constant, $A$ 13]. This is called the "low nu method" of flux extractions. For DIS events with low energy transfer and hence low hadronic en$\operatorname{ergy}\left(5 \lesssim E_{\text {had }} \lesssim 10 \mathrm{GeV}\right), N_{\nu D I S}^{\text {low } E_{\text {had }}}=\Phi^{\nu} A$ and $N_{\bar{\nu} D I S}^{\text {low } E_{h} a d}=\Phi^{\bar{\nu}} A$. The result is that the electroweak parameters can be extracted using the ratio

$$
\begin{equation*}
\frac{N_{\nu D I S}^{l o w} E_{\text {had }}}{N_{\bar{\nu} D I S}^{l o w} E_{\text {had }}} \times \frac{N\left(\bar{\nu}_{\mu} e^{-} \rightarrow \bar{\nu}_{\mu} e^{-}\right)}{N\left(\nu_{\mu} e^{-} \rightarrow \mu^{-} \nu_{e}\right)}=\frac{\Phi^{\nu}}{\Phi^{\bar{\nu}}} \times \frac{\sigma_{N C}^{\bar{\nu} e} \times \Phi^{\bar{\nu}}}{\sigma^{I M D} \times \Phi^{\nu}} . \tag{17}
\end{equation*}
$$

The first ratio cancels the DIS cross section, leaving the energy-integrated $\nu$ to $\bar{\nu}$ flux ratio. The IMD events in the denominator of the second term cancel the integrated $\nu$ flux. The NC elastic events cancel the integrated $\bar{\nu}$ flux.

Because of the added layer of complexity, the antineutrino ES measurement would have a higher systematic error than the neutrino ES scattering measurement. The potentially higher error is one factor leading to the plan that NuSOnG concentrate on neutrino running for the ES studies.

As shown in Fig. 2. IMD events have a kinematic threshold at 10.9 GeV . These events also have other interesting kinematic properties. The minimum energy of the outgoing muon in the lab frame is given by

$$
\begin{equation*}
E_{\mu l a b}^{\min }=\frac{m_{\mu}^{2}+m_{e}^{2}}{2 m_{e}}=10.9 \mathrm{GeV} \tag{18}
\end{equation*}
$$

In the detector described above, muons of this energy and higher will reach the toroid spectrometer without ranging-out in the glass. An interesting consequence is that, independent of $E_{\nu}$, the energy transfer in the interaction has a maximum value of

$$
\begin{equation*}
y_{\max }=1-\frac{10.9 \mathrm{GeV}}{E_{\nu}} \tag{19}
\end{equation*}
$$

Thus at low $E_{\nu}$, the cutoff in $y$ is less than unity, as shown in Fig. 5 (left). The direct consequence of this is

FIG. 6: Reconstructed neutrino energy (red) for IMD events before cuts compared to true neutrino energy (black).
a strong cutoff in angle of the outgoing muon, shown in Fig. 5 (right). In principle, one can reconstruct the full neutrino energy in these events:

$$
\begin{equation*}
E_{\nu}^{I M D}=\frac{1}{2} \frac{2 m_{e} E_{\mu}-m_{e}^{2}-m_{\mu}^{2}}{m_{e}-E_{\mu}+p_{\mu} \cos \theta_{\mu}} \tag{20}
\end{equation*}
$$

This formula depends on $\theta_{\mu}$, which is small. The reconstructed $E_{\nu}$ is smeared by resolution effects as seen in Fig. 6. While the analysis can be done by summing over all energies, these distributions indicate that an energy binned analysis may be possible. This is more powerful because one can fit for the energy dependence of backgrounds. For the illustrative analyzes below, however, we do not employ this technique.

The error on $\sin ^{2} \theta_{W}$ extracted from this ratio, $R_{E S / I M D}$, assuming a Standard Model value for $\rho$, is the same as the error on the ratio:

$$
\begin{equation*}
\frac{\delta\left(\sin ^{2} \theta_{W}\right)}{\sin ^{2} \theta_{W}} \approx \frac{\delta R_{E S / I M D}}{R_{E S / I M D}} \tag{21}
\end{equation*}
$$

Ref. [14] provides a useful summary of radiative corrections for the ES and IMD processes, which were originally calculated in Ref. [15]. The error from radiative corrections is expected to be below $0.1 \%$. It is noted that to reduce the error below $0.1 \%$, leading two-loop effects must be included. A new evaluation of the radiative corrections is underway [16].

## C. IMD Normalization vs. $\bar{\nu}$ Normalization

NuSOnG can measure both the $\nu / \bar{\nu}$ ES ratio, as in the case of past experiments shown in Eq. 13 , as well as the ES/IMD ratio. In the case of the former, to obtain the best measurement in a 5 year run, one would choose a 1:3 ratio of run time in $\nu$ versus $\bar{\nu}$ mode. In the latter case, one would maximize running in $\nu$ mode. The result of the two cases is a nearly equal error on $\sin ^{2} \theta_{W}$, despite the fact that the error on the $\nu / \bar{\nu} \mathrm{ES}$ is nearly twice that of the ES/IMD ratio. To understand this, compare Eq. (15) to Eq. 21. However, the ES/IMD ratio is substantially stronger for reasons of physics. Therefore, our conceptual design calls for running mainly with a $\nu$ beam. In this section we explore the issues for these two methods of measurement further. We also justify why the precision measurement requires high energies, only available from a Tevatron-based beam.

## 1. Comparison of the Two Measurement Options

From the point of view of physics, The ES/IMD ratio is more interesting than the $\nu / \bar{\nu} \mathrm{ES}$ ratio. This is because $\rho$ has canceled in the $\nu / \bar{\nu}$ ES ratio of Eq. (13), leaving the ratio insensitive to physics which manifests itself through changes in the NC coupling. Many of the unique physics goals of NuSOnG, discussed in Sec. IV, depend upon sensitivity to the NC coupling.

An equally important concern was one of systematics. The $\nu$ and $\bar{\nu}$ fluxes for a conventional neutrino beam are substantially different. For the case of NuSOnG, the fluxes are compared in Fig. 3. Predicting the differences in these fluxes from secondary production measurements and simulations leads to substantial systematic errors. For beams at high energies $(>30 \mathrm{GeV})$, such as $\mathrm{Nu}-$ SOnG, the "low nu" method [13] for determining the ratio of the neutrino to antineutrino fluxes from Deep Inelastic events, developed by CCFR and NuTeV and described in Sec. IIIB, can be employed. However, this leads to the criticism that one has introduced a new process into the purely-leptonic analysis.

Neither criticism is relevant to the ES/IMD ratio. The sensitivity to the new physics through the couplings does not cancel. Because both processes are in neutrino mode, the flux exactly cancels, as long as the neutrino energies are well above the IMD threshold (this will be illustrated in the analysis presented in Sec. IIID). This ratio has the added advantage of needing only neutrino-mode running,
which means that very high statistics can be obtained. This is clearly the more elegant solution.

It should be noted that nothing precludes continued running of NuSOnG beyond the 5 -year plan presented here. This run-length was selected as "reasonable" for first results. If interesting physics is observed in this first phase, an extended run in antineutrino mode may be warranted, in which case both the ES/IMD and $\nu / \bar{\nu}$ ES ratios could be measured. The latter would then constrain $\sin ^{2} \theta_{W}$ in a pure neutrino measurement and the former is then used to extract $\rho$.

To measure the ES/IMD ratio to high precision, there must be little low energy flux. This is because the IMD has a threshold of 10.9 GeV , and does not have substantial rate until $\sim 30 \mathrm{GeV}$. The low-energy cut-off in the flux (see Fig. 3) coming from the energy-angle correlation of neutrinos from pion decay, is ideal.

## 2. Why a Tevatron-based Beam is Best for Both Options

The ES/IMD measurement is not an option for the planned beams from the Main Injector at Fermilab. For both presently planned Main Injector experiments at Fermilab [17] and for the proposed Project-X DUSEL beam [18], the neutrino flux is peaked at $\sim 5 \mathrm{GeV}$. The majority of the flux of these beams is below 5 GeV , and most of the flux is below the 10.9 GeV IMD threshold. Because of this, one simply cannot use the IMD events to normalize.

In principle, the $\nu / \bar{\nu} \mathrm{ES}$ ratio could be used. However, in practice this will have large systematics. The $\nu$ and $\bar{\nu}$ fluxes for a horn beam are significantly different. First principles predictions of secondary mesons are not sufficient to reduce this error to the precision level. The energy range is well below the deep inelastic region where the "low nu" method can be applied to accurately extract a $\bar{\nu} / \nu$ flux ratio. Other processes, such as charged-current quasi-elastic scattering, could be considered for normalization, but the differences in nuclear effects in neutrino and antineutrino scattering for these events is not sufficiently well understood to yield a precision measurement.

Lastly, the ES rates for the present Main Injector beams are too low for a high statistics measurement. This is because the cross section falls linearly with energy. Event samples on the order of 10k may be possible with extended running in the Project X DUSEL beam in the future. From the point of view of statistics, even though two orders of magnitude more protons on target are supplied in such a beam, the Tevatron provides a substantially higher rate of ES per year of running.

Compared to the Main Injector beam, a Tevatronbased beam does not face these issues. The choice of running in neutrino mode provides the highest precision measurement while optimizing the physics.

| Quantity | Assumed Value | Uncertainty | Source of Estimate |
| :---: | :---: | :---: | :---: |
| Muon |  |  |  |
| Energy Resolution | $\delta E / E=10 \%$ | 2.5\% | NuTeV testbeam measurement |
| Energy Scale Error | $E_{\text {rec }}=1.0 \times E_{\text {true }}$ | 0.5\% | NuTeV testbeam measurement |
| Angular Resolution | $\delta \theta=0.011 / E^{0.96} \mathrm{rad}$ | 2.5\% | Multiple scattering fit simulation |
| Electron |  |  |  |
| Energy Resolution | $\delta E / E=0.23 / E^{0.5}$ | 1.0\% | Same as CHARM II |
| Energy Scale Error | $E_{\text {rec }}=1.0 \times E_{\text {true }}$ | 1.0\% | Scaled from CHARM II with NuSOnG statistics |
| Angular Resolution | $\delta \theta=0.008 / E^{0.5} \mathrm{rad}$ | 2.5\% | 2 better than CHARM II due to sampling |
| Flux |  |  |  |
| Normalization | 1.0 | $3 \%$ | Current total cross section uncertainty |
| Shape Uncertainty | 1.0 | 1\% | Similar to NuTeV low-nu method |
| Backgrounds |  |  |  |
| $\nu_{\mu} \mathrm{CCQE}$ | $1.0$ | 5\% | Extrapolated from NuTeV |
| $\nu_{e} \mathrm{CCQE}$ | 1.0 | $3 \%$ | Extrapolated from CHARM II |

TABLE II: Resolutions and systematic uncertainty estimates used in the parameterized Monte Carlo studies. The NuTeV estimates are based on Ref. [19] and the CHARM II estimates from Ref. 9]. Units for angles are radians and energies are in GeV .

## D. A $0.7 \%$ Measurement Goal for the ES to IMD Ratio

Achieving $0.7 \%$ precision on the ES/IMD measurement depends on reducing the backgrounds to an acceptable level without introducing significant systematics and while maintaining high signal statistics. Many of the systematic uncertainties will tend to cancel. The most important background for both the $\nu$-e neutral current and IMD events comes from charged current quasi-elastic (CCQE) scatters ( $\nu_{e} n \rightarrow p e$ and $\left.\nu_{\mu} n \rightarrow p \mu\right)$. These background CCQE processes have a much broader $Q^{2}$ as compared to the signal processes and, therefore, can be partially eliminated by kinematic cuts on the outgoing muon or electron. Initial cuts on the scattering angle and energy of the outgoing muon or electron can easily reduce the CCQE background by factors of 60 and 14 respectively while retaining over $50 \%$ of the $\nu-e$ neutral current and IMD signal. This leaves events with very forward scatters and outgoing scattered protons of low kinetic energy.

Because the NuSOnG design is at the conceptual stage and in order to be conservative, we have developed two different strategies for achieving a $0.7 \%$ error. This serves as a proof of principle that this level of error, or better, can be reached. The first method relies on detecting protons from the quasi-elastic scatter. The second method uses the beam kinematics to cut the low energy flux which reduces the CCQE background.

These methods were checked via two, independently written, parameterized Monte Carlos. The parameterized Monte Carlos made the assumptions given in Table II] where both the assumed values and uncertainties are presented. These estimates of resolutions and systematic errors are based on previous experimental measurements or on fits to simulated data. One Monte Carlo used the Nuance event generator 20 to produce events, while the other was an independently written event gen-
erator. Both Monte Carlos include nuclear absorption and binding effects.

The first strategy uses the number of protons which exit the glass to constrain the total rate of the background. In $\sim 33 \%$ of the events, a proton will exit the glass, enter a chamber and traverse the gas. This samples protons of all energies and $Q^{2}$, since the interactions occur uniformly throughout the glass. After initial cuts, the protons are below 100 MeV , and therefore highly ionizing. If we define 1 MIP as the energy deposited by a single minimum ionizing particle, like a muon, then the protons consistently deposit greater than 5 MIPs in the chamber. Thus, one can identify CCQE events by requiring $>4$ MIPS in the first chamber. The amount of remaining CCQE background after this requirement can be measured if a fraction such as $10 \%$ of the detector is made from scintillating glass that can directly identify CCQE events from light associated with the outgoing proton. A wide range of scintillating glasses have been developed 21 for nuclear experiments. These glasses are not commonly used in high energy physics experiments because the scintillation time constant is typically on the order of 100 ns . In a neutrino experiment, which has inherently lower rates than most particle experiments, this is not an issue. CCQE events can be identified by the scintillation light from the proton assuming reasonable parameters for the glass and readout photomultiplier tubes: 450 photons $/ \mathrm{MeV}$, an attenuation length of 2 m , eight phototubes per glass sheet, quantum efficiency of the tubes of $20 \%$. Using the identified CCQE events from the instrumented glass, the uncertainty in the residual background can be reduced to $2.0 \%$ for the IMD measurement. For the CCQE background to the $\nu_{\mu}-e$ neutral current measurement, the uncertainty is assumed to be $3 \%$ for the Monte Carlo prediction. Combining all the systematic errors leads to a $\sim 0.7 \%$ accuracy on the $\nu-e$ measurement as shown in Tab. III

In Tab. III, the cancellation of the flux errors should be
noted. This occurred because we use the ES/IMD ratio, as discussed in the previous section.

The second strategy involves reducing the relative CCQE background to signal by using a harder flux for the analysis. This study used the same Monte Carlos, with the resolutions listed in Tab. II, as the first analysis. The total systematic and statistical error achieved was $0.6 \%$. Below, we explain how a harder flux is obtained for the analysis. Then, we explain how this flux improves the signal-to-background in both the ES and IMD analyzes.

The strong correlation between energy and angle at the NuSOnG detector is used to isolate the harder flux. This is simplest to express in the non-bend view of the beamline, where it is given for pions by the well-known off-axis formula:

$$
\begin{equation*}
E_{\nu}=\frac{0.43 E_{\pi}}{1+\gamma^{2} \theta^{2}} \tag{22}
\end{equation*}
$$

where $\theta$ is the off-axis angle, $\gamma=E_{\pi} / m_{\pi}, E_{\pi}$ is the energy of the pion and $E_{\nu}$ is the energy of the neutrino. For the NuTeV beam and detector lay-out, this angle-energy dependence resulted in the sharp cutoff of the flux for $<30 \mathrm{GeV}$ shown in Fig. 3. Using the NuTeV G3 beam Monte Carlo [7], we have shown that by selecting vertices in the central region of the detector, one can adjust the energy where the flux sharply cuts off. Adjusting the aperture to retain flux above 50 GeV reduces the total event rate by $55 \%$.

A harder flux allows for background reduction in both the ES and the IMD samples while maintaining the signal at high efficiency. In the case of ES events, the background is from $\nu_{e}$ CCQE. The energy distribution of the electron is substantially different in the two cases. In the case of $\nu_{e}$ CCQE events, the electron carries most of the energy of the incoming neutrino because the exchange energy in the interaction is small. Thus the CCQE events produced by the harder flux populate the visible energy range above 50 GeV . On the other hand, the outgoing electron in ES events tends to populate the low visible energy region due to the combination of a flat $y$ distribution for the process convoluted with the incident neutrino energy spectrum. The result is that a cut on the visible energy less than 50 GeV reduces the error from the $\nu_{e}$ CCQE background to a negligible level. To understand the improvement in the IMD analysis, consider Fig. 2, which shows the threshold effects. The IMD signal is also rising with energy. In contrast, the $\nu_{\mu}$ CCQE rate, which is the most significant background, is flat with energy for fluxes above 1 GeV . This signal-to-background is greatly improved with a high energy flux. This allows looser cuts to be applied, which in turn reduces the systematics.

These two analyzes use substantially different strategies and can, in principle, be combined. Given these preliminary studies, we feel confident that as the detector moves from a conceptual to real design, we will be able to achieve a better than $0.7 \%$ error. However, for this paper we take the conservative approach of assuming $0.7 \%$.

## E. Neutrino Quark Scattering

Substantially higher precision has been obtained using neutrino-quark scattering, which compares neutralcurrent ( NC ) to charged-current (CC) scattering to extract $\sin ^{2} \theta_{W}$. However, these experiments are subject to issues of modeling in the quark sector. Fig. 4(bottom) reviews the history of these measurements.

The lowest systematic errors come from implementing a "Paschos-Wolfenstein style" [6] analysis. This PW technique would be used by any future experiment, including NuSOnG. This requires high purity $\nu$ and $\bar{\nu}$ beams, for which the following ratios of DIS events could be formed:

$$
\begin{align*}
R^{\nu} & =\frac{\sigma_{N C}^{\nu}}{\sigma_{C C}^{\nu}}  \tag{23}\\
R^{\bar{\nu}} & =\frac{\sigma_{N C}^{\bar{\nu}}}{\sigma_{C C}^{\bar{\nu}}} \tag{24}
\end{align*}
$$

Paschos and Wolfenstein [6] recast these as:

$$
\begin{equation*}
R^{-}=\frac{\sigma_{N C}^{\nu}-\sigma_{N C}^{\bar{\nu}}}{\sigma_{C C}^{\nu}-\sigma_{C C}^{\bar{\nu}}}=\frac{R^{\nu}-r R^{\bar{\nu}}}{1-r} \tag{25}
\end{equation*}
$$

where $r=\sigma_{C C}^{\bar{\nu}} / \sigma_{C C}^{\nu}$. In $R^{-}$many systematics cancel to first order, including the effects of the quark and antiquark seas for $u, d, s$, and $c$. Charm production only enters through $d_{\text {valence }}$ (which is Cabibbo suppressed) and at high $x$; thus the error from the charm mass is greatly reduced. The cross section ratios can be written in terms of the effective neutrino-quark coupling parameters $g_{L}^{2}$ and $g_{R}^{2}$ as

$$
\begin{align*}
R^{\nu} & =g_{L}^{2}+r g_{R}^{2}  \tag{26}\\
R^{\bar{\nu}} & =g_{L}^{2}+\frac{1}{r} g_{R}^{2}  \tag{27}\\

\end{align*}
$$

in which

$$
\begin{align*}
g_{L}^{2} & =\left(2 g_{L}^{\nu} g_{L}^{u}\right)^{2}+\left(2 g_{L}^{\nu} g_{L}^{d}\right)^{2} \\
& =\rho^{2}\left(\frac{1}{2}-\sin ^{2} \theta_{W}+\frac{5}{9} \sin ^{4} \theta_{W}\right)  \tag{29}\\
g_{R}^{2} & =\left(2 g_{L}^{\nu} g_{R}^{u}\right)^{2}+\left(2 g_{L}^{\nu} g_{R}^{d}\right)^{2} \\
& =\rho^{2}\left(\frac{5}{9} \sin ^{4} \theta_{W}\right) \tag{30}
\end{align*}
$$

In a variation on the PW idea, rather than directly form $R^{-}$, NuTeV fit simultaneously for $R^{\nu}$ and $R^{\bar{\nu}}$ to extract $\sin ^{2} \theta_{W}$, obtaining the value $\sin ^{2} \theta_{W}=0.2277 \pm$ 0.00162. Events were classified according to the length of hits in the scintillator planes of the NuTeV detector, with long events identified as CC interactions and short events as NC. An important background in the CC sample came from pion decay-in-flight, producing a muon in

TABLE III: Estimates of the IMD and ES uncertainties using a $>5$ MIP cut on the first downstream chamber. The columns give the errors for each process and then for the ratio. Errors are included for statistical uncertainties and uncertainties associated with the knowledge of resolution smearing, energy scale, flux shape, and backgrounds. The flux shape uncertainties are significantly reduced in the ratio measurement.
a NC shower. Significant backgrounds in the NC sample came from muons which ranged out or exited and from $\nu_{e}$ CC scatters which do not have a muon and thus are classified as "short."

In this paper, we present the sensitivity of NuSOnG to new physics if the NuTeV errors are reduced by a factor of $\sim 2$. This is a very conservative estimate, since most of the improvement comes from higher statistics. Only a $90 \%$ improvement in the systematics is required to reach this goal. Tab. IV argues why a $90 \%$ reduction in systematic error should be straightfroward to achieve. It is likely that the NuSOnG errors will be lower, but this requires detailed study.

In Table IV, we list the errors which NuTeV identified in their original analysis and indicate how NuSOnG will improve each error. Many of the largest experimental systematics of NuTeV are improved by introducing a fine-grained sampling calorimeter. The NuTeV detector had four inches of iron between unsegmented scintillator planes and eight inches between drift chamber planes. Better lateral segmentation and transverse detection will improve identification of scatters from intrinsic $\nu_{e} \mathrm{~s}$ in the beam and separation of CC and NC events by improved three-dimensional shower shape analyzes. The NuTeV analyzes of the intrinsic $\nu_{e}$ content [22] and the $\mathrm{CC} / \mathrm{NC}$ separation for the $\sin ^{2} \theta_{W}$ analysis which relied strictly on event length. With this said, the power of classifying by event length is shown by the fact that the NuTeV intrinsic $\nu_{e}$ analysis was sensitive to a discrepancy in the predicted intrinsic $\nu_{e}$ rate which was recently resolved with a new measurement of the $K_{e 3}$ branching ratio that
was published in 2003. Details of these issues are considered in the next section.

## F. The NuTeV Anomaly

From Fig. 4, it is apparent that the NuTeV measurement is in agreement with past neutrino scattering results, although these have much larger errors; however, in disagreement with the global fits to the electroweak data which give a Standard Model value of $\sin ^{2} \theta_{W}=0.2227$ [25]. Expressed in terms of the couplings, NuTeV measures:

$$
\begin{gather*}
g_{L}^{2}=0.30005 \pm 0.00137  \tag{31}\\
g_{R}^{2}=0.03076 \pm 0.00110 \tag{32}
\end{gather*}
$$

which can be compared to the Standard Model values of $g_{L}^{2}=0.3042$ and $g_{R}^{2}=0.0301$, respectively.

NuTeV is one of a set of $Q^{2} \ll m_{Z}^{2}$ experiments measuring $\sin ^{2} \theta_{W}$. It was performed at $Q^{2}=1$ to $140 \mathrm{GeV}^{2}$, $\left\langle Q_{\nu}^{2}\right\rangle=26 \mathrm{GeV}^{2},\left\langle Q_{\bar{\nu}}^{2}\right\rangle=15 \mathrm{GeV}^{2}$, which is also the expected range for NuSOnG. Two other precision low $Q^{2}$ measurements are from atomic parity violation [26] (APV), which samples $Q^{2} \sim 0$; and SLAC E158, a Møller scattering experiment at average $Q^{2}=0.026 \mathrm{GeV}^{2}$ [27]. Using the measurements at the $Z$-pole with $Q^{2}=M_{z}^{2}$ to fix the value of $\sin ^{2} \theta_{W}$, and evolving to low $Q^{2}[28]$, the APV and SLAC E158 are in agreement with the Standard Model. However, the radiative corrections to neutrino interactions allow sensitivity to high-mass par-

| Source | NuTeV <br> Error | Method of reduction in NuSOnG |

TABLE IV: Source and value of NuTeV errors on $\sin ^{2} \theta_{W}$, and reason why the error will be reduced in the PW-style analysis of NuSOnG. This paper assumes NuSOnG will reduce the total NuTeV error by a factor of two. This is achieved largerly through the improved statistical precision and requires only a $90 \%$ reduction in the overal NuTeV systematic error. This table argues that a better than $90 \%$ reduction is likely, but further study, once the detector design is complete, is required.
ticles which are complementary to the APV and Møllerscattering corrections. Thus, these results may not be in conflict with NuTeV. The NuSOnG measurement will provide valuable additional information on this question.

Since the NuTeV result was published, more than 300 papers have been written which cite this result. Several "Standard-Model" explanations have been suggested. While some constraints on these ideas can come from outside experiments, it will be necessary for any future neutrino scattering experiment, such as NuSOnG, to be able to directly address these proposed solutions. Also various Beyond Standard Model explanations have been put forward; those which best explain the result require a follow-up experiment which probes the neutral weak couplings specifically with neutrinos, such as NuSOnG. Here, we consider the explanations which are "within the Standard Model" and address the Beyond Standard Model later.

Several systematic adjustments to the NuTeV result have been identified since the result was published but have not yet been incorporated into a new NuTeV analysis. As discussed here, the corrections due to the two new inputs, a new $K_{e 3}$ branching ratio and a new strange sea symmetry, are significant in size but are in opposite direction - away and toward the Standard Model. So a re-analysis can be expected to yield a central value for NuTeV which will not change significantly. However, the error is expected to become larger.

In 2003, a new result from BNL865 [29] yielded a $K_{e 3}$ branching ratio which was $2.3 \sigma$ larger than past measurements and a value of $\left|V_{u s}\right|^{2}$ which brought the CKM matrix measurements into agreement with unitarity in

FIG. 7: Effect of various "Standard Model" explanations on the NuTeV anomaly. The $y$-axis is the deviation $\left(\delta \sin ^{2} \theta_{W}=\right.$ $\left.\sin ^{2} \theta_{W}^{S M}-\sin ^{2} \theta_{W}^{N u T e V}\right)$. The solid line is the published NuTeV deviation. Thick black lines extending from the NuTeV deviation show the range of possible pulls from NLO QCD and various isospin violation models. Note that the isospin violation models are mutually exclusive and so should not be added in quadrature. They are, from left to right, the full bag model, the meson cloud model, and the isospin QED model.
the first row 30. The measurement was confirmed by CERN NA48/2 [31]. The resulting increased $K_{e 3}$ branching ratio [12] increases the absolute prediction of intrinsic $\nu_{e} \mathrm{~s}$ in the NuTeV beam. This does not significantly change the error because the error on $K e 3$ was already included in the analysis. However, it introduces a correction moving the NuTeV result further away from the Standard Model, since it implies that in the original analysis, NuTeV under-subtracted the $\nu_{e}$ background in the NC sample. The shift in $\sin ^{2} \theta_{W}$ can be estimated in a back of envelope calculation to be about $\sim 0.001$ away from the Standard Model [32].

The final NuTeV measurement of the difference between the strange and anti-strange sea momentum distributions, was published in 2007 [33]. This "strange sea asymmetry" is defined as

$$
\begin{equation*}
x s^{-}(x) \equiv x s(x)-x \bar{s}(x) \tag{33}
\end{equation*}
$$

Because of mass suppression for the production of charm in CC scatters from strange quarks, a difference in the momentum distributions will result in a difference in the CC cross sections for neutrinos and antineutrinos. Thus a correction to the denominator of Eq. 25 would be required. The most recent next-to-leading order analysis finds the asymmetry, integrated over $x$ is $0.00195 \pm 0.00055 \pm 0.00138$ [33]. An integrated asymmetry of 0.007 is required to explain the published NuTeV result [33], and so one can estimate that this is a shift of about 0.0014 in $\sin ^{2} \theta_{W}$ toward the Standard Model. In this case, the errors on the NuTeV result will become larger because this effect was not originally considered in the analysis. A very naive estimate of the size of the increase can be derived by scaling the error on the integrated strange sea, quoted above, and is about 0.001 toward the Standard Model. If this naive estimate of the systematic error is borne out, then this could raise the NuTeV error on $\sin ^{2} \theta_{W}$ from 0.0016 to 0.0018 . NuSOnG will directly address the strange sea asymmetry in its QCD measurement program, as described in ref. [2].

In ref. [34, additional electromagnetic radiative corrections have been suggested as a source of the discrepancy. However, this paper only considered the effect of these corrections on $R^{\nu}$ and not $R^{\bar{\nu}}$ and for fixed beam energy of $E_{\nu}=80 \mathrm{GeV}$. The structure of the code from these authors has also made it difficult to modify for use in NuTeV . This has prompted a new set of calculations by other authors which are now under way [16]. There are, as yet, only estimates for the approximate size of newly identified effects, which are small.

The NuTeV analysis was not performed at a full NLO level in QCD; any new experiment, such as NuSOnG will need to undertake a full NLO analysis. This is possible given recently published calculations [35, 36, including those on target mass corrections 37. On Fig. 7, we show an early estimate of the expected size and direction of the pull [38]. On this plot, the solid horizontal line indicates the deviation of NuTeV from the Standard Model. The thick vertical lines, which emanate from the NuTeV
deviation, show the range of pulls estimated for various explanations. The range of pull for the NLO calculation is shown on the left.

The last possibility is that there is large isospin violation (or charge symmetry violation) in the nucleus. The NuTeV analysis assumed isospin symmetry, that is, $u(x)^{p}=d(x)^{n}$ and $d(x)^{p}=u(x)^{n}$. Isospin violation can come about from a variety of sources and is an interesting physics question in its own right. NuSOnG's direct constraints on isospin violation are discussed in ref. [2], which also considers the constraints from other experiments. Various models for isospin violation have been studied and their pulls range from less than $1 \sigma$ away from the Standard Model to $\sim 1 \sigma$ toward the Standard Model 39. We have chosen three examples 39] for illustration on Fig. 7 . the full bag model, the meson cloud model, and the isospin QED model. These are mutually exclusive models, so only one of these can affect the NuTeV anomaly.

## IV. THE TERASCALE PHYSICS REACH OF NUSONG

Even when new states are too heavy to be produced at resonance in collisions they can make their presence known indirectly, as virtual particles which affect SM processes through interference with SM contributions to amplitudes. The new heavy states induce small shifts in observables from SM predictions, and conversely precise measurements of these observables can constrain or detect new physics at mass scales well above the energies of the colliding particles. In this way the precision neutrino scattering measurements at NuSOnG will place TeV -scale indirect constraints on many classes of new physics, or perhaps detect new physics by measuring deviations from SM predictions. The effects of new high-scale physics may be reduced to a small number of effective operators along with corresponding parameters which may be fit to data. Although the particular set of operators used depends on broad assumptions about the new physics, the approach gives a parameterization of new physics which is largely model-independent.

For concreteness we will assume that NuSOnG will be able to measure the neutrino $\mathrm{ES} / \mathrm{IMD}$ ratio to a precision of $0.7 \%, \sigma\left(\bar{\nu}_{\mu} e\right)$ (normalized as per Sec. IIIB) to $1.3 \%$, and that NuSOnG will be able to halve the errors on NuTeV's measurement of DIS effective couplings, to $\Delta g_{L}^{2}=0.0007$ and $\Delta g_{R}^{2}=0.0006$ (where $g_{L}$ and $g_{R}$ were defined in Eqs. 29) and (30)).

We first parameterize new physics using the oblique parameters $S T$, which is appropriate when the important effects of the new physics appear in vacuum polarizations of gauge bosons. We next assume new physics effects manifest as higher-dimensional operators made of SM fermion fields. We separately consider the possibility that the gauge couplings to neutrinos are modified.

| Topic | Contribution of NuSOnG Measurement |
| :--- | :--- |
| Oblique Corrections | Four distinct and complementary probes of $S$ and $T$. <br>  <br> In the case of agreement with LEP/SLD: $\sim 25 \%$ improvement in electroweak precision. |

TABLE V: Summary of NuSOnG's contribution to general Terascale physics studies.

Realistic models usually introduce several new operators with relations among the coefficients; we consider several examples. A summary of the contributions of NuSOnG to the study of Terascale Physics is provided in Table V .

## A. Oblique corrections

For models of new physics in which the dominant loop corrections are vacuum polarization corrections to the $S U(2)_{L} \times U(1)_{Y}$ gauge boson propagators ("oblique" corrections), the $S T U$ (40, 41 parameterization provides a convenient framework in which to describe the effects of new physics on precision electroweak data. Differences between the predictions of a new physics model and those of a reference Standard Model (with a specified Higgs boson and top quark mass) can be expressed as nonzero values of the oblique correction parameters $S, T$ and $U . T$ and $U$ are sensitive to new physics that violates isospin, while $S$ is sensitive to isospin-conserving physics. Predictions of a Standard Model with Higgs or top masses different from the reference Standard Model may also be subsumed into shifts in $S$ and $T$ (in many models $U$ is much smaller than $S$ and $T$ and is largely unaffected by the Higgs mass, so it is often omitted in fits). Within a specific model of new physics the shift on the $S T$ plot away from the SM will be calculable [42. For example,

- A heavy Standard Model Higgs boson will make a positive contribution to $S$ and a larger negative contribution to $T$.
- Within the space of $Z^{\prime}$ models, a shift in almost any direction in $S T$ space is possible, with larger shifts for smaller $Z^{\prime}$ masses.
- Models with a fourth-generation of fermions will shift $S$ positive, and will shift $T$ positive if there are violations of isospin.

In constructing models incorporating several types of new physics the corresponding shifts to $S$ and $T$ combine; if contributions from different sectors are large, then they must conspire to cancel.

FIG. 8: The impact of NuSOnG on the limits of $S$ and $T$. The reference SM is $m_{t}=170.9 \mathrm{GeV}$, and $m_{H}=115 \mathrm{GeV}$. $1 \sigma$ bands due to NuSOnG observables are shown against the $90 \%$ contour from LEP/SLD. The central ellipses are the $68 \%$ and $90 \%$ confidence limit contours with NuSOnG included. See Eqs. 29) and 30 for the definitions of $g_{L}$ and $g_{R}$.

The constraints on $S$ and $T$ from the full set of precision electroweak data strongly restrict the models of new physics which are viable. The strongest constraints are from LEP/SLD, which give a current bound of

$$
\begin{align*}
S & =-0.02 \pm 0.11 \\
T & =+0.06 \pm 0.13 \\
\operatorname{Corr}(S, T) & =0.91 \tag{34}
\end{align*}
$$

The ES and DIS measurements from NuSOnG provide four distinct and complementary probes of $S$ and $T$, as shown in Fig. 8. If the target precision is achieved, and assuming the NuSOnG agree with SM predictions, NuSOnG will further reduce the errors on $S$ and $T$ from the LEP/SLD values to

$$
\begin{aligned}
& S=-0.05 \pm 0.09 \\
& T=+0.02 \pm 0.10
\end{aligned}
$$

$$
\begin{equation*}
\operatorname{Corr}(S, T)=0.87 \tag{35}
\end{equation*}
$$

The $\sim 25 \%$ reduction in the errors is primarily due to the improved measurement of $g_{L}^{2}$. We note that the error $g_{L}^{2}$ is likely to be further reduced (see Sec. IIIE), and so the this is conservative estimate of NuSOnG's contribution to the physics.

## B. Non-standard interactions

NuSOnG will probe new physics that modifies neutrino-quark and neutrino-electron scattering. If the masses associated to the new degrees of freedom are much larger than the center of mass energy $\left(s=2 m_{e} E_{\text {beam }} \lesssim\right.$ $0.5 \mathrm{GeV}^{2}$ ) then modifications to these processes are welldescribed by higher-dimensional effective operators. In the context of neutrino reactions, these operators are also referred to as non-standard interactions (NSI's). In a model-independent effective Lagrangian approach these effective operators are added to the SM effective Lagrangian with arbitrary coefficients. Expressions for experimental observables can be computed using the new effective Lagrangian, and the arbitrary coefficients can then be constrained by fitting to data. Typically, bounds on the magnitude of the coefficients are obtained using only one or a few of the available effective operators. This approach simplifies the analysis and gives an indication of the scale of constraints, although we must be mindful of relationships among different operators that will be imposed by specific assumptions regarding the underlying physics.

To assess the sensitivity of NuSOnG to "heavy" new physics in neutral current processes, we introduce the following effective Lagrangian for neutrino-fermion interactions [44, 48, 49]:

$$
\begin{align*}
\mathcal{L}_{\mathrm{NSI}}=-\sqrt{2} G_{F}\left[\bar{\nu}_{\alpha} \gamma_{\sigma} P_{L} \nu_{\beta}\right] & {\left[\varepsilon_{\alpha \beta}^{f V} \bar{f} \gamma^{\sigma} f-\varepsilon_{\alpha \beta}^{f A} \bar{f} \gamma^{\sigma} \gamma_{5} f\right] } \\
=-2 \sqrt{2} G_{F}\left[\bar{\nu}_{\alpha} \gamma_{\sigma} P_{L} \nu_{\beta}\right][ & {\left[\varepsilon_{\alpha \beta}^{f L} \bar{f} \gamma^{\sigma} P_{L} f\right.} \\
& \left.+\varepsilon_{\alpha \beta}^{f R} \bar{f} \gamma^{\sigma} P_{R} f\right] . \tag{36}
\end{align*}
$$

where $\alpha, \beta=e, \mu, \tau$ and $L, R$ represent left-chiral and right-chiral fermion fields. If $\alpha \neq \beta$, then the $\alpha \leftrightarrow \beta$ terms must be Hermitian conjugates of each other, i.e. $\varepsilon_{\beta \alpha}=\varepsilon_{\alpha \beta}^{*}$. NuSOnG is sensitive to the $\beta=\mu$ couplings. This effective Lagrangian is appropriate for parameterizing corrections to neutral current processes; an analysis of corrections to charged-current processes requires a different set of four-fermion operators.

Assuming $\varepsilon_{\alpha \beta}=0$ for $\alpha \neq \beta$ we need consider only the terms $\varepsilon_{\mu \mu}^{f *}(*=V, A, L, R)$. If we rewrite Eq. (2) as

$$
\begin{align*}
\mathcal{L}=-\sqrt{2} G_{F}\left[\bar{\nu} \gamma_{\mu} P_{L} \nu\right] & {\left[g_{V}^{\nu f} \bar{f} \gamma^{\mu} f-g_{A}^{\nu f} \bar{f} \gamma^{\mu} \gamma_{5} f\right] } \\
=-2 \sqrt{2} G_{F}\left[\bar{\nu} \gamma_{\mu} P_{L} \nu\right][ & {\left[g_{L}^{\nu f} \bar{f} \gamma^{\mu} P_{L} f\right.} \\
& \left.+g_{R}^{\nu f} \bar{f} \gamma^{\mu} P_{R} f\right] \tag{37}
\end{align*}
$$

where

$$
\begin{align*}
g_{V}^{\nu f} & =2 g_{L}^{\nu} g_{V}^{f}=\rho\left(I_{3}^{f}-2 Q^{f} \sin ^{2} \theta_{W}\right) \\
g_{A}^{\nu f} & =2 g_{L}^{\nu} g_{A}^{f}=\rho\left(I_{3}^{f}\right) \\
g_{L}^{\nu f} & =2 g_{L}^{\nu} g_{L}^{f}=\rho\left(I_{3}^{f}-Q^{f} \sin ^{2} \theta_{W}\right) \\
g_{R}^{\nu f} & =2 g_{L}^{\nu} g_{R}^{f}=\rho\left(-Q^{f} \sin ^{2} \theta_{W}\right) \tag{38}
\end{align*}
$$

then we see that adding Eq. (36) to the SM Lagrangian will simply shift the effective couplings:

$$
\begin{align*}
g_{V}^{\nu f} \longrightarrow \tilde{g}_{V}^{\nu f} & =g_{V}^{\nu f}+\varepsilon_{\mu \mu}^{f V} \\
g_{A}^{\nu f} \longrightarrow \tilde{g}_{A}^{\nu f} & =g_{A}^{\nu f}+\varepsilon_{\mu \mu}^{f A} \\
g_{L}^{\nu f} \longrightarrow \tilde{g}_{L}^{\nu f} & =g_{L}^{\nu f}+\varepsilon_{\mu \mu}^{f L} \\
g_{R}^{\nu f} \longrightarrow \tilde{g}_{R}^{\nu f} & =g_{R}^{\nu f}+\varepsilon_{\mu \mu}^{f R} \tag{39}
\end{align*}
$$

Consequently, errors on the $g_{P}^{\nu f}$,s translate directly into errors on the $\varepsilon_{\mu \mu}^{f P}$ 's, $P=V, A$ or $P=L, R$.

## 1. Neutrino-lepton NSI

A useful review of present constraints on non-standard neutrino-electron interactions can be found in ref. 45]. As this paper states, and as we show below, an improved measurement of neutrino-elecron scattering is needed.

The world average value for neutrino-electron effective couplings, dominated by CHARM II, is

$$
\begin{align*}
g_{V}^{\nu e} & =-0.040 \pm 0.015 \\
g_{A}^{\nu e} & =-0.507 \pm 0.014 \\
\operatorname{Corr}\left(g_{V}^{\nu e}, g_{A}^{\nu e}\right) & =-0.05 \tag{40}
\end{align*}
$$

The current $1 \sigma$ bounds from CHARM II, Eq. 40) translates to $\left|\varepsilon_{\mu \mu}^{e P}\right|<0.01,(P=L, R)$ with a correlation of 0.07 [44]. At the current precision goals, NuSOnG's $\nu_{\mu} e$ and $\bar{\nu}_{\mu} e$ will significantly reduce the uncertainties on these NSI's, to

$$
\begin{align*}
\left|\varepsilon_{\mu \mu}^{e V}\right| & <0.0036, \\
\left|\varepsilon_{\mu \mu}^{e A}\right| & <0.0019, \\
\operatorname{Corr}\left(\varepsilon_{\mu \mu}^{e V}, \varepsilon_{\mu \mu}^{e A}\right) & =-0.57, \tag{41}
\end{align*}
$$

or in terms of the chiral couplings,

$$
\begin{align*}
\left|\varepsilon_{\mu \mu}^{e L}\right| & <0.0015, \\
\left|\varepsilon_{\mu \mu}^{e R}\right| & <0.0025, \\
\operatorname{Corr}\left(\varepsilon_{\mu \mu}^{e L}, \varepsilon_{\mu \mu}^{e R}\right) & =0.64 . \tag{42}
\end{align*}
$$

Even in the absence of a $\sigma\left(\bar{\nu}_{\mu} e\right)$ measurement $\varepsilon_{\mu \mu}^{e L}$ and $\varepsilon_{\mu \mu}^{e R}$ can be constrained from the $\nu_{\mu} e$ scattering data alone through a fit to the recoil electron energy spectrum (see Eq. (9).

We first consider the constraint on $\varepsilon_{\mu \mu}^{e L}$ and $\varepsilon_{\mu \mu}^{e R}$ from the total cross section $\sigma\left(\nu_{\mu} e\right)$. It is convenient to recast the effective interaction slightly, as

$$
\begin{align*}
\mathcal{L}_{\mathrm{NSI}}^{e} & =-2 \sqrt{2} G_{F}\left[\bar{\nu}_{\alpha} \gamma_{\sigma} P_{L} \nu_{\mu}\right]\left[\varepsilon_{\alpha \mu}^{e L} \bar{e} \gamma^{\sigma} P_{L} e+\varepsilon_{\alpha \mu}^{e R} \bar{e} \gamma^{\sigma} P_{R} e\right] \\
& =+\frac{\sqrt{2}}{\Lambda^{2}}\left[\bar{\nu}_{\alpha} \gamma_{\sigma} P_{L} \nu_{\mu}\right]\left[\cos \theta \bar{e} \gamma^{\sigma} P_{L} e+\sin \theta \bar{e} \gamma^{\sigma} P_{R} e\right] \tag{43}
\end{align*}
$$

The new physics is parameterized by two coefficients $\Lambda$ and $\theta . \Lambda$ represents the broadly-defined new physics scale while $\theta \in[0,2 \pi]$ defines the relative coupling of left-chiral and right-chiral electrons to the new physics. As an example, a scenario with a purely "left-handed" $Z^{\prime}$ that couples to leptons with coupling $g^{\prime}$ would be described by $\Lambda \propto M_{Z^{\prime}} / g^{\prime}$ and $\theta=0$ or $\theta=\pi$, depending on the relative sign between $g^{\prime}$ and the electroweak couplings. $\Lambda$ and $\theta$ are related to to the NSI parameters in Eq. (36) by

$$
\begin{equation*}
\varepsilon_{\alpha \mu}^{e L}=-\frac{\cos \theta}{2 G_{F} \Lambda^{2}}, \quad \varepsilon_{\alpha \mu}^{e R}=-\frac{\sin \theta}{2 G_{F} \Lambda^{2}} . \tag{44}
\end{equation*}
$$

Note that we have generalized from our assumption of the previous section and not taken $\alpha=\mu$ necessarily. At NuSOnG, new physics modifies (pseudo)elastic neutrinoelectron scattering. Here we use the word "pseudo" to refer to the fact that we cannot identify the flavor of the final-state neutrino, which could be different from the incoming neutrino flavor in the case of flavor changing neutral currents.

The shift in the total cross section is

$$
\begin{align*}
\frac{\delta \sigma\left(\nu_{\mu} e\right)}{\sigma\left(\nu_{\mu} e\right)}= & \frac{\left\{2 g_{L}^{\nu e} \varepsilon_{\mu \mu}^{e L}+\left(\varepsilon_{\mu \mu}^{e L}\right)^{2}\right\}+\frac{1}{3}\left\{2 g_{R}^{\nu e} \varepsilon_{\mu \mu}^{e R}+\left(\varepsilon_{\mu \mu}^{e R}\right)^{2}\right\}}{\left(g_{L}^{\nu e}\right)^{2}+\frac{1}{3}\left(g_{R}^{\nu e}\right)^{2}} \\
\approx & -\left(\frac{516 \mathrm{GeV}}{\Lambda}\right)^{2} \cos (\theta-\phi) \\
& +0.096\left(\frac{516 \mathrm{GeV}}{\Lambda}\right)^{4}\left(1+2 \cos ^{2} \theta\right) \tag{45}
\end{align*}
$$

where

$$
\begin{equation*}
\tan \phi=\frac{g_{R}^{\nu e}}{3 g_{L}^{\nu e}} \approx-0.28 \tag{46}
\end{equation*}
$$

When $\mathcal{O}\left(\varepsilon^{2}\right)$ terms are negligible, a $0.7 \%$ measurement of $\sigma\left(\nu_{\mu} e\right)$ translates into a $95 \%$ confidence level bound of

$$
\begin{equation*}
\Lambda>(4.4 \mathrm{TeV}) \times \sqrt{|\cos (\theta-\phi)|} \tag{47}
\end{equation*}
$$

from elastic scattering.
The measurement of the electron recoil energy will allow us to do better. Fig. 9(dark line) depicts the $95 \%$ confidence level sensitivity of NuSOnG to the physics described by Eq. (43) when $\nu_{\alpha}=\nu_{\mu}$, obtained after fitting the recoil electron kinetic energy distribution. Fig. 9 (closed contour) represents how well NuSOnG should be able to measure $\Lambda$ and $\theta$, at the $95 \%$ level. Weaker bounds from pseudoelastic scattering are also shown. We have not included "data" from $\bar{\nu}_{\mu}$-electron

FIG. 9: (DARK LINES) $95 \%$ confidence level sensitivity of NuSOnG to new heavy physics described by Eq. 43) when $\nu_{\alpha}=\nu_{\mu}$ (higher curve) and $\nu_{\alpha} \neq \nu_{\mu}$ (lower curve). (CLOSED CONTOURS) NuSOnG measurement of $\Lambda$ and $\theta$, at the $95 \%$ level, assuming $\nu_{\alpha}=\nu_{\mu}, \Lambda=3.5 \mathrm{TeV}$ and $\theta=2 \pi / 3$ (higher, solid contour) and $\nu_{\alpha} \neq \nu_{\mu}, \Lambda=1 \mathrm{TeV}$ and $\theta=4 \pi / 3$ (lower, dashed contour). Note that in the pseudoelastic scattering case $\left(\nu_{\alpha} \neq \nu_{\mu}\right) \theta$ and $\pi+\theta$ are physically indistinguishable.
scattering. While there will be fewer of these events, they should qualitatively improve our ability to pin down the new physics parameters given the distinct dependency on $g_{V}^{\nu e}$ and $g_{A}^{\nu e}$ (see Sec. III A).

Eq. (43) does not include all effective dimension-six operators that contribute to neutrino-electron (pseudo) elastic scattering. All neglected terms will either not contribute at NuSOnG, or were assumed to be suppressed with respect to Eq. 43). In turn, terms proportional to a right-handed neutrino current $\bar{\nu}_{R} \gamma_{\sigma} \nu_{R}$ lead to negligibly small effects since neutrino masses are negligibly small and we are dealing with neutrino beams produced by pion and muon decay (i.e., for all practical purposes, we have a purely left-handed muon neutrino beam and a purely right-handed muon antineutrino beam). Chirality violating effective operators (e.g. $\left(\bar{\nu}_{R} \nu_{L}\right)\left(\bar{e}_{L} e_{R}\right)$ ), on the other hand, are expected to be suppressed with respect to Eq. (43) by terms proportional to neutrino masses and the electron mass (measured in units of $\Lambda$ ). The reason is that, in the limit of massless neutrinos or a massless electron, chiral symmetry is restored while such operators explicitly violate it. For the same reason, dimension-five magnetic moment-type operators ( $\bar{\nu} \sigma_{\rho \sigma} \nu F^{\rho \sigma}$ ) have also been neglected.

We note also that Eq. (43) violates $S U(2)_{L}$ unless one also includes similar terms where $\nu_{L} \leftrightarrow \ell_{L}(\ell=$ $e, \mu, \tau)$. In this case, certain flavor combinations would be
severely constrained by electron-electron scattering and rare muon and tau decays. One way around such constraints is to postulate that the operators in Eq. (43) are dimension-eight operators proportional to $\bar{L} H^{*} \gamma_{\sigma} L H$, where $L$ is the left-chiral lepton doublet and $H$ is the Higgs scalar doublet. In this case, $1 / \Lambda^{2}$ should be replaced by $v^{2} / \Lambda^{4}$, where $v=246 \mathrm{GeV}$ is the scale of electroweak symmetry breaking.

Finally, another concern is whether modifications to the charged current neutrino-electron (pseudo)quasielastic scattering ((pseudo)IMD, $\left.\nu_{\mu} e \rightarrow \nu_{\alpha} \mu\right)$ can render the translation of NuSOnG data into constraints or measurements of $\theta$ and $\Lambda$ less straightforward. This turns out not to be the case, since new physics contributions to $\nu_{\mu} e \rightarrow \nu_{\alpha} \mu$ are already very well constrained by precision studies of muon decay. Hence, given the provisos of the two previous paragraph, Eq. 43) is expected to capture all "heavy" new physics effects in (pseudo)elastic neutrino electron scattering.

## 2. Neutrino-quark NSI

We next consider the $f=u, d$ case. The change in the parameters $g_{L}^{2}$ and $g_{R}^{2}$ (see Eqs. 2930 ) due to the NSI's is

$$
\begin{align*}
\Delta g_{L}^{2} & =2 g_{L}^{\nu u} \varepsilon_{\mu \mu}^{u L}+2 g_{L}^{\nu d} \varepsilon_{\mu \mu}^{d L} \\
& \approx+0.69 \varepsilon_{\mu \mu}^{u L}-0.85 \varepsilon_{\mu \mu}^{d L} \\
\Delta g_{R}^{2} & =2 g_{R}^{\nu u} \varepsilon_{\mu \mu}^{u R}+2 g_{R}^{\nu d} \varepsilon_{\mu \mu}^{d R} \\
& \approx-0.31 \varepsilon_{\mu \mu}^{u R}+0.15 \varepsilon_{\mu \mu}^{d R} . \tag{48}
\end{align*}
$$

so only these linear combinations are constrained. The bounds from NuTeV (rescaled to $1 \sigma$ bounds from ref. (44) are:

$$
\begin{align*}
\varepsilon_{\mu \mu}^{u L} & =-0.0053 \pm 0.0020 \\
\varepsilon_{\mu \mu}^{d L} & =+0.0043 \pm 0.0016 \\
\left|\varepsilon_{\mu \mu}^{u R}\right| & <0.0035 \\
\left|\varepsilon_{\mu \mu}^{d R}\right| & <0.0073 \tag{49}
\end{align*}
$$

These bounds are obtained by setting only one of the parameters be non-zero at a time. If NuSOnG reduces the errors on the NuTeV measurement of $g_{L}^{2}$ and $g_{R}^{2}$ by a factor of 2 , the $1 \sigma$ bounds on the NSI parameters are similarly reduced:

$$
\begin{align*}
\left|\varepsilon_{\mu \mu}^{u L}\right| & <0.001 \\
\left|\varepsilon_{\mu \mu}^{d L}\right| & <0.0008 \\
\left|\varepsilon_{\mu \mu}^{u R}\right| & <0.002 \\
\left|\varepsilon_{\mu \mu}^{d R}\right| & <0.004 \tag{50}
\end{align*}
$$

In terms of a new physics scale defined as $\Lambda=1 / \sqrt{2 \mathrm{G}_{\mathrm{F}}} \varepsilon$, these constraints range from $\Lambda>3 \mathrm{TeV}$ to $\Lambda>7 \mathrm{TeV}$.

We note that neutrino-quark scattering will also be sensitive to NSIs which correct CC interactions. These interactions are not included in Eq. (36). If they are
important, as is the case in some of the scenarios we treat later, a new analysis is necessary and the bounds above cannot be used. This is to be contrasted to the neutrinolepton case, discussed in the previous subsection.

## C. Neutrissimos, Neutrino Mixing and Gauge Couplings

FIG. 10: Potential constraint on $\epsilon_{e}$ and $\epsilon_{\mu}$ from NuSOnG (see Eq. 55). This is a two-dimensional projection of a 4 parameter fit with $S, T, \epsilon_{e}$ and $\epsilon_{\mu}$. The green ellipse is the $90 \%$ CL contour of a fit to all the charge current particle decay data + LEP/SLD.

In those classes of models which include moderately heavy electroweak gauge singlet ("neutrissimo") states, with masses above 45 GeV , the mixing of the $S U(2)_{L^{-}}$ active neutrinos and the sterile states may lead to a suppression of the neutrino-gauge couplings. The resulting pattern of modified interactions is distinct from those of the previous section since they will also induce correlated shifts to the charged-current coupling. For example, Ref. 46] presents models with one sterile state per active neutrino flavor and intergenerational mixing among neutrinos. In these models the flavor eigenstates are linear combinations of mass eigenstates, and those mass eigenstates too heavy to be produced in final states result in an effective suppression of the neutrino-gauge boson coupling. This suppression may be flavor-dependent depending on the structure of the neutrino mixing matrix. If the mass matrix contains Majorana terms, such models permit both lepton flavor violation and lepton universality violation.

Neutrinos couple to the $W$ and the $Z$ through interactions described by:

$$
\mathcal{L}=\frac{g}{\sqrt{2}} W_{\mu}^{-} \bar{\ell}_{L} \gamma^{\mu} \nu_{\ell L}+\frac{g}{\sqrt{2}} W_{\mu}^{+} \bar{\nu}_{\ell L} \gamma^{\mu} \ell_{L}
$$

$$
\begin{equation*}
+\frac{e}{2 s c} Z_{\mu} \bar{\nu}_{\ell L} \gamma^{\mu} \nu_{\ell L} \tag{51}
\end{equation*}
$$

where $\ell=e, \mu, \tau$. If the neutrinos mix with gauge singlet states so that the $S U(2)_{L}$ interaction eigenstate is a superposition of mass eigenstates $\nu_{\ell, \text { light }}$ and $\nu_{\ell, \text { heavy }}$

$$
\begin{equation*}
\nu_{\ell L}=\nu_{\ell, \text { light }} \cos \theta_{\ell}+\nu_{\ell, \text { heavy }} \sin \theta_{\ell} \tag{52}
\end{equation*}
$$

then the interaction of the light states is given by

$$
\begin{align*}
\mathcal{L} & \left.\overline{\overline{ }} g W_{\mu}^{-} \bar{\ell}_{L} \gamma^{\mu} \nu_{\ell, \text { light }}+\frac{g}{\sqrt{2}} W_{\mu}^{+} \bar{\nu}_{\ell, \text { light }} \gamma^{\mu} \ell_{L}\right) \cos \theta_{\ell} \\
& (53)  \tag{53}\\
& +\left(\frac{e}{2 s c} Z_{\mu} \bar{\nu}_{\ell, \text { light }} \gamma^{\mu} \nu_{\ell, \text { light }}\right) \cos ^{2} \theta_{\ell}
\end{align*}
$$

Defining

$$
\begin{equation*}
\epsilon_{\ell} \equiv 1-\cos ^{2} \theta_{\ell} \tag{54}
\end{equation*}
$$

the shift in the Lagrangian due to this mixing is

$$
\begin{align*}
\delta \mathcal{L} & =-\left(\frac{g}{\sqrt{2}} W_{\mu}^{-} \bar{\ell}_{L} \gamma^{\mu} \nu_{\ell}+\frac{g}{\sqrt{2}} W_{\mu}^{+} \bar{\nu}_{\ell} \gamma^{\mu} \ell_{L}\right) \frac{\epsilon_{\ell}}{2} \\
& -\left(\frac{e}{2 s c} Z_{\mu} \bar{\nu}_{\ell} \gamma^{\mu} \nu_{\ell}\right) \epsilon_{\ell} \tag{55}
\end{align*}
$$

where we have dropped the subscript "light" from the neutrino fields.

Lepton universality data from $W$ decays and from charged current $\pi, \tau$ and $K$ decays [47] constraint differences $\epsilon_{\ell_{i}}-\epsilon_{\ell_{j}}$. LEP/SLD and other precision electroweak data will imposed additional constraints on $\epsilon_{\ell}$ in combination with the oblique parameters, as will NuSOnG. A fit to all the charge current decay data and LEP/SLD with $S, T, \epsilon_{e}$ and $\epsilon_{\mu}$ yields

$$
\begin{align*}
S & =-0.05 \pm 0.11 \\
T & =-0.44 \pm 0.28 \\
\epsilon_{e} & =0.0049 \pm 0.0022 \\
\epsilon_{\mu} & =0.0023 \pm 0.0021 \tag{56}
\end{align*}
$$

If we now included hypothetical data from NuSOnG, assuming NuSOnG achieves its precision goals and measures central values consistent with the Standard Model, we see the constraints on $\epsilon_{\mu}$ and $\epsilon_{e}$ are substantially improved. In this case, the fit yields

$$
\begin{align*}
S & =0.00 \pm 0.10 \\
T & =-0.11 \pm 0.12 \\
\epsilon_{e} & =0.0030 \pm 0.0017 \\
\epsilon_{\mu} & =0.0001 \pm 0.0012 \tag{57}
\end{align*}
$$

Fig. 10 shows the two dimensional cross section in the $\epsilon_{e}-\epsilon_{\mu}$ plane of the four dimensional fit. The likelihood coutours are 2 D projections. Though not obvious from the figure, it is NuSOnG's improved measurement of $g_{L}^{2}$ which contributes the most to strengthening the bounds on the $\epsilon_{\ell}$.

In models of this class lepton flavor violating decays such as $\mu \rightarrow e \gamma$ impose additional constraints on products $\epsilon_{\ell_{i}} \epsilon_{\ell_{j}}$. For example, the strong constraint from
$\mu \rightarrow e \gamma$ implies $\epsilon_{e} \epsilon_{\mu} \approx 0$. This type of model has been proposed as a solution to the NuTeV anomaly. If we take take only one of $\epsilon_{e}$ or $\epsilon_{\mu}$ to be nonzero (to respect the constraint from $\mu \rightarrow e \gamma$ ), the NuTeV value of $g_{L}^{2}$ is accommodated in the fit by best-fit values of $\epsilon$ that are large and positive and best-fit values of T are large and negative (consistent with a heavy Higgs).

## D. Right-handed coupling of the neutrino to the $Z$

In the Standard Model, neutrino couplings to the $W$ and $Z$-bosons are purely left-handed. The fact that the neutrino coupling to the $W$-boson and an electron is purely left-handed is, experimentally, a well-established fact (evidence includes precision measurements of pion and muon decay, nuclear processes, etc.). By contrast, the nature of the neutrino coupling to the $Z$ boson is, experimentally, far from being precisely established 50 . The possibility of a right-handed neutrino- $Z$-boson coupling is not included in the previous discussions, and is pursued separately in this subsection.

The best measurement of the neutrino coupling to the $Z$-boson is provided by indirect measurements of the invisible $Z$-boson width at LEP. In units where the Standard Model neutrino- $Z$-boson couplings are $g_{L}^{\nu}=0.5$, $g_{R}^{\nu} \equiv 0$, the LEP measurement [51] translates into $\left(g_{L}^{\nu}\right)^{2}+\left(g_{R}^{\nu}\right)^{2}=0.2487 \pm 0.0010$. Note that this result places no meaningful bound on $g_{R}^{\nu}$.

Precise, model-independent information on $g_{L}^{\nu}$ can be obtained by combining $\nu_{\mu}+e$ scattering data from CHARM II and LEP and SLD data. Assuming modelindependent couplings of the fermions to the $Z$-boson, $\nu_{\mu}+e$ scattering measures $g_{L}^{\nu}=\sqrt{\rho} / 2$, while LEP and SLD measure the left and right-handed couplings of the electron to the $Z$. The CHARM II result translates into $\left|g_{L}^{\nu}\right|=0.502 \pm 0.017$ [50], assuming that the chargedcurrent weak interactions produce only left-handed neutrinos. In spite of the good precision of the CHARM II result (around 3.5\%), a combination of all available data allows $\left|g_{R}^{\nu} / g_{L}^{\nu}\right| \sim 0.4$ at the two $\sigma$ confidence level 50.

Significant improvement in our understanding of $g_{R}^{\nu}$ can only be obtained with more precise measurements of $\nu+e$ scattering, or with the advent of a new high intensity $e^{+} e^{-}$collider, such as the ILC. By combining ILC running at the $Z$-boson pole mass and at $\sqrt{s}=170 \mathrm{GeV}$, $\left|g_{R}^{\nu} / g_{L}^{\nu}\right| \lesssim 0.3$ could be constrained at the two $\sigma$ level after analyzing $e^{+} e^{-} \rightarrow \gamma+$ missing energy events 50].

Assuming that $g_{L}^{\nu}$ can be measured with $0.7 \%$ uncertainty, Fig. 11 depicts an estimate of how precisely $g_{R}^{\nu}$ could be constrained once NuSOnG "data" is combined with LEP data. Fig. 11 (left) considers the hypothesis that the Standard Model expectations are correct. In this case, NuSOnG data would reveal that $g_{R} / g_{L}$ is less than 0.2 at the two sigma level. On the other hand, if $g_{R} / g_{L}=0.25-$ in good agreement with the current CHARM II and LEP data - NuSOnG data should reveal that $g_{R} \neq 0$ at more than the two sigma level, as depicted

FIG. 11: Precision with which the right-handed neutrino- $Z$-boson coupling can be determined by combining NuSOnG measurements of $g_{L}^{\nu}$ with the indirect determination of the invisible $Z$-boson width at LEP if (left) the $\nu+e$ scattering measurement is consistent with the Standard Model prediction $g_{L}^{\nu}=0.5$ and (right) the $\nu+e$ scattering measurement is significantly lower, $g_{L}^{\nu}=0.485$, but still in agreement with the CHARM II measurement(at the one sigma level). Contours (black, red) are one and two sigma, respectively. The star indicates the Standard Model expectation.
in Fig. 11(right).
The capability of performing this measurement in other experiments has been examined. The NuSOnG measurement compares favorably, and complements, the ILC capabilities estimated in [50]. Ref [52] studied measurements using other neutrino beams, including reactor fluxes and beta beams. NuSOnG's reach is equivalent to or exceeds the most optimistic estimates for these various neutrino sources.

## V. SPECIFIC THEORETICAL MODELS AND EXPERIMENTAL SCENARIOS

If NuSOnG's measurements agree with the SM within errors, we will place stringent constraints on new physics models; if they disagree, it will be a signal for new physics. In the latter case the availability of both DIS and ES channels will improve our ability to discriminate among new physics candidates. NuSOnG will also provide an important complement to the LHC. The LHC will provide detailed information about the spectrum of new states directly produced. However, measurements of the widths of these new states will provide only limited information about their couplings. NuSOnG will probe in multiple ways the couplings of these new states to neutrinos and to other SM particles.

In this section we provide several case studies of NuSOnG sensitivity to specific models of new physics. These include several typical $Z^{\prime}$ models, leptoquark models, models of R-parity violating supersymmetry, and models with extended Higgs sectors. We examine how
these will affect $\nu_{\mu} e$ ES and $\nu_{\mu} N$ DIS at tree-level. Our list is far from exhaustive but serves to illustrate the possibilities. We summarize our contributions in Table V

The opposite way to approach this problem is to ask: in the face of evidence for new Terascale Physics, how can we differentiate between specific models? NuSOnG has the potential to discover new physics through indirect probes, in the event that one or more of its measurements definitively contradicts SM predictions. We discuss several possible patterns of deviation of modelindependent parameters from SM predictions and some interpretations in terms of particular models. This is presented in the context of various expectations for LHC to illustrate how NuSOnG enhances the overall physics program. Since the NuTeV reanalysis is ongoing, and since the ES constraints from CHARM-II are weak, it is prudent that we commit to no strong assumptions about the central value of the NuSOnG measurements but instead consider all reasonable outcomes.

## A. Sensitivity in the Case of Specific Theoretical Models

We next consider the constraints imposed by the proposed NuSOnG measurements on explicit models of BSM physics. An explicit model provides relations among effective operators which give stronger and sometimes better-motivated constraints on new physics than is obtained from bounds obtained by considering effective op-

| Model | Contribution of NuSOnG Measurement |
| :---: | :--- |
| Typical $Z^{\prime}$ Choices: $(B-x L),(q-x u),(d+x u)$ | At the level of, and complementary to, LEP II bounds. |
| Extended Higgs Sector | At the level of, and complementary to $\tau$ decay bounds. |
| R-parity Violating SUSY | Sensitivity to masses $\sim 2 \mathrm{TeV}$ at $95 \%$ CL. <br> Improves bounds on slepton couplings by $\sim 30 \%$ and <br> on some squark couplings by factors of 3-5. |
| Intergenerational Leptoquarks with non-degenerate masses | Accesses unique combinations of couplings. <br> Also accesses coupling combinations explored by $\pi$ decay bounds, <br> at a similar level. |

TABLE VI: Summary of NuSOnG's contribution in the case of specific models

FIG. 12: Some examples of NuSOnG's $2 \sigma$ sensitivity to new high-mass particles commonly considered in the literature. For explanation of these ranges, and further examples, see text.
erators one by one, but at the expense of the generality of the conclusions. Many models can be analyzed using the effective Lagrangian of Eq. (36), but others introduce new operators and must be treated individually. The list of models considered is not exhaustive, but rather illustrates the new physics reach of NuSOnG.

## 1. $Z^{\prime}$ models

Massive $Z^{\prime}$ fields are one of the simplest signatures of physics beyond the Standard Model. (For a recent review, see [53].) $Z^{\prime}$ vector bosons are generic in grand unified theories and prevalent in theories that address the electroweak gauge hierarchy. They may stabilize the weak scale directly by canceling off quadratic divergences of Standard Model fields, as in theories of extradimensions or Little Higgs theories. In supersymmetric models, $Z^{\prime}$ fields are not needed to cancel quadratic divergences, but are still often tied to the scale of softbreaking (and hence the electroweak scale). In these last two cases, the $Z^{\prime}$ typically has a TeV -scale mass, and is an attractive target for NuSOnG.

|  | $U(1)_{B-x L}$ | $U(1)_{q+x u}$ | $U(1)_{10+x \overline{5}}$ | $U(1)_{d-x u}$ |
| :---: | :---: | :---: | :---: | :---: |
| $\nu_{\mu L}, e_{L}$ | $-x$ | -1 | $x / 3$ | $(-1+x) / 3$ |
| $e_{R}$ | $-x$ | $-(2+x) / 3$ | $-1 / 3$ | $x / 3$ |

TABLE VII: Charges of $\nu_{\mu L}, e_{L}, e_{R}$ under 4 phenomenologically viable classes of $U(1)^{\prime}$ symmetries. Each value of $x$ corresponds to a different $U(1)^{\prime}$ symmetry that is considered.

If the $Z^{\prime}$ mass is sufficiently large, its exchange is welldescribed at NuSOnG energies by the effective operator of Eq. 43). In this case, the new physics scale is related to the $Z^{\prime}$ model by $\Lambda \sim M_{Z^{\prime}} / g_{Z^{\prime}}$, the ratio of the $Z^{\prime}$ mass to its gauge-coupling. Further model-dependence shows up in the ratio of fermion charges under the $\mathrm{U}(1)^{\prime}$ symmetry associated with the $Z^{\prime}$, and the presence of any $Z-Z^{\prime}$ mixing. With reasonable theoretical assumptions, the absence of new sources of large flavor-changing neutral currents, the consistency of Yukawa interactions, and anomaly cancellation with a minimal number of exotic fermions, the number of interesting models can be reduced substantially, to four discrete families of generic $U(1)^{\prime}$ models each containing one free parameter, $x$ [54]. In Table V A 1 we indicate the charges of $\nu_{\mu L}, e_{L}, e_{R}$ under these families of $U(1)^{\prime}$ symmetries.

Using the sensitivity of NuSOnG to the scale $\Lambda$ in $\nu_{\mu}$ scattering shown in Figure 9, we can bound the combination $M_{Z^{\prime}} / g_{Z^{\prime}}$ for the four families of $Z^{\prime}$ models as a function of $x$. It is important to note that these bounds are competitive with the LEP-II bounds found in [54], which are based on $Z^{\prime}$ decays to all fermions, not just electrons and neutrinos.

There are $Z^{\prime}$ models which distinguish among generations can affect neutrino scattering. These will be probed by NuSOnG at the TeV scale [55, 56, 57, 58, 59]. Among these, $B-3 L_{\mu}$ was suggested as a possible explanation for the NuTeV anomaly [60, 61, however, we show here that this is not the case. Nevertheless, it remains an interesting example to consider.

In the gauged $B-3 L_{\mu}$ the $Z^{\prime}$ modifies $\nu_{\mu} N$ DIS. The exchange of the $Z^{\prime}$ between the $\nu_{\mu}$ and the quarks induces operators with coefficients

$$
\varepsilon_{\mu \mu}^{u L}=\varepsilon_{\mu \mu}^{u R}=\varepsilon_{\mu \mu}^{d L}=\varepsilon_{\mu \mu}^{d R}
$$

FIG. 13: $95 \%$ confidence level sensitivity of NuSOnG to the indicated $Z^{\prime}$ models. The charges of the electrons and neutrinos under the underlying $U(1)^{\prime}$ gauge symmetry are described in Table VA 1 The bounds are plotted as functions of the parameter $x$, which scans over allowed fermion charges for each family of $U(1)^{\prime}$ symmetries, versus the ratio $M_{z^{\prime}} / g_{Z^{\prime}}$.

$$
\begin{equation*}
=-\frac{1}{2 \sqrt{2} G_{F}} \frac{g_{Z^{\prime}}^{2}}{M_{Z^{\prime}}^{2}} \equiv \varepsilon_{B-3 L_{\mu}} \tag{58}
\end{equation*}
$$

which shift $g_{L}^{2}$ and $g_{R}^{2}$ by

$$
\begin{equation*}
\Delta g_{L}^{2}=\Delta g_{R}^{2}=-\frac{2 s^{2}}{3} \varepsilon_{B-3 L_{\mu}} \tag{59}
\end{equation*}
$$

It should be noted that since $\varepsilon_{B-3 L_{\mu}}$ is negative, this shows that both $g_{L}^{2}$ and $g_{R}^{2}$ will be shifted positive. This, in fact, excludes gauged $B-3 L_{\mu}$ as an explanation of the NuTeV anomaly. With this said, a NuSOnG measurement of $g_{L}^{2}$ and $g_{R}^{2}$ that improves on NuTeV errors by a factor of 2 yields a $2 \sigma$ bound

$$
\begin{equation*}
\frac{M_{Z^{\prime}}}{g_{Z^{\prime}}}>2.2 \mathrm{TeV} \tag{60}
\end{equation*}
$$

which is comparable and complementary to the existing bound from D0, and thus interesting to consider.

## 2. Models with extended Higgs sectors

In the Zee 62] and Babu-Zee 63] models, an isosinglet scalar $h^{+}$with hypercharge $Y=+1$ is introduced, which couples to left-handed lepton doublets $\ell$ as

$$
\begin{equation*}
\mathcal{L}_{h}=\lambda_{a b}\left(\overline{\ell_{a L}^{c}} i \sigma_{2} \ell_{b L}\right) h^{+}+h . c . \tag{61}
\end{equation*}
$$

where $(a b)$ are flavor indices: $a, b=e, \mu, \tau$. The exchange of a charged Higgs induces the effective operator from

Eq. (36) which with coefficient

$$
\begin{equation*}
\varepsilon_{\mu \mu}^{e L}=-\frac{1}{\sqrt{2} G_{F}} \frac{\left|\lambda_{e \mu}\right|^{2}}{M_{h}^{2}}, \quad \varepsilon_{\mu \mu}^{e R}=0 \tag{62}
\end{equation*}
$$

From Eq. 42, the $95 \%$ bound is:

$$
\begin{equation*}
\frac{M_{h}}{\left|\lambda_{e \mu}\right|}>5.2 \mathrm{TeV} \tag{63}
\end{equation*}
$$

competitive with current bound from $\tau$-decay of 5.4 TeV.

## 3. $R$-parity violating SUSY

Assuming the particle content of the Minimal Supersymmetric Standard Model (MSSM), the most general Rparity violating superpotential (involving only tri-linear couplings) has the form 64]

$$
\begin{equation*}
W_{R}=\frac{1}{2} \lambda_{i j k} \hat{L}_{i} \hat{L}_{j} \hat{E}_{k}+\lambda_{i j k}^{\prime} \hat{L}_{i} \hat{Q}_{j} \hat{D}_{k}+\frac{1}{2} \lambda_{i j k}^{\prime \prime} \hat{U}_{i} \hat{D}_{j} \hat{D}_{k} \tag{64}
\end{equation*}
$$

where $\hat{L}_{i}, \hat{E}_{i}, \hat{Q}_{i}, \hat{D}_{i}$, and $\hat{U}_{i}$ are the left-handed MSSM superfields defined in the usual fashion, and the subscripts $i, j, k=1,2,3$ are the generation indices. $S U(2)_{L}$ gauge invariance requires the couplings $\lambda_{i j k}$ to be antisymmetric in the first two indices:

$$
\begin{equation*}
\lambda_{i j k}=-\lambda_{j i k} \tag{65}
\end{equation*}
$$

The purely baryonic operator $\hat{U}_{i} \hat{D}_{j} \hat{D}_{k}$ is irrelevant to neutrino scattering, so only the $9 \lambda_{i j k}$ and $27 \lambda_{i j k}^{\prime}$ couplings are of interest.

From the $\hat{L} \hat{L} \hat{E}$ part of the Eq. 64 slepton exchange will contribute to $\nu_{\mu} e \mathrm{ES}$ at NuSOnG. These induce fourfermion operators appearing in Eq. (36) with corresponding coefficients

$$
\begin{align*}
\varepsilon_{\mu \mu}^{e L} & =-\frac{1}{4 \sqrt{2} G_{F}} \sum_{k=1}^{3} \frac{\left|\lambda_{21 k}\right|^{2}}{M_{\tilde{e}_{k R}}^{2}} \\
\varepsilon_{\mu \mu}^{e R} & =+\frac{1}{4 \sqrt{2} G_{F}} \sum_{j=1,3} \frac{\left|\lambda_{2 j 1}\right|^{2}}{M_{\tilde{e}_{j L}}^{2}} \tag{66}
\end{align*}
$$

If we place bounds on the sleptons one at a time, then Eq. (42) translates to the $2 \sigma$ bounds shown in TableVIII, presented for masses of 100 GeV . To rescale to different masses, use $\left(\frac{M}{100 \mathrm{GeV}}\right)$. This can be compared to current bounds Ref. 65]. NuSOnG improves all of these bounds.

From the $\hat{L} \hat{Q} \hat{D}$ part of Eq. 64, squark exchange will contribute to contribute to NC $\nu_{\mu} N$ DIS and CC $\nu_{\mu} N$ DIS. The resulting shifts in $g_{L}^{2}$ and $g_{R}^{2}$ are

$$
\begin{align*}
\delta g_{L}^{2} & =2\left[g_{L}^{\nu d} \varepsilon_{\mu \mu}^{d L}-g_{L}^{2} \varepsilon_{c}\right] \\
\delta g_{R}^{2} & =2\left[g_{R}^{\nu d} \varepsilon_{\mu \mu}^{d R}-g_{R}^{2} \varepsilon_{c}\right] \tag{67}
\end{align*}
$$

where

$$
\varepsilon_{\mu \mu}^{d L}=-\frac{1}{4 \sqrt{2} G_{F}} \sum_{k=1}^{3} \frac{\left|\lambda_{21 k}^{\prime}\right|^{2}}{M_{\tilde{d}_{k R}}^{2}}
$$

| Coupling | 95\% NuSOnG bound | lurrent $95 \%$ bound |
| :---: | :---: | :--- |
| $\left\|\lambda_{121}\right\|$ | 0.03 | $0.05\left(V_{u d}\right)$ |
| $\left\|\lambda_{122}\right\|$ | 0.04 | $0.05\left(V_{u d}\right)$ |
| $\left\|\lambda_{123}\right\|$ | 0.04 | $0.05\left(V_{u d}\right)$ |
| $\left\|\lambda_{231}\right\|$ | 0.05 | $0.07(\tau$ decay $)$ |
| $\left\|\lambda_{21}^{\prime}\right\|$ | 0.05 | $0.06(\pi$ decay $)$ |
| $\left\|\lambda_{212}^{\prime}\right\|$ | 0.06 | $0.06(\pi$ decay $)$ |
| $\left\|\lambda_{213}^{\prime}\right\|$ | 0.06 | $0.06(\pi$ decay $)$ |
| $\left\|\lambda_{221}^{\prime}\right\|$ | 0.07 | $0.21(D$ meson decay $)$ |
| $\left\|\lambda_{231}^{\prime}\right\|$ | 0.07 | $0.45\left(Z \rightarrow \mu^{+} \mu^{-}\right)$ |

TABLE VIII: Potential bounds on the R-parity violating $L L E$ (top) and $L Q D$ (bottom) couplings from NuSOnG, assuming that only one coupling is non-zero at a time for each set. All squark and slepton masses are set to 100 GeV . To obtain limits for different masses, rescale by $\left(\frac{M}{100 \mathrm{GeV}}\right)$. Current bounds are from Ref. 65].

$$
\begin{align*}
\varepsilon_{\mu \mu}^{d R} & =-\frac{1}{4 \sqrt{2} G_{F}} \sum_{j=1}^{3} \frac{\left|\lambda_{2 j 1}^{\prime}\right|^{2}}{M_{\tilde{d}_{j L}}^{2}} \\
\varepsilon_{c} & =+\frac{1}{4 \sqrt{2} G_{F}} \sum_{k=1}^{3} \frac{\left|\lambda_{21 k}^{\prime}\right|^{2}}{M_{\tilde{d}_{k R}}^{2}}=-\varepsilon_{\mu \mu}^{d L} \tag{68}
\end{align*}
$$

$\varepsilon_{\mu \mu}^{d L}$ and $\varepsilon_{\mu \mu}^{d R}$ are associated with terms of Eq. 36p, while $\varepsilon_{c}$ is associated with a four-fermion interaction that corrects charged currents,

$$
\begin{equation*}
-2 \sqrt{2} G_{F} \varepsilon_{c}\left[\left(\overline{\mu_{L}} \gamma_{\sigma} \nu_{\mu L}\right)\left(\overline{u_{L}} \gamma^{\sigma} d_{L}\right)+h . c .\right] . \tag{69}
\end{equation*}
$$

The shifts in $g_{L}^{2}$ and $g_{R}^{2}$ are:

$$
\begin{align*}
\delta g_{L}^{2} & =2\left(g_{L}^{\nu d}+g_{L}^{2}\right) \varepsilon_{\mu \mu}^{d L} \\
\delta g_{R}^{2} & =2 g_{R}^{2} \varepsilon_{\mu \mu}^{d L}+2 g_{R}^{\nu d} \varepsilon_{\mu \mu}^{d R} \tag{70}
\end{align*}
$$

Assuming the projected precision goals for NuSOnG on $g_{L}^{2}$ and $g_{R}^{2}$, and allowing only one of the couplings to be nonozero at a time, the $2 \sigma$ bounds are given in TableVIII mass of 100 GeV , in all cases. To obtain limits for different masses, one simply rescales by $\left(\frac{M}{100 \mathrm{GeV}}\right)$. NuSOnG's measurements are competitive with $\pi$ decay bounds, and improves the current bounds on the 221 and 231 couplings by factors of 3 and 5 , respectively.

## 4. Intergenerational leptoquark models

Measurements of $g_{L}^{2}$ and $g_{R}^{2}$ are sensitive to leptoquarks. Because the exchange of a leptoquark can interfere with both $W$ and $Z$ exchange processes, we cannot use the limits on the NSI's of Eq. (36), since we must also include the effects of the four-fermion operators associated with charged-current processes. Instead, the interactions of leptoquarks with ordinary matter can be described in a model-independent fashion by an effective low-energy Lagrangian as discussed in Refs. 66, 68 for generation-universal leptoquark couplings. For leptoquarks to contribute to $\nu_{\mu} N$ DIS, they must couple second generation leptons to first generation quarks, so we
use the more general Lagrangian of 67, 69, which allows the coupling constants to depend on the generations of the quarks and leptons that couple to each leptoquark. We summarize the quantum numbers and couplings of the various leptoquarks fields in Table IX, our notation conventions are those of Ref. 69.

The four-fermion operators induced by leptoquark exchange will affect NC and/or CC processes, and at NuSOnG the effect manifests itself in shifts $g_{L}^{2}$ and $g_{R}^{2}$. Assuming degenerate masses within each iso-multiplet, the shifts in $g_{L}^{2}$ and $g_{R}^{2}$ can be written generically as

$$
\begin{align*}
& \delta g_{L}^{2}=C_{L} \frac{\left|\lambda_{L Q}^{12}\right|^{2} / M_{L Q}^{2}}{g^{2} / M_{W}^{2}}=\frac{C_{L}}{4 \sqrt{2} G_{F}} \frac{\left|\lambda_{L Q}^{12}\right|^{2}}{M_{L Q}^{2}} \\
& \delta g_{R}^{2}=C_{R} \frac{\left|\lambda_{L Q}^{12}\right|^{2} / M_{L Q}^{2}}{g^{2} / M_{W}^{2}}=\frac{C_{R}}{4 \sqrt{2} G_{F}} \frac{\left|\lambda_{L Q}^{12}\right|^{2}}{M_{L Q}^{2}} \tag{71}
\end{align*}
$$

where $\lambda_{L Q}^{12}$ denotes the $(i j)=(12)$ coupling of the leptoquark and $M_{L Q}$ is its mass. In table $X$ we list what they are, and in figure 14 we plot the dependence of $\delta g_{L}^{2}$ and $\delta g_{R}^{2}$ on the ratio $\left|\lambda_{L Q}\right|^{2} / M_{L Q}^{2}$. Table X also lists the projected NuSOnG bounds on the coupling constants [70]. Existing bounds on $S_{1}, \vec{S}_{3}, V_{1}$, and $\vec{V}_{3}$ couplings from $R_{\pi}=\operatorname{Br}(\pi \rightarrow e \nu) / \operatorname{Br}(\pi \rightarrow \mu \nu)$ are already much stronger, but could be circumvented for $\vec{S}_{3}$ and $\vec{V}_{3}$ if the masses within the multiplet are allowed to be non-degenerate.

## B. Interplay with LHC to Isolate the Source of New Physics

By the time NuSOnG runs, the LHC will have accumulated a wealth of data and will have begun to change the particle physics landscape. The message from LHC data may be difficult to decipher, however. As discussed below, NuSOnG will be able to help elucidate the new physics revealed at the LHC. The discovery of a Higgs along with the anticipated measurement of the top mass to 1 GeV precision would effectively fix the center of the $S T$ plot and will enhance the power of the precision electroweak data as a tool for discovering new physics. If additional resonances are discovered at the LHC, it is still likely that little will be learned about their couplings.

The NuSOnG experiment provides complementary information to LHC. Rather than generalize, to illustrate the power of NuSOnG, two specific examples are given here. We emphasize that these are just two of a wide range of examples, but they serve well to demonstrate the point. Here we have chosen examples from typical new physics models other than $Z^{\prime}$ models which were discussed above, in order to demonstrate the physics range which can be probed by NuSOnG.

| Leptoquark |  | Spin | F | $S U(3)_{C}$ | $I_{3}$ | $Y$ | $Q_{\text {em }}$ | Allowed Couplings |

TABLE X: Potential and existing $95 \%$ bounds on the leptoquark couplings squared when the leptoquark masses are set to 100 GeV . To obtain the limits for different leptoquark masses, multiply by $\left(M_{L Q} / 100 \mathrm{GeV}\right)^{2}$. Existing bounds on the $S_{1}, \vec{S}_{3}$, $V_{1}$, and $\vec{V}_{3}$ couplings from $R_{\pi}=\operatorname{Br}(\pi \rightarrow e \nu) / \operatorname{Br}(\pi \rightarrow \mu \nu)$ are also shown.

First, extend the Standard Model to include a nondegenerate $S U(2)_{L}$ triplet leptoquark $\left(\vec{S}_{3}\right.$ or $\vec{V}_{3}$ in the notation of [66], with masses in the $0.5-1.5 \mathrm{TeV}$ range. At the LHC these leptoquarks will be produced primarily in pairs through gluon fusion, and each leptoquark will decay to a lepton and a jet [72]. The peak in the lepton-jet invariant mass distribution will be easily detected over background. This will provide the leptoquark masses but yield little information about their couplings to fermions. The leptoquarks will also shift the neutrinonucleon effective coupling $g_{L}^{2}$ in a way that depends sensitively on both the leptoquark couplings and masses. Such a leptoquark-induced shift could provide an explanation for the NuTeV anomaly 61, 67, 73]. In this scenario, NuSOnG would find that isospin and the strange sea can be constrained to the point that they do not provide an explanation for the NuTeV anomaly, thus the NuTeV anomaly is the result of new physics. The NuSOnG PW
measurement of $\sin 2 \theta_{W}$ will agree with $\mathrm{NuTeV} ; g_{R}^{2}$ and the $\nu e$ and $\bar{\nu} e$ elastic scattering measurements will agree with LEP. Fig. 15 illustrates this example. NuSOnG's measurement of $g_{L}^{2}$ would provide a sensitive measurement of the leptoquark couplings when combined with the LHC mass measurements as inputs.

A second example is the existence of a fourth generation family. A fourth family with non-degenerate masses (i.e. isospin violating) is allowed within the LEP/SLD constraints 74. As a model, we choose a fourth family with mass splitting on the order of $\sim 75 \mathrm{GeV}$ and a 300 GeV Higgs. This is consistent with LEP at $1 \sigma$ and perfectly consistent with $M_{W}$, describing the point $(0.2,0.19)$ on the $S T$ plot. In this scenario, LHC will measure the Higgs mass from the highly enhanced $H \rightarrow Z Z$ decay. An array of exotic decays which will be difficult to fully reconstruct, such as production of 6 W 's and 2 b 's, will be observed at low rates. In this scenario, isospin

FIG. 14: Shifts in $g_{L}^{2}$ and $g_{R}^{2}$ due to leptoquarks. Horizontal lines indicate the projected $1 \sigma$ limits of NuSOnG.

FIG. 15: NuSOnG expectation in the case of a Tev-scale triplet leptoquark. For clarity, this plot and the two following cases, show the expectation from only the two highest precision measurements from NuSOnG: $g_{L}^{2}$ and $\nu$ ES.
violation explains the NuTeV anomaly, thus the NuTeV PW and the NuSOnG PW measurements agree with the $\nu$ eES measurements. These three precision neutrino results, all with "LEP-size" errors, can be combined and will intersect the one-sigma edge of the LEP measurements. Fig. 16 illustrates this example. From this, the source, a fourth generation with isospin violation, can be

FIG. 16: NuSOnG expectation if the NuTeV anomaly is due to isospin violation and there is a heavy 4th generation with isospin violation.

FIG. 17: If LHC sees a Standard Model Higgs and no evidence of new physics, NuSOnG may reveal new physics in the neutrino sector.
demonstrated.
Lastly, while it seems unlikely, it is possible that LHC will observe a Standard Model Higgs and no signatures of new physics. If this is the case, it is still possible for NuSOnG to add valuable clues to new physics. This is because the experiment is uniquely sensitive to the neutrino sector. If a situation such as is illustrated on Fig. 17 arose, the only explanation would be new physics unique to neutrino interactions.

## VI. SUMMARY AND CONCLUSIONS

NuSOnG is an experiment which can search for new physics from keV through TeV energy scales, as well as make interesting QCD measurements. This article has focussed mainly on the Terascale physics which can be accessed through this new high energy, high statistics
neutrino scattering experiment. The case has been made that this new neutrino experiment would be a valuable addition to the presently planned suite of experiments with Terascale reach.

The NuSOnG experiment design draws on the heritage of the CHARM II and CCFR/NuTeV experiments. A high energy, flavor-pure neutrino flux is produced using 800 GeV protons from the Tevatron. The detector consists of four modules, each composed of a finelysegmented glass-target $\left(\mathrm{SiO}_{2}\right)$ calorimeter followed by a muon spectrometer. In its five-year data acquisition period, this experiment will record almost one hundred thousand neutrino-electron elastic scatters and hundreds of millions of deep inelastic scattering events, exceeding the current world data sample by more than an order of magnitude. This experiment can address concerns related to model systematics of electroweak measurements in neutrino-quark scattering by direct constraints using $i n$-situ structure function measurements.

NuSOnG will be unique among present and planned experiments for its ability to probe neutrino couplings to Beyond Standard Model physics. This experiment offers four distinct and complementary probes of $S$ and $T$. Two are of high precision with the proposed run-plan, and the precision of the other two would be improved by a follow-up five-year antineutrino run. Neutrino-lepton non-standard interactions can be probed with an order of magnitude improvement in the measured effective couplings. Neutrino-quark non-standard interactions can be probed by an improvement in the measured neutrinoquark effective couplings of a factor of two or better. The
experiment is sensitive to new physics up to energy scales $\sim 5 \mathrm{TeV}$ at $95 \%$ CL. The measurements are sensitive to universality of the couplings and an improvement in the $e$-family of $30 \%$ and $\mu$-family of $75 \%$ will allow for probes of neutrissimos. As a unique contribution, NuSOnG measures $g_{R} / g_{L}$, which is not accessible by other near-future experiments. This article described NuSOnG's physics contribution under several specific models. These included models of $Z^{\prime}$ s, extended Higgs models, leptoquark models and $R$-parity violating SUSY models. We also considered how, once data are taken at LHC and NuSOnG, the underlying physics can be extracted. The opportunity for direct searches related to these indirect electroweak searches was also described. The conclusion of our analysis is that a new neutrino experiment, such as NuSOnG, would substantially enhance the presently planned Terascale program.

## Acknowledgments

#### Abstract

We propose a 3500 ton ( 3000 ton fiducial volume) $\mathrm{SiO}_{2}$ neutrino detector with sampling calorimetry, charged particle tracking, and muon spectrometers to run in a Tevatron Fixed Target Program. Improvements to the Fermilab accelerator complex should allow substantial increases in the neutrino flux over the previous NuTeV quad triplet beamline. With $4 \times 10^{19}$ protons on target/year, a 5 year run would achieve event statistics more than 100 times higher than NuTeV . With 100 times the statistics of previous high energy neutrino experiments, the purely weak processes $\nu_{\mu}+e^{-} \rightarrow$ $\nu_{\mu}+e^{-}$and $\nu_{\mu}+e^{-} \rightarrow \nu_{e}+\mu^{-}$(inverse muon decay) can be measured with high accuracy for the first time. The inverse muon decay process is independent of strong interaction effects and can be used to significantly improve the flux normalization for all other processes. The high neutrino and antineutrino fluxes also make new searches for lepton flavor violation and neutral heavy leptons possible. In this document, we give a first look at the physics opportunities, detector and beam design, and calibration procedures.

## 1 Introduction

The Neutrino Scattering on Glass (NuSOnG) experiment will consist of four detector modules, each composed of a finely segmented calorimeter followed by a muon spectrometer. The detector will be illuminated by a neutrino or antineutrino beam from the Tevatron. In its five-year data acquisition period, NuSOnG will make precise measurements of three types of neutrino scattering and will accumulate the world's largest sample of electron-neutrino scatters. These data will provide unique opportunities to discover physics beyond the Standard Model (including, inter alia, lepton flavor violation and new particles) as well as determine structure functions over a wide range of $x$ and $Q^{2}$. The breadth of anticipated measurements makes NuSOnG a program rather than an experiment; the design heritage ensures that the approach is low-risk and cost-effective.

This Expression of Interest arises from our view that an experiment probing the high energy interactions of neutrinos is a necessary complement to the LHC and an important lead-in to the ILC. In the next few years, the LHC will reveal the nature of electroweak symmetry breaking; the Higgs mass will cease being a prediction of the electroweak theory and will become an input to the theory. Without the Higgs mass as a fit parameter, precision electroweak data, including neutrino scattering data, will be much more powerful as a tool for constraining that physics beyond the Standard Model which directly influences the electroweak sector. More important still, precision neutrino scattering will probe areas of phenomenology that may be inaccessible to the LHC and ILC. NuSOnG is not a precision test of the Standard Model; NuSOnG is a discovery experiment aimed at the terrain not covered by the collider experiments.

This Expression of Interest presents the physics case and initial design for NuSOnG. The detector draws on the heritage of FMMF, CDHS, CHARM and CCFR/NuTeV. The design uses an $\mathrm{SiO}_{2}$ target in one-quarter radiation length panels interleaved with active detector elements (proportional tubes and/or scintillator). This will provide the very high segmentation needed to ensure good separation between different classes of events. We will develop these ideas in the coming months and submit a proposal to the Fermilab Directorate.

Our report is organized as follows: the physics opportunities follow in Section 2, Section 3 describes the flux and expected event rates; and Section 4 describes our preliminary design for the NuSOnG beam and apparatus. We summarize in Section 5 .

## 2 Physics Opportunities

The physics opportunities of the experiment arise from NuSOnG's uniquely high statistics: $>20 \mathrm{k}$ neutrino-electron scatters and $>100 \mathrm{M}$ neutrino-quark scatters. Roughly equal statistics will be obtained from antineutrino scattering. More information on the event rates for various processes is given in Sec. 3. These rates present a wide range of physics opportunities including precision electroweak measurements, direct searches for new physics, and parton distribution studies.

### 2.1 Electroweak Precision Measurements

NuSOnG's considerable discovery potential derives from its ability to do precision electroweak tests through two independent channels: electron scattering and quark scattering. These measurements probe for new particles and new neutrino properties beyond the present Standard Model. As examples, NuSOnG will be sensitive to extra $Z$ bosons with masses beyond the 1 TeV scale (depending on the model), and to compositeness scales above 5 TeV . Thus the energy scales explored by this experiment overlap the LHC, and we present the discovery potential for the new physics we will explore within this context. This experiment also directly addresses questions raised by the "NuTeV anomaly," an electroweak precision measurement in disagreement with the Standard Model.

### 2.1.1 Electroweak Measurements in Neutrino Scattering

NuSOnG is sensitive to new physics through neutral current (NC) scattering. The exchange of the $Z$ boson between the neutrino $\nu$ and fermion $f$ leads to the effective interaction:

$$
\left.\left.\left.\left.\begin{array}{rl}
\mathcal{L}= & -\sqrt{2} G_{F}[
\end{array}\right] \bar{\nu} \gamma_{\mu}\left(g_{V}^{\nu}-g_{A}^{\nu} \gamma_{5}\right) \nu\right]\left[\bar{f} \gamma^{\mu}\left(g_{V}^{f}-g_{A}^{f} \gamma_{5}\right) f\right]\right] \text { - } \sqrt{2} G_{F}\left[g_{L}^{\nu} \bar{\nu} \gamma_{\mu}\left(1-\gamma_{5}\right) \nu+g_{R}^{\nu} \bar{\nu} \gamma_{\mu}\left(1+\gamma_{5}\right) \nu\right]\right] .
$$

where the Standard Model values of the couplings are:

$$
\begin{align*}
g_{L}^{\nu} & =\sqrt{\rho}\left(+\frac{1}{2}\right) \\
g_{R}^{\nu} & =0 \\
g_{L}^{f} & =\sqrt{\rho}\left(I_{3}^{f}-Q^{f} \sin ^{2} \theta_{W}\right), \\
g_{R}^{f} & =\sqrt{\rho}\left(-Q^{f} \sin ^{2} \theta_{W}\right), \tag{2}
\end{align*}
$$

or equivalently,

$$
\begin{aligned}
& g_{V}^{\nu}=g_{L}^{\nu}+g_{R}^{\nu}=\sqrt{\rho}\left(+\frac{1}{2}\right) \\
& g_{A}^{\nu}=g_{L}^{\nu}-g_{R}^{\nu}=\sqrt{\rho}\left(+\frac{1}{2}\right)
\end{aligned}
$$

$$
\begin{align*}
& g_{V}^{f}=g_{L}^{f}+g_{R}^{f}=\sqrt{\rho}\left(I_{3}^{f}-2 Q^{f} \sin ^{2} \theta_{W}\right), \\
& g_{A}^{f}=g_{L}^{f}-g_{R}^{f}=\sqrt{\rho}\left(I_{3}^{f}\right) . \tag{3}
\end{align*}
$$

Here, $I_{3}^{f}$ and $Q^{f}$ are the weak isospin and electromagnetic charge of fermion $f$, respectively. In these formulae, $\rho$ is the relative coupling strength of the neutral to charged current interactions ( $\rho=1$ at tree level in the Standard Model). The weak mixing parameter, $\sin ^{2} \theta_{W}$, is related (at tree level) to to $G_{F}, M_{Z}$ and $\alpha$ by

$$
\begin{equation*}
\sin ^{2} 2 \theta_{W}=\frac{4 \pi \alpha}{\sqrt{2} G_{F} M_{Z}^{2}} \tag{4}
\end{equation*}
$$

NuSOnG is unique in its ability to test the NC couplings by studying scattering of neutrinos from both electrons and quarks. A deviation from the Standard Model predictions in both the electron and quark measurements will present a compelling case for new physics.

## Neutrino Electron Scattering

The differential cross section for muon neutrino and antineutrino scattering from electrons, defined using the coupling constants described above, is:

$$
\begin{align*}
d \sigma=\frac{2 G_{F}^{2} m_{e} E_{\nu}}{\pi} & {\left[\left(g_{L}^{\nu} g_{V}^{e} \pm g_{L}^{\nu} g_{A}^{e}\right)^{2} \frac{d T}{E_{\nu}}\right.} \\
& +\left(g_{L}^{\nu} g_{V}^{e} \mp g_{L}^{\nu} g_{A}^{e}\right)^{2}\left(1-\frac{T}{E_{\nu}}\right)^{2} \frac{d T}{E_{\nu}} \\
& \left.-\left\{\left(g_{L}^{\nu} g_{V}^{e}\right)^{2}-\left(g_{L}^{\nu} g_{A}^{e}\right)^{2}\right\} \frac{m_{e} T}{E_{\nu}^{2}} \frac{d T}{E_{\nu}}\right] \tag{5}
\end{align*}
$$

The upper and lower signs corresponding to the neutrino and anti-neutrino cases, respectively. In this equation, $E_{\nu}$ is the incident $\nu_{\mu}$ energy and $T$ is the electron recoil kinetic energy.

More often in the literature, the cross section is defined in terms of the parameters $\left(g_{V}^{\nu e}, g_{A}^{\nu e}\right)$, which are defined as

$$
\begin{align*}
g_{V}^{\nu e} & \equiv\left(2 g_{L}^{\nu} g_{V}^{e}\right)=\rho\left(-\frac{1}{2}+2 \sin ^{2} \theta_{W}\right) \\
g_{A}^{\nu e} & \equiv\left(2 g_{L}^{\nu} g_{A}^{e}\right)=\rho\left(-\frac{1}{2}\right) \tag{6}
\end{align*}
$$

In terms of these parameters, we can write:

$$
\begin{align*}
d \sigma=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi} & {\left[\left(g_{V}^{\nu e} \pm g_{A}^{\nu e}\right)^{2} \frac{d T}{E_{\nu}}+\left(g_{V}^{\nu e} \mp g_{A}^{\nu e}\right)^{2}\left(1-\frac{T}{E_{\nu}}\right)^{2} \frac{d T}{E_{\nu}}\right.} \\
& \left.-\left\{\left(g_{V}^{\nu e}\right)^{2}-\left(g_{A}^{\nu e}\right)^{2}\right\} \frac{m_{e} T}{E_{\nu}^{2}} \frac{d T}{E_{\nu}}\right] \tag{7}
\end{align*}
$$

When $m_{e} \ll E_{\nu}$, the third terms in these expressions can be neglected. If we introduce the variable $y=T / E_{\nu}$, then

$$
\begin{equation*}
\frac{d \sigma}{d y}=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi}\left[\left(g_{V}^{\nu e}+g_{A}^{\nu e}\right)^{2}+\left(g_{V}^{\nu e}-g_{A}^{\nu e}\right)^{2}(1-y)^{2}\right] \tag{8}
\end{equation*}
$$

Integrating over the region $0 \leq y \leq 1$, we obtain the total cross sections which are

$$
\begin{equation*}
\sigma=\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi}\left[\left(g_{V}^{\nu e} \pm g_{A}^{\nu e}\right)^{2}+\frac{1}{3}\left(g_{V}^{\nu e} \mp g_{A}^{\nu e}\right)^{2}\right] \tag{9}
\end{equation*}
$$

Note that

$$
\begin{align*}
& \left(g_{V}^{\nu e}+g_{A}^{\nu e}\right)^{2}=\rho^{2}\left(-1+4 \sin ^{2} \theta_{W}\right)^{2}=\rho^{2}\left(1-2 \sin ^{2} \theta_{W}+4 \sin ^{4} \theta_{W}\right) \\
& \left(g_{V}^{\nu e}-g_{A}^{\nu e}\right)^{2}=\rho^{2}\left(2 \sin ^{2} \theta_{W}\right)^{2}=\rho^{2}\left(4 \sin ^{4} \theta_{W}\right) \tag{10}
\end{align*}
$$

Therefore,

$$
\begin{align*}
\sigma\left(\nu_{\mu} e\right) & =\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi} \rho^{2}\left[1-4 \sin ^{2} \theta_{W}+\frac{16}{3} \sin ^{4} \theta_{W}\right] \\
\sigma\left(\bar{\nu}_{\mu} e\right) & =\frac{G_{F}^{2} m_{e} E_{\nu}}{2 \pi} \frac{\rho^{2}}{3}\left[1-4 \sin ^{2} \theta_{W}+16 \sin ^{4} \theta_{W}\right] \tag{11}
\end{align*}
$$

The ratio of the integrated cross sections for neutrino to antineutrino electron scattering is

$$
\begin{equation*}
R_{e}=\frac{\sigma\left(\nu_{\mu L} e\right)}{\sigma\left(\bar{\nu}_{\mu L} e\right)}=3 \frac{1-4 \sin ^{2} \theta_{W}+\frac{16}{3} \sin ^{4} \theta_{W}}{1-4 \sin ^{2} \theta_{W}+16 \sin ^{4} \theta_{W}} \tag{12}
\end{equation*}
$$

Many systematics, including flux errors, cancel in this ratio, as does the $\rho$ dependence. Fig. 1(top) shows the results for $\sin ^{2} \theta_{W}$ from many past experiments.

NuSOnG will make independent measurements of the electroweak parameters for both $\nu_{\mu}$ and $\bar{\nu}_{\mu}$-electron scattering. We can achieve this via ratios or by direct extraction of the cross section. In the case of $\nu_{\mu}$-electron scattering, we will use the ratio of the number of events in neutrino-electron elastic scattering to inverse muon decay:

$$
\begin{equation*}
\frac{N\left(\nu_{\mu} e^{-} \rightarrow \nu_{\mu} e^{-}\right)}{N\left(\nu_{\mu} e^{-} \rightarrow \mu^{-} \nu_{e}\right)}=\frac{\sigma_{N C}^{\nu e} \times \Phi^{\nu}}{\sigma^{I M D} \times \Phi^{\nu}} \tag{13}
\end{equation*}
$$

Because the cross section for IMD events is well determined by the standard model, this ratio should have low errors and will isolate the EW parameters from NC scattering. In the case of $\bar{\nu}_{\mu}$ running, the ratio is more complex because there is no equivalent process to inverse muon decay (since there are no positrons in the detector). In this case, we use the fact that, for low exchange energy in Deep Inelastic Scattering, the cross sections in neutrino and antineutrino scattering approach the same constant, $A$, as is explained in Sec. 3.3.2. Thus, for Deep Inelastic events with low energy transfer and hence low hadronic energy $\left(5 \lesssim E_{h a d} \lesssim 10 \mathrm{GeV}\right), N_{\nu D I S}^{l o w} E_{h a d}=\Phi^{\nu} A$ and $N_{\bar{\nu} D I S}^{l o w}{ }_{h} a d=\Phi^{\bar{\nu}} A$. The result is that we can extract the electroweak parameters to high precision using the ratio:

$$
\begin{equation*}
\frac{N_{\nu D I S}^{l o w} E_{\text {had }}}{N_{\bar{\nu} D I S}^{\text {low } E_{\text {had }}}} \times \frac{N\left(\bar{\nu}_{\mu} e^{-} \rightarrow \bar{\nu}_{\mu} e^{-}\right)}{N\left(\nu_{\mu} e^{-} \rightarrow \mu^{-} \nu_{e}\right)}=\frac{\Phi^{\nu}}{\Phi^{\bar{\nu}}} \times \frac{\sigma_{N C}^{\bar{\nu} e} \times \Phi^{\bar{\nu}}}{\sigma^{I M D} \times \Phi^{\nu}} \tag{14}
\end{equation*}
$$

The first ratio cancels the DIS cross section, leaving the energy-integrated $\nu$ to $\bar{\nu}$ flux ratio. The IMD events in the denomenator of the second term cancel the integrated $\nu$ flux. The NC elastic events cancel the integrated $\bar{\nu}$ flux. Alternatively, because we will have accurate knowledge of the flux as a function of the energy (see Sec. 3.3) we could directly measure the cross sections.

Figure 1: Measurements of $\sin ^{2} \theta_{W}$ from past experiments. Top: neutrino-electron elastic scattering experiments. Bottom: neutrino DIS experiments. All DIS results are adjusted to the same charm mass (relevant for experiments not using P-W method). The Standard Model value, indicated by the line, is 0.2227 .

An important point is that the two independent measurements, one in neutrino and the other in antineutrino mode, will in turn allow independent extraction of $g_{A}^{\nu e}$ and $g_{V}^{\nu e}$. The previous best measurement from $\nu_{\mu}$ and $\bar{\nu}_{\mu}$ cross-section measurements is from CHARM II, which used $2677 \pm 82$ events in neutrino mode and $2752 \pm 88$ events in antineutrino mode [1] to find

$$
\begin{gather*}
g_{V}^{\nu e}=-0.035 \pm 0.012(\text { stat }) \pm 0.012(\mathrm{sys})  \tag{15}\\
g_{A}^{\nu e}=-0.503 \pm 0.006(\text { stat }) \pm 0.016(\mathrm{sys}) \tag{16}
\end{gather*}
$$

This can be compared to electroweak measurements from LEP provide a very precise prediction of these parameters [2]:

$$
\begin{align*}
g_{V}^{\nu e} & =-0.0397 \pm 0.0003  \tag{17}\\
g_{A}^{\nu e} & =-0.5065 \pm 0.0001 . \tag{18}
\end{align*}
$$

The CHARM II results are in agreement with LEP, but with large errors. Errors on the neutrino measurement must be substantially reduced in order to meaningfully probe for physics beyond the Standard Model. The goal of NuSOnG is to measure the neutrino-electron and antineutrino-electron cross sections to $0.7 \%$.

### 2.1.1.1 Neutrino Quark Scattering

Substantially higher precision has been obtained using neutrino-quark scattering, which compares neutral-current (NC) to charged-current (CC) scattering to extract $\sin ^{2} \theta_{W}$. However, these experiments are subject to issues of modeling in the quark sector. Fig. 1(bottom) reviews the history of these measurements.

The lowest systematic errors come from implementing a "Paschos-Wolfenstein style" [3] analysis, which would be the technique used by NuSOnG. This requires separated $\nu$ and $\bar{\nu}$ beams, for which the following ratios could be formed:

$$
\begin{align*}
R^{\nu} & =\frac{\sigma_{N C}^{\nu}}{\sigma_{C C}^{\nu}}  \tag{19}\\
R^{\bar{\nu}} & =\frac{\sigma_{N C}^{\bar{\nu}}}{\sigma_{C C}^{\bar{\nu}}} \tag{20}
\end{align*}
$$

Paschos and Wolfenstein [3] recast these as:

$$
\begin{equation*}
R^{-}=\frac{\sigma_{N C}^{\nu}-\sigma_{N C}^{\bar{\nu}}}{\sigma_{C C}^{\nu}-\sigma_{C C}^{\bar{\nu}}}=\frac{R^{\nu}-r R^{\bar{\nu}}}{1-r} \tag{22}
\end{equation*}
$$

where $r=\sigma_{C C}^{\bar{\nu}} / \sigma_{C C}^{\nu}$. In $R^{-}$many systematics cancel to first order, including the effects of the quark and antiquark seas for $u, d, s$, and $c$. Charm production only enters through $d_{\text {valence }}$ (which is Cabbibo suppressed) and at high $x$; thus the error from the charm mass is greatly reduced. The cross section ratios can be written in terms of the effective neutrino-quark coupling parameters $g_{L}^{2}$ and $g_{R}^{2}$ as

$$
\begin{align*}
R^{\nu} & =g_{L}^{2}+r g_{R}^{2}  \tag{23}\\
R^{\bar{\nu}} & =g_{L}^{2}+\frac{1}{r} g_{R}^{2}  \tag{24}\\
R^{-} & =g_{L}^{2}-g_{R}^{2}=\rho^{2}\left(\frac{1}{2}-\sin ^{2} \theta_{W}\right) \tag{25}
\end{align*}
$$

| Source | Error | Reduction in NuSOnG |
| :---: | :---: | :---: |
| Statistics | 0.00135 | 100 times the statistics |
| $\nu_{e}, \bar{\nu}_{e}$ flux prediction | 0.00039 | see Sec. 3.3 .6 |
| Interaction vertex position | 0.00030 | Better detector segmentation and <br> more sophisticated shower identification. |
| Shower length model | 0.00027 | Better segmentation and <br> more sophisticated shower identification. |
| Counter efficiency and noise | 0.00023 | Better, Minos-style counter design |
| Energy Measurement | 0.00018 | Likely to be at a similar level. |
| Charm production, strange sea | 0.00047 | See Sec. 2.4 .4 |
| $R_{L}$ | 0.00032 | Likely to be at a similar level. |
| $\sigma^{\bar{\nu}} / \sigma^{\nu}$ | 0.00022 | See Sec. 2.4 .5 |
| Higher Twist | 0.00014 | Likely to be at a similar level. |
| Radiative Corrections | 0.00011 | Likely to be at a similar level. |

Table 1: Source and value of NuTeV error on $\sin ^{2} \theta_{W}$, and reason why the error will be reduced in the PW-style analysis of NuSOnG.
in which

$$
\begin{align*}
g_{L}^{2} & =\left(2 g_{L}^{\nu} g_{L}^{u}\right)^{2}+\left(2 g_{L}^{\nu} g_{L}^{d}\right)^{2}=\rho^{2}\left(\frac{1}{2}-\sin ^{2} \theta_{W}+\frac{5}{9} \sin ^{4} \theta_{W}\right)  \tag{26}\\
g_{R}^{2} & =\left(2 g_{L}^{\nu} g_{R}^{u}\right)^{2}+\left(2 g_{L}^{\nu} g_{R}^{d}\right)^{2}=\rho^{2}\left(\frac{5}{9} \sin ^{4} \theta_{W}\right) \tag{27}
\end{align*}
$$

NuTeV fit for $R^{\nu}$ and $R^{\bar{\nu}}$ simultaneously to extract $\sin ^{2} \theta_{W}$, obtaining the value $\sin ^{2} \theta_{W}=0.2277 \pm 0.00162$. The goal of NuSOnG is to improve on this error by a factor of two. Table 1 lists the errors which NuTeV identified and indicates those for which NuSOnG expects improvement. Many of the largest experimental systematics of NuTeV came from the method of separating CC and NC events, which relied on length. NuSOnG will have a more sophisticated model for differentiating CC and NC events, using shower shape and identification of Michel-electron followers from low energy pion decays.

From Fig. 1, it is apparent that the NuTeV measurement is in agreement with past neutrino scattering results, although these have much larger errors. However, the NuTeV result is in disagreement with the global fits to the electroweak data which give a Standard Model value of $\sin ^{2} \theta_{W}=0.2227$ [4]. Expressed in terms of the couplings, NuTeV measures:

$$
\begin{gather*}
g_{L}^{2}=0.30005 \pm 0.00137  \tag{28}\\
g_{R}^{2}=0.03076 \pm 0.00110 \tag{29}
\end{gather*}
$$

which can be compared to the Standard Model values of $g_{L}^{2}=0.3042$ and $g_{R}^{2}=0.0301$, respectively. Sec. 2.2 (below) considers possible sources for this disagreement, both within and outside the Standard Model.

### 2.1.2 NuSOnG and New Physics

NuSOnG will provide important probes of physics beyond the Standard Model distinct from and complementary to those of the LHC. NuSOnG will seek indirect evidence for new physics by addressing anomalies in the precision electroweak data, and by providing unique information about neutrino coupling to the $Z$. In addition, precision measurements from NuSOnG will help to disentangle the complicated set of observations that will be present at the LHC and, in doing so, elucidate the mechanism of electroweak symmetry breaking. NuSOnG and the LHC provide distinct probes of new physics because new physics enters collider and neutrino scattering processes differently: neutrino physics measures different combinations of couplings to light quarks; neutrino scattering probes new physics at space-like momentum transfer (versus the time-like scattering at colliders); and systematics are very different between low and high energy experiments. Finally, NuSOnG will directly search for new particles and interactions in the lepton sector that might be missed by the LHC and must otherwise await discovery by the ILC.

### 2.1.2.1 New Physics Observed through Coupling to the $Z$

NuSOnG is unique among experiments in its ability to address the nature of the neutrino couplings to the $Z$ boson in the near future. In the Standard Model, the neutrino coupling to the $Z$ - and $W$-bosons is purely left-handed. Indeed, the fact that the neutrino coupling to the $W$-boson and an electron is purely left-handed is, experimentally, a well-established fact (evidence includes precision measurements of pion and muon decay, nuclear processes, etc.). By contrast, the nature of the neutrino coupling to the $Z$ boson is, experimentally, far from being precisely established [5].

The best measurement of the neutrino coupling to the $Z$-boson is provided by indirect measurements of the invisible $Z$-boson width at LEP. In units where the Standard Model neutrino- $Z$-boson couplings are $g_{L}^{\nu}=0.5, g_{R}^{\nu} \equiv 0$, the LEP measurement [6] translates into $\left(g_{L}^{\nu}\right)^{2}+\left(g_{R}^{\nu}\right)^{2}=0.2487 \pm 0.0010$. Note that this result places no meaningful bound on $g_{R}^{\nu}$.

Precise, model-independent information on $g_{L}^{\nu}$ can be obtained by combining $\nu_{\mu}+e$ scattering data from CHARM II and LEP and SLD data. Assuming model-independent couplings of the fermions to the $Z$-boson, $\nu_{\mu}+e$ scattering measures $g_{L}^{\nu}=2 \rho$, while LEP and SLD measure the left and right-handed couplings of the electron to the $Z$. The CHARM II result translates into $\left|g_{L}^{\nu}\right|=0.502 \pm 0.017$ [5], assuming that the charged-current weak interactions produce only left-handed neutrinos. In spite of the good precision of the CHARM II result (around 3.5\%), a combination of all available data allows $\left|g_{R}^{\nu} / g_{L}^{\nu}\right| \sim 0.4$ at the two $\sigma$ confidence level [5].

Significant improvement in our understanding of $g_{R}^{\nu}$ can only be obtained with more precise measurements of $\nu+e$ scattering, or with the advent of a new high intensity $e^{+} e^{-}$collider, such as the ILC. By combining ILC running at the $Z$-boson pole mass and at $\sqrt{s}=170 \mathrm{GeV},\left|g_{R}^{\nu} / g_{L}^{\nu}\right| \lesssim 0.3$ could be constrained at the two $\sigma$ level after analyzing $e^{+} e^{-} \rightarrow \gamma+$ missing energy events [5].

At NuSOnG, we estimate that $g_{L}^{\nu}$ can be measured at around the $0.86 \%$ level. This estimate is obtained by combining the statistical uncertainty $(20,000 \nu+e$ elastic scattering events) with an estimated $0.5 \%$ systematic uncertainty from the flux estimate. Fig. 2 (left) depicts an estimate of how precisely $g_{R}^{\nu}$ could be constrained if the Nu -

Figure 2: Precision with which the right-handed neutrino- $Z$-boson coupling can be determined by combining NuSOnG measurements of $g_{L}^{\nu}$ with the indirect determination of the invisible $Z$-boson width at LEP. In the left panel, we assume that the $\nu+e$ scattering measurement is consistent with the Standard Model prediction $g_{L}^{\nu}=0.5$, while in the right panel we assume that the $\nu+e$ scattering measurement is significantly lower, $g_{L}^{\nu}=0.485$, but still in agreement with the CHARM II measurement (at the one sigma level). Contours (black, red) are one and two sigma, respectively, while the star indicates the Standard Model expectation. See [5] for more details.

SOnG result, assumed to agree with the Standard Model prediction, is combined with the indirect LEP constraints. One can clearly see that this measurement $\left(\left|g_{R}^{\nu} / g_{L}^{\nu}\right| \lesssim 0.2\right.$ at the two sigma level) compares favorably with the ILC capabilities described above. If the NuSOnG result is incompatible with Standard Model expectations but still in agreement with the CHARM II experiment, a combined NuSOnG-LEP analysis should be able to establish that $g_{R}^{\nu} \neq 0$, as depicted in Fig. 2 (right).

### 2.1.2.2 New Physics Observed through Oblique Corrections

Precision neutrino scattering measurements made at NuSOnG can reveal new physics even when new particles are not created in the final state, through the effects of these particles in loops. For models of new physics in which the dominant loop corrections are vacuum polarization corrections to the gauge boson propagators ("oblique" corrections), the $S T$ parameterization introduced by Peskin and Takeuchi [7] provides a convenient framework in which to describe the effects of the new physics.

The $S T$ parameterization begins with a reference Standard Model, including reference values for the Higgs and top masses, and predictions for observables in this reference Standard Model. Differences between predicted and experimental values of the observables are then parameterized by and used to fit for $S$ and $T$, which can then be compared to predictions from new physics. The full set of precision electroweak data can then be used to constrain $S$ and $T$, as shown in Fig. 3. The $T$ parameter is

Figure 3: Three projected electroweak measurements from NuSOnG in S-T plane. LEP/SLD error ellipse is shown in red and the current $\mathrm{NuTeV} \nu-q$ measurement is shown as a light blue band. The ochre band shows NuSOnG $\bar{\nu}-e$, the dark blue band shows NuSOnG $\nu-q$ and the green shows NuSOnG $\nu-e$. The width of the bands correspond to $68 \%$ confidence level for statistics as described in the text. The NuSOnG measurements assume $(S, T)=(0,0)$.
sensitive to new physics that violates isospin and is zero for new physics that conserves isospin. Isospin-breaking new physics such as heavy non-degenerate fermion doublets or scalar multiplets would affect the $T$ parameter. The $S$ parameter is sensitive to isospin-conserving physics, such as heavy degenerate fermion doublets.

The status of electroweak measurements are shown in Fig. 3 [8]. The combined analysis of the LEP and SLD data by the LEP Electroweak Working Group (EWWG) $[9$ indicates an allowed region shown by the small oval, centered at $S=0.05 \pm 0.10$ and $T=0.07 \pm 0.11$. A different choice of reference Higgs or top mass changes Standard Model predictions for observables and thus shifts the center of the $S T$ plot [10]; setting the Higgs mass to 1000 GeV would shift the center of the oval to roughly $(S, T)=$ $(0.12,-0.36)$. Measurements of the $W$ mass, which are not shown, are also consistent with the LEP measurements. The highest precision neutrino result comes from $\nu q$ and $\bar{\nu} q$ scattering by the NuTeV experiment. This result clearly disagrees with the other
measurements, as discussed in Sec. 2.2.
The goal of NuSOnG is to make measurements which are competitive with or better than past electroweak measurements. These goals are indicated by the magenta ellipse and orange band on Fig. 3. The magenta ellipse shows the area in $S T$ space which can be probed if a $0.7 \%$ measurement of the $\nu$ and $\bar{\nu}$ NC electron-scattering cross sections is achieved. The orange band shows the improvement in the neutrino-quark, "Paschos-Wolfenstein"-style measurement which is expected from NuSOnG.

Disregarding the NuTeV offset for the moment, one can now ask: how will this plot look in the era of LHC and what will NuSOnG add? We consider this question in light of three scenarios:

1. a light Higgs (115-200 GeV)
2. a heavy Higgs ( $200-1000 \mathrm{GeV}$ )
3. no Higgs signal.

### 2.1.2.3 NuSOnG Impact for a Light Higgs (115-200 GeV) Scenario

A light Higgs is consistent with LEP/SLD and $W$ mass data. The fit to the electroweak data excluding NuTeV indicates a mass less than 144 GeV at $95 \%$ CL. This is also consistent with the current best direct-search limit which finds $m_{H}>114 \mathrm{GeV}[9]$. In the case of the lightest Higgs masses, where the cleanest signal may be in $H \rightarrow \gamma \gamma$, a clear observation above background will be experimentally difficult and may take some time.

Once the LHC measurement of the Higgs mass is made, the center of the $S T$ ellipse (Fig. 3) will be fixed at a point (modulo any remaining uncertainty in the top mass). Our experiment is especially interesting if the NuSOnG result disagrees with this LEP+SLD+LHC point. If the LHC measurement is high, i.e. $m_{H} \sim 200 \mathrm{GeV}$, the result would be marginally inconsistent with the $M_{W}$ analysis, which is $85_{-28}^{+39} \mathrm{GeV} 9$. In this case, comparison with the $\nu_{\mu}$ scattering results from NuSOnG could resolve the question of a discrepancy between these measurements.

If all other electroweak results are in good agreement, but disagree with NuSOnG, this would indicate new properties associated exclusively with the neutrino. An example would be decreased coupling of the neutrino to the $Z$ boson, where suppression of the coupling comes from intergenerational mixing of the light neutrino with a moderately heavy neutrino:

$$
\begin{equation*}
\nu_{\mu}=(\cos \alpha) \nu_{\text {light }}+(\sin \alpha) \nu_{\text {heavy }} . \tag{30}
\end{equation*}
$$

The $Z \nu_{\mu} \nu_{\mu}$ coupling is modified by $\cos ^{2} \alpha$ and the $W \mu \nu_{\mu}$ coupling is modified by $\cos \alpha$. This model, inspired by the NuTeV anomaly (see Sec. 2.2), would yield a measurement in NuSOnG with a low NC-to-CC ratio in both the case of electron and quark scattering.

These moderately heavy right-handed states, dubbed "neutrissimos" [12], could have masses as low as just above the current bound of the $Z$ mass. They may well be within the reach of the LHC and may appear as missing energy in events [12. Some models allow for neutrissimos as light as $\sim 100 \mathrm{GeV}$ [13]. The neutrissimos decay very quickly, but not always invisibly. For example, in the reaction $N \rightarrow \ell+W$, the $W$ may decay to either two jets or a neutrino-charged-lepton pair; only the latter case has missing energy. This may make recognition of the neutrissimo at LHC rather
difficult. In the case of $m_{H}<130 \mathrm{GeV}$, a dominant decay mode of the Higgs (along with $b \bar{b}$ ) could be into $\nu N$, where the neutrissimo subsequently decays. Reconstructing the Higgs in this case may be difficult at LHC; if neutrissimos exist, the result from NuSOnG may significantly improve our understanding of LHC results.

With a large tuning among the neutrino Yukawa couplings [13] neutrissimos could be the seesaw right-handed neutrinos. Relatively "large" mixing is marginally consistent with other constraints, including neutrinoless double-beta decay, which constrains $\left|U_{e 4}\right|^{2}$ to be less than a few $\times 10^{-5}$ for a 100 GeV right-handed neutrino, and rare pion and tau decays, which constrain $\left|U_{\mu 4}\right|^{2}$ to be less than, most conservatively, 0.004 and $\left|U_{\tau 4}\right|^{2}$ to be less than 0.006 . Other bounds come from $\mu \rightarrow e$ conversion in nuclei and other charged-lepton-flavor violation. A new experiment to search for $\mu \rightarrow e$ has been proposed at Fermilab [14] should also be sensitive to neutrissimos. The combination of NuSOnG and this experiment will be powerful in identifying the existence of these particles.

If the neutrissimo is a Majorana particle, it could be instrumental in elucidating the mechanism for leptogenesis. The present models of leptogenesis require very high mass scales for the neutral lepton, but theorists are pursuing ways to accommodate lower masses [15]. There also may be a wide mass spectrum for these particles, with one very heavy state required by standard leptogenesis models and others with masses in the range observable at LHC [16].

### 2.1.2.4 NuSOnG Contribution in a Heavy Higgs (200-1000 GeV) Scenario

While present electroweak data excluding NuTeV favor a light Higgs ( $\lesssim 200 \mathrm{GeV}$ ), as indicated in Fig. 3, the Higgs mass can extend up to about 1000 GeV without violating unitarity [17]. Thus, if LHC finds that the Higgs is between ~200 and 1000 GeV and the LEP+SLD ellipse has no major systematic error, then new physics must explain the discrepancy. Candidate models of new physics may well affect the neutrino scattering and $e^{+} e^{-}$scattering differently, so the high-precision neutrino scattering measurements from NuSOnG will provide an important piece of the puzzle if the Higgs mass found at LHC is genuinely inconsistent with LEP + SLD predictions.

Introduction of a fourth family would compensate for a modestly heavy ( $\sim 300$ GeV ) Higgs by shifting the LEP + SLD allowed region back up in $S$ and $T$ [18]. This family would need to exist above the bounds of direct searches, which is $\gtrsim 300 \mathrm{GeV}$. Mixing must be confined within the allowed bounds of the CKM matrix measurements [20]. A nice feature of this model is that a fourth-generation Majorana neutrino could play the role of dark matter. Depending on the underlying physics, evidence of a fourth family would be apparent in a shift of the NuSOnG result on the $S T$ plot. This could be especially important if the physics introducing the fourth family is from a mechanism like "Top See Saw" [21, which will not be observable at LHC. The impact of this particular model on neutrino scattering is not yet thoroughly explored, but could prove interesting [22].

A classic method for masking a heavy Higgs is to introduce heavy $Z$ bosons [23], which, as shown in ref. [10, tend to move the LEP-SLD ellipse upward in $T$, compensating for the heavy Higgs. Introduction of a $Z^{\prime}$ tends to increase NC rate in neutrino scattering and also to move the neutrino result upward on the $S T$ plot (although with a different dependence than the LEP-SLD result).

There are good theoretical reasons for considering the existence of additional neutral heavy gauge bosons. Extra $Z$ bosons appear in various GUT and string-motivated extensions to the Standard Model [24]. For example, the $E(6)$ breakdown to $S O(10) \times$ $U(1)_{\psi}$ results in the $Z_{\psi}$. The $S O(10)$ break down to $S U(5) \times U(1)_{\chi}$ yields the $Z_{\chi}$. Thus the new exchange boson could be: $Z^{\prime}=Z_{\chi} \cos \beta+Z_{\psi} \sin \beta$, where the mixing angle $\beta$ is an arbitrary parameter. Extra $Z$ bosons also appear in other beyond Standard Model theories, including extra dimensions with gauge fields in the bulk [25]; little Higgs theories [26], which use heavy $Z$ s to cancel divergences in the Higgs mass; and topcolor in which they drive electroweak symmetry breaking [27]. Heavy $Z \mathrm{~s}$ provide a mechanism for new SUSY theories to evade the LEP bound of $m_{H}=114 \mathrm{GeV}$ [28]. These models all produce new physics signatures at LHC. The precision measurement from NuSOnG can aid in differentiating models.

Models which introduce new physics to mask a heavy Higgs may seem contrived until one looks at the LEP+SLD data more closely. Up to this point we have considered the LEP+SLD measurements as a single result, however, many measurements enter this fit, and larger than expected inconsistencies between these measurements exist [29]. For example, there is a $3.2 \sigma$ discrepancy between the forward-backward $\left(A_{F B}\right)$ and leftright $\left(A_{L R}\right)$ asymmetry measurements. Excluding the $A_{F B}$ result, the LEP+SLD fit yields $m_{H}<115 \mathrm{GeV}$ at $95 \%$, with the best fit at 42 GeV - i.e. a range already excluded by direct searches, which require $m_{H}>114 \mathrm{GeV}$ at $95 \%$ CL.

There are several ways to interpret this deviation. It may simply be that there are systematics involved in the $A_{F B}$ measurement which have yet to be identified and which would bring this result into agreement with the others. In this case, we are in the dramatic situation of having already ruled out the Higgs. The scenario of no Higgs is considered in the next section. Alternatively, new physics is involved. This result is dominated by purely leptonic measurements. On the other hand, the fit to the hadronic asymmetries, dominated by $A_{F B}^{b}$ has two $\chi^{2}$ minima, at 450 and 3000 GeV . Thus, one may either introduce new physics which produces a $20 \%$ shift on $A_{F B}^{b}$ alone; or introduce new physics which would indicate apparently low values of $m_{H}$ in the lepton-based measurements, when actually the value is large. Within any of these scenarios, new precision results from NuSOnG will be valuable for understanding the underlying physics.

### 2.1.2.5 NuSOnG and the Case of No Higgs

Higgsless models do not employ the Higgs mechanism to render the Standard Model renormalizable [30]; instead they introduce some other scheme. The Higgs mechanism enforces unitarity in the scattering amplitudes of longitudinally polarized gauge bosons, $W_{L}^{ \pm}+Z_{L}^{o} \rightarrow W_{L}^{ \pm} Z_{L}^{o}$, for example. A requirement that the transition probability remains less than one gives the energy scale $\Lambda$ at which a new mechanism must come into play,

$$
\begin{equation*}
\Lambda \sim \frac{4 \pi M_{W}}{g} \sim 1.8 \mathrm{TeV} \tag{31}
\end{equation*}
$$

Higgsless theories generally contain new mass bosons $V_{i}$ with masses on the TeV scale that act to cancel the divergences in gauge boson scattering. Cancelling the amplitudes while respecting bounds from current electroweak couplings typically give small
couplings:

$$
\begin{equation*}
g_{W Z V}<\frac{g_{w w z} M_{Z}^{2}}{\sqrt{3} M_{1}^{ \pm} M_{W}}=0.04 \tag{32}
\end{equation*}
$$

for $M_{1}^{ \pm}=700 \mathrm{GeV}$.
At the LHC, the typical cross sections for $V_{i}$ are hundreds of femtobarns, so, after cuts, the LHC experiments will record tens to hundreds of events in the first years of data taking. Since the $V_{i}$ resonances serve the same purpose as the Higgs boson, additional information will be necessary to determine whether these resonances originate from spontaneous symmetry breaking or from strong coupling between the known gauge bosons. The electroweak measurements from NuSOnG will play a role in understanding the origin of such events, en route to a more complete explanation provided by the ILC.

### 2.2 The NuTeV Anomaly

The NuTeV anomaly is a $3 \sigma$ deviation of $\sin ^{2} \theta_{W}$ from the Standard Model prediction 4. NuTeV employed the PW-inspired method discussed in Sec. 2.1.1.1, which resulted in a $0.75 \%$ measurement of the weak mixing angle (see Tab. 11). Two systematic adjustments to the NuTeV result have been identified since the result was published. The first is the new measurement of the $K_{e 3}$ branching ratio from KTeV , which does not significantly reduce the error, but introduces a correction moving the result away from the Standard Model. The second is the final measurement of the difference between the strange and antistrange seas (called "the strange sea asymmetry", see Sec. 2.4.4., which will pull the NuTeV result toward the Standard Model. A new analysis of the NuTeV data which will include these two corrections is expected be available in late summer, 2007 [32]. It should be noted that while an error from the strange sea appeared in the NuTeV analysis, no error on a strange sea asymmetry appeared in the original NuTeV analysis; this will be included in the upcoming re-analysis.

NuTeV is one of a set of $Q^{2} \ll m_{Z}^{2}$ experiments measuring $\sin ^{2} \theta_{W}$. It was performed at $Q^{2}=1$ to $140 \mathrm{GeV}^{2},\left\langle Q_{\nu}^{2}\right\rangle=26 \mathrm{GeV}^{2},\left\langle Q_{\bar{\nu}}^{2}\right\rangle=15 \mathrm{GeV}^{2}$, which is also the expected range for NuSOnG. Two other precision low $Q^{2}$ measurements are from atomic parity violation [34] (APV), which samples $Q^{2} \sim 0$; and SLAC E158, a Møller scattering experiment at average $Q^{2}=0.026 \mathrm{GeV}^{2}$ [35]. Using the measurements at the $Z$-pole with $Q^{2}=M_{z}^{2}$ to fix the value of $\sin ^{2} \theta_{W}$, and evolving to low $Q^{2}$, Fig. 4 from ref. [31], shows that APV and SLAC E158 are in agreement with the Standard Model. However, the radiative corrections to neutrino interactions allow sensitivity to highmass particles which are complementary to the APV and Møller-scattering corrections. Thus, these results may not be in conflict with NuTeV . The NuSOnG measurement will provide valuable additional information on this question.

Since the NuTeV result was published, more than 300 papers have been written which cite this result. Various Beyond-the-Standard-Model explanations have been put forward; those which best explain the result require a follow-up experiment which probes the neutral weak couplings specifically with neutrinos, such as NuSOnG. Several "within-Standard-Model" explanations have also been put forward, based on the inherent issues involving scattering off quarks. NuSOnG can address these criticisms in two ways. First, we will provide better constraints of the quark-related distributions at issue. Second, we perform the measurement of the weak mixing angle in both a

Figure 4: Measurements of $\sin ^{2} \theta_{W}$ as a function of $Q$; from ref. [31]. The curve shows the Standard Model expectation.
purely leptonic mode (scattering from electrons) and via the PW method. Agreement between the two results would address the questions which have been raised.

### 2.2.1 Explanations Within the Standard Model

Four explanations for the NuTeV anomaly that are "within the Standard Model" have been proposed. These are: electromagnetic radiative corrections; higher order QCD corrections; isospin (or charge symmetry) violation; and the strange sea asymmetry. The radiative corrections will be disregarded here, since the results of this paper 36] are not reproducible.

The effect of the possible explanations is illustrated in Fig. 5. On this plot, the solid horizontal line indicates the deviation of NuTeV from the Standard Model. The thick vertical lines, which emanate from the NuTeV deviation, show the range of pulls estimated for each explanation, as discussed below. The dashed horizontal line shows the estimated shift due the new $K_{e 3}$ branching ratio. We do not yet have an estimated shift due to the new NuTeV strange sea measurement, but it is expected that this will move the dashed line toward the Standard Model [32].

Three "Standard Model" explanations may be considered next [37, 38]. First, the NuTeV analysis was not performed at a full NLO level; NuSOnG will need to undertake a full NLO analysis. But the effect of going to NLO on NuTeV can be estimated [39], and the expected pull is away from the Standard Model, as shown on Fig. 5. Second, the NuTeV analysis assumed isospin symmetry, that is, $u(x)^{p}=d(x)^{n}$ and $d(x)^{p}=u(x)^{n}$. Isospin violation can come about from a variety of sources and is interesting in its own right. NuSOnG's contribution to this study is discussed in Section 2.4.3. Various models for isospin violation have been studied and their pulls range from less than $1 \sigma$ away from the Standard Model to $\sim 1 \sigma$ toward the Standard Model [40]. We have chosen three examples [40] for illustration on Fig. 5 the full bag model, the meson cloud model, and the isospin QED model. These are mutually exclusive models, so only one of these can affect the NuTeV anomaly. Third, variations in the predicted strange sea asymmetry can either pull the result toward or away from the Standard Model expectation [41, 42, 43]. This issue is considered in detail in Sec. 2.4.4.

### 2.2.2 Beyond Standard Model Interpretations

Chapter 14 of the APS Neutrino Study White Paper on Neutrino Theory [44] is dedicated to "the physics of NuTeV" and provides an excellent summary. The discussion presented here is drawn from this source.

The NuTeV measurements of $R^{\nu}$ and $R^{\bar{\nu}}$, the NC-to-CC cross sections, are low. If one is assumes that the Higgs is light, then this must be interpreted as Beyond-Standard-Model physics that suppresses the NC rate with respect to the CC rate. Two types of models produce this effect and remain consistent with the other electroweak measurements: 1) models which affect only the $Z$ couplings, e.g., the introduction of a heavy $Z^{\prime}$ boson which interferes with the Standard Model $Z$; or 2) models which affect only the neutrino couplings, e.g., the introduction of moderate mass neutral heavy leptons which mix with the neutrino.

As discussed in Sec. 2.1.2.4, introduction of $Z^{\prime}$ bosons tend to increase the NC rate rather than suppress it. Thus there is only a small subset of models which produce the destructive interference needed to explain the NuTeV result. Models which introduce

Figure 5: Effect of various "Standard Model" explanations on the NuTeV anomaly. The $y$-axis is the deviation from the Standard Model. The solid line is the NuTeV deviation. The dashed line is an estimate of the effect of correcting for the new $K_{e 3}$ branching ratio. Thick black lines extending from the NuTeV deviation show the range of possible pulls from the various suggested sources, as described in the text.
a $Z^{\prime}$ which selectively suppresses neutrino scattering, without significantly affecting the other electroweak measurements, include cases where the $Z^{\prime}$ couples to $B-3 L_{\mu}$ [45] or to $L_{\mu}-L_{\tau}$ [46]. In the former case, fitting the NuTeV anomaly requires that $M_{Z^{\prime}} / g_{Z^{\prime}} \sim 3 \mathrm{TeV}$. From the bounds from direct searches, this sets a limit on $M_{Z^{\prime}}>600$ GeV if the coupling is on the order of unity, but as low as 2 to 10 GeV if the coupling is $\sim 0.1 \%$. The latter case is an example which improves the agreement between NuTeV and other results, but does not entirely address the problem. Its effectiveness in solving the NuTeV anomaly is limited by the data constraining lepton universality. This model addresses more than just the NuTeV anomaly. It is inspired by attempts to address bimaximal mixing in the neutrino sector. It has the nice features of also addressing the muon $(g-2)$ measurement and producing a distinctive dimuon signature at LHC.

The case of models involving moderate-mass neutral heavy leptons, a.k.a. neutrissimos, have been discussed in the Sec. 2.1.2.3 and examples of viable models appear in ref. [11. Eq. 30 described how the muon neutrino couplings might be modified by mixing. This idea can be extended to all three flavors, leading to a suppression factor for the $Z$ coupling which is expressed as $\left(1-\epsilon_{\ell}\right)$ and for the $W$ by $\left(1-\epsilon_{\ell} / 2\right)$, where $\ell=e, \mu$, or $\tau$. This addresses the NuTeV anomaly and at the same time suppresses the invisible width of the $Z$, describing the LEP I data.

If the NuTeV anomaly is due to Beyond Standard Model physics, then the effect will be visible in the neutrino-electron elastic scattering measurement also. Thus, if the NuTeV anomaly is borne out, NuSOnG would observe an $S T$ plot similar to Fig. 6.

### 2.3 Direct Searches for New Physics

### 2.3.1 Light Neutrino Properties

Evidence for three light neutrino masses has now been established through neutrino oscillations in solar, atmospheric, and reactor experiments (see references [47] through [61). Furthermore, although the MiniBooNE experiment recently refuted the LSND two-neutrino oscillation scenario at $\Delta m^{2} \sim 1 \mathrm{eV}^{2}$ [62], the question of the existence of multiple light sterile neutrinos still remains open [63]. These observations already require beyond-the-Standard-Model physics, and consequently raise phenomenological questions, such as: what are the mass and mixing parameters still allowed in sterile neutrino models? What do sterile neutrinos imply about neutrino mixing? Is the neutrino mixing matrix unitary, or is there effective freedom of mixing parameters? As we illustrate in the following sections, these are some of the questions that NuSOnG can potentially address.

### 2.3.1.1 Matrix Freedom

Perhaps the most interesting study of light neutrino properties which can be performed at NuSOnG is the search for evidence of "matrix freedom" or "nonunitarity." For example, in the case of existence of sterile neutrinos, the neutrino mixing matrix is extended to an $N \times N$ matrix, where $N>3$. Under that assumption, it has been suggested that the $3 \times 3$ part of the matrix describing the three active (SM) neutrinos is not necessarily unitary; or, equivalently, the three flavor eigenstates are non-orthogonal (the $3 \times 3$ neutrino mixing matrix is free) [64].

Figure 6: Three projected electroweak measurements from NuSOnG in S-T plane for a model model with a heavy Higgs inspired by the NuTeV measurement [11]. In this model, $(S, T)=(0.12,-0.36)$. The labeling is as in Fig. 3.

This introduces striking changes to the probability formula for neutrino flavor transitions. Assuming unitarity, the survival probability formula for a neutrino produced as flavor $\alpha$ is

$$
\begin{equation*}
P_{\alpha \alpha}^{\text {unitary }}=1-4\left|U_{\alpha 3}\right|^{2}\left[1-\left|U_{\alpha 3}\right|^{2}\right] \sin ^{2} \Delta_{31}, \tag{33}
\end{equation*}
$$

where one has made use of $\Delta_{31}=\Delta m_{31}^{2} \frac{L}{4 E}$, and $\Delta m_{21}^{2} \frac{L}{4 E} \ll 1$. In the case of matrix freedom, the mixing matrix is no longer unitary. The level at which unitarity is violated can be defined as $X_{\alpha}$, where

$$
\begin{equation*}
\sum_{j}\left|U_{\alpha j}\right|^{2}=1-X_{\alpha}, \tag{34}
\end{equation*}
$$

with $X_{\alpha}$ being small. Under that assumption, the survival probability formula is then found to be

$$
\begin{equation*}
P_{\alpha \alpha}^{\text {general }}=P_{\alpha \alpha}^{\text {unitary }}-2 X_{\alpha}\left[1-2\left|U_{\alpha 3}\right|^{2} \sin ^{2} \Delta_{31}\right]+X_{\alpha}^{2} . \tag{35}
\end{equation*}
$$

As implied by Eq. 35 one of the main consequences of such scenario is instantaneous ( $L=0$ ) flavor transitions in a neutrino beam. This occurs regardless of the size of the mass splitting between the mostly sterile and mostly active states, and thus allows for a full-mass-range search for evidence of sterile neutrinos. A recent study [65] suggests that current experimental data limit such an effect to up to the order of a few percent.

As a result, several interesting and potentially observable phenomena can occur. Extending the argument of ref. [65], for instance, the non-orthogonality of $\nu_{\mu}$ and $\nu_{e}$ that matrix freedom introduces, results in an instantaeous transition at $L=0$ from $\nu_{\mu}$ to $\nu_{e}$ [64. Thus one could observe an excess of $\nu_{e}$ events in a pure $\nu_{\mu}$ beam.

The trick to searching for this instantaneous transition is to focus on an energy range where the $\nu_{e}$ background is low and well constrained. In the case of NuSOnG, this is on the high energy tail of the flux, above $\mathrm{E} \gtrsim 250 \mathrm{GeV}$. For the limits on $\nu_{\mu}$ transformation to $\nu_{e}$ [65], which are at the $\sim 1 \times 10^{-4}$ level, NuSOnG would see an excess of $\sim 200 \nu_{e}$ events in this high energy region. Fig. 7 shows the ratio of $\nu_{e}$ flux with $\nu_{\mu}$ transitions to $\nu_{e}$ flux without transitions. The abrupt cutoff is due to Monte Carlo statistics; higher energies can be explored. Assuming that such transitions indeed happen at the $10^{-4}$ level, one would expect up to a $10 \%$ increase in flux for $\mathrm{E} \sim 350$ GeV . In that high energy region, the $\nu_{e}$ flux is mainly from $K^{+}$decay, which is well constrained by the $\nu_{\mu}$ events. Such an excess should therefore be measurable.

Other interesting effects of matrix freedom [64] include the oscillatory behavior in the total (flavor-summed) CC event rate as a function of $L / E$, and (fake) CP-violating effects in the $\nu$ and $\bar{\nu}$ neutral-current event rates (the two rates oscillate differently with $L / E)$. Potential observation of those effects at NuSOnG has not been explicitly considered at this stage, although it would be interesting to address this and we are planning to do so in the near future. Regardless of that, evidence of $\nu_{e}$ contamination in a $\nu_{\mu}$ beam above expected background levels, something for which NuSOnG can search, would strongly support the matrix freedom hypothesis.

### 2.3.1.2 Sterile Neutrino Oscillations

Direct observation of sterile neutrino oscillations may also be possible in NuSOnG, depending on the mass and mixing parameters. Oscillations of active to light sterile neutrinos have been introduced to explain the LSND anomaly, as dark matter candidates, and in describing the supernova collapse models. These ideas span a wide

Figure 7: Ratio of enhanced $\nu_{e}$ flux due to $\nu_{\mu}$ transitions to $\nu_{e}$ flux assuming no transitions. Obtained assuming $100 \mathrm{M} \nu_{\mu}$ deep inelastic scattering events.
range of $\Delta m^{2}$ values. The LSND anomaly requires a sterile neutrino in the range of $\sim 1 \mathrm{eV}^{2}$ with moderate mixing ( $\lesssim 1 \%$ ), while dark matter candidates and supernova collapse models require ( $\gtrsim 1 \mathrm{keV})^{2}$. These models also require tiny mixing $\left(10^{-13}<\sin ^{2} 2 \theta<10^{-7}\right)$ 66]. NuSOnG probes an intermediate range of $\Delta m^{2}$, between the LSND and astrophysical allowed regions. However, since sterile neutrinos may come in families, it is worth exploring this previously uncharted territory.

The NuSOnG experimental design consists of a $30-600 \mathrm{GeV}$ muon neutrino beam, peaked at $\sim 100 \mathrm{GeV}$, incident on a $\sim 200$-meter long detector located at $\mathrm{L} \sim 1.5 \mathrm{~km}$ from the neutrino source. This detector design allows for $\nu_{\mu}$ disappearance studies across the detector length by examining the $\nu_{\mu}$ scattering rate variation across the detector. Such searches would be limited by the detector energy resolution. Preliminary studies have shown that, assuming a $10 \%$ energy resolution, $\Delta m^{2} \sim 600 \mathrm{eV}^{2}$ regions with mixing of $\lesssim 0.1$ can be probed easily. NuSOnG may also be able to explore smaller mixings and higher $\Delta m^{2} \mathrm{~s}$, depending on the final experimental design.

NuSOnG can also probe for $\nu_{\mu}$ and $\nu_{e}$ disappearance in the range of $L / E=$ $(1.5 \mathrm{~km} / 100 \mathrm{GeV})=0.015$, thus in the range of $\Delta m^{2} \sim 50 \mathrm{eV}^{2}$. This is a range which has been covered by past experiments including CCFR [67], CHDS [68], and NOMAD [69]. However, the improved quality of the first principles prediction due to the new SPY secondary production data [70], discussed in sec. 3.3, should allow improvement of these limits.

### 2.3.2 New Interactions

### 2.3.2.1 Lepton Number Violation Searches

The NuSOnG experiment possesses two valuable characteristics for the search for lepton number violation. First, it relies upon a high purity, high intensity beam as
its source of neutrinos; secondly, it employs an instrumented detector optimized to measure inverse muon decay with high accuracy. An experiment with these two features naturally lends itself to searches for the process:

$$
\begin{equation*}
\bar{\nu}_{\mu}+e^{-} \rightarrow \mu^{-}+\bar{\nu}_{e} . \tag{36}
\end{equation*}
$$

This interaction is forbidden by the Standard Model since it violates lepton family number conversation ( $\Delta L_{e}=-\Delta L_{\mu}=2$ ). As such, observation of this reaction would immediately constitute direct observation of physics beyond the Standard Model.

A number of theories beyond the Standard Model predict that lepton number is not a true conserved quantum number; this means that processes that violate lepton number are allowed to occur. Theories which incorporate multiplicative lepton number conservation [71, 72], left-right symmetry [73], or the existence of bileptons [74] fall under this category.

The differential cross-section for lepton-violating processes can be parametrized in the following form:

$$
\begin{equation*}
\frac{d \sigma}{d y}=\lambda \frac{G_{F}^{2} s}{\pi}\left(A_{V} \cdot y(y-r)+A_{S} \cdot(1-r)\right) \tag{37}
\end{equation*}
$$

where $y$ is the fractional energy carried by the outgoing lepton, $G_{F}$ the weak coupling constant, $s$ the square of the center of mass energy of the system, and $r$ the threshold factor, defined as $m_{\mu}^{2} / s$. The parameters $\lambda, A_{V}$, and $A_{S}$ describe the strength of the reaction and whether the process is vector or scalar in nature. It is typical to compare this process to that of inverse muon decay:

$$
\begin{equation*}
\frac{\sigma\left(\bar{\nu}_{\mu} e^{-} \rightarrow \mu^{-} \bar{\nu}_{e}\right)}{\sigma\left(\nu_{\mu} e^{-} \rightarrow \mu^{-} \nu_{e}\right)}=\lambda \cdot\left(A_{V} \cdot\left(\frac{1+r / 2}{3}\right)+A_{S}\right) . \tag{38}
\end{equation*}
$$

The signature for such a reaction is the tagging of an $\mu^{-}$during antineutrino running with the same signature as expected from inverse muon decays. The main backgrounds to this reaction include (a) $\nu_{\mu}$ contamination, (b) $\nu_{e}$ contamination, and (c) charge misidentification of candidate events. Our current estimates place a very small beam contamination during antineutrino running: about $0.4 \%$ contamination of $\nu_{\mu} \mathrm{s}$ and a $2.3 \%$ contamination of $\nu_{e}$ and $\bar{\nu}_{e}$ neutrinos (See Sec. 3.1). Charge misidentification is expected to be very small, on the order of $10^{-5}$. If we assume a conservative knowledge of the backgrounds at the $5 \%$ level, this would imply a limit on the lepton number violation cross-section ratio of better than $0.2 \%$ (at $90 \%$ C.L.) for V-A couplings and less than $0.06 \%$ for scalar couplings. Previous searches, based on $1.6 \times 10^{18}$ protons on target and smaller target masses, have placed limits on this cross-section ratio to less than $1.7 \%$ at $90 \%$ C.L. for V-A couplings and less than $0.6 \%$ for scalar couplings [75]. The NuSOnG experiment can therefore reach an improvement of over an order of magnitude compared to previous searches. This limit can be improved if further selection criteria are used in removing unwanted beam impurities or the quasi-elastic background contamination.

### 2.3.2.2 Inverse Muon Decay

The study of inverse muon decay, $\nu_{\mu}+e^{-} \rightarrow \mu^{-}+\nu_{e}$ provides access to the helicity structure of the weak interaction distinct from muon decay experiments. The weak
interaction polarizes the incident $\nu_{\mu}$, making inverse muon decay an excellent place to study departures from $V-A$ couplings. For inverse muon decay, $\sigma \propto\left(g_{L}^{V, e} g_{L}^{V, \mu}\right)^{2}(1-\epsilon)$ [76] where $\epsilon=h-(-1)$ and $h$ is the helicity of the incident muon. Ref. [77] has measured $\epsilon<4.1 \times 10^{-3}$ and the current limit on $g_{L L}^{V}=\left(g_{L}^{V, e} g_{L}^{V, \mu}\right)>0.96$ [78]. For a measurement of the total cross section scaled to the predicted cross section, the uncertainty on the coupling is $g_{L L}^{V}=(1 / 2) \sigma_{\sigma} / \sigma_{S M}$.

For NuSOnG, we expect $>200 \mathrm{k}$ inverse muon decay events, which would give a statistical uncertainty of 0.002 on $g_{L L}^{V}$. However, we will need to determine the neutrino flux. Taking the $\nu_{\mu}+e^{-} \rightarrow \nu_{\mu}+e^{-}$cross section as known gives the neutrino flux to $0.7 \%$. Since we plan to use the inverse muon decay events for determining the flux for the electroweak measurements, NuSOnG will need to measure the efficiency and fiducial volume for both processes to better than $0.7 \%$. Combined with other systematics, we should be able to achieve an total uncertainty of about $1-2 \%$ on $g_{L L}^{V}$, an improvement by a factor of four.

The key background will come from CCQE events that have small hadronic energy. We expect our high granularity will allow us to keep the systematic error from this source well below $1 \%$, but this needs study.

Obviously, the manner of analysis described above is somewhat questionable. Ultimately, one would want to carry out a combined analysis of both neutrino elastic scattering on electrons and quarks and of inverse muon decay in the context of a specific model which relates the charged and neutral current coupling constants. For such an analysis, $1-2 \%$ uncertainty should still be achievable.

### 2.3.3 New Particles

### 2.3.3.1 Long-lived, Light Neutral Heavy Leptons

Another interesting NuTeV result arose from the search for long-lived, light ( $<15$ GeV ) neutral heavy leptons. This was performed in a helium-filled decay region located upstream of the calorimeter. In the mass region of $2.2-15 \mathrm{GeV}, \mathrm{NuTeV}$ has a small expected background ( $0.07 \pm 0.01$ events), but observed three events. All events had two muons originating from a vertex within the helium decay region and missing energy. [79.

Since publication in 2001, no widely accepted explanation has been found. In 2006, D0 published a search for a similar decay signature in proton-antiproton interactions 80. No events were found and some production models were excluded. The most viable remaining model is by Dedes et al., which hypothesizes that the events are from decay of long-lived neutralinos. These are produced in the NuTeV beam dump through $B$ hadron decays [81]. No other experiment has been able to match NuTeV's running conditions to further explore this intriguing result.

NuSOnG can address the question by including a low-mass (helium-filled) decay region between the calorimeter segments. Assuming parameters similar to those of NuTeV (except for a 20 -fold increase in the number of protons on target), NuSOnG would expect to see 60 events with an expected background of 1-2 events. The sensitivity would scale directly with the decay volume, so the increased length compared to $\mathrm{NuTeV}(26 m \rightarrow \approx 40 \mathrm{~m})$ would increase this to 90 signal events over a $2-3$ event background. Observing no signal would finally settle this outstanding question.

These decay regions allow exploration for a signal from a beyond-the-StandardModel particle in other decay modes as well; other interesting modes include $\mu \pi, \mu e$, $e \pi$ and $e e$. NuSOnG's sensitivity to other new particles is similarly improved over NuTeV by the increase in beam intensity and decay volume, allowing us to study new regions of phase space.

### 2.3.3.2 Muonic Photons

In the mid-1990's there was interest in searching for "leptonic photons" - massless vector particles that couple according to flavor. Electronic, muonic, and tauonic photons, $\gamma_{e}, \gamma_{\mu}$, and $\gamma_{\tau}$ were introduced [82]. Production occurs in secondary meson decays such as $\pi \rightarrow \nu_{\mu} \mu \gamma_{\mu}$, and detection can proceed through $\gamma_{\mu}+Z \rightarrow \mu^{+}+\mu^{-}+Z$, where $Z$ is the charged nucleus. These events have small missing $p_{T}$ compared to the "trident" background, $\nu+Z \rightarrow \nu+\mu^{+} \mu^{-}+Z$. The search by CHARM II sets the best limit at $1.6 \times 10^{-6}$ [83].

Since this time, neutrino oscillations have been confirmed (see references 47] through [61]). This complicates the theory of "muonic photons," since, in this case, lepton flavor-charge is not conserved. As pointed out in reference [82], a theory with a nonconserved charge cannot have massless vector particles and a Coulomb-like potential. It appears very difficult to evade this problem.

Nevertheless, NuSOnG should search for these events. With higher rate and better segmentation than CHARM II, NuSOnG should have sensitivity in the range of $\sim 10^{-7}$. A significant excess would be quite startling.

### 2.4 Measurement of Parton Distribution Functions

The Deeply Inelastic Scattering (DIS) process provides crucial information about the structure of the proton which is used to determine the Parton Distribution Functions (PDFs). For example, in the recent CTEQ6HQ analysis, DIS data accounted for more than two-thirds of the data points used in the analysis 11 As such, the DIS measurements form the foundation for the many calculations which make use of the PDFs.

In the basic DIS process, leptons scatter from hadrons via the exchange of an intermediate vector boson: $\left\{\gamma, W^{ \pm}, Z\right\}$. Different boson probes couple to the hadrons with different factors, and it is important to combine data from these different probes to separate the different flavor components in the hadron. Unfortunately, three of the four DIS probes $\left\{W^{ \pm}, Z\right\}$ have a (relatively) large mass and couple only weakly; this introduces a number of complications:

- The statistics for these weak processes are limited as compared with the photonexchange processes.
- To compensate for the weak cross section, typically heavy nuclear targets (e.g., Fe and Pb ) are used; this introduces nuclear corrections when the results are scaled from the heavy target back to proton or isoscalar targets.

The NuSOnG experiment will generate high statistics ( $>100 \mathrm{M}$ DIS events) measurements on an intermediate atomic-weight nuclear target $\left(\mathrm{SiO}_{2}\right)$. This will provide

[^290]precise information on the linear combinations of PDFs which couple to the weak charged currents ( $W^{ \pm}$), which can significantly improve the parton distribution fits. In this section, we first introduce the basics of DIS and the connection to parton distribution functions. Then we concentrate on three aspects of parton distribution studies where NuSOnG can make a unique contribution to the physics:

- Improved understanding of nuclear effects in neutrino scattering.
- Study of Charge Symmetry Violation
- Measurement of the Strange Sea
- Measurement of $\sigma^{\nu}$ and $\sigma^{\bar{\nu}}$

The latter two items are directly relevant to the electroweak studies proposed for NuSOnG (see Sec. 2.2.1).

### 2.4.1 Deep Inelastic Scattering and Parton Distribution Functions

The differential cross section for neutrino DIS depends on three structure functions: $F_{2}, x F_{3}$ and $R_{L}$. It is given by:

$$
\begin{align*}
\frac{d^{2} \sigma^{\nu(\bar{\nu}) N}}{d x d y}= & \frac{G_{F}^{2} M E_{\nu}}{\pi\left(1+Q^{2} / M_{W}^{2}\right)^{2}} \\
& {\left[F_{2}^{\nu(\bar{\nu}) N}\left(x, Q^{2}\right)\left(\frac{y^{2}+(2 M x y / Q)^{2}}{2+2 R_{L}^{\nu(\bar{\nu}) N}\left(x, Q^{2}\right)}+1-y-\frac{M x y}{2 E_{\nu}}\right)\right.} \\
& \left. \pm x F_{3}^{\nu(\bar{\nu}) N} y\left(1-\frac{y}{2}\right)\right] \tag{39}
\end{align*}
$$

where the $\pm$ is $+(-)$ for $\nu(\bar{\nu})$ scattering. In this equation, $x$ is the Bjorken scaling variable, $y$ the inelasticity, and $Q^{2}$ the squared four-momentum transfer.

The function $x F_{3}\left(x, Q^{2}\right)$ is unique to the DIS cross section for the weak interaction. It originates from the parity-violating term in the product of the leptonic and hadronic tensors. For an isoscalar target, in the quark-parton model,

$$
\begin{align*}
x F_{3}^{\nu N}(x)= & x(u(x)+d(x)+2 s(x)  \tag{40}\\
& -\bar{u}(x)-\bar{d}(x)-2 \bar{c}(x)), \\
x F_{3}^{\bar{\nu} N}(x)= & x F_{3}^{\nu N}(x)-4 x(s(x)-c(x)) . \tag{41}
\end{align*}
$$

Defining $x F_{3}=\frac{1}{2}\left(x F_{3}^{\nu N}+x F_{3}^{\bar{\nu} N}\right)$, at leading order in QCD,

$$
\begin{equation*}
x F_{3, L O}=\sum_{i=u, d . .} x q\left(x, Q^{2}\right)-x \bar{q}\left(x, Q^{2}\right) . \tag{42}
\end{equation*}
$$

To the level that the sea quark distributions have the same $x$ dependence, and thus cancel, $x F_{3}$ can be thought of as probing the valence quark distributions. The difference between the neutrino and antineutrino parity violating structure functions, $\Delta\left(x F_{3}\right)=$ $x F_{3}^{\nu N}-x F_{3}^{\bar{\nu} N}$, probes the strange and charm seas.

Analogous functions for $F_{2}\left(x, Q^{2}\right)$ and $R_{L}\left(x, Q^{2}\right)$ appear in both the cross section for charged lepton ( $e$ or $\mu$ ) DIS and the cross section for $\nu$ DIS. At leading order,

$$
\begin{equation*}
F_{2, L O}=\sum_{i=u, d . .} e^{2}\left(x q\left(x, Q^{2}\right)+x \bar{q}\left(x, Q^{2}\right)\right), \tag{43}
\end{equation*}
$$

where $e$ is the charge associated with the interaction. In the weak interaction, this charge is unity. For charged-lepton scattering mediated by a virtual photon, the fractional electromagnetic charge of each quark flavor enters. Thus $F_{2}^{\nu N}$ and $F_{2}^{e(\mu) N}$ are analogous but not identical and comparison yields useful information about specific parton distributions 87. $R_{L}\left(x, Q^{2}\right)$ is the longitudinal to transverse virtual boson absorption cross-section ratio. The best measurements for this come from charged lepton scattering rather than neutrino scattering. In the past, neutrino experiments have used the charged lepton fits to $R_{L}$ as an input to the measurements of $x F_{3}$ and $F_{2}[85]$. This, however, is just a matter of the statistics needed for a global fit to all of the unknown structure functions in $x$ and $Q^{2}$ bins [86]. With the high statistics of NuSOnG, precise measurement of $R_{L}$ will be possible from neutrino scattering for the first time.

In addition to fitting to the inclusive DIS sample, neutrino scattering can also probe parton distributions through exclusive samples. A unique and important case is the measurement of the strange sea through opposite sign dimuon production. When the neutrino interacts with an $s$ or $d$ quark, it produces a charm quark that fragments into a charmed hadron. The charmed hadron's semileptonic decay (with branching ratio $B_{c} \sim 10 \%$ ) produces a second muon of opposite sign from the first:

$$
\begin{align*}
\nu_{\mu}+\mathrm{N} \longrightarrow \mu^{-}+ & c+\mathrm{X}  \tag{44}\\
& \hookrightarrow s+\mu^{+}+\nu_{\mu} . \tag{45}
\end{align*}
$$

Similarly, with antineutrinos, the interaction is with an $\bar{s}$ or $\bar{d}$,

$$
\begin{align*}
\bar{\nu}_{\mu}+\mathrm{N} \longrightarrow \mu^{+}+ & \bar{c}+\mathrm{X}  \tag{46}\\
& \hookrightarrow \bar{s}+\mu^{-}+\bar{\nu}_{\mu} . \tag{47}
\end{align*}
$$

The opposite sign of the two muons can be determined for those events where both muons reach the toroid spectrometer. Study of these events as a function of the kinematic variables allows extraction of the strange sea, the charm quark mass, the charmed particle branching ratio $\left(B_{c}\right)$, and the Cabibbo-Kobayashi-Maskaka matrix element, $\left|V_{c d}\right|$.

For a more in-depth review of precision measurement of parton distributions in neutrino scattering, see ref. [88].

### 2.4.2 Nuclear Effects

Historically, neutrino experiments have played a major role in expanding our understanding of parton distribution functions through high statistics experiments such as CCFR [85], NuTeV [89, and CHORUS [90]. However, the high statistics extract a price since the large event samples require the use of nuclear targets - iron in the case of both CCFR and NuTeV and lead in the case of the Chorus experiment. The problem is that if one wants to extract information on nucleon PDFs, then the effects of the nuclear targets must first be removed. NuSOnG can provide key measurements which will improve these corrections.

In the case of charged lepton deep inelastic scattering, there are data available from nuclear targets covering the range from deuterium through iron and beyond. Thus, it has been possible to perform detailed studies of the $A$-dependence as a function of $x$ and $Q^{2}$ from both the cross section and the structure function $F_{2}$. Such is not the case
in $\nu$ and $\bar{\nu}$ interactions where the corrections can be different for both cross sections or, equivalently, for $F_{2}$ and $x F_{3}$. In this case one must rely on theoretical models of the nuclear corrections. This is an unsatisfactory situation since one is essentially measuring quantities sensitive to the convolution of the the desired PDFs and unknown - or model dependent - nuclear corrections.

It is important to address the question of nuclear effects in neutrino scattering so that the neutrino data can be used in fits without bringing in substantial uncertainties. For example, in a recent analysis [91] the impact of new neutrino data on global fits for PDFs was assessed. The conclusion reached in this analysis was that the uncertainties associated with nuclear corrections precluded using the neutrino data to constrain the nucleon PDFs. If this uncertainty is addressed, the neutrino data will be a powerful addition to these fits.

Furthermore, nuclear effects are interesting in their own right. Comparison of the charged and neutral lepton scattering data can provide clues to the sources of the major features which appear in nuclear effects: shadowing, antishadowing, and the EMC effect. There is phenomenological evidence which suggests that the nuclear corrections for the $\nu$ and $\bar{\nu}$ cross sections might be rather similar and, in both cases, somewhat smaller than the corresponding corrections in charged lepton deep inelastic scattering. These latter two observations differ from the pattern suggested by the theoretical model 92 for nuclear corrections used in the analysis.

Fig. 8 shows some results from Ref. [91] in the form of "data/theory" averaged over $Q^{2}$ and presented versus $x$. The results are from a global fit but are plotted without the model-dependent nuclear corrections which were used in the fits. What is striking is the similarity of the $\nu$ and $\bar{\nu}$ results, and the overall pattern of deviations, similar to that seen in charged lepton DIS, although the deviations from unity are somewhat smaller. It is interesting to note that there is no clear indication of the turnover at low $x$ which is observed in charged lepton scattering, called shadowing. However, this may be due to kinematic limits of the measurements.

To make progress in understanding nuclear corrections in neutrino interactions, access to high-statistics data on a variety of nuclear targets will be essential. This will allow the $A$-dependence to be studied as a function of both $x$ and $Q^{2}$, as has been done in charged lepton deep inelastic scattering. PDFs from global fits without the neutrino data can then be used to make predictions to be compared with the $A$-dependent $\nu$ and $\bar{\nu}$ cross sections, thereby allowing the nuclear corrections to be mapped out for comparison with theoretical models.

The primary target of NuSOnG will be $\mathrm{SiO}_{2}$. However, we can address this issue by replacing a few slabs of glass with alternative target materials: $\mathrm{C}, \mathrm{Al}, \mathrm{Fe}$, and Pb . This range of nuclear targets would both extend the results of Miner $\nu$ a to the NuSOnG kinematic region, and provide a check (via the Fe target) against the NuTeV measurement.

Given the NuSOnG neutrino flux, we anticipate $58 k \nu$-induced and $30 k \bar{\nu}$-induced CC DIS events per ton of material. A single ton would be sufficient to extract $F_{2}(x)$ and $x F_{3}(x)$ averaged over all $Q^{2}$; a single $5 \mathrm{~m} \times 5 \mathrm{~m} \times 2.54 \mathrm{~cm}$ slab of any of the above materials will weigh more than that. The use of additional slabs would permit further extraction of the structure functions into separate $\left(x, Q^{2}\right)$ bins as was done in the NuTeV analysis, at the potential expense of complicating the shower energy resolution in the sub-detectors containing the alternative targets; this issue will be studied via

Figure 8: Comparison between the reference fit and the unshifted Chorus and NuTeV neutrino data without any nuclear corrections.

| Material | Mass of <br> 2.54 cm slab (tons) | Number of slabs needed <br> for NuTeV-equivalent statistics |
| :---: | :---: | :---: |
| C | 1.6 | 33 |
| Al | 1.9 | 27 |
| Fe | 5.5 | 10 |
| Pb | 7.9 | 7 |

Table 2: Alternative target materials for cross-section analysis
simulation.
Table 2 shows that two 50 -module stacks would be sufficient to accumulate enough statistics on alternative nuclear targets for a full structure-function extraction for each material. However, for basic cross-section ratios in $x$, a single slab of each would suffice.

### 2.4.3 Isospin Violations

When we relate DIS measurements from heavy targets such as ${ }_{26}^{56} \mathrm{Fe}$ or ${ }_{82}^{207} \mathrm{~Pb}$ back to a proton or isoscalar target, we generally make use of isospin symmetry where we assume that the proton and neutron PDFs can be related via a $u \leftrightarrow d$ interchange. While isospin symmetry is elegant and well-motivated, the validity of this exact charge symmetry must ultimately be established by experimental measurement. There have been a number of studies investigating isospin symmetry violation [93, 94, 95, 96; therefore, it is important to be aware of the magnitude of potential violations of isospin symmetry and the consequences on the extracted PDF components. For example, the naive parton model relations are modified if we have a violation of exact $p \leftrightarrow n$ isospinsymmetry, (or charge symmetry); e.g., $u_{n}(x) \not \equiv d_{p}(x)$ and $u_{p}(x) \not \equiv d_{n}(x)$.

Combinations of structure functions can be particularly sensitive to isospin violations, and NuSOnG is well suited to measure some of these observables. For example, residual $u, d$-contributions to $\Delta x F_{3}=x F_{3}^{\nu}-x F_{3}^{\bar{\nu}}$ from charge symmetry violation (CSV) would be amplified due to enhanced valence components $\left\{u_{v}(x), d_{v}(x)\right\}$, and because the $d \rightarrow u$ transitions are not subject to slow-rescaling corrections which strongly suppress the $s \rightarrow c$ contribution to $\Delta x F_{3}$. 95] Here the ability of NuSOnG to separately measure $x F_{3}^{\nu}$ and $x F_{3}^{\bar{\nu}}$ over a broad kinematic range will provide powerful constraints on the sensitive structure function combination $\Delta x F_{3}$.

There are a wide variety of models that study CSV [93, 94, 95, 96]. One method to quantify possible CSV contributions is via a one-parameter "toy" model where we characterize the CSV as a rotation in isospin space: $q_{n}^{\mathrm{CSV}}=N_{q} \sum_{q^{\prime}} R_{q q^{\prime}}(\theta) q_{p}^{\prime}$, where $R$ is a rotation matrix, and $N_{q}$ is the normalization factor. For example, the $u$-distribution in the neutron can be related to the proton distributions via:

$$
\begin{equation*}
u_{n}^{\mathrm{CSV}}\left(x, Q^{2}\right)=N_{u}^{2}\left[\cos ^{2}(\theta) u_{p}\left(x, Q^{2}\right)+\sin ^{2}(\theta) d_{p}\left(x, Q^{2}\right)\right] . \tag{48}
\end{equation*}
$$

For $\theta=\pi / 2$, we recover the symmetric limit $u_{p}\left(x, Q^{2}\right)=d_{n}\left(x, Q^{2}\right)$. While this parameterization does not offer any explanation for the source of the CSV, it does provide a simple one-parameter $(\theta)$ characterization which is flexible enough to quantify the range of CSV effects. (For more details, cf. Ref. 95].)

At present, there are constraints on isospin violation from a number of experiments which cover different ranges of $x$ and $Q^{2}$. For example, we note that while the above
"toy" model leaves the neutron singlet combination $(q+\bar{q})$ invariant at the $\lesssim 2 \%$ level in the region $x \epsilon[0.01 ; 0.1]$, it would lower the NC observable $\left[\frac{4}{9}(u+\bar{u})+\frac{1}{9}(d+\bar{d})\right]_{n}$ in this region by about $10 \%$. An effect of this size would definitely be visible in the NMC $F_{2}^{n} / F_{2}^{p}$ data which has an uncertainty of order a few percent. 87] The measurement of the lepton charge asymmetry in W decays from the Tevatron [97, 98] places tight constraints on the up and down quark distributions in the range $0.007<x<0.24$. While only strictly telling us about parton distributions in the proton, these data rule out isospin violations at the $5 \%$ level, as demonstrated in Ref. [98. In addition, there are also fixed-target Drell-Yan experiments such as NA51 [99] and E866 [100] which precisely measure $\bar{d} / \bar{u}$ in the range $0.04<x<0.27$; these are also sensitive to isospin-violating effects.

NuSOnG will be able to provide high statistics DIS measurements across a wide $x$ range. Because the target material $\left(\mathrm{SiO}_{2}\right)$ is very nearly isoscalar, this will essentially allow a direct extraction of the isoscalar observables. Consequently, if isospin violations are present, they can be measured more precisely than would be the case on a highly non-isoscalar target.

### 2.4.4 Measurement of the Strange Sea

There are several reasons why an improved measurement of the strange sea is of interest. First, it contributes to the low- $Q^{2}$ properties of the nucleon in the nonperturbative regime - a question of practical as well as intellectual interest, since many precision oscillation experiments are being performed in the 1 to 20 GeV (hence, nonperturbative) range. It is critical for charm production which provides an important testing ground for NLO QCD calculations. In addition, understanding the threshold behavior associated with the heavy charm mass is of interest to future neutrino experiments.

Distinguishing the difference between the $s(x)$ and $\bar{s}(x)$ distributions,

$$
\begin{equation*}
x s^{-}(x) \equiv x s(x)-x \bar{s}(x), \tag{49}
\end{equation*}
$$

is even more important, and poses additional challenges. First, it is of intrinsic interest in nucleon structure models [43, 38, 37, 101, 102]. Second, the integrated strange sea asymmetry,

$$
\begin{equation*}
S^{-} \equiv \int_{0}^{1} s^{-}(x) d x, \tag{50}
\end{equation*}
$$

has important implications for the precision measurement of the weak mixing angle in deep inelastic scattering of neutrinos ( $c f$. Sec. 2.2 and references [41, 43, 37, 38, [41, 101, 42]). This was not recognized at the time of the $\mathrm{NuTeV} \sin ^{2} \theta_{W}$ publication; an error due to $S^{-}$will be included in the NuTeV reanalysis, to be presented in late summer 2007 [32].

Historically, information on the $s(x)$ and $\bar{s}(x)$ distributions was derived from inclusive cross sections for neutral and charged current DIS via $\Delta\left(x F_{3}\right)$. These analyses made the implicit assumption that the $s(x)$ and $\bar{s}(x)$ seas had the same distribution in $x$. Because the strange sea is relatively small compared to the dominant $u(x)$ and $d(x)$ processes, the resulting uncertainties on the strange sea components were large. For example, the strangeness content of the nucleon, as measured by the momentum fraction carried by $s$ or $\bar{s}$, is of order $3 \%$ at $Q=1.5 \mathrm{GeV}$. For this reason, the strange PDF was typically parametrized using the ansatz $s(x)=\bar{s}(x)=\kappa(\bar{u}+\bar{d}) / 2$, where $\kappa$ measured the deviation from $S U(3)$ flavor symmetry at some low value of $Q$.

Figure 9: $\quad x s^{-}(x)$ vs $x$ at $Q^{2}=16 \mathrm{GeV}^{2}$. Outer band is combined errors, inner band is without $B_{c}$ uncertainty.

Introducing information from opposite sign dimuon production allows substantial improvement in the strange PDF measurement. Neutrino-induced dimuon production, $(\nu / \bar{\nu}) N \rightarrow \mu^{+} \mu^{-} X$, proceeds primarily through the sub-processes $W^{+} s \rightarrow c$ and $W^{-} \bar{s} \rightarrow \bar{c}$ (respectively), so this provides a mechanism to directly probe the $s(x)$ and $\bar{s}(x)$ distributions without being overwhelmed by the larger $u(x)$ and $d(x)$ distributions. Hence, the recent high-statistics dimuon measurements [103, 104, 105, 106, 107] play an essential role in constraining the strange component of the proton.

The highest precision study of $s^{-}$to date is from the NuTeV experiment [108]. The sign selected beam allowed measurement of the strange and antistrange seas independently, recording 5163 neutrino-induced dimuons, and 1380 antineutrino-induced dimuon events in its iron target. Figure 9 shows the measured asymmetry between the strange and antistrange seas. With more than 100 times the statistics of NuTeV , NuSOnG will have substantially finer binning.

The integrated strange sea asymmetry from NuTeV has a positive central value: $0.00196 \pm 0.00046$ (stat) $\pm 0.00045$ (syst) ${ }_{-0.00107}^{+0.00148}$ (external). The "external" error on the measurement is dominated by the error on the average charm semi-muonic branching ratio, $B_{c}$ which is determined by other experiments. This error currently is about $10 \%$. A rescan of Chorus data, which would increase the statistics, is under consideration [109].

The key to an improved result on the strange sea from NuSOnG is in a more precise measurement of $B_{c}$ at NuSOnG energies. This can be accomplished in two ways. First, the very high statistics of NuSOnG allow for an accurate fit to $B_{c}$ and the $s$ and $\bar{s}$

Figure 10: World measurements of $B_{c}$.
distributions simultaneously. Second, we plan to incorporate an emulsion detector into the design. The emulsion will be scanned by the Nagoya University group. This group has substantial expertise, having provided the emulsion and scanning for Chorus, DoNuT and other emulsion-based experiments. The goal will be to obtain $>10 \mathrm{k}$ events in the emulsion during the NuSOnG run.

Beyond this, we will also consider placing a liquid argon TPC of similar size to microBooNE [110] (70 tons fiducial volume) or even Gargamelle ( 20 tons fiducial volume) in the gap between two of the NuSOnG subdetectors to directly measure $B_{c}$. If one were to, for example, use a volume comparable to the Gargamelle bubble chamber, we could observe on the order of one million charged current events within it for $5 \times 10^{19}$ POT. This would yield approximately 100,000 events with charm in the final state, and about 10,000 dimuon events.

In addition to an improved measurement of $B_{c}$, the more finely-grained liquid argon TPC and/or emulsion detectors could be used to aid the calibration of the four glass detector modules by measuring any differences between hadron and electron showers from pion and electron beams versus those within a neutrino induced event. Coupled with the precision test beam, it may also be possible to improve understanding of the background due to muons produced by pion and kaon decays in the hadron shower. An improved parameterization of this background, currently from a CCFR measurement [111, 112, 113] could help extend the kinematic range of charmed dimuon measurements beyond what was possible for the NuTeV and CCFR experiments.

### 2.4.5 Measurement of the Total Cross Section

Precision measurement of the total neutrino and antineutrino cross sections at high energies will be valuable to a future neutrino factory experiment which seeks to make

Figure 11: World measurements of the total $\nu$ and $\bar{\nu}$ cross sections. See references [89] and [114] through [128].
precision measurement of CP violation. Because NuSOnG can measure the flux to $0.5 \%$ (see Sec. 3.3, precise measurements can be made. Also, higher accuracy on the ratio of $\sigma^{\bar{\nu}} / \sigma^{\nu}$ will also improve the electroweak measurement (see Tab,1).

Fig. 11 shows $\sigma / E_{\nu}$ for the muon neutrino and antineutrino charged-current total cross-section as a function of neutrino energy ([89] and [114]-[128]). The error bars include both statistical and systematic errors. The results are from a wide range of target materials, but the experiments with the smallest errors and largest energy range used iron. The straight lines are the isoscalar-corrected total cross-section values averaged over $30-200 \mathrm{GeV}$ as measured by the experiments in Refs. [115] to [117. The fit [129] gives: $\sigma^{\nu I s o} / E_{\nu}=(0.677 \pm 0.014) \times 10^{-38} \mathrm{~cm}^{2} / \mathrm{GeV} ; \sigma^{\bar{\nu} I s o} / E_{\bar{\nu}}=(0.334 \pm$ $0.008) \times 10^{-38} \mathrm{~cm}^{2} / \mathrm{GeV}$. The average ratio of the antineutrino to neutrino crosssection in the energy range $30-200 \mathrm{GeV}$ is $\sigma^{\bar{\nu}}$ Iso $/ \sigma^{\nu}$ Iso $=0.504 \pm 0.003$ as measured by Refs. [89] and [114]-[117]. Note the change in the energy scale at 30 GeV .

The most precise measurements are systematics limited. The largest contributions to the systematics in recent experiments (CCFR, NuTeV ) come from flux normalization, the model parameterization used in determination of the flux, and the charm mass used to parameterize charm threshold. NuSOnG measures the neutrino flux normalization to high precision via the IMD events. Also, as discussed in Sec. 3.3.2, NuSOnG's high statistics allow cuts which substantially improve the model parameterization error. Lastly, the charm mass, $m_{c}$ is expected to be improved from the high statistics fits to the opposite sign dimuon events described in the previous section. While more study is needed, it likely that NuSOnG can substantially improve on the world measurements of the total cross section and the cross section ratios.

Figure 12: NuSOnG flux in neutrino mode (left) and antineutrino mode (right). Black: muon neutrino flux, red: muon antineutrino flux, blue: electron neutrino and antineutrino flux

## 3 Neutrino Flux and Event Rates

### 3.1 The Neutrino Flux

For the purposes of this expression of interest, we assume the same SSQT design as was used at NuTeV . The resulting neutrino (antineutrino) flux [33] is shown in Fig. 12 , left (right). The $\nu_{\mu}$ flux is shown in black, $\bar{\nu}_{\mu}$ in red, and $\nu_{e}+\bar{\nu}_{e}$ in blue. The shape of the flux is dominated by the dichromatic neutrino spectrum from $\pi$ and $K$ two-body decay.

In neutrino mode, $98.2 \%$ of neutrino interactions are due to $\pi^{+}$and $K^{+}$secondaries, while in antineutrino mode $97.3 \%$ come from $\pi^{-}$and $K^{-}$. The "wrong sign" content is very low, with an $0.03 \%$ antineutrino contamination in neutrino mode and $0.4 \%$ neutrino contamination in antineutrino mode. The electron-flavor content is $1.8 \%$ in neutrino mode and $2.3 \%$ in antineutrino mode. The major source of these neutrinos is
$K_{e 3}^{ \pm}$decay, representing $1.7 \%$ of the total flux in neutrino mode, and $1.6 \%$ in antineutrino mode. Other contributions come from $K_{L e 3}, K_{S e 3}$, charmed meson, muon, $\Lambda_{C}$, $\Lambda$, and $\Sigma$ decays.

Precise knowledge of the electron-flavor content is crucial for many NuSOnG analyses. The largest source of error in the knowledge of the electron-flavor content in NuTeV was from the $K_{e 3}^{ \pm}$branching ratio, which led to an error on $\nu_{e}$ content of $1.4 \%$ [33]. While the other sources of $\nu_{e}$ s have large fractional errors, they constitute a much smaller fraction of the flux. An error of $1.5 \%$ for the electron-flavor contamination, consistent with NuTeV, will be assumed for NuSOnG.

### 3.2 Event Rates

The approximate event rates presented here serve to set the scale for the physics case presented in this document. They are based on running the Nuance event generator [130] with the NuTeV flux, and then scaling to the expectations of NuSOnG assuming a 3 kton fiducial mass. Some simplifying assumptions, which will be corrected as the simulation develops, have been made. For example, $\mathrm{C}_{2}$ is used as a target rather than $\mathrm{SiO}_{2}$. Also, note that Nuance is not yet tuned as a high energy event generator. Thus, these event rates are only representative.

For neutrino running, approximate event rates for $5 \times 10^{19}$ protons are:

| $507 k$ | $\nu_{\mu}$ CC quasi - elastic scatters |
| ---: | :--- |
| $178 k$ | $\nu_{\mu}$ NC - elastic scatters |
| $1016 k$ | $\nu_{\mu} \mathrm{CC} \pi^{+}$ |
| $302 k$ | $\nu_{\mu} \mathrm{CC} \pi^{0}$ |
| $272 k$ | $\nu_{\mu}$ NC $\pi^{0}$ |
| $226 k$ | $\nu_{\mu}$ NC $\pi^{ \pm}$ |
| $1379 k$ | $\nu_{\mu}$ CC and NC Resonance multi - pion |
| $202 M$ | $\nu_{\mu}$ CC Deep Inelastic Scattering |
| $63 M$ | $\nu_{\mu}$ NC Deep Inelastic Scattering |
| $24 k$ | $\nu_{\mu}$ neutrino - electron NC elastic scatters |
| $235 k$ | $\nu_{\mu}$ neutrino - electron CC quasielastic scatters (IMD) |

For antineutrino running, which assumes $1.5 \times 10^{20}$ protons on target, approximate event rates are:

| $548 k$ | $\bar{\nu}_{\mu}$ CC quasi - elastic scatters |
| ---: | :--- |
| $195 k$ | $\bar{\nu}_{\mu}$ NC - elastic scatters |
| $1103 k$ | $\bar{\nu}_{\mu}$ CC $\pi^{+}$ |
| $321 k$ | $\bar{\nu}_{\mu}$ CC $\pi^{0}$ |
| $297 k$ | $\bar{\nu}_{\mu}$ NC $\pi^{0}$ |
| $246 k$ | $\bar{\nu}_{\mu}$ NC $\pi^{ \pm}$ |
| $1516 k$ | $\bar{\nu}_{\mu}$ CC and NC Resonance multi - pion |
| $102 M$ | $\bar{\nu}_{\mu}$ CC Deep Inelastic Scattering |
| $36 M$ | $\bar{\nu}_{\mu}$ NC Deep Inelastic Scattering |

```
21k }\mp@subsup{\overline{\nu}}{\mu}{}\mathrm{ neutrino - electron NC elastic scatters
    0k }\mp@subsup{\overline{\nu}}{\mu}{}\mathrm{ neutrino - electron CC quasielastic scatters (IMD)
```

The above were run for $\nu_{\mu}$ and $\bar{\nu}_{\mu}$ beams. The relative ratios of event-weighted contents in neutrino mode are: $\nu_{\mu}-98.33 \%, \bar{\nu}_{\mu}-0.08 \%, \nu_{e}-1.56 \%, \bar{\nu}_{e} 0.03 \%$. The relative ratios of event-weighted contents in antineutrino mode are: $\nu_{\mu}-0.42 \%, \bar{\nu}_{\mu}-$ $98.07 \%, \nu_{e}-0.26 \%, \bar{\nu}_{e} 1.26 \%$.

### 3.3 Precision Measurement of the Flux from Events in the Detector

Precise knowledge of the neutrino flux is key to many of the physics goals of the experiment. The goal, which is ambitious, will be to measure the neutrino flux as a function of energy to a precision better than $0.5 \%$. This goal is a design-driver for the experiment. In this section, we outline an analysis plan to achieve this goal using the event types described in the previous section.

The flux will be determined through the following steps:

1. The inverse muon decay (IMD) events $\left(\nu_{\mu}+e^{-} \rightarrow \mu^{-}+\nu_{e}\right)$ are, in principle, ideal for measuring the total flux because the IMD cross section is well known in the Standard Model. Therefore, these events will be used to determine the normalization of the flux. An important background to this measurement, however, comes from the CCQE events ( $\nu_{\mu}+n \rightarrow \mu+p$ ), which must be subtracted. In this step, the predicted number of CCQE events is based on external cross section measurements. The error on the external cross section is likely to be the limiting systematic on the normalization determined in this step.
2. The shape of the flux is measured using the traditional "fixed $\nu$ " measurement method, which was applied in CCFR [85, 114]. and NuTeV [89], and is currently being used for in the Minos Experiment [131 to measure the shape of both the neutrino and antineutrino flux. The flux shape is then normalized by the IMD events from step 1 to obtain the initial flux prediction.
3. The initial flux prediction is used to determine a more precise CCQE cross section based on the NuSOnG data.
4. Step 1 is repeated using the more precise cross section determined in step 3 . This produces the final normalization which is used to scale the results of step 2, yielding the final flux.

When the analysis is performed, it may be more effective and efficient to combine the above steps into a single multiparameter fit to the IMD and CCQE data, constrained by the external cross section information. However, for transparency we will consider the stepwise approach below.

Reaching the goal of $\lesssim 0.5 \%$ systematic error depends mainly on the systematics of the IMD total event rate measurement. To set the scale of the problem, the best measurement of IMD events to date, from CHARM II, had a systematic error of $3 \%$ [132. Thus, we must achieve an order of magnitude improvement in the IMD total systematic error. While we present a well-grounded back-of-the-envelope argument below, this level of measurement has yet to be demonstrated by simulation. That is a priority for future work on the development of NuSOnG.

Figure 13: Momentum distribution of protons in $\nu$ CCQE events, from the Nuance Event generator.

Two useful cross checks of the measured NuSOnG flux are possible. First, one can extract an energy binned neutrino flux from the IMD events in step 1. Because of angular resolution, this flux may have substantial smearing, but it can be used as a compelling cross-check of the flux shape derived in step 2. Second, the neutrino to antineutrino flux ratio can be compared to the first principles prediction based on secondary production measurements.

### 3.3.1 Step 1: The IMD Measurement for Normalization

NuSOnG expects to observe > 200k IMD events during neutrino running. The high statistics is a consequence of both the high neutrino flux and high neutrino energy. High energy is required because the threshold for IMD scattering is $E_{\nu} \geq E_{\mu} \geq \frac{m_{\mu}^{2}}{2 m_{e}}=10.9$ GeV . The SSQT beam design for NuSOnG produces minimal flux below 30 GeV , well within the range of IMD production. This indicates that there will be high statistics for IMD events in all flux bins.

These events will be used for total flux normalization, with the shape determined using the Fixed $\nu$ method described in step 2. This is done because, while these events can in principle be fully reconstructed assuming that the incoming neutrino enters parallel to the z-axis, the reconstruction in practice suffers substantial smearing. At $\sim 100 \mathrm{GeV}$, IMD events will have scattering angles of $\lesssim 1 \mathrm{mrad}$. This is similar in magnitude to the expected divergence of the beam, which was 0.62 mrad in NuTeV . Angular resolution errors are expected to be at a similar level.

IMD events must be separated from background, mainly due to CCQE-like interac-
tions (which include both real CCQE interactions and single $\pi$ events where the pion was absorbed in the nucleus, and thus are effectively CCQE events). IMD events are qualitatively different from CCQE-like ones in two ways: there is no hadronic energy in the event, and there is a strict kinematic limit on the transverse momentum of the outgoing muon, $p_{T} \leq 2 m_{e} E_{\mu}$. It is therefore crucial to design NuSOnG for observation of very low hadronic energy in the presence of a muon track, and for excellent angular resolution on the outgoing muon. The fine segmentation of NuSOnG should allow hadron identification in the presence of a muon to substantially lower energy ( $\sim 0.75$ GeV ) compared to 1.5 GeV for Charm II [132] and 3 GeV for $\mathrm{NuTeV}[75]$. One can see from the momentum distribution of the protons produced in CCQE interactions, shown in Fig. 13, that this approach will allow NuSOnG to cut more of the CCQE background than was possible in the previous experiments. NuSOnG also expects better IMD resolution than Charm II, due to the finer segmentation, which will reduce backgrounds.

Events which produce very low energy pions can also produce a background, although at a lower level than the CCQE background. NuSOnG's open trigger will allow many of the low multiplicity DIS events and $\mathrm{CC} \pi^{+}$events to be identified and cut due to the presence of subsequent michel electrons which come from the $\pi^{+} \rightarrow \mu^{+} \rightarrow e^{+}$ decay chain. A 50 MeV michel electron will traverse 12 cm of glass, producing hits in up to four chambers in the vicinity of the interaction vertex.

The IMD method for determining the flux proceeds in the following manner. After cutting on hadronic energy, minimum energy for the outgoing muon, and no michel electrons near the vertex, the plot of muon $p_{T}$ will show a sharp peak at $p_{T} \sim 0$ superimposed on a broad continuum of background events extending to high $p_{T}$. The continuum is fit and extrapolated under the IMD peak, to extract the number of IMD events. This is divided by the theoretical cross section to yield the flux.

At the high energies of NuSOnG, the only nuclear effect expected for CCQE events comes from the Pauli exclusion effect. This produces an overall suppression of the cross section across all energies. Both the NuTeV and Charm II measurements suffered from the lack of availability of precise information on the Pauli exclusion effect. This resulted in an error on the Charm II measurement from the CCQE model of $2.1 \%$.

NuSOnG will be in the fortunate position that a number of new measurements of the CCQE cross section on nuclear targets will be available as inputs into the CCQE model. Results from MiniBooNE [133] and SciBooNE [134] will address Pauli suppression in CCQE interactions on carbon. Minerva [135] is studying a series of nuclear targets, and are willing to consider running a glass target for NuSOnG, if we were to supply the target panels. The precision on the CCQE cross section in the NuSOnG era may be $5 \%$, which is $\sim 5$ times better than the CHARM II era measurements. Thus, at this step, the CCQE model error for NuSOnG may be as low as $0.4 \%$.

A CCQE model error which was not addressed in the Charm II analysis was the long-standing discrepancy between models and data at low $Q^{2}$ 133. Low $Q^{2}$ events having small scattering angles represents a significant error on the extrapolation under the IMD peak. This discrepancy has recently been resolved by MiniBooNE under a dipole form-factor model [133]. Minerva plans to address the $Q^{2}$ dependence of the form factor in a model-independent way [136]. We will assume that the discrepancy will be fully addressed by the time of the NuSOnG run.

Another $1.5 \%$ systematic error in Charm II came from the model of the other sources
of low hadronic energy CC events, which are dominated by $\Delta$ resonant production. As described above, NuSOnG expects a substantially lower contamination from these sources because of the lower energy threshold and the michel electron veto. For those background events which are not cut, the modeling of these sources will substantially improved using Minerva data. In Minerva, the tracks from $\mathrm{CC} \pi^{+}$events are well reconstructed, so models $p_{T}$ distribution of outgoing muons can be tuned. Similarly, Minerva offers the opportunity to accurately parametrize CCpi ${ }^{0}$ events. Again, the total error on the low hadron multiplicity events in 2015 is expected to be on the order of $5 \%$, so the modeling of these backgrounds should not be a limiting systematic.

IMD events can be cut from the sample due to electromagnetic radiation of the muon near the vertex region which is mistakenly identified as hadronic energy at the vertex. The NuTeV IMD analysis [75] assigned a $1 \%$ systematic error due to radiative effects. We address this error in two ways. First, in the NuTeV experiment, the photons immediately converted in the 10 cm iron plates, while in NuSOnG, the 2.5 cm glass plates are $0.25 \lambda_{0}$, giving photons a $50 \%$ probability of traversing three plates before showering. Fewer IMD radiative events will therefore be misidentified as events with hadronic energy at the vertex. Second, because of the higher segmentation, NuSOnG will employ an improved model of electromagnetic showers, reducing the systematic error.

### 3.3.2 Step 2: The Fixed- $\nu$ Measurement to Determine the Shape

The central premise of the Fixed $\nu$ method for measuring the flux is that, for small hadronic energy exchange $(\nu)$, the differential cross section is independent of energy to a good approximation. The Fixed $-\nu$ method utilizes this fact to measure the relative flux between energy bins and the relative flux between neutrino and antineutrino interactions. External input is then needed to determine the overall normalization.

To motivate the premise, consider the differential cross section at a fixed $\nu$ integrated over all $x$ :

$$
\begin{equation*}
\frac{d \sigma}{d \nu}=A\left(1+\frac{B}{A} \frac{\nu}{E_{\nu}}-\frac{C}{A} \frac{\nu^{2}}{2 E_{\nu}^{2}}\right) . \tag{51}
\end{equation*}
$$

In this equation,

$$
\begin{align*}
A & =k \int F_{2}\left(x, Q^{2}\right) d x  \tag{52}\\
B & =-k \int\left[F_{2}\left(x, Q^{2}\right) \mp x F_{3}\left(x, Q^{2}\right)\right] d x  \tag{53}\\
C & =B-k \int F_{2}\left(x, Q^{2}\right)\left(\frac{\frac{1+2 M x}{\nu}}{1+R\left(x, Q^{2}\right)}-\frac{M x}{\nu}-1\right) d x, \tag{54}
\end{align*}
$$

where $k=\left(G_{F}^{2} M\right) / \pi$, and $\mp$ refers to neutrinos $(-)$ or antineutrinos $(+)$. For simplicity, first consider $\nu \rightarrow 0$. The cross section becomes equivalent to $A$, which is a constant. Since it is impossible to measure scattering for $\nu=0$, consider scattering for $\nu=\nu_{0}$ where $\nu_{0} \ll E_{\nu}$. As long as $\nu_{0}$ is small enough, the terms which depend on $\nu_{0} / E_{\nu}$ will have negligible contribution. Thus for a fixed, low value of $\nu, d \sigma / d \nu \rightarrow A$, independent of beam energy. Note that terms $B$ and $C$ differ for neutrinos and antineutrinos. However, as long as $\nu_{0} / E_{\nu}$ is negligible, these terms do not contribute and the cross section for antineutrinos is equal to the cross section for neutrinos.

From this, one can see how to measure the relative fluxes. If one measures the number of events at a given $\nu_{0}$ in bins of $E_{\nu}$, one can solve for the flux:

$$
\begin{equation*}
\Phi\left(E_{\nu}\right)=N\left(E_{\nu}, \nu_{0}\right) / A . \tag{56}
\end{equation*}
$$

The relative change of flux between two energy bins is independent of $A$ :

$$
\begin{equation*}
\Phi\left(E_{\nu}^{b i n 1}\right) / \Phi\left(E_{\nu}^{b i n 2}\right)=N^{b i n 1}\left(E_{\nu}, \nu_{0}\right) / N\left(E_{\nu}^{b i n 2}, \nu_{0}\right) \tag{57}
\end{equation*}
$$

Since the neutrino and antineutrino cross sections are equal, this method also allows the relative fluxes to be extracted, independent of $A$.

$$
\begin{equation*}
\Phi\left(E_{\nu}\right) / \Phi\left(E_{\bar{\nu}}\right)=N\left(E_{\nu}, \nu_{0}\right) / N\left(E_{\bar{\nu}}, \nu_{0}\right) \tag{58}
\end{equation*}
$$

Thus one can extract the relative bin-to-bin and neutrino-to-antineutrino fluxes strictly from the data, with no theoretical input on the value of $A$.

In practice one uses a low $\nu$ region, defined by $\nu<\nu_{0}$ where $\nu_{0}$ is some appropriate upper limit. CCFR and NuTeV, used $\nu<\nu_{0}=20 \mathrm{GeV}$, which allowed high statistical precision for the measurement. From the theoretical point of view, however, this was not optimal since the goal was to measure the flux down to $E_{\nu}=30 \mathrm{GeV}$, thus at $\nu=20 \mathrm{GeV}$, the $\nu / E_{\nu}$ terms were not negligible. The flux is then given by:

$$
\begin{equation*}
\Phi\left(E_{\nu}\right)=\int_{0}^{\nu_{0}} \frac{\frac{d N}{d \nu}}{1+\frac{B}{A} \frac{\nu}{E_{\nu}}-\frac{C}{A} \frac{\nu^{2}}{2 E_{\nu}^{2}}} d \nu . \tag{59}
\end{equation*}
$$

A fit to $d N / d \nu$ determines $B / A$ and $C / A$. One can test the quality of the bin-to-bin result by fitting $\sigma / E$ to a line. A good fit results in small slope, due to QCD effects on the order of a few percent (somewhat smaller in antineutrino mode), with small error. NuTeV found values consistent with expectation [89]:

$$
\begin{align*}
& \frac{\Delta\left(\frac{\sigma^{\nu}}{E}\right)}{\Delta E}=(-2.2 \pm 0.8) \% / 100 \mathrm{GeV}  \tag{60}\\
& \frac{\Delta\left(\frac{\sigma^{\bar{\nu}}}{E}\right)}{\Delta E}=(-0.2 \pm 0.8) \% / 100 \mathrm{GeV} \tag{61}
\end{align*}
$$

The NuTeV analysis indicated a good fit to a straight line, as expected. The extracted shape of the flux was obtained to very high precision across the full energy range by this approach.

NuSOnG has an important advantage over NuTeV when implementing this method, in that the high statistics and good segmentation will all us to reduce this range of the low $\nu$ substantially, perhaps to as low as $\nu<\nu_{0}=10 \mathrm{GeV}$. This should allow an even more precise measure of the shape than was obtained by past experiments, since the contribution of the fit to the $B$ and $C$ terms will be reduced. In particular, the systematic error contribution from the charm mass will be substantially reduced.

NuTeV also required $\nu>5 \mathrm{GeV}$ to cut the resonance region. NuSOnG is also likely to introduce such a cut. However, this should be revisited in light of the expected new data from Minerva in the resonance region.

The most important detector systematic to this measurement is likely to be the muon energy scale. NuTeV achieved knowledge of the muon energy scale to $0.7 \%$, although the absolute calibration beam was known to $0.3 \%$. The difficulty was mapping
across the full area of the toroids. For NuSOnG to achieve its goal of measuring the flux with $\lesssim 0.5 \%$ total error, the muon energy scale will need to be known to about $0.25 \%$. Careful thought must be put in to understand how to achieve this.

In past experiments, the next step was to obtain the absolute flux by normalizing to the world's total, which is $\sigma / E_{\nu}=0.667 \pm 0.014 \times 10^{-} 38 \mathrm{~cm}^{2} / \mathrm{GeV}$. It necessarily introduces a $2 \%$ normalization error into this method. NuSOnG will use the IMD events to perform the absolute normalization, rather than relying on the world average neutrino cross section measurement. This is done by scaling the total flux measured in neutrino mode with the Fixed $\nu$ method to $\sum_{i} N^{I M D}\left(E_{i}\right) \int \sigma^{I M D} d E$. At the end of this step, the predicted flux is expected to be known to $\sim 1 \%$.

### 3.3.3 Step 3: A Precise Measurement of the CCQE Cross Section

At this point in the procedure, the limiting systematic is likely to be the CCQE cross section model error in the IMD normalization. In this step, this cross section is further constrained using the CCQE data in NuSOnG.

The background to the CCQE cross section analysis will be the low hadronic energy events. These can be reduced using the michel veto method discussed in Step 1. Beyond this, because CCQE scatters extend to higher angles, excess hits due to the presence of charged pions and photons from $\pi^{0}$ decay should be more easily resolved from the photon track. NuSOnG expects $\sim 500 \mathrm{k}$ CCQE events, and thus stringent cuts can be applied to remove backgrounds without substantial statistical error, assuming the efficiency of the cuts can be well-understood.

The goal will be for NuSOnG to measure the CCQE cross section to $\lesssim 2 \%$. This would be a very valuable measurement in its own right, as well as allowing for improvement in the flux extraction in the following steps. This result can be used to constrain the normalization for a glass-target measurement in Minerva. Ratios to the other nuclear target cross section measurements by Minerva then allow precisely determined measurements at low E across a wide range of nuclei. This will be useful input to future precision neutrino oscillation measurements.

### 3.3.4 Step 4: The Final NuSOnG Flux

Once the CCQE cross section has been determined at the $\lesssim 2 \%$ level, one can iterate the IMD analysis of step 2 and then renormalize the distributions in step 3 . The resulting flux is expected to have errors of $\lesssim 0.5 \%$.

### 3.3.5 Cross Checks

Two useful cross checks of the flux are possible. The first takes the measured flux and compares it to the IMD event rate in energy bins. The second uses external data to cross check the shape and normalization of the antineutrino flux.

The first cross check compares the shape of the neutrino flux determined at step 1 to the shape determined through step 2. This will be done by running the final flux through the MC and using it to predict the IMD rate in energy bins. We will then extract the predicted flux in energy bins to compared to the measurement performed in step 1. This provides a powerful consistency check.

We can also cross check the fluxes obtained by the above method using a firstprinciples prediction based on external secondary production measurements. The absolute predictions in neutrino and antineutrino mode are unlikely to be an effective cross check because of large errors in the secondary production predictions, which vary from 5 to $10 \%$. However, the prediction of the ratio of the neutrino to antineutrino fluxes may be possible to high precision. This requires some investigation.

Reference [139] provides a compendium of secondary production experiments in Table 3. None extend up to 800 GeV . The most relevant experiment was NA56/SPY at 450 GeV , which took data on beryllium targets 70 . This experiment published yields of $\pi^{+}, \pi^{-}, K^{+}$and $K^{-}$with errors on each measurement of $\sim 5 \%$. However, because many of the systematics cancel in ratio, the $\pi^{-} / p i^{+}, K^{-} / K^{+}$and $\pi / K$ ratios are each determined to $\sim 2.5 \%$. This data should allow a good cross check of the individual $\pi$ and $K$ shape contributions. We may choose to run for a short period at 450 GeV in order to have an exact cross-comparison.

### 3.3.6 The Electron Neutrino Flux

We will begin by tuning the NuSOnG Beam Monte Carlo using the recent secondary meson production measurements described above. The new $K$ production results will improve the first principles prediction for electron neutrinos beyond those of NuTeV . The electron neutrino contamination then can be further constrained through the precision measurement of the $\nu_{\mu}$ flux, which can be tied to the $\nu_{e}$ flux, and through the measurement of $\nu_{e}$ CCQE events.

Once the muon neutrino flux is measured to high precision, it can be used to constrain the electron neutrino flux. This is because the $\nu_{e}\left(\bar{\nu}_{e}\right)$ background is largely due to $K^{+}\left(K^{-}\right)$decays in neutrino (antineutrino mode). Using the measured $\nu_{\mu}$ peak from $K^{+}$events, the beam Monte Carlo can be precisely tuned. Having measured the CCQE cross section precisely in the process of determining the $\nu_{\mu}$ flux, this result can then be applied to $\nu_{e}$ CCQE events to cross check the $\nu_{e}$ flux prediction.

## 4 Preliminary Design

This report focuses upon the determination of the physics goals of the experiment. In order to maintain realistic goals, we have developed a preliminary design for a beam and detector based on existing technology. There are two particularly challenging aspects of the design. The first is the high Tevatron intensity discussed in sec. 4.1. The second is the high precision required for the detector calibration discussed in sec. 4.3.3.

The 2007 Fermilab Steering Group Report considers the Tevatron-based neutrino beam described here. The preliminary concept for the facility recieved an endorsement [137.

### 4.1 Proton Delivery to NuSOnG

Our goal is to obtain $2 \times 10^{20}$ protons on target during a 5 -year run. This section outlines how we might achieve this goal.

Proton delivery occurs via the following lines:

- The Linac
- The Booster
- The Main Injector
- The Tevatron
- Extraction to targeting

The existing Linac and the Booster should perform to the level needed by NuSOnG without problems. The Booster fills the MI in batches of $5 \times 10^{12}$ protons and will operate between 9 and 15 Hz by 2015. The Proton Plan projects $7 \times 10^{13}$ protons in each MI fill by 2010 [138]. Two pulses from the MI are used to fill the Tevatron. In principle, therefore, it is conceivable that the Tevatron could receive nearly $1.5 \times 10^{14}$ protons per fill under this scenario.

Let's suppose that with care the Tevatron can accelerate $8 \times 10^{13}$ ppp to 800 GeV using two pulses from the Main Injector at $4 \times 10^{13}$ each pulse, similar to today's MI operation. To date, the highest intensities extracted from the Tevatron in a single pulse at 800 GeV were around 2.5 to $3 \times 10^{13}$. The limiting issue was longitudinal instabilities for energies above 600 GeV at high intensities, as the bunch length shrank. "Bunch spreaders" were used to compensate. A better method to compensate will be required for NuSOnG. However, advances in rf techniques and technology and in damper systems make finding a satisfactory solution conceivable. More detailed study is needed.

Our proposal is for a Tevatron cycle time of 40 s , with a 1 s flattop at 800 GeV . Since the MI cycle time will be 2.2 s , and we need two injections, our impact on NuMI is $4.4 / 40=11 \%$ of their run time.

If the uptime for the Tevatron is $66 \%$, then we will receive $5 \times 10^{5}$ cycles per year. At $8 \times 10^{13} \mathrm{ppp}$, this gives $4 \times 10^{19}$ protons per year. We then achieve our goal in five years of running.

### 4.2 Neutrino Beam Design

### 4.2.1 Target

Beryllium oxide was the target material in NuTeV and prior high energy neutrino beamlines [140, 141]. Beryllium is efficient at producing secondary mesons, and BeO has good structural and thermal properties. The NuTeV target consisted of two 30 cm long, 2.5 cm diameter segmented rods in a copper cooling block, mounted on a movable drive that could select between centering the beam on either of the two targets or no target. This target was designed to accept up to $1 \times 10^{13}$ protons per pulse (ppp). A similar target will be acceptable for NuSOnG, but it may be a challenge to provide adequate cooling at our design intensity of $8 \times 10^{13}$ protons per cycle. The NuTeV protons were delivered in five 4 msec "pings" separated by 0.5 sec ; we intend to have one pulse of about 200 msec . This means that our instantaneous heating rate will be somewhat lower than NuTeV's, but the total number of protons per cycle is eight times higher. In NuTeV the beam width was 0.6 mm , which was significantly smaller than necessary; a wider more diffuse beam would help relieve the localized heating problem. Careful design of the target support and cooling system will be a necessity.

### 4.2.2 SSQT

A Sign Selecting Quadrupole Train (SSQT) can be used to provide beams of either neutrinos or antineutrinos with very low contamination from either wrong-sign muon neutrinos or electron neutrinos from neutral kaons. The NuTeV SSQT utilized two dipoles and six quadrupoles, with two dumps [140, 141]. The first dipole provided a 6.1 mrad bend for 250 GeV daughter mesons of the selected sign. In antineutrino mode the unreacted protons are bent in the opposite direction and are absorbed in the first dump. In neutrino mode the protons are absorbed in the second dump. The first two quadrupoles capture the secondary beam. A second dipole then bends the beam by another 1.6 mrad , enhancing the sign separation and sweeping out low energy particles produced by scraping in upstream magnets. Neutral particles are not bent and therefore travel away from the detector. NuSOnG will use a similar SSQT. The only challenge will be designing the proton dumps for our significantly higher intensity. In the NuTeV upstream dump in antineutrino mode, the dump temperature approached 100 C at $1.3 \times 10^{13}$ protons per pulse; the temperature limit was 110 C . The NuSOnG dumps will need to be water-cooled.

### 4.2.3 Monitoring

Primary beam monitoring in NuTeV was accomplished with four beam position monitors (BPMs), four vacuum segmented wire ionization chambers (SWICs), four secondary emission electron detectors (SEEDs), a beam current toroid, and a thin foil secondary emission monitor (SEM) [140, 141. The toroid, SEM, SEEDs and BPMs measured proton intensity; the BPMs, SWICs, and SEEDs monitored position. It was found that the SEM degraded over the course of the run, so the beam toroid was used as the primary measure of intensity. The BPMs and SEEDs gave closely correllated position measurements, and the SWICs and SEEDs gave beam profiles that agreed well except in the tails; the SEED tails dropped more rapidly than those from the SWICs. With the exception of the SEMs, which would suffer even more radiation damage at

| Parameter | Value |
| :--- | ---: |
| Total target mass | 3.492 |
| Fiducial mass | 2.975 kt |
| Total length | 192 m |
| Number of glass planes | 2500 |
| Number of toroid washers | 96 |
| Number of muon detector wire planes | 60 |
| (two coordinates each) |  |

Table 3: Summary of NuSOnG detector parameters.
our higher intensities, a combination of any of these monitoring devices could be used by NuSOnG.

### 4.3 Detector Design

This section details our first ideas about the detector configuration; these are summarized in Tab. 3. In thinking about NuSOnG, we have drawn on previous large, high energy neutrino detectors whose characteristics are summarized in Table 4 . NuSOnG represents a natural evolution of these designs and we believe this makes construction low risk. Of particular note regarding Table 4 is the excellent performance achieved by CHARM II using digital proportional tubes, a glass target, and fine granularity.

The primary event signatures NuSOnG will need to identify are:

- charged current deep inelastic scattering, characterized by a hadronic shower and a high energy muon
- neutral current deep inelastic scattering, characterized by a hadronic shower
- inverse muon decay, $\nu_{\mu}+e^{-} \rightarrow \mu^{-}+\bar{\nu}_{e}$, which is characterized by a high energy muon accompanied by no hadronic activity.
- neutrino and antineutrino electron scattering, characterized by an electromagnetic shower with no hadronic activity
- stopped muon decay, which results in an electromagnetic shower with energy up to 50 MeV . These events will be used to reject low hadronic energy events which are tagged through the $\pi \rightarrow \mu \rightarrow e$ decay chain (see sec. 3.3.1).
In order to achieve the rates and carry out the measurements given in Section 3, NuSOnG consists of a 3.5 kton ( 3 kton fiducial volume) isoscalar target with high segmentation resulting in good separation between electromagnetic and hadronic showers and muon tracks with good energy resolution for each. Good separation between hadronic and electromagnetic showers and good muon identification are necessary for separation of neutral and charged current events, and for low systematic errors on the measurements of the neutrino and antineutrino electron scattering cross sections. Finally, good muon identification is critical for detecting inverse muon decay events for a precise flux measurement.

Given the large size of the detector, ease of construction and low cost technologies are important. The long running time requires high stability and robust operation.

|  | EM | Resolution <br> Hadronic <br> $\left(\sigma_{E} / E\right)$ | Muon <br> $\left(\sigma_{p} / p\right)$ | Sampling | Absorber |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  | $1.04 / \sqrt{E}$ | $0.72 / \sqrt{E}$ | $8 \%$ | $0.11 \mathrm{X}_{o}$ | sand/shot |
| FMMF <br> (Flash tubes, <br> digital) |  |  | $5 \%$ | $2.8 / 8.3 \mathrm{X}_{o}$ | steel |

| (Scintillator) <br> CHARM II <br> (Prop. tubes, <br> digital) | $0.52 / \sqrt{E}+0.02$ | $0.24 / \sqrt{E}+0.34$ | $5 \%$ |  |  |
| NuTeV <br> (Scintillator) | $0.86 / \sqrt{E}+0.022$ | $0.5 / \sqrt{E}+0.042$ | $10 \%$ | $5.8 \mathrm{X}_{o}$ | steel |

Table 4: Comparison of high energy neutrino detectors.

Our first design is shown in Figs. 14 and 15 and summarized in Table 3. NuSOnG consists of four calorimeters each with a muon spectrometer. 15 m decay volumes separate the four detector elements. Interspersing the decay volumes between the detectors will allow a calibration beam to be brought to each of the four detector regions.

Each calorimeter has $500 \mathrm{SiO}_{2} 2.5 \mathrm{~cm}\left(\mathrm{X}_{o} / 4\right)$ glass target planes interleaved with active detectors with two dimensional readout. The active detectors could be proportional tubes, scintillator panels, or a combination of both. These three options are discussed below. Neutrinos interact in the target planes, creating secondary particles; the active detector determines the total energies of the hadronic and electromagnetic secondaries. The muon detector measures the momentum of muon secondaries and serves to identify them. The pattern of the shower serves to identify the shower type: showers in which all the energy resides in ten of fifteen planes will be electromagnetic, and more extended showers will be hadronic. The lateral extent of the shower also resolves electromagnetic from hadronic showers.

We have chosen an $\mathrm{SiO}_{2}$ target. This material provides a balance between longer radiation length, important to particle ID issues, and shorter detector length, important for acceptance and calibration issues. The target could be commercial glass or thin walled plastic boxes filled with sand. Glass planes have the advantage of being easy to install and require no construction. Sand-filled boxes could be much less expensive. We will investigate both possibilities. Either way, $\mathrm{SiO}_{2}$ has the advantage of being isoscalar $\left(\left\langle N_{u}\right\rangle>/\left\langle N_{d}\right\rangle=0.998\right)$. $\mathrm{SiO}_{2}$ has a density of $2.2 \mathrm{~g} / \mathrm{cm}^{3}$; a high energy muon will lose 10 MeV per plane, which gives 5 GeV across all 500 planes in one calorimeter. Energy loss will also occur through electromagnetic showers. An example straightthrough muon event from our initial GEANT4 detector simulation is shown in Fig. 16 . A michel electron with 30 MeV energy should be clearly visible across three planes. Each calorimeter is followed by a toroidal muon spectrometer consisting of magnetized iron plates interleaved with drift chambers.

Other target materials, including emulsion, are under consideration, as has been discussed in previous sections of this document. These materials are not yet incor-

porated into the preliminary design presented here, but should be straightforward to include in the future.

The design must address beam correlated backgrounds. These include backgrounds arising from debris (muons, remnants of hadronic showers) from neutrino interactions in the earth surrounding the detector. We plan for a forward veto consisting of a three layer scintillator hodoscope. Since our detector is so long, we may also need a veto system along the sides, top, and bottom of the calorimeters. We plan a Monte Carlo study of veto requirements in the coming months. Cosmic rays muons and their attendant showers present a beam-uncorrelated background which we will need to eliminate. We envisage a counter on the top of the detector similar to that used by the MINOS experiment.

NuTeV showed the value of continuous beam calibration and this will be discussed in a separate section.

While our detector is quite large, the robust, simple design will make the cost and construction manageable. The modules design makes upgrades and improvements straightforward. While we are designing with an initial four to five year run in mind, this detector can be put to other uses should the physics warrant.

### 4.3.1 Active detector options

The active detector performs two roles: first, it tracks the particles emerging from a neutrino interaction; second, it samples the particle's energy loss along the trajectory giving an measurement of the total energy. Simplicity, robustness, and high efficiency are essential, as is low cost.

Two technologies immediately present themselves: gas-filled proportional tubes and plastic scintillator read out by phototubes. Both have been used in several experiments (see Table 4). At this point, it is not clear to us which is the best approach for NuSOnG. We are also considering a design with both proportional tubes and scintillator. In the coming months, we plan to study the performance of each via simulation, develop preliminary design prototypes, and carry out a detailed cost estimate. We describe each detector concept below.

### 4.3.1.1 Proportional Tubes

A first design for a proportional tube active detector is shown in Fig. 17. Each active detector plane is made from five $1 \mathrm{~m} \times 5 \mathrm{~m}$ extruded aluminum panels. Each panel contains fifty $1 \mathrm{~cm} \times 2 \mathrm{~cm}$ drift cells. A $50 \mu \mathrm{~m}$ wire is strung down the center of each tube, and the applied high voltage produces both drift and proportional amplification fields. Ar: $\mathrm{CO}_{2}$ (80:20) provides a good candidate for a fill gas; with $1.8-2 \mathrm{kV}$ applied to the wire, the drift field will give a drift velocity of about $50 \mu \mathrm{~m} / \mathrm{ns}$ and a gain of 3000. A minimum ionizing particle crossing the 1 cm cell will deposit 2.7 keV of energy, liberating about 160 drift electrons in ten or so clusters. The drift time across the cell will be about 500 ns and proportional multiplication will give a collected charge of 80 fC over a time of 250 ns .

As an example of a readout scheme, we look to the ATLAS Transition Radiation Tracker (TRT) ASIC chips. The TRT readout has a peaking time of 7.5 ns and a charge threshold of 2 fC , making them well matched to our proportional tubes. Each chip set reads out sixteen channels and can be configured to provide trigger information.

Figure 17: Proportional tubes design.

The TRT system, which is based around 6 mm straw tubes, has achieved a spatial resolution of $127 \mu \mathrm{~m}$, albeit with higher energy deposition resulting from the use of a xenon mixture. Scaling by the energy deposition gives a resolution of $200 \mu \mathrm{~m}$ for our argon-filled tubes. The TRT readout chip set has sufficient charge sensitivity to allow us to use charge division; this should give position resolution of $5-10 \mathrm{~cm}$ along the wire.

### 4.3.1.2 Scintillating Strips

The second option uses planes of scintillator strips read out with green wavelengthshifting fibers fed into multi-anode photomultipliers. This option would be similar to that used for the SciBar detector in K2K, the Minos neutrino detector, and the Opera neutrino detector. NuSOnG would have 25005 m by 5 m planes with each plane made up of $1283.9 \mathrm{~cm} \times 1.3 \mathrm{~cm}$ strips. Each 64 strip plane will be separately wrapped in an Al skin that will provide the light seal and strength for the module.

The scintillator strips will be coextruded with a $\mathrm{TiO}_{2}$ reflective coating and have a 1.8 mm diameter hole in the middle. A 1.5 mm diameter green wavelength-shifting fiber will be put in the hole and routed to multianode photomultipliers for readout. The 64
wavelength-shifting fibers on one side of a plane will be coupled to a Hamamatsu M64 multianode photomultiplier tube. The readout side will alternate between subsequent planes to improve uniformity. The fiber end opposite to the tubes will be polished and mirrored to increase the light output and uniformity. Planes will alternate between horizontal and vertical strips to provide two view tracking; readout tubes will alternate.

The readout would be based on a custom ASIC combined with a standard FPGA. One example is the 64 channel MAROC2 custom integrated circuit, designed at LAL (Orsay) for the ATLAS luminosity monitor. This chip allows adjustment of the electronic gain of each of the 64 channels, which will be needed to correct for the expected factor of 3 pixel-to-pixel gain variation of the M64 tubes. The system provides a selftriggering analog readout into an external flash ADC. A fast discriminator signal for triggering is also available for each strip with a common threshold.

Based on the performance of the SciBar detector, a minimum ionizing particle traversing a strip will yields about 20 photoelectons close to the tube, and the strip/fiber system will have an attenuation length of 3.5 m . This would then produce about 10 photoelectrons at the center of the detector per plane.

### 4.3.1.3 Hybrid Design

Our initial estimates indicate the scintillator option may cost more than the proportional tube option. However, the scintillator system described above does provide a stable, easy to characterize active detector. In particular, scintillating strips offer very stable response that does not vary with pressure or temperature. We will investigate a hybrid system in which every fourth or eighth plane (one or two radiation lengths) would be a scintillator panel. The high granularity of the proportional tube design would give good pattern recognition, and the excellent energy resolution of the scintillator would give a better energy measurement. Reducing the fiber spacing in the scintillator may be possible; this would reduce the cost.

One issue with adding $12-25 \%$ scintillator would be the change in the fraction of protons in the detector. The precise change depends on the scintillator used, but for $\mathrm{CH}_{4}$ and one scintillator panel every quarter radiation length, the proton-neutron ratio changes from 0.998 to 0.940 . The impact of this change will have to be balanced against the cost reduction and stability improvement. This will be part of our Monte Carlo effort in the coming months.

### 4.3.2 Toroid Spectrometers

High energy muons produced in charged-current interactions will be momentum analyzed in three iron toroid spectrometers downstream of each subdetector (set of ten "stacks"). Each spectrometer will be composed of layers of magnetized iron instrumented with drift chambers for tracking.

Since NuSOnG will see muons of the same energies as NuTeV/CCFR a similar arrangement for measuring muon momenta would be suitable. CCFR used sections of 8 " thick steel washers instrumented with scintillator hodoscopes for calorimeter ${ }^{2}$

[^291]

Figure 18: Conceptual Schematic for a NuSOnG toroid element. The three sections contain the same amount of steel (eight washers of 8 " each). The upstream most section has additional drift chamber stations to improve acceptance for low energy muons. Each of the five drift chamber stations has 3 x and 3y view chambers.

Tracking was performed using four views of each x and y chambers ( 0.5 mm coordinate resolution) in three gaps located after each 1.6 m of steel. The magnetic field was produced by four coils carrying approximately 1500 A each which passed through the center hole. The field was nearly radially symmetric and pointed in the azimuthal direction with magnitude ranging from 1.9 T near the center hole to 1.55 T near the outer edge (at $\mathrm{R}=1.8 \mathrm{~m}$ ). Details can be found in reference [142].

Figure 18 shows a possible arrangement for a NuSOnG toroid spectrometer. One "Upstream section" and two downstream "Standard sections" are shown. The downstream sections contain eight 8 " washers with one drift chamber station with 3 x and $3 y$ view chambers each. The most upstream section of a spectrometer unit has two additional drift chamber stations to improve acceptance for low energy muons. To pass the coil through this arrangement the upstream chamber stations would be half size (the same chambers but rotated for each view). Each of the three sections contain the same amount of steel. Hodoscope paddles could be added in each chamber station for triggering purposes. Resolution of this arrangement would be dominated by multiple Coulomb scattering and would be $\sim 11 \%$ independent of momentum.

The NuSOnG arrangement will provide good acceptance for high energy primary muons of both signs since in a sign-selected beam the can be routinely operated with the polarity set to focus the primary muon. Very high energy particles can be tracked into the downstream target sections with a long lever arm and their momentum analyzed. (resolution for very high energy muons ( $>150 \mathrm{GeV}$ was limited in NuTeV and CCFR; this resulted in large uncertainties in measuring flux in the high energy tail of the beam). Improving flux measurements in this region may help constrain kaon fluxes and therefore electron neutrino beam contamination.

### 4.3.3 Detector Calibration

A thorough and precise calibration of the entire detector will be required to achieve the physics goals of NuSOnG. Some of the response features of the detector can be understood using beam and cosmic ray muon samples, but a dedicated calibration effort will be required to study the hadronic and electromagnetic response of the detector and to measure the absolute energy scales. Precise calibration of a detector of this size will require a dedicated in situ calibration beam such as was used in NuTeV for this purpose [143].

The requirements for NuSOnG calibration beam would be similar to those of NuTeV. Tagged beams of hadrons, electrons, and muons over a wide energy range $(5-200 \mathrm{GeV})$ would be required. The calibration beam should have the ability to be steered over the transverse face of the detector in order to map the magnetic field of each toroid with muons. This could be accomplished in several ways; for example, gaps of a few meters in front of each toroid could be incorporated into the design, and the beam could be steered into each toroid in turn; or the toroids could each be moved into the test beam for these calibration runs. Steering for hadrons and electrons would be less crucial than it was in NuTeV's case but would still be useful.

The calibration beam can be constructed with a similar design to NuTeV. Upstream elements were used to select hadrons, electrons, or muons. An enhanced beam of electrons was produced by introducing a thin lead radiator into the beam and detuning the portion of the beam downstream of the radiator. A radiator was also used in the nominal beam tune to remove electrons. Particle ID (a threshold cerenkov and TRDs) was incorporated in the spectrometer and used to tag electrons when running at low energy. A pure muon beam was produced by introducing a 7 m long beryllium filter in the beam as an absorber.

The NuTeV calibration spectrometer was able to determine incoming particle momenta with a precision of better than $0.3 \%$ absolute. This was accomplished by two means. First, precisely calibrated dipole spectrometer magnets were used, with $\int B d \ell$ known to better than $0.1 \%$ in the region traversed by the beam. Secondly, the bend angle was determined to better than $0.1 \%$ using drift chambers positioned over the 150 m spectrometer. This long lever arm allowed a modest alignment uncertainty of a few mm to translate into only a $0.1 \%$ uncertainty in the absolute momentum scale. The event-by-event resolution of the spectrometer, dominated by multiple scattering in the drift chamber walls, was better than $0.3 \%$ for most energies. (Helium in the region between the last dipole and the upstream part of the detector reduced the scattering in air).

Figure 19 shows the NuTeV calibration beam configuration and the long lever arm spectrometer used to tag particle momenta with an absolute precision of better than $0.3 \%$. The most downstream dipole was mounted on a rotating stand which gave the ability to steer the beam out of the plane.

The NuSOnG goal of the calibration precision would be to measure energy scales to a precision of about $0.5 \%$. NuTeV achieved $0.43 \%$ precision on absolute hadronic energy scale and $0.7 \%$ on absolute muon energy scale (dominated by the ability to accurately determine the toroid map). Precise knowledge of the muon energy scale is especially important in order to achieve high measurement accuracy on the neutrino fluxes using the low- $\nu$ method. For example a $0.5 \%$ precision on muon energy scale translates into about a $1 \%$ precision on the flux. Both energy scales are important

Figure 19: (Top) Components of the NTEST beamline used to calibrate the NuTeV detector. Four different thicknesses of converter material at NTACON were used to select pure hadrons or electrons. The 7 m long Be filter(NTBBE) was used to select pure muons. The numbers on the left-hand-side of each component indicate the relative distance of the component to the primary target (NT8TGT) in meters. (Bottom) NuTeV's long lever arm spectrometer. The four dipole bend magnets were located in an enclosure approximately 70 m upstream of the Lab E detector. The spectrometer spanned over 150 m in length; this allowed precision measurement of the bending angle.
for precision structure function measurements and were the largest contributions to structure function measurement uncertainties in NuTeV 89 .

### 4.4 Possible Locations

Fig. 20 shows a possible location for the NuSOnG beam target hall and detector. Other layouts are possible; this is just meant to provide an example.

This layout assumes that the beam is extracted at A0 from the TeVatron and directed through the Switchyard Complex to a new targeting hall. This location allows low luminosity extraction down existing beamlines for the calibration beam.

The detector is located near the New Muon Lab. This is a region with more than 200 m of clear length, with roads and utilities nearby.

The calibration beam could be delivered to the NuSOnG hall using a scheme similar to that used in NuTeV with the NTest beamline. Only a short extension of the existing NTest line would be required to reach a detector located near the New Muon Lab. The beam was split off from the same beamline (Ncenter) and then bent around to impinge on the detector at a 43 mrad angle.

Figure 20: Aerial view of Fermilab showing the Tevatron, external beam lines and potential site for NuSOnG target and detector halls.

## 5 Summary

NuSOnG is an experimental program with high discovery potential. The precision neutrino scattering measurements probe terascale physics and will complement discoveries at the LHC. Through precision electroweak measurements, NuSOnG will be sensitive to such new phenomena as extra $Z$ bosons with masses beyond the 1 TeV (depending on the model) and compositeness scales above 5 TeV . The NuSOnG measurement of the coupling to the $Z$, when combined with the LEP measurement of the invisible width, is a more sensitive method to search for new physics than this same measurement at the ILC. NuSOnG can also probe the existence of neutrissimos, moderately heavy neutral heavy leptons which may be produced at the LHC, but which could be difficult to reconstruct and identify. A wide range of direct searches for new particles and interactions can be accomplished. The high neutrino flux and isoscalar target will make allow measurements which probe deeper into nuclear structure.

The high energy neutrino facility, which uses 800 GeV protons from the TeVatron, has been endorsed by the 2007 Fermilab Steering Group. While NuSOnG is the first to propose an experiment for this facility, a wide range of interesting measurements can be made on this line.

The proposed 3 kton (fiducial) NuSOnG detector design, which is opitmized for the physics goals, is based largely on the experiences of NuTeV and CHARM II. The basic technology is straightforward, although challenges exist because of the high precision demanded by the physics goals. Detailed simulations of the detector are now underway

Our plan is to develop these ideas over the coming months. We plan to submit a proposal to the Fermilab Directorate in the near future.

Received 23 June 2009

We extend the physics case for a new high－energy，ultra－high statistics neutrino scat－ tering experiment，NuSOnG（Neutrino Scattering On Glass）to address a variety of issues including precision QCD measurements，extraction of structure functions，and the derived Parton Distribution Functions（PDF＇s）．This experiment uses a Tevatron－based neutrino beam to obtain a sample of Deep Inelastic Scattering（DIS）events which is over two orders of magnitude larger than past samples．We outline an innovative method for

#### Abstract

fitting the structure functions using a parametrized energy shift which yields reduced systematic uncertainties. High statistics measurements, in combination with improved systematics, will enable NuSOnG to perform discerning tests of fundamental Standard Model parameters as we search for deviations which may hint of "Beyond the Standard Model" physics.

Keywords: Neutrino scattering on glass.

## 1. Introduction

### 1.1. NuSOnG: Precision structure functions and incisive QCD measurements

The search for new physics at the "Terascale" - energy scales of $\sim 1 \mathrm{TeV}$ and beyond - is the highest priority for particle physics. NuSOnG is a proposed high energy, high statistics neutrino scattering experiment that can search for "new physics" from the keV through TeV energy scales via precision electroweak and QCD measurements. During its five-year data acquisition period, the NuSOnG experiment could record almost one hundred thousand neutrino-electron elastic scatters, and hundreds of millions of Deep Inelastic Scattering (DIS) events, exceeding the current world data sample by more than an order of magnitude. This experiment can address concerns related to extraction of structure functions and their derived Parton Distribution Functions (PDF's), investigate nuclear corrections, constrain isospin violation limits, and perform incisive measurement of heavy quarks.

For example, with its high intensity sign-selected $\nu$ and $\bar{\nu}$ beams, NuSOnG can generate a very large ( $\sim 600$ million event) DIS sample. This extraordinary sample can be used to measure up to six structure functions (three on neutrinos and three on antineutrinos), which in turn provide knowledge of the PDF's which describe the momentum distribution of quarks as a function of $Q^{2}$. These measurements influence a variety of topics including nuclear effects and isospin violation.

NuSOnG is particularly well suited to study both the strange and antistrange PDF's using the sign-selected beam. The strange PDF's provide the input to the Paschos-Wolfenstein (PW) ${ }^{1}$ style analysis from which the electroweak parameters are extracted; NuSOnG should have sufficient data to do a fully self-consistent analysis. ${ }^{\text {a }}$

NuSOnG can also generate a wealth of neutrino elastic scattering (ES) and quasielastic scattering, including Inverse Muon Decay (IMD) events which would also provide unparalleled precision measurements. In particular, the ES measurement is a theoretically robust, purely leptonic measurement, hence this quantity is well suited for incisive Standard Model tests.

In the present paper, we discuss those aspects of NuSOnG that impact the QCD measurements, both directly and indirectly; this includes the extraction of

[^292]Table 1. Comparison of statistics and targets for parton distribution studies in NuSOnG compared to the two past highest statistics DIS neutrino scattering experiments.

| Experiment | $\nu$ DIS <br> events | $\bar{\nu}$ DIS <br> events | Main <br> target | Isoscalar <br> correction |
| :---: | :---: | :---: | :---: | :---: |
| CCFR | 0.95 M | 0.17 M | iron | $5.67 \%$ (Ref. 4) |
| NuTeV | 0.86 M | 0.24 M | iron | $5.74 \%$ (Ref. 5) |
| NuSOnG | 606 M | 34 M | glass | isoscalar |

the structure functions and the resulting PDF's, associated nuclear effects, isospin (charge symmetry) violation, and heavy quark issues. The purely electroweak measurements have been addressed in a separate publication. ${ }^{3}$ The combined set of NuSOnG measurement provides a rich multifaceted program for performing precision measurements and searching for new phenomena at energies ranging from the keV to TeV scales.

## 2. Deep Inelastic Scattering and Parton Distribution Functions

Obtaining a high quality model of the parton distribution functions in neutrino and antineutrino scattering is crucial to the NuSOnG electroweak measurements. ${ }^{3}$ NuSOnG will go a step beyond past experiments in addressing the systematics of PDF's by making high statistics measurements for neutrino and antineutrino data separately. Table 1 shows the large improvement in statistics for NuSOnG compared to NuTeV and CCFR, the previous highest statistics experiments. Issues of uncertainties on the nuclear corrections are avoided by extracting PDF's on $\mathrm{SiO}_{2}$ directly, in similar fashion to the NuTeV PW analysis.

The differential cross-sections for neutrino and antineutrino CC DIS each depend on three structure functions: $F_{2}, x F_{3}$ and $R_{L}$. They are given by

$$
\begin{align*}
\frac{d^{2} \sigma^{\nu(\bar{\nu}) N}}{d x d y}= & \frac{G_{F}^{2} M E_{\nu}}{\pi\left(1+Q^{2} / M_{W}^{2}\right)^{2}} \\
& \times\left[F_{2}^{\nu(\bar{\nu}) N}\left(x, Q^{2}\right)\left(\frac{y^{2}+(2 M x y / Q)^{2}}{2+2 R_{L}^{\nu(\bar{\nu}) N}\left(x, Q^{2}\right)}+1-y-\frac{M x y}{2 E_{\nu}}\right)\right. \\
& \left. \pm x F_{3}^{\nu(\bar{\nu}) N} y\left(1-\frac{y}{2}\right)\right] \tag{1}
\end{align*}
$$

where $+(-)$ is for $\nu(\bar{\nu})$ scattering. In this equation, $x$ is the Bjorken scaling variable, $y$ the inelasticity, and $Q^{2}$ the squared four-momentum transfer. The structure functions are directly related to the PDF's.

The function $x F_{3}\left(x, Q^{2}\right)$ is unique to the DIS cross-section for the weak interaction. It originates from the parity-violating term in the product of the leptonic
and hadronic tensors. For an isoscalar target, in the quark-parton model, where $s=\bar{s}$ and $c=\bar{c}$,

$$
\begin{align*}
& x F_{3}^{\nu N}(x)=x(u(x)+d(x)+2 s(x)-\bar{u}(x)-\bar{d}(x)-2 \bar{c}(x)),  \tag{2}\\
& x F_{3}^{\bar{\nu} N}(x)=x F_{3}^{\nu N}(x)-4 x(s(x)-c(x)) \tag{3}
\end{align*}
$$

In past experiments, the average of $x F_{3}$ for neutrinos and antineutrinos has been measured. Defining $x F_{3}=\frac{1}{2}\left(x F_{3}^{\nu N}+x F_{3}^{\bar{\nu} N}\right)$, at leading order in QCD,

$$
\begin{equation*}
x F_{3, \mathrm{LO}}=\sum_{i=u, d \cdots} x q_{i}\left(x, Q^{2}\right)-x \overline{q_{i}}\left(x, Q^{2}\right) . \tag{4}
\end{equation*}
$$

To the level that the sea quark distributions have the same $x$ dependence, and thus cancel, $x F_{3}$ can be thought of as probing the valence quark distributions. The difference between the neutrino and antineutrino parity violating structure functions, $\Delta\left(x F_{3}\right)=x F_{3}^{\nu N}-x F_{3}^{\bar{\nu} N}$, probes the strange and charm seas (cf. Sec. 6).

The function $F_{2}\left(x, Q^{2}\right)$ appears in both the cross-section for charged lepton ( $e$ or $\mu$ ) DIS and the cross-section for $\nu$ DIS. At leading order,

$$
\begin{equation*}
F_{2, \mathrm{LO}}=\sum_{i=u, d \cdots} e_{i}^{2}\left(x q_{i}\left(x, Q^{2}\right)+x \overline{q_{i}}\left(x, Q^{2}\right)\right), \tag{5}
\end{equation*}
$$

where $e_{i}$ is the charge associated with the interaction. In the weak interaction, this charge is unity. For charged-lepton scattering mediated by a virtual photon, $e_{i}$ is the fractional electromagnetic charge of the quark flavor. Thus $F_{2}^{\nu N}$ and $F_{2}^{e(\mu) N}$ are analogous but not identical and comparison yields useful information about specific parton distribution flavors ${ }^{6}$ and charge symmetry violation as discussed below. In past neutrino experiments, $F_{2}^{\nu}$ and $F_{2}^{\bar{\nu}}$ have been taken to be identical and an average $F_{2}$ has been extracted, although this is not necessarily true in nuclear targets, as discussed below.

Similarly, $R_{L}\left(x, Q^{2}\right)$, the longitudinal to transverse virtual boson absorption cross-section ratio, appears in both the charged-lepton and neutrino scattering cross-sections. To extract $R_{L}$ from the cross-section, one must bin in the variables $x, Q^{2}$ and $y$. This requires a very large data set. To date, the best measurements for $R_{L}$ come from charged lepton scattering rather than neutrino scattering. ${ }^{7}$ Therefore, neutrino experiments have used charged lepton fits to $R_{L}$ as an input to the measurements of $x F_{3}$ and $F_{2} .{ }^{8}$ This, however, is just a matter of the statistics needed for a global fit to all of the unknown structure functions in $x$ and $Q^{2}$ bins. ${ }^{9}$ With the high statistics of NuSOnG, precise measurement of $R_{L}$ will be possible from neutrino scattering for the first time.

As an improvement on past experiments, the high statistics of NuSOnG allows measurement of up to six structure functions: $F_{2}^{\nu}, F_{2}^{\bar{\nu}}, x F_{3}^{\nu}, x F_{3}^{\bar{\nu}}, R_{L}^{\nu}$ and $R_{L}^{\bar{\nu}}$. This is done by fitting the neutrino and antineutrino data separately in $x, y$ and $Q^{2}$ as described in Eq. (1). The first steps toward fitting all six structure functions independently were made by the CCFR experiment, ${ }^{10}$ however statistics were such that only $x F_{3}^{\nu}, x F_{3}^{\bar{\nu}}$, and $F_{2}$-average and $R$-average could be measured, where the
average is over $\nu$ and $\bar{\nu}$. A global fit of up to six structure functions in NuSOnG would allow separate parametrizations of the underlying PDF's which can account for the nuclear and isospin violation issues discussed below.

In addition to fitting to the inclusive DIS sample, neutrino scattering can also probe parton distributions through exclusive samples. A unique and important case is the measurement of the strange sea through charged current (CC) opposite sign dimuon production. When the neutrino interacts with an $s$ or $d$ quark, it can produce a charm quark that fragments into a charmed hadron. The charmed hadron's semileptonic decay (with branching ratio $B_{c} \sim 10 \%$ ) produces a second muon of opposite sign from the first:

$$
\begin{align*}
\nu_{\mu}+N \rightarrow \mu^{-}+ & c+X \\
& \hookrightarrow s+\mu^{+}+\nu_{\mu} . \tag{6}
\end{align*}
$$

Similarly, with antineutrinos, the interaction is with an $\bar{s}$ or $\bar{d}$,

$$
\begin{align*}
\bar{\nu}_{\mu}+N \rightarrow \mu^{+}+ & \bar{c}+X \\
& \hookrightarrow \bar{s}+\mu^{-}+\bar{\nu}_{\mu} . \tag{7}
\end{align*}
$$

The opposite sign of the two muons can be determined for those events where both muons reach the toroid spectrometer. Study of these events as a function of the kinematic variables allows extraction of the strange sea, the charm quark mass, the charmed particle branching ratio $\left(B_{c}\right)$, and the Cabibbo-Kobayashi-Maskaka matrix element, $\left|V_{c d}\right|$.

## 3. Experimental Extraction of Structure Functions in NuSOnG

### 3.1. Description of NuSOnG

The NuSOnG detector was designed to be sensitive to a wide range of neutrino interactions from $\nu$-electron scattering as well as $\nu$-nucleon scattering, though this paper focuses mainly on the latter process. The design has been described in detail in Refs. 3 and 11 and so we provide only a brief summary here.

The neutrino beam would be produced via a high energy external proton beam from a high intensity accelerator with energy of $\sim 1 \mathrm{TeV}$. The Fermilab Tevatron is an existing example. The CERN SPS,$+{ }^{12,13}$ which is presently under consideration because of its value to the LHC energy and luminosity upgrades and to a future beta beam, is a second example.

The NuSOnG beam design will be based on the one used by the NuTeV experiment, which is the most recent high energy, high statistics neutrino experiment. The experiment would use 800 GeV protons on target followed by a quad-focused, sign-selected magnetic beam-line. The beam flux, shown in Fig. 1, has very high neutrino or antineutrino purity ( $\sim 98 \%$ ) and small $\nu_{e}$ contamination ( $\sim 2 \%$ ) from kaon and muon decay. Using an upgraded Tevatron beam extraction it is expected that NuSOnG could collect $5 \times 10^{19}$ protons/yr, an increase by a factor of 20 from NuTeV . With this high intensity, such a new facility would also produce a neutrino beam from the proton dump having a sizable fraction of tau neutrinos for study.

Fig. 1. (Color online) The assumed energy-weighted flux ( $E d \phi / d E / 10^{6}$ POT) based on the NuTeV experiment in (a) neutrino mode (left) and (b) antineutrino mode (right). (a) In neutrino mode the fluxes are ordered: upper (black), muon neutrino; middle (blue), electron neutrino and antineutrino; lower (red), muon antineutrino. (b) In antineutrino mode the fluxes are ordered: upper (red), muon antineutrino; middle (blue), electron neutrino and antineutrino; lower (black), muon neutrino.

The baseline detector design is composed of a fine-grained target calorimeter for electromagnetic and hadronic shower reconstruction followed by a toroid muon spectrometer to measure outgoing muon momenta. The target calorimeter will be composed of $2,5002.5 \mathrm{~cm} \times 5 \mathrm{~m} \times 5 \mathrm{~m}$ glass planes interspersed with proportional tubes or scintillator planes. This gives a target which is made of isoscalar material with fine $1 / 4$ radiation length sampling. The detector will be composed of four target sections each followed by muon spectrometer sections and low mass decay regions to search for long-lived heavy neutral particles produced in the beam. The total length of the detector is $\sim 200 \mathrm{~m}$ and the fiducial mass for the four target calorimeter modules will be 3 kiloton which is 6 times larger than NuTeV or CHARM II. Figure 2 shows a simulated $\nu_{\mu}$ charged current event in the detector.

### 3.2. Description of $N u S O n G$ calibration beam

The requirements for NuSOnG calibration beam would be similar to those of NuTeV. Tagged beams of hadrons, electrons, and muons over a wide energy range $(5-200 \mathrm{GeV})$ would be required. The calibration beam will have the ability to be steered over the transverse face of the detector in order to map the magnetic field of each toroid with muons. Steering for hadrons and electrons would be less crucial than it was in NuTeV's case, but would still be useful.

The calibration beam can be constructed with a similar design to NuTeV . Upstream elements were used to select hadrons, electrons, or muons. An enhanced beam of electrons was produced by introducing a thin lead radiator into the beam and detuning the portion of the beam downstream of the radiator. A radiator was also used in the nominal beam tune to remove electrons. Particle ID (a threshold Cerenkov and TRD's) was incorporated in the spectrometer and used to tag

Fig. 2. A simulated muon neutrino, charged current event in the NuSOnG detector.
electrons when running at low energy. A pure muon beam was produced by introducing a 7 m long beryllium filter in the beam as an absorber.

The NuTeV calibration spectrometer determined incoming particle momenta with a precision of better than $0.3 \%$ absolute. ${ }^{14}$ The NuSOnG goal for calibrationbeam precision would be to measure energy scales to a precision of about $0.5 \%$, and we demonstrate (in later text of this paper) that this can be improved with fits to neutrino data.

For comparison, using the calibration beam, NuTeV achieved $0.43 \%$ precision on absolute hadronic energy scale and $0.7 \%$ on absolute muon energy scale (dominated by the ability to accurately determine the toroid map). Precise knowledge of the muon energy scale is especially important in order to achieve high measurement accuracy on the neutrino fluxes using the low- $\nu$ method. For example, a $0.5 \%$ precision on muon energy scale translates into about a $1 \%$ precision on the flux. Both energy scales are important for precision structure function measurements, and were the largest contributions to structure function measurement uncertainties in NuTeV. ${ }^{15}$

### 3.3. Experimental extraction of structure functions in $N u S O n G$

The high statistics of the NuSOnG experiment makes it possible to extract the structure functions directly from the $y$-distributions within bins of $\left(x, Q^{2}\right)$. Previous lower-statistics high-energy neutrino experiments either extracted structure functions by comparing the number of $\nu$ versus $\bar{\nu}$ events in an $\left(x, Q^{2}\right)$ bin, ${ }^{4}$ or by extracting the cross-sections $d \sigma / d y$ within the $\left(x, Q^{2}\right)$ bin and fitting for the structure functions using Eq. (1). ${ }^{15}$ Either method assumes a value for $R_{L}=\sigma_{L} / \sigma_{T}$ as
measured by other experiments, ${ }^{16}$ and depends on a measurement of the strange sea from dimuon events. ${ }^{17,18}$ With sufficient statistics, we can explore the possibility of measuring $x F_{3}^{\nu}\left(x, Q^{2}\right), x F_{3}^{\bar{\nu}}\left(x, Q^{2}\right), F_{2}\left(x, Q^{2}\right)$ and $R\left(x, Q^{2}\right)$ from the same data. ${ }^{10}$

Let us consider the cross-section of Eq. (1) as a function of $\left\{x F_{3}, F_{2}, R\right\}$; we denote this as $d \sigma^{\nu(\bar{\nu})}\left(x F_{3}, F_{2}, R\right)$, where the $\left(x, y, Q^{2}\right)$-dependence is assumed, and the structure functions can be different for neutrinos and antineutrinos. One can then fit for the structure functions $\left\{x F_{3}^{\mathrm{fit}}, F_{2}^{\mathrm{fit}}, R^{\text {fit }}\right\}$ in each $\left(x, Q^{2}\right)$ bin by minimizing the function

$$
\begin{equation*}
\chi^{2}=\sum_{\nu, \bar{\nu}} \sum_{y \text {-bins }} \frac{\left[N_{\mathrm{data}}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)-N_{\mathrm{MC}, \text { pred }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)\right]^{2}}{N_{\mathrm{data}}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)} . \tag{8}
\end{equation*}
$$

We will define the quantities of Eq. (8) in the following. Here, $N_{\text {data }}^{\nu(\bar{\nu})}$ is the number of $\nu$ or $\bar{\nu}$ data events in the $\left(x, y, Q^{2}\right)$ bin. To compute $\chi^{2}$, we first generate (gen) a sample of Monte Carlo events using an assumed set of structure functions $\left\{x F_{3}^{\text {gen }}, F_{2}^{\text {gen }}, R^{\text {gen }}\right\}$ to produce the cross-section $d \sigma^{\nu, \bar{\nu}}\left(x F_{3}^{\text {gen }}, F_{2}^{\text {gen }}, R^{\text {gen }}\right)$; we can then compute the number of generated events in each $\left(x, y, Q^{2}\right)$ bin, $N_{\mathrm{MC}, \mathrm{gen}}^{\nu(\bar{\nu})}$.

We next compute the predicted (pred) number of events in each $\left(x, y, Q^{2}\right)$ bin, $N_{\mathrm{MC}, \text { pred }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)$, by reweighting the Monte Carlo generated events as follows:

$$
\begin{equation*}
N_{\mathrm{MC}, \text { pred }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)=\sum_{\substack{\nu(\bar{\nu}) \text { events in } \\\left(x, y, Q^{2}\right) \text { bin }}} \frac{d \sigma^{\nu(\bar{\nu})}\left(x F_{3}^{\mathrm{fit}}, F_{2}^{\mathrm{fit}}, R^{\mathrm{fit}}\right)}{d \sigma^{\nu(\bar{\nu})}\left(x F_{3}^{\text {gen }}, F_{2}^{\text {gen }}, R^{\text {gen }}\right)} N_{\mathrm{MC}, \text { gen }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right) \tag{9}
\end{equation*}
$$

Here, $d \sigma^{\nu(\bar{\nu})}\left(x F_{3}^{\mathrm{fit}}, F_{2}^{\mathrm{fit}}, R^{\mathrm{fit}}\right)$ is the cross-section computed with the structure functions $\left\{x F_{3}^{\mathrm{fit}}, F_{2}^{\mathrm{fit}}, R^{\mathrm{fit}}\right\}$ which are the result of the $\chi^{2}$-minimization of Eq. (8). In principle, $\left\{x F_{3}^{\text {fit }}, F_{2}^{\text {fit }}, R^{\text {fit }}\right\}$ can be fit separately for the $\nu$ and $\bar{\nu}$ structure functions.

In the following, we will concentrate on the measurement of up to four separate structure functions, $\Delta x F_{3}\left(x, Q^{2}\right)=x F_{3}^{\nu}\left(x, Q^{2}\right)-x F_{3}^{\bar{\nu}}\left(x, Q^{2}\right), x F_{3}^{\text {avg }}=$ $\left(x F_{3}^{\nu}+x F_{3}^{\bar{\nu}}\right) / 2, F_{2}\left(x, Q^{2}\right)$ and $R\left(x, Q^{2}\right)$ where we assume that $F_{2}\left(x, Q^{2}\right)$ and $R\left(x, Q^{2}\right)$ are the same for neutrinos and antineutrinos; i.e. $F_{2}\left(x, Q^{2}\right)=F_{2}^{\nu}\left(x, Q^{2}\right)=$ $F_{2}^{\bar{\nu}}\left(x, Q^{2}\right)$ and $R\left(x, Q^{2}\right)=R^{\nu}\left(x, Q^{2}\right)=R^{\bar{\nu}}\left(x, Q^{2}\right)$.

### 3.4. Fitting for $\Delta x F_{3}$

We have studied the extraction of the structure function from the 600 million neutrino and 33 million antineutrino DIS events expected in the full NuSOnG data set. The dominant systematic error comes from the measurement of the muon momentum in the toroidal spectrometer. At NuTeV , the systematic uncertainty was $0.7 \%$ and we assume NuSOnG will achieve $0.5 \%$. Our studies are carried out by fitting the $y$-distribution in each $\left(x, Q^{2}\right)$ bin for $F_{2}$, the average value of $x F_{3}=x F_{3}^{\text {avg }}=\left(x F_{3}^{\nu}+x F_{3}^{\bar{\nu}}\right) / 2, \Delta x F_{3}=x F_{3}^{\nu}-x F_{3}^{\bar{\nu}}$ and $R$. In the first set of
studies, $R\left(x, Q^{2}\right)$ is set equal to the measured value ${ }^{16}$ and fits are done for the three structure functions, $F_{2}, x F_{3}^{\text {avg }}$ and $\Delta x F_{3}$.

Our fitting procedure begins with a set of Monte Carlo generated events, $N^{\text {gen }}\left(x, y, Q^{2}\right)$, sampled from the CCFR structure functions, and the nominal value for $\Delta x F_{3}$ from NuTeV, $\left\{F_{2}^{\text {nom }}, x F_{3}^{\text {nom }}\right\}$. We fit in bins of $\left(x, Q^{2}\right)$ as a function of $y$ and obtain the fit spectra by reweighting the original sample:

$$
\begin{aligned}
N^{\mathrm{fit}}\left(x, y, Q^{2}\right)= & \frac{F_{2}^{\mathrm{fit}}\left(x, Q^{2}\right)\left(2-2 y+y^{2} /(1+R)\right) \pm x F_{3}^{\mathrm{fit}}\left(x, Q^{2}\right)\left(1-(1-y)^{2}\right)}{F_{2}^{\mathrm{nom}}\left(x, Q^{2}\right)\left(2-2 y+y^{2} /(1+R)\right) \pm x F_{3}^{\text {nom }}\left(x, Q^{2}\right)\left(1-(1-y)^{2}\right)} \\
& \times N^{\mathrm{gen}}\left(x, y, Q^{2}\right),
\end{aligned}
$$

where the upper sign is for neutrinos and the lower for antineutrinos. In order to study the effects of the systematic energy scale shift, we produce a Monte Carlo sample where the muon energy scale is shifted by $0.5 \%, E_{\mu}^{\text {meas }}=1.005 E_{\mu}^{\text {true }}$, for each event. The fractional change in the number of events in each bin due to the energy scale shift is shown in Fig. 3.

Fig. 3. Fractional change in number of events for two characteristic $\left(x, Q^{2}\right)$ bins as a function of $y$. The fractional change comes from scaling the energy of each event by a factor of 1.005 .

This shifted event distribution, $N^{\text {shift }}\left(x, y, Q^{2}\right)$, is then used to carry out a three parameter fit to Eq. (8) where $F_{2}, x F_{3}^{\text {avg }}$, and $\Delta x F_{3}$ are varied. Large shifts in $\Delta x F_{3}$ result. For example, the shift from the input value in the $\left(x, Q^{2}\right)=$ $\left(0.08,12.6 \mathrm{GeV}^{2}\right)$ bin is $19.01 \%$, and the shift in other bins is even larger.

The effects of the energy scale uncertainty can be practically eliminated by including energy scale shift parameters in the fit. A muon energy scale change shifts the events in the various $y$-bins by an amount that is not consistent with that expected from changes in the structure functions. Therefore, fits to the $y$ distributions can isolate the effects of an energy scale shift and significantly reduce the structure function uncertainty from this systematic error. To estimate the systematic error reduction for this technique, three additional energy scale parameters are introduced in the fit to the $y$-distributions. These three parameters are used to produce an energy scale shift parametrization in each $\left(x, y, Q^{2}\right)$ bin given by

$$
E_{\mu \text { scale }}=E_{\mu \text { scale } 1}+E_{\mu \text { scale } 2} E_{\mu}+E_{\mu \text { scale } 3} E_{\mu}^{2}
$$

The updated prediction for the number of events in a given $\left(x, y, Q^{2}\right)$ bin is

$$
\begin{aligned}
N_{\mathrm{pred}}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)= & N_{\mathrm{MC}, \text { pred }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right) \\
& +E_{\mu \text { scale }}\left[N^{\mathrm{shift}}\left(x, y, Q^{2}\right)-N^{\mathrm{gen}}\left(x, y, Q^{2}\right)\right]
\end{aligned}
$$

and the $\chi^{2}$ used in the minimization is similar to Eq. (8) with the addition of pull terms associated with the three energy scale parameters

$$
\begin{align*}
\chi^{2}= & \sum_{\nu, \bar{\nu}} \sum_{y \text {-bins }} \frac{\left[N_{\text {data }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)-N_{\text {pred }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)\right]^{2}}{N_{\text {data }}^{\nu(\bar{\nu})}\left(x, y, Q^{2}\right)} \\
& +E_{\mu \text { scale } 1}+\frac{E_{\mu \text { scale } 2}}{(0.02)^{2}}+\frac{E_{\mu \text { scale } 3}}{(0.0002)^{2}} . \tag{10}
\end{align*}
$$

These pull terms correspond to an energy scale uncertainty of about $0.5 \%$ for muon energy values averaging between 50 and 70 GeV . This fitting technique renders the systematic error from the scale shift to be small in comparison with the statistical error. For example, in the bin $\left(x, Q^{2}\right)=\left(0.275,32 \mathrm{GeV}^{2}\right)$, the systematic error for $\Delta x F_{3}$ is $0.3 \%$ while the statistical error is $10 \%$; the value of the $E_{\mu \text { scale } 1}$ parameter is also determined to about $10 \%$.

In the ultimate analysis, the fit will be carried out simultaneously over all $x$ and $Q^{2}$ bins with one set of energy scale parameters. We have studied this using eight $x$ bins and six to eight $Q^{2}$ bins. Figure 4 shows the fractional error on $\Delta x F_{3}$ for different $x$ bins as a function of $Q^{2}$. In general, we believe NuSOnG can measure $\Delta x F_{3}$ over most of the ( $x, Q^{2}$ ) range to better than $10 \%$; in many cases around $3 \%$. Typical values for NuTeV are shown in two $x$ bins in Fig. 4. Since more than one $\left(x, Q^{2}\right)$ bin is being used to determine the energy scale shift parameters, the value of the $E_{\mu \text { scale 1 }}$ parameter can also be determined to about $3 \%$ from these fits.

Fig. 4. Fractional uncertainty for the fit value of $\Delta x F_{3}$ in different $x$ bins as a function of $Q^{2}$. The fit is to multiple $x$ and $Q^{2}$ bins extracting the three structure functions, $F_{2}, x F_{3}^{\text {avg }}$ and $\Delta x F_{3}$. For each of the fits, a global set of energy scale parameters is also determined from the fit. The dashed lines show the fractional error for the $\mathrm{NuTeV} 2 \mu$ measurement.

Simulation studies have also been made to estimate the uncertainties associated with doing fits to extract the four structure functions, $F_{2}, x F_{3}^{\text {avg }}, \Delta x F_{3}$ and $R$. The procedure is the same as used for the three structure function fits where the $\chi^{2}$ in Eq. (10) is minimized simultaneously over a number of $x$ and $Q^{2}$ bins with one set of energy scale parameters. In this case, the $\Delta x F_{3}$ and $R_{\text {long }}$ structure functions can be determined to between $5 \%$ and $20 \%$ for most of the $x$ and $Q^{2}$ range as shown in Figs. 5 and 6. The simulated $R_{\text {long }}$ measurements are shown in Fig. 7 along with previous measurements. ${ }^{16}$ As indicated from this figure, the capabilities of the NuSOnG to measure $R_{\text {long }}$ is much more precise that any previous experiment.

In summary, due to the very high statistics of a NuSOnG type experiment, an almost complete set of structure functions over a broad range of $x$ and $Q^{2}$ can be extracted from the data without introducing theoretical or experimental approximations. Further, systematic uncertainties that have limited the precision of previous structure function measurements can be eliminated by including fits to these uncertainties in the extraction procedure. We believe that with these techniques the structure function measurements will be statistics limited even for NuSOnG.

## 4. Nuclear Effects

Historically, neutrino experiments have played a major role in expanding our understanding of parton distribution functions through high statistics experiments such as CCFR, ${ }^{8}$ NuTeV, ${ }^{15,19,8}$ and CHORUS. ${ }^{20}$ However, the high statistics extract a price since the large event samples require the use of nuclear targets - iron in the case of both CCFR and NuTeV , and lead in the case of the CHORUS experiment. The problem is that if one wants to extract information on nucleon PDF's, then the effects of the nuclear targets must first be removed. NuSOnG can provide key measurements which will improve these corrections.

Charged lepton DIS has been measured on a wide range of targets. The most simplistic expectation for the structure functions might be that they would be given by an average of the appropriate number of proton and neutron results as in

$$
F_{2}^{A}\left(x, Q^{2}\right)=\frac{Z}{A} F_{2}^{P}\left(x, Q^{2}\right)+\frac{A-Z}{A} F_{2}^{n}\left(x, Q^{2}\right) .
$$

However, the results from a wide range of experiments show a much more complex behavior for the structure functions on nuclei. The typical behavior of the ratio of $F_{2}^{A}\left(x, Q^{2}\right)$ to $F_{2}^{d}\left(x, Q^{2}\right)$ where $d$ denotes a deuterium target shows four distinct regions as sketched in Fig. 8.

At small $x$ the ratio dips below one in what is called the shadowing region. At somewhat larger values of $x$ the ratio rises above one in the antishadowing region. At still larger values of $x$ the ratio again falls below one in the EMC region. Finally, as $x$ approaches one, Fermi motion smearing causes a significant rise in the ratio.

Fig. 5. Fractional uncertainty for the fit value of $\Delta x F_{3}$ in different $x$ bins as a function of $Q^{2}$. The fit is to multiple $x$ and $Q^{2}$ bins extracting the four structure functions, $F_{2}, x F_{3}^{\text {avg }}, \Delta x F_{3}$ and $R$. For each of the fits, a global set of energy scale parameters is also determined.

Fig. 6. Fractional uncertainty for the fit value of $R$ in different $x$ bins as a function of $Q^{2}$. The fit is to multiple $x$ and $Q^{2}$ bins extracting the four structure functions, $F_{2}, x F_{3}^{\text {avg }}, \Delta x F_{3}$ and $R$. For each of the fits, a global set of energy scale parameters is also determined.

Fig. 7. Extracted values of $R$ (labeled NuSOnG) from the four structure function fits as compared to previous measurements ${ }^{16}$ (labeled SLAC).

Fig. 8. Typical behavior of the ratio of the structure function on a nuclear target $A$ to that on a deuterium target.

This behavior shows only a modest dependence on $A$ for values above beryllium, with the shape remaining qualitatively the same and the amount of the suppression at $x \approx 0.6$ increasing slowly with $\log (A)$. Furthermore, there is little, if any, observed dependence on $Q^{2}$. These features are summarized nicely in the results shown in Ref. 21.

The mechanisms of nuclear scattering have also been studied theoretically. These mechanisms appear to be different for small and large Bjorken $x$ as viewed from the laboratory system. Bjorken $x$ is defined as $x=Q^{2} / 2 M \nu$, where $\nu$ and $\boldsymbol{q}$ are energy and momentum transfer to the target and $Q^{2}=\boldsymbol{q}^{2}-\nu^{2}$. The physical quantity which is responsible for the separation between large and small $x$ regions is a characteristic scattering time, which is also known as Ioffe time (or length) $\tau_{I}=\nu / Q^{2} .{ }^{22}$ If $\tau_{I}$ is smaller than the average distance between bound nucleons in a nucleus then the process can be viewed as incoherent scattering off bound nucleons. This happens at larger $x(>0.2)$.

### 4.1. Nuclear effects at small $\boldsymbol{x}$

We expect to find a difference between charged-lepton nucleus and neutrino nucleus scattering at small- $x$ because the space-time pictures for the two processes are different in this region. The underlying physical mechanism in the laboratory reference frame can be sketched as a two-stage process. At the first stage, the virtual photon $\gamma^{*}$, or $W^{*}$ or $Z^{*}$ in case of neutrino interactions, fluctuates into a quark-antiquark (or hadronic) state. In the second stage, this hadronic state then interacts with the
target. The uncertainty principle allows an estimate of the average lifetime of such hadronic fluctuation as

$$
\begin{equation*}
\tau=\frac{2 \nu}{m^{2}+Q^{2}}=\frac{1}{x M} \frac{Q^{2}}{m^{2}+Q^{2}}, \tag{11}
\end{equation*}
$$

where $m$ is the invariant mass of the hadrons into which the virtual boson converts, and $M$ is the proton mass. The same scale $\tau$ also determines characteristic longitudinal distances involved in the process. At small $x, \tau$ exceeds the average distance between bound nucleons. For this reason coherent multiple interactions of this hadronic fluctuation in a nucleus are important in the small- $x$ kinematic region. It is well known that the nuclear shadowing effect for structure functions is a result of coherent nuclear interactions of hadronic fluctuations of virtual intermediate boson. ${ }^{\text {b }}$

For neutrino interactions which are mediated by the axial-vector current, the fluctuation time $\tau$ is also given by Eq. (11). However, there are some open questions here; it was argued in Ref. 24 that the fluctuation and coherence lengths are not the same for the axial-vector current case. The experimental study of shadowing with neutrinos can provide an excellent test of the properties of the axial vector current, and the high energy of the NuSOnG beam will allow the kinematic reach and the resolution to study this phenomena. ${ }^{25}$

### 4.2. Nuclear effects in neutrino interactions

As there has been no systematic experimental study of $\nu$ and $\bar{\nu}$ nucleus interactions, one must then rely on theoretical models of the nuclear corrections. This is an unsatisfactory situation since one is essentially measuring quantities sensitive to the convolution of the the desired PDF's and unknown - or model dependent nuclear corrections.

As noted above, theoretically there are substantial differences between charged lepton and neutrino interactions on the same nucleus. There are other expected differences for neutrinos. For example, the relative nuclear shadowing effects for the structure function $F_{3}$ is predicted to be substantially different from that for $F_{2} .{ }^{26}$ This is because the structure function $F_{3}$ describes the correlation between the vector and the axial-vector current in neutrino scattering. In terms of helicity cross-sections, the structure function $F_{3}$ is given by the cross-section asymmetry between the left- and right-polarized states of a virtual $W$ boson. It is known that such a difference of cross-sections is strongly affected by Glauber multiple scattering corrections in nuclei. ${ }^{27-29}$ This causes an enhanced nuclear shadowing effect for the structure function $F_{3}$.

It is important to experimentally address the question of nuclear effects in neutrino scattering so that the neutrino data can be used in proton fits without bringing

[^293]

Fig. 9. Comparison between the reference fit and the unshifted CHORUS and NuTeV neutrino data without any nuclear corrections.
in substantial nuclear uncertainties. For example, in a recent analysis ${ }^{30}$ the impact of new neutrino data on global fits for PDF's was assessed. The conclusion reached in this analysis was that the uncertainties associated with nuclear corrections precluded using the neutrino data to constrain the nucleon PDF's. If NuSOnG can address these uncertainties, then the neutrino data can play an even more prominent role in the global fits to the proton PDF.

Furthermore, nuclear effects are interesting in their own right. Parametrizations of nuclear PDF's on various targets exist in the literature. However, there is no universally accepted model which describes these nuclear corrections over the entire range of $x$ from first principles. This makes it difficult to generalize the above behavior observed in charged lepton DIS to DIS with $\nu$ or $\bar{\nu}$ beams. Models such as that in Ref. 31 exist, but to date there have been no high statistics studies of $\nu$ or $\bar{\nu}$ DIS over a wide range of nuclear targets with which to test them.

A study presented in Ref. 30 examined the role of new lepton pair production data from E-866 and new neutrino DIS data from the NuTeV and CHORUS collaborations in global fits for nucleon PDF's. For the actual fitting of the PDF's it was necessary to include nuclear corrections for the neutrino and antineutrino cross-sections and the model of Ref. 31 was used. As a byproduct of that analysis, it was possible to compare a reference fit, obtained without using data on nuclear targets, to the neutrino and antineutrino data in order to obtain an estimate of what the nuclear corrections should look like. This comparison is shown in Fig. 9.

This figure shows some results from Ref. 30 in the form of "data/theory" averaged over $Q^{2}$ and presented versus $x$. The results are from a global fit but are plotted without the model-dependent nuclear corrections which were used in
the fit (the neutrino data were not used in the reference fit). It is notable that the overall pattern of deviations shown in Fig. 9 are, in general, similar to that seen in charged lepton DIS as sketched in Fig. 8. However, the deviations from unity are perhaps smaller. At high $x$, the effect of Fermi smearing is clear. At moderate $x$ the EMC effect is observable. It is interesting to note that there is no clear indication of a turnover at low $x$ in the shadowing region for $\nu$ data. Also, note the striking similarity between the $\nu$ and $\bar{\nu}$ results. This appears to imply that the differences in the nuclear effects between neutrino and antineutrino DIS are small. As discussed later, when we consider $\Delta x F_{3}$ and isospin violation, it is crucial to model differences in the nuclear effects between $\nu$ and $\bar{\nu}$ scattering as a function of $x$.

To make progress in understanding nuclear corrections in neutrino interactions, access to high statistics data on a variety of nuclear targets will be essential. This will allow the $A$-dependence to be studied as a function of both $x$ and $Q^{2}$, as has been done in charged lepton deep inelastic scattering. PDF's from global fits without the neutrino data can then be used to make predictions to be compared with the $A$-dependent $\nu$ and $\bar{\nu}$ cross-sections, thereby allowing the nuclear corrections to be mapped out for comparison with theoretical models.

The primary target of NuSOnG will be $\mathrm{SiO}_{2}$. However, we can investigate a range of $A$-values by replacing a few slabs of glass with alternative target materials: $\mathrm{C}, \mathrm{Al}, \mathrm{Fe}$ and Pb . This range of nuclear targets would both extend the results of MINER $\nu$ A to the NuSOnG kinematic region, and provide a check (via the Fe target) against the NuTeV measurement.

Given the NuSOnG neutrino flux, we anticipate $58 k \nu$-induced and $30 k \bar{\nu}$ induced CC DIS events per ton of material. A single ton would be sufficient to extract $F_{2}(x)$ and $x F_{3}(x)$ averaged over all $Q^{2}$; a single $5 \mathrm{~m} \times 5 \mathrm{~m} \times 2.54 \mathrm{~cm}$ slab of any of the above materials will weigh more than that. The use of additional slabs would permit further extraction of the structure functions into separate ( $x, Q^{2}$ ) bins as was done in the NuTeV analysis, at the potential expense of complicating the shower energy resolution in the subdetectors containing the alternative targets; this issue will be studied via simulation.

Table 2 shows that two 50 -module stacks would be sufficient to accumulate enough statistics on alternative nuclear targets for a full structure-function extraction for each material. However, for basic cross-section ratios in $x$, a single slab of each would suffice.

Table 2. Alternative target materials for cross-section analysis.

| Material | Mass of <br> 2.54 cm slab (tons) | Number of slabs needed <br> for <br> NuTeV-equivalent statistics |
| :---: | :---: | :---: |
| C | 1.6 | 33 |
| Al | 1.9 | 27 |
| Fe | 5.5 | 10 |
| Pb | 7.9 | 7 |

### 4.3. Measuring nuclear effects with the MINER $A$ and NuSOnG detectors

The MINER $\nu \mathrm{A}$ experiment will also be studying neutrino induced nuclear effects and will be starting its initial physics run in early 2010. To study nuclear effects in MINER $\nu$ A, a cryogenic vessel containing liquid helium ( 0.2 ton fiducial mass) will be installed upstream of the MINER $\nu$ A detector. ${ }^{\text {c }}$ Within the MINER $\nu$ A detector, solid carbon, iron and lead targets will be installed upstream of the pure scintillator active detector. The total mass is 0.7 ton of $\mathrm{Fe}, 0.85$ ton of $\mathrm{Pb}, 0.4$ ton of He and somewhat over 0.15 ton of C. Since the pure scintillator active detector essentially acts as an additional $3-5$ ton carbon target $(\mathrm{CH})$, the pure graphite $(\mathrm{C})$ target is mainly to check for consistency. For a run consisting of $4.0 \times 10^{20} \mathrm{POT}$ in the NuMI Low Energy (LE) beam and $12 \times 10^{20}$ POT in the NuMI Medium Energy (ME) beam, MINER $\nu$ A would collect over 2 M events on $\mathrm{Fe}, 2.5 \mathrm{M}$ events on $\mathrm{Pb}, 600 \mathrm{~K}$ on helium and 430 K events on C as well as 9.0 M events on the scintillator within the fiducial volume.

Studying nuclear effects with the NuSOnG detector will involve fewer nuclear targets but considerably more statistics on each. In addition, the much higher energy of the incoming neutrinos with NuSOnG means a much wider kinematic range of study. In particular, NuSOnG will have a much higher $Q^{2}$ for a given low- $x$ to study shadowing by neutrinos and will be able to measure the shadowing region down to much smaller $x$ for the same $Q^{2}$ range as MINER $\nu$ A. A significant addition to the study of nuclear effects with neutrinos would be the addition of a large, perhaps active ("Bubble Chamber"), cryogenic target containing hydrogen or deuterium. With the intense NuSOnG neutrino beam, a significant sample of neutrino-hydrogen and neutrino-deuterium events could provide the normalization we need to further unfold nuclear effects in neutrino-nucleus interactions.

## 5. QCD Fits

The extraction of up to six structure functions from the cross-sections of neutrino and antineutrino DIS discussed so far (cf. Eq. (1)) has been completely modelindependent relying only on some fundamental principles such as Lorentz-invariance of the cross-section and gauge-invariance of the hadronic tensor which is expanded in terms of the structure functions which parametrize the unknown hadronic physics.

More can be said about the structure functions in QCD. While it is still not possible to accurately compute the $x$-dependence of the structure functions from first principles, QCD allows us to derive renormalization group equations (RGE's) which relate the structure functions at different (perturbative) scales $Q$. Note that the structure functions at the scale $Q$ can be directly related to structure functions at a different scale $Q_{0}$ (see, e.g. Eqs. (5.58) and (5.76) in Ref. 33). However, it

[^294]is more convenient to work in the QCD-improved parton model where the RGE's governing the scale-dependence of the parton distribution functions (PDF's) are the familiar DGLAP evolution equations; these can also be used to compute the structure functions at $Q$ given the PDF's at that scale. ${ }^{34-36}$ Furthermore, this approach has the crucial advantage that the universal PDF's allow us to make predictions for other observables as well. In addition to the $Q$-dependence, the QCD calculations provide certain (approximate) relations between different structure functions as will be visible from the parton model expressions below.

In this section we will discuss the analysis of the cross-section data within the framework of the QCD-improved parton model. Already in the past, high statistics measurements of neutrino DIS on heavy nuclear targets (CCFR, NuTeV, Nomad, CHORUS ...) have attracted much interest in the literature since they provide valuable information for global fits of PDF's. ${ }^{37,38}$

Due to the weak nature of neutrino interactions, the use of nuclear targets is unavoidable; this complicates the extraction of free nucleon PDF's, because modeldependent corrections must be applied to the data (cf. Sec. 4). Of course, these same data are also useful for extracting the nuclear parton distribution functions (NPDF's) and for such an analysis no nuclear correction factors are required. Conversely, the NPDF's can be utilized to compute the required nuclear correction factors within the QCD parton model. ${ }^{39}$ Similar to proton PDF's, universal nuclear PDF's are needed for the description of many processes with nuclei in the initial state. This involves physics at other neutrino experiments, heavy ion colliders (RHIC, LHC), and a possible future electron-ion collider (EIC).

The NuSOnG experiment will have two orders of magnitude higher statistics than the NuTeV and CCFR experiments (over an extended kinematic range), and so it will be possible to study small effects such as the strangeness asymmetry with better precision, or to establish for the first time isospin violation in the light quark sector. Better understanding these effects is relevant for improving the extraction of the weak mixing angle in a Paschos-Wolfenstein-type analysis.

### 5.1. PDF's

NuSOnG will perform measurements on different nuclear targets. The PDF's for a nucleus $(A, Z)$ are constructed as

$$
\begin{equation*}
f_{i}^{A}(x, Q)=\frac{Z}{A} f_{i}^{p / A}(x, Q)+\frac{(A-Z)}{A} f_{i}^{n / A}(x, Q) \tag{12}
\end{equation*}
$$

In the following discussion we take into account deviations from isospin symmetry, a nonvanishing strangeness asymmetry, and the possibility to have nonisoscalar targets. For this purpose we introduce the following linear combinations of strange quark PDF's:

$$
\begin{equation*}
s^{+, A}=s^{A}+\bar{s}^{A}, \quad s^{-, A}=s^{A}-\bar{s}^{A}, \tag{13}
\end{equation*}
$$

where the strangeness asymmetry is described by a nonvanishing PDF $s^{-}$. Note however that we continue to assume $s^{p / A}=s^{n / A}$ and $\bar{s}^{p / A}=\bar{s}^{n / A}$. Also, we neglect any possible charm asymmetry, i.e. we use $c^{A}=\bar{c}^{A}$ such that $c^{-, A}=c^{A}-\bar{c}^{A}=0$ and $c^{+, A}=c^{A}+\bar{c}^{A}=2 c^{A}$.

Deviations from isospin symmetry can be parametrized in the following way:

$$
\begin{array}{ll}
\delta u_{v}^{p / A}=u_{v}^{p / A}-d_{v}^{n / A}, & \delta d_{v}^{p / A}=d_{v}^{p / A}-u_{v}^{n / A}, \\
\delta \bar{u}^{p / A}=\bar{u}^{p / A}-\bar{d}^{n / A}, & \delta \bar{d}^{p / A}=\bar{d}^{p / A}-\bar{u}^{n / A} . \tag{15}
\end{array}
$$

These definitions allow us to write the PDF's in a way which makes deviations from isoscalarity and isospin symmetry manifest:

$$
\begin{align*}
& 2 u_{v}^{A}=\left[u_{v}^{p / A}+d_{v}^{p / A}-\delta d_{v}^{p / A}\right]-\Delta\left[u_{v}^{p / A}-d_{v}^{p / A}+\delta d_{v}^{p / A}\right],  \tag{16}\\
& 2 d_{v}^{A}=\left[u_{v}^{p / A}+d_{v}^{p / A}-\delta u_{v}^{p / A}\right]+\Delta\left[u_{v}^{p / A}-d_{v}^{p / A}-\delta u_{v}^{p / A}\right],  \tag{17}\\
& 2 \bar{u}^{A}=\left[\bar{u}^{p / A}+\bar{d}^{p / A}-\delta \bar{d}^{p / A}\right]-\Delta\left[\bar{u}^{p / A}-\bar{d}^{p / A}+\delta \bar{d}^{p / A}\right],  \tag{18}\\
& 2 \bar{d}^{A}=\left[\bar{u}^{p / A}+\bar{d}^{p / A}-\delta \bar{u}^{p / A}\right]+\Delta\left[\bar{u}^{p / A}-\bar{d}^{p / A}-\delta \bar{u}^{p / A}\right], \tag{19}
\end{align*}
$$

where $\Delta=(N-Z) / A$ parametrizes the deviation from isoscalarity. We have written Eqs. (16)-(19) so that the r.h.s. is expressed explicitly in terms of proton PDF's and the four $\delta$-terms $\left\{\delta u_{v}^{p / A}, \delta d_{v}^{p / A}, \delta \bar{u}^{p / A}, \delta \bar{d}^{p / A}\right\}$; the $\delta$-terms vanish individually if isospin symmetry is preserved.

### 5.2. Structure functions

The structure functions for a nuclear target $(A, Z)$ are given by

$$
\begin{equation*}
F_{i}^{A}(x, Q)=\frac{Z}{A} F_{i}^{p / A}(x, Q)+\frac{(A-Z)}{A} F_{i}^{n / A}(x, Q) \tag{20}
\end{equation*}
$$

such that they can be computed in next-to-leading order as convolutions of the nuclear PDF's with the conventional Wilson coefficients, i.e. generically

$$
\begin{equation*}
F_{i}^{A}(x, Q)=\sum_{k} C_{i k} \otimes f_{k}^{A} . \tag{21}
\end{equation*}
$$

In order to discuss which information can be extracted from a high statistics measurement of neutrino and antineutrino DIS cross-sections, we briefly review the parton model expressions for the 6 structure functions. For simplicity, we first restrict ourselves to leading order, neglect heavy quark mass effects (as well as the associated production thresholds), and assume a diagonal CKM matrix. In our numerical results, these effects are taken into account.

The neutrino-nucleus structure functions are given by (suppressing the dependence on $x$ and $Q^{2}$ ):

$$
\begin{align*}
& F_{1}^{\nu A}=d^{A}+s^{A}+\bar{u}^{A}+\bar{c}^{A}+\cdots  \tag{22}\\
& F_{2}^{\nu A}=2 x F_{1}^{\nu A}  \tag{23}\\
& F_{3}^{\nu A}=2\left[d^{A}+s^{A}-\bar{u}^{A}-\bar{c}^{A}+\cdots\right] . \tag{24}
\end{align*}
$$

The structure functions for antineutrino scattering are obtained by exchanging the quark and antiquark PDF's in the corresponding neutrino structure functions:

$$
\begin{equation*}
F_{1,2}^{\bar{\nu} A}=F_{1,2}^{\nu A}[q \leftrightarrow \bar{q}], \quad F_{3}^{\bar{\nu} A}=-F_{3}^{\nu A}[q \leftrightarrow \bar{q}] . \tag{25}
\end{equation*}
$$

Explicitly this gives

$$
\begin{align*}
& F_{1}^{\bar{\nu} A}=u^{A}+c^{A}+\bar{d}^{A}+\bar{s}^{A}+\cdots,  \tag{26}\\
& F_{2}^{\bar{\nu} A}=2 x F_{1}^{\bar{\nu} A},  \tag{27}\\
& F_{3}^{\bar{\nu} A}=2\left[u^{A}+c^{A}-\bar{d}^{A}-\bar{s}^{A}+\cdots\right] . \tag{28}
\end{align*}
$$

The longitudinal structure function can be obtained with the help of the following relation:

$$
\begin{equation*}
F_{L}^{\nu A}=r^{2} F_{2}^{\nu A}-2 x F_{1}^{\nu A}=\frac{4 x^{2} M^{2}}{Q^{2}} F_{2}^{\nu A} \tag{29}
\end{equation*}
$$

where $r^{2}=1+4 x^{2} M^{2} / Q^{2}$. Finally, it is customary to introduce the ratio of longitudinal to transverse structure functions:

$$
\begin{equation*}
R_{L}^{\nu A}=\frac{F_{L}^{\nu A}}{2 x F_{1}^{\nu A}}=\frac{r^{2} F_{2}^{\nu A}}{2 x F_{1}^{\nu A}}-1=\frac{4 x^{2} M^{2}}{Q^{2}} . \tag{30}
\end{equation*}
$$

Similar equations hold for antineutrino scattering. At leading order (LO) it is clear that $R_{L}^{\nu}=R_{L}^{\bar{\nu}}$. Figure 10 displays $R_{L}^{\nu,(\bar{\nu})}$ for both LO and NLO; we observe that at NLO the difference between $R_{L}^{\nu}$ and $R_{L}^{\bar{\nu}}$ can be neglected in the following discussion.

Fig. 10. Structure function ratio $R_{L}$ for neutrino and antineutrino nucleon $\left.(N=(p+n) / 2)\right)$ scattering at $Q^{2}=20 \mathrm{GeV}^{2}$. The solid and dashed lines show NLO results obtained with the GRV98 PDF's, ${ }^{40}$ while the dotted line shows the LO result of Eq. (30).

### 5.3. Constraints on the PDF's

The differential cross-section in Eq. (1) can be written as

$$
\begin{equation*}
\frac{d \sigma}{d x d y}=K\left[A+B(1-y)^{2}+C y^{2}\right] \tag{31}
\end{equation*}
$$

with $K=\frac{G_{F}^{2} M E}{2 \pi\left(1+Q^{2} / M_{W}^{2}\right)^{2}}, A=F_{2} \pm x F_{3}, B=F_{2} \mp x F_{3}$ and $C=\frac{2 x^{2} M^{2}}{Q^{2}} F_{2}-F_{L}$ where the upper sign refers to neutrino and the lower one to antineutrino scattering. This form of $d \sigma$ shows that the (anti)neutrino cross-section data naturally encodes information on the four structure function combinations $F_{2}^{\nu A} \pm x F_{3}^{\nu A}$ and $F_{2}^{\bar{\nu} A} \pm$ $x F_{3}^{\bar{\nu}} A$ in separate regions of the phase space. In addition, at large $y$ the structure function combination $C$ contributes. However, to good accuracy $C^{\nu}=C^{\bar{\nu}}$ so that $C$ drops out in the difference of neutrino and antineutrino cross-sections.

Assuming $s^{A}=\bar{s}^{A}$ and $c^{A}=\bar{c}^{A}$, the structure functions $F_{2}^{\nu A}$ and $F_{2}^{\bar{\nu} A}$ constrain the valence distributions $d_{v}^{A}=d^{A}-\bar{d}^{A}, u_{v}^{A}=u^{A}-\bar{u}^{A}$ and the flavor-symmetric sea $\Sigma^{A}:=\bar{u}^{A}+\bar{d}^{A}+\bar{s}^{A}+\bar{c}^{A}+\cdots$ via the relations:

$$
\begin{align*}
& \frac{1}{x} F_{2}^{\nu A}=2\left[d_{v}^{A}+\Sigma^{A}\right]  \tag{32}\\
& \frac{1}{x} F_{2}^{\bar{\nu} A}=2\left[u_{v}^{A}+\Sigma^{A}\right] \tag{33}
\end{align*}
$$

Furthermore, we have

$$
\begin{align*}
& \frac{1}{x} F_{2}^{\nu A}+F_{3}^{\nu A}=4\left(d^{A}+s^{A}\right),  \tag{34}\\
& \frac{1}{x} F_{2}^{\bar{\nu} A}-F_{3}^{\bar{\nu} A}=4\left(\bar{d}^{A}+\bar{s}^{A}\right) . \tag{35}
\end{align*}
$$

Since we constrain the strange distribution utilizing the dimuon data, the latter two structure functions are useful to separately extract the $d^{A}$ and $\bar{d}^{A}$ distributions.

For an isoscalar nucleus we encounter further simplifications. In this case, $u^{A}=$ $d^{A}$ and $\bar{u}^{A}=\bar{d}^{A}=: \bar{q}^{A}$ which implies $u_{v}^{A}=d_{v}^{A}=: v^{A}$. Hence, the independent quark distributions are $\left\{v^{A}, \bar{q}^{A}, s^{A}=\bar{s}^{A}, c^{A}=\bar{c}^{A}, \ldots\right\}$. In particular, we have $F_{2}^{\nu A}=F_{2}^{\bar{\nu} A}$ for an isoscalar target such that our original set of 6 independent structure functions reduces to three independent functions (say $F_{2}^{\nu A}, F_{3}^{\nu A}, F_{3}^{\bar{\nu} A}$ ) under the approximations made.

In a more refined analysis, allowing for a nonvanishing strangeness asymmetry and isospin violation we can evaluate the nonsinglet structure function $\Delta F_{2}^{\nu} \equiv$ $F_{2}^{\nu A}-F_{2}^{\bar{\nu} A}$ with the help of the relations in Eqs. (16)-(19):

$$
\begin{equation*}
\Delta F_{2}^{\nu}=2 x s^{-, A}+x \delta d_{v}^{p / A}-x \delta u_{v}^{p / A}+\Delta x\left[2 u_{v}^{p / A}-2 d_{v}^{p / A}+\delta d_{v}^{p / A}-\delta u_{v}^{p / A}\right] . \tag{36}
\end{equation*}
$$

For a nuclear isoscalar target $(Z=N=A / 2, \Delta=0)$ this expression simplifies to

$$
\begin{equation*}
\Delta F_{2}^{\nu}=2 x s^{-, A}+x \delta d_{v}^{p / A}-x \delta u_{v}^{p / A} \tag{37}
\end{equation*}
$$

As one can see, $\Delta F_{2}^{\nu}$ will be small and sensitive to the strangeness asymmetry and isospin violating terms for the valence quarks.

The difference of the neutrino and antineutrino cross-sections provides, in principle, access to this quantity:

$$
\begin{equation*}
\frac{d^{2} \sigma^{\nu} A}{d x d y}-\frac{d^{2} \sigma^{\bar{\nu}} A}{d x d y} \simeq K\left[\Delta F_{2}^{\nu}+x F_{3}^{\nu}+(1-y)^{2}\left(\Delta F_{2}^{\nu}-x F_{3}^{\nu}\right)\right] \tag{38}
\end{equation*}
$$

with $F_{3}^{\nu}=F_{3}^{\nu A}+F_{3}^{\bar{\nu} A}$.
It is important to note that in the global fit to extract structure functions we do not make use of the above simplifications, but instead we perform a complete $\chi^{2}$-analysis of all neutrino and antineutrino cross-section data.

## 6. Isospin (Charge Symmetry) Violation and $\Delta x F_{3}$

The question of isospin violation is central to the PW electroweak measurement. In the NuTeV analysis, isospin symmetry was assumed. As discussed in Ref. 3, various models which admit isospin violation can pull the $\mathrm{NuTeV} \sin \theta_{W}$ measurement toward the Standard Model. However it would take significantly larger isospin violation to bring NuTeV into agreement with the rest of the world's data. Better constraints of isospin violation will be crucial to the interpretation of the NuSOnG results.

When we relate DIS measurements from heavy targets such as ${ }_{26}^{56} \mathrm{Fe}$ (used in NuTeV ) or ${ }_{82}^{207} \mathrm{~Pb}$ (CHORUS) back to a proton or isoscalar target, we generally make use of isospin symmetry where we assume that the proton and neutron PDF's can be related via a $u \leftrightarrow d$ interchange. While isospin symmetry is elegant and well motivated, the validity of this exact charge symmetry must ultimately be established by experimental measurement. There have been a number of studies investigating isospin symmetry violation; ${ }^{41-47}$ therefore, it is important to be aware of the magnitude of potential violations of isospin symmetry and the consequences on the extracted PDF components. For example, the naive parton model relations are modified if we have a violation of exact $p \leftrightarrow n$ isospin-symmetry, or charge symmetry violation (CSV); e.g. $u^{n}(x) \not \equiv d^{p}(x)$ and $u^{p}(x) \not \equiv d^{n}(x)$.

It is noteworthy that a violation of isospin symmetry is automatically generated once QED effects are taken into account. ${ }^{48-50}$ This is because the photon couples to the up quark distribution $u^{p}(x)$ differently than to the down quark distribution $d^{n}(x)$. These terms can be as much as a few percent in the medium $x$ range, see e.g. Fig. 1 in Ref. 50.

Combinations of structure functions can be particularly sensitive to isospin violations, and NuSOnG is well suited to measure some of these observables. For example, residual $u, d$-contributions to $\Delta x F_{3}=x F_{3}^{\nu}-x F_{3}^{\bar{\nu}}$ from charge symmetry violation would be amplified due to enhanced valence components $\left\{u_{v}(x), d_{v}(x)\right\}$, and because the $d \rightarrow u$ transitions are not subject to slow-rescaling corrections which suppress the $s \rightarrow c$ contribution to $\Delta x F_{3} \cdot{ }^{43}$ Here the ability of NuSOnG to separately measure $x F_{3}^{\nu}$ and $x F_{3}^{\bar{\nu}}$ over a broad kinematic range will provide powerful constraints on the sensitive structure function combination $\Delta x F_{3}$.

Separately, the measurement of $\Delta F_{2} \equiv \frac{5}{18} F_{2}^{\mathrm{CC}}\left(x, Q^{2}\right)-F_{2}^{\mathrm{NC}}\left(x, Q^{2}\right)$ in Charged Current (CC) $W^{ \pm}$exchange and Neutral Current (NC) $\gamma / Z$ exchange processes can also constrain CSV; ${ }^{45}$ because NuSOnG will measure $F_{2}^{\mathrm{CC}}$ on a variety of targets, this will reduce the systematics associated with the heavy nuclear target corrections thus providing an additional avenue to study CSV.

In the following, we provide a detailed analysis of CSV which also investigates the various experimental systematics associated with each measurement. We shall find it is important to consider all the systematics which impact the various experimental measurements to assess the discriminating power.

## 6.1. $\Delta x F_{3}$ and isospin violations

We recall the leading-order relations of the neutrino structure function $F_{3}$ on a general nuclear target:

$$
\begin{align*}
& \frac{1}{2} F_{3}^{\nu A}(x)=d^{A}+s^{A}-\bar{u}^{A}-\bar{c}^{A}+\cdots  \tag{39}\\
& \frac{1}{2} F_{3}^{\bar{\nu} A}(x)=u^{A}+c^{A}-\bar{d}^{A}-\bar{s}^{A}+\cdots \tag{40}
\end{align*}
$$

where $A$ represents the nuclear target $A=\{p, n, d, \ldots\}$, and the "..." represent higher-order contributions and terms from the third generation $\{b, t\}$ quarks. Note that to illustrate the general features of these processes, we use a schematic notation as in Eqs. (39) and (40); for the numerical calculations, the full NLO expressions are employed including mass thresholds, "slow-rescaling" variables, target mass corrections, and CKM elements where appropriate.

For a nuclear target $A$ we can construct $\Delta x F_{3}^{A}$ as

$$
\begin{align*}
\Delta x F_{3}^{A}= & x F_{3}^{\nu A}-x F_{3}^{\bar{\nu} A} \\
= & 2 x \Delta\left[\left(u^{p / A}-d^{p / A}\right)+\left(\bar{u}^{p / A}-\bar{d}^{p / A}\right)+\frac{1}{2} \delta I^{A}\right] \\
& +2 x s^{+, A}-2 x c^{+, A}+x \delta I^{A}+\mathcal{O}\left(\alpha_{S}\right) \tag{41}
\end{align*}
$$

where $\mathcal{O}\left(\alpha_{S}\right)$ represents the higher-order QCD corrections, and the isospin violations are given by $\delta I^{A}$ :

$$
\begin{equation*}
\delta I^{A}=\delta d-\delta u+\delta \bar{d}-\delta \bar{u} \tag{42}
\end{equation*}
$$

For a flux-weighted linear combination of $F_{3}^{\nu}$ and $F_{3}^{\bar{\nu}}$, terms proportional to the strange quark asymmetry can enter Eq. (41), cf. Refs. 45, 46 and 41. For a signselected $\nu / \bar{\nu}$ beam as for NuTeV or NuSOnG, this complication is not necessary. As before, we have defined $s^{ \pm, A}(x)=\left[s^{A}(x) \pm \bar{s}^{A}(x)\right]$ and $c^{ \pm, A}(x)=\left[c^{A}(x) \pm \bar{c}^{A}(x)\right]$.

In the limit of isospin symmetry, all four terms on the r.h.s. of Eq. (42) vanish individually. For a nuclear isoscalar target, $Z=N=A / 2$, we can construct $\Delta x F_{3}$ from the above:

$$
\begin{equation*}
\Delta x F_{3}=x F_{3}^{\nu A}-x F_{3}^{\bar{\nu} A}=2 x s^{+, A}-2 x c^{+, A}+x \delta I^{A}+\mathcal{O}\left(\alpha_{S}\right) . \tag{43}
\end{equation*}
$$

Note in Eq. (41) that for a nuclear target $A$ which is close to isoscalar, we have $Z \sim N$ such that the up and down quark terms are suppressed; this is a benefit of the NuSOnG glass $\left(\mathrm{SiO}_{2}\right)$ target which is very nearly isoscalar. More specifically, for $\mathrm{SiO}_{2}$ we have $Z(\mathrm{O})=8, Z(\mathrm{Si})=14, m(\mathrm{O})=15.994, m(\mathrm{Si})=28.0855$. Using $A=Z+N$ we have $(N-Z) / A=(A-2 Z) / A$ for the prefactor in Eq. (41) which yields $(N-Z) / A \sim-0.000375$ for O and $(N-Z) / A \sim 0.00304$ for Si.

In Eq. (41) the PDF's $\left\{u^{p / A}, d^{p / A}, \ldots\right\}$ represent quark distributions bound in a nucleus $A$. With a single nuclear target, we can determine the CSV term $\delta I^{A}$ for this specific $A$; measurements on different nuclear targets would be required in order to obtain the $A$ dependence of $\delta I^{A}$ if we need to scale to a proton or isoscalar target.

Thus, an extraction of any isospin violation $\delta I^{A}$ requires a careful separation of these contributions from the strange, charm, and higher-order terms. Theoretical NLO calculations for $\Delta x F_{3}$ are available; thus the $\mathcal{O}\left(\alpha_{S}\right)$ corrections can be addressed. Additionally, NuSOnG can use the dimuon process $\left(\nu N \rightarrow \mu^{+} \mu^{-} X\right)$ to constrain the strange sea.

In conclusion we find that while this is a challenging measurement, NuSOnG's high statistics measurement of $\Delta x F_{3}$ should provide a window on CSV which is relatively free of large experimental systematics. We emphasize that $\Delta x F_{3}$ may be extracted from a single target, thereby avoiding the complications of introducing nuclear corrections associated with different targets. This is in contrast to the other measurements discussed below. However, if we desire to rescale the $\delta I^{A}$ effects to a different nucleus $A$, then multiple targets would be required.

### 6.2. Measurement of $\Delta F_{2} \equiv \frac{5}{18} F_{2}^{\mathrm{CC}}\left(x, Q^{2}\right)-F_{2}^{\mathrm{NC}}\left(x, Q^{2}\right)$

A separate determination of CSV can be achieved using the measurement of $F_{2}$ in CC and NC processes via the relation:

$$
\begin{align*}
\Delta F_{2} \equiv & \frac{5}{18} F_{2}^{\mathrm{CC}, A}\left(x, Q^{2}\right)-F_{2}^{\mathrm{NC}, A}\left(x, Q^{2}\right) \\
\simeq & \frac{1}{6} x \frac{(N-Z)}{A}\left[\left(u^{p / A}-d^{p / A}\right)+\left(\bar{u}^{p / A}-\bar{d}^{p / A}\right)\right] \\
& +\frac{1}{6} x s^{+, A}(x)-\frac{1}{6} x c^{+, A}(x)+\frac{1}{6} x \frac{N}{A} \delta I^{A}+\mathcal{O}\left(\alpha_{s}\right) \tag{44}
\end{align*}
$$

with the definitions

$$
F_{2}^{\mathrm{CC}, A}=\frac{1}{2}\left[F_{2}^{\nu A}+F_{2}^{\bar{\nu} A}\right], \quad F_{2}^{\mathrm{NC}, A}=F_{2}^{\ell A}
$$

In Eq. (44), the first term is proportional to $(N-Z) / A$ which vanishes for an isoscalar target. The second and third terms are proportional to the heavy quark distributions $s^{+, A}$ and $c^{+, A}$. The next term is the CSV contribution which is proportional to $\delta I^{A}$ given in Eq. (42). It is curious that this has the same form as the CSV contribution for $\Delta x F_{3}$ of Eq. (41). Finally, the last term represents the higher-order QCD corrections.

While the character of the terms on the l.h.s. of Eqs. (43), (44) are quite similar, the systematics of measuring $\Delta F_{2}$ may differ substantially from that of $\Delta x F_{3}$. For example, the measurement of $\Delta F_{2}$ requires the subtraction of structure functions from two entirely different experiments. The CC neutrino-nucleon data are extracted from heavy nuclear targets (to accumulate sufficient statistics); as such, these data are generally subject to large nuclear corrections so that the heavy targets can be related to the isoscalar $N=\frac{1}{2}(p+n)$ limit. Conversely, the NC charged-lepton-nucleon process proceeds via the electromagnetic interaction. Therefore sufficient statistics can be obtained for light targets including $H$ and $D$ and no large heavy target corrections are necessary. Therefore, we must use the appropriate nuclear correction factors when we combine $F_{2}^{\mathrm{CC}}$ and $F_{2}^{\mathrm{NC}}$, and this will introduce a systematic uncertainty.

Separately, the heavy quark production mechanism is different in the CC and NC processes. Specifically, in the CC case we encounter the process $s+W^{+} \rightarrow c$ where the charm mass threshold kinematics must be implemented. On the other hand, the NC process is $c+\gamma \rightarrow c$ which is proportional to the charm sea distribution and has different threshold behavior than the CC process. Even though the charm production process is modeled at NLO, the theoretical uncertainties which this introduces can dominate precision measurements.

### 6.3. Other measurements of CSV

We very briefly survey other measurements of CSV in comparison to the above.
The measurement of the lepton charge asymmetry in $W$ decays from the Tevatron can constrain the up and down quark distributions. ${ }^{51,52}$ In this case, the extraction of CSV constraints is subtle; while isospin symmetry is not needed to relate $p$ and $\bar{p}$, this symmetry is typically used in a global fit of the PDF's to reduce data on heavy targets to $p$.

In the limit that all the data in the analysis were from proton targets, CSV would not enter; hence this limit only arises indirectly from the mix of targets which enter a global fit. At present, while much of the data does come from proton targets (H1, ZEUS, CDF, D0), there are some data sets from both $p$ and $d$ (BCDMS, NMC, E866), and some that use heavier targets (E-605, NuTeV). ${ }^{30,53}$ Thus, an outstanding question is if CSV were present, to what extent would this be "absorbed" into a global fit. The ideal procedure would be to parametrize the CSV and include this in a global analysis. While this step has yet to be implemented, there is a recent effort to include the nuclear corrections as a dynamic part of a global fit. ${ }^{39}$

Additionally, NMC measures $F_{2}^{n} / F_{2}^{p}$ data which has an uncertainty of order a few percent. ${ }^{54}$ There are also fixed-target Drell-Yan experiments such as NA51 ${ }^{47}$ and $\mathrm{E} 866^{55}$ which are sensitive to the ratio $\bar{d} / \bar{u}$ in the range $0.04<x<0.27$. We will soon have LHC data $(p p)$ to add to our collection, thus providing additional constraints in a new kinematic region.

### 6.4. Conclusions on charge symmetry violation

NuSOnG will be able to provide high statistics DIS measurements across a wide $x$ range. Because the target material $\left(\mathrm{SiO}_{2}\right)$ is nearly isoscalar, this will essentially allow a direct extraction of the isoscalar observables.
$\Delta x F_{3}$ is one of the cleaner measurements of CSV in terms of associated experimental systematic uncertainties as this measurement can be extracted from a single target. The challenge here will be to maximize the event samples, and the NuSOnG high statistics will play an important role in this regard.

The measurement of $\Delta F_{2}$ is more complicated as this must combine measurements from both CC and NC experiments which introduces nuclear correction factors. ${ }^{56,39}$ Since NuSOnG will provide high statistics $F_{2}^{\mathrm{CC}}$ measurements for a variety of $A$ targets, this will yield an alternate handle on the CSV and also improve our understanding of the associated nuclear corrections.

The combination of these high statistics measurements, together with external constraints, will yield important information on this fundamental symmetry.

## 7. Measurements of the Heavy Quarks

### 7.1. Measurement of the strange sea

Charged current neutrino-induced charm production, $(\nu / \bar{\nu}) N \rightarrow \mu^{+} \mu^{-} X$, proceeds primarily through the subprocesses $W^{+} s \rightarrow c$ and $W^{-} \bar{s} \rightarrow \bar{c}$ (respectively), so this provides a unique mechanism to directly probe the $s(x)$ and $\bar{s}(x)$ distributions. Approximately $10 \%$ of the charmed particles decay into $\mu+X$, adding a second oppositely signed muon in the CC event final state. These "dimuon" events are easily distinguishable, and make up approximately $1 \%$ of the total CC event sample. Hence, the recent high statistics dimuon measurements ${ }^{17,57,18,58,59}$ play an essential role in constraining the strange and antistrange components of the proton. On NuSOnG, the dimuon data will be used in the same manner.

Distinguishing the difference between the $s(x)$ and $\bar{s}(x)$ distributions,

$$
\begin{equation*}
s^{-}(x) \equiv s(x)-\bar{s}(x), \tag{45}
\end{equation*}
$$

is necessary for the PW style analysis. This analysis is sensitive to the integrated strange sea asymmetry,

$$
\begin{equation*}
S^{-} \equiv \int_{0}^{1} x s^{-}(x) d x \tag{46}
\end{equation*}
$$

through its effect on the denominator of the PW ratio, as has been recognized in numerous references. ${ }^{60-64}$

Note that the quantity $\int_{0}^{1} s^{-}(x) d x$ must vanish as the proton carries no net strangeness. Indeed, this condition is a strong constraint on the form of the strange quark distributions. It requires that $s^{-}(x)$ have at least one sign change, which can be see in Fig. 11 at small $x$.

Fig. 11. NuTeV measurement of $x s^{-}(x)$ vs $x$ at $Q^{2}=16 \mathrm{GeV}^{2}$. Outer band is combined errors, inner band is without $B_{c}$ uncertainty.

The highest precision study of $s^{-}$to date is from the NuTeV experiment. ${ }^{57,65}$ The sign selected beam allowed measurement of the strange and antistrange seas independently, recording 5163 neutrino-induced dimuons, and 1380 antineutrino induced dimuon events in its iron target. Figure 11 shows the fit for the asymmetry between the strange and antistrange seas in the NuTeV data.

The integrated strange sea asymmetry from NuTeV has a positive central value: $0.00196 \pm 0.00046$ (stat) $\pm 0.00045$ (syst) $)_{-0.00107}^{+0.00148}$ (external). In NuSOnG, as in NuTeV , the statistical error will be dominated by the antineutrino data set and is expected to be about 0.0002 . The systematic error is dominated by the $\pi$ and $K$ decay-in-flight subtraction. This can be addressed in NuSOnG through test-beam measurements which will allow a more accurate modeling of this background, as well as applying the techniques of CCFR to constrain this rate. ${ }^{66-68}$ We expect to be able to reduce this error to about 0.0002 . The combination of these reduces the total error by about $10 \%$, because the main contribution comes from the external inputs.

The external error on the measurement is dominated by the error on the average charm semimuonic branching ratio, $B_{c}$ :

$$
\begin{equation*}
B_{c}=\Sigma_{i} \int \phi(E) f_{i}(E) B_{\mu-i} d E \tag{47}
\end{equation*}
$$

where $\phi$ is the neutrino flux in energy bins, $f_{i}$ is the energy dependent production fraction for each hadron, and $B_{\mu-i}$ is the semimuonic branching ratio for each hadron. In the NuTeV analysis, this is an external input, with an error of about $10 \%$. To make further progress, this error must be reduced.

Fig. 12. World measurements of $B_{c}$. See Refs. 17, 69-71, 59, 58, 72.

Figure 12 shows the world measurements of $B_{c}$, taken from Refs. 17, 69-71, $59,58,72$. Measuring $B_{c}$ directly requires the capability to resolve the individual charmed particles created in the interaction. The best direct measurements are from experiments using emulsion detectors (E531, CHORUS) where the decay of the charmed meson is well tagged. ${ }^{71,72}$ Since the cross-section for charmed meson production is energy dependent, it is important to make a measurement near the energy range of interest. The NuTeV strange sea asymmetry study used a re-analysis of 125 charm events measured by the FNAL E531 experiment ${ }^{71}$ in the energy range of the NuTeV analysis $\left(E_{\nu}>20 \mathrm{GeV}\right) . B_{c}$ has also been constrained through indirect measurement via fits.

For NuSOnG, our goal is to reduce the error on $B_{c}$ using an in situ measurement on glass by at least a factor of 1.5 . One method is to include $B_{c}$ as a fit parameter in the analysis of the dimuon data. The unprecedented high statistics will allow a fit as a function of neutrino energy for the first time. Dimuons from high $x$ neutrino DIS almost exclusively result from scattering off valence quarks, such that the dimuon cross-section in that region isolates $B_{c}$ from the strange sea. In dimuon fits, the assumption is that $B_{c-\nu}=B_{c-\bar{\nu}}, B_{c}$ may be measured directly from the dimuon data.

Unfortunately, the antineutrino charm production process is not well measured by past experiments; hence, there is concern that the assumption $B_{c-\nu}=B_{c-\bar{\nu}}$ may not be accurate. For example, the fact that the process $\nu n \rightarrow \mu^{-} \Lambda_{c}$ has no analogous reaction in the antineutrino channel may lead to a difference in the neutrino and antineutrino branching ratios.

These arguments provide the motivation for including a high resolution target/ tracker in the NuSOnG design that can directly measure the semileptonic branching ratio to charm in both $\nu$ and $\bar{\nu}$ running modes. There are two feasible detector technologies. The first is to use emulsion, as in past experiments; this is proven technology and scanning could be done at the facility in Nagoya, Japan. The second is to use the NOMAD-STAR detector ${ }^{73,74}$ or a similar design. This is a 45 kg silicon vertex detector which ran in front of the NOMAD experiment. The target was boron carbide interleaved with the silicon. This detector successfully measured 45 charm events in that beam, identifying $D^{+}, D^{0}$ and $D_{s}$. A similar detector of this size in the NuSOnG beam would yield about $900 \nu$ events and $300 \bar{\nu}$ events. This has the advantage of being a low- $Z$ material which is isoscalar and close in mass to the $\mathrm{SiO}_{2}$ of the detector.

### 7.2. Strange quark contribution to the proton spin

An investigation of the strange quark contribution to the elastic vector and axial form factors of the proton is possible in NuSOnG, by observing NC elastic and CC quasielastic scattering events; namely $\nu p \rightarrow \nu p$ and $\nu n \rightarrow \mu^{-} p$ events in neutrino mode, and $\bar{\nu} p \rightarrow \bar{\nu} p$ and $\bar{\nu} p \rightarrow \mu^{+} n$ events in antineutrino mode. The motivation for making this measurement comes from a number of recent (and not so recent) studies of proton structure.

Over the last 15 years a tremendous effort has been made at MIT-Bates, Jefferson Lab, and Mainz to measure the strange quark contribution to the vector form factors (that is, the electromagnetic form factors) of the proton via parity-violating electron scattering from protons, deuterons, and ${ }^{4} \mathrm{He} .{ }^{75-85}$ The technique is to observe the parity-violating beam spin asymmetry in elastic scattering of longitudinally polarized electrons from these unpolarized targets; this asymmetry is caused by an interference between the one-photon and one- $Z$ exchange amplitudes. ${ }^{86}$ As a result, the weak neutral current analog of the electromagnetic form factors of the proton may be measured and this gives access to the strange quark contribution. This worldwide experimental program will soon be complete. The results available to date (from global analyses ${ }^{87-89}$ ) indicate a small (and nearly zero) contribution of the strange quarks to the elastic electric form factor, $G_{E}^{s}$; this is not surprising, as the total electric charge in the proton due to strange quarks is zero. At the same time, these same data point to a small but likely positive contribution of the strange quarks to the elastic magnetic form factor, $G_{M}^{s}$, indicating a small positive contribution of the strange quarks to the proton magnetic moment. Due to the prominent role played by the $Z$-exchange amplitude, these experiments are also sensitive to the strange quark contribution to the elastic axial form factor, which is related to the proton spin structure.

It is now well established by leptonic deep inelastic scattering experiments that the spins of the valence and sea quarks in the proton together contribute about $30 \%$ of the total proton intrinsic angular momentum of $\hbar / 2$. The strange quark
contribution is estimated to be about $-10 \%$ for inclusive DIS (an analysis which makes use of $\mathrm{SU}(3)$-flavor symmetry), ${ }^{90}$ but is found to be approximately zero in semiinclusive DIS (an alternative analysis which makes no use of $\mathrm{SU}(3)$ but needs fragmentation functions instead). ${ }^{91} \mathrm{~A}$ recent global analysis ${ }^{92}$ made use of both inclusive and semiinclusive DIS, and allowed for the possibility of SU(3)-flavor violation; this analysis found no need for any violation of $\operatorname{SU}(3)$, and also concluded that the strange quark contribution to the proton spin was small and negative. In the deep inelastic context, the contribution of the strange quarks to the proton spin is encapsulated in the spin-dependent strange quark parton distribution function,

$$
\Delta s(x)=s^{\rightarrow}(x)-s^{\leftarrow}(x)
$$

where $s^{\rightarrow}(x)\left[s^{\leftarrow}(x)\right]$ is the probability density for finding a strange quark of momentum fraction $x$ with its spin parallel [antiparallel] to the proton spin. The axial current relates the first moment of this parton distribution function to the elastic axial form factor of the proton, ${ }^{93} G_{A}^{s}$, at $Q^{2}=0$ :

$$
\int_{0}^{1} d x \Delta s(x)=G_{A}^{s}\left(Q^{2}=0\right) .
$$

The strange quark contribution to the elastic axial form factor can be measured by combining data from neutrino NC elastic scattering from the proton with data from parity-violating elastic $\overrightarrow{e p}$ scattering. ${ }^{94}$ In this way the strange quark contribution to the proton spin can be measured in a completely independent way using low$Q^{2}$ elastic scattering instead of high- $Q^{2}$ deep inelastic scattering. An analysis done using this method ${ }^{87}$ indicates that $G_{A}^{s}$ may in fact be negative at $Q^{2}=0$, but this conclusion is not definitive due to the limitations of the currently available neutrino data.

Since the neutrino experiments will undoubtedly be carried out on nuclear targets (perhaps carbon or argon), then the extraction of the strangeness form factors of the proton from these data needs to be done with care. Recent theoretical investigations suggest that ratio of NC to CC events is an ideal observable as the nuclear effects appear to largely cancel in this ratio. ${ }^{95}$ This is an area where the improved nuclear corrections discussed in Sec. 4 would prove a valuable cross check on these measurements.

The only available data on neutrino NC elastic scattering is from the BNL E734 experiment; ${ }^{96}$ the uncertainties reported from that experiment are considerable, and therefore limit the accuracy of any extraction of $G_{A}^{s}$ based on this data. If NuSOnG can provide more precise measurements of NC elastic scattering extended to lower $Q^{2}$ values, then the promise of this analysis technique can be fulfilled. Since the integrated luminosity of NuSOnG will be very much larger, far more statistics will be collected on the NC elastic process than in BNL E734. As this process has not been modeled for the proposed NuSOnG detector with a detailed Monte Carlo calculation, we cannot make any quantitative statement about the systematic uncertainties at present.

### 7.3. Measurements of the charm sea

### 7.3.1. Charm production

We can also study the charm-sea component of the proton which can arise from the gluon splitting process $g \rightarrow c \bar{c}$ producing charm constituents inside the proton. ${ }^{97-99}$ In a measurement complementary to the above strange sea extraction, the charm sea, $c(x, \mu)$, can be measured using the following process:

$$
\begin{aligned}
\nu_{\mu}+c \rightarrow \nu_{\mu}+ & c \\
& \hookrightarrow s+\mu^{+}+\nu_{\mu}
\end{aligned}
$$

In this process, we excite a constituent charm quark in the proton via the NC exchange of a $Z$ boson; the final state charm quark then decays semileptonically into $s \mu^{+} \nu_{\mu}$. We refer to this process as Wrong Sign Muon (WSM) production as the observed muon is typically the opposite sign from the expected $\nu_{\mu} d \rightarrow \mu^{-} u$ DIS process. For antineutrino beams, there is a complementary process $\bar{\nu}_{\mu}+\bar{c} \rightarrow \bar{\nu}_{\mu}+\bar{c}$ with a subsequent $\bar{c} \rightarrow \bar{s}+\mu^{-}+\bar{\nu}_{\mu}$ decay with yields a WSM with respect to the conventional $\bar{\nu}_{\mu} u \rightarrow \mu^{+} d$ process. Here, the ability of NuSOnG to have sign-selected beams is crucial to this measurement as it allows us to distinguish the secondary muons, and thus extract the charm-sea component.

In the conventional implementation of the heavy quark PDF's, the charm quark becomes an active parton in the proton when the scale $\mu$ is greater than the charm mass $m_{c}$; i.e. $f_{c}(x, \mu)$ is nonzero for $\mu>m_{c}$. Additionally, we must "rescale" the Bjorken $x$ variable as we have a massive charm in the final state. The original rescaling procedure is to make the substitution $x \rightarrow x\left(1+m_{c}^{2} / Q^{2}\right)$ which provides a kinematic penalty for producing the heavy charm quark in the final state. ${ }^{100}$ As the charm is pair-produced by the $g \rightarrow c \bar{c}$ process, there are actually two charm quarks in the final state - one which is observed in the semileptonic decay, and one which decays hadronically and is part of the hadronic shower. Thus, the appropriate rescaling is not $x \rightarrow x\left(1+m_{c}^{2} / Q^{2}\right)$ but instead $x \rightarrow \chi=x\left(1+4 m_{c}^{2} / Q^{2}\right)$; this rescaling is implemented in the ACOT- $\chi$ scheme, for example. ${ }^{101-103}$ The factor $\left(1+4 m_{c}^{2} / Q^{2}\right)$ represents a kinematic suppression factor which will suppress the charm process relative to the lighter quarks.

The differential cross-section for NC neutrino scattering is
$\frac{d \sigma}{d x d y}(\nu p \rightarrow \nu c)=\frac{G_{F}^{2} M_{N} E_{\nu}}{\pi} R_{Z}^{2}\left(Q^{2}\right)\left[g_{L}^{2}+g_{R}^{2}(1-y)^{2}-\frac{1}{2}\left(2 g_{L} g_{R}\right) \frac{M_{N}}{E_{\nu}}\right] \xi c(\xi, \mu)$,
where $g_{L}=t_{3}-Q_{c}^{2} \sin ^{2} \theta_{W}, g_{R}=-Q_{c}^{2} \sin ^{2} \theta_{W}$, and for charm $t_{3}=1 / 2$ and $Q_{c}=2 / 3$. The factor $R_{Z}\left(Q^{2}\right)=1 /\left(1+Q^{2} / M_{Z}^{2}\right)$ arises from the $Z$-boson propagator. The corresponding result for the anticharm is given with the substitutions $g_{L} \leftrightarrow g_{R}$ and $c \leftrightarrow \bar{c}$.

In the limit we can neglect the $M_{N} / E_{\nu}$ term, we have the approximate expressions for the total cross-section: ${ }^{98}$

$$
\begin{equation*}
\sigma(\nu p \rightarrow \nu c) \sim \frac{G_{F}^{2} M_{N} E_{\nu}}{\pi}(0.129) C \tag{48}
\end{equation*}
$$

and

$$
\begin{equation*}
\sigma(\nu p \rightarrow \nu \bar{c}) \sim \frac{G_{F}^{2} M_{N} E_{\nu}}{\pi}(0.063) \bar{C} \tag{49}
\end{equation*}
$$

with $C=\int_{\xi_{\text {min }}}^{1} \xi c(\xi, \mu) d \xi$ and $\bar{C}=\int_{\xi_{\text {min }}}^{1} \xi \bar{c}(\xi, \mu) d \xi$. We take $\xi=x\left(1+4 m_{c}^{2} / Q^{2}\right)$ and $\xi_{\text {min }}=m_{c}^{2} /\left(2 M_{N} \nu\right)$.

We will be searching for the WSM signal compared to the conventional CC DIS process; therefore it is useful to benchmark the rate for WSM production by comparing this to the usual CC DIS process,

$$
\begin{equation*}
\frac{d \sigma}{d x d y}\left(\nu p \rightarrow \mu^{-} X\right)=\frac{G_{F}^{2} M_{N} E_{\nu}}{\pi} R_{W}^{2}\left(Q^{2}\right)\left[q(x)+(1-y)^{2} \bar{q}(x)\right] \tag{50}
\end{equation*}
$$

with $R_{W}\left(Q^{2}\right)=1 /\left(1+Q^{2} / M_{W}^{2}\right)$. We can again integrate over $x$ and $y$ to obtain an estimate of the total cross-section in terms of the integrated PDF's as in Eqs. (48) and (49):
$\sigma\left(\nu N \rightarrow \mu^{-} X\right) \sim \frac{G_{F}^{2} M_{N} E_{\nu}}{\pi} R_{W}^{2}\left(Q^{2}\right) \frac{1}{2}\left[U+D+2 S+\frac{1}{3}(\bar{U}+\bar{D}+2 \bar{C})\right]$,
where $\{U, D, S\}$ are defined analogously to $C$, and we have used $N=\frac{1}{2}(p+n)$ for an isoscalar target.

The relative rate for NC charm production is determined by the above factors together with a ratio of integrated PDF's. For a mean neutrino energy of 100 GeV , the massive charm cross-section is down a factor of $\sim 0.005$ compared to the total inclusive cross-section. As the muon from the NC charm process is a secondary muon, we must additionally fold in the semileptonic branching ratio $B_{c} \sim 10 \%$, and the acceptance factor of observing the secondary muon in the detector $\left(A_{\mu} \sim 20 \%\right) .{ }^{17}$ Combining the relevant factors, we estimate the rate for NC charm production is approximately a factor of $10^{-4}$ as compared to the CC DIS process. Thus, for an anticipated design of $600 \mathrm{M} \nu_{\mu}$ CC events, one would expect on the order of 60 K NC charm events. This estimate is also consistent with a direct scaling from the NuTeV result of Ref. 99.

### 7.3.2. Backgrounds

Extrapolating from investigations by CCFR, ${ }^{98}$ and $\mathrm{NuTeV},{ }^{99}$ the dominant background for the measurement of the charm sea comes from $\bar{\nu}_{\mu}$ contamination. In these studies, it was determined that by demanding $E_{\text {vis }}>100 \mathrm{GeV}$, the background rate could be reduced to $2.3 \times 10^{-4}$. Other background processes include $\nu_{e}$ induced dilepton production, misidentified dimuon events, and NC interactions with a $\pi / K$ decay in the hadron shower; these processes contribute approximately an additional $1.5 \times 10^{-4}$ to the background rate. As compared to CCFR and NuTeV , the NuSOnG design has a number of improvements such as lower mass density for improved shower measurement; hence, comparable background reductions should be achievable.

Fig. 13. Integrated momentum fractions $\int_{0}^{1} x f_{i}(x, Q)$ of charm (upper curve) and bottom (lower curve) PDF's (in percent) vs $Q$ in GeV . Both the quark and antiquark contributions are included. Horizontal lines at $0.5 \%$ and $1.0 \%$ are indicated as this is the typical size of postulated intrinsic contributions.

### 7.3.3. Intrinsic charm

In the above discussion we have assumed that the charm component of the proton arises perturbatively from gluons splitting into charm quark pairs, $g \rightarrow c \bar{c}$; in this scenario the charm PDF typically vanishes at scales below the charm mass $\left(f_{c}\left(x, \mu<m_{c}\right)=0\right)$, and for $\mu>m_{c}$ all the charm partons arise from gluon splitting.

There is an alternative picture where the charm quarks are taken to be intrinsic to the proton; in this case there are intrinsic charm partons present at scales $\mu<m_{c}$. For $\mu>m_{c}$, the charm PDF is then a combination of this "intrinsic" PDF and the "extrinsic" PDF component arising from the $g \rightarrow c \bar{c}$ process.

A number of analyses have searched for an intrinsic charm component of the proton, and this intrinsic component is typically constrained to have an integrated momentum fraction less than a percent or two. ${ }^{104,105}$

In Fig. 13 we display the integrated momentum fraction, $\int_{0}^{1} x f_{i}(x, \mu)$, for charm and bottom as a function of $\mu$ due to the "extrinsic" PDF component arising from the $g \rightarrow c \bar{c}$ or $g \rightarrow b \bar{b}$ process. These momentum fractions start from zero at the corresponding quark mass, and increase slowly as the partonic components pick up momentum from the gluon splitting process.

If we are searching for an additional intrinsic component with a momentum fraction of $\sim 1 \%$, we will be most sensitive to such a component in the threshold region where the "intrinsic" component is not overwhelmed by the "extrinsic" contribution. In this regard, NuSOnG is well suited to search for these intrinsic terms as it will provide good statistics in the threshold region. Measuring the charm production process described above, NuSOnG can attempt to extract the charm PDF as a function of the $\mu$ scale, and then evolve back to $\mu=m_{c}$. Three outcomes are possible:
(i) $f_{c}\left(x, \mu=m_{c}\right)<0$, which would imply the data are inconsistent with the normal QCD evolution. ${ }^{\text {d }}$
(ii) $f_{c}\left(x, \mu=m_{c}\right)=0$, which would imply the data is consistent with no intrinsic charm PDF.
(iii) $f_{c}\left(x, \mu=m_{c}\right)>0$, which would imply the data is consistent with an intrinsic charm PDF.

By making accurate measurements of charm induced processes in the threshold region, NuSOnG can provide a discriminating test to determine which of the above possibilities is favored. Hence, the high statistics of NuSOnG in the threshold region are well suited to further constrain the question of an intrinsic charm component.

## 8. Summary and Conclusions

The NuSOnG experiment can search for "new physics" from the keV through TeV energy scales. This article has focused mainly on the QCD physics which can be accessed with this new high energy, high statistics neutrino scattering experiment. During its five-year data acquisition period, the NuSOnG experiment could record almost one hundred thousand neutrino-electron elastic scatters and hundreds of millions of DIS events, exceeding the current world data sample by more than an order of magnitude.

With this wealth of data, NuSOnG can address a wide variety of topics including the following.

- NuSOnG can increase the statistics of the Elastic Scattering (ES) and Deeply Inelastic Scattering (DIS) data sets by nearly two orders of magnitude.
- The unprecedented statistics of NuSOnG allow the possibility to perform separate extractions of the structure functions: $\left\{F_{2}^{\nu}, x F_{3}^{\nu}, R_{L}^{\nu}, F_{2}^{\bar{\nu}}, x F_{3}^{\bar{\nu}}, R_{L}^{\bar{\nu}}\right\}$. This allows us to test many of the symmetries and assumptions which were employed in previous structure function determinations.
- NuSOnG will help us to disentangle the nuclear effects which are present in the PDF's. Furthermore, this may help us address the long-standing tensions between the NC charged-lepton and CC neutrino DIS measurements.
- High precision NuSOnG measurements are sensitive to Charge Symmetry Violation (CSV) and other "new physics" processes. Such effects can significantly influence precision Standard Model parameter extractions such as $\sin \theta_{W}$. In particular, $\Delta x F_{3}$ is a sensitive probe of both the heavy quark components, and CSV effects.
- NuSOnG dimuon production provides an exceptional probe of the strange quark PDF's, and the sign-selected beam can separately study $s(x)$ and $\bar{s}(x)$. Additionally, NuSOnG can probe the $s$-quark contribution to the proton spin.

[^295]- The high statistics of NuSOnG may allow the measurement of the charm sea and an method to prove the intrinsic-charm content of the proton. While this is a difficult measurement, the NuSOnG kinematics allow the measurement of charm-induced processes in the threshold region where the "intrinsic" character can most easily be discerned.

While the above list presents a very compelling physics case for NuSOnG, this is only a subset of the full range of investigations that can be addressed with this facility.

## Acknowledgments

We thank the following people for their informative discussions regarding neutrinonucleus interactions, and their thoughtful comments on the development of this physics case: Andrei Kataev, Sergey Kulagin, P. Langacker, Roberto Petti, M. Shaposhnikov, F. Vannucci and J. Wells. We acknowledge the support of the following funding agencies for the authors of this paper: Deutsche Forschungsgemeinschaft, The Kavli Institute for Theoretical Physics, The United States Department of Energy and The United States National Science Foundation.

### 17.3 RESULTS OF THE COMPARISON

In this section, we compare the results of different theoretical descriptions for $W+n$-jets production at the LHC. The number $n$ can take values from 2 and above, as we will mostly consider inclusive samples. The four descriptions, which we will compare here in more detail, are

- the $B H S$ calculation of $W+2$-jets at NLO,
- the combined sample of $W+2,3,4$-jet events at NLO from $B H S$, as described in the 17.2 section,
- the $S$-MEPS merged $W+n$-jets sample using LO tree-level matrix elements up to $n=5$, and
- the approach of $H E J$.

Throughout this study, we will consider inclusive samples of $W^{-}$boson production in association with at least two hard jets identified by the anti- $k_{T}$ jet algorithm using $R=0.4$. The jets are required to have $p_{T, j}>25 \mathrm{GeV}$. We look only in the $W^{-} \rightarrow e^{-} \bar{\nu}_{e}$ decay channel and use the cuts given in Tab. 12 where $M_{\perp, W}$ is defined as $M_{\perp, W}=\sqrt{\left(\left|\vec{p}_{T, e}\right|+\left|\vec{p}_{T, \nu}\right|\right)^{2}-\left(\vec{p}_{T, e}+\vec{p}_{T, \nu}\right)^{2}}$.

The HEJ predictions use the geometric mean of the jet transverse momenta to determine the renormalisation and factorisation scale, i.e. $\left(\prod p_{T, j}\right)^{1 / n}$. This central choice will be varied by a factor of two in either direction to provide an envelope (marked by dotted lines in the corresponding figures) around the HEJ default prediction. The BHS predictions instead use $\hat{H}_{T}^{\prime} / 2$ as the NLO calculation becomes unstable for a scale which is too low. In the $S$-MEPS calculation, scales are chosen according to the default prescription given by ME\&TS [426].

The variables $H_{T, 2}, p_{T, W}$ and $p_{T, j_{1}}$ are less sensitive to the presence of additional radiation than $H_{T}$, as discussed in the introduction. The plots, which we present in Figs. 56 and 57 address the alternative question: given a particular value of $H_{T}, H_{T, 2}$ etc. how many jets are typically found in the event?

Figs. 56 and 57 show the stacked results for the average number of jets as a function of $p_{T, W}, p_{T, j_{1}}$, $H_{T}$ and $H_{T, 2}$ visualising the contributions from each exclusive 2,3,4-jet sample and the inclusive 5 -jet

Fig. 57: The contribution from different multiplicities to the average number of jets as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the BHS exclusive sums prediction, while the lower ones are extracted from S-MEPS.
sample. The left (right) plot in Fig. 56 and the upper (lower) rows of plots in Fig. 57 depict the results as obtained from the combined BHS sample (the $S$-MEPS sample). In all cases the different colours correspond to the terms in the numerator of the formula for the average number of jets,

$$
\begin{equation*}
\langle N\rangle_{5}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{106}
\end{equation*}
$$

where blue, green, red and magenta stand for $i=2,3,4$ and $i=5$, respectively. The subscript to $\langle N\rangle$ clarifies that we truncate the determination of the average after the fifth jet bin, noting that $\langle N\rangle_{k} \rightarrow\langle N\rangle$ for a sufficiently large number of jet bins. This makes no difference for the BHS predictions employed here since the jet multiplicity de facto is limited to five, but it does for the $S$-MEPS and HEJ computations where events with $i>5$ jets do occur. We have defined $n_{k}^{\text {exc } / \mathrm{inc}}=d \sigma_{k}^{\text {exc } / \mathrm{inc}} / d O$ where $O$ denotes an observable like $H_{T}$, or $\Delta y$ presented later on. Note that in Fig. 57 the 5 -jet part contributes to the average number of jets with a factor of 5 , while the 2 -jet part, for example, contributes with a factor of 2 only.

The layout of Fig. 58 (including the colour coding) is the same as before: here, we however display, wrt. $n_{2}^{\text {inc }}$, the relative fractions of the different multiplicities corresponding to the terms in the denominator of Eq. (106). In other words, in Fig. 58 we consider the partitioning of

$$
\begin{equation*}
1=\frac{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{107}
\end{equation*}
$$

Fig. 58: The fraction of the total rate from different multiplicities as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the $B H S$ exclusive sums prediction, while the lower ones are extracted from $S$-MEPS.

Although there is just a $30 \%$ fraction of inclusive 5 -jet events to the total cross section, we observe that their contribution to the build-up of $\langle N\rangle\left(H_{T}\right)$ for very large $H_{T}$ gets close to $50 \%$. Also, for an $H_{T} \sim$ 500 GeV , the average number of jets is composed evenly between the 2,3 -jet and 4,5 -jet contributions, while the relative fraction of the 2,3 -jet events is nearly $70 \%$. This emphasizes the dominance of multijet events in forming large $H_{T}$ values. It also can be seen that for medium $H_{T}$ values, $400<H_{T}<$ 700 GeV , all the multiplicities give roughly the same contribution to the variable $\langle N\rangle\left(H_{T}\right)$, while for low $H_{T}$, the average is primarily described by 2-jet events.

Going clockwise through Figs. 56 and 57 we see that the average number of jets is indeed sensitive to higher multiplicities when considered as a function of $p_{T, W}, p_{T, j_{1}}$ and $H_{T, 2}$, but in all these cases this happens to a lesser extent as if considered as a function of $H_{T}$. As expected, the dependence is mildest for $p_{T, W}$, the most inclusive observable studied here. We also observe that the jet-bin decomposition of $p_{T, j_{1}}$ and $H_{T, 2}$ turns out very similar. Most strikingly we note the increase in the contribution from the highest multiplicity events, the ones containing more or at least five jets. For $H_{T, 2}$, we furthermore display to the right of Fig. 58 the relative fractions as done in the $H_{T}$ case. Even for largest $H_{T, 2}$ values, the fraction arising from 2,3 -jet events remains close to $65 \%$ stressing once more the lower sensitivity of $H_{T, 2}$ versus $H_{T}$ regarding multiple jet production.

Finally, we compare the plots from the combined BHS samples in all figures to the corresponding ones generated with the $S$-MEPS sample. Interestingly, the outcome looks very similar although ME\&TS handles the single terms in Eq. (105) rather differently. They are calculated at least at leading (soft/collinear) logarithmic accuracy improved by LO $n$-jet effects. Presumably, for the exclusive jet bins, this description (which allows a better treatment of jet vetoes) is not too far off the exclusive sums

Fig. 59: Average number of jets as a function of $H_{T}$ (left) and $\Delta y$ (right) in two BHS descriptions, from $H E J$ and from $S$-MEPS, the latter using the $\langle N\rangle_{7}$ definition. The bands shown with dotted lines for the HEJ prediction are a result of varying the scale by a factor of 2 in each direction.
approach, since the unresolved $\mathcal{O}\left(\alpha_{s}\right)$ corrections are also present in the Sudakov form factors applied in the ME\&TS approach. Also, the combined BHS samples as well as the $S$-MEPS sample use the same tree-level matrix elements, namely up to $W+5$-parton matrix elements. Clearly, it has to be studied further whether this similarity in the results is a coincidence or not.

It is clear that the impact of the higher multiplicity samples is significant throughout, especially in the high $H_{T}$ tail. This is precisely the region, which would be probed for signs of new physics, and therefore it is essential that we fully understand our theoretical descriptions in this region. This is the subject of the remainder of this contribution, where we compare all four different methods of modelling hard QCD radiation in inclusive $W+2$-jet events.

The left plot of Fig. 59 shows the final comparison plot between the exclusive sums and inclusive 2-jet $B H S$ results as well as the $H E J$ and $S-M E P S$ predictions for the average number of jets as a function of $H_{T}$. The differences in the descriptions are significantly larger than the scale uncertainty band on the $H E J$ prediction. For the $W+2$-jet NLO result, the number of jets rises to 2.6 already at $H_{T}=500 \mathrm{GeV}$ but that levels off significantly below the $S-M E P S$, exclusive $B H S$ sum and $H E J$ results. The $H E J$ results level off at a higher value of about 3.0 , starting to clearly disagree with the exclusive sums and $S$-MEPS predictions above 500 GeV , from where those two curves keep rising to a final level of around 3.7 to 4.0. The $S$-MEPS comes in highest at largest $H_{T}$, where $\langle N\rangle_{7}$ is shown, cf. Eq. (106), in order to determine the average number of jets for this $S$-MEPS result. The reason for giving slightly higher $\langle N\rangle$ than the exclusive sums lies in the contribution of additional parton-shower jets present in the $S$-MEPS calculation and more accurately accounted for by the use of the $\langle N\rangle_{7}$ definition as compared to the earlier result based on $\langle N\rangle_{5}$ presented in Fig. 57 to the lower left.

In the right panel of Fig. 59, we have plotted the average number of jets as a function of the rapidity span, $\Delta y$, instead of $H_{T}$ as before. Again the differences are larger than the scale variation shown on the HEJ result, but the ordering is different to that of the left plot of Fig. 59. All four descriptions increase linearly with $\Delta y$ but the gradient is steepest for the HEJ predictions where the average rises above 3.0 for $\Delta y$ values as large as 6.0. The BHS exclusive sum result is consistently below this, reaching about 2.8 at $\Delta y=6.0$, and agrees pretty well with the $S$-MEPS result based on $\langle N\rangle_{7}$. The NLO $W+2$-jet prediction given by $B H S$ is lower still, between 2.4 and 2.5 for $\Delta y \sim 5.0$.

It may seem surprising that on the plot on the left-hand side the exclusive sums and S-MEPS lie higher for most of the distribution whereas on the right-hand side these approaches as well as $H E J$ give predicitions that are commensurate. The region of high $H_{T}$ and that of high $\Delta y$ however are largely distinct as it is very expensive to have both a large rapidity and large $p_{T}$ for the jets. Also while radiating

Fig. 60: The ratio of the inclusive 3 -jet and 2 -jet rates in the inclusive $W+2$-jet NLO and exclusive sum description of $B H S$ as well as in the $S$-MEPS and $H E J$ approaches as a function of $H_{T}$ (left) and $\Delta y$ (right). Again, the dotted lines indicate the uncertainty band from varying the scale in $H E J$ by a factor of 2 in each direction.
an additional jet automatically moves an event towards the higher $H_{T}$ direction, radiating an additional jet tends to not change the rapidity difference. So, we expect the higher multiplicies to have a smaller effect on the average number of jets as a function of $\Delta y$ compared to as a function of $H_{T}$. This is indeed the case in Fig. 59.

Lastly, in Fig. 60 we plot the ratio of the inclusive 3 -jet to the inclusive 2 -jet rate as a function of $H_{T}$ (left) and $\Delta y$ (right), again for all four descriptions used here. The predicted $\left(d \sigma_{3}^{\text {inc }} / d H_{T}\right) /\left(d \sigma_{2}^{\text {inc }} / d H_{T}\right)$ all agree very well below 400 GeV . The fixed order $B H S$ result for $W+2$ jets is highest for large $H_{T}$, however is known to become unreliable here, since the probability that an inclusive 2 -jet event is at least a 3 -jet event turns too large, being in conflict with the expected behaviour of an $\mathcal{O}\left(\alpha_{s}\right)$ correction. The BHS exclusive sums, the S-MEPS and the HEJ results, in this order, level off considerably lower with the HEJ fraction staying below $60 \%$ to $70 \%$, which leaves the other predictions again above the $H E J$ uncertainty envelope. In contrast, when the same ratio of jet rates is plotted against $\Delta y$, the $H E J$ prediction is consistently higher throughout. This again emphasises that differences in the descriptions come to light in different kinematic regions. However, in both cases here the magnitude of the differences is relatively small and would be rather difficult to distinguish in present experimental data.

### 17.4 CONCLUSIONS

We have compared a number of theoretical descriptions of $W^{-}$production in association with at least two jets. After outlining one possible method of combining NLO calculations of different multiplicities, we compared this with a pure NLO calculation of $W+2$-jets production obtained by BLACKHAT+SHERPA, a sample of leading-order events merged using the ME\&TS method of SHERPA, and the high-energy resummation of the HEJ framework.

We studied the average number of jets and the ratio of the 3 -jet and 2 -jet inclusive cross sections as a function of $\Delta y$ and of $H_{T}$. We find, with these simple cuts, some clear differences in the predictions when we study the average number of jets as a function of both $\Delta y$ and $H_{T}$. Smaller differences, which would be more difficult to disentangle experimentally, are found when we study the ratio of inclusive rates.

It would be very valuable to have an experimental study, which probed the average number of jets in $W$ production in association with at least two jets, to test our different descriptions of these important Standard Model processes.

FFNS for small $Q$, and the ZM-VFNS for large $Q$. In Fig. $2(\mathrm{~b})$, we plot $F_{2}^{c}$ as a function of the quark mass $m$ for a fixed $Q=10 \mathrm{GeV}$ for the MS ZM-VFNS and ACOT schemes. We observe that when $m$ is within a decade or two of $\mu$, the quark mass plays a dynamic role; however, for $m \ll \mu$, the quark mass purely serves as a regulator and the specific value is not important. Operationally, it means we can obtain the $\overline{\mathrm{MS}} \mathrm{ZM}-V F N S$ result either by (i) computing the terms using dimensional regularization and setting the regulator to zero, or (ii) by computing the terms using the quark mass as the regulator and then setting this to zero.

Fig. 2. (a) $F_{2}^{c}$ for $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable Flavor Number Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical. (b) Comparison of $F_{2}^{c}(x, Q)$ (scaled by $10^{4}$ ) vs. the quark mass $m$ in GeV for fixed $x=0.1$ and $Q=10 \mathrm{GeV}$. The full (red) dots are the full ACOT result, and the solid (blue) line is the massless $\overline{\mathrm{MS}}$ result.

The ACOT scheme is minimal in the sense that the construction of the massive short distance cross sections does not need any observabledependent extra contributions or any regulators to smooth the transition between the high and low scale regions. The ACOT prescription is: (a) calculate the massive partonic cross sections, and (b) perform the factorization using the quark mass as regulator.

It is in this sense that we claim the ACOT scheme is the minimal massive extension of the $\overline{\mathrm{MS}}$ ZM-VFNS. In the limit $m / \mu \rightarrow 0$ it reduces exactly to the $\overline{\mathrm{MS}} \mathrm{ZM}-V F N S$, in the limit $m / \mu \gtrsim 1$ the heavy quark decouples from the PDFs and we obtain exactly the FFNS for $m / \mu \gg 1$ and no finite renormalizations are needed.

### 2.2. S-ACOT

In a corresponding application, it was observed that the heavy quark mass could be set to zero in certain pieces of the hard scattering terms without any loss of accuracy. This modification of the ACOT scheme goes by the name Simplified-ACOT (S-ACOT) and can be summarized as follows [8].

Fig. 2: a) $F_{2}^{c}$ for $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable Flavor Number Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical.
b) Comparison of $F_{2}^{c}(x, Q)$ (scaled by $10^{4}$ ) vs. the quark mass $m$ in GeV for fixed $x=0.1$ and $Q=10 \mathrm{GeV}$. The red dots are the full ACOT result, and the blue line is the massless $\overline{M S}$ result.

Operationally, it means we can obtain the $\overline{M S}$ ZM-VFNS result either by i) computing the terms using dimensional regularization and setting the regulator to zero, or ii) by computing the terms using the quark mass as the regulator and then setting this to zero.

The ACOT scheme is minimal in the sense that the construction of the massive short distance cross sections does not need any observabledependent extra contributions or any regulators to smooth the transition between the high and low scale regions. The ACOT prescription is: a) calculate the massive partonic cross sections, and b) perform the factorization using the quark mass as regulator.

It is in this sense that we claim the ACOT scheme is the minimal massive extension of the $\overline{M S}$ ZM-VFNS. In the limit $m / \mu \rightarrow 0$ it reduces exactly to the $\overline{M S}$ ZM-VFNS, in the limit $m / \mu \gtrsim 1$ the heavy quark decouples from the PDFs and we obtain exactly the FFNS for $m / \mu \gg 1$ and no finite renormalizations are needed.

## 2.2. $S$-ACOT

In a corresponding application, it was observed that the heavy quark mass could be set to zero in certain pieces of the hard scattering terms without any loss of accuracy. This modification of the ACOT scheme goes by the name Simplified-ACOT (S-ACOT) and can be summarized as follows [8].

S-ACOT: For hard-scattering processes with incoming heavy

Fig. 17: Example Feynman diagrams contributing to DIS heavy quark production (from left): LO $\mathcal{O}\left(\alpha_{S}^{0}\right)$ quark-boson scattering $Q V \rightarrow Q$, NLO $\mathcal{O}\left(\alpha_{S}^{1}\right)$ boson-gluon scattering $g V \rightarrow Q \bar{Q}$, NNLO $\mathcal{O}\left(\alpha_{S}^{2}\right)$ boson-gluon scattering $g V \rightarrow g Q \bar{Q}$ and $\mathrm{N}^{3} \mathrm{LO} \mathcal{O}\left(\alpha_{S}^{3}\right)$ boson-gluon scattering $g V \rightarrow g g Q \bar{Q}$.
prediction for $F_{L}$ is a challenge, particularly in the region of low $Q^{2}$ and small $x$.
In this paper, we will briefly outline the method we used to incorporate the higher order terms, the key elements of the ACOT scheme, and the treatment of the heavy quark masses. We then present results for the $F_{2}$ and $F_{L}$ neutral current DIS structure functions.

### 9.2 THE ACOT SCHEME AND ITS EXTENSION BEYOND NLO

Fig. 18: Comparison of schemes for $F_{2}^{c}$ at $x=0.1$ for NLO DIS heavy quark production as a function of $Q$. We display calculations using the ACOT, S-ACOT, Fixed-Flavor Number Scheme (FFNS), and Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS). The ACOT and S-ACOT results are virtually identical.

The ACOT scheme [322, 323] is based upon the factorization theorem for heavy quarks[324]; hence, it is valid at any order of perturbation theory. The factorization proof ensures that the ACOT scheme can be applied throughout the full kinematic regime, and that there is a smooth transition from a massless result $(m=0)$ to the heavy-mass decoupling limit $(m \rightarrow \infty)$.

In the limit where the quark $Q$ of mass $m$ is relatively heavy compared to the characteristic energy scale ( $\mu \lesssim m$ ), the ACOT result naturally reduces to the Fixed-Flavor-Number-Scheme (FFNS). In the FFNS, the heavy quark is treated as being extrinsic to the hadron, and there is no corresponding heavy quark PDF, $f_{Q}(x, \mu)=0$. Conversely, in the limit where the quark mass is relatively light $(\mu \gtrsim m)$, the ACOT result reduces to the $\overline{M S}$ Zero-Mass Variable-Flavor-Number-Scheme (ZM-VFNS) exactlywithout any finite renormalizations. In this limit, the quark mass $m$ no longer plays any dynamical role; it serves purely as a regulator. This feature is presented in Fig. 18 where we can see that the ACOT scheme precisely matches the results of the FFNS and ZM-VFNS schemes in their respective limits.

Additionally Fig. 18 shows the results obtained within the Simplified-ACOT scheme (SACOT) [325]. The S-ACOT scheme drops the heavy quark mass dependence for the hard-scattering

$$
\begin{array}{ll}
\left|\eta_{e}\right|<2.5 & p_{T, e}>20 \mathrm{GeV} \\
M_{\perp, W}>20 \mathrm{GeV} & p_{T, \nu}>20 \mathrm{GeV} \\
\left|\eta_{j}\right|<4.5 & p_{T, j}>25 \mathrm{GeV}
\end{array}
$$

Table 12: Summary of the cuts applied in the analysis.

Fig. 56: The average number of jets as a function of $p_{T, W}$ (left) and $p_{T, j_{1}}$ (right). The $p_{T, W}$ plot shows the $B H S$ exclusive sums prediction, while the $p_{T, j_{1}}$ plot is obtained from $S$-MEPS.

### 17.3 RESULTS OF THE COMPARISON

In this section, we compare the results of different theoretical descriptions for $W+n$-jets production at the LHC. The number $n$ can take values from 2 and above, as we will mostly consider inclusive samples. The four descriptions, which we will compare here in more detail, are

- the $B H S$ calculation of $W+2$-jets at NLO,
- the combined sample of $W+2,3,4$-jet events at NLO from $B H S$, as described in the 17.2 section,
- the $S$-MEPS merged $W+n$-jets sample using LO tree-level matrix elements up to $n=5$, and
- the approach of $H E J$.

Throughout this study, we will consider inclusive samples of $W^{-}$boson production in association with at least two hard jets identified by the anti- $k_{T}$ jet algorithm using $R=0.4$. The jets are required to have $p_{T, j}>25 \mathrm{GeV}$. We look only in the $W^{-} \rightarrow e^{-} \bar{\nu}_{e}$ decay channel and use the cuts given in Tab. 12 where $M_{\perp, W}$ is defined as $M_{\perp, W}=\sqrt{\left(\left|\vec{p}_{T, e}\right|+\left|\vec{p}_{T, \nu}\right|\right)^{2}-\left(\vec{p}_{T, e}+\vec{p}_{T, \nu}\right)^{2}}$.

The HEJ predictions use the geometric mean of the jet transverse momenta to determine the renormalisation and factorisation scale, i.e. $\left(\prod p_{T, j}\right)^{1 / n}$. This central choice will be varied by a factor of two in either direction to provide an envelope (marked by dotted lines in the corresponding figures) around the HEJ default prediction. The BHS predictions instead use $\hat{H}_{T}^{\prime} / 2$ as the NLO calculation becomes unstable for a scale which is too low. In the $S$-MEPS calculation, scales are chosen according to the default prescription given by ME\&TS [426].

The variables $H_{T, 2}, p_{T, W}$ and $p_{T, j_{1}}$ are less sensitive to the presence of additional radiation than $H_{T}$, as discussed in the introduction. The plots, which we present in Figs. 56 and 57 address the alternative question: given a particular value of $H_{T}, H_{T, 2}$ etc. how many jets are typically found in the event?

Figs. 56 and 57 show the stacked results for the average number of jets as a function of $p_{T, W}, p_{T, j_{1}}$, $H_{T}$ and $H_{T, 2}$ visualising the contributions from each exclusive 2,3,4-jet sample and the inclusive 5 -jet

Fig. 57: The contribution from different multiplicities to the average number of jets as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the BHS exclusive sums prediction, while the lower ones are extracted from S-MEPS.
sample. The left (right) plot in Fig. 56 and the upper (lower) rows of plots in Fig. 57 depict the results as obtained from the combined BHS sample (the $S$-MEPS sample). In all cases the different colours correspond to the terms in the numerator of the formula for the average number of jets,

$$
\begin{equation*}
\langle N\rangle_{5}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}=\frac{\sum_{i=2,3,4} i n_{i}^{\mathrm{exc}}+5 n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{106}
\end{equation*}
$$

where blue, green, red and magenta stand for $i=2,3,4$ and $i=5$, respectively. The subscript to $\langle N\rangle$ clarifies that we truncate the determination of the average after the fifth jet bin, noting that $\langle N\rangle_{k} \rightarrow\langle N\rangle$ for a sufficiently large number of jet bins. This makes no difference for the BHS predictions employed here since the jet multiplicity de facto is limited to five, but it does for the $S$-MEPS and HEJ computations where events with $i>5$ jets do occur. We have defined $n_{k}^{\text {exc } / \mathrm{inc}}=d \sigma_{k}^{\text {exc } / \mathrm{inc}} / d O$ where $O$ denotes an observable like $H_{T}$, or $\Delta y$ presented later on. Note that in Fig. 57 the 5 -jet part contributes to the average number of jets with a factor of 5 , while the 2 -jet part, for example, contributes with a factor of 2 only.

The layout of Fig. 58 (including the colour coding) is the same as before: here, we however display, wrt. $n_{2}^{\text {inc }}$, the relative fractions of the different multiplicities corresponding to the terms in the denominator of Eq. (106). In other words, in Fig. 58 we consider the partitioning of

$$
\begin{equation*}
1=\frac{\sum_{i=2,3,4} n_{i}^{\mathrm{exc}}+n_{5}^{\mathrm{inc}}}{n_{2}^{\mathrm{inc}}} \tag{107}
\end{equation*}
$$

Fig. 58: The fraction of the total rate from different multiplicities as a function of $H_{T}$ and $H_{T, 2}$. The upper plots show the $B H S$ exclusive sums prediction, while the lower ones are extracted from $S$-MEPS.

Although there is just a $30 \%$ fraction of inclusive 5 -jet events to the total cross section, we observe that their contribution to the build-up of $\langle N\rangle\left(H_{T}\right)$ for very large $H_{T}$ gets close to $50 \%$. Also, for an $H_{T} \sim$ 500 GeV , the average number of jets is composed evenly between the 2,3 -jet and 4,5 -jet contributions, while the relative fraction of the 2,3 -jet events is nearly $70 \%$. This emphasizes the dominance of multijet events in forming large $H_{T}$ values. It also can be seen that for medium $H_{T}$ values, $400<H_{T}<$ 700 GeV , all the multiplicities give roughly the same contribution to the variable $\langle N\rangle\left(H_{T}\right)$, while for low $H_{T}$, the average is primarily described by 2-jet events.

Going clockwise through Figs. 56 and 57 we see that the average number of jets is indeed sensitive to higher multiplicities when considered as a function of $p_{T, W}, p_{T, j_{1}}$ and $H_{T, 2}$, but in all these cases this happens to a lesser extent as if considered as a function of $H_{T}$. As expected, the dependence is mildest for $p_{T, W}$, the most inclusive observable studied here. We also observe that the jet-bin decomposition of $p_{T, j_{1}}$ and $H_{T, 2}$ turns out very similar. Most strikingly we note the increase in the contribution from the highest multiplicity events, the ones containing more or at least five jets. For $H_{T, 2}$, we furthermore display to the right of Fig. 58 the relative fractions as done in the $H_{T}$ case. Even for largest $H_{T, 2}$ values, the fraction arising from 2,3 -jet events remains close to $65 \%$ stressing once more the lower sensitivity of $H_{T, 2}$ versus $H_{T}$ regarding multiple jet production.

Finally, we compare the plots from the combined BHS samples in all figures to the corresponding ones generated with the $S$-MEPS sample. Interestingly, the outcome looks very similar although ME\&TS handles the single terms in Eq. (105) rather differently. They are calculated at least at leading (soft/collinear) logarithmic accuracy improved by LO $n$-jet effects. Presumably, for the exclusive jet bins, this description (which allows a better treatment of jet vetoes) is not too far off the exclusive sums

Fig. 59: Average number of jets as a function of $H_{T}$ (left) and $\Delta y$ (right) in two BHS descriptions, from $H E J$ and from $S$-MEPS, the latter using the $\langle N\rangle_{7}$ definition. The bands shown with dotted lines for the HEJ prediction are a result of varying the scale by a factor of 2 in each direction.
approach, since the unresolved $\mathcal{O}\left(\alpha_{s}\right)$ corrections are also present in the Sudakov form factors applied in the ME\&TS approach. Also, the combined BHS samples as well as the $S$-MEPS sample use the same tree-level matrix elements, namely up to $W+5$-parton matrix elements. Clearly, it has to be studied further whether this similarity in the results is a coincidence or not.

It is clear that the impact of the higher multiplicity samples is significant throughout, especially in the high $H_{T}$ tail. This is precisely the region, which would be probed for signs of new physics, and therefore it is essential that we fully understand our theoretical descriptions in this region. This is the subject of the remainder of this contribution, where we compare all four different methods of modelling hard QCD radiation in inclusive $W+2$-jet events.

The left plot of Fig. 59 shows the final comparison plot between the exclusive sums and inclusive 2-jet $B H S$ results as well as the $H E J$ and $S-M E P S$ predictions for the average number of jets as a function of $H_{T}$. The differences in the descriptions are significantly larger than the scale uncertainty band on the $H E J$ prediction. For the $W+2$-jet NLO result, the number of jets rises to 2.6 already at $H_{T}=500 \mathrm{GeV}$ but that levels off significantly below the $S-M E P S$, exclusive $B H S$ sum and $H E J$ results. The $H E J$ results level off at a higher value of about 3.0 , starting to clearly disagree with the exclusive sums and $S$-MEPS predictions above 500 GeV , from where those two curves keep rising to a final level of around 3.7 to 4.0. The $S$-MEPS comes in highest at largest $H_{T}$, where $\langle N\rangle_{7}$ is shown, cf. Eq. (106), in order to determine the average number of jets for this $S$-MEPS result. The reason for giving slightly higher $\langle N\rangle$ than the exclusive sums lies in the contribution of additional parton-shower jets present in the $S$-MEPS calculation and more accurately accounted for by the use of the $\langle N\rangle_{7}$ definition as compared to the earlier result based on $\langle N\rangle_{5}$ presented in Fig. 57 to the lower left.

In the right panel of Fig. 59, we have plotted the average number of jets as a function of the rapidity span, $\Delta y$, instead of $H_{T}$ as before. Again the differences are larger than the scale variation shown on the HEJ result, but the ordering is different to that of the left plot of Fig. 59. All four descriptions increase linearly with $\Delta y$ but the gradient is steepest for the HEJ predictions where the average rises above 3.0 for $\Delta y$ values as large as 6.0. The BHS exclusive sum result is consistently below this, reaching about 2.8 at $\Delta y=6.0$, and agrees pretty well with the $S$-MEPS result based on $\langle N\rangle_{7}$. The NLO $W+2$-jet prediction given by $B H S$ is lower still, between 2.4 and 2.5 for $\Delta y \sim 5.0$.

It may seem surprising that on the plot on the left-hand side the exclusive sums and S-MEPS lie higher for most of the distribution whereas on the right-hand side these approaches as well as $H E J$ give predicitions that are commensurate. The region of high $H_{T}$ and that of high $\Delta y$ however are largely distinct as it is very expensive to have both a large rapidity and large $p_{T}$ for the jets. Also while radiating

Fig. 60: The ratio of the inclusive 3 -jet and 2 -jet rates in the inclusive $W+2$-jet NLO and exclusive sum description of $B H S$ as well as in the $S$-MEPS and $H E J$ approaches as a function of $H_{T}$ (left) and $\Delta y$ (right). Again, the dotted lines indicate the uncertainty band from varying the scale in $H E J$ by a factor of 2 in each direction.
an additional jet automatically moves an event towards the higher $H_{T}$ direction, radiating an additional jet tends to not change the rapidity difference. So, we expect the higher multiplicies to have a smaller effect on the average number of jets as a function of $\Delta y$ compared to as a function of $H_{T}$. This is indeed the case in Fig. 59.

Lastly, in Fig. 60 we plot the ratio of the inclusive 3 -jet to the inclusive 2 -jet rate as a function of $H_{T}$ (left) and $\Delta y$ (right), again for all four descriptions used here. The predicted $\left(d \sigma_{3}^{\text {inc }} / d H_{T}\right) /\left(d \sigma_{2}^{\text {inc }} / d H_{T}\right)$ all agree very well below 400 GeV . The fixed order $B H S$ result for $W+2$ jets is highest for large $H_{T}$, however is known to become unreliable here, since the probability that an inclusive 2 -jet event is at least a 3 -jet event turns too large, being in conflict with the expected behaviour of an $\mathcal{O}\left(\alpha_{s}\right)$ correction. The BHS exclusive sums, the S-MEPS and the HEJ results, in this order, level off considerably lower with the HEJ fraction staying below $60 \%$ to $70 \%$, which leaves the other predictions again above the $H E J$ uncertainty envelope. In contrast, when the same ratio of jet rates is plotted against $\Delta y$, the $H E J$ prediction is consistently higher throughout. This again emphasises that differences in the descriptions come to light in different kinematic regions. However, in both cases here the magnitude of the differences is relatively small and would be rather difficult to distinguish in present experimental data.

### 17.4 CONCLUSIONS

We have compared a number of theoretical descriptions of $W^{-}$production in association with at least two jets. After outlining one possible method of combining NLO calculations of different multiplicities, we compared this with a pure NLO calculation of $W+2$-jets production obtained by BLACKHAT+SHERPA, a sample of leading-order events merged using the ME\&TS method of SHERPA, and the high-energy resummation of the HEJ framework.

We studied the average number of jets and the ratio of the 3 -jet and 2 -jet inclusive cross sections as a function of $\Delta y$ and of $H_{T}$. We find, with these simple cuts, some clear differences in the predictions when we study the average number of jets as a function of both $\Delta y$ and $H_{T}$. Smaller differences, which would be more difficult to disentangle experimentally, are found when we study the ratio of inclusive rates.

It would be very valuable to have an experimental study, which probed the average number of jets in $W$ production in association with at least two jets, to test our different descriptions of these important Standard Model processes.

parametrize the nPDFs at the initial $Q_{0}^{2}=1 \mathrm{GeV}^{2}$ using Eq. (5.134) and

$$
\begin{equation*}
R_{i}\left(x_{B}, Q_{0}^{2}, A, Z\right)=1+\left(1-\frac{1}{A^{\alpha}}\right) \frac{a_{i}+b_{i} x+c_{i} x^{2}+d_{i} x^{3}}{(1-x)^{\beta_{i}}} \tag{5.135}
\end{equation*}
$$

The determined $u_{v}, \bar{q}$, and $g$ nPDFs from the HKN07 analysis [38] are shown for the calcium nucleus in Fig. 5.55 at $Q^{2}=1 \mathrm{GeV}^{2}$. LO and NLO results are shown with uncertainty bands, showing that nPDFs are determined more accurately at NLO. We obtain $\chi_{\text {min }}^{2} /$ d.o.f. $=1.35$ and 1.21 for the LO and NLO fits, respectively.

The valence-quark modifications are well determined because of accurate measurements on the $F_{2}$ ratios at medium $x$. The small- $x$ region is fixed by the baryon-number and charge conservations together with the modifications in the medium- and large- $x$ regions. The antiquark modifications are also determined well at small $x$ due to measurements on $F_{2}$ shadowing, and they are also fixed at $x \sim 0.1$ because of Fermilab Drell-Yan measurements. However, the region at $x>0.2$ is not determined at all. The E906/SeaQuest collaboration is currently measuring this medium- $x$ region, and there is also a possibility to measure this region with an experiment at J-PARC. In the near future, the uncertainty bands should be significantly reduced for the antiquark.

The gluon distribution has the largest uncertainties since it contributes to the $F_{2}$ and Drell-Yan ratios only as higher-order effects, and the $Q^{2}$ dependence of $F_{2}^{A} / F_{2}^{A^{\prime}}$ is not measured accurately on nuclear targets, which makes it difficult to pin down the gluon modifications measured by scaling violations of $F_{2}$. The small- $x$ nPDFs are dominated by huge gluon distributions, so that it is essential to determine them accurately for new discoveries by high-energy heavyion experiments. Therefore, it is important to mea-

Figure 5.55. Determined nuclear modifications in Ca [38]. sure the $Q^{2}$ dependence of $F_{2}^{A} / F_{2}^{A^{\prime}}$ at EIC for determining nuclear gluon distributions.

In HKN07, the nPDFs are also investigated for the deuteron. In obtaining the "nucleonic" PDFs, deuteron data are used after crude nuclear corrections. Since the current PDFs could possibly contain nuclear effects, appropriate nuclear corrections should be applied in future for excluding such effects. Our codes for calculating the nPDFs and their uncertainties are available at the web site [970]. The technical details are explained in Refs. $[965,38]$ and within the subroutine.

FIG. 14: Shifts in $g_{L}^{2}$ and $g_{R}^{2}$ due to leptoquarks. Horizontal lines indicate the projected $1 \sigma$ limits of NuSOnG.

FIG. 15: NuSOnG expectation in the case of a Tev-scale triplet leptoquark. For clarity, this plot and the two following cases, show the expectation from only the two highest precision measurements from NuSOnG: $g_{L}^{2}$ and $\nu$ ES.
violation explains the NuTeV anomaly, thus the NuTeV PW and the NuSOnG PW measurements agree with the $\nu$ eES measurements. These three precision neutrino results, all with "LEP-size" errors, can be combined and will intersect the one-sigma edge of the LEP measurements. Fig. 16 illustrates this example. From this, the source, a fourth generation with isospin violation, can be

FIG. 16: NuSOnG expectation if the NuTeV anomaly is due to isospin violation and there is a heavy 4th generation with isospin violation.

FIG. 17: If LHC sees a Standard Model Higgs and no evidence of new physics, NuSOnG may reveal new physics in the neutrino sector.
demonstrated.
Lastly, while it seems unlikely, it is possible that LHC will observe a Standard Model Higgs and no signatures of new physics. If this is the case, it is still possible for NuSOnG to add valuable clues to new physics. This is because the experiment is uniquely sensitive to the neutrino sector. If a situation such as is illustrated on Fig. 17 arose, the only explanation would be new physics unique to neutrino interactions.

## VI. SUMMARY AND CONCLUSIONS

NuSOnG is an experiment which can search for new physics from keV through TeV energy scales, as well as make interesting QCD measurements. This article has focussed mainly on the Terascale physics which can be accessed through this new high energy, high statistics

Figure 3: Three projected electroweak measurements from NuSOnG in S-T plane. LEP/SLD error ellipse is shown in red and the current $\mathrm{NuTeV} \nu-q$ measurement is shown as a light blue band. The ochre band shows NuSOnG $\bar{\nu}-e$, the dark blue band shows NuSOnG $\nu-q$ and the green shows NuSOnG $\nu-e$. The width of the bands correspond to $68 \%$ confidence level for statistics as described in the text. The NuSOnG measurements assume $(S, T)=(0,0)$.
sensitive to new physics that violates isospin and is zero for new physics that conserves isospin. Isospin-breaking new physics such as heavy non-degenerate fermion doublets or scalar multiplets would affect the $T$ parameter. The $S$ parameter is sensitive to isospin-conserving physics, such as heavy degenerate fermion doublets.

The status of electroweak measurements are shown in Fig. 3 [8]. The combined analysis of the LEP and SLD data by the LEP Electroweak Working Group (EWWG) [9] indicates an allowed region shown by the small oval, centered at $S=0.05 \pm 0.10$ and $T=0.07 \pm 0.11$. A different choice of reference Higgs or top mass changes Standard Model predictions for observables and thus shifts the center of the $S T$ plot [10]; setting the Higgs mass to 1000 GeV would shift the center of the oval to roughly $(S, T)=$ $(0.12,-0.36)$. Measurements of the $W$ mass, which are not shown, are also consistent with the LEP measurements. The highest precision neutrino result comes from $\nu q$ and $\bar{\nu} q$ scattering by the NuTeV experiment. This result clearly disagrees with the other

Figure 6: Three projected electroweak measurements from NuSOnG in S-T plane for a model model with a heavy Higgs inspired by the NuTeV measurement [11]. In this model, $(S, T)=(0.12,-0.36)$. The labeling is as in Fig. 3.

(Dated: March 12, 2010)

#### Abstract

By using a single formalism to handle charm, strange and light valence quarks in full lattice QCD for the first time, we are able to determine ratios of quark masses to $1 \%$. For $m_{c} / m_{s}$ we obtain $11.85(16)$, an order of magnitude more precise than the current PDG average. Combined with $1 \%$ determinations of the charm quark mass now possible this gives $\bar{m}_{s}(2 \mathrm{GeV})=92.4(1.5) \mathrm{MeV}$. The MILC result for $m_{s} / m_{l}=27.2(3)$ yields $\bar{m}_{l}(2 \mathrm{GeV})=3.40(7) \mathrm{MeV}$ for the average of $u$ and $d$ quark masses.

Introduction. - The masses of $u, d$ and $s$ quarks are some of the least well-known parameters of the Standard Model. Even the most inaccurate lepton mass (that of the $\tau$ ) is known to better than $0.01 \%$ and yet errors on light quark masses of $30 \%$ are quoted in the Particle Data Tables [1]. The reason for the mismatch is the confinement property of the strong force that obscures the connection between the properties of the quark constituents and the hadron physics that is accessible to experiment. To make this connection requires accurate calculations in QCD and accurate experimental results for appropriate hadronic quantities. A method particularly well-suited to this is lattice QCD. Here we will demonstrate its use by determining $m_{c} / m_{s}$ to $1 \%$ and obtaining as a result $1.5 \%$ errors for light quark masses, which brings them almost into line with those of heavy quarks.

Heavy quark masses, $m_{Q}$, can be determined accurately because $\alpha_{s}\left(m_{Q}\right)$ is relatively small. $1 \%$ errors for charm and bottom quark masses have recently become possible using $\mathcal{O}\left(\alpha_{s}^{3}\right)$ calculations in QCD perturbation theory for the heavy quark vacuum 'bubble' [2] and therefore for the energy-derivative (or time) moments of correlation functions for a heavy quark-antiquark pair at zero momentum. Since the scale of $\alpha_{s}$ is naturally related to the relevant heavy quark mass, the expressions can be evaluated accurately. To extract the quark mass the perturbative result is compared to a nonperturbative determination containing information from experiment. For a $1^{--} Q \bar{Q}$ configuration moments of the experimentally measured cross-section for $\left(e^{+} e^{-} \rightarrow \gamma^{*} \rightarrow\right.$ hadrons $)$ can be used after isolating the heavy quark contribution and using dispersion relations [3]. Alternatively the time-moments for heavy quark current-current correlation functions of various $J^{P C}$ can be directly determined in lattice QCD calculations that have been tuned so that a charmonium or bottomonium mass agrees with experi-
ment [4, 5]. The time moments must be extrapolated to the zero lattice spacing (continuum) limit before the comparison to QCD perturbation theory. These two methods give results that agree, with $1 \%$ errors for $m_{c}(3 \mathrm{GeV})$ in the $\overline{M S}$ scheme. The more traditional 'direct' lattice QCD method, although somewhat less accurate, also gives results in good agreement [6. We can conclude from this that $m_{c}$ is now accurately known.

The strange quark mass, $m_{s}$, being much smaller, cannot be determined this way and is poorly known at present. Instead of a direct determination of $m_{s}$, however, we can use the leverage of an accurate result for the ratio $m_{c} / m_{s}$ combined with the accurate $m_{c}$ above [7]. But simple ratios of hadron mass differences give unreliable estimates of $m_{c} / m_{s}$. Two such estimates:

$$
\begin{equation*}
\frac{m\left(B_{c}\right)-m\left(B_{u}\right)}{m\left(B_{s}\right)-m\left(B_{u}\right)}=11 ; \frac{m\left(\Sigma_{c}\right)-m(N)}{m(\Sigma)-m(N)}=6 \tag{1}
\end{equation*}
$$

differ by almost a factor of 2 . The ratio of $m_{s} / m_{l}$ (where $\left.m_{l}=\left(m_{u}+m_{d}\right) / 2\right)$ is known to about $10 \%$ from ratios of squared masses of $K$ and $\pi$ mesons using $\mathrm{SU}(3)$ chiral perturbation theory [1]. Clearly neither ratio is determined well enough this way to provide the accuracy we need, because the relationship between hadron mass and well-defined running quark mass is more complicated than these simple ratios must assume.

Lattice QCD, on the other hand, can give very accurate results for the ratio of two quark masses but only if the same formalism is used for both quarks. This has already been used to give accurate results for $m_{s} / m_{l}$, although neither $m_{s}$ nor $m_{l}$ is very well determined. Here, for the first time, we give an accurate result for $m_{c} / m_{s}$ by using the same formalism for charm, strange and light quarks and this enables us to cascade the accuracy of the heavy quark mass down to the light quarks.

The Lattice QCD calculation. - Lattice QCD gives
direct access to quark masses through the lattice QCD Lagrangian. Tuning of the masses is done by calculating an appropriate hadron mass and adjusting the quark mass until the hadron mass agrees with experiment. Experimental measurements of appropriate hadron masses are extremely accurate in most cases, with errors at the level of tenths or hundredths of a percent. To make maximum use of this precision we need to calculate the hadron mass in lattice QCD with small statistical and systematic errors. In particular it requires the full effect of sea quarks in the hadron to be included. This is now possible in lattice QCD [8]. Fixing the four quark masses $\left(m_{l}\right.$, $m_{s}, m_{c}, m_{b}$ ) from four 'gold-plated' hadrons $\left(\pi, K, \eta_{c}\right.$, $\Upsilon$ ) enables other quantities to be calculated with errors of a few percent and agreement with experiment is obtained [8, 9]. This is an important test that QCD, with only one scale parameter and one mass parameter per quark flavor, describes the full range of hadron physics consistently.

The lattice quark mass is a perfectly well-defined running quark mass. However, it is scheme-dependent and so varies with the discretisation of the Dirac equation used in the lattice calculation. For wider applicability it is more useful to convert the lattice quark mass to a standard continuum scheme such as $\overline{M S}$. This renormalization has been a major source of systematic error in previous determinations of light and strange quark masses. The best existing result for $m_{s}(2 \mathrm{GeV})$, with a $7 \%$ error, uses the direct method of converting the tuned quark mass in the lattice QCD Lagrangian to the $\overline{M S}$ scheme using $\alpha_{s}^{2}$ lattice QCD perturbation theory [10]. The error is dominated by the error in the renormalization and it is the error that we will remove here, by instead determining $m_{c} / m_{s}$ accurately. The Highly Improved Staggered Quark action [11, 12] allows us to use the same discretization of QCD for both charm and strange quarks because it is a fully relativistic 'light quark' action that can also be used for charm quarks. Then the mass renormalisation factor cancels in the quark mass ratio.

We work with eight different ensembles of gluon field configurations provided by the MILC collaboration. These include the effect of $u, d$ and $s$ sea quarks using the improved staggered quark (asqtad) formalism using the fourth root 'trick'. This procedure, although 'ugly', appears to be a valid discretization of QCD 13-16. Tests include studies of the Dirac operator and comparisons to effective field theories. Configurations are available with large spatial volumes $\left(>2.4(\mathrm{fm})^{3}\right)$ at multiple values of the light sea masses (using $m_{u}=m_{d}=m_{l}$ ) and for a wide range of values of the lattice spacing, $a$. We use configurations at five values of $a$ between 0.15 fm and 0.05 fm with parameters as listed in Table $\mathbb{Z}$.

On these configurations we have calculated quark propagators for charm quarks, strange quarks and light quarks (again $m_{u}=m_{d}=m_{l}$ ) using the HISQ action. The numerical speed of HISQ means that we have been able to

TABLE II: Results for the masses in lattice units of the goldstone pseudoscalars made from valence HISQ charm or strange quarks on the different MILC ensembles enumerated in Table Columns 2 and 3 give the corresponding bare charm quark mass, and Naik coefficient respectively. Column 6 gives the bare strange quark mass ( $\epsilon=0$ in that case).
use several nearby quark masses for charm and strange to allow accurate interpolation to the correct values. Table II gives masses for the goldstone pseudoscalar mesons made from either a charm quark-antiquark pair or a strange one (the $\eta_{c}$ and the $\eta_{s}$ ), which are used for tuning. In the charm case, as well as the quark mass, we list the coefficient of the 'Naik' term in the HISQ action that corrects for discretisation errors through $\left(a m_{0 c}\right)^{4}$. The quark propagators are generated from random wall sources and the goldstone mesons have good signal/noise properties so the meson masses can be determined to high precision using a standard multi-exponential fit [17].

The meson masses can be converted to physical units with a determination of the lattice spacing. On an en-

FIG. 1: Grey points show the raw data for every ratio of $m_{c} / m_{s}$ on each ensemble (Table II); these ratios are fit to eq. 4 The dashed line and associated grey error band (and red point at $a=0$ ) show our extrapolation of the resulting tuned $m_{c} / m_{s}$ to the continuum limit. Blue points with error bars are from a simple interpolation, separately for each ensemble, to the correct $m_{c} / m_{s}$, and are shown for illustration.
semble by ensemble basis this is taken from a parameter in the heavy quark potential called $r_{1}$. Values for $r_{1} / a$ determined by the MILC collaboration [14] are given in Table They have errors of $0.3-0.5 \%$. The physical value for $r_{1}$ must then be obtained by comparing to experimentally known quantities and we use the value $0.3133(23)$ fm obtained from a set of four such quantities, tested for consistency in the continuum limit [18, 19].

Using the information about meson masses that we have on each ensemble we can interpolate to the correct ratio for $a m_{0 c}$ and $a m_{0 s}$ using appropriate continuum values for the masses of the $\eta_{c}$ and $\eta_{s}$. We correct the experimental value of $m_{\eta_{c}}$ of 2.9803 GeV to $m_{\eta_{c}, \text { phys }}=2.9852(34) \mathrm{GeV}$. This allows for electromagnetic effects $(2.4 \mathrm{MeV}) 18$ and $\eta_{c}$ annihilation to gluons $(2.5 \mathrm{MeV})[11$, both of which are missing from our calculation, so increasing the $\eta_{c}$ mass. We take a $50 \%$ error on each of these corrections and also increase the experimental error to 3 MeV to allow for the spread of results from different $\eta_{c}$ production mechanisms [1]. Since the total shift is only around $0.2 \%$ of the $\eta_{c}$ mass it has a negligible effect as can be seen from our error budget below.

The $\eta_{s}$ is not a physical particle in the real world because of mixing with other flavor neutral combinations to make the $\eta$ and $\eta^{\prime}$. However, in lattice QCD, the particle calculated (as here) from only 'connected' quark propagtors does not mix and is a well-defined meson. Its mass must be determined by relating its properties to those of mesons such as the $\pi$ and $K$ that do appear in experiment. From an analysis of the lattice spacing and $m_{l}$-dependence of the $\pi, K$, and $\eta_{s}$ masses we conclude that the value of the $\eta_{s}$ mass in the continuum and physical $m_{l}$ limits is $0.6858(40) \mathrm{GeV}$ [18].

The connection between the $\overline{M S}$ mass at a scale $\mu$ and
the lattice bare quark mass is given by [10, 20]:

$$
\begin{gather*}
\bar{m}(\mu)=\frac{a m_{0}}{a} Z_{m}\left(\mu a, m_{0} a\right)  \tag{2}\\
Z_{m}=1+\alpha_{s}\left(-\frac{2}{\pi} \log (\mu a)+C+b\left(a m_{0}\right)^{2}+\ldots\right)+\ldots
\end{gather*}
$$

From these two equations it is clear that

$$
\begin{equation*}
\frac{\bar{m}_{c}(\mu)}{\bar{m}_{s}(\mu)}=\left.\frac{a m_{0 c}}{a m_{0 s}}\right|_{\mathrm{phys}} \tag{3}
\end{equation*}
$$

where phys denotes extrapolation to the continuum limit and physical sea quark mass limit.

On each ensemble the ratios we have for $a m_{0 c} / a m_{0 s}$ then differ from the physical value because of three effects: mistuning from the correct physical meson mass; finite $a$ effects that need to be extrapolated away and effects because the sea light quark masses are not correct. We incorporate these into our fitting function:

$$
\begin{align*}
& \left.\frac{m_{0 c}}{m_{0 s}}\right|_{\text {lat }}=\left.\frac{m_{0 c}}{m_{0 s}}\right|_{\text {phys }} \times\left(1+d_{\text {sea }} \frac{\delta m_{\mathrm{tot}}^{\mathrm{sea}}}{m_{s}}\right)  \tag{4}\\
& \times\left(1+\sum_{i, j, k, l} c_{i j k l} \delta_{c}^{i} \delta_{s}^{j}\left(\frac{a m_{\eta_{c}}}{2}\right)^{2 k}\left(a m_{\eta_{s}}\right)^{2 l}\right) \\
& \delta_{c}=\frac{m_{\eta_{c}, M C}-m_{\eta_{c}, \text { phys }}}{m_{\eta_{c}, \text { phys }}} ; \delta_{s}=\frac{m_{\eta_{s}, M C}^{2}-m_{\eta_{s}, \text { phys }}^{2}}{m_{\eta_{s}, \text { phys }}^{2}} \tag{5}
\end{align*}
$$

are the measures of mistuning, where $M C$ denotes lattice values converted to physical units. The last bracket fits the finite lattice spacing effects as a power series in even powers of $a$. These can either have a scale set by $m_{c}$ (for which we use $a m_{\eta_{c}} / 2$ ) or by $\Lambda_{Q C D}$ (for which we use $\left.a m_{\eta_{s}}\right) . i, j, k, l$ all start from zero and are varied in the ranges: $i, j \leq 3, k \leq 6, l \leq 2$ with $i+j+k+l \leq 6$. Doubling any of the upper limits has negligible effect on the final result. The prior on $c_{i j k l}$ is set to $0(1)$. $\delta m_{\text {tot }}^{\text {sea }}$ is the total difference between the sea-quark masses used in the simulation and the correct value for $2 m_{l}+m_{s}$ [18]. This has a tiny effect and we simply use a linear term (adding higher orders has negligible effect). The prior for $d_{\text {sea }}$ is $0.0(1)$. Figure 1 shows the results of the fit, giving $m_{c} / m_{s}$ in the continuum limit as $11.85(16)\left(\chi^{2} /\right.$ dof $=$ 0.42 ). The error budget is given in Table III.
$m_{s} / m_{l}$ is known to $1 \%$ from lattice QCD as a byproduct of standard chiral extrapolations of $m_{\pi}^{2}$ and $m_{K}^{2}$ to the physical point [21]. MILC quote 27.2(3) using asqtad quarks [14. Our HISQ analysis in [12] gave a result in agreement at 27.8(3), using a Bayesian fit to a function including terms from chiral perturbation theory up to third order in $m_{l}$ and allowing for discretisation errors up to and including $a^{4}$ and for mixed terms (i.e $m_{l}$-dependent discretisation errors). A full error budget is given in Table III, the data are given in [18].

|  | $m_{c} / m_{s} m_{s} / m_{l}$ |  |
| :--- | :--- | :--- |
| overall $r_{1}$ uncertainty | $0.4 \%$ | $0.1 \%$ |

TABLE III: Error budgets for $m_{c} / m_{s}$ and $m_{s} / m_{l}$.

Conclusions. - Our $m_{c} / m_{s}$ can be used with any value for $m_{c}$ to give $m_{s}$. The best existing result [4] (converted from $n_{f}=4$ to 3 ) is $\bar{m}_{c}^{(3)}(2.0 \mathrm{GeV})=1.095(11) \mathrm{GeV}$ or $\bar{m}_{c}^{(3)}(3.0 \mathrm{GeV})=0.990(10) \mathrm{GeV}$. Dividing by $11.85(16)$ gives $\bar{m}_{s}^{(3)}(2.0 \mathrm{GeV})=92.4(1.5) \mathrm{MeV}$ and $\bar{m}_{s}^{(3)}(3.0 \mathrm{GeV})$ $=83.5(1.4) \mathrm{MeV}$.

FIG. 2: Our results for the 4 lightest quark masses compared to the current PDG evaluations (shaded bands) [1]. Each mass is quoted in the $\overline{M S}$ scheme at its conventional scale: 2 GeV for $u, d, s\left(n_{f}=3\right) ; m_{c}$ for $c\left(n_{f}=4\right)$.

Using the MILC values for $m_{s} / m_{l}$ and $m_{u} / m_{d}$ (0.42(4) [14]) we can then obtain: $\bar{m}_{l}^{(3)}(2.0 \mathrm{GeV})$ $=3.40(7) \mathrm{MeV}$ and $\bar{m}_{l}^{(3)}(3.0 \mathrm{GeV})=3.07(6) \mathrm{MeV}$; $\bar{m}_{u}^{(3)}(2.0 \mathrm{GeV})=2.01(14) \mathrm{MeV}$ and $\bar{m}_{d}^{(3)}(2.0 \mathrm{GeV})=$ 4.79 (16) MeV . The values for all four quark masses are plotted in Figure 2 in comparison to the current evaluations from the Particle Data Tables [1].

Thus our high accuracy on $m_{c} / m_{s}$ allows us to leverage $2 \%$ accurate values for $m_{s}$ and $m_{l}$ that are completely nonperturbative in lattice QCD , for the first time. Our $m_{s}$ mass is higher, by around $1 \sigma$, than our previous value of $\bar{m}_{s}(2 \mathrm{GeV})=87(6) \mathrm{MeV}$ which used 2-loop lattice QCD perturbation theory [10]. Then the error was dominated by unknown $\alpha_{s}^{3}$ terms. Our new result, which does not have this limitation, has an error almost five times smaller. Our new error is almost an order of magnitude smaller than other lattice QCD results from full

QCD [22, 23]. These use direct methods of converting the lattice mass to the $\overline{M S}$ mass, and have $10 \%$ errors.

Acknowledgements We are grateful to MILC for configurations and to H . Leutwyler for useful discussions. Computing was done at the Ohio Supercomputer Centre, USQCD's Fermilab cluster and at the Argonne Leadership Computing Facility supported by DOE-AC0206 CH 11357 . We used chroma for some analysis. (Dated: March 26, 2010)

#### Abstract

We extend our earlier lattice-QCD analysis of heavy-quark correlators to smaller lattice spacings and larger masses to obtain new values for the $c$ mass and QCD coupling, and, for the first time, values for the $b$ mass: $m_{c}\left(3 \mathrm{GeV}, n_{f}=4\right)=0.986(6) \mathrm{GeV}, \alpha_{\overline{\mathrm{MS}}}\left(M_{Z}, n_{f}=5\right)=0.1183(7)$, and $m_{b}\left(10 \mathrm{GeV}, n_{f}=5\right)=3.617(25) \mathrm{GeV}$. These are among the most accurate determinations by any method. We check our results using a nonperturbative determination of the mass ratio $m_{b}\left(\mu, n_{f}\right) / m_{c}\left(\mu, n_{f}\right)$; the two methods agree to within our $1 \%$ errors and taken together imply $m_{b} / m_{c}=4.51(4)$. We also update our previous analysis of $\alpha_{\overline{M S}}$ from Wilson loops to account for revised values for $r_{1}$ and $r_{1} / a$, finding a new value $\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}, n_{f}=5\right)=0.1184(6)$; and we update our recent values for light-quark masses from the ratio $m_{c} / m_{s}$. Finally, in the Appendix, we derive a procedure for simplifying and accelerating complicated least-squares fits.

## I. INTRODUCTION

Precise values for the QCD coupling $\alpha_{\overline{\mathrm{MS}}}$ and the quark masses are important for high-precision tests of the Standard Model of particle physics. In a recent paper we showed how to use realistic lattice QCD simulations to extract both the coupling and the charm quark's mass $m_{c}$ from zero-momentum moments of correlators built from the $c$ quark's (UV cutoff-independent) pseudoscalar density operator $m_{c} \bar{\psi}_{c} \gamma_{5} \psi_{c}$ [1]. In this paper we refine our previous analysis and extend it to include other quark masses, up to and including the $b$-quark mass. As a result our coupling constant and mass determinations from these correlators are among the most accurate by any method.

Low moments of heavy-quark correlators are perturbative and several are now known through $\mathcal{O}\left(\alpha_{s}^{3}\right)$ in perturbation theory (that is, four-loop order) [2-6]. Moments of correlators built from the electromagnetic currents can be estimated nonperturbatively, using dispersion relations, from experimental data for the electron-positron annihilation cross section, $\sigma\left(e^{+} e^{-} \rightarrow \gamma^{*} \rightarrow X\right)$. Accurate values for both the $c$ and $b$ masses can be obtained by comparing these perturbative and nonperturbative determinations of the moments (for a recent discussion see [7]).

In our earlier paper we showed that heavy-quark correlator moments are easily and accurately computed nonperturbatively using lattice QCD simulations, in place of experimental data, provided: 1) the electromagnetic

[^296]current is replaced by the pseudoscalar density multiplied by the bare quark mass; 2) the discretization of the quark action has a partially conserved axial vector current (PCAC); and 3) the discretization remains accurate when applied to heavy quarks. In our simulations we use the HISQ discretization of the quark action, which is a highly corrected version of the standard staggeredquark action [8]. It has a chiral symmetry (PCAC) and has been used in a wide variety of accurate simulations involving $c$ quarks [8-12].

Here we show that the HISQ action can be pushed to still higher masses - indeed, very close to the $b$ mass on new lattices, from the MILC collaboration [13], with the smallest lattice spacings available today ( 0.044 fm ). Currently most high-precision lattice work on $b$ physics relies upon nonrelativistic effective field theories, like NRQCD 10, 12, 14, 15]. In this paper we show how to obtain accurate $b$ physics using the fully relativistic HISQ action on these new lattices.

In what follows, we first review how the QCD coupling and quark masses are extracted from heavy-quark correlators, in Section II. Then in Section III we describe our lattice QCD simulations and discuss in detail the chief systematic errors in our simulation results. In Section IV we describe our fitting procedure and the results of our analysis of the heavy-quark correlators. We check our calculation using a different, nonperturbative method to determine $m_{b} / m_{c}$ in Section V. We then, in Section VI, update our previous calculation of the QCD coupling from Wilson loops to compare with our new result from the correlators. We summarize our findings in Section VII and compare our results with work by others. There we also update our recent calculations of the light-quark masses from the $c$ mass. In the Appendix we present a powerful simplification for complicated least-
squares fits that can greatly reduce the computing required for fits. We use this technique in dealing with finite- $a$ errors in our analysis.

## II. HEAVY-QUARK CORRELATOR MOMENTS

Following our earlier paper [1], we focus on correlators formed from the pseudoscalar density of a heavy quark, $j_{5}=\bar{\psi}_{h} \gamma_{5} \psi_{h}:$

$$
\begin{equation*}
G(t)=a^{6} \sum_{\mathbf{x}}\left(a m_{0 h}\right)^{2}\langle 0| j_{5}(\mathbf{x}, t) j_{5}(0,0)|0\rangle \tag{1}
\end{equation*}
$$

where $m_{0 h}$ is the heavy quark's bare mass (from the lattice QCD lagrangian), $t$ is euclidean and periodic with period $T$, and the sum over spatial positions $\mathbf{x}$ sets the total three momentum to zero. In our earlier paper we examined only $c$ quarks; here we will consider a range of masses between the $c$ and $b$ masses. While we have written this formula for use with the lattice regulator, it is important to note that the correlator is UV-finite because we include the factors of $a m_{0 h}$. Consequently lattice and continuum $G(t)$ s are equal when $t \neq 0$ up to $\mathcal{O}\left(\left(a m_{h}\right)^{m}\right)$ corrections, which vanish in the continuum limit.

The moments of $G(t)$ are particularly simple to analyze:

$$
\begin{equation*}
G_{n} \equiv \sum_{t}(t / a)^{n} G(t) \tag{2}
\end{equation*}
$$

where, on our periodic lattice,

$$
\begin{equation*}
t / a \in\{0,1,2 \ldots T / 2 a-1,0,-T / 2 a+1 \ldots-2,-1\} \tag{3}
\end{equation*}
$$

Low moments emphasize small $t$ s and so are perturbative; and moments with $n \geq 4$ are UV-cutoff independent. Therefore

$$
\begin{equation*}
G_{n}=\frac{g_{n}\left(\alpha_{\overline{\mathrm{MS}}}(\mu), \mu / m_{h}\right)}{\left(a m_{h}(\mu)\right)^{n-4}}+\mathcal{O}\left(\left(a m_{h}\right)^{m}\right) \tag{4}
\end{equation*}
$$

for small $n \geq 4$, where $m_{h}(\mu)$ is the heavy quark's $\overline{\mathrm{MS}}$ mass at scale $\mu$, and the dimensionless factor $g_{n}$ can be computed using continuum perturbation theory.

Again following our previous paper, we introduce reduced moments to suppress both lattice artifacts and tuning errors in the heavy quark's mass [16]:

$$
R_{n} \equiv \begin{cases}G_{4} / G_{4}^{(0)} & \text { for } n=4  \tag{5}\\ \frac{a m_{\eta_{h}}}{2 a m_{0 h}}\left(G_{n} / G_{n}^{(0)}\right)^{1 /(n-4)} & \text { for } n \geq 6\end{cases}
$$

where $G_{n}^{(0)}$ is the moment in lowest-order, weak-coupling perturbation theory, using the lattice regulator, and $m_{\eta_{h}}$ is the (nonperturbative) mass of the pseudo-Goldstone $h \bar{h}$ boson. The reduced moments can again be written in terms of continuum quantities:

$$
R_{n} \equiv \begin{cases}r_{4}\left(\alpha_{\overline{\mathrm{MS}}}, \mu / m_{h}\right) & \text { for } n=4  \tag{6}\\ z\left(\mu / m_{h}, m_{\eta_{h}}\right) r_{n}\left(\alpha_{\overline{\mathrm{MS}}}, \mu / m_{h}\right) & \text { for } n \geq 6\end{cases}
$$

up to $\mathcal{O}\left(\left(a m_{h}\right)^{m} \alpha_{s}\right)$ corrections, where

$$
\begin{equation*}
z\left(\mu / m_{h}, m_{\eta_{h}}\right) \equiv \frac{m_{\eta_{h}}}{2 m_{h}(\mu)}, \tag{7}
\end{equation*}
$$

and $r_{n}$ is obtained from $g_{n}$ (Eq. (4)) and its value, $g_{n}^{(0)}$, in lowest-order continuum perturbation theory:

$$
r_{n}= \begin{cases}g_{4} / g_{4}^{(0)} & \text { for } n=4  \tag{8}\\ \left(g_{n} / g_{n}^{(0)}\right)^{1 /(n-4)} & \text { for } n \geq 6\end{cases}
$$

Our strategy for extracting quark masses and the QCD coupling relies upon lattice simulations to determine nonperturbative values for the $R_{n}$, using simulation results for $a m_{\eta_{h}} / a m_{0 h}$. We then compare this simulation "data" to the continuum perturbation theory formulas (Eq. (6)). That is, we find values for $\alpha_{\overline{\mathrm{MS}}}(\mu)$ and $z\left(\mu / m_{h}, m_{\eta_{h}}\right)$ that make lattice and continuum results agree for small $n \geq 4$. The function $z\left(\mu / m_{h}, m_{\eta_{h}}\right)$ can then be combined with experimental results for $m_{\eta_{c}}$ and $m_{\eta_{b}}$ to obtain masses for the $c$ and $b$ quarks:

$$
\begin{equation*}
m_{c}(\mu)=\frac{m_{\eta_{c}}^{\exp }}{2 z\left(\mu / m_{c}, m_{\eta_{c}}^{\exp }\right)} \quad m_{b}(\mu)=\frac{m_{\eta_{b}}^{\exp }}{2 z\left(\mu / m_{b}, m_{\eta_{b}}^{\exp }\right)} \tag{9}
\end{equation*}
$$

Parameter $\mu$ sets the scale for $\alpha_{\overline{\mathrm{MS}}}$ in the perturbative expansions of the $r_{n}$. An obvious choice for this parameter is $\mu=m_{h}$ since the quark mass, together with $n$, sets the momentum scale in our correlators. As noted in our previous paper, however, perturbation theory is somewhat more convergent if we use larger $\mu \mathrm{s}$ in the $c$ quark case. Consequently here we take $\mu / m_{h}=3$, which is approximately what we did in our previous paper.

The mass and coupling determinations were done separately in our previous paper. Here we extract them simultaneously, to guarantee consistency between results. Also in our previous paper we considered only heavyquark masses near the $c$ mass. Here we explore a variety of masses ranging from just below the $c$ mass to just below the $b$ mass. This allows us to obtain a value for $b$-quark's mass.

## III. LATTICE QCD SIMULATIONS

## A. Simulation Results

The gluon-configuration sets we use were created by the MILC collaboration. The relevant simulation parameters are listed in Table I

Given a lattice spacing, the QCD action is specified completely by the values of the bare coupling constant and the bare quark masses. In our analyses we set the $u$ and $d$ quark masses equal; this approximation results in negligible errors ( $\ll 1 \%$ ) for the quantities studied in this paper. It is too costly to simulate QCD at the correct value for the $u / d$ mass; we typically use masses that are $2-5$ times too large and extrapolate to values that give

TABLE I: Parameter sets used to generate the gluon configurations analyzed in this paper. The lattice spacing is specified in terms of the static-quark potential parameter $r_{1}=0.3133(23) \mathrm{fm}$; values for $r_{1} / a$ are from 13]. The bare quark masses are for the ASQTAD formalism and $u_{0}$ is the fourth root of the plaquette. The spatial $(L)$ and temporal $(T)$ lengths of the lattices are also listed, as are the number of gluon configurations ( $N_{\mathrm{cf}}$ ) and the number of time sources ( $N_{\mathrm{ts}}$ ) per configuration used in each case. Sets with similar lattice spacings are grouped.

| Set | $r_{1} / a$ | $a u_{0} m_{0 u / d}$ | $a u_{0} m_{0 s}$ | $u_{0}$ | $L / a$ | $T / a$ | $N_{\text {cf }} \times N_{\text {ts }}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | $2.152(5)$ | 0.0097 | 0.0484 | 0.860 | 16 | 48 | $631 \times 2$ |
| 2 | $2.138(4)$ | 0.0194 | 0.0484 | 0.861 | 16 | 48 | $631 \times 2$ |
| 3 | $2.647(3)$ | 0.005 | 0.05 | 0.868 | 24 | 64 | $678 \times 2$ |
| 4 | $2.618(3)$ | 0.01 | 0.05 | 0.868 | 20 | 64 | $595 \times 2$ |
| 5 | $2.618(3)$ | 0.01 | 0.05 | 0.868 | 28 | 64 | $269 \times 2$ |
| 6 | $3.699(3)$ | 0.0062 | 0.031 | 0.878 | 28 | 96 | $566 \times 4$ |
| 7 | $3.712(4)$ | 0.0124 | 0.031 | 0.879 | 28 | 96 | $265 \times 4$ |
| 8 | $5.296(7)$ | 0.0036 | 0.018 | 0.888 | 48 | 144 | $201 \times 2$ |
| 9 | $7.115(20)$ | 0.0028 | 0.014 | 0.895 | 64 | 192 | $208 \times 2$ |

the correct mass for the $\pi^{0}$-meson. We tune the strange quark mass to give the correct mass for the (fictitious) $\eta_{s}$ meson [10]. The $c$ and $b$ masses are tuned to give correct masses for the $\eta_{c}$ and $\eta_{b}$ mesons, respectively.

It is convenient in QCD simulations to specify a value for the bare coupling constant and then extract the value of the lattice spacing from the simulation. We set the lattice spacing using MILC results for $r_{1} / a$, computed from the heavy-quark potential, and [10]

$$
\begin{equation*}
r_{1}=0.3133(23) \mathrm{fm} \tag{10}
\end{equation*}
$$

The MILC configurations include vacuum polarization contributions from only the lightest three quark flavors, using the ASQTAD discretization. Vacuum polarization effects from the heavier $c$ and $b$ quarks are easily incorporated into our final results for quark masses and the QCD coupling using perturbation theory.

We computed heavy-quark correlators (Eq. (11) using the HISQ discretization [8] for a variety of bare heavyquark masses $a m_{0 h}$ on the MILC gluon configurations. Our results for the reduced moments $R_{n}$ with $n=4-18$ are given in Table II.

In Table II, we also give masses $a m_{\eta_{h}}$ from the simulations for the pseudo-Goldstone meson made from two heavy quarks. These were computed using singleexponential fits to $G(t)$ for the middle $30 \%$ of $t$ s on the lattice for all configurations except the two smallest lattice spacings where we used only $8 \%$ of the $t$. We have less statistics for the two finest lattice spacings and consequently the fits did not work as well for these. We increased the statistical errors on our results for $a m_{\eta_{h}}$ by factors of 1.4 and 2 for the next-to-finest and finest lattice spacings (sets 8 and 9 ), respectively, to account for this. The statistical errors here are very small and have only a small impact on our final results. We also verified our results with multi-exponential fits in every case.

## B. Systematic Errors

As discussed above, our goal is to find values for $\alpha_{\overline{\mathrm{MS}}}(\mu)$ and $z\left(\mu / m_{h}, m_{\eta_{h}}\right)$ (Eq. (77)) that make the theoretical results from perturbative QCD agree, to within statistical and systematic errors, with Monte Carlo simulation "data" for the reduced moments. We simultaneously analyze results for all of our lattice spacings and most of our masses, and for moments with $4 \leq n \leq 10$. We focus on these particular moments for our final results since their perturbation theory is known to third order.

Systematic errors are larger here than statistical errors, which contribute less than $0.3 \%$. We discuss the most important sources of systematic error in this section.

## 1. $m_{h}$ Extrapolations

We need the $m_{\eta_{h}}$ dependence of the mass-ratio function $z\left(\mu / m_{h}=3, m_{\eta_{h}}\right)$ in order to extract $c$ and $b$ masses from our simulation (using Eq. (9)). We parameterize this dependence as follows:

$$
\begin{equation*}
z\left(\mu / m_{h}, m_{\eta_{h}}\right)=\sum_{j=0}^{N_{z}} z_{j}\left(\mu / m_{h}\right)\left(\frac{2 \Lambda}{m_{\eta_{h}}}\right)^{j} \tag{11}
\end{equation*}
$$

where the $z_{j}$ s are determined in our fit. This is an expansion in the QCD scale, which we take to be

$$
\begin{equation*}
\Lambda=0.5 \mathrm{GeV} \tag{12}
\end{equation*}
$$

divided by $m_{\eta_{h}} / 2$, which we use as a proxy for the quark mass. The expansion is adequate for the range of quark masses used in our analysis, where $\left(2 \Lambda / m_{\eta_{h}}\right)^{2}$ ranges approximately between $1 / m_{\eta_{b}}^{2}=0.01$ and $\left(1 / m_{\eta_{c}}\right)^{2}=0.1$; the singular point $m_{h}=0$ is infinitely far away in this parameterization. In our fits we keep terms only through order $N_{z}=4$, but, as we discuss later, our results are unchanged by additional terms. On dimensional grounds, we assume a priori that the coefficients are

$$
\begin{equation*}
z_{j}(3)=0 \pm 1 \tag{13}
\end{equation*}
$$

## 2. Finite-Lattice Spacing Errors

Discretization errors are of order $\left(a m_{h}\right)^{2 i} \alpha_{s}$ for $i \geq 1$. We model these by

$$
\begin{equation*}
R_{n}^{\text {latt }}=R_{n}\left(\mu, m_{\eta_{h}}, a, N_{a m}\right) \tag{14}
\end{equation*}
$$

where: fit function $R_{n}\left(\mu, m_{\eta_{h}}, a, N_{a m}\right)$ has the double expansion

$$
\begin{align*}
& R_{n}\left(\mu, m_{\eta_{h}}, a, N_{a m}\right) \equiv R_{n}^{\mathrm{cont}} /  \tag{15}\\
& \qquad\left(1+\sum_{i=1}^{N_{a m}} \sum_{j=0}^{N_{z}} c_{i j}^{(n)}\left(\frac{a m_{\eta_{h}}}{2}\right)^{2 i}\left(\frac{2 \Lambda}{m_{\eta_{h}}}\right)^{j}\right)
\end{align*}
$$

TABLE II: Results for the reduced moments $R_{n}$ and pseudoscalar-meson mass $a m_{\eta_{h}}$ obtained from ( $n_{f}=3$ ) simulations using different bare heavy-quark (HISQ) masses $a m_{0 h}$ and gluon configuration sets (see Table I). The errors listed here are statistical errors from the Monte Carlo simulation. Results where $a m_{\eta_{h}}>1.95$ are omitted from our final analysis, as are $R_{n} s$ with $n>10$.

| Set | $a m_{0 h}$ | $a m_{\eta}$ | $R_{4}$ | $R_{6}$ | $R_{8}$ | $R_{10}$ | $R_{12}$ | $R_{14}$ | $R_{16}$ | $R_{18}$ |

|  | 0.700 | 1.7518(1) | 1.0900(1) | 1.2765(1) | 1.2261(1) | 1.1949(1) | 1.1718(1) | 1.1542(1) | 1.1407(1) | 1.1299(1) |
|  | 0.850 | 2.0428(1) | 1.0712(1) | 1.2327(1) | 1.1983(1) | 1.1760(1) | 1.1574(1) | 1.1418(1) | 1.1290(1) | 1.1185(1) |

the $c_{i j}^{(n)} \mathrm{s}$ are determined in our fit, $R_{n}^{\text {cont }}$ is given by Eq. (6),

$$
\begin{equation*}
i+j \leq \max \left(N_{a m}, N_{z}\right) \tag{16}
\end{equation*}
$$

and again we use $m_{\eta_{h}} / 2$ in place of the quark mass. This expansion allows for finite- $a$ corrections involving $\left(a m_{\eta_{h}} / 2\right)^{2},(a \Lambda)^{2}$, and cross terms, with $m_{\eta_{h}}$-dependent coefficients. We assume a priori that

$$
\begin{equation*}
c_{i j}^{(n)}=0 \pm 2 / n \tag{17}
\end{equation*}
$$

which implies smaller $a$ dependence for larger $n \mathrm{~s}$. This is expected (and obvious in our simulation data) since the reduced moments become more infrared as $n$ increases. The exact functional form of the $n$ dependence has little effect on our results, as we show later.

In our fits we take $N_{z}=4$. While low orders suffice for the $2 \Lambda / m_{\eta_{h}}$ expansion, expansion parameter $a m_{\eta_{h}} / 2$ ranges between 0.3 and 1.1, and higher orders are necessary, especially given our tiny statistical errors. We find that our fit results don't converge well unless $N_{a m}$ is larger than 10-20. Also we have difficulty getting good fits if we include data with $a m_{\eta_{h}}>1.95$ from Table II

The $a m_{\eta_{h}} / 2$ expansion may not converge for these last cases and therefore we exclude such data from our final analysis.

The fit function has many more fit parameters $c_{i j}^{(n)}$ than we have simulation data points when $N_{a m}$ is so large. This does not cause problems in (Bayesian) constrained fits since the parameters' priors (Eq. (17)) are included in the fit as extra data [17]. Each parameter has a prior and therefore we always have more data than parameters.

It is, however, very time consuming to fit a function with so many fit parameters. Although it is not essential for our analysis, there is a trick that greatly accelerates this kind of fit. The idea is to fit a modified moment $\bar{R}_{n}^{\text {latt }}$ in place of $R_{n}^{\text {latt }}$ where

$$
\begin{align*}
& \bar{R}_{n}^{\text {latt }} \equiv R_{n}^{\mathrm{latt}}+  \tag{18}\\
& R_{n}^{\mathrm{latt}} \sum_{i=\bar{N}_{a m}+1}^{N_{a m}} \sum_{j=0}^{N_{z}} c_{i j}^{(n)}\left(\frac{a m_{\eta_{h}}}{2}\right)^{2 i}\left(\frac{2 \Lambda}{m_{\eta_{h}}}\right)^{j} .
\end{align*}
$$

and $\bar{N}_{a m} \ll N_{a m}$. The modified moment is fit with the
much simpler formula (simpler since $\bar{N}_{a m} \ll N_{a m}$ )

$$
\begin{equation*}
\bar{R}_{n}^{\text {latt }}=R_{n}\left(\mu, m_{\eta_{h}}, a, \bar{N}_{a m}\right) \tag{19}
\end{equation*}
$$

where $R_{n}(\ldots)$ is again given by Eq. (15). To evaluate $\bar{R}_{n}^{\text {latt }}$ from Eq. (18), we treat the coefficients $c_{i j}^{(n)}$ with $i>\bar{N}_{a m}$ as new data with means and standard deviations specified by the prior, Eq. (17). Uncertainties coming from the $c_{i j}^{(n)} \mathrm{s}$ are combined in quadrature with the statistical error in $R_{n}^{\text {latt }}$ to obtain a new error estimate for $\bar{R}_{n}^{\text {latt }}$ (but leaving the central value unchanged). In effect we are increasing the error in the reduced moment to account for high-order $\left(a m_{\eta_{h}} / 2\right)^{2 i}$ terms omitted from the fit formula Eq. (19). By choosing $\bar{N}_{a m} \ll N_{a m}$, most of the $a m_{\eta_{h}} / 2$ terms are incorporated into $\bar{R}_{n}^{\text {latt }}$ (Eq. (18)), where they are inexpensive, and relatively few end up in the fit function $\bar{R}_{n}(\ldots)$ (Eq. (15)), where they add parameters to the fit and increase its cost. Note that the new errors introduce correlations between $\bar{R}_{n}^{\text {latt }} \mathrm{S}$ computed with different lattice spacings or quark masses, since the same $c_{i j}^{(n)}$ s are used for all $a$ s and $m_{\eta_{h}} \mathrm{~s}$. These correlations are important and need to be preserved in the fit.

Our procedure, whereby terms are moved out of the fitting function and incorporated into new (correlated) errors in the Monte Carlo fit data, is generally useful. Somewhat remarkably, final fit results are completely (or almost completely) independent of the number of terms that are transferred when fits are linear (or almost linear) in the associated parameters. (The general theorem from which this result follows is proven in the Appendix.) Consequently, in our analysis here, we can take $N_{a m}$ very large-say, $N_{a m}=80$ - and still have very fast fits by keeping $\bar{N}_{a m}$ very small. With $N_{a m}=80$ we find, for example, that setting $\bar{N}_{a m}=0$ in $\bar{R}_{n}(\ldots)$ (no terms) gives essentially identical results for our quark masses and coupling as setting $\bar{N}_{a m}=30$ (140 terms), even though the latter fit requires 22 times more computing. We used this procedure, with $\bar{N}_{a m}=0$, for most of our testing and development in this project.

## 3. Truncated Perturbation Theory

The perturbative part,

$$
\begin{equation*}
r_{n}\left(\alpha_{\overline{\mathrm{MS}}}, \mu / m_{h}\right)=1+\sum_{j=1}^{N_{\mathrm{pth}}} r_{n j}\left(\mu / m_{h}\right) \alpha_{\overline{\mathrm{MS}}}^{j}(\mu) \tag{20}
\end{equation*}
$$

of the reduced moments is known at best through third order. We present coefficients $r_{n j}$ through $j=3$ in Table III (2-6]; the values for $n=4-10$ are exact, while $r_{n 3}$ is estimated for the others. In our fits we include higherorder terms by treating the coefficients of these terms as fit parameters with prior

$$
\begin{equation*}
r_{n j}(1)=0 \pm 0.5 \tag{21}
\end{equation*}
$$

TABLE III: Perturbation theory coefficients ( $n_{f}=3$ ) for $r_{n}$ [2-6]. Coefficients are defined by $r_{n}=1+\sum_{j=1} r_{n j} \alpha_{\overline{\mathrm{MS}}}^{j}(\mu)$ for $\mu=m_{h}(\mu)$. The third-order coefficients are exact for $4 \leq n \leq 10$. The other coefficients are based upon estimates; we assign conservative errors to these.

| $n$ | $r_{n 1}$ | $r_{n 2}$ | $r_{n 3}$ |
| ---: | ---: | ---: | ---: |
| 4 | 0.7427 | -0.0577 | 0.0591 |
| 6 | 0.6160 | 0.4767 | -0.0527 |
| 8 | 0.3164 | 0.3446 | 0.0634 |
| 10 | 0.1861 | 0.2696 | 0.1238 |
| 12 | 0.1081 | 0.2130 | $0.1(3)$ |
| 14 | 0.0544 | 0.1674 | $0.1(3)$ |
| 16 | 0.0146 | 0.1293 | $0.1(3)$ |
| 18 | -0.0165 | 0.0965 | $0.1(3)$ |

for any coefficient that hasn't been computed in perturbation theory. We set $N_{\text {pth }}=6$ since then contributions from still higher orders should be less than $0.1 \%$ (and setting $N_{\text {pth }}=8$ doesn't change our results).

The perturbative coefficients for $\mu / m_{h}=1$ (Table III) are small and relatively uncorrelated from order-to-order. This is less true for $\mu / m_{h}=3$, which is where we wish to work (see Section II), because of $\log \left(\mu / m_{h}\right)^{m}$ terms. In order to capture these effects, we use renormalization group equations to express the $r_{n j}(3)$ coefficients (for all $j \leq N_{\text {pth }}$ ) in terms of the $r_{n j}(1)$ coefficients and $\log \left(\mu / m_{h}\right)$, and substitute the results from Table III for $j \leq 3$ and from the prior (Eq. (21)) for $j>3$. This procedure generates (correlated) priors for the unknown coefficients at $\mu / m_{h}=3$ that properly account for renormalization-group logarithms.

## 4. $\alpha_{\overline{\mathrm{MS}}}$ Evolution

As discussed above, we fix the ratio of $\mu / m_{h}(\mu)$ in our analysis. This means that the renormalization scale $\mu$ varies over a wide range of values for the different $m_{h} \mathrm{~S}$ we use. The coupling constant $\alpha_{\overline{\mathrm{MS}}}(\mu)$ used in the perturbative expansions for the $r_{n} \mathrm{~s}$ is specified at $\mu=5 \mathrm{GeV}$ by fit parameter $\alpha_{0}$, with prior

$$
\begin{equation*}
\alpha_{0}=0.20 \pm 0.01 \tag{22}
\end{equation*}
$$

where

$$
\begin{equation*}
\alpha_{0} \equiv \alpha_{\overline{\mathrm{MS}}}\left(5 \mathrm{GeV}, n_{f}=3\right) \tag{23}
\end{equation*}
$$

The prior corresponds to $\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}\right)=0.118(3)$ - a very broad range, which means that the prior has little impact on our final fit results. The coupling value at any scale $\mu \neq 5 \mathrm{GeV}$ is obtained by integrating (numerically) the QCD evolution equation for $\alpha_{\overline{\mathrm{MS}}}(\mu)$ starting with value $\alpha_{0}$ at scale 5 GeV . We use the $\overline{\mathrm{MS}}$ beta function
through sixth order in $\alpha_{\overline{\mathrm{MS}}}$,

$$
\begin{align*}
\mu^{2} \frac{d \alpha_{\overline{\mathrm{MS}}}(\mu)}{d \mu^{2}}= & -\beta_{0} \alpha \frac{2}{\overline{\mathrm{MS}}}-\beta_{1} \alpha \frac{3}{\overline{\mathrm{MS}}}-\beta_{2} \alpha \frac{4}{\overline{\mathrm{MS}}}  \tag{24}\\
& -\beta_{3} \alpha \frac{5}{\overline{\mathrm{MS}}}-\beta_{4} \alpha \frac{6}{\overline{\mathrm{MS}}}
\end{align*}
$$

where $\beta_{0} \ldots \beta_{3}$ are known from perturbation theory and $\beta_{4}$ is taken as a fit parameter with prior

$$
\begin{equation*}
\beta_{4}=0 \pm \sigma_{\beta} \tag{25}
\end{equation*}
$$

where $\sigma_{\beta}$ is the root-mean-square average of $\beta_{0} \ldots \beta_{3} 18$, 19]. We include this last term to estimate the uncertainties in our final results caused by unknown terms in the beta function.

Our simulations include vacuum polarization effects from only the three lightest quarks. We use perturbation theory, together with the $c$ and $b$ masses that come out of our analysis, to incorporate vacuum polarization effects from the heavier quarks into our final results for the masses and QCD coupling (using formulas from [20, 21] to add the $c$ and $b$ quarks at scales $\mu=m_{c}$ and $m_{b}$, respectively).

## 5. Nonperturbative Condensates

As discussed in our previous paper, nonperturbative effects dominate the reduced moments when $n$ is large. The dominant nonperturbative contribution, which is from the gluon condensate, is quite small, however, for the range of $n$ s and quark masses we use here. We correct for it by replacing

$$
\begin{equation*}
R_{n}^{\mathrm{latt}} \rightarrow R_{n}^{\mathrm{latt}}\left(1+d_{n} \frac{\left\langle\alpha_{s} G^{2} / \pi\right\rangle}{\left(2 m_{h}\right)^{4}}\right) \tag{26}
\end{equation*}
$$

where $d_{n}$ is computed to leading order in perturbation theory [22] with $m_{h}=m_{h}\left(m_{h}\right)$, which we approximate by $m_{\eta_{h}} / 2.27$. We take

$$
\begin{equation*}
\left\langle\alpha_{s} G^{2} / \pi\right\rangle=0 \pm 0.012 \mathrm{GeV}^{4} \tag{27}
\end{equation*}
$$

which covers the range of most current estimates [23]. The correction factor in Eq. (26) adds (slightly) to the error in $R_{n}^{\text {latt }}$ (and introduces new correlations between different moments, since the same $\left\langle\alpha_{s} G^{2} / \pi\right\rangle$ is assumed for every moment, lattice spacing and quark mass).

## 6. Finite Volume Errors

We expect small errors due to the fact that our simulation lattices are only about 2.5 fm across. We allow for the possibility of finite-volume errors by replacing

$$
\begin{equation*}
R_{n}^{\text {latt }} \rightarrow R_{n}^{\text {latt }}\left(1+f_{n} \frac{\Delta R_{n}^{\text {pth }}}{R_{n}^{\text {pth }}}\right) \tag{28}
\end{equation*}
$$

where $\Delta R_{n}^{\text {pth }}$ is the finite volume error in leading-order perturbation theory and

$$
\begin{equation*}
f_{n}=0 \pm 0.5 \tag{29}
\end{equation*}
$$

The true finite-volume errors are expected to be smaller, because of quark confinement, than the perturbative errors that we use to model them here. We verified this by running two sets of simulations that were identical except for the spatial volume (gluon configuration sets 4 and 5 in Table【I). The differences between the two simulations are smaller than our statistical errors, but the statistical errors are much smaller than our estimate above. Our error estimate here is very conservative, but has negligible impact on our final results.

## 7. Sea-Quark Masses

The sea-quark masses used in our simulations are not exactly correct. To correct for this we replace

$$
\begin{equation*}
R_{n}^{\mathrm{latt}} \rightarrow R_{n}^{\mathrm{latt}}\left(1+g_{n} \frac{2 \delta m_{l}+\delta m_{s}}{m_{s}}\right) \tag{30}
\end{equation*}
$$

where $\delta m_{l}$ and $\delta m_{s}$ are the errors in the $u / d$ and $s$ masses (see 10] for more details), respectively, and

$$
\begin{equation*}
g_{n}=0 \pm 0.01 \tag{31}
\end{equation*}
$$

This correction introduces (correlated) errors into the $R_{n}^{\text {latt }}$ s that are of order $0.5-1 \%$. Direct comparison of results from configuration sets 6 and 7 (or 1-2 and $3-$ 4) in Table $\square$ suggests that sea-quark mass effects are no larger than $0.1 \%$, so our error estimate is conservative.

We have only included the leading dependence on the sea-quark mass, which comes from nonperturbative (chiral) effects. Quadratic terms from perturbation theory and other nonperturbative sources are negligible.

## IV. ANALYSIS AND RESULTS

We have computed reduced moments for 30 different sets of lattice spacing, lattice volume and quark masses (Table III). To extract quark masses and the QCD coupling, we fit moments with $4 \leq n \leq 10$ from 22 of these parameter sets (the ones with $a m_{\eta_{h}} \leq 1.95$ ) - 88 pieces of simulation data in all. In this section we first describe the fitting method used to extract the masses and coupling, and then we review our results.

## A. Constrained Fits

We analyze all four $R_{n}$ s for all 22 parameter sets simultaneously using a constrained fitting procedure based
upon Bayesian ideas [17]. In this procedure we minimize an augmented $\chi^{2}$ function of the form

$$
\begin{equation*}
\chi^{2}=\sum_{i n, j m} \Delta R_{n i}\left(\sigma_{R}^{-2}\right)_{i n, j m} \Delta R_{m j}+\sum_{\xi} \delta \chi_{\xi}^{2} \tag{32}
\end{equation*}
$$

where:

$$
\begin{equation*}
\Delta R_{n i} \equiv R_{n i}^{\text {latt }}-R_{n}\left(\mu_{i}, m_{\eta_{h} i}, a_{i}, N_{a m}\right) ; \tag{33}
\end{equation*}
$$

the $R_{n}^{\text {latt }}$ come from Table II with corrections from Eqs. (26), (28) and (30); fit function $R_{n}(\ldots)$ is defined by Eq. (15); and $\sigma_{R}^{2}$ is the error covariance matrix for the $R_{n}^{\text {latt }}$. The sums $i, j$ are over the 22 sets of lattice spacings and quark masses; the sums $n, m$ range over of the moments $4,6,8,10$.

Function $R_{n}\left(\mu_{i}, m_{\eta_{h} i}, a_{i}, N_{a m}\right)$ depends upon a large number of parameters, all of which are varied in the fit to minimize $\chi^{2}$. Priors $\delta \chi_{\xi}^{2}$ are included for each of these:

- parameters $z_{j}$, with prior Eq. (13), from the $1 / m_{\eta_{h}}$ expansion of $z\left(\mu / m_{h}, m_{\eta_{h}}\right)$;
- parameters $c_{i j}^{(n)}$, with prior Eq. (17), from the finite-lattice spacing corrections;
- unknown perturbative coefficients $r_{n j}$, with prior Eq. (21) (evolved to $\mu / m_{h}=3$ );
- coupling parameter $\log \left(\alpha_{0}\right)$, with prior Eq. (22);
- $\beta_{4}$ in the QCD $\beta$-function, with prior Eq. (25);
- lattice spacings $a_{i}$ for each gluon configuration set, with priors specified by simulation results for $r_{1} / a$ (Table【) and the current value for $r_{1}$ (Eq. (10));
- values for $a m_{\eta_{h} i}$, with priors specified by our simulation results (Table II).

The renormalization scales $\mu_{i}$ are obtained from the ratio $\mu / m_{h}=3$, simulation results for $m_{\eta_{h}}$, and Eq. (7). We take $N_{a m}=30$ for our final results.

## B. Results

We fit our simulation data for the reduced moments $R_{n}^{\text {latt }}$ (Table III) using fit function $R_{n}(\ldots)$ (Eq. (15)) with $N_{a m}=30$, as discussed in the previous section. The best-fit values for parameters $z_{j}$ give us the mass-ratio function $z\left(\mu / m_{h}=3, m_{\eta_{h}}\right)$ (Eq. (7)), which we plot in Figure 1 We also show our simulation results there for $R_{n}^{\text {latt }} / r_{n}$, together with the best-fit lines for each lattice spacing. Results are shown for the three moments that depend upon $z, 5$ different lattice spacings, and quark masses ranging from below the $c$ mass almost to the $b$ mass. The simulation data were all fit simultaneously, using the same functions $z\left(3, m_{\eta_{h}}\right)$ and $\alpha_{\overline{\mathrm{MS}}}(\mu)$ (with $\left.\mu=3 m_{\eta_{h}} /(2 z)\right)$ for all moments. The fits are excellent, with $\chi^{2} / 88=0.19$ for the 88 pieces of simulation data we fit.

FIG. 1: Function $z\left(\mu / m_{h}=3, m_{\eta_{h}}\right) \equiv m_{\eta_{h}} /\left(2 m_{h}\right)$ as a function of $m_{\eta_{h}}$. The solid line, plus gray error envelope, shows the $a=0$ extrapolation obtained from our fit. This is compared with simulation results for $R_{n} / r_{n}$ for $n=6,8,10$ from our 5 different lattice spacings, together with the best fits (dashed lines) corresponding to those lattice spacings. Dashed lines for smaller lattice spacings extend further to the right. The points marked by an " $x$ " are for the largest mass we tried (last line in Table II); these are not included in the fit because $a m_{\eta_{h}}$ is too large. Finite- $a$ errors become very small for the larger- $n$ moments, causing points from different lattice spacings to overlap.

Evaluated at $m_{\eta_{c}}=2.985(3) \mathrm{GeV}$ [24], the massratio function is $z\left(3, m_{\eta_{c}}\right)=1.507(7)$. Combining this with Eq. (9) and perturbation theory, we can obtain the following results for the $\overline{\mathrm{MS}} c$-quark mass at different scales:

$$
\begin{align*}
m_{c}\left(3 m_{c}, n_{f}=3\right) & =0.991(5) \mathrm{GeV},  \tag{34}\\
m_{c}\left(3 \mathrm{GeV}, n_{f}=4\right) & =0.986(6) \mathrm{GeV}, \\
m_{c}\left(m_{c}, n_{f}=4\right) & =1.273(6) \mathrm{GeV} .
\end{align*}
$$

Similarly at $m_{\eta_{b}}=9.395(5) \mathrm{GeV}$ [25], the mass-ratio function is $z\left(3, m_{\eta_{b}}\right)=1.296(8)$, and we obtain the following results for the $\overline{\text { MS }} b$-quark mass at different scales:

$$
\begin{align*}
m_{b}\left(3 m_{b}, n_{f}=3\right) & =3.622(22) \mathrm{GeV} .  \tag{35}\\
m_{b}\left(10 \mathrm{GeV}, n_{f}=5\right) & =3.617(25) \mathrm{GeV}, \\
m_{b}\left(m_{b}, n_{f}=5\right) & =4.164(23) \mathrm{GeV} .
\end{align*}
$$

Note that the ratio $m_{b}\left(\mu, n_{f}\right) / m_{c}\left(\mu, n_{f}\right)$ is independent of $\mu$ and $n_{f}$. We obtain the following result for this

FIG. 2: QCD coupling $\alpha_{\overline{\mathrm{MS}}}\left(\mu, n_{f}=3\right)$ as a function of $m_{\eta_{h}}$ where $\mu=3 m_{h}$. The solid line, plus gray error envelope, shows the best-fit coupling from our fit when perturbative evolution is assumed. The data points are values of $\alpha_{\overline{\text { MS }}}$ extracted from individual simulation results for $R_{n}$ after extrapolating to $a=0$ and dividing out $z\left(3, m_{\eta_{h}}\right)(n>4)$. Results are given for moments $n=4-10$ and all 5 lattice spacings. Several points from different lattice spacings overlap in these plots.
mass ratio:

$$
\begin{equation*}
m_{b} / m_{c}=4.53(4) \tag{36}
\end{equation*}
$$

The other important output from our fit is a value for the parameter

$$
\begin{equation*}
\alpha_{0} \equiv \alpha_{\overline{\mathrm{MS}}}\left(5 \mathrm{GeV}, n_{f}=3\right)=0.2034(21) \tag{37}
\end{equation*}
$$

To compare with other determinations of the coupling, we add vacuum polarization corrections from the $c$ and $b$ quarks, using the masses above, and evolve to the $Z$ meson mass 18 21]:

$$
\begin{equation*}
\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}, n_{f}=5\right)=0.1183(7) \tag{38}
\end{equation*}
$$

TABLE IV: Sources of uncertainty for the QCD coupling and mass determinations in this paper. In each case the uncertainty is given as a percentage of the final value.

|  | $\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}\right)$ | $m_{b}(10)$ | $m_{b} / m_{c}$ | $m_{c}(3)$ |
| :---: | :---: | :---: | :---: | :---: |

| Total | $0.6 \%$ | $0.7 \%$ | $0.8 \%$ | $0.6 \%$ |

Figure 2 shows how consistent our simulation results are with the theoretical curve for $\alpha_{\overline{\mathrm{MS}}}\left(\mu, n_{f}=3\right)$ corresponding to our value for $\alpha_{0}$. For this figure we extracted values for $\alpha_{\overline{\mathrm{MS}}}$ from each $R_{n}$ separately by dividing out the $a^{2}$ dependence and $z\left(3, m_{\eta_{h}}\right)$ using our best-fit parameters, and then solving for $\alpha_{\overline{\mathrm{MS}}}$ by matching with perturbation theory for $r_{n}$. (In our fit, of course, we fit all $R_{n} \mathrm{~S}$ simultaneously to obtain a single $\alpha_{\overline{\mathrm{MS}}}$ for all of them.)

The dominant sources of error for our results are listed in Table IV. The largest uncertainties come from: extrapolations to $a=0$, especially for quantities involving $b$ quarks; unknown higher-order terms in perturbation theory, especially for quantities involving $c$ quarks; statistical fluctuations; extrapolations in the heavy quark mass, especially for quantities involving $b$ quarks; and uncertainties in static-quark parameters $r_{1} / a$ and $r_{1}$. The pattern of errors is as expected in each case. The nonperturbative contribution from the gluon condensate is negligible except for $m_{c}$, again as expected; and errors due to mistuned sea-quark masses, finite volume errors, and uncertainties in $\overline{\mathrm{MS}}$ coupling and mass evolution are negligible ( $<0.05 \%$ ).

The $a^{2}$ extrapolations of our data are not large. This is illustrated for $m_{h} \approx m_{c}$ in Figure 3, which shows the $a^{2}$ dependence of the reduced moments. The smallest two lattice spacings are sufficiently close to $a=0$ that the extrapolation is almost linear from those points. The $a=$ 0 extrapolated values we obtain here for the $R_{n}$ agree to within (smaller) errors with those in our previous paper: here we get $1.282(4), 1.527(4), 1.373(3), 1.304(2)$ with $n=4,6,8,10$, respectively, for the masses used in the figure.

We tested the stability of our analysis in several ways:

- Vary perturbation theory: We chose $\mu=3 m_{h}$ in order to keep scales large and $\alpha_{\overline{\mathrm{MS}}}(\mu)$ small. Our results are quite insensitive to $\mu$, however. Choosing $\mu=m_{h}$, for example, shifts none of our results by more than $0.2 \sigma$, and leaves all errors unchanged except for $m_{c}(3)$, where the error increases by a third. Taking $\mu=9 m_{h}$ shifts results by less than

FIG. 3: Lattice spacing dependence of $R_{n}$ for masses $m_{\eta_{h}}$ within $5 \%$ of $m_{\eta_{c}}$ and moments $n=4,6,8,10$. The dashed lines show our fit for the average of these masses, and the points at $a=0$ are the continuum extrapolations of our data.
$0.4 \sigma$, and reduces the $m_{c}$ error by a third, leaving others only slightly reduced. Adding more terms to the perturbative expansions $\left(N_{\text {pth }}=6 \rightarrow 8\right)$ also has essentially no effect on the results. The prior for the unknown perturbative coefficients (Eq. (21)) is twice as wide as suggested by our simulation results (using the empirical Bayes criterion [17]); we choose the larger width to be conservative.

- Include more/fewer finite-a corrections: We set $N_{a m}=30$ for our results above. Using $N_{a m}=15$ gives results that differ by less than $0.5 \sigma$ for $m_{b}$ and much less for the other quantities. Much larger $N_{a m} \mathrm{~s}$ can be tested easily using the trick described in Section IIIB 2, For example, replacing $R_{n}^{\text {latt }}$ by $\bar{R}_{n}^{\text {latt }}$ (Eq. (18)) with $N_{a m}=80$ and $\bar{N}_{a m}=30$ gives results that are essentially identical to those above. As discussed above, taking $\bar{N}_{a m}=0$ with the same $N_{a m}$ also gives the same results and is 22 times faster (see the appendix for further discussion).
- Change $n$ dependence of finite-a corrections: Replacing the $n$-dependent prior for the expansion coefficients (Eq. (17)) by the $n$-independent prior $0 \pm$ 0.5 causes changes that are less than $0.3 \sigma$. The width of the original prior is optimal according to the empirical Bayes criterion - that is, it is the width suggested by the size of finite- $a$ deviations observed in our simulation data.
- Add more/fewer $\Lambda / m \eta_{h}$ terms in $z$ : Increasing the number of terms in the expansion for $z$ from $N_{z}=4$ to 6 changes nothing by more than $0.1 \sigma$. Decreasing to $N_{z}=3$ also has no effect. Again the width of the prior is optimal according to the empirical Bayes criterion.
- Include more/fewer moments: Keeping all mo-
ments $4 \leq n \leq 18$ changes nothing by more than $0.5 \sigma$ and reduces errors slightly for everything other than $m_{b}$, where the errors are cut almost in half: $m_{b}(10)=3.623(15) \mathrm{GeV}$ or $m_{b}\left(m_{b}\right)=$ $4.170(13) \mathrm{GeV}$, both for $n_{f}=5$. We continue to restrict ourselves to moments with $n \leq 10$ because these are the only moments for which we have exact third-order perturbation theory. Keeping just $n=4,6$ gives almost identical results for $m_{c}$ and $\alpha_{\overline{\mathrm{MS}}}$, with almost the same errors, but doubles the error on $m_{b}$.
- Omit simulation data: The coarsest two lattice spacings (configuration sets $1-5$ ) affect our results only weakly. Leaving these out shifts no result by more than $0.5 \sigma$ and leaves errors almost unchanged. Leaving out the smallest lattice spacing, however, increases errors significantly (almost double for $\alpha_{\overline{\mathrm{MS}}}$ ), while still shifting central values by less than $0.5 \sigma$.
- Add large masses: Including cases with $a m_{\eta_{h}}>$ 1.95 from Table II leads to poor fits. The excluded data, however, do not deviate far from the best-fit lines. For example, the points marked with an " $x$ " in Figure 1 are for the largest mass we studied, corresponding to $m_{\eta_{h}}=9.15 \mathrm{GeV}$ (last line in Table III). Although $a m_{\eta_{h}}$ is too large for this case to be included in our fit, the values of $R_{n} / r_{n}$ are only slightly below the fit results.

## V. NONPERTURBATIVE $m_{b} / m_{c}$

It is possible to extract the ratio of quark masses $m_{b} / m_{c}$ directly, without using the moments and without using perturbation theory. This provides an excellent nonperturbative check on our results from the moments.

Ratios of quark masses are UV-cutoff independent and therefore the ratio of $\overline{\mathrm{MS}}$ masses

$$
\begin{equation*}
\frac{m_{b}\left(\mu, n_{f}\right)}{m_{c}\left(\mu, n_{f}\right)}=\frac{m_{0 b}}{m_{0 c}}+\mathcal{O}\left(\alpha_{s} a^{2} m_{b}^{2}\right) \tag{39}
\end{equation*}
$$

for any $\mu$ and $n_{f}$, where $m_{0 b}$ and $m_{0 c}$ are the bare quark masses in the lattice quark action that give correct masses for the $\eta_{c}$ and $\eta_{b}$, respectively. We obtain accurate mass ratios from this relationship by extrapolating to $a=0$. We used such a method recently to determine $m_{c} / m_{s}$ [11].

Here we have to modify our earlier method slightly because we cannot reach the $b$-quark mass directly, but rather must simultaneously extrapolate to the $b$ mass and the continuum limit. This is most simply done by determining the functional dependence of the ratio

$$
\begin{equation*}
w\left(m_{\eta_{h}}, a\right) \equiv \frac{2 m_{0 h}}{m_{\eta_{h}}} \tag{40}
\end{equation*}
$$

on the $\eta_{h}$ mass and the lattice spacing. The ratio of $\overline{\mathrm{MS}}$ masses is then given by the experimental masses of the $\eta_{c}$ and $\eta_{b}$ and the equation:

$$
\begin{equation*}
\frac{m_{b}\left(\mu, n_{f}\right)}{m_{c}\left(\mu, n_{f}\right)}=\frac{m_{\eta_{b}}^{\exp } w\left(m_{\eta_{b}}^{\exp }, 0\right)}{m_{\eta_{c}}^{\exp } w\left(m_{\eta_{c}}^{\exp }, 0\right)} \tag{41}
\end{equation*}
$$

It might seem simpler to fit $m_{0 h}$ directly, rather than the ratio $w$; but using $w$ significantly reduces the $m_{\eta_{h}}$ dependence (and therefore our extrapolation errors), and also makes our results quite insensitive to uncertainties in our values for the lattice spacing.

We parameterize function $w$ with an expansion modeled after the one we used to fit the moments:

$$
\begin{align*}
& w\left(m_{\eta_{h}}, a\right)=Z_{m}(a)\left(1+\sum_{n=1}^{N_{w}} w_{n}\left(\frac{2 \Lambda}{m_{\eta_{h}}}\right)^{n}\right) /  \tag{42}\\
&\left(1+\sum_{i=1}^{N_{a m}} \sum_{j=0}^{N_{w}} c_{i j}\left(\frac{a m_{\eta_{h}}}{2}\right)^{2 i}\left(\frac{2 \Lambda}{m_{\eta_{h}}}\right)^{j}\right)
\end{align*}
$$

where, as for the moments,

$$
\begin{equation*}
i+j \leq \max \left(N_{a m}, N_{w}\right) \tag{43}
\end{equation*}
$$

Coefficients $c_{i j}$ and $w_{n}$ are determined by fitting function $w\left(m_{\eta_{h}}, a\right)$ to the values of $2 a m_{0 h} /\left(a m_{\eta_{h}}\right)$ from Table II. The fit also determines the parameters $Z_{m}(a)$, one for each lattice spacing, which account for the running of the bare quark masses between different lattice spacings.

The finite- $a$ dependence is smaller here than for the moments, because the $\eta_{h}$ is nonrelativistic (finite- $a$ errors are suppressed by additional powers of $v / c$ [8]), and the variation with $m_{\eta_{h}}$ stronger (twice that of $z\left(3, m_{\eta_{h}}\right)$ ). So here we use priors

$$
\begin{align*}
c_{i j} & =0 \pm 0.05  \tag{44}\\
w_{n} & =0 \pm 4 \\
Z_{m}(a) & =1 \pm 0.5
\end{align*}
$$

with $N_{w}=8$. We again take $N_{a m}=30$, although identical results are obtained with $N_{a m}=15$.

Our fit results are illustrated by Figure 4 which plots the ratio $m_{0 h} / m_{\eta_{h}}$ divided by $m_{0 c} / m_{\eta_{c}}$ for a range of $\eta_{h}$ masses. Our data for different lattice spacings is compared with our fit, and with the $a=0$ limit of our fit (solid line). The fit is excellent, with $\chi^{2} / 22=0.42$ for the 22 pieces of data we fit (we again exclude cases with $\left.a m_{\eta_{h}}>1.95\right)$. Using the $\eta_{c}$ and $\eta_{b}$ masses from Section IVB, and Eq. (41) with the best-fit values for the parameters, we obtain finally

$$
\begin{align*}
\frac{m_{0 b}}{m_{0 c}} & \rightarrow 4.49(4) \quad \text { as } a \rightarrow 0  \tag{45}\\
& =\frac{m_{b}\left(\mu, n_{f}\right)}{m_{c}\left(\mu, n_{f}\right)}
\end{align*}
$$

which agrees well with our result from the moments (Eq. (36) ).

FIG. 4: Ratio $m_{0 h} / m_{\eta_{h}}$ divided by $m_{0 c} / m_{\eta_{c}}$ (which we approximate by $w\left(m_{\eta_{c}}, a\right) / 2$ from our fit) as a function of $m_{\eta_{h}}$. The solid line shows the $a=0$ extrapolation obtained from our fit. This is compared with simulation results for our 4 smallest lattice spacings, together with the best fits (dashed lines) corresponding to those lattice spacings. The point marked by an " $x$ " is for the largest mass we tried (last line in Table 【I); this was not included in the fit because $a m_{\eta_{h}}$ is too large.

## VI. $\alpha_{\overline{\text { MS }}}$ FROM WILSON LOOPS

In a recent paper [26], we presented a very accurate determination of the QCD coupling from simulation results for Wilson loops. Here we want to compare those results to the value we obtain from heavy-quark correlators. First, however, we must update our earlier analysis to take account of the new value for $r_{1}$ [10] given in Eq. (10) and improved values for $r_{1} / a$ (13] given in Table (The Wilson-loop paper uses some additional configuration sets: from Table II in that paper, sets $1,6,9$, and 11 whose new $r_{1} / a$ s are 1.813(8), 2.644(3), 5.281(8) and $5.283(8)$, respectively.) We have rerun our earlier analysis, updating $r_{1}, r_{1} / a$, and the $c$ and $b$ masses. The results are shown in Figure 5. Combining results as in the earlier paper we obtain a final value from the Wilson-loop quantities of

$$
\begin{equation*}
\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}, n_{f}=5\right)=0.1184(6), \tag{46}
\end{equation*}
$$

with $\chi^{2} / 22=0.3$ for the 22 quantities in the figure. This agrees very well with the result in the earlier paper, $\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}\right)=0.1183(8)$, but has a slightly smaller error, as expected given the smaller error in $r_{1}$. This new value also agrees well with our very different determination from heavy-quark correlators (Eq. (38)). A breakdown of the error into its different sources can be found in Table IV of [26] (reduce the $r_{1}$ and $r_{1} / a$ errors in that table by half to account for the improved values used here).

FIG. 5: Updated values for the 5 -flavor $\alpha_{\overline{\mathrm{MS}}}$ at the $Z$-meson mass from each of 22 different short-distance quantities built from Wilson loops. The gray band indicates a composite average, $0.1184(6) . \chi^{2}$ per data point is 0.3 .

## VII. CONCLUSIONS

In this paper, we improve significantly on our previous determinations of the QCD coupling and $c$-quark mass from heavy-quark correlators. This is principally due to the inclusion of a new, smaller lattice spacing in our analysis. We also generated results for a variety of quark masses near $m_{c}$, allowing us to interpolate more accurately to the physical value of $m_{c}$. New third-order perturbation theory makes $R_{10}$ as useful now as $R_{4}, R_{6}$, and $R_{8}$ were in the earlier paper. Finally, in this paper, we fit multiple moments simultaneously, determining consistent values simultaneously for both the QCD coupling and the quark masses for all moments. Previously we examined each moment or ratio of moments independently, extracting $m_{c}$ s or $\alpha_{\overline{\mathrm{MS}}} \mathrm{s}$ independently of each other. Our

FIG. 6: $z\left(\mu / m_{h}, m_{\eta_{h}}\right)$ versus $m_{\eta_{h}}$ (in GeV ) for three different values of $\mu / m_{h}$. The curve for $\mu=3 m_{h}$ comes from the best fit to the moments. The other curves are obtained by evolving perturbatively from $\mu=3 m_{h}$.

FIG. 7: Simulation results for reduced moments $R_{n}$ with $n=$ $6,8,10$ as functions of $m_{\eta_{h}}$ for 5 different lattice spacings. The dashed lines show the corresponding behavior of our fit function, with the best-fit parameters. The curves for smaller lattice spacings extend further to the right. The solid lines show the $a=0$ limit of our best fit.
new results,

$$
\begin{align*}
m_{c}\left(3 \mathrm{GeV}, n_{f}\right. & =4)  \tag{47}\\
\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}, n_{f}\right. & =5)
\end{align*}=0.986(6) \mathrm{GeV}, 1183(7), ~ \$
$$

agree well with our older results of $0.986(10) \mathrm{GeV}$ and $0.1174(12)$, respectively [1].

The much heavier $b$ quark is usually analyzed using effective field theories like NRQCD or the static-quark approximation. By using very small lattice spacings and the very highly improved HISQ discretization for the heavy quarks, we are able to extend our analysis almost to the $b$-quark mass, using the same relativistic discretization that we use for $c$ and lighter quarks. A $1.5 \%$ extrapolation of $z\left(3, m_{h}\right)$, from the largest $m_{\eta_{h}}$ used in our fits to $m_{\eta_{b}}$, gives us a new, accurate determination of the $b$-quark mass,

$$
\begin{equation*}
m_{b}\left(10 \mathrm{GeV}, n_{f}=5\right)=3.617(25) \mathrm{GeV} \tag{48}
\end{equation*}
$$

This calculation demonstrates the utility of the HISQ formalism for studying $b$ quarks on lattices that are computationally accessible today. This represents a breakthrough for $b$ physics on the lattice since far greater precision becomes possible when all quarks are treated using the same formalism, and that formalism is relativistic and has a chiral symmetry. Even better would be to work right at the $b$ mass, as opposed to extrapolating from nearby; this would require a lattice spacing of order 0.03 fm .

Both of our new $c$ and $b$ masses agree well with non-lattice determinations from vector-current correlators and experimental $e^{+} e^{-}$collisions. A recent analysis of the continuum data gives [7]

$$
\begin{align*}
m_{c}\left(3 \mathrm{GeV}, n_{f}\right. & =4) \tag{49}
\end{align*}=0.986(13) \mathrm{GeV},{ }_{b}\left(m_{b}, n_{f}=5\right)=4.163(16) \mathrm{GeV}
$$

which compare well with our values of $0.986(6) \mathrm{GeV}$ and $4.164(23) \mathrm{GeV}$, respectively. This provides strong evidence that the different systematic errors in each calculation are understood.

Function $z\left(\mu / m_{h}, m_{\eta_{h}}\right)$ is a by-product of our analysis. It relates the $\overline{\mathrm{MS}}$ quark mass $m_{h}(\mu)$ to the $\eta_{h}$ mass (Eq. (7)). We show our result again in Figure 6 for $\mu=3 m_{h}$, as well as for $\mu=m_{h}$ and $\mu=m_{h} / 2$, which we obtain by evolving perturbatively from $\mu=3 m_{h}$. The latter two curves are relatively flat, and the last surprisingly close to 1 for most masses.

Questions have been raised about the way perturbation theory is used in analyzing the perturbative parts of the moments [27]. Like 7] we favor using larger scales than $m_{c}$ for $c$-quark correlators, but, as we have shown, our results are quite insensitive to $\mu$ over a broad range. Furthermore, the fact that our results, from pseudoscalar-density correlators, agree so well with the continuum results, from vector-current correlators, is also compelling evidence that perturbation theory is being handled correctly. We also find consistent results from several different moments, which is only possible if perturbation theory is working well. Compare, for example, Figure 7 for the moments, as a function of $m_{\eta_{h}}$, with the plots of $R_{n} / r_{n}$ in Figure 1 Figure 7 shows very different $m_{\eta_{h}}$ behavior, at the 10-20\% level, for different moments $R_{n}$; Figure 1, where the perturbative part $r_{n}$ is divided out, shows behavior that is almost momentindependent.

An additional check on our use of perturbation theory comes from the close agreement between our perturbative result for the ratio $m_{b} / m_{c}$ of $\overline{\mathrm{MS}}$ masses (Eq. (36)) and our nonperturbative result for the ratio of HISQ masses (Eq. (45)). These should be and are equal to within our 1\% errors. Taken together they suggest a composite result of:

$$
\begin{equation*}
\frac{m_{b}\left(\mu, n_{f}\right)}{m_{c}\left(\mu, n_{f}\right)}=4.51(4) \quad \text { (composite). } \tag{50}
\end{equation*}
$$

The validity of our perturbative analyses is further supported by the close agreement between the

FIG. 8: The 5 -flavor QCD coupling $\alpha_{\overline{\text { MS }}}$ at the $Z$ mass as determined by a variety of different methods. The non-lattice numbers used here are from the review in [28].

QCD coupling we get from the heavy-quark correlators, $\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}\right)=0.1183(7)$, and that obtained from Wilson loops, $0.1184(6)$. These are radically different methods for determining the coupling. The first relies upon a continuum quantity, extrapolated to $a=0$, and continuum perturbation theory. The second relies upon quantities that are highly sensitive to the UV cutoff $(\pi / a)$ but are analyzed to all orders in the cutoff using lattice perturbation theory. Systematic errors are almost completely different in the two cases. The fact that they agree to within our $0.6 \%$ uncertainties is highly nontrivial evidence that perturbative and other potential errors are understood.

Our coupling values also agree well with determinations from non-lattice methods. Figure 8 summarises recent results that were included in a world average by Bethke [28]. The world average result, 0.1184(7), was dominated by our previous determination from the Wilson loop analysis. The average excluding our result was 0.1186(11), which also agrees well. Including our new results into a new error-weighted world average gives $\alpha_{\overline{\mathrm{MS}}}\left(M_{Z}\right)=0.1184(4)$.

Our new $c$ mass is the most accurate currently available. With it we can improve slightly on our recent determination of light quark masses using an accurate value for $m_{c} / m_{s}, 11.85(16)$, derived completely nonperturbatively from lattice calculations [11]. Our new $c$ mass, which becomes $1.093(6) \mathrm{GeV}$ when converted to $n_{f}=3$ at 2 GeV , implies:

$$
\begin{align*}
& m_{s}\left(2 \mathrm{GeV}, n_{f}=3\right)=92.2(1.3) \mathrm{MeV}  \tag{51}\\
& m_{d}\left(2 \mathrm{GeV}, n_{f}=3\right)=4.77(15) \mathrm{MeV} \\
& m_{u}\left(2 \mathrm{GeV}, n_{f}=3\right)=2.01(10) \mathrm{MeV}
\end{align*}
$$

Our results for all 5 quark masses are compared with the

FIG. 9: $\overline{\mathrm{MS}}$ masses, for the 5 lightest quarks, from this paper compared with the Particle Data Group's current estimates 29]. Each mass is quoted at its conventional scale: 2 GeV for $u, d, s\left(n_{f}=3\right) ; m_{c}$ for $c\left(n_{f}=4\right) ; m_{b}$ for $b\left(n_{f}=5\right)$.

Particle Data Group's 2009 values in Figure 9 . Agreement is excellent, but our uncertainties are much smaller in every case, and by an order of magnitude for the strange and light quarks.

Finally we note that the consistency between quark masses from lattice and non-lattice analyses, and between couplings from heavy-quark correlators and Wilson loops provides further evidence that taste-changing interactions in the HISQ and ASQTAD quark formalisms are understood and vanish as $a \rightarrow 0$. While early concerns about the validity of these formalisms have been largely addressed both by formal arguments [13, 30-34] and by extensive empirical studies 8-11, 26, 35-39], it remains important to test the simulation technology of lattice QCD with increasing precision, given the growing importance of lattice results for phenomenology.

## Acknowledgements

We are grateful to MILC for configurations and thank Hans Kühn for useful discussions. Computing was done at the Ohio Supercomputer Centre, USQCDs Fermilab cluster and at the Argonne Leadership Computing Facility supported by DOE-AC02-06CH11357. We used chroma for some analyses 40]. We acknowledge support by the STFC, SUPA, MICINN, NSF and DoE.

## Appendix: Accelerated Fitting

In Section III B 2 we used a trick to simplify our fits by, in effect, transferring fit terms from the fit function into the errors of the fit data. This trick can greatly speed up complicated fits. Here we present a formal derivation of this procedure for three increasingly complicated situations.

## A. Linear Least Squares - Exact Data

Assuming we know $D$ values $y_{i}$ for a quantity $y$ which can be expressed as a power series in $x$,

$$
\begin{equation*}
y=\sum_{n} c_{n} x^{n} \tag{52}
\end{equation*}
$$

we wish to obtain a best fit for the first $F$ unknown coefficients $c_{n}$. The $c_{n}$ are then our random variables. If we are able to make reasonable estimates for their means and standard deviations $\sigma_{n}$, in the absence of additional information, maximizing entropy suggests a Gaussian prior of

$$
\begin{equation*}
P(c) \propto e^{-\sum_{n} c_{n}^{2} / 2 \sigma_{n}^{2}} \tag{53}
\end{equation*}
$$

For simplicity, we assume throughout that the $c_{n}$ are uncorrelated and have a prior mean of zero; extending to more general cases is straightforward.

If we knew all coefficient values, then the data $y_{i}$ would be completely determined, with

$$
\begin{equation*}
P(y \mid c) \propto \prod_{i=0}^{D-1} \delta\left(y_{i}-\sum_{n} c_{n} x_{i}^{n}\right) \tag{54}
\end{equation*}
$$

Bayes' theorem

$$
\begin{equation*}
P(c \mid y) \propto P(y \mid c) P(c) \tag{55}
\end{equation*}
$$

allows us to convert this into a distribution for $c$ given the data $y$.

If we are only interested in fitting a subset of coefficients $c_{n_{<}}$with $n<F$, we integrate over the remaining $c_{n_{>}}$, giving

$$
\begin{align*}
P\left(c_{<} \mid y\right) & \propto e^{-\sum_{n_{<}} c_{n<}^{2} / 2 \sigma_{n}^{2}} \times  \tag{56}\\
& {\left[\int d c_{>} \delta^{D}\left(y-\sum_{n} c_{n} x^{n}\right) e^{-\sum_{n>} c_{n>}^{2} / 2 \sigma_{n}^{2}}\right] . }
\end{align*}
$$

We replace the delta function by its Fourier representation, integrate over first the $c_{n_{>}}$, then the Fourier variables, to obtain

$$
\begin{align*}
P\left(c_{<} \mid y\right) & \propto e^{-\sum_{n_{<}} c_{n_{<}}^{2} / 2 \sigma_{n}^{2}} \times  \tag{57}\\
& \left(\operatorname{det} \sigma_{\Delta}^{2}\right)^{-1 / 2} e^{-\Delta y \cdot\left(2 \sigma_{\Delta}^{2}\right)^{-1} \cdot \Delta y}
\end{align*}
$$

Here

$$
\begin{equation*}
\Delta y_{i} \equiv y_{i}-\sum_{n_{<}} c_{n_{<}} x_{i}^{n} \tag{58}
\end{equation*}
$$

is the discrepancy between the measured $y_{i}$ and the portion of the series to be kept in the fit, the dot product sums over the $D$ data points, and

$$
\begin{equation*}
\sigma_{\Delta i j}^{2} \equiv \sum_{n>} x_{i}^{n} \sigma_{n}^{2} x_{j}^{n} \tag{59}
\end{equation*}
$$

The correlation matrix $\sigma_{\Delta}^{2}$ is independent of $c_{<}$(so the determinant is constant), and is the same as one would compute directly by

$$
\begin{equation*}
\left\langle\Delta y_{i} \Delta y_{j}\right\rangle_{c_{>}}=\left\langle\sum_{m_{>}} c_{m>} x_{i}^{m} \sum_{n_{>}} c_{n>} x_{j}^{n}\right\rangle_{c_{>}} \tag{60}
\end{equation*}
$$

using

$$
\begin{equation*}
\left\langle c_{m>} c_{n>}\right\rangle_{c_{>}}=\sigma_{n}^{2} \delta_{m n} \tag{61}
\end{equation*}
$$

Finally, we fit $c_{<}$by minimizing $\chi^{2}$, which includes these correlations and is augmented by the remaining $c_{<}$priors. Because the distribution is Gaussian, the $c_{<}$at their minima are equal to their average values.

The correlation matrix $\sigma_{\Delta}^{2}$ properly accounts for correlations in the discrepancy, due to the neglected terms, between $y$ and the portion of the series retained. If $F$ terms are kept in the series, $\sigma_{\Delta}$ is $\mathcal{O}\left(x^{F}\right)$, enforcing agreement between $y$ and the finite series to this order, as appropriate. It also suggests an alternative but equivalent approach. We may define new random (rather than exact) versions of $y$, whose correlation matrix is $\sigma_{\Delta}^{2}$, by moving the $c_{>}$terms to the left side of Eq. (52). Using the truncated series as a model for these random data, straightforward application of Bayes' theorem [17] again implies the distribution in Eq. (57).

One useful consequence is that, as long as we include the correlations for the $c_{>}$, we may arbitrarily reduce the number of coefficients $c_{<}$retained, even to as few as one, and still obtain the same minimization values. To see this, note that to compute a particular $\left\langle c_{n_{<}}\right\rangle$, we could start with the full distribution and integrate over all $c s$. The integral over $c_{>}$produces $P\left(c_{<} \mid y\right)$, which we then use in the integral over $c_{<}$; the result will be the same regardless of where the dividing line is set, as long as it does not include $c_{n_{<}}$. (We could even include in $\sigma_{\Delta}^{2}$ terms of order less than $n$.) Because averaging and minimization give the same result, the minimization value for $c_{n_{<}}$will also remain unchanged. This is also true of the $c_{n_{<}}$error. While the result is the same, reducing the number of terms in the series to fit can significantly improve the fitting time.

## B. Fits to Nonlinear Functions - Exact Data

We now consider fitting to the data $y_{i}$ a general function $g_{i}\left(c_{n}\right)$ not necessarily linear in the parameters $c$, and
where we assume $y_{i}=g_{i}\left(c_{n}\right)$ exactly for properly chosen $c_{n}$. Now

$$
\begin{equation*}
P(y \mid c) \propto \prod_{i=0}^{D-1} \delta\left(y_{i}-\sum_{n} g_{i}\left(c_{n}\right)\right) \tag{62}
\end{equation*}
$$

Combining with the prior $P(c)$ and integrating over the $c_{>}$gives $P\left(c_{<} \mid y\right)$.

If our estimate of prior means is good, expanding $g$ around $c_{>}=0$ should give a reasonable approximation; an expansion to first order gives a Gaussian. More specifically, defining

$$
\begin{equation*}
g_{i}\left(c_{<}\right) \equiv g_{i}\left(c_{<}, c_{>}=0\right) \tag{63}
\end{equation*}
$$

and

$$
\begin{equation*}
\Delta y_{i} \equiv y_{i}-g_{i}\left(c_{<}\right) \tag{64}
\end{equation*}
$$

and integrating over $c_{>}$in this Gaussian approximation gives as before

$$
\begin{align*}
P\left(c_{<} \mid y\right) & \propto e^{-\sum_{n<} c_{n<}^{2} / 2 \sigma_{n}^{2}} \times  \tag{65}\\
& \left(\operatorname{det} \sigma_{\Delta}^{2}\left(c_{<}\right)\right)^{-1 / 2} e^{-\Delta y \cdot\left(2 \sigma_{\Delta}^{2}\left(c_{<}\right)\right)^{-1} \cdot \Delta y}
\end{align*}
$$

but with

$$
\begin{equation*}
\sigma_{\Delta}^{2}\left(c_{<}\right)_{i j} \equiv \sum_{n>} \partial_{n} g_{i}\left(c_{<}\right) \sigma_{n}^{2} \partial_{n} g_{j}\left(c_{<}\right) \tag{66}
\end{equation*}
$$

This is again the correlation one would compute directly for $\left\langle\Delta y_{i} \Delta y_{j}\right\rangle_{c>}$ after expanding $g$ to first order in $c_{>}$.

We have not expanded in $c_{<}$, so $\sigma_{\Delta}^{2}$ depends on $c_{<}$, the determinant in front is not constant, and the dependence of $\Delta y$ on $c_{<}$is not in general linear. In practice, however, we will often further approximate the distribution by setting the $c_{<}$to their prior means in $\sigma_{\Delta}^{2}\left(c_{<}\right)$before minimization.

Because $g\left(c_{<}\right)$is nonlinear, $c_{<}$from minimization can differ slightly from $\left\langle c_{<}\right\rangle$, and due to approximations made, can vary somewhat with the number of terms retained.

## C. Fits to Data with Intrinsic Statistical Errors

Finally we consider the most general case, in which the data $y$ contribute intrinsic statistical uncertainties in addition to those associated with the truncated series. If we measure a range of values for $y$ with an average $\langle y\rangle$ and correlation matrix $\sigma_{y}^{2}$, then for sufficiently large samples we expect a Gaussian distribution

$$
\begin{equation*}
P(\langle y\rangle \mid c) \propto e^{-(\langle y\rangle-g(c)) \cdot\left(2 \sigma_{y}^{2}\right)^{-1} \cdot(\langle y\rangle-g(c))} \tag{67}
\end{equation*}
$$

rather than the delta function above. Combining with the prior $P(c)$ gives $P(c \mid\langle y\rangle)$.

Expanding $g_{i}\left(c_{<}, c_{>}\right)$to first order around $c_{>}=0$, defining

$$
\begin{equation*}
\Delta y_{i} \equiv\left\langle y_{i}\right\rangle-g_{i}\left(c_{<}\right) \tag{68}
\end{equation*}
$$

and integrating $P(c \mid\langle y\rangle)$ over $c_{>}$gives

$$
\begin{align*}
P\left(c_{<} \mid\langle y\rangle\right) & \propto e^{-\sum_{n<} c_{n<}^{2} / 2 \sigma_{n}^{2}} \times  \tag{69}\\
& \left(\operatorname{det} \sigma_{y \Delta}^{2}\left(c_{<}\right)\right)^{-1 / 2} e^{-\Delta y \cdot\left(2 \sigma_{y \Delta}^{2}\left(c_{<}\right)\right)^{-1} \cdot \Delta y}
\end{align*}
$$

The resulting correlation matrix is a combination of true statistical and neglected series contributions, with

$$
\begin{equation*}
\sigma_{y \Delta}^{2}\left(c_{<}\right) \equiv \sigma_{y}^{2}+\sigma_{\Delta}^{2}\left(c_{<}\right) \tag{70}
\end{equation*}
$$

as one would obtain by including both sources of uncertainty in computing $\left\langle\Delta y_{i} \Delta y_{j}\right\rangle$ directly. With no statistical fluctuations in $y, \sigma_{y}^{2}=0$, and it reduces to the previous result. When $\sigma_{y}^{2}$ is nonzero but small, $\sigma_{\Delta}^{2}$ still makes an important contribution.

## D. Application to this Paper

We used the technique described here in much of our testing and tuning (but not for our final results) to speed up the $\left(a m_{\eta_{h}} / 2\right)^{2}$ fit. As described in Section III B 2, we kept corrections through order $N_{a m}=80$ but moved all but $\bar{N}_{a m} \ll N_{a m}$ out of the fit function and into the errors for the reduced moments. If we set $\bar{N}_{a m}=3$, for example, our fit to the $R_{n}$ simulation data changes from Figure 7 to Figure 10. The small $\bar{N}_{a m}$ means that each point in Figure 10 has much larger error bars, coming from $\left(a m_{\eta_{h}} / 2\right)^{2}$ terms moved into the $R_{n}$ s. The final fit results, however, are almost identical in both cases (to within less than $0.1 \sigma$ ), with the same errors. Note that the $R_{n}$ errors in Figure 10 are highly correlated, which is why the fit curve passes through the central value for each point. As discussed above these correlations are essential if results are to be independent of the value of $\bar{N}_{a m}$.

[24] We use the Particle Data Group value for $m_{\eta_{c}}$ : C. Amsler et al. (Particle Data Group), PL B667, 1 (2008) and 2009 partial update for the 2010 edition (URL: http://pdg.lbl.gov). We correct the $\eta_{c}$ mass for quark annihilation (2.4(1.2) MeV [8]), and electromagnetic corrections ( $2.6(1.2) \mathrm{MeV}$ ), which are dominated by the Coulombic interaction between the heavy quark and antiquark. Neither effect is in our simulation. See [10] for more details.
[25] We average over recent experiments to obtain a value of $9.931(3) \mathrm{GeV}$ for $m_{\eta_{b}}$, and then include corrections for quark annihilation and electromagnetic corrections (see [24]) that together we estimate at $4(4) \mathrm{MeV}$. The current-current correlator method has been used successfully to obtain very accurate results for quark masses and the coupling $\alpha_{s}$. The calculations were done using Highly Improved Staggered Quarks (HISQ) and heavy-heavy meson correlators. We now extend this work to the significantly more challenging heavy-light case, reporting the first results here. The aim is to determine nonperturbative $Z$ factors for NRQCD heavy-light currents, but first we test the method in the HISQ case where $Z=1$.

The XXVIII International Symposium on Lattice Filed Theory
June 14-19,2010
Villasimius, Sardinia Italy

[^297]
## 1. Motivation

In the study of semileptonic and leptonic processes, like $B \rightarrow \pi l v$ and $B \rightarrow l v$, the nonperturbative $Z$ factors for heavy-light currents are needed. One way to try to calculate these (nonperturbatively on the lattice) is the current-current correlator method, that has been successfully tested and used in the heavyonium case [ [ ] , $]$. We now want to extend these results and use the same method in the heavy-light case. Here we report on the first results using the HISQ action. The eventual aim is to extract NRQCD heavy-light $Z$ factors.

## 2. Current-current correlator method

The idea is to match time moments of meson correlators to energy-derivative moments at $q^{2}=0$ of polarization functions $\Pi$ calculated in continuum QCD perturbation theory to high order.

The pseudoscalar current-current correlators are defined as

$$
\begin{equation*}
G(t)=a^{6} \sum_{\vec{x}}\left(a m_{q}\right)^{2}\langle 0| j_{5}(\vec{x}, t) j_{5}(0,0)|0\rangle . \tag{2.1}
\end{equation*}
$$

Then the time moments are

$$
\begin{equation*}
G_{n}=\sum_{t}\left(\frac{t}{a}\right)^{n} G(t) \tag{2.2}
\end{equation*}
$$

(see e.g. [1] []). To help reducing the errors we divide each moment by the tree level value, $G_{n}^{(0)}$, and define reduced moments $R_{n}$ as

$$
\begin{equation*}
R_{4}^{\text {latt }}=\frac{G_{4}}{G_{4}^{(0)}}, \quad \text { and } \quad R_{n}^{\text {latt }}=\left(\frac{G_{n}}{G_{n}^{(0)}}\right)^{\frac{1}{n-4}} \text { for } \quad n \geq 6 \tag{2.3}
\end{equation*}
$$

In the continuum the reduced moments are

$$
\begin{equation*}
R_{4}^{\text {cont }}=\frac{g_{4}}{g_{4}^{(0)}}, \quad \text { and } \quad R_{n}^{\text {cont }}=\frac{m_{\eta_{h}}}{2 m_{h}(\mu)} \frac{g_{n}}{g_{n}^{(0)}} \quad \text { for } \quad n \geq 6 \tag{2.4}
\end{equation*}
$$

The $g_{n}$ are perturbative series in $\alpha_{s}(\mu)$, known for the heavy-heavy case through $\alpha_{s}^{3}(\mu)$ [3] and for heavy-light through $\alpha_{s}^{2}(\mu)[母]$. The mass $m_{h}$ is the heavy quark mass in the $\overline{\mathrm{MS}}$ scheme at the scale $\mu$. Comparing the lattice and continuum $R_{n}$ allows us to extract the mass ratio $m_{\eta_{h}} /\left(2 m_{h}(\mu)\right)$, and thus the quark mass. The calculation above is for the case with no $Z$ factor. If the lattice current has a $Z$ factor then that can also be extracted.

## 3. Heavy-light JJ correlators

We compare lattice calculations to continuum perturbation theory through $\alpha_{s}^{2}(\mu)$. In this work we have used coarse, fine, superfine and ultrafine MILC lattice configurations. We calculate heavy-light correlators using the HISQ action [ $[5]$ for both quarks with several heavy quark masses from charm up to the $b$ quark mass. Note that $Z=1$ in the HISQ case. Some of the calculated reduced moments $R_{n}$ are shown in Fig. 1 as examples of our results. Comparing heavy-strange, heavy-charm and heavy-heavy correlator reduced moments shows that we can clearly distinguish between these three cases. In the following subsections we address some challenges of the heavylight calculations.

Figure 1: Top figure: Heavy-strange correlator reduced moments $R_{n}$ as a function of heavy-heavy meson mass $M_{\eta_{h}}$ (in GeV ). The other two figures show the heavy-strange, heavy-charm and heavy-heavy reduced moments $R_{4}$ and $R_{10}$ as a function of $M_{\eta_{h}}$. The range is from charm (at about 3 GeV ) to $b$ (about 10 GeV ).

Figure 2: The reduced moments in the free, non-interacting theory depend on the volume.

Figure 3: The ratio of reduced moments calculated on two different coarse lattices (one with $L=20$, other one with $L=28$ ) shows that there is no volume dependence in the interacting case.

### 3.1 Volume dependence

The tree level (free) moments depend on volume - note that this is an artifact of the free case only. This is illustrated in Figures 2 and 3 - the $R_{n}$ depend on volume in the non-interacting theory, but not in the interacting case. Therefore we need to calculate the tree level moments in the infinite volume limit. We do this by calculating the free moments using different volumes, $L^{3}$, and fitting them with

$$
\begin{equation*}
A_{0}+A_{1} \frac{e^{-A_{2} L}}{L} . \tag{3.1}
\end{equation*}
$$

The result in the infinite volume limit is then simply given by the fit parameter $A_{0}$.

Figure 4: Fraction of the tree level $q \bar{q}$ condensate in reduced moment $R_{n}$ as a function of the heavy-heavy meson mass $M_{\eta_{h}}$ (in GeV ).

### 3.2 Quark condensate

The quark condensate appears in the reduced moment $R_{n}$ at tree level as [6]

$$
\begin{equation*}
\frac{4 \pi^{2}}{3} \frac{(n-1)(n-2)(n-3)\left[-\frac{m_{h}}{m_{l}}+\frac{n}{2}\right]}{1+\frac{(n-3) m_{l}}{m_{h}}} \frac{\left\langle m_{l} \psi \bar{\psi}\right\rangle}{m_{h}^{4}} \tag{3.2}
\end{equation*}
$$

The quark condensate is not present in the heavy-heavy case, but it is sizeable in the heavy-light case - the fraction of tree level $q \bar{q}$ condensate in $R_{n}$ can easily be $10-30 \%$ for heavy quark masses masses between $c$ and $b$, as can be seen in Fig. 4. Note that the leading term is $1 / m_{h}^{3}$. This poses a challenge, as the $\alpha_{s}$ corrections to the condensate are not known. The gluon condensate contribution is much smaller and can be safely neglected in the analysis.

## $3.3 m_{l} / m_{h}$ corrections to perturbative series

Perturbation theory with $m_{q}=0$ is not sufficient, as $m_{l}(\mu) / m_{h}(\mu)$ corrections become important for $B_{c}: m_{c}(\mu) / m_{b}(\mu) \approx 0.22$. At small values of the ratio the $m_{l}(\mu) / m_{h}(\mu)$ expansion is good, i.e. it works for $B_{s}$. At large values of the ratio the expansion is not good enough. This is illustrated in Fig. 5. However, we now have the exact coefficients for given ratios $m_{l}(\mu) / m_{h}(\mu)$ for tree level (shown in the plot as bursts) and order $\alpha_{s}$, so this problem can be partly avoided. The exact coefficients are still needed for $\alpha_{s}^{2}$ and higher orders.

### 3.4 Fits

We fit the lattice data $R_{n}^{\text {latt }}, n \geq 6$, with

$$
\begin{align*}
R_{n}^{\mathrm{fit}}= & \left(\frac{m_{\eta_{h}}}{2 m_{h}(\mu)}\right)\left(1+c_{1} \alpha_{s}+c_{2} \alpha_{s}^{2}+c_{3} \alpha_{s}^{3}+c_{4} \alpha_{s}^{4}+c_{5} \alpha_{s}^{5}+c_{6} \alpha_{s}^{6}+q \bar{q} \quad \text { condensate }\right)  \tag{3.3}\\
& \left(1+b_{1}\left(a m_{h}(\mu)\right)^{2}+b_{2}\left(a m_{h}(\mu)\right)^{4}+b_{3}\left(a m_{h}(\mu)\right)^{6}+d_{1} a^{2}+d_{2} a^{4}\right)
\end{align*}
$$

Figure 5: $m_{l}(\mu) / m_{h}(\mu)$ corrections to continuum perturbation theory coefficients. Here $x=m_{l} / m_{h}$. The tree level values of the coefficients have been divided by the tree level value at $m_{l} / m_{h}=0$.
and choose the scale $\mu=m_{h}$. We take the first few coefficients ( $c_{1}$ and $c_{2}$ in the heavy-light case) from continuum perturbation theory, and treat the coefficients for the higher order $\alpha_{s}$ terms as fit parameters. The quark condensate is given in Eq. 3.2 at tree level. We take the $q \bar{q}$ condensate value to be $\left\langle m_{s} s \bar{s}\right\rangle=(0.2 \mathrm{GeV})^{4}$ from the Gell-Mann - Oakes - Renner relation, allowing the $s \bar{s}$ condensate to be 0.7 times the light quark condensate. We also allow for the presence of higher order condensate terms estimating them with powers of the leading condensate. In $B_{c}$ there is no condensate contribution, and we get a good fit using the exact coefficients (order $\alpha_{s}$ ). As the lattice calculations are done at a non-zero lattice spacing $a$, we include $a$-dependent terms in the fit function - even powers of $a$ and $a m_{h}(\mu)$.

To extract the mass ratio $m_{\eta_{h}} /\left(2 m_{h}(\mu)\right)$ we use the lattice simulation data (Eq. 2.3), with $a m_{\eta_{h}} / a m_{h}$ from the lattice simulations, and compare these $R_{n}^{\text {latt }}$ to the continuum perturbation theory result (Eq. 2.4). That is, we find values for $\alpha_{\overline{\mathrm{MS}}}(\mu)$ and $m_{\eta_{h}} /\left(2 m_{h}(\mu)\right)$ that make lattice and continuum results agree for small $n>4$. This can then be combined with experimental results for the $\eta_{b}, \eta_{c}$ meson masses to obtain the quark masses. In the heavy-light case we can use the $\alpha_{\overline{\mathrm{MS}}}(\mu)$ values extracted from the heavy-heavy calculation.

To test the method in the heavy-light case we look at the mass ratio $m_{\eta_{h}} /\left(2 m_{h}(\mu)\right)$ and compare to heavy-heavy results. This is shown in Figure 6. In the heavy-strange case the fits are to one $R_{n}$ at a time, not to all $R_{n}$ simultaneously as in the heavy-heavy case. The mass ratio extracted from the heavy-strange correlator moments is the same as in the heavy-heavy case, as expected, but currently a lot less accurate.

## 4. Conclusions and future

We are extending the use of current-current correlator method, earlier used to study heavyheavy systems, to heavy-light systems. The full analysis of heavy-light data is still in progress, but we can already say that the JJ correlator method works well. The quark condensate sets some

Figure 6: The mass ratio $m_{\eta_{h}} /\left(2 m_{h}(\mu)\right)$.
limitations - we can not use high moments in the $B_{s}$ case. However, in $B_{c}$ there is no condensate contribution. Our aim is to extract $Z$ for NRQCD - there the challenge is to control relativistic corrections.

#### Abstract

We present a new determination of the $B_{s}$ leptonic decay constant from lattice QCD simulations that use gluon configurations from MILC and a highly improved discretization of the relativistic quark action for both valence quarks. Our result, $f_{B_{s}}=0.225(4) \mathrm{GeV}$, is almost three times more accurate than previous determinations. We analyze the dependence of the decay constant on the heavy quark's mass and obtain the first empirical evidence for the leading $1 / \sqrt{m_{h}}$ dependence predicted by Heavy Quark Effective Theory (HQET). As a check, we use our analysis technique to calculate the $m_{B_{s}}-m_{\eta_{b}} / 2$ mass difference. Our result agrees with experiment to within errors of 11 MeV (better than $2 \%$ ). We discuss how to extend our analysis to other quantities in $B_{s}$ and $B$ physics, making $2 \%$-precision possible for the first time.

PACS numbers: 11.15.Ha,12.38.Aw,12.38.Gc

Lattice simulations of QCD have become essential for high-precision experimental studies of $B$-meson decays - studies that test our understanding and the limitations of the standard model of weak, electromagnetic and strong interactions, and also determine fundamental parameters, like the CKM matrix, in that model. Accurate theoretical calculations of QCD contributions to meson masses, decay constants, mixing amplitudes, and semileptonic form factors are critical for this program, and lattice simulation is the main tool for providing these calculations. A major complication for the lattice simulations has been the large mass of the $b$ quark, which has necessitated the use of non-relativistic effective field theories like NRQCD to describe $b$ dynamics in the simulations. The need for effective field theories has made it difficult to achieve better than 5-10\% precision for many important quantities.

Recently we overcame the analogous problem for $c$ quarks by introducing a highly improved discretization of the relativistic quark action that gives accurate results even on quite coarse lattices: the Highly Improved Staggered-Quark (HISQ) discretization [1]. With this formalism, $c$ quarks are analyzed in the same way as $u$, $d$, and $s$ quarks, which greatly reduces the uncertainties in QCD simulations of $D$ physics [2-7]. More recently we showed that the HISQ action can be pushed to much higher masses - indeed, very close to the $b$ mass - using new lattices, from the MILC collaboration, with the smallest lattice spacing available today ( $a=0.044 \mathrm{fm}$ ). This allowed us to extract a value for the $b$ 's $\overline{\mathrm{MS}}$ mass that was accurate to better than $1 \%$. Here we extend that work in a new analysis of the $B_{s}$ meson's leptonic decay constant $f_{B s}$, which produces the most accurate theoretical value to date.

We also compute the mass difference $m_{B_{s}}-m_{\eta_{b}} / 2$, as
an additional test of our analysis method. This difference is particularly sensitive to QCD dynamics because the leading (and uninteresting) dependence on the heavy quark's mass mostly cancels in the difference.

It would be quite expensive to extend our new analysis directly to $B$-meson quantities, because of the added costs associated with very light valence and sea quarks. This is unnecessary, however, because heavy-quark effective field theories like NRQCD already give accurate results for ratios of $B_{s}$ to $B$ quantities, like $f_{B_{s}} / f_{B}$. This is because the largest systematic errors from these effective theories, due to operator matching, cancel in such ratios. The ratio of the decay constants, for example, is known to $\pm 2 \%$ from effective field theories 8]. So the combination of accurate $B_{s}$ quantities from HISQ simulations, as discussed in this paper, with $B_{s} / B$ ratios from NRQCD or other effective field theories provides a potent new approach to high-precision $b$ physics generally. Note that no operator matching is required in our relativistic analysis of $f_{B_{s}}$ because of the exact chiral symmetry of the HISQ formalism in the massless limit.

In our simulations for this paper, we computed decay constants and masses for non-physical $H_{s}$ mesons composed of an $s$ quark, and heavy quarks $h$ with various masses $m_{h}$ ranging from below the $c$ mass to just below the $b$ mass. This data allows us to extrapolate to the $b$ mass, where $m_{H_{s}}=m_{B_{s}}$. We repeated our analysis for five different lattice spacings, allowing us also to extrapolate our results to zero lattice spacing.

The gluon configuration sets we used are from the MILC collaboration [9] and are described in Table [I. Our simulation results for the decay constants and meson masses, for various values of the $h$ mass, are presented in Table [II. We also give results for the mass of the pseudoscalar $h \bar{h}$ meson, $m_{\eta_{h}}$, and for the mass of the $\eta_{s}$

FIG. 1. The leptonic decay constant $f_{H_{s}}$ for pseudoscalar $h \bar{s}$ mesons $H_{s}$, plotted on the left versus the $H_{s}$ mass as the $h$ quark's mass is varied. The solid line and gray band show our best-fit estimates for the decay constants extrapolated to zero lattice spacing. Best-fit results (dashed lines) and simulation data are also shown for five different lattice spacings, with results for smaller lattice spacings extending to higher masses (since we restrict $a m_{h}<1$ ). The simulation data points have been corrected for small mistunings of the $s$ quark's mass. On the right the same simulation data and fits are plotted for $\sqrt{m_{H_{s}}} f_{H_{s}}$ versus $1 / m_{H_{s}}$.

TABLE I. Parameter sets used to generate the 3-flavor gluon configurations analyzed in this paper. The lattice spacing is specified in terms of the static-quark potential parameter $r_{1}=0.3133(23) \mathrm{fm}$ 10]; values for $r_{1} / a$ are from [9]. The bare quark masses are for the ASQTAD formalism and $u_{0}$ is the fourth root of the plaquette. The spatial $(L)$ and temporal $(T)$ lengths of the lattices are also listed, as are the number of gluon configurations ( $N_{\mathrm{cf}}$ ) and the number of time sources ( $N_{\text {ts }}$ ) per configuration used in each case.

| Set | $r_{1} / a$ | $a u_{0} m_{0 u / d}$ | $a u_{0} m_{0 s}$ | $u_{0}$ | $L / a$ | $T / a$ | $N_{\text {cf }} \times N_{\text {ts }}$ |

meson. The $\eta_{s}$ is an unphysical pseudoscalar $s \bar{s}$ meson whose valence quarks are not allowed to annihilate; we use its mass to tune the bare mass of the $s$ quark: simulations show that its mass is $m_{\eta_{s}, \text { phys }}=0.6858(40) \mathrm{GeV}$ when the $s$ mass is correctly tuned [10].

We expect some statistical correlation between results from the same configuration set but with different $h$ quark masses. We have not measured these, but we have verified that our results are insensitive (at the level of $\pm \sigma / 4$ ) to such correlations. We introduce a $50 \%$ correlation for our fits, which increases our final error estimates slightly.

Our strategy for extracting $f_{B_{s}}$ is first to fit our simu-

TABLE II. Simulation results for each of the five configuration sets (Table (I) and several values of the heavy-quark's mass $m_{h}$. The $s$-quark's mass $m_{s}$ is tuned to be close to its physical value. Results are given for: the leptonic decay constant $f_{H_{s}}$ and mass $m_{H_{s}}$ of the pseudoscalar $h \bar{s}$ meson, and masses of the pseudoscalar $h \bar{h}$ and $s \bar{s}$ mesons, $m_{\eta_{h}}$ and $m_{\eta_{s}}$ respectively.

lation results for $f_{H_{s}}$ to the HQET-inspired formula 11]

$$
\begin{align*}
& f_{H_{s}}\left(a, m_{H_{s}}, m_{\eta_{s}}\right)= \\
& \quad\left(m_{H_{s}}\right)^{b}\left(\frac{\alpha_{V}\left(m_{H_{s}}\right)}{\alpha_{V}\left(m_{D_{s}}\right)}\right)^{-2 / \beta_{0}} \sum_{i=0}^{N_{m}-1} C_{i}(a)\left(\frac{1}{m_{H_{s}}}\right)^{i} \\
& \quad+c_{s}\left(m_{\eta_{s}}^{2}-m_{\eta_{s}, \text { phys }}^{2}\right) \tag{1}
\end{align*}
$$

where $\beta_{0}=11-2 n_{f} / 3=9$ in our simulations 12], $\alpha_{V}$ is
the QCD coupling in the $V$ scheme [5, 13], and constant $b=-0.5$ from HQET. Here we use $m_{H_{s}}$ as a proxy for the $h$-quark mass since its value for $b$ quarks is known from experiment. The last term in Eq. (11) corrects for tuning errors in the $s$-quark mass; we determined that $c_{s}=0.06(1)$ by repeating our calculations with slightly different $s$ masses [14]. We parameterize

$$
\begin{equation*}
C_{i}(a)=\sum_{j, k, l=0}^{N_{a}-1} c_{i j k l}\left(\frac{a m_{h}}{\pi}\right)^{2 j}\left(\frac{a m_{s}}{\pi}\right)^{2 k}\left(\frac{a \Lambda_{\mathrm{QCD}}}{\pi}\right)^{2 l} \tag{2}
\end{equation*}
$$

with $N_{m}=N_{a}=4$. This expansion is in powers of quark masses and the QCD scale parameter $\Lambda_{\mathrm{QCD}} \approx 0.5 \mathrm{GeV}$ divided by the ultraviolet cutoff for the lattice theory: $\Lambda_{\mathrm{UV}} \approx \pi / a$. The fit parameters are the coefficients $c_{i j k l}$ for each of which we use a prior of $0 \pm 1.5$, which is conservative 15].

Our data for five different lattice spacings and a wide range of masses $m_{H_{s}}$ are presented with our fit results in Fig 1. The reach in $m_{H_{s}}$ grows as the lattice spacing decreases (since we restrict $a m_{h}<1$ ), and deviations from the continuum curve get smaller. The fit is excellent, with a $\chi^{2}$ per degree of freedom of 0.36 while fitting all 17 measurements. The small $\chi^{2}$ results from our conservative priors (we get excellent fits and smaller errors with priors that are half the width).

Having determined the parameters in Eq. (11), the second step in our analysis is to set $M_{H_{s}}=M_{B_{s}}, a=0$, and $m_{\eta_{s}}=m_{\eta_{s} \text {, phys }}$ in that formula to obtain our final value for $f_{B_{s}}$,

$$
\begin{equation*}
f_{B_{s}}=0.225(4) \mathrm{GeV} \tag{3}
\end{equation*}
$$

which agrees well with the previous best NRQCD result of $0.231(15) \mathrm{GeV}$ [16] but is almost four times more accurate. Our result also agrees with the recent result of $0.232(10) \mathrm{GeV}$ from the ETM collaboration, although that analysis includes only two of the three light quarks in the quark sea [17].

The error budget for our result is given in Table III] and shows that the dominant errors come from statistical uncertainties in the simulations, the $m_{H_{s}} \rightarrow m_{B_{s}}$ extrapolation, the $a^{2} \rightarrow 0$ extrapolation, and uncertainties in the scale-setting parameter $r_{1}$. Our analysis of $f_{D_{s}}$ in [6] indicates that finite volume errors, errors due to mistuned sea-quark masses, errors from the lack of electromagnetic corrections, and errors due to lack of $c$ quarks in the sea are all significantly less than $1 \%$, and so negligible compared with our other uncertainties. Our final result is also insensitive to the detailed form of the fit function; for example, doubling the number of terms has negligible effect $(0.03 \sigma)$ on the errors and value.

We have also included in Fig. 1 (right) a plot of $\sqrt{m_{H_{s}}} f_{H_{s}}$ for different values of $m_{H_{s}}$. This shows that there are large non-leading terms in $f_{H_{s}}$, beyond the leading $1 / \sqrt{m_{H_{s}}}$ behavior predicted by HQET. Our simulation nevertheless provides evidence for the leading

TABLE III. Dominant sources of uncertainty in our determinations of the $B_{s}$ decay constant and the $B_{s}-\eta_{b}$ mass difference. Contributions are shown from the extrapolations in $m_{H_{s}}, a^{2}$ and $m_{s}$, as well as statistical errors in the simulation data and errors associated with the scale-setting parameter $r_{1}$. Other errors are negligible.

term. Treating exponent $b$ in Eq. (11) as a fit parameter, rather than setting it equal to -0.5 , we find a best-fit value of $b=-0.51(13)$, in excellent agreement with the HQET prediction. This is the first empirical evidence for this behavior.

Our analysis also yields a value for $f_{D_{s}}$, which agrees with [6]. It is also clear from Fig. [1 (left) that $f_{H_{s}}$ peaks between $f_{D_{s}}$ and $f_{B_{s}}$, and that $f_{B_{s}}$ is smaller - we find:

$$
\begin{equation*}
f_{B_{s}} / f_{D_{s}}=0.906(14) \tag{4}
\end{equation*}
$$

HQET suggests a ratio less than one, but previous lattice QCD results have been ambiguous about this point.

To check our $f_{B s}$ analysis technique, we adapted the same technique to compute the mass difference [18]

$$
\begin{equation*}
\Delta \equiv m_{H_{s}}-m_{\eta_{h}} / 2 \tag{5}
\end{equation*}
$$

using, as inputs, the masses $m_{\eta_{h}}$ computed in our simulations for pseudoscalar $h \bar{h}$ mesons made of our heavy quark. Our values for $\Delta$ come from the results in Table II. We fit them to

$$
\begin{align*}
& \Delta\left(a, m_{H_{s}}, m_{\eta_{s}}\right)= \\
& \quad m_{H_{s}} \sum_{i=0}^{N_{m}-1} D_{i}(a)\left(\frac{1}{m_{H_{s}}}\right)^{i}+d_{s}\left(m_{\eta_{s}}^{2}-m_{\eta_{s}, \mathrm{phys}}^{2}\right) \tag{6}
\end{align*}
$$

where our simulations indicate that $d_{s}=0.18$ (1) [19], and $D_{i}(a)$ has an expansion similar to that for $C_{i}(a)$ (Eq. (2)), with the same priors.

We show the best fit to our simulation data in Fig. 2. Again, the fit is excellent, which a $\chi^{2}$ per degree of freedom of 0.13 while fitting all 17 measurements. Extrapolating to the $b$ mass, we obtain our best fit value for the mass splitting,

$$
\begin{equation*}
m_{B_{s}}-m_{\eta_{b}} / 2=0.658(11) \mathrm{GeV} \tag{7}
\end{equation*}
$$

which agrees well with experiment: experiment gives $0.671(2) \mathrm{GeV}$ which becomes $0.666(4)$ after removing

FIG. 2. The $H_{s}-\eta_{h} / 2$ mass difference plotted versus $m_{H_{s}}$ as the $h$ quark's mass is varied. The solid line and gray band show our best-fit estimates for the mass differences extrapolated to zero lattice spacing. Best-fit results (dashed lines) and simulation data are also shown for five different lattice spacings, with results for smaller lattice spacings extending to larger masses (since we require $a m_{h}<1$ ). The simulation data points have been corrected for small mistunings in the $s$ quark's mass. Data points (in black) at $m_{D_{s}}$ and $m_{B_{s}}$ are the experimental values after correcting for small effects from electromagnetism, $\eta_{b}$ annihilation, and $c$ quarks in the sea, none of which are included in the simulation.
corrections from electromagnetism, $\eta_{b}$ annihilation, and $c$ quarks in the sea (not included in our simulations) [18, 20]. Our fit also gives a value for $m_{D_{s}}-m_{\eta_{c}} / 2$; it also agrees well with experiment [6].

In this paper, we have shown how to use a highly improved discretization of the relativistic quark action to make accurate calculations for mesons containing $b$ quarks. Our result for the $B_{s}$ decay constant, $f_{B_{s}}=$ $0.225(4) \mathrm{GeV}$, agrees with other determinations from lattice QCD but is almost three times more accurate than the most precise previous result. The reliability of our extrapolations is underscored both by our previous determination of the $b$-quark's $\overline{\mathrm{MS}}$ mass, which agrees with other determinations to within errors of less than $\pm 1 \%$, and by our calculation here of the $m_{B_{s}}-m_{\eta_{b}} / 2$ mass difference, which agrees with experiment to within errors of $\pm 11 \mathrm{MeV}$ or less than $2 \%$. Our analysis of the decay constant gives the most extensive information to date on the heavy-quark mass dependence of the decay constant, and provides the first empirical evidence for the leading $1 / \sqrt{m_{h}}$ dependence predicted by HQET. Further results on the $B_{c}$ mesons, and the decay constant $f_{\eta_{h}}$ will be presented elsewhere 21].

Our analysis has important implications for future lattice simulations of $B$ physics. Other $B_{s}$ quantities, like semileptonic form factors, can be analyzed in the same way, bringing few-percent precision within reach. Similar precision for $B$ quantities is possible by combining $B_{s}$
calculations like these with precise calculations of $B_{s} / B$ ratios using (very efficient) non-relativistic effective field theories for $b$-quark dynamics.

We are grateful to the MILC collaboration for the use of their configurations. We thank Jack Laiho and Junko Shigemitsu for useful discussions. #### Abstract

We illustrate a technique for fitting lattice QCD correlators to sums of exponentials that is significantly faster than traditional fitting methods - 10-40 times faster for the realistic examples we present. Our examples are drawn from a recent analysis of the $\Upsilon$ spectrum, and another recent analysis of the $D \rightarrow \pi$ semileptonic form factor. For single correlators, we show how to simplify traditional effective-mass analyses.

PACS numbers: 11.15.Ha,12.38.Gc

Most physics results in lattice QCD come from fits of lattice correlators to sums of exponentials. For example, we study a particular hadron by computing Monte Carlo simulation estimates $G_{a b}^{\mathrm{MC}}(t)$ of hadronic correlators,

$$
\begin{equation*}
\sum_{\mathbf{x}}\langle 0| \Gamma_{b}(\mathbf{x}, t) \Gamma_{a}(0,0)|0\rangle, \tag{1}
\end{equation*}
$$

with different sources $\Gamma_{a}$ and sinks $\Gamma_{b}$ that create and destroy the hadron. The sum over all spatial sites $\mathbf{x}$ restricts the hadrons to states with zero total three-momentum. Such a correlator can be decomposed into contributions from energy eigenstates $\left|E_{j}\right\rangle$ in QCD [1]:

$$
\begin{equation*}
G_{a b}(t ; N)=\sum_{j=1}^{N} a_{j} b_{j} \exp \left(-E_{j} t\right) \tag{2}
\end{equation*}
$$

where $E_{j}$ is the energy, with $E_{j} \geq E_{j-1}$, and the amplitudes are matrix elements, with

$$
\begin{align*}
a_{j}^{*} & =\langle 0| \Gamma_{a}(0,0)\left|E_{j}\right\rangle \\
b_{j} & =\langle 0| \Gamma_{b}(0,0)\left|E_{j}\right\rangle \tag{3}
\end{align*}
$$

The physics is in the energies and the matrix elements, and these are determined by fitting fomula (2) to the Monte Carlo data $G_{a b}^{\mathrm{MC}}(t)$ for a variety of sources and sinks.

In principle, the number of terms $N$ in Eq. (2) is infinite, but, in practice, we need only retain a finite number of terms because the exponentials suppress high-energy states. The number needed depends upon the precision of the simulation data $G_{a b}^{\mathrm{MC}}$, but it is not uncommon to require $N=10$ or more terms for good fits to accurate data. The fitting process becomes both cumbersome and time consuming if many correlators must be fit simultaneously while using such large $N \mathrm{~s}$. In this paper we introduce a method that can dramatically simplify and accelerate such fits.

The key to this new approach lies in how priors are introduced. Two types of input data are required for these fits. The

[^298]first is simulation data for the correlators, consisting of Monte Carlo averages $\bar{G}$ for each $a, b$ and $t$, and a covariance matrix $\sigma^{2}$ that specifies both the statistical uncertainties in each average and the correlations between them:
\[

$$
\begin{equation*}
G_{a b}^{\mathrm{MC}}(t) \leftrightarrow\left\{\bar{G}_{a b}(t), \sigma_{a b, a^{\prime} b^{\prime}}^{2}\left(t, t^{\prime}\right)\right\} \tag{4}
\end{equation*}
$$

\]

This data contributes

$$
\begin{gather*}
\chi_{\mathrm{MC}}^{2}\left(a_{j}, b_{j}, E_{j}\right)=\sum_{t, a, b t^{\prime}, a^{\prime}, b^{\prime}} \sum_{a b}\left(G_{a b}(t ; N)-\bar{G}_{a b}(t)\right) \\
\sigma_{a b, a^{\prime} b^{\prime}}^{-2}\left(t, t^{\prime}\right)\left(G_{a^{\prime} b^{\prime}}\left(t^{\prime} ; N\right)-\bar{G}_{a^{\prime} b^{\prime}}\left(t^{\prime}\right)\right) \tag{5}
\end{gather*}
$$

to the $\chi^{2}$ function that is minimized by varying parameters $a_{j}$, $b_{j}$, and $E_{j}$ in a conventional fit.

The second type of input data consists of Bayesian priors for each fit parameter. Complicated multi-correlator, multiparameter fits are impossible without a priori estimates for each fit parameter [2]:

$$
\begin{gather*}
a_{j}^{\mathrm{pr}} \equiv \bar{a}_{j} \pm \sigma_{a_{j}}, \\
b_{j}^{\mathrm{pr}} \equiv \bar{b}_{j} \pm \sigma_{b_{j}}, \\
E_{j}^{\mathrm{pr}} \equiv \bar{E}_{j} \pm \sigma_{E_{j}} . \tag{6}
\end{gather*}
$$

This information is included in a conventional fit by adding extra terms to $\chi^{2}\left(a_{j}, b_{j}, E_{j}\right): \chi^{2}=\chi_{\mathrm{MC}}^{2}+\chi_{\mathrm{pr}}^{2}$ where

$$
\begin{align*}
& \chi_{\mathrm{pr}}^{2}\left(a_{j}, b_{j}, E_{j}\right)= \\
& \quad \sum_{j=1}^{N}\left\{\frac{\left(a_{j}-\bar{a}_{j}\right)^{2}}{\sigma_{a_{j}}^{2}}+\frac{\left(b_{j}-\bar{b}_{j}\right)^{2}}{\sigma_{b_{j}}^{2}}+\frac{\left(E_{j}-\bar{E}_{j}\right)^{2}}{\sigma_{E_{j}}^{2}}\right\} . \tag{7}
\end{align*}
$$

The priors can also be combined to give a priori estimates for the correlators,

$$
\begin{equation*}
G_{a b}^{\mathrm{pr}}(t ; N) \equiv \sum_{j=1}^{N} a_{j}^{\mathrm{pr}} b_{j}^{\mathrm{pr}} \exp \left(-E_{j}^{\mathrm{pr}} t\right) \tag{8}
\end{equation*}
$$

where the means and covariance matrix for $G_{a b}^{\mathrm{pr}}(t)$ are computed, using standard error propagation, from the means and covariance matrix of the priors (Eq. (6)).

The cost of a traditional analysis goes up rapidly with the number of parameters needed to obtain a good fit. In practice, however, we are rarely interested in parameters from the large$j$ terms in fit function (2), even when these terms are needed for a good fit. Rather than including them in the fit, we can incorporate the large- $j$ terms into the Monte Carlo data before fitting. To do this, we use the priors to generate an a priori estimate for these terms, and then subtract that estimate from the Monte Carlo data. This effectively removes the large- $j$ terms from the data. Finally we fit the modified data with a simpler formula that includes only small- $j$ terms.

More explicitly, we can remove terms having $n<j \leq N$ by replacing $G_{a b}^{\mathrm{MC}}(t)$ with (first definition)

$$
\begin{equation*}
\tilde{G}_{a b}^{\mathrm{MC}}(t ; n) \equiv G_{a b}^{\mathrm{MC}}(t)-\Delta G_{a b}^{\mathrm{pr}}(t ; n) \tag{9}
\end{equation*}
$$

where

$$
\begin{align*}
\Delta G_{a b}^{\mathrm{pr}}(t ; n) & \equiv G_{a b}^{\mathrm{pr}}(t ; N)-G_{a b}^{\mathrm{pr}}(t ; n) \\
& =\sum_{j=n+1}^{N} a_{j}^{\mathrm{pr}} b_{j}^{\mathrm{pr}} \exp \left(-E_{j}^{\mathrm{pr}} t\right) \tag{10}
\end{align*}
$$

is the $j>n$ part of the fit function. Having removed the $j>n$ terms, we can fit $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ with the simpler fit function, $G_{a b}(t ; n)$, rather than $G_{a b}(t ; N)$.

Here we assume that $N$ is sufficiently large that $\Delta G_{a b}^{\mathrm{pr}}(t ; n)$ and therefore $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ are independent of $N$ to within their statistical errors. The covariance matrix for $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ is obtained by adding the covariance matrices of $G_{a b}^{\mathrm{MC}}(t)$ and $\Delta G_{a b}^{\mathrm{pr}}(t ; n)$ (that is, adding the errors in quadrature) [4].

Removing high- $j$ terms from both the fit function and the fit data replaces the original fitting problem - fit an $N$-term function $G_{a b}(t ; N)$ to $G_{a b}^{\mathrm{MC}}(t)$ - by a simpler problem that can have far fewer fit parameters: fit an $n$-term function $G_{a b}(t ; n)$ to $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$, where $n<N$. Remarkably, as we showed in [3], these two problems are equivalent for high statistics data even when $n$ is quite small: that is, fit results (means and standard deviations) for the low- $j$ parameters are the same in both cases. In the second case, the $j>n$ terms have been "marginalized," or, in effect, integrated out of the Bayesian probability distribution, but in a way that does not affect the analysis of the $j \leq n$ terms. When $n \ll N$, the fit parameters that remain are many fewer than what would be required in a standard fit, and fitting is much faster.

In this paper we use a variation of this marginalization procedure which we find to be more robust when fitting correlators that fall exponentially quickly with increasing $t$. In this variation the modified correlators are given by (second definition)

$$
\begin{equation*}
\tilde{G}_{a b}^{\mathrm{MC}}(t ; n) \equiv G_{a b}^{\mathrm{MC}}(t) \frac{G_{a b}^{\mathrm{pr}}(t ; n)}{G_{a b}^{\mathrm{pr}}(t ; N)} \tag{11}
\end{equation*}
$$

which is analogous to the first definition (Eq. (9)) but applied to the logarithm of the correlator rather than the correlator itself. Again, terms with $j>n$ have been removed, and therefore the modified correlator data can be fit with the simpler fit function, $G_{a b}(t ; n)$.

FIG. 1. Fit $\chi^{2}$ per degree of freedom for sequential fits of $25 \Upsilon$ correlators with $n=1,2,3 \ldots$ terms in fit function (2). Results are plotted versus the cumulative time required for fitting, and are for fits of: a) the unmodified simulation data $G_{a b}^{\mathrm{MC}}(t)$ (red circles and dotted line); and b) the modified simulation data $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ (Eq. (11)) (blue circles and dashed line). The region of good fits is indicated by the gray band.

We now illustrate our new method by applying it to QCD simulation data from two recent analyses. For each analysis, we fit a function, like $G_{a b}(t ; n)$, with $n$ terms both to untouched simulation data $G_{a b}^{\mathrm{MC}}(t)$, and to modified simulation data $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$, from which $j>n$ terms have been removed using Eq. (11). We vary $n$, doing sequential fits with $n=1,2,3 \ldots$, where the best-fit parameter values from one fit are used as starting values for the next fit. Sequential fitting with increasing $n$ is a standard approach to complicated multiparameter correlator fits; $n$ is increased until the fit's $\chi^{2}$ stops changing, at which point enough terms have been include to reflect accurately the uncertainties introduced by large- $j$ terms. Here we examine the best-fit parameters for each $n$ to investigate the rate at which correct results emerge from this process. This allows a detailed comparison of our two fitting strategies.

The first data set is a collection of 25 correlators for the $\Upsilon(1 S)$ meson and its radial excitations $(\Upsilon(2 S), \Upsilon(3 S)$, etc.) [5]. These correlators were made using five different operators for both sources and sinks. They were fit to formula (2) with priors (in lattice units):

$$
\begin{align*}
\log \left(E_{1}\right) & =\log (0.3 \pm 0.1)=-1.2 \pm 0.3 \\
\log \left(E_{j+1}-E_{j}\right) & =\log (0.25 \pm 0.125)=-1.4 \pm 0.5 \\
a_{j} & =0.1 \pm 1.0 \tag{12}
\end{align*}
$$

except for a local source for which the priors were $\log \left(a_{j}\right)=$ $\log (0.1 \pm 0.2)=-2.3 \pm 2$ (local source). These are broad priors - more than 100 times broader than the final errors for the quantities we examine below. We set $N=20$ when defining $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ (Eq. (11)); this is roughly twice the size it needs to be, but it costs little to make $N$ large. In general $N$ should be chosen so that terms with $j>N$ are negligible compared with statistical errors.

In Fig. 11 we plot the $\chi^{2}$ per degree of freedom for each method versus the time required to get to that value [6]. As expected, the new algorithm reaches a reasonable $\chi^{2}$ with just a few terms $(n=2-3)$, in 20-30 seconds; the traditional al-

FIG. 2. Best-fit results from sequential fits of $25 \Upsilon$ correlators with $n=1,2,3 \ldots$ terms in fit function (2). Results are plotted versus the cumulative time required for fitting, and are for fits of: a) the unmodified simulation data $G_{a b}^{\mathrm{MC}}(t)$ (red circles and dotted line); and b) the modified simulation data $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ (Eq. (111) (blue circles and dashed line). Results are given for mass splittings between different vector $S$-states, and for the wave functions at the origin for the lowest two states. All results are in lattice units. The gray bands show the best-fit result from the modified data after convergence.
gorithm requires $n=10-11$ to obtain a good $\chi^{2}$, and 600700 seconds. Similar differences are evident if we look at physical quantities extracted from the simulations. In Fig. 2 we show results for the $2 S-1 S$ mass splitting (in lattice units), for the $3 S-1 S$ mass splitting divided by the $2 S-1 S$ splitting, and for the $1 S$ and $2 S$ mesons' (nonrelativistic) wave functions at the origin, which come from fit parameters $a_{j}$ for a local source. In every case the two algorithms agree on the final result, but the new algorithm converges to correct results

FIG. 3. Best-fit results from sequential fits of 13 two-point and threepoint correlators for $D$ and $\pi$ mesons with $n=1,2,3 \ldots$ terms in fit function (2). Results are plotted versus the cumulative time required for fitting, and are for fits of: a) the unmodified simulation data (red circles and dotted line); and b) the modified simulation data (Eq. 11) (blue circles and dashed line). Results are given for the $D$-meson mass $m_{D}$ and decay constant $f_{D}$, and for the $D \rightarrow \pi$ scalar form factor at zero recoil momentum $f_{0}(0,0,0)$. All results are in lattice units. The gray bands show the best-fit result from the modified data after convergence.

## 10-40 times faster.

Our second example is from a recent analysis of the $D \rightarrow$ $\pi$ semileptonic form factor [7]. To extract the form factor at four different momenta, this analysis uses a simultaneous fit of 13 two-point and three-point correlators: a) a $D$-meson correlator with a pseudoscalar local source and sink; b) four $\pi$-meson correlators, one for each pion momentum of interest, again with local pseudoscalar sources and sinks; and c) two three-point correlators $D \rightarrow J_{\text {scalar }} \rightarrow \pi$ for each of the four pion momenta. The fit functions are more complicated for this case. For example, the $D$-meson correlator is fit by a function:

$$
\begin{equation*}
G_{D}(t ; n)=\sum_{j=1}^{n} a_{j} f\left(E_{j}, t\right)-(-1)^{t} a_{j}^{o} f\left(E_{j}^{o}, t\right) \tag{13}
\end{equation*}
$$

where $f\left(E_{j}, t\right) \equiv \exp \left(-E_{j} t\right)+\exp \left(-E_{j}(T-t)\right)$ is periodic with period $T=64$, and the second (oscillating) term is due to

FIG. 4. The $D$-meson's effective mass $m_{\text {eff }}(t)$ versus $t$ computed from modified simulation data $\tilde{G}_{D}^{\mathrm{MC}}(t)$ from which every state other than the ground state has been removed (using priors). The (very thin) gray band shows the weighted average of all $m_{\text {eff }}(t) \mathrm{s}$, taking account of correlations. The thickness of the band indicates the uncertainty of the average. Note that the largest $t \mathrm{~s}$ shown here correspond to the middle $t$ range. The error bars grow there because $m_{\text {eff }}(t)$ becomes very sensitive to statistical errors in this region (since periodic boundary conditions imply that the derivative of the correlator's nonoscillating part vanishes at the midpoint).
opposite-parity states in the correlator (a feature of staggeredquark formalisms like that used in this analysis). The details for the other correlators, and the priors are given in [7].

Despite the complexity of dealing with both two-point and three-point correlators, this is a simpler fit than the $\Upsilon$ case; but even here we find that marginalizing most of the fit function makes the analysis about 30 times faster. We show results in Fig. 3for the $D$-meson's mass $m_{D}$ and leptonic decay constant $f_{D}$, as well as for the $D \rightarrow \pi$ scalar form factor $f_{0}(0,0,0)$ at zero recoil momentum. All results are in lattice units. Again the two approaches agree on the results but the new approach has correct results even with only a single term $(n=1)$ in the fit functions. For these fits we set $N=10$ when computing the modified data $\tilde{G}_{a b}^{\mathrm{MC}}(t ; n)$ (Eq. (11)), which is twice as large as it needs to be.

Some insight into how marginalization works can be gained by focusing just on the $D$ correlator from this analysis and fitting the modified data,

$$
\begin{equation*}
\tilde{G}_{D}^{\mathrm{MC}}(t) \equiv G_{D}^{\mathrm{MC}}(t) \frac{a_{1}^{\mathrm{pr}} f\left(E_{1}^{\mathrm{pr}}, t\right)}{G_{D}^{\mathrm{pr}}(t ; N)} \tag{14}
\end{equation*}
$$

with only the non-oscillating part of the first term in Eq. (13) - that is, with $a_{1} f\left(E_{1}, t\right)$. This situation is sufficiently simple that fitting is not required. The $D$ mass, for example, can be obtained by averaging the "effective mass,"

$$
\begin{equation*}
m_{\mathrm{eff}}(t) \equiv \operatorname{arccosh}\left(\frac{\tilde{G}_{D}^{\mathrm{MC}}(t+1)+\tilde{G}_{D}^{\mathrm{MC}}(t-1)}{2 \tilde{G}_{D}^{\mathrm{MC}}(t)}\right) \tag{15}
\end{equation*}
$$

over all $t$, taking account of correlations between different $t \mathrm{~s}$.

The effective mass is plotted as a function of $t$ in Fig. 4 It is compared with the weighted average of all $27 m_{\text {eff }}(t) \mathrm{s}$ (gray band), which at $m_{\text {eff }}^{\text {avg }}=1.1584(11)$ agrees well with the best result, 1.1593(7), from full multi-term fits (top panel in Fig. 37.

The first excited state in the $D$ correlator is the oppositeparity contribution, which accounts for the oscillation in $m_{\text {eff }}(t)$. Strong statistical correlations between different points result in an average $m_{\text {eff }}$ whose error is more than 7 times smaller than the best error from an individual $m_{\text {eff }}(t)$. The errors in $m_{\text {eff }}(t)$ when $t \leq 16$ come almost entirely from marginalized terms absorbed into the fit data using Eq. (14); the original Monte Carlo simulation errors are negligible there.

Absent marginalization, contributions from excited states would limit a traditional effective mass analysis of this data to values with $t>16$. With marginalization, all $t \mathrm{~s}$ are used, except for a small number at very small $t$ where the fit function is invalid (because of temporal non-locality in the lattice quark action). Using $28 t \mathrm{~s}$ is possible because we have removed the excited states through Eq. (14). As a result different $m_{\text {eff }}(t) \mathrm{s}$ agree with each other to within their errors: fitting all 27 values in Fig. 4 to a constant gives an excellent fit, with a $\chi^{2}$ per degree of freedom of 0.6 . (The result of the fit is, by definition, the same as the weighted average reported above.)

Our new implementation of effective-mass analyses is simpler and less ambiguous than traditional analyses because we are not limited to large $t \mathrm{~s}$. More importantly our implementation also allows us to quantify the contribution to the uncertainty in the final $m_{\text {eff }}^{\text {avg }}$ due to the excited states: here the priors for non-oscillating terms in Eq. (13) contribute $0.44 \sigma_{m}$, those from oscillating terms contribute $0.07 \sigma_{m}$, and the uncertainties in the Monte Carlo data contribute $0.89 \sigma_{m}$, where $\sigma_{m}$ is the standard deviation of $m_{\mathrm{eff}}^{\text {avg }}$. Such information is essential for assessing the reliability of the final result, as well as for planning improvements to the analysis.

In this paper we have shown how to accelerate multiexponential fits to multiple hadronic correlators by removing contributions due to excited states from both the fit function and the simulation data, before fitting. This technique for marginalizing large parts of the fit function greatly reduces the number of fit parameters needed in the realistic examples presented here, and makes fitting 10-40 times faster. Marginalization also simplifies effective-mass analyses, and generalizes easily to analogous multi-state (generalized eigenvalue) methods.

This work was supported by the DOE (DE-FG0204ER41299, DE-FG02-91ER40690), the NSF (PHY0757868), and the STFC. We used the Darwin Supercomputer of the Cambridge High Performance Computing Service as part of the DiRAC facility jointly funded by STFC, BIS and the Universities of Cambridge and Glasgow. We also used facilities of the USQCD collaboration funded by the Office of Science of the DOE and at the Ohio Supercomputer Center.
[1] Lattice QCD simulations use Euclidean time and so -it is replaced by $-t$ in the exponentials. Also simulations are for finite
volumes in space, and therefore all states, including multi-hadron
states, have discrete energy eigenvalues.

The formula for $\chi_{\mathrm{pr}}^{2}$ generalizes trivially if there are correlations between the priors for different parameters.
[3] For a proof, see the appendix of C. McNeile, C. T. H. Davies, E. Follana, K. Hornbostel, G. P. Lepage, Phys. Rev. D82, 034512 (2010). [arXiv:1004.4285 [hep-lat]].
[4] Again the covariance matrix for $\Delta G_{a b}(t ; n)$ is computed using standard error propagation - for example, $f\left(\bar{x} \pm \sigma_{x}\right)=\bar{f} \pm \sigma_{f}$ with $\bar{f} \approx f(\bar{x})$ and $\sigma_{f}^{2} \approx f^{\prime}(\bar{x})^{2} \sigma_{x}^{2}$. We have compared this linearized analysis with Monte Carlo evaluations of $\Delta G$ (from normal distributions for the priors). We find the Monte Carlo results to be both much more expensive and also less robust for correlators that decay exponentially quickly. Note also that it is essential to retain the off-diagonal elements (correlations) in the covariance matrix for $\Delta G_{a b}(t ; n)$; correlations arise because, for
example, the prior data used for a parameter is the same for all $t$ values.
[5] The simulations used 0.09 fm lattices with $n_{f}=4$ sea quarks (HISQ discretization), and NRQCD dynamics for the $b$ quark. The gluon configurations were provided by the MILC collaboration. For further details see: R. J. Dowdall, et al., [arXiv:1110.6887][hep-lat]].
[6] The absolute computer times quoted here are obviously of little relevance since they depend upon specific details of hardware and software. What is relevant is the comparison between methods.
[7] The simulations used 0.12 fm lattices with $n_{f}=3$ light sea quarks (ASQTAD discretization), and HISQ relativistic dynamics for valence quarks. The gluon configurations were provided by the MILC collaboration. For further details see (set C2): H. Na, C. T. H. Davies, E. Follana, J. Koponen, G. P. Lepage, J. #### Abstract

We determine masses and decay constants of heavy-heavy and heavy-charm pseudoscalar mesons as a function of heavy quark mass using a fully relativistic formalism known as Highly Improved Staggered Quarks for the heavy quark. We are able to cover the region from the charm quark mass to the bottom quark mass using MILC ensembles with lattice spacing values from 0.15 fm down to 0.044 fm . We obtain $f_{B_{c}}=0.427(6) \mathrm{GeV} ; m_{B_{c}}=6.285(10) \mathrm{GeV}$ and $f_{\eta_{b}}=0.667(6)$ GeV. Our value for $f_{\eta_{b}}$ is within a few percent of $f_{\Upsilon}$ confirming that spin effects are surprisingly small for heavyonium decay constants. Our value for $f_{B_{c}}$ is significantly lower than potential model values being used to estimate production rates at the LHC. We discuss the changing physical heavyquark mass dependence of decay constants from heavy-heavy through heavy-charm to heavy-strange mesons. A comparison between the three different systems confirms that the $B_{c}$ system behaves in some ways more like a heavy-light system than a heavy-heavy one. Finally we summarise current results on decay constants of gold-plated mesons.

## I. INTRODUCTION

Lattice QCD calculations offer particular promise for $B$ meson physics where a number of relatively simple weak decay processes give access to elements of the CKM matrix that are important for constraining the unitarity triangle of the Standard Model [1]. The theoretical calculation of the appropriate weak matrix elements must be done with percent accuracy for stringent constraints, making optimal use of the experimental results. This has not yet been achieved, despite the enormous success of lattice QCD over the last five years and its acceptance as a precision tool for QCD physics [2]. Work is ongoing on several different approaches. Here we continue discussion of an alternative method for $B$ meson physics that may offer a faster route to high accuracy for some quantities than other methods currently in use. Following work on accurate $b$ and $c$ quark masses [3] and heavy-strange decay constants [4, we show results for masses and decay constants of $B_{c}$ and $\eta_{b}$ mesons and map out their heavy-quark mass dependence. As well as showing that high accuracy can be achieved, these results provide an interesting comparison of how heavy-charm mesons sit between heavy-heavy and heavy-light.

The calculations use a discretisation of the quark Lagrangian onto the lattice known as the Highly Improved Staggered Quark (HISQ) action 5]. This has the advantages of being numerically very fast along with having small discretisation errors and enough chiral symmetry

[^299](a PCAC relation) that the weak current that causes charged pseudoscalar mesons to decay leptonically is absolutely normalised. This action readily gives $\pi$ and $K$ meson decay constants with errors below $1 \%$ on gluon field configurations that include the full effect of $u, d$ and $s$ quarks in the sea [6, 7]. Results from multiple values of the lattice spacing and multiple sea $u / d$ quark masses allow extrapolation to the real world with physical $u / d$ quark masses at zero lattice spacing.

The HISQ action gives similarly accurate results for mesons containing $c$ quarks [6], significantly improving on previous methods that use a nonrelativistic effective theory such as the Fermilab action [8] or NRQCD [9]. The key advantages are clear: the HISQ action has no errors from missing higher order terms in the effective theory or from the renormalisation of the decay constant [1]. The price to be paid is that of the discretisation errors. These errors are much larger for $c$ quarks than for $u / d$ and $s$, since their size is now set by $m_{c} a$ rather than $\Lambda_{Q C D} a$. They can be well controlled, however, using the HISQ action on gluon configurations with a wide range of lattice spacing values down to 0.045 fm where $m_{c} a=$ 0.2 [10]. Discretisation errors are in fact the only issue for the $D_{s}$ meson, for which particularly accurate results can be obtained. This meson has no valence light quarks and the dependence of both its mass and decay constant on the $u / d$ quark masses is seen to be very small [10], meaning that uncertainties from the chiral extrapolation are not significant.

It is less clear what to do for $b$ quarks because they are so much heavier. To achieve $m_{b} a<1$ we need a lattice spacing, $a<0.04 \mathrm{fm}$. Using NRQCD or the Fermilab formalism we can readily handle $b$ quarks on much coarser lattices, with $a \approx 0.1 \mathrm{fm}$, but must then take a substan-
tial error (currently $4 \%$ for NRQCD [11]) from matching the weak annihilation current to full QCD perturbatively. Work is underway to reduce this error [12]. It should also be emphasised that this matching error is not present in ratios of decay constants, for example $f_{B_{s}} / f_{B}$ which is known to $2 \%$ from NRQCD [11].

Here we show what accuracy is possible using the HISQ action for $b$ quarks. We use quark masses heavier than that of the $c$ quark and map out the heavy quark mass dependence of both masses and decay constants for a variety of different pseudoscalar mesons. By using experience from the $D_{s}[10$ and concentrating on mesons that do not contain valence light quarks we do not have to worry significantly about the extrapolation to the physical $u / d$ quark mass limit. The key issue is that of discretisation errors, as for $f_{D_{s}}$, and we therefore work with the same large range of lattice spacing values from 0.15 fm to 0.044 fm , so that we can account fully for the $a$ dependence. It is important to separate discretisation effects from physical dependence on the heavy quark mass since we do also have to extrapolate to the physical $b$ mass from the quark masses that we are able to reach on these lattices. We are only able to obtain results directly at close to the physical $b$ mass on the finest, 0.044 fm lattice.

We have already demonstrated how well this method works in determining the decay constant of the $B_{s}$ meson [4], one of the key quantities of interest for CKM studies. Mapping out the $B_{s}$ decay constant as a function of heavy quark mass showed that the decay constant peaks around the $D_{s}$ and then falls slowly. We found that $f_{B_{s}} / f_{D_{s}}=0.906(14)$, the first significant demonstration that this ratio is less than 1.

Here we extend this work to map out results for the decay constants of the $\eta_{b}$ and $B_{c}$ mesons, along with the $B_{c}$ meson mass. The $B_{c}$ meson mass is known experimentally but its leptonic decay rate has not yet been measured and so we provide the first prediction of that in full lattice QCD. The masses and decay constants also reveal information about the nature of these mesons that can provide useful input to model calculations. For example, does the $B_{c}$ meson look more like a heavy-heavy meson or a heavy-light meson? It is important to emphasise that both the results determined at the $b$ quark mass and the dependence on the heavy quark mass (and on any light quark masses) have physical meaning: the former can be tested against experiment but the latter can provide stringent tests of models and comparison between lattice QCD calculations.

The layout of the paper is as follows: section II describes the lattice calculation and then section III gives results for heavy-heavy and heavy-charm mesons in turn. We compare the $B_{c}$ meson mass to experiment and predict its decay constant as well as comparing the behaviour of heavy-charm mesons to that of heavyonium and heavy-strange mesons. Section V gives our conclusions, looking forward to what will be possible for $b$ quark physics on even finer lattices in future.

TABLE I: Ensembles (sets) of MILC configurations used for this analysis. The sea asqtad quark masses $m_{l}^{a s q}(l=u / d)$ and $m_{s}^{a s q}$ are given in the MILC convention where $u_{0}$ is the plaquette tadpole parameter. The lattice spacing values in units of $r_{1}$ after 'smoothing' are given in the second column [13]. Set 1 is 'very coarse'; set 2 , 'coarse'; set 3 , 'fine'; set 4 'superfine' and set 5 'ultrafine'. The size of the lattices is given by $L^{3} \times T$. The final column gives the number of configurations used and the number of time sources for propagators per configuration.

## II. LATTICE CALCULATION

We use ensembles of lattice gluon configurations at 5 different, widely separated, values of the lattice spacing, provided by the MILC collaboration. The configurations include the effect of $u, d$ and $s$ quarks in the sea with the improved staggered (asqtad) formalism. Table $\square$ lists the parameters of the ensembles. The $u$ and $d$ masses are taken to be the same, and the ensembles have $m_{u / d} / m_{s}$ approximately 0.2 . As discussed in section I, we expect sea quark mass effects to be small for the gold-plated mesons with no valence light quarks that we study here.

The lattice spacing is determined on an ensemble-byensemble basis using a parameter $r_{1}$ that comes from fits to the static quark potential calculated on the lattice [13]. This parameter can be determined with very small statistical/fitting errors. However, its physical value is not accessible to experiment and so must be determined using other quantities, calculated on the lattice, that are. We have determined $r_{1}=0.3133(23) \mathrm{fm}$ using four different quantities ranging from the $(2 \mathrm{~S}-1 \mathrm{~S})$ splitting in the $\Upsilon$ system to the decay constant of the $\eta_{s}$ (fixing $f_{K}$ and $f_{\pi}$ from experiment) [14]. Using our value for $r_{1}$ and the MILC values for $r_{1} / a$ given in Table we can determine $a$ in fm on each ensemble or, equivalently, $a^{-1}$ in GeV needed to convert lattice masses to physical units. It is important to note that the relative values of $a$ (from $\left.r_{1} / a\right)$ are determined more accurately than the absolute values of $a$ (from $r_{1}$ ). Our fits account for this to give two separate errors in our error budgets.

Table $\square$ lists the number of configurations used from each ensemble and the number of time sources for the valence HISQ propagators per configuration. To increase statistics further we use a 'random wall' source for the quark propagators from a given time source. When quark propagators are combined this effectively increases the number of meson correlators sampled and reduces the statistical noise by a large factor for the case of pseudoscalar mesons. We also take a random starting point for our time sources for the very coarse, coarse and fine
ensembles.
We use many different masses for the HISQ valence quarks varying from masses close to that of the $s$ quark to much heavier values for $c$ quarks and for quarks with masses between $c$ and $b$. On all sets the largest valence quark mass in lattice units that we use is $m_{h} a=0.85$. These propagators are combined to make goldstone pseudoscalar meson correlators at zero momentum with all possible combinations of valence quark masses. We separate them into 'heavy-heavy' correlators when both masses are the same and are close to charm or heavier; 'heavy-charm' when one mass is close to charm and the other is heavier and 'heavy-strange' when one mass is close to strange and the other is close to charm or heavier.

The meson correlation function is averaged over time sources on a single configuration so that any correlations between the time sources are removed. Autocorrelations between results on successive configurations in an ensemble were visible by binning only on the finest lattices. We therefore bin the correlators on superfine and ultrafine lattices by a factor of two.

The meson correlators are fit as a function of the time separation between source and sink, $t$, to the form:

$$
\begin{equation*}
\bar{C}(t)=\sum_{i} a_{i}\left(e^{-M_{i} t}+e^{-M_{i}(T-t)}\right) \tag{1}
\end{equation*}
$$

for the case of equal mass quark and antiquark. $i=1$ is the ground state and larger $i$ values denote radial or other excitations with the same $J^{P C}$ quantum numbers. $T$ is the time extent of the lattice. For the unequal mass case there are additional 'oscillating' terms coming from opposite parity states, denoted $i_{p}$ :

$$
\begin{equation*}
\bar{C}(t)=\sum_{i, i_{p}} a_{i} e^{-M_{i} t}+(-1)^{t} a_{i_{p}} e^{-M_{i_{p}} t}+(t \rightarrow T-t) \tag{2}
\end{equation*}
$$

To fit we use a number of exponentials $i$, and where appropriate $i_{p}$, in the range $2-6$, loosely constraining the higher order exponentials by the use of Bayesian priors [15]. As the number of exponentials increases, we see the $\chi^{2}$ value fall below 1 and the results for the fitted values and their errors for the parameters for the ground state $i=1$ stabilise. This allows us to determine the ground state parameters $a_{1}$ and $M_{1}$ as accurately as possible whilst allowing the full systematic error from the presence of higher excitations in the correlation function. We take the fit parameters to be the logarithm of the ground state masses $M_{1}$ and $M_{1_{p}}$ and the logarithms of the differences in mass between successive radial excitations (which are then forced to be positive). The Bayesian prior value for $M_{1}$ is obtained from a simple 'effective mass' in the correlator and the prior width on the value is taken as a factor of 1.5 . The prior value for the mass splitting between higher excitations is taken as roughly 600 MeV with a width of 300 MeV . Where oscillating states appear in the fit, the prior value for $M_{1_{p}}$ is taken as roughly 600 MeV above $M_{1}$ with a prior width of

300 MeV and the splitting between higher oscillating excitations is taken to be the same as for the non-oscillating states. The amplitudes $a_{i}$ and $a_{i_{p}}$ are given prior widths of 1.0 . We apply a cut on the range of eigenvalues from the correlation matrix that are used in the fit of $10^{-3}$ or $10^{-4}$. We also cut out very small $t$ values from our fit, typically below 3 or 4 , to reduce the effect of higher excitations.

The amplitude, $a_{1}$, from the fits in equations (1) and $(2)$ is directly related to the matrix element for the local pseudoscalar operator to create or destroy the groundstate pseudoscalar meson from the vacuum. Using the PCAC relation this can be related to the matrix element for the temporal axial current and thence to the decay constant. The PCAC relation guarantees that no renormalisation of the decay constant is needed. We have:

$$
\begin{equation*}
f_{P}=\left(m_{a}+m_{b}\right) \sqrt{\frac{2 a_{1}}{M_{1}^{3}}} \tag{3}
\end{equation*}
$$

for meson $P$. Here $m_{a}$ and $m_{b}$ are the quark masses used in the lattice QCD calculation.
$f_{P}$ is clearly a measure of the internal structure of a meson and in turn is related, for charged pseudoscalars such as the $\pi, K, D, D_{s}, B$ and $B_{c}$ mesons, to the experimentally measurable leptonic branching fraction via a $W$ boson:

$$
\begin{equation*}
\mathcal{B}\left(P \rightarrow l \nu_{l}(\gamma)\right)=\frac{G_{F}^{2}\left|V_{a b}\right|^{2} \tau_{P}}{8 \pi} f_{P}^{2} m_{l}^{2} m_{P}\left(1-\frac{m_{l}^{2}}{m_{P}^{2}}\right)^{2} \tag{4}
\end{equation*}
$$

up to calculable electromagnetic corrections. $V_{a b}$ is the appropriate CKM element for quark content $a \bar{b}, \tau_{P}$ is the pseudoscalar meson lifetime. For neutral mesons there is no possibility to annihilate to a single particle via the temporal axial current. However, in the Standard Model the $B_{s}$ and $B$ are expected to annihilate to $\mu^{+} \mu^{-}$with a rate that is proportional to $f_{P}^{2}\left|V_{t b}^{*} V_{t q}\right|^{2}$ via 4 -fermion operators in the effective weak Hamiltonian [16]. For the heavy-heavy pseudoscalar, the decay rate to two photons is related to its decay constant but only at leading order in a nonrelativistic expansion. In section III we compare the pseudoscalar decay constant to that of its associated vector meson, determined directly from its decay to leptons.

The results for masses and decay constants from fits in eqs. (1) and (2) and using eq. (3) are in units of the lattice spacing, and given in this form in the tables of section III. To convert to physical units, as discussed earlier, we determine the lattice spacing using the parameter $r_{1}$.

We then fit the results in physical units as a function of heavy quark mass to determine the heavy quark mass dependence and the physical value at the $b$ quark mass. Because the bare heavy quark mass used in the lattice action runs with lattice spacing we need a proxy for it that is a physical quantity, such as a meson mass. In 4] we used the heavy-strange pseudoscalar mass since we were focussing on heavy-strange mesons. Here we choose

| electromagnetism $c$-in-sea |  |  |  |
| :--- | :---: | :---: | :---: |

TABLE II: Estimates of shifts in MeV to be applied to the masses determined in lattice QCD to allow for missing electromagnetism, $c$ quarks in the sea and annihilation to gluons for the $\eta_{b}$ and $\eta_{c}$ mesons [10, 18]. The electromagnetic shift is estimated from a potential model for $\eta_{b}, \eta_{c}$ and $B_{c}$ and from a comparison of charged and neutral meson masses for $B_{s}$ and $D_{s}$. The $c$-in-sea and gluon annihilation shifts are estimated from perturbation theory. The errors on the shifts are given in brackets. Note that for the $\eta_{S}$ there are no shifts because the mass is fixed in lattice QCD [14].
the mass of the heavy-heavy pseudoscalar meson, $\eta_{h}$, to provide the same $x$-axis for all of our plots showing dependence on the heavy quark mass. The positions of $c$ and $b$ on these plots are then determined by the values of the $\eta_{c}$ and $\eta_{b}$ masses.

The experimental results for the $\eta_{b}$ and $\eta_{c}$ meson masses are $9.391(3) \mathrm{GeV}$ and $2.981(1) \mathrm{GeV}$ respectively [17. Our lattice QCD calculation, however, is missing some ingredients from the real world which means that we must adjust the experimental values we use in our calibration. The key missing ingredients are electromagnetism, $c$ quarks in the sea and the possibility for the $\eta_{b}$ and $\eta_{c}$ mesons to annihilate to gluons, which we do not allow for in determining our $\eta_{c}$ and $\eta_{b}$ correlators. These effects all act in the same direction, that of lowering the meson mass in the real world compared to that in our lattice QCD world. We estimate the total shift from these effects for the $\eta_{c}$ to be $-5.4(2.7) \mathrm{MeV}$ and for the $\eta_{b}$, as $-9(6) \mathrm{MeV}$ [18]. The appropriate 'experimental' masses for the $\eta_{c}$ and $\eta_{b}$ for our calculations are then $2.986(3) \mathrm{GeV}$ and $9.400(7) \mathrm{GeV}$.

Since we need to allow for the three ingredients missing from our lattice QCD calculation when we determine meson masses in section III, we give in Table II a summary of our estimates of these effects [10, 18]. These estimates will be used to shift the lattice QCD results for comparison to experiment. Effects on decay constants are much smaller and we do not apply shifts in that case but simply include an additional uncertainty in the error budget.

For consistency we fit a similar functional form to all quantities. This form must take account of physical heavy quark mass-dependence; discretisation errors and, for heavy-charm and heavy-strange mesons, mistuning of $c$ and $s$ quark masses. We use the standard constrained fitting techniques that we earlier applied to the correlators [15]. For the dependence on heavy quark mass and

|  | form of $f_{0}$ | $b$ | $A$ | $c_{0000}$ | $c_{i j k l}$ |

| $\Delta_{H_{c}, h h}$ | $A\left(\left(M\left(-M_{\eta_{c}}\right) / M_{0}\right)^{b}\right.$ | 1 | 1 | $0 \pm 2$ | $0 \pm 1.5$ |
| $f_{H_{c}}$ | $A\left(\frac{\alpha_{V}(M)}{\alpha_{V}\left(M_{\eta_{c}}\right)}\right)^{-2 / 9}\left(\frac{M}{M_{0}}\right)^{b}$ | -0.5 | $0 \pm 2$ | 1 | $0 \pm 3$ |
| $\Delta_{H_{c}, h s}$ | $A\left(M / M_{0}\right)^{b}$ | 0 | 1 | $0 \pm 2$ | $0 \pm 1.5$ |

TABLE III: The functional form for $f_{0}(M)$, the leading power dependence on the heavy quark mass, used in fitting the different quantities described in section III using equation (5). The third and fourth columns give the prior values and widths for the parameters $A$ and $b$. In most cases $b$ was fixed and then a single number is given. Likewise the sixth column gives the prior value and width for the $c_{i j k l}$ where the sum was normalised so that $c_{0000}$ was set equal to 1 .
lattice spacing for each set of results $f(M, a)$, we use

$$
\begin{align*}
& f(M, a)=f_{0}(M) \times \\
& \sum_{i=0}^{7} \sum_{j, k=0}^{3} \sum_{l=0}^{1} c_{i j k l}\left(\frac{M_{0}}{M}\right)^{i}\left(\frac{a m_{1}}{\pi}\right)^{2 j}\left(\frac{a m_{2}}{\pi}\right)^{2 k}\left(\frac{a \Lambda}{\pi}\right)^{2 l} \\
& +\delta f_{s}+\delta f_{c} \tag{5}
\end{align*}
$$

The quantity that we use for the heavy quark mass, $M$, is given by $M=M_{\eta_{h}}$. $f_{0}$ is a function giving the 'leading power' behaviour expected for each quantity. This is either derived from HQET or potential model expectations and takes the general form $A\left(M / M_{0}\right)^{b}$. For the decay constants $f_{H_{c}}$ and $f_{H_{s}}$ we multiply this by the ratio of $\alpha_{s}$ values at the $b$ and the $c$ raised to the power of $-2 / \beta_{0}=-2 / 9$ for $n_{f}=3$. This is the expected prefactor from resumming leading logarithms in HQET [19]. For $\alpha_{s}$ we take $\alpha_{V}$ from lattice QCD [3, 20. We take $M_{0}$ to have the value 2 GeV so that the factor $M_{0} / M$ is approximately $1 \mathrm{GeV} / m_{b}$. We tabulate the different forms for $f_{0}$ in Table III along with the prior values taken for $A$ and $b . b$ is allowed to float for the fit to $f_{\eta_{h}}$. In other cases it is fixed to the expected value but we have checked that allowing it to float returns the expected value within errors. We take the same prior for $A$ of $0 \pm 2$ in all cases.

The sum to the right of the leading term includes higher order corrections to the physical massdependence. These take the form of powers of $M_{0} / M$, again using $M_{0}=2 \mathrm{GeV}$. We allow for 8 terms in the sum so that there is enough leeway to describe (by Taylor's theorem) any physically reasonable functional form in the fixed mass range from $c$ to $b$. For the heavy-charm case we in fact fit from $M=4 \mathrm{GeV}$ upwards so that the functional form is that appropriate to the unequal valence mass case.

The other terms in the sum of eq. (5) allow for systematic errors resulting from sensitivity to the lattice spacing. Such discretisation errors depend on the lattice momentum cut-off, $\pi / a$, but can have a scale set by the different masses involved in the quantity under study. We allow for discretisation errors appearing with a scale of
$m_{1}$ and $m_{2}$, where $m_{1}$ and $m_{2}$ are the two quark masses in the meson (they will be the same in heavyonium). To be conservative we allow in addition further discretisation errors with a scale of $\Lambda_{\mathrm{QCD}}$ where we take $\Lambda_{\mathrm{QCD}}=$ 0.5 GeV . The powers of lattice spacing that appear in the terms must be even since discretisation errors only appear as even powers for staggered quarks. For the decay constants the $c_{i j k l}$ are normalised so that $c_{0000}=1$. For the mass differences the fits are normalised so that $A$ is 1 and $c_{0000}$ floats. This is simply so that the fit can allow for significant discretisation errors when the physical mass difference is very small (particularly for the case of the $B_{c}$ to be discussed in section III C). The prior values for the other $c_{i j k l}$ are taken to be the same for all $i, j, k$ and $l$ but vary depending on the size of discretisation errors for the quantity being fit. They are larger for heavyonium than for heavy-strange quantities, for example. The values used are tabulated in Table III.

The mistuning of the strange and charm quark masses, where relevant, can be handled very simply because our tuning of these masses is in fact very good. We simply include an additional additive factor in the fit of

$$
\begin{align*}
\delta f_{s}= & \left(c_{s}+\frac{d_{s}}{M}+e_{s}\left[\left(\frac{a m_{1}}{\pi}\right)^{2}+\left(\frac{a m_{2}}{\pi}\right)^{2}\right]\right) \times \\
& \left(m_{\eta_{s}, \text { latt }}^{2}-m_{\eta_{s}, \text { contnm }}^{2}\right) \tag{6}
\end{align*}
$$

for heavy-strange mesons and

$$
\begin{align*}
\delta f_{c}= & \left(c_{c}+\frac{d_{c}}{M}+e_{c}\left[\left(\frac{a m_{1}}{\pi}\right)^{2}+\left(\frac{a m_{2}}{\pi}\right)^{2}\right]\right) \times \\
& \left(m_{\eta_{c}, \text { latt }}-m_{\eta_{c}, \text { contnm }}\right) \tag{7}
\end{align*}
$$

for heavy-charm mesons. The forms above allow for linear quark mass dependence away from the tuned point. We do not need to include higher order terms because we are so close to the tuned point but we do allow for an $M$-dependent slope with discretisation errors (although in most cases neither of these additions makes any difference).

To tune the strange quark mass we use the $\eta_{s}$, an unphysical $s \bar{s}$ pseudoscalar meson whose valence quarks are not allowed to annihilate. Lattice QCD simulations show that its mass $m_{\eta_{s}, \text { contnm }}=0.6858(40) \mathrm{GeV}$ [14] when the strange quark mass is tuned (from the $K$ meson). Being a light pseudoscalar meson, the square of its mass is proportional to the quark mass. To tune the $c$ quark mass we use the $\eta_{c}$ meson, as discussed earlier. The $\eta_{c}$ meson is far from the light quark limit and so the meson mass is simply proportional to the quark mass. $c_{s}$ and $c_{c}$ are dimensionful coefficients that represent physical light quark mass dependence and can be compared between lattice QCD calculations and with models.

We do not include correlations between the results for different $M$ on a given ensemble. We have not measured these correlations and the empirical Bayes criterion suggests that they are small. If we include a correlation matrix by hand for the results it makes very little difference, a fraction of a standard deviation, to the final results.

TABLE IV: Results for the masses and decay constants in lattice units of the goldstone pseudoscalars made from valence HISQ heavy quarks on the different MILC ensembles, enumerated in Table Columns 2 and 3 give the corresponding bare heavy quark mass and the $\epsilon$ parameter, calculated at tree-level in $m_{h} a$ [10]. This corresponds to a coefficient for the Naik 3 -link discretisation correction of $1+\epsilon$. Meson masses from fitting these correlators using a simpler fitting form are given in [3]. Results given here are in agreement but somewhat more accurate. The results for heavy quark masses close to charm are also given in [10.

We also do not include effects from sea quark massdependence but, based on earlier work [10, we are able to estimate an uncertainty for that in our final results.

## III. RESULTS

## A. $f_{\eta_{b}}$

The correlators for pseudoscalar heavyonium mesons have very little noise and we can readily obtain groundstate masses with statistical errors in the fourth or fifth decimal place and ground-state decay constants with errors of $0.1 \%$. Our results on each ensemble are given in Table IV

Results for $f_{\eta_{h}}$ are plotted against $M_{\eta_{h}}$ in Figure 1. Discretisation errors are apparent in this plot and lead

FIG. 1: Results for the pseudoscalar heavyonium decay constant plotted as a function of the pseudoscalar heavyonium mass. Results for very coarse, coarse, fine, superfine and ultrafine lattices appear from left to right. The colored dashed lines give the fitted function for that lattice spacing. The black line with grey error band gives the physical curve derived from our fit. The black circles with error bars at $M_{\eta_{c}}$ and $M_{\eta_{b}}$ are the values for the heavyonium vector decay constant at these physical points derived from the experimental leptonic widths for the $J / \psi$ and $\Upsilon$. The left-most black circle corresponds to the fictitious pseudoscalar $\eta_{s}$ particle whose decay constant was determined in 14 .
to results at each value of the lattice spacing deviating substantially from the physical curve as the quark mass is increased. We fit the results to a physical curve allowing for discretisation errors as a function of the mass, as described in section $\Pi$ and using the priors from Table III. The power, $b$, in eq. (5) is allowed to float in the fit.

The obvious approach from which to gain some physical insight in this case is that of the nonrelativistic potential model. In its simplest form this involves solving Schrödinger's equation for the wavefunction of a twoparticle system with reduced mass $\mu\left(=m_{b} / 2\right.$ for two $b$ quarks) in a potential $V(r)$ which is a function of the radial separation, $r$. At short distances we expect a Coulomb-like potential from QCD, and at large distances a string-like linear potential. However, other phenomenological forms that interpolate between these two at intermediate distances also work well at reproducing the bound-state spectrum, see for example [21]. The wavefunction is useful for a first approximation in calculations of transition rates. In this sense, the wavefunction at the origin, $\psi(0)$, can be related to the decay constant by $\psi(0)=f_{\eta_{h}} \sqrt{M_{\eta_{h}} / 12}$. However, $\psi(0)$ must be renormalised before it can be related to a physical matrix element and some of the radiative corrections are very substantial 21. In addition values of $\psi(0)$ vary widely with different forms for the potential that reproduce the same bound state spectrum because the spectrum itself provides little constraint on the potential at short distances [22]. Here we will make comparisons of our lattice

QCD results to those from potential models but it is important to realise that the lattice QCD results for decay constants represent well-defined matrix elements in QCD and not model calculations.

For a potential model with potential $r^{N}$ power counting arguments yield $\psi(0) \propto \mu^{3 /(4+2 N)}$ (see, for example, [23]). Then we would expect our fit for $f_{\eta_{h}}$ to need $b=1$ for $N=-1$ but $b=0$ for $N=1$, the two extremes of the QCD heavy quark potential. Simply from comparing values at $c$ and $b$ we might infer $b \approx 0.5$. In fact our fit gives the result $b=-0.08(10)$ but with significant power corrections in $1 / M$, so that a simple power in $M$ does not describe the results using our parameterisation. The physical curve that we extract of dependence on the heavyonium meson mass is shown as the grey band in Figure 1.

The fit has $\chi^{2}$ of 1.2 for 29 degrees of freedom and allows us to extract results for $c$ and $b$ quarks. The result for $f_{\eta_{c}}$ agrees within $1 \sigma$ with our earlier result of $0.3947(22) \mathrm{GeV}$ [10] where we fit results at $c$ only but included additional ensembles at different values of the sea $u / d$ quark masses. Results for $b$ quarks give:

$$
\begin{align*}
f_{\eta_{b}} & =0.667(6)(2) \mathrm{GeV} \\
f_{\eta_{b}} / f_{\eta_{c}} & =1.698(13)(5) \tag{8}
\end{align*}
$$

The first error comes from the fit and the second from additional systematic errors from effects not included in our lattice QCD calculation, i.e. electromagnetism, $c$ quarks in the sea and (since we have not extrapolated to physical $u / d$ sea quark masses here) sea quark mass effects. Both errors are split into their component parts in the error budget of Table V. We estimated the effects of electromagnetism on $f_{\eta_{c}}$ from a potential model in [10. We take the same $0.4 \%$ error for $f_{\eta_{b}}$ since it is a more tightly bound particle but with smaller electromagnetic charges. There is then some cancellation of the effect in the ratio $f_{\eta_{b}} / f_{\eta_{c}}$. The effects of $c$ quarks in the sea were shown to be similar to that of the hyperfine potential in 10 and the effect on $f_{\eta_{h}}$ can then be estimated from the difference between $f_{\eta_{h}}$ and its associated vector particle. This is very small as we show below. We therefore expect that missing $c$ in the sea has a negligible effect on $f_{\eta_{c}}$ and we estimate $0.2 \%$ on $f_{\eta_{b}}$ where it is magnified by $\left(m_{b} / m_{c}\right)^{2}$. Sea quark mass effects on $f_{\eta_{c}}$ were shown to be very small in [10], at the same level as the statistical errors of $0.1 \%$. For $f_{\eta_{b}}$ we expect even smaller effects because it is a smaller particle. We take a $0.1 \%$ error nevertheless, but allow for some cancellation in the ratio of $f_{\eta_{b}} / f_{\eta_{c}}$.

The two rightmost black points (at $M_{\eta_{b}}$ and $M_{\eta_{c}}$ ) in Fig. 1 give the experimental values for the decay constants of the corresponding vector heavyonium mesons, $J / \psi$ and $\Upsilon$, for comparison to the results calculated here in lattice QCD for the $\eta_{c}$ and $\eta_{b}$. The decay constant for a vector meson can be defined by:

$$
\begin{equation*}
\sum_{i}<0\left|\bar{\psi} \gamma_{i} \psi\right| V_{i}>/ 3=f_{V} m_{V} \tag{9}
\end{equation*}
$$

| Error | $f_{\eta_{b}}$ | $f_{\eta_{b}} / f_{\eta_{c}}$ |
| :--- | :---: | :---: |
| statistics | 0.6 | 0.6 |
| $M$ extrapoln | 0.2 | 0.1 |
| $a^{2}$ extrapoln | 0.5 | 0.4 |
| $r_{1}$ | 0.4 | 0.1 |
| $r_{1} / a$ | 0.5 | 0.3 |
| $M_{\eta_{c}}$ | 0.00 | 0.05 |
| sea quark mass effects | 0.1 | 0.05 |
| electromagnetism | 0.4 | 0.2 |
| $c$ in the sea | 0.2 | 0.2 |
| Total $(\%)$ | 1.0 | 0.9 |

TABLE V: Full error budget for $f_{\eta_{b}}$ and the ratio $f_{\eta_{b}} / f_{\eta_{c}}$ in $\%$. See text for a fuller description of each error. The total error is obtained by adding the individual errors in quadrature.

It has the advantage here that it can be extracted very accurately from experiment because vector heavyonium mesons can annihilate, through the vector currrent, to a photon, seen as two leptons in the final state. The relationship between the leptonic decay width and the decay constant is:

$$
\begin{equation*}
\Gamma\left(V_{h} \rightarrow e^{+} e^{-}\right)=\frac{4 \pi}{3} \alpha_{Q E D}^{2} e_{h}^{2} \frac{f_{V}^{2}}{m_{V}} \tag{10}
\end{equation*}
$$

where $e_{h}$ is the electric charge of the heavy quark in units of $e$. The experimental results [17] give $f_{J / \psi}=407(5)$ MeV and $f_{\Upsilon}=689(5) \mathrm{GeV}$, remembering that the electromagnetic coupling constant runs with scale and using $1 / \alpha_{Q E D}\left(m_{c}\right)=134$ and $1 / \alpha_{Q E D}\left(m_{b}\right)=132[24$. Thus $1 \%$ accurate results for this decay constant are available from experiment, and can be used to test lattice QCD. Lattice QCD calculations of the $\Upsilon$ decay constant can be done [25] but they are not yet as accurate as the results we give here for the $\eta_{b}$.

The surprising result that we find on comparing the vector decay constant from experiment to the pseudoscalar decay constant from lattice QCD is how close they are. In the nonrelativistic limit, where spin effects disappear, the vector and pseudoscalar become the same particle. Away from this point, however, there can be substantial relativistic corrections, particularly for charmonium. Instead we find that the pseudoscalar decay constant is $3 \%$ lower than the vector in both cases with an error of 1-2\%.

Unfortunately this cannot be directly tested through decay modes of the $\eta_{c}$ or $\eta_{b}$. The decay rate to two photons is indirectly related to the decay constant as the leading term in a nonrelativistic approximation:

$$
\begin{equation*}
\Gamma\left(\eta_{h} \rightarrow \gamma \gamma\right)=\frac{12 \pi e_{h}^{4} \alpha_{Q E D}^{2}|\psi(0)|^{2}}{m_{h}^{2}} \tag{11}
\end{equation*}
$$

This formula has radiative and relativistic corrections at the next order. The decay width is not known for the $\eta_{b}$ and only very poorly known for the $\eta_{c}$, with the Particle Data Group estimate given as $7.2(2.1) \mathrm{keV}$ [17]. Substi-
tuting this into eq. (11) and taking $m_{c}=M_{\eta_{c}} / 2$, justifiable at this order, gives $f_{\eta_{c}}=0.4(1) \mathrm{GeV}$, where only the large error from experiment is shown. This is consistent with our value but much less accurate so does not provide a useful test.

As discussed earlier, a direct comparison of lattice QCD results for $f_{\eta_{h}}$ and potential model values for $\psi(0)$ is not particularly useful. Values for $\psi(0)$ for the ground state in bottomonium vary by a factor of 1.5 for different forms for the potential in [22]. This variation is reduced somewhat, and radiative corrections cancel, if we compare the ratio of values at $b$ and $c$. Here the lattice QCD result above of 1.698(14) favours the strong variation of $\psi(0)$ with quark mass seen in the Cornell potential. For this potential [22] gives a ratio $\psi_{b}(0) / \psi_{c}(0)$ of 3.1 , yielding a decay constant ratio of 1.8 .

Figure 1 also includes as the leftmost black point a value for the decay constant of the $\eta_{s}$ as determined from lattice QCD [14. Although our fit becomes unstable below $M$ of 2 GeV , it is interesting to see that $f_{\eta_{s}}$ does not look out of place on this plot as the light and heavy sectors are smoothly connected together.

## B. $m_{B_{s}}$ and $f_{B_{s}}$

Our calculations for heavy-strange mesons were described in [4] and so we only add briefly to that discussion here. In Table VI we give our full set of results, including values at a variety of strange quark masses for completeness. In [4] we used the heavy-strange mass itself as a proxy for the heavy quark mass and obtained good agreement for the mass of the $B_{s}$ with experiment and a value for $f_{B_{s}}$ of $225(4) \mathrm{MeV}$.

Here, for consistency with the other calculations, we use instead $M_{\eta_{h}}$ for the heavy quark mass and the fit form given in eq. (5). For the heavy-strange meson mass, as in [4], we fit to the mass difference:

$$
\begin{equation*}
\Delta_{H_{s}, h h}=m_{H_{s}}-\frac{m_{\eta_{h}}}{2} \tag{12}
\end{equation*}
$$

We take account of mistuning of the strange quark mass using the factor given in eq. (6). For the decay constant fit we fix the power of the leading $M$-dependence, $b=$ -0.5 . Allowing $b$ to float gives results for $b$ in agreement with this value to within $20 \%$.

Our fit to $\Delta_{H_{s}, h h}$ a is shown in Figure 2 and gives $\chi^{2}=0.2$ for 17 degrees of freedom. The values extracted at the $c$ and $b$ masses agree well, within $1 \sigma$, with our earlier results [4, 10]. When account is taken of electromagnetic and other effects missing in the lattice calculation these earlier results translate into values for $m_{D_{s}}=1.969(3) \mathrm{GeV}$ [10] and $m_{B_{s}}=5.358(12) \mathrm{GeV}$ 4]. The increased error at the $b$ results from increased statistical and discretisation errors for heavier quark masses as well as the extrapolation in $M$. Our result for $m_{B_{s}}$ agrees within the 12 MeV error with that determined from full lattice QCD using a completely different

TABLE VI: Results for the masses and decay constants in lattice units of the goldstone pseudoscalars made from valence HISQ heavy quarks with valence HISQ strange quarks on the different MILC ensembles, enumerated in Table प Column 2 gives the $s$ mass in lattice units, with several values on some ensembles around the correctly tuned value. Column 3 gives the corresponding mass for the goldstone pseudoscalar made from the $s$ quarks, which is used for tuning. Column 4 gives the heavy quark mass. The corresponding values of the Naik coefficient are given in Table IV. Many of these results were given earlier in 4, 10.
method (NRQCD) for the $b$ quark [18] with very different systematic errors, providing a stringent test of lattice QCD. Our results also agree well with experiment [17] ( $m_{D_{s}}=1.968 \mathrm{GeV}$ and $m_{B_{s}}=5.367 \mathrm{GeV}$ ) and this provides a very strong test of QCD.

The fit to the decay constant, $f_{H_{s}}$, is shown in Figure 3 and gives $\chi^{2}=0.3$ for 17 degrees of freedom. Again results at the $b$ and $c$ agree within $1 \sigma$ with our earlier results which are: $f_{D_{s}}=0.2480(25) \mathrm{GeV}$ [10] and $f_{B_{s}}=$ $0.225(4) \mathrm{GeV}$ [4].

Figures 2 and 3 give the physical fit curves as a func-

FIG. 2: Results for the difference, $\Delta_{H_{s}, h h}$ between the heavystrange pseudoscalar meson mass and one half of the pseudoscalar heavyonium mass. Results for very coarse, coarse, fine, superfine and ultrafine lattices appear from left to right. The lattice QCD results have been adjusted for slight mistuning of the $s$ quark mass. The colored dashed lines give the fitted function for that lattice spacing. The black dashed line with grey error band gives the physical curve derived from our fit. The black circles with error bars at $M_{\eta_{c}}$ and $M_{\eta_{b}}$ are the experimental values adjusted for the effects from electromagnetism, $\eta_{b} / \eta_{c}$ annihilation and $c$ quarks in the sea, none of which is included in the lattice QCD calculation.

FIG. 3: Results for the pseudoscalar heavy-strange decay constant plotted as a function of the pseudoscalar heavyonium mass. The colored dashed lines give the fitted function for that lattice spacing. The black dashed line with grey error band gives the physical curve derived from our fit.
tion of $M_{\eta_{h}}$. As expected, the curves are very similar to those in [4] since to a large extent the change is simply a rescaling of the $x$-axis. However they provide a consistency check that the parameterisation we use here, taking a different quantity to represent the heavy quark mass, works just as well.

TABLE VII: Results for the masses and decay constants in lattice units of the goldstone pseudoscalars made from valence HISQ heavy quarks with valence HISQ charm quarks on the different MILC ensembles, enumerated in Table $\mathbb{1}$ Set 1 is missing because $m_{c} a$ is already close to the highest heavy quark mass that we use. Column 2 gives the $c$ mass in lattice units, with several values on some ensembles around the tuned $c$ mass, and column 3 the heavy quark mass. The corresponding values of the Naik coefficient are given in Table IV

$$
\text { C. } \quad m_{B_{c}} \text { and } f_{B_{c}}
$$

Heavy-charm mesons are of interest because a family of gold-plated $b \bar{c}$ mesons exists of which only one, the pseudoscalar $B_{c}$ [26, 27], has been seen. Traditionally these particles have been viewed as further examples, beyond $b \bar{b}$ and $c \bar{c}$, of a heavy-heavy system and therefore a test of our understanding of this area. $b \bar{c}$ mesons, however, have a lot in common with heavy-light systems. In fact they provide a bridge between heavy-heavy and heavylight and so test our contol of QCD much more widely. The more accurately we can do these tests, the better they are.

Lattice QCD calculations of the $B_{c}$ mass can be done very accurately. Indeed the mass of the $B_{c}$ was predicted ahead of experiment with a 22 MeV error 28 using NRQCD for the $b$ quark and the 'Fermilab' clover action for the $c$ quark. The error was later reduced to 10 MeV by using a more highly improved action, HISQ, for the charm quark 18. Here we use the HISQ action for both the $c$ quark and the heavier quark up to the $b$ mass to obtain results in a completely different heavy quark formalism. In addition we calculate the decay constant of the $B_{c}$ for the first time in full lattice QCD.

To determine the $B_{c}$ mass we use the mass difference to the average of the associated heavyonium states:

$$
\begin{equation*}
\Delta_{H_{c}, h h}=M_{H_{c}}-\frac{1}{2}\left(M_{\eta_{c}}+M_{\eta_{h}}\right) \tag{13}
\end{equation*}
$$

FIG. 4: Results for the mass difference between the $H_{c}$ meson and the average of the associated heavyonium pseudoscalar meson masses plotted as a function of the pseudoscalar heavyonium mass. Results for coarse, fine, superfine and ultrafine lattices appear from left to right. The lattice QCD results have been adjusted for slight mistuning of the $c$ quark mass. The colored dashed lines give the fitted function for that lattice spacing. The black line with grey error band gives the physical curve derived from our fit. The black circle with error bar at $M_{\eta_{b}}$ gives the experimental value adjusted for the effects from electromagnetism, $\eta_{b} / \eta_{c}$ annihilation and $c$ quarks in the sea, none of which is included in the lattice QCD calculation.

FIG. 5: Results for the mass difference between the $H_{c}$ meson and the average of the associated heavyonium pseudoscalar meson masses plotted as a function of the pseudoscalar charmonium mass. Results are given for two heavy quark masses on fine lattice set 3 (pink bursts) and four heavy quark masses on superfine lattices set 4 (green crosses). Lines are drawn to guide the eye.
$\Delta_{H_{c}, h h}$ is a measure of the difference in binding energy between the symmetric heavyonium states made of $c$ and $h$ quarks and the heavyonium state made of two different mass quarks, $c$ and $h$. Here we map out $\Delta_{H_{c}, h h}$ as a function of the heavy quark mass, and reconstruct $M_{B_{c}}$ from $\Delta_{H_{c}, h h}$ determined at $h=b . \Delta_{H_{c}, h h}$ can be determined with high statistical accuracy because all of the states involved have very little noise. The fact that $\Delta_{H_{c}, h h}$ is
very small ( 0 for $m_{h}=m_{c}$ by definition and less than 100 MeV when $m_{h}=m_{b}$ ) also means that lattice errors from, for example, the uncertainty in the lattice spacing are very small. In fact, for this calculation, as discussed below, key sources of error are the uncertainties from electromagnetic, annihilation and $c$-in-the-sea shifts to the masses.

Table VII gives our results for the masses and decay constants of the $H_{c}$ mesons calculated using quark masses that are close to that of the $c$ quark mass on each ensemble and then all the heavier masses for $h$. We give results for more than one value of the $c$ quark mass on the fine and superfine ensembles (sets 3 and 4) so that slight mis-tuning in the $c$ quark mass can be corrected for. It is clear from the results that $\Delta_{H_{c}, h h}$ can be calculated with a statistical accuracy of better than 1 MeV . Errors from uncertainties in the lattice spacing are also at this level.

Figure 4 shows $\Delta_{H_{c}, h h}$ plotted against $M_{\eta_{h}}$ for the results at different values of the lattice spacing. A fairly clear linear dependence is evident. $\Delta_{H_{c}, h h}$ would be expected to increase linearly with $M_{\eta_{h}}$ at large $M_{\eta_{h}}$, in the same way as $\Delta_{H_{s}, h h}$, from a simple potential model argument. The binding energy of the $\eta_{h}$ becomes increasingly negative, roughly in proportion to $M_{\eta_{h}}$ as it increases (at least for a $r^{N}$ potential with $N=-1$ ), whilst the binding energy of the $H_{c}$ meson does not change. A corollary of this is that the dependence of $\Delta_{H_{c}, h h}$ on $M_{\eta_{c}}$ (as proxy for $m_{c}$ ) would also then be expected to be linear with a slope of opposite sign and roughly three times the magnitude. The factor of three is because the binding energy of the $\eta_{c}$ becomes more negative as $M_{\eta_{c}}$ increases, with the same dependence as the $\eta_{h}$ binding energy has on $M_{\eta_{h}}$. The $H_{c}$ binding energy will also become more negative but have double the slope because the reduced mass of the $H_{c}$ system is roughly $m_{c}$ rather than $m_{c} / 2$ for the $\eta_{c}$. On top of this $M_{\eta_{c}}$ appears halved in $\Delta_{H_{c}, h h}$.

Interestingly this factor of -3 does seem to be approximately true in comparing Figure 5, which shows the dependence of $\Delta_{H_{c}, h h}$ on $M_{\eta_{c}}$, with Figure 4. Figure 4 gives a slope of $\approx 0.012$ (over the full range) and Figure 5 gives slopes varying from -0.03 to -0.04 over a small range in $M_{\eta_{c}}$, as $M_{\eta_{h}}$ increases. In our fit to $\Delta_{H_{c}, h h}$ we include the effect of mistuning $m_{c}$ (from eq. (7)) and obtain consistent values from that.

We fit $\Delta_{H_{c}, h h}$ as a function of $M_{\eta_{h}}$ (above 4 GeV ) using the fit form described in section II. The leading mass dependence is taken to be $M_{\eta_{h}}-M_{\eta_{c}}$, so that $\Delta_{H_{c}, h h}$ vanishes when $M_{\eta_{h}}=M_{\eta_{c}}$ as it must by definition. As described in section III we include a sum of power correction terms and lattice spacing dependent terms with priors given in Table III. The fit gives $\chi^{2}$ of 0.3 for 11 degrees of freedom and result:

$$
\begin{equation*}
\Delta_{B_{c}, b b}=0.065(9) \mathrm{GeV} \tag{14}
\end{equation*}
$$

The resulting physical curve of heavy quark mass dependence is shown in grey on Figure 4. The comparison to experiment is given by the black dot with error bar at

| Error | $\Delta_{B_{c}, b b}$ | $f_{B_{c}}$ | $\Delta_{B_{c}, b s}$ |

TABLE VIII: Full error budget for $\Delta_{B_{c}, b b}, f_{B_{c}}$ and $\Delta_{B_{c}, b s}$ given as a percentage of the value. See the text for a fuller description of each error. The total error is obtained by adding the individual errors in quadrature, except for the final three systematic errors (starred) for $\Delta_{B_{c}, b b}$ and $\Delta_{B_{c}, b s}$ which are correlated and so simply added together before being combined in quadrature with the others.
$h=b$. This experimental result has been shifted to be the appropriate value to compare to our lattice QCD calculation as we now describe. The current world-average experimental result for $M_{B_{c}}-0.5\left(M_{\eta_{c}}+M_{\eta_{b}}\right)$ is $92(6)$ MeV [17]. There is a sizeable experimental error coming mainly from the $B_{c}$ but also from the $\eta_{b}$. Our lattice QCD calculation is done in a world without electromagnetism or $c$ quarks in the sea and in which the $\eta_{b}$ and $\eta_{c}$ do not annihilate. The absence of these effects (i.e. to compare to our lattice result) produces shifts to the masses as discussed in section II Estimated values for the shifts are given in Table II. The net effect is to shift the experimental value of $\Delta_{B_{c}, h h}$ down by $-8(7) \mathrm{MeV}$, where the error takes the shifts to be correlated. The 'experimental' value of $\Delta_{B_{c}, h h}$ to compare to our lattice result is then $84(9) \mathrm{MeV}$, marked on Figure 4. Our lattice result agrees with experiment, once these shifts are made, within $2 \sigma$.

From $\Delta_{B_{c}, b b}$ we can reconstruct the $B_{c}$ meson mass, now applying the shifts above to the lattice QCD calculation to obtain a result that can be compared to experiment. This gives the result

$$
\begin{equation*}
M_{B_{c}}=6.259(9)(7) \mathrm{GeV} \tag{15}
\end{equation*}
$$

Here the first error comes from the fit and the second error from the shifts applied to include missing real world effects as well as experimental uncertainties in the $\eta_{b}$ and $\eta_{c}$ masses. As can be seen, this is a sizeable part of the total error in this case. We also include in this second error an estimate of sea quark mass effects using results from [10]. There we saw no such for an equivalent quantity for $m_{D_{s}}$ within 1 MeV statistical errors and so take that as the error here. Table VIII gives the complete error budget for $\Delta_{B_{c}, b b}$ breaking down both errors into their components.

Our result for $M_{B_{c}}$ can be compared to experiment (6.277(6) GeV) and to our result from lattice QCD using a completely different formalism, NRQCD, for the $b$

FIG. 6: Results for the heavy-charm decay constant plotted as a function of the $c$ quark mass, given by the mass of the $\eta_{c}$ meson. Results are given for multiple heavy quark masses on fine lattices (pink bursts) and superfine lattices (green crosses). Lines are drawn to guide the eye.
quark ( $6.280(10) \mathrm{GeV}$ [18]). We agree, within $2 \sigma$ with both results even allowing for the fact that the comparison within lattice QCD can be done before any shifts are made or errors allowed for them. This is a strong confirmation of the control over errors that we now have in lattice QCD.

The method given here for determining $m_{B_{c}}$ (as for the method for $m_{B_{s}}$ in section III B) does depend on the experimental $\eta_{b}$ mass; the mass difference determined in lattice QCD is not particularly sensitive to it but when the mass is reconstructed from the difference, $m_{\eta_{b}} / 2$ is added in. Recent results from the Belle collaboration [29] have $M_{\eta_{b}}=9.402(2) \mathrm{GeV}$, significantly higher than the previous world-average [17]. Using the Belle result for $M_{\eta_{b}}$ pushes our values for $m_{B_{c}}$ and $m_{B_{s}} 6 \mathrm{MeV}$ higher. In both cases this improves the agreement with experiment but is not significant given the 11 MeV error. Note that our earlier NRQCD results are hardly affected at all by a change in the $\eta_{b}$ mass because they determined a mass difference to the spin-average of the $\Upsilon$ and $\eta_{b}$ masses, which is dominated by the $\Upsilon$ mass.

Results for the $H_{c}$ decay constant, $f_{H_{c}}$, are also given in Table VII. The rate for $B_{c}$ leptonic decay to $l \nu$ via a $W$ boson is proportional to the square of the decay constant multiplied by CKM element $V_{c b}$ as in eq. (4). In practice this decay will be very hard to see experimentally, but a lattice QCD calculation of the decay constant also provides a useful test for phenomenological model calculations.

The results at different values of $m_{c}$ can again be used to tune the decay constant accurately to the result at the physical $c$ quark mass. Figure 6 shows the dependence of $f_{H_{c}}$ on $M_{\eta_{c}}$ acting as a proxy for the $c$ quark mass. Results on fine and superfine lattices are shown - there is clear agreement on the physical slope of $f_{H_{c}}$ with $M_{\eta_{c}}$ between superfine and fine and it does not vary with the heavy quark mass. The slope is small, approximately 0.06 , but clearly visible. We will compare this to the

FIG. 7: Results for the heavy-charm decay constant plotted as a function of the pseudoscalar heavyonium mass. Results for coarse, fine, superfine and ultrafine lattices appear from left to right. The lattice QCD results have been adjusted for slight mistuning of the $c$ quark mass. The colored dashed lines give the fitted function for that lattice spacing. The black line with grey error band gives the physical curve derived from our fit.
slope for $f_{H_{s}}$ with $m_{s}$ in section IV.
The $H_{c}$ decay constant is plotted as a function of $M_{\eta_{h}}$ in Figure 7. Notice that it is much flatter than the corresponding plot for $f_{\eta_{h}}$ (Figure 1). We expect behaviour as $1 / \sqrt{M_{\eta_{h}}}$ whether we view heavy-charm as a heavylight system (in which case the behaviour will be similar to heavy-strange) or as a heavy-heavy system (in which case the argument becomes that $\psi(0)$ depends on the reduced mass $\mu$, tending to $m_{c}$ for large $m_{h}$, and then the decay constant falls as the square root of the heavy mass).

As before, we fit $f_{H_{c}}$ to the function of $M_{\eta_{h}}$ (above 4 GeV ) described in section II. We take the leading term given in Table III to be that expected from HQET arguments appropriate to heavy-light physics. Our fit has $\chi^{2}=0.7$ for 11 degrees of freedom and gives result:

$$
\begin{equation*}
f_{B_{c}}=0.427(6)(2) \mathrm{GeV} \tag{16}
\end{equation*}
$$

Here the first error is from the fit and the second from additional systematic effects missing from our lattice QCD calculation. These we estimate based on the arguments given for the $\eta_{h}$ in section III A. The error from missing electromagnetism and from sea quark mass effects we take to be the same as for the $\eta_{b}$ at $0.4 \%$ and $0.1 \%$ respectively; missing $c$ in the sea should be a factor of $m_{c} / m_{b}$ smaller at $0.04 \%$. Table VIII gives the complete error budget.
$f_{B_{c}}$ can be converted into a branching fraction for leptonic decay using the formula of eq. (4) and the unitarity value of $V_{c b}$. We predict a branching fraction to $\tau \nu$ of $0.0194(18)$. The error here comes mainly from the experimental determination of the $B_{c}$ lifetime with a smaller effect from the uncertainty in $V_{c b}$. Our value for $f_{B_{c}}$ contributes a $3 \%$ error. Because of helicity suppression the
branching fraction smaller for other lepton final states ( $8 \times 10^{-5}$ to $\mu \nu$, for example).

The value we obtain for $f_{B_{c}}$ can be compared to results from potential models. As discussed earlier in the context of $f_{\eta_{h}}$, potential model results have a lot of variability and raw values for $\psi(0)$ need renormalisation. A more useful comparison is to compare ratios. Our lattice QCD results give $f_{B_{c}} / f_{\eta_{c}}=1.08(1)$ and $f_{\eta_{h}} / f_{B_{c}}=1.57(2)$. The range of potentials considered in [22] give values from 0.90 to 1.02 for $f_{B_{c}} / f_{\eta_{c}}$ and 1.34 to 1.72 for $f_{\eta_{h}} / f_{B_{c}}$. Again the largest number is always from the Cornell potential. Potential model values for $\psi(0)$ converted to $f_{B_{c}}$ simply using $f=\psi(0) \sqrt{12 / M_{B_{c}}}$ yield results varying from 0.5 to 0.7 GeV i.e. significantly larger than the well-defined value for $f_{B_{c}}$ from lattice QCD .

The values for $f_{B_{c}}$ from potential models provide input to estimates of the production cross-section of the $B_{c}$ at the LHC. In the factorisation approach the cross-section is proportional to the square of $f_{B_{c}}$, with typical values for $f_{B_{c}}$ being taken as 0.48 GeV 30 . Our results indicate that this could be leading to a $25 \%$ overestimate of the production rate.

## IV. DISCUSSION

An interesting issue is to what extent the $B_{c}$ meson is a heavy-heavy particle and to what extent, a heavylight one at the physical values we have for $b$ and $c$ quark masses. Here we address this by comparing the behaviour of $B_{c}$ properties to those of $\eta_{h}$ and $B_{s}$ using the results from section III.

An alternative to calculating $\Delta_{H_{c}, h h}$ to study the heavy-charm meson mass is to take differences between heavy-charm and heavy-strange and charmstrange mesons. We define

$$
\begin{equation*}
\Delta_{H_{c}, h s}=M_{H_{s}}+M_{D_{s}}-M_{H_{c}} \tag{17}
\end{equation*}
$$

so that $\Delta_{H_{c}, h s}$ is a positive quantity. Once again it amounts to a difference in binding energies but now between a set of mesons that are all effectively 'heavy-light' states. Indeed a study of $\Delta_{H_{c}, h s}$ shows us to what extent the $B_{c}$ can be considered a heavy-light particle rather than, or as well as, a heavy-heavy one.

Figure 8 shows $\Delta_{H_{c}, h s}$, with all results tuned accurately to the correct $c$ and $s$ masses, as a function of the heavy quark mass, again given by the $\eta_{h}$ mass. In fact $\Delta_{H_{c}, h s}$ shows very little dependence on the heavy quark mass above a value of $M_{\eta_{h}}$ of about 6 GeV . HQET would expect the leading $m_{h}$-dependent piece of $\Delta_{B_{c}, h s}$ to be given by the difference of the expectation values of the kinetic energy operator, $p_{h}^{2} / 2 m_{h}$, for the heavy quark in a heavy-charm meson and a heavy-strange meson, ignoring the effect of spin-dependent terms which are expected to be smaller. Figure 8 shows that this difference is not large i.e. the charm quark is behaving in a similar way to a light quark (but does have a larger expectation value for its kinetic energy operator as might be expected) when
combined with a heavy quark of order twice its mass or heavier.

We fit $m_{H_{c}, h s}$ as described in section IT and using the fit form and priors tabulated in Table III. Our fit has $\chi^{2}$ of 0.3 for 14 degrees of freedom. It returns the coefficient of the first term in $M_{\eta_{h}}^{-1}$ as $-0.4(8) \mathrm{GeV} / M_{\eta_{h}}$. This quantifies the statement made above about the slope of $1 / m_{h}$ corrections. The coefficient is not very accurately determined because we allow for many higher order terms. In fact the sign of the slope is clear from Figure 8 with a positive slope with $M_{\eta_{h}}$ corresponding to a negative value for the coefficient of the $1 / M$ term, as expected.

The variation of $\Delta_{H_{c}, h s}$ with $M_{\eta_{c}}$ agrees well with that found in our calculation using NRQCD $b$ quarks [18] giving a slope of 0.07 at the $b$. Likewise the variation with $M_{\eta_{s}}^{2}$ also agrees well with the slope of 0.4 found in [18].

Our fit to $\Delta H_{c}, h s$ is independent of our earlier fit to $\Delta_{H_{c}, h h}$ (although it uses some of the same numbers) and so the results provide a consistency check. We find at $h=b$ that:

$$
\begin{equation*}
\Delta_{B_{c}, b s}=1.052(9)(3) \mathrm{GeV} \tag{18}
\end{equation*}
$$

which agrees well within $1 \sigma$ with the same quantity calculated using NRQCD $b$ quarks [18. The result when $h=c$ is consistent within $1 \sigma$ with double the result from $m_{D_{s}}-m_{\eta_{c}} / 2$ given in [10]. The first error above is from the fit and the second from the systematic error for sea quark mass effects, taking the same 1 MeV as for $\Delta_{B_{c}, b b}$, and the effects of missing electromagnetism and $c$ in the sea. The shifts and errors for these latter effects are given in Table III and we take those errors to be correlated. The value above for $\Delta_{B_{c}, b s}$ combined with experimental results for $M_{B_{s}}$ and $M_{D_{s}}$ [17] (the net shift from Table II amounts to a negligible 0.2 MeV ) gives:

$$
\begin{equation*}
M_{B_{c}}=6.285(9)(3) \mathrm{GeV}, \tag{19}
\end{equation*}
$$

consistent within $2 \sigma$ with our result from $\Delta_{B_{c}, b b}$ given in section III, and slightly more accurate. We therefore adopt it as our final result here. The complete error budget for $\Delta_{B_{s}, b s}$ is given in Table VIII.

In figure 9 we show the ratio of $\eta_{h}$ and $H_{c}$ decay constants to that of the $H_{s}$, plotted from our physical curves as a function of $M_{\eta_{h}}$. The ratio $f_{\eta_{h}} / f_{H_{s}}$ rises strongly with $M_{\eta_{h}}$, because of the big difference in the dynamics of heavy-heavy and heavy-strange mesons, whereas the ratio $f_{H_{c}} / f_{H_{s}}$ tends to a constant at large $M_{\eta_{h}}$. As explained in section IIIC this latter behaviour would be expected whether the heavy-charm is viewed as a heavyheavy or heavy-light state, because the reduced mass of the heavy-charm system is controlled by the charm mass in the large heavy mass limit.

Further insight comes from comparing the dependence of the heavy-charm and heavy-strange decay constants on $m_{c}$ and $m_{s}$ respectively. Figure 10 plots the relative change of $f_{H_{c}}$ or $f_{H_{s}}$ to its value at the tuned mass point for a given relative change in the light quark mass. The strange quark mass is monitored by the value of $M_{\eta_{s}}^{2}$,

FIG. 8: Results for the mass difference between the heavycharm meson and the corresponding heavy-strange and charm-strange mesons plotted as a function of the pseudoscalar heavyonium mass. Results for coarse, fine, superfine and ultrafine lattices appear from left to right. The lattice QCD results have been adjusted for slight mistuning of the $c$ and $s$ quark masses. The colored dashed lines give the fitted function for that lattice spacing. The black line with grey error band gives the physical curve derived from our fit. The black circles with error bars at $M_{\eta_{b}}$ and $M_{\eta_{c}}$ give experimental values adjusted for the effects from electromagnetism, $\eta_{b} / \eta_{c}$ annihilation and $c$ quarks in the sea, none of which is included in the lattice QCD calculation.

FIG. 9: Results for the ratio of pseudoscalar decay constants, heavy-charm and heavy-heavy to heavy-strange plotted as a function of the pseudoscalar heavyonium mass. The results are obtained from the physical curves given in Figures 1, 3 and 7 .
the charm mass by $M_{\eta_{c}}$. The results come from the fine lattices, set 3 , where we have multiple $m_{c}$ and $m_{s}$ values close to the tuned point. Results are plotted for two values of the heavy quark mass, $m_{h} a=0.7$ and $m_{h} a=$ 0.85 but little difference between them is seen.

The dependence of $f_{H_{s}}$ on $m_{s}$ is not very strong [4, as expected since $f_{H_{s}}$ and $f_{H}$ differ only by around $20 \%$ for a change by a factor of 27 in light quark mass. The dependence of $f_{H_{c}}$ on $m_{c}$ is larger by about a factor of

FIG. 10: Comparison of the effect of 'detuning' the charm and strange quark masses on the heavy-charm and heavy-strange decay constants. Open squares show the fractional change in $f_{H_{c}}$ for a given fractional change in $M_{\eta_{c}}$ (as proxy for $m_{c}$ ) for two different heavy quark masses (in blue $m_{h} a=0.7$ and red $m_{h} a=0.85$ ) on the fine lattices set 3. Burst show the fractional change in $f_{H_{s}}$ for a given fractional change in $M_{\eta_{s}}^{2}$ (as proxy for $m_{s}$ ) for the same two heavy quark masses on set 3. Lines are drawn to guide the eye.

| $M_{\eta_{h}}$ | $f_{\eta_{h}}$ | $f_{H_{s}}$ | $f_{H_{c}}$ | $\Delta_{H_{s}, h h}$ | $\Delta_{H_{c}, h h}$ | $\Delta_{H_{c}, h s}$ |

TABLE IX: Values for the various quantities that we fit here evaluated at masses, $M_{\eta_{h}}$, between that of $c$ and $b$. These are obtained from our fit functions at $a=0$ and tuned $s$ and $c$ masses. All numbers are in GeV . There is no result for $f_{H_{c}}$ at 3 GeV because that point is not included in that fit.
two. However the slope of the Figure 10 is $1 / 3$ (see also Figure 6), much less than the slope of 1 expected if $f_{B_{c}} \propto$ $m_{c}$. This latter behaviour would be approximately that expected in a heavy-heavy picture in which $\psi(0) \propto \mu$, with the reduced mass, $\mu$, close to $m_{c}$ in the $B_{c}$ case. The linear behaviour of $\psi(0)$ would be consistent with the picture we have of the $\eta_{h}$ in Figure 1, where $\mu \approx M_{\eta_{h}} / 4$, using $b \approx 0.5$.

## V. CONCLUSIONS

By using a relativistic approach to heavy quarks (HISQ) which has relatively small discretisation errors we have been able to map out the dependence on heavy quark mass of the pseudoscalar heavyonium, heavystrange and heavy-charm decay constants and the heavystrange and heavy-charm meson masses, complementing results in [3, 4].

We find the heavyonium decay constant surprisingly

FIG. 11: Summary of heavy quark mass dependence of decay constants for the pseudoscalar $H_{c}, H_{s}$ and $\eta_{h}$ mesons. The grey bands show our physical curves from Figures 1, 3 and 7.
close in value to the experimental results for the charmonium and bottomonium vector decay constants. Work is underway to confirm this result using NRQCD for the heavy quark and to establish accurate results for the corresponding vector decay constants in lattice QCD. Although the $\eta_{h}$ decay constant has no simple connection to an observed experimental rate, it is useful for comparison and calibration of lattice QCD calculations in heavy quark physics since it can be determined to $1 \%$, as we have done here.

Our result for the $B_{c}$ meson mass agrees well using the two different mass splittings, $\Delta_{B_{c}, h h}$ and $\Delta_{B_{c}, h s}$ and also agrees with the experimental value. This is confirmation of our earlier result [18] using NRQCD $b$ quarks and HISQ light quarks.

We determine the $B_{c}$ decay constant as $427(6) \mathrm{MeV}$, for the first time in full QCD , predicting a leptonic branching ratio for the $B_{c}$ to $\tau \nu$ of $1.9(2) \%$ (where the uncertainty comes from $t_{B_{c}}$, not $f_{B_{c}}$ ). Our result for $f_{B_{c}}$ is significantly smaller than that from some potential model calculations, including those being used to estimate LHC production cross-sections 30. The best way to determine the $B_{c}$ leptonic decay rate, and hence $f_{B_{c}}$, from experiment may be using a high luminosity $e^{+} e^{-}$ collider operating at the $Z$ peak [36, 37].

By mapping out the dependence on the heavy quark mass of the $H_{c}, H_{s}$ and $\eta_{h}$ decay constants we are able to see the differences between the three systems. This is summarised in Figure 11 where we give the physical curves determined from our fits. In section IV we provide evidence that the $B_{c}$ behaves, at least in some ways, more like a heavy-light system than a heavy-heavy one. We previously noticed this effect in [38] when finding that the mass difference between $B_{c}^{*}$ and $B_{c}$ was very close to the difference between $B_{s}^{*}$ and $B_{s}$.

Table IX gives results extracted from our fits at intermediate values of $M_{\eta_{h}}$ from $M_{\eta_{c}}$ to $M_{\eta_{b}}$ for com-
parison to future lattice QCD calculations or to phenomenological models. The values are determined by evaluating our fit function in the continuum limit and at tuned $s$ and $c$ masses, corresponding to the black line in Figs. 1, 2, 3, 4, 7 and 8.

In Figure 12 we summarise the current picture for the decay constants of gold-plated mesons, determined from lattice QCD and from experiment. For lattice QCD we use the best existing results which dominate the world averages [1, 4, 10, 11, 31, 32]. For the experimental values for the unflavored vectors we use leptonic widths to $e^{+} e^{-}$from the Particle Data Tables 17 and eq. 10 . For the flavored pseudoscalars the determination of the decay constant from experiment requires the input of a value for the associated CKM element, for example from the unitarity fit to the CKM matrix [17. We update the $D$ and $D_{s}$ experimental determinations to the averages including new results from BESIII [34] and Belle [35] respectively.

This plot goes beyond the traditional plot of the mass spectrum [1] to look at a number which is related to the internal structure of the meson. The energy scale for decay constants is controlled by internal momenta inside the meson and so is much compressed over the scale for masses (which covers a large range simply because quark masses have a large range). The pseudoscalar meson decay constants are well filled in but more work is needed to obtain the vector decay constants to the same level of accuracy. This is underway and once complete, this plot will provide a very stringent test of QCD that would be impossible with any method other than lattice QCD.

From our results here and in [3, 4] we see that the relativistic heavy quark approach using the HISQ formalism can successfully give results for the $b$ quark. Future work will use even finer lattices. For $a=0.03 \mathrm{fm}$, for example, the $b$ quark mass in lattice units is around 0.5 and so we can easily achieve this mass without the need for extrapolation.

#### Abstract

We calculate the $J / \psi$ mass, leptonic width and radiative decay rate to $\gamma \eta_{c}$ from lattice QCD including $u, d$ and $s$ quarks in the sea for the first time. We use the Highly Improved Staggered Quark formalism and nonperturbatively normalised vector currents for the leptonic and radiative decay rates. Our results are: $M_{J / \psi}-M_{\eta_{c}}=116.5(3.2) \mathrm{MeV} ; \Gamma\left(J / \psi \rightarrow e^{+} e^{-}\right)=5.48(16) \mathrm{keV}$; $\Gamma\left(J / \psi \rightarrow \gamma \eta_{c}\right)=2.49(19) \mathrm{keV}$. The first two are in good agreement with experiment, with $\Gamma(J / \psi \rightarrow$ $e^{+} e^{-}$) providing a test of a decay matrix element in QCD, independent of CKM uncertainties, to $2 \%$. At the same time results for the time moments of the correlation function can be compared to values from the charm contribution to $\sigma\left(e^{+} e^{-} \rightarrow\right.$ hadrons $)$, giving a $1.5 \%$ test of QCD. Our results show that an improved experimental error would enable a similarly strong test from $\Gamma\left(J / \psi \rightarrow \gamma \eta_{c}\right)$.

## I. INTRODUCTION

Precision tests of lattice QCD against experiment are critical to provide benchmarks against which to calibrate the reliability of predictions from lattice QCD [1]. Most tests to date have relied on the spectrum of gold-plated hadron masses - for example, the mass of the $D_{s}$ meson can be calculated in lattice QCD with an error of 3 MeV (having fixed the masses of the $c$ and $s$ masses from other mesons) and the result agrees with experiment [2, 3]. Here we give another such test by determining the mass of the $J / \psi$ to a precision of 3 MeV .

Tests of decay matrix elements are harder to do very accurately. We need precision tests of these because it is the predictions of decay matrix elements from lattice QCD that enable, for example, progress with the flavor physics programme [4] of over-determining the CKM matrix to find signs of new physics [5]. The leptonic decay rate of the $\pi$ via a $W$ boson provides one such test. The QCD input to this is the pion decay constant, which is determined to $1 \%$ in lattice QCD [6]. If we take $V_{u d}$ from nuclear $\beta$ decay [7], we have a $2 \%$ determination of the leptonic decay rate to be compared to experiment. The leptonic decay rates of other charged pseudoscalars can also be determined to a few percent from lattice QCD 4 but then the comparison with experiment is generally needed to determine the appropriate CKM element. Independent tests of matrix elements, without CKM uncertainties, come only from electromagnetic decays. Here we provide two such tests through two different decay rates

[^300]of the $J / \psi$ : annihilation to $e^{+} e^{-}$via a photon and radiative decay to the $\eta_{c}$. We give the first results from full lattice QCD including $u, d$ and $s$ quarks in the sea, although earlier calculations have been done in quenched QCD [8] and including $u$ and $d$ sea quarks [9, 10].

We are able to determine these matrix elements to a few percent because of our development of an accurate and fully relativistic approach to $c$ quarks (as well as $u, d$ and $s$ ) in lattice QCD called the Highly Improved Staggered Quark (HISQ) formalism [11]. In this formalism we are able to normalise the vector current which mediates the electromagnetic decay accurately and nonperturbatively and we show how to do that here.

The layout of the paper is as follows: section III describes the lattice calculation and then section III gives results for the $J / \psi$ mass, leptonic width (along with time moments of the $J / \psi$ correlator) and radiative decay rate in turn. We compare our results to experiment and to previous lattice QCD calculations in section IV. Section $\square$ gives our conclusions. The Appendices discuss the more technical issues of discretisation errors and our two different methods for current renormalisation.

## II. LATTICE CALCULATION

We use 6 ensembles of lattice gluon configurations at 4 different, widely separated, values of the lattice spacing, provided by the MILC collaboration [12]. The configurations include the effect of $u, d$ and $s$ quarks in the sea with the improved staggered (asqtad) formalism. The $u$ and $d$ masses are taken to be the same with $m_{u / d} / m_{s}$ approximately 0.2 on most of the ensembles. Based on our experience of other gold-plated mesons [2] we expect sea quark mass effects to be small for the $J / \psi$ because it

| Set | $r_{1} / a$ | $a u_{0} m_{l}^{a s q}$ | $a u_{0} m_{s}^{a s q}$ | $L_{s} / a$ | $L_{t} / a$ | $\delta x_{l}$ | $\delta x_{s}$ |

TABLE I: Ensembles (sets) of MILC configurations used for this analysis. The sea asqtad quark masses $m_{l}^{\text {asq }}(l=u / d)$ and $m_{s}^{a s q}$ are given in the MILC convention where $u_{0}$ is the plaquette tadpole parameter. The lattice spacing values in units of $r_{1}$ after 'smoothing' are given in the second column [12. Here sets 1, 2 and 3 are 'coarse'; set 4, 'fine'; set 5 'superfine' and set 6 'ultrafine'. The size of the lattices is given by $L_{s}^{3} \times L_{t}$. The final two columns give the difference between the sea quark mass and its physical value in units of the $s$ quark mass [2].
has no valence light quarks. We can test this by comparison of results on sets 1 and 2 where the sea value of $m_{u, d}$ changes by a factor of two and with set 3 where the sea value of $m_{s}$ changes by $70 \%$. Table $\mathbb{\square}$ lists the parameters of the ensembles.

The lattice spacing is determined on an ensemble-byensemble basis using a parameter $r_{1}$ that comes from fits to the static quark potential calculated on the lattice 12 . This parameter has small statistical/fitting errors but its physical value is not accessible to experiment and so must be determined using other quantities, calculated on the lattice, that are. We have determined $r_{1}=0.3133(23) \mathrm{fm}$ using four different quantities ranging from the ( $2 \mathrm{~S}-1 \mathrm{~S}$ ) splitting in the $\Upsilon$ system to the decay constant of the $\eta_{s}$ (fixing $f_{K}$ and $f_{\pi}$ from experiment) [13]. Using our value for $r_{1}$ and the MILC values for $r_{1} / a$ given in Table I we can determine $a$ in fm on each ensemble or, equivalently, $a^{-1}$ in GeV needed to convert lattice quantities to physical units.

On these ensembles we calculate $c$ quark propagators using the HISQ action and combine them into meson correlation functions. The quark propagators are made from a 'random wall' source - a color 3-vector of $\mathrm{U}(1)$ random numbers - on a given timeslice to reduce the statistical noise. An added reduction comes from the use of a random starting point for the equally spaced time-sources we use on the coarse and fine ensembles. We include only connected correlation functions here disconnected contributions for the $J / \psi$ are related to its hadronic width which is in keV and therefore negligible here.

The $c$ quark mass is tuned from the $\eta_{c}$ meson mass [2]. The appropriate 'experimental' mass for the $\eta_{c}$ for our calculations is $2.986(3) \mathrm{GeV}$, differing from the experimental result of $2.981(1) \mathrm{GeV}$ [7] because of missing electromagnetic, $\eta_{c}$ annihilation and $c$-in-the-sea effects that we estimate perturbatively [14]. The HISQ lattice $c$ quark masses for the ensembles we are using were determined in [2].

Meson masses and decay constants are determined from simple ' 2 -point' meson correlation functions made from combining quark propagators with appropriate spin matrices at source and sink to project onto the correct $J^{P C}$. For staggered quarks, where the spin degree of freedom has disappeared, the spin projection matrices are replaced with space-time-dependent phases of $\pm 1$. Because of fermion-doubling, there are in fact 16 'tastes' of every meson made by combining a point-splitting of the quark and antiquark source and sink along with the appropriate $\pm 1$ phases. The most accurate meson correlation functions come from either local or 1-link separated sources and sinks and we will restrict ourselves to these here. Because the taste-splittings are discretisation effects we are free to use whichever taste is the most convenient for a given calculation.

For the pseudoscalar mesons the mass differences between the different tastes have a simple picture with the mass increasing as the amount of point-splitting in the source/sink operator increases. The lightest mass particle is the Goldstone meson whose correlator is simply the modulus squared of the propagator and whose squared mass vanishes linearly with the quark mass. This is the one that is used to tune the quark mass. The other taste pseudoscalar mesons have a mass for which the difference of mass-squared with the Goldstone meson is a constant with quark mass which vanishes as $\alpha_{s}^{2} a^{2}$. These tastesplitting discretisation errors are particularly small with the HISQ action [11]. They also become smaller, in proportion to the meson mass, as the meson mass increases and so are very small for mesons made of $c$ quarks [11]. The mass difference between the Goldstone meson and the next heaviest pseudoscalar meson is visible, however. Both masses can be determined very accurately in lattice QCD because they both correspond to local operators. The Goldstone meson corresponds to the local $\gamma_{5}$ operator and the local non-Goldstone to the local $\gamma_{0} \gamma_{5}$ operator. We will use both of these mesons in our calculation of the radiative decay rate of the $J / \psi$.

Vector meson taste-splittings are significantly smaller than for pseudoscalars and typically not visible for light mesons above the statistical errors. For the charmonium vectors we use the local $\gamma_{i}$ operator to determine the leptonic decay rate and two different 1-link split operators for the radiative decay. We discuss mass differences from taste-splittings further in Appendix A.

## III. RESULTS

$$
\text { A. } M_{J / \psi}
$$

The determination of the mass of the $J / \psi$ is most accurately done through the determination of the charmonium hyperfine splitting, i.e. the mass difference with the pseudoscalar $\eta_{c}$ meson. For the $\eta_{c}$ we use the Goldstone meson, as discussed in section II, because this is the most accurately determined in lattice QCD and is the meson
we use to fix the $c$ quark mass. We studied this meson in detail in [2]. For the $J / \psi$ we use the local $\gamma_{i}$ operator to create and destroy the vector meson. The $J / \psi$ correlators are then obtained by combining quark propagators from the default random wall with antiquark propagators from a source using the same random wall but patterned with phases, for example $(-1)^{x}$ for the vector polarised in the $x$ direction. $(-1)^{x}$ is also inserted at the sink where the propagators are tied together.

The $J / \psi$ and $\eta_{c}$ correlators at zero spatial momentum are fit simultaneously so that correlations between them are taken into account. The fit form for the average $J / \psi$ correlator as a function of time separation between source and sink, $t$, is:

$$
\begin{equation*}
\bar{C}_{2 p t}(t)=\sum_{i_{n}, i_{o}} a_{i_{n}}^{2} \mathrm{fn}\left(M_{i_{n}}, t\right)-\tilde{a}_{i_{o}}^{2} \mathrm{fo}\left(\tilde{M}_{i_{o}}, t\right) \tag{1}
\end{equation*}
$$

with

$$
\begin{align*}
\operatorname{fn}(M, t) & =e^{-M t}+e^{-M\left(L_{t}-t\right)} \\
\operatorname{fo}(M, t) & =(-1)^{t / a} \operatorname{fn}(M, t) \tag{2}
\end{align*}
$$

and $L_{t}$ the time extent of the lattice. $i_{n}=0$ is the ground state and larger $i_{n}$ values denote radial or other excitations with the same $J^{P C}$ quantum numbers. The $M_{i_{n}}$ are the masses of the corresponding particles. There are 'oscillating' terms coming from opposite parity states, denoted $i_{o}$. The Goldstone $\eta_{c}$ meson has the same fit form except that there are no oscillating contributions (when the $\eta_{c}$ is at rest). Note that we do not use any 'smearing' functions for the propagators at either source or sink.

To fit we use a number of exponentials $i_{n}$, and where appropriate $i_{o}$, in the range $2-6$, loosely constraining the higher order exponentials by the use of Bayesian priors [15]. As the number of exponentials increases, we see the $\chi^{2}$ value fall below 1 and the results for the fitted values and errors for the parameters for the ground state $i=0$ stabilise. This allows us to determine the ground state parameters $a_{0}$ and $M_{0}$ as accurately as possible whilst including the full systematic error from the presence of higher excitations in the correlation function. We take the fit parameters to be the logarithm of the ground state masses $M_{0}$ and $\tilde{M}_{0}$ and the logarithms of the differences in mass between successive radial excitations (which are then forced to be positive). The Bayesian prior value for $M_{0}$ for the $\eta_{c}$ is obtained from a simple 'effective mass' in the correlator and the prior width on the value is taken as 0.3 . The prior value on $M_{0}$ for the $J / \psi$ is taken to be $100 \pm 50 \mathrm{MeV}$ above the $\eta_{c}$. The prior value for mass splittings to and between excitations is taken as $600(300) \mathrm{MeV}$. The amplitudes $a_{i_{n}}$ and $a_{i_{o}}$ are given prior widths of 1.0 . We apply a cut on the range of eigenvalues from the correlation matrix that are used in the fit of $10^{-4}$. We also cut out small $t / a$ (and $\left.\left(L_{t}-t\right) / a\right)$ values below 6 from our fit to reduce the effect of higher excitations.

FIG. 1: Our average $J / \psi$ correlator divided by the ground state exponential ( $\mathrm{fn}\left(M_{0}, t\right)$ from eq. 2 Z ) as a function of lattice time. Lines are drawn to join the points (which include statistical errors) for clarity. The fitted result for the ground state amplitude, $a_{0}^{2}$, is given by the blue band. The fit includes 6 normal exponentials and 6 oscillating ones, which are responsible for the oscillating behaviour clearly seen in the results.

Figure 1 shows the quality of our results with a plot of the $J / \psi$ correlation function. It is divided by the groundstate exponential function so that it shows a plateau in the centre of value $a_{0}^{2}$. The results for the ground-state masses in lattice units of the $J / \psi$ and $\eta_{c}$ and the difference between them, $a \Delta M_{h y p}$, are given in Table II. The difference is typically more accurate than that obtained by simply subtracting the masses because of the correlation between the correlators.

The hyperfine splitting is converted to physical units using the values for $a$ on each ensemble as discussed in section III The results are shown in Figure 2. Figure 2 includes the error from the determination of the lattice spacing on each point. This dominates the error but is correlated between the points and that should be borne in mind in looking at the figure. It is important to realise that the naive lattice spacing error is magnified by a factor of approximately two in the hyperfine splitting because of the inverse relationship between hyperfine splitting and quark mass. For example, a shift by uncertainty $\delta$ upwards in the inverse lattice spacing causes a shift upwards in the meson mass by the same proportion. To determine the total effect of this on the hyperfine splitting we must include the effect of retuning the $c$ quark mass to make the meson mass correct again. This means in this case retuning the quark mass down by fraction $\delta$ which shifts the hyperfine splitting upward by a further factor of $\delta$ to that coming simply from the lattice spacing change. Thus the change in the hyperfine splitting, rep-

TABLE II: Results in lattice units for the masses of $\eta_{c}$ and $J / \psi$ and their difference on each ensemble along with the raw (unrenormalised) decay constant and $Z$ factor for the $J / \psi$. Columns 3 and 4 give the bare HISQ charm quark mass, tuned from the $\eta_{c}$ and the corresponding coefficient $\epsilon$ used in the Naik discretization improvement term of the HISQ action [2]. All of the charm quark masses are very well tuned except for the lower result on set 2 ( $m_{c} a=0.66$ ), which was deliberately mistuned to assess the sensitivity of quantities to the tuning. Of the remaining masses the least well-tuned is on superfine set 5 where $M_{\eta_{c}}$ is $0.5 \%$ too high. Column 2 gives the number of configurations used and the number of time sources for propagators on each configuration. Results are binned on time sources and binned over neighbouring configurations for sets 5 and 6 . The $J / \psi$ correlators are averaged over polarisations except on sets 2 and 3 where only one polarisation was calculated. The results for the $\eta_{c}$ masses are also given in [2]. They differ slightly from these in some cases because of fitting simultaneously with $J / \psi$ correlators. The $Z$ factors are taken from moment 4 of the nonperturbative (on the lattice) current-current correlator method described in Appendix B1.

FIG. 2: Results for the charmonium hyperfine splitting plotted as a function of lattice spacing. For the $x$-axis we use $\left(m_{c} a\right)^{2}$ to allow the $a$-dependence of our fit function (eq. (3)) (blue dashed line with grey error band) to be displayed simply. The data points have been corrected for $c$ quark mass mistuning and sea quark mass effects, but the corrections are smaller than the error bars. We do not include on the plot the deliberately mistuned $c$ mass but it is included in the fit to constrain the $c$ mass dependence. The errors shown include (and are dominated by) uncertainties from the determination of the lattice spacing $a$ (from the physical value of the parameter $r_{1}$ ) that are correlated between the points. The experimental average is plotted as the black point at the origin, offset slightly from the $y$-axis for clarity.
resenting its uncertainty, is approximately $2 \delta[16]^{1}$. Thus lattice spacing uncertainties are typically much more important in the determination of hyperfine splittings than

[^301]statistical errors.
We fit the hyperfine splitting as a function of lattice spacing and sea quark masses to the form:
\[

$$
\begin{align*}
f\left(a, \delta x_{l}, \delta x_{s}\right)= & f_{0} \times  \tag{3}\\
& \sum_{i j k l} c_{i j k l}\left(a m_{c}\right)^{2 i}\left(\frac{\delta x_{1}}{10}\right)^{j}\left(\frac{\delta x_{2}}{10}\right)^{k}\left(\frac{\delta x_{3}}{10}\right)^{l} \\
+ & \left(d_{0}+d_{1}\left(a m_{c}\right)^{2}\right)\left(M_{\eta_{c}, \text { latt }}-M_{\eta_{c}, \text { expt }}\right) .
\end{align*}
$$
\]

Here $f_{0}$ is the physical result, the sum over $i j k l$ allows for discretisation errors and sea quark effects and the final term allows for mistuning of the $c$ quark mass. We allow the discretisation errors, which are evident in our results, to have a scale set by the $c$ quark mass. These appear only as even powers of $a$ for staggered quarks. $\delta x_{l}$ and $\delta x_{s}$ are the mistuning of the sea quark masses:

$$
\begin{equation*}
\delta x_{q}=\frac{m_{q, \text { sea }}-m_{q, \text { phys }}}{m_{s, \text { phys }}} . \tag{4}
\end{equation*}
$$

$\delta x_{l}$ and $\delta x_{s}$ values are given for each ensemble in Table I and are taken from Appendix A of [2]. Eq. (3) includes a term for each sea quark ( $u / d$ appearing twice, and $s$ ), with the coefficients constrained to be the same so that the fit function is symmetric with respect to interchange of any two. The division by 10 is because the scale for dependence on light quark masses from chiral perturbation theory is $4 \pi f_{\pi} \approx 10 m_{s}$. We see no significant sea quark mass dependence in the hyperfine splitting. A fairly strong dependence was seen in the twisted mass calculations 10. However, at least some of that dependence could be attributed to the sea quark mass dependence of the lattice spacing, since that is determined only in the chiral limit. Here we determine the lattice spacing for each ensemble and hence separate lattice spacing dependence from physical sea quark mass effects. The sum over $i j k l$ in eq. (3) allows for the possibility of lattice spacing dependent sea quark mass effects.

We take a Bayesian prior [15] on $f_{0}$ of $0.1(1)$ and then fix $c_{0000}$ to 1 . The other $c_{i j k l}$ are given priors of $0.0 \pm 1.0$ except for the $c_{0 j k l}$ which determine the $a$-independent sea quark mass dependence. These are taken to have priors $0.0 \pm 0.33$ because we expect sea quark mass effects to be typically a factor of 3 smaller than valence quark mass effects which would have chiral perturbation theory coefficients of $\mathcal{O}(1)$. We include 5 terms in the $a$-dependence and 3 in the $\delta x$ dependence. Including additional terms makes no difference to the value for $f_{0}$ or its error. The priors for $d_{0}$ and $d_{1}$ are taken as $0.00(5)$, informed by the expectation that the hyperfine splitting should be inversely proportional to the mass, and by the effect of our mistuned $c$ mass on set 2 which agrees roughly with that expectation.

The fit gives $f_{0}=116.5(2.1) \mathrm{MeV}$, as the result for the hyperfine splitting in the absence of electromagnetism, $c$ -in-the-sea and $\bar{c} c$ annihilation. The first two affect the $\eta_{c}$ and $J / \psi$ equally and so have no effect on the hyperfine splitting. The third affects the $\eta_{c}$ more than the $J / \psi$, which has negligible width. A perturbative estimate of the shift of the $\eta_{c}$ mass resulting from its annihilation to two gluons 11 related this to the total $\eta_{c}$ width and obtained a shift downwards of the $\eta_{c}$ mass of $2.4 \mathrm{MeV}^{2}$. Using this, we have since applied a shift of $2.4(1.2) \mathrm{MeV}$ for this effect to determine the $\eta_{c}$ mass to which to tune our $c$ quark mass, as in section [II] For this purpose the impact of the shift is completely negligible, amounting to less than $0.1 \%$ of the $\eta_{c}$ mass. For the hyperfine splitting, however, this shift could be a relatively large effect. Nonperturbative calculations of the contribution of 'disconnected diagrams' to the $\eta_{c}$ mass have agreed on a small value of a few MeV for the shift from $\eta_{c}$ annihilation but obtained the opposite sign [17]. The argument is that the perturbative result may be modified significantly by the $g g$ intermediate state forming a resonance such as a glueball which is lighter in mass than the $\eta_{c}$, or a lighter hadron state. To allow for this possibility and be consistent with the nonperturbative calculations we do not apply a shift to the hyperfine splitting obtained from our fit above, but instead take an additional systematic error of 2.4 MeV , corresponding to our original shift, to allow for the effect.

Our final result for the hyperfine splitting is then:

$$
\begin{equation*}
\Delta M_{\mathrm{hyp}}=116.5(2.1)(2.4) \mathrm{MeV} \tag{5}
\end{equation*}
$$

where the errors are in turn from statistics/fitting and $\eta_{c}$ annihilation. The uncertainty from $\eta_{c}$ annihilation dominates the error. A complete error budget is given in Table III.

This is to be compared to the difference of the experimental averages of the two masses of $115.9(1.1)$

MeV [7. Quite a spread of results make up the average. Recent values tend to be at the lower end of the hyperfine splitting range. For example, the 2011 Belle result for the $\eta_{c}$ mass gives a hyperfine splitting of $111.5\binom{+1.6}{-2.5} \mathrm{MeV}$ [18], and a recent result from BESIII gives $112.6(0.9) \mathrm{MeV}$ [19].

## B. $\Gamma\left(J / \psi \rightarrow e^{+} e^{-}\right)$and $R_{e^{+} e^{-}}$

The amplitude, $a_{0}$, from the fit in equation (1) to our $J / \psi$ correlators is directly related to the matrix element for the local vector operator to create or destroy the ground-state vector meson from the vacuum. The vector meson decay constant, $f_{v}$, for meson $v$ is defined by:

$$
\begin{equation*}
\langle 0| \bar{\psi} \gamma^{i} \psi|v\rangle=f_{v} m_{v} \epsilon^{i} \tag{6}
\end{equation*}
$$

where $\epsilon^{i}$ is the meson polarization. $f_{v}$ for the $J / \psi$ is then determined from our lattice QCD correlators, in terms of the ground-state parameters from our fit (eq. (11) by:

$$
\begin{equation*}
\frac{f_{v}}{Z}=a_{0} \sqrt{\frac{2}{M_{0}}} \tag{7}
\end{equation*}
$$

where $Z$ is the renormalisation constant required to match the local vector current in lattice QCD used here to that of continuum QCD at each value of the lattice spacing.
$f_{v}$ is clearly a measure of the internal structure of a meson and in turn is related to the experimentally measurable leptonic branching fraction:

$$
\begin{equation*}
\Gamma\left(v_{h} \rightarrow e^{+} e^{-}\right)=\frac{4 \pi}{3} \alpha_{Q E D}^{2} e_{h}^{2} \frac{f_{v}^{2}}{m_{v}} \tag{8}
\end{equation*}
$$

where $e_{h}$ is the electric charge of the heavy quark in units of $e(2 / 3$ for $c)$. The experimental average, $\Gamma(J / \psi \rightarrow$ $\left.e^{+} e^{-}\right)=5.55(14) \mathrm{keV}$ [7] gives $f_{J / \psi}=407(5) \mathrm{MeV}$, remembering that the electromagnetic coupling constant runs with scale and using $1 / \alpha_{Q E D}\left(m_{c}\right)=134$ [20]. This can then provide a test of QCD at the $1 \%$ level. Electromagnetic corrections are small since the $J / \psi$ must decay to an odd number of photons [21].

Our results for $f_{J / \psi} / Z$ are given in Table II. The final column of that table gives the values of $Z$ determined from current-current correlators as described in Appendix B. This method uses continuum perturbation theory through $\mathcal{O}\left(\alpha_{s}^{3}\right)$ to normalise the lattice QCD correlators at small times. $Z$ then results from a combination of non-perturbative lattice QCD calculations with continuum perturbation theory in a similar approach to that of the RI-MOM scheme ${ }^{3}$ used to renormalise the currents for the same calculation using twisted mass quarks in [10]. The current-current correlator method has the advantage that we can use the same correlators from which we also extract, at large times, the nonperturbative information on the ground-state mass and decay constant. Indeed this allows some cancellation of discretisation errors apparent in the unrenormalized decay constant.

Multiplying $f_{J / \psi} / Z$ by $Z$ and then by $a^{-1}$ in GeV gives the physical results for the decay constant plotted in Figure 3. We fit these to the same function of lattice spacing and sea quark mass used for the hyperfine splitting, eq. (3). The only differences are that the prior on $f_{0}$ is taken as $0.5(5)$ in this case and the priors on the slope of the variation of $f_{J / \psi}$ with $M_{\eta_{c}}$ are taken as: $d_{0}, 0.065(5)$ and $d_{1}, 0.00(25)$. These are informed by the variation we see for the deliberately mistuned $c$ mass on set 2 and also by our extensive study of the behaviour of $f_{\eta_{c}}$ with $M_{\eta_{c}}$ in [2]. There we find a strong $a$-dependence in the slope of the decay constant with mass and so we allow for that here.

The physical result that we obtain in the continuum limit is:

$$
\begin{equation*}
f_{J / \psi}=405(6)(2) \mathrm{MeV} \tag{9}
\end{equation*}
$$

The first error is from the fit and is dominated by the error from the $Z$ factor. The second error is an estimate of systematic effects from missing electromagnetism in our lattice QCD calculation [2]. The effect of missing $c$-in-the-sea is negligible in this case. A complete error budget is given in Table III.

The leptonic width is determined by the amplitude of the ground-state that dominates the correlator at large times. We can also determine the charm contribution to $R_{e^{+} e^{-}}$through the time moments of the $J / \psi$ correlator which depend on the behaviour at short times. The moments are defined by:

$$
\begin{equation*}
G_{n}^{V}=Z^{2} C_{n}^{V}=Z^{2} \sum_{\tilde{t}} \tilde{t}^{n} \bar{C}_{J / \psi}(\tilde{t}) \tag{10}
\end{equation*}
$$

where $\tilde{t}$ is lattice time symmetrised around the centre of the lattice (see Appendix $B$ ). Results for $\left(G_{n}^{V} / Z^{2}\right)^{1 /(n-2)}$ in lattice units on each of our ensembles are given in Table IV for $n=4,6,8$ and 10 . The power $1 /(n-2)$ is

[^303]

FIG. 3: Results for the charmonium vector decay constant plotted as a function of lattice spacing. For the $x$-axis we use ( $\left.m_{c} a\right)^{2}$ to allow the $a$-dependence of our fit function (eq. (3)) (blue dashed line with grey error band) to be displayed simply. The data points have been corrected for $c$ quark mass mistuning and sea quark mass effects, but the corrections are smaller than the error bars. We do not include on the plot the deliberately mistuned $c$ mass but it is included in the fit to constrain the $c$ mass dependence. The errors shown include (and are dominated by) uncertainties from the determination of the current renormalization factor, $Z$, that are correlated between the points. The experimental average is plotted as the black point at the origin, offset slightly from the $y$-axis for clarity.
taken to reduce all the moments to the same dimension. We take the $Z$ factor for the vector current to be the same one used for the leptonic width above, determined in Appendix B. Figure 4 then shows the physical results for the moments as a function of lattice spacing. The gray bands show our fits which use the same function of lattice spacing and sea quark masses as given in eq. (3). We reduce the prior width on the lattice spacing dependent terms by a factor of 4 because the moments are not as sensitive to short distances as the leptonic width or hyperfine splitting.

The physical results that we obtain for each moment in the continuum limit are given by:

$$
\begin{align*}
\left(G_{4}^{V}\right)^{1 / 2} & =0.3152(41)(9) \mathrm{GeV}^{-1} \\
\left(G_{6}^{V}\right)^{1 / 4} & =0.6695(57)(13) \mathrm{GeV}^{-1} \\
\left(G_{8}^{V}\right)^{1 / 6} & =0.9967(65)(10) \mathrm{GeV}^{-1} \\
\left(G_{10}^{V}\right)^{1 / 8} & =1.3050(65)(6) \mathrm{GeV}^{-1} \tag{11}
\end{align*}
$$

The first error comes from the fit and the second allows for electromagnetism (e.g. photons in the final state) missing from our calculation but present in experiment. The error is estimated by substituting $\alpha_{Q E D}$ for $\alpha_{s}$ in the perturbative QCD analysis of the moments [22]. A complete error budget for our results is given in Table V.

The results agree well with the values extracted for the $q^{2}$ derivative moments, $\mathcal{M}_{k}(n=2 k+2)$, of the charm quark vacuum polarization using experimental values for

$R_{e^{+} e^{-}}=\sigma\left(e^{+} e^{-} \rightarrow\right.$ hadrons $) / \sigma_{p t}$ [22, 23]. The values, extracted from experiment by [22] and appropriately normalised for the comparison to ours, are:

$$
\begin{align*}
\left(M_{1}^{\exp } 4!/\left(12 \pi^{2} e_{c}^{2}\right)\right)^{1 / 2} & =0.3142(22) \mathrm{GeV}^{-1} \\
\left(M_{2}^{\exp } 6!/\left(12 \pi^{2} e_{c}^{2}\right)\right)^{1 / 4} & =0.6727(30) \mathrm{GeV}^{-1} \\
\left(M_{3}^{\exp } 8!/\left(12 \pi^{2} e_{c}^{2}\right)\right)^{1 / 6} & =1.0008(34) \mathrm{GeV}^{-1} \\
\left(M_{4}^{\exp } 10!/\left(12 \pi^{2} e_{c}^{2}\right)\right)^{1 / 8} & =1.3088(35) \mathrm{GeV}^{-1} \tag{12}
\end{align*}
$$

Our results from lattice QCD have approximately double the error of the experimental values but together these results provide a further test of QCD to better than $1.5 \%$.

$$
\text { C. } \quad \Gamma\left(J / \psi \rightarrow \gamma \eta_{c}\right)
$$

The radiative decay of the $J / \psi$ meson to the $\eta_{c}$ requires the emission of a photon from either the charm quark or antiquark and a spin-flip, so it is an M1 transition. Because it is sensitive to relativistic corrections this rate is hard to predict in nonrelativistic effective theories and potential models (see, for example, [24, 25]) Here we use a fully relativistic method in lattice QCD with a nonperturbatively determined current renormalisation and so none of these issues apply. In addition, of course, the lattice QCD result is free from model-dependence.

The quantity that parameterises the nonperturbative QCD information (akin to the decay constant of the previous section) is the vector form factor, $V\left(q^{2}\right)$, where $q^{2}$ is the square of the 4 -momentum transfer from $J / \psi$ to

FIG. 4: Results for the 4th, 6th, 8th and 10th time moments of the charmonium vector correlator shown as blue points and plotted as a function of lattice spacing. The errors shown (the same size or smaller than the points) include (and are dominated by) uncertainties from the determination of the current renormalization factor, $Z$, that are correlated between the points. The data points have been corrected for $c$ quark mass mistuning and sea quark mass effects, but the corrections are smaller than the error bars (the value for the deliberately mistuned $c$ mass on set 2 is not shown). The blue dashed line with grey error band displays our continuum/chiral fit. Experimental results determined from $R_{e^{+} e^{-}}$(eq. (12)) are plotted as the black points at the origin offset slightly from the $y$-axis for clarity.
$\eta_{c}$. The form factor is related to the matrix element of the vector current between the two mesons by:

$$
\begin{equation*}
\left\langle\eta_{c}\left(p^{\prime}\right)\right| \bar{c} \gamma^{\mu} c|J / \psi(p)\rangle=\frac{2 V\left(q^{2}\right)}{\left(M_{J / \psi}+M_{\eta_{c}}\right)} \varepsilon^{\mu \alpha \beta \gamma} p_{\alpha}^{\prime} p_{\beta} \epsilon_{J / \psi, \gamma} \tag{13}
\end{equation*}
$$

Note that the right-hand-side vanishes unless all the vectors are in different directions. Here we use a normalisation for $V\left(q^{2}\right)$ appropriate to a lattice QCD calculation in which the vector current is inserted in one $c$ quark line only and the quark electric charge $(2 e / 3)$ is taken as a separate factor. The decay rate is then given by [8]:

$$
\begin{equation*}
\Gamma\left(J / \psi \rightarrow \eta_{c} \gamma\right)=\alpha_{Q E D} \frac{64|\vec{q}|^{3}}{27\left(M_{\eta_{c}}+M_{J / \psi}\right)^{2}}|V(0)|^{2} \tag{14}
\end{equation*}
$$

where it is the form factor at $q^{2}=0$ that contributes because the real photon is massless. $|\vec{q}|$ is the corresponding momentum of the $\eta_{c}$ in the $J / \psi$ rest-frame.

FIG. 5: A schematic diagram of the connected '3-point' function in lattice QCD for $J / \psi$ to $\eta_{c}$ radiative decay. The lines all represent $c$ quark propagators in this case. The propagator labelled 1 is the spectator quark; 2 and 3 are the initial and final active quarks respectively. 0 and $T$ label the position in time of the $\eta_{c}$ and $J / \psi$ operators. The vector current is inserted at time $t$ which takes all values between 0 and $T$.

The most recent experimental result from CLEO-c [26] of $1.98(31) \%$ for the branching fraction, combined with the total width of the $J / \psi$ of $92.9(2.8) \mathrm{keV}[7]$ gives

$$
\begin{equation*}
V(0)_{\mathrm{expt}}=1.63(14) \tag{15}
\end{equation*}
$$

where we have used $\alpha_{Q E D}=1 / 137$ and $|\vec{q}|=\left(M_{J / \psi}-\right.$ $\left.M_{\eta_{c}}\right)\left(M_{J / \psi}+M_{\eta_{c}}\right) /\left(2 M_{J / \psi}\right)$. The value of $|\vec{q}|$ from experiment is $0.1137(11) \mathrm{GeV}$ where the error comes from the uncertainty in the $\eta_{c}$ mass. $V(0)$ is then the quantity that can be calculated in lattice QCD and compared to experiment.

The radiative decay of the $J / \psi$ to $\eta_{c}$ meson needs the calculation of a ' 3 -point' function in lattice QCD. The 3 points (in lattice time) correspond to: the position of the $\eta_{c}$ operator, which we take as the origin; the position of the $J / \psi$ operator which we denote $T$ and the position of the insertion of a vector operator, $\mathcal{V}=\bar{c} \gamma_{\mu} c$, which couples to the photon at time $t . t$ varies from 0 to $T$. Sums over spatial points are implied at each time. The 'connected' correlator that we calculate is illustrated in Figure 5. Disconnected correlators are expected to be negligible here based on perturbative and phenomenological arguments 8 and we do not include them.

The 3-point function is calculated in lattice QCD by combining 3 quark propagators together with appropriate spin projection matrices. As discussed in section II for staggered quarks these $\gamma$ matrices become $\pm 1$ phases. Tastes must be combined in a staggered quark correlator so that the overall correlation function is 'tasteless'. What this means for a 3-point function is that only certain taste combinations of $J / \psi, \eta_{c}$ and $\mathcal{V}$ operators are allowed. To optimise statistical errors we need to keep to a minimum the amount of point-splitting in the operators. It is also convenient, for renormalisation purposes, to have a vector current, $\mathcal{V}$, which corresponds to a local operator (and this is also what we used for the decay constant in section III B.

We therefore choose the $\eta_{c}$ operator to be the local $\gamma_{5}$ operator (so that the $\eta_{c}$ is the Goldstone pseudoscalar with spin-taste $\gamma_{5} \otimes \gamma_{5}$ ) and the $J / \psi$ operator to be a one-link separated $\gamma_{0} \gamma_{i}$ operator in which the polarisation of the $J / \psi$ and the one-link separation are both in an orthogonal spatial direction to the polarisation of the vector current, $\mathcal{V}=\bar{c} \gamma_{k} c$ (this $J / \psi$ has spin-taste structure $\gamma_{0} \gamma_{i} \otimes \gamma_{0} \gamma_{i} \gamma_{j}$ ).

To implement this configuration is simple. The spectator quark propagator (number 1 in Figure 5 ) is generated from the default random wall at time 0 . Active propagator 2 is then generated from a source which is made from a symmetric point-splitting of propagator 1 at time $T$ patterned by a phase. For a $J / \psi$ with polarisation $x$ we take a point-splitting in the $y$ direction and phase $(-1)^{x+z}$. Active propagator 3 is made from the same default random wall as 1 . Finally 2 and 3 are combined together at $t$ by summing over space with a patterning of $(-1)^{z}$ to implement a local vector current in the $z$ direction.

To achieve the configuration corresponding to $q^{2}=0$ we keep the $J / \psi$ at rest in the frame of the lattice and give the $\eta_{c}$ an appropriate spatial momentum. The $\eta_{c}$ momentum is implemented by calculating propagator 3 with a 'twisted boundary condition' [27, 28]. If propagator 3 is calculated with boundary condition:

$$
\begin{equation*}
\chi\left(x+\hat{e}_{j} L\right)=e^{2 \pi i \theta_{j}} \chi(x) \tag{16}
\end{equation*}
$$

then the momentum of the $\eta_{c}$ meson made by combining propagators 1 and 3 with our random wall sources and summing over spatial sites at the sink is:

$$
\begin{equation*}
p_{j}=\frac{2 \pi}{L_{s}} \theta_{j} \tag{17}
\end{equation*}
$$

The boundary condition in eq. 16) is actually implemented by multiplying the gluon links in the $j$ direction by phase $\exp \left(2 \pi i \theta_{j} / L_{s}\right)$. We take $j$ to be the $y$ direction here so that the momentum is in an orthogonal direction to the polarisation of both the $J / \psi$ and $\mathcal{V}$.

The 3-point function is then given by:

$$
\begin{align*}
& C_{3 p t}(0, t, T)=\sum_{s_{T}, s_{t}} \frac{1}{4}(-1)^{x_{T}+z_{T}}(-1)^{z_{t}} \times  \tag{18}\\
& \operatorname{Tr}\left\{g(t, T)\left[g\left(T+1_{y}, 0\right)+g\left(T-1_{y}, 0\right)\right] g_{\theta}^{\dagger}(t, 0)\right\}
\end{align*}
$$

where $g$ represent staggered $c$ quark propagators, with $g_{\theta}$ computed with a phase on the gluon field, the trace is over color and sums are done over spatial sites $s_{t}$ and $s_{T}$ at $t$ and $T$. The $1 / 4$ is the taste factor for the normalisation of a staggered quark loop. The corresponding 2-point function for the $\eta_{c}$ meson is

$$
\begin{equation*}
C_{\eta_{c}, 2 p t}(0, t)=\sum_{s_{t}} \frac{1}{4} \times \operatorname{Tr}\left[g(t, 0) g_{\theta}^{\dagger}(t, 0)\right] \tag{19}
\end{equation*}
$$

TABLE VI: Results from simultaneous fits for 3-point and 2-point correlators for $J / \psi \rightarrow \gamma \eta_{c}$ decay. The upper table gives results from our preferred jpsigamma0 method; the lower table from etacgamma0. See the text for a definition of the two methods. Column 2 gives the number of configurations and time sources for 0 on each configuration. Column 3 gives the different values of the end-point of the 3 -point function, $T$, included in the fit. The lattice $c$ quark mass and $\epsilon$ parameter are the same as those used in section III A (the lower table includes the deliberately mistuned mass on set 2 for comparison). $a M_{J / \psi}$ and $a M_{\eta_{c}}$ are the zero-momentum meson masses for the tastes of $J / \psi$ and $\eta_{c}$ mesons used here. $2 \pi \theta$ indicates the value of the phase at the boundary used to achieve the kinematics of $q^{2}=0$ in the $J / \psi \rightarrow \eta_{c}$ decay. The $a^{2} q^{2}$ values actually obtained with those kinematics are given in the final column (rows 2 and 3 of the upper table compare two different values of $a^{2} q^{2}$ close to zero). $a E_{\eta_{c}}$ gives the energy of the $\eta_{c}$ at the value of the spatial momentum corresponding to $\theta$. $V_{n n}^{00}$ from the 3 -point fit of eq 25 is given in column 9 and this is converted to a value of $V(0) / Z$ in column 10 using eq. 27). Column 11 gives the values of the renormalisation parameter, $Z$, obtained from the vector form factor method of Appendix B 2

The 2-point function for the $J / \psi$ is given by

$$
\begin{align*}
& C_{J / \psi, 2 p t}(0, t)=\sum_{s_{t}} \frac{1}{4}(-1)^{y_{0}+t_{0}}(-1)^{y_{t}+t_{t}} \times  \tag{20}\\
& \operatorname{Tr}\left[g(t, 0)\left(g^{\dagger}\left(t+1_{y}, 1_{y}\right)+g^{\dagger}\left(t-1_{y}, 1_{y}\right)+\{1 \leftrightarrow-1\}\right)\right]
\end{align*}
$$

As an alternative configuration we can take the $\eta_{c}$ operator to be the local $\gamma_{0} \gamma_{5}$ operator (so that the $\eta_{c}$ is the local non-Goldstone meson with spin-taste structure $\left.\gamma_{0} \gamma_{5} \otimes \gamma_{0} \gamma_{5}\right)$ and the $J / \psi$ operator to be a one-link separated $\gamma_{i}$ operator in which the polarisation of the $J / \psi$ and the one-link separation are both in an orthogonal spatial direction to the polarisation of the vector current, $\mathcal{V}$ (this has spin-taste structure $\gamma_{i} \otimes \gamma_{i} \gamma_{j}$ ). The 3-point function is then given by:

$$
\begin{align*}
& C_{3 p t}(0, t, T)=\sum_{s_{T}, s_{t}} \frac{1}{4}(-1)^{x_{0}+y_{0}+z_{0}}(-1)^{y_{T}}(-1)^{z_{t}} \times \\
& \operatorname{Tr}\left[g(t, T)\left(g\left(T+1_{y}, 0\right)+g\left(T-1_{y}, 0\right)\right) g_{\theta}^{\dagger}(t, 0)\right] \quad(21 \tag{21}
\end{align*}
$$

and the corresponding 2-point functions are:

$$
\begin{align*}
C_{\eta_{c}, 2 p t}(0, t)= & \sum_{s_{t}} \frac{1}{4}(-1)^{x_{0}+y_{0}+z_{0}}(-1)^{x_{t}+y_{t}+z_{t}} \times \\
& \operatorname{Tr}\left[g(t, 0) g_{\theta}^{\dagger}(t, 0)\right] . \tag{22}
\end{align*}
$$

and

$$
\begin{aligned}
& C_{J / \psi, 2 p t}(0, t)=\sum_{s_{t}} \frac{1}{4}(-1)^{x_{0}+z_{0}+t_{0}}(-1)^{x_{t}+z_{t}+t_{t}} \times \quad(23) \\
& \operatorname{Tr}\left[g(t, 0)\left(g^{\dagger}\left(t+1_{y}, 1_{y}\right)+g^{\dagger}\left(t-1_{y}, 1_{y}\right)+\{1 \leftrightarrow-1\}\right)\right] .
\end{aligned}
$$

We call this configuration the 'etacgamma0' configuration and the original configuration of eq. (19) the 'jpsigamma0' configuration. In fact, as we shall see, the jpsigamma0 configuration is to be preferred on the basis of statistical errors but the results agree between the two.

The 3-point function in both cases is calculated along with the 2 -point functions for the $\eta_{c}$ and $J / \psi$ mesons that appear in it. We use multiple time-sources for point 0 on each configuration and also multiple values for $T$. Figure 6 shows results for the 3 -point function on fine set 4 , normalising it to the product of the relevant 2 point functions. The two plots compare results for the jpsigamma0 method and the etacgamma0 method. The two differ in the amount of oscillation that is seen at the two ends of the plot. Not surprisingly the jpsigamma0 method shows more oscillation on the $J / \psi$ end ( $t$ near $T)$ since the $\eta_{c}$ in this case would not oscillate at rest. The etacgamma0 method has relatively large oscillations for the $\eta_{c}$ side but smaller oscillations on the $J / \psi$ side. In both cases statistical errors are very small enabling us to fit both normal and oscillating terms. The figure also shows how having multiple $T$ values improves our determination of the ground-state transition amplitude.

We fit the 3 -point function and 2-point functions simultaneously to a multi-exponential that determines the ground-state amplitudes accurately because it includes excited state contributions. The fit form for the 2-point functions was already given in eq. (1). Here both the $J / \psi$ and $\eta_{c}$ correlators have oscillating contributions and, in the $\eta_{c}$ case, the exponent gives the energy of the meson at momentum $p_{j}$ (eq. 17)) rather than the mass. The

FIG. 6: A plot of the ratio $C_{3 p t}(t, T) /\left(C_{2 p t, \eta_{c}}(t) C_{2 p t, J / \psi}(T-\right.$ $t)$ ) for the three values of $T$ on the fine ensemble, set 4 and for our two different methods. Lines join the points (which have statistical errors on them) for clarity. We only include points in the central region of $t$ i.e. $t \geq 5$ or $t \leq T-5$. The pink shaded band shows the ratio of fit parameters $V_{00}^{n n} / a_{0} b_{0}$ which is the ground-state contribution to this ratio. These come from a fit that included 6 normal exponentials and 5 oscillating ones (which produce the oscillations evident in the figure). The top plot shows the results for the case where $\gamma_{0}$ is included in the $J / \psi$ operator (jpsigamma0 method) and the lower plot shows the results for the case where $\gamma_{0}$ is included in the $\eta_{c}$ operator (etacgamma0 method).
fit form for the 3-point function is then:

$$
\begin{aligned}
& C_{3 p t}(t, T)= \\
& \sum_{i_{n}, j_{n}} a_{i_{n}} \operatorname{fn}\left(E_{a, i_{n}}, t\right) V_{i_{n}, j_{n}}^{n n} b_{j_{n}} \operatorname{fn}\left(E_{b, j_{n}}, T-t\right) \\
& -\sum_{i_{n}, j_{o}} a_{i_{n}} \operatorname{fn}\left(E_{a, i_{n}}, t\right) V_{i_{n}, j_{o}}^{n o} \tilde{b}_{j_{o}} \mathrm{fo}\left(\tilde{E}_{b, j_{o}}, T-t\right) \\
& -\sum_{i_{o}, j_{n}} \tilde{a}_{i_{o}} \mathrm{fo}\left(\tilde{E}_{a, i_{o}}, t\right) V_{i_{o}, j_{n}}^{o n} b_{j_{n}} \mathrm{fn}\left(E_{b, j_{n}}, T-t\right) \\
& +\sum_{i_{o}, j_{o}} \tilde{a}_{i_{o}} \mathrm{fo}\left(\tilde{E}_{a, i_{o}}, t\right) V_{i_{o}, j_{o}}^{o o} \tilde{b}_{j_{o}} \mathrm{fo}\left(\tilde{E}_{b, j_{o}}, T-t\right)
\end{aligned}
$$

and, again:

$$
\begin{align*}
\mathrm{fn}(E, t) & =e^{-E t}+e^{-E\left(L_{t}-t\right)} \\
\mathrm{fo}(E, t) & =(-1)^{t / a} \mathrm{fn}(E, t) \tag{25}
\end{align*}
$$

with $L_{t}$ again the time extent of the lattice. Here $n$ denotes the normal contributions and $o$ the contributions from oscillating states. The ground-state energies/masses that we need are $E_{\eta_{c}, 0}$ and $E_{J / \psi, 0}=M_{J / \psi}$ and the matrix element between them that is proportional to $V_{0,0}^{n n}$. By matching to a continuum correlator with a relativistic normalisation of states and allowing for a renormalisation of the lattice vector current we see that:

$$
\begin{equation*}
\left\langle\eta_{c}\right| V|J / \psi\rangle=2 Z \sqrt{M_{J / \psi} E_{\eta_{c}}} V_{0,0}^{n n} . \tag{26}
\end{equation*}
$$

The vector form factor that we need, $V(0)$, is then, from eq. (13), given by:

$$
\begin{equation*}
\frac{V(0)}{Z}=\frac{M_{J / \psi}+M_{\eta_{c}}}{2 M_{J / \psi} p_{j}} 2 \sqrt{M_{J / \psi} E_{\eta_{c}}} V_{0,0}^{n n} \tag{27}
\end{equation*}
$$

with $p_{j}$ from eq. 17). The determination of $Z$ will be discussed below.

To perform the joint fit to the 3pt correlators using eq. (25) and the 2 pt correlators using eq.(11) we use the same approach as outlined in section III A. For both the $\eta_{c}$ and $J / \psi$, the prior for the ground-state mass comes from the effective mass of the correlator. We use priors of 600 MeV with a width of 300 MeV for the difference in mass between the ground state and the lowest oscillating mass and between all radial excitations, both normal and oscillating. The 2 -point amplitudes, $a_{i}$ and $b_{i}$, have prior widths of 0.5 and the 3 -point amplitudes, $V_{i j}$, have widths of 0.25 . We omit $t$ values below a certain $t_{\text {min }}$ to reduce the effect of excited states. $t_{\min }=4(5)$ for the coarse(fine) lattices for the etacgamm0 method and 6 for the jpsigamm0 method.

Table VI gives our results from fits that include 6 normal exponentials and 5 oscillating. We work on ensembles 1,2 and 4 of Table $\square$ but using more configurations than in section III A to reduce statistical errors. Table VI gives the number of configurations and time sources as well as the values of $T$ used in the 3 -point functions. It is important to use both even and odd values of $T$ to separate clearly the normal and oscillating contributions. Having determined the mass of the local non-Goldstone $\eta_{c}$ and 1-link vector from separate 2-point function fits we then determine the value of $\theta$ needed to achieve $q^{2}=0$. The final fits are done as a simultaneous fit to the 3-point function and 2-point functions for zero momentum and finite momentum $\eta_{c}$ and zero momentum $J / \psi$.

The key parameters to be determined from the fit, as discussed above, are the ground-state masses of the $\eta_{c}$ and $J / \psi$, the ground state energy at non-zero momentum of the $\eta_{c}$ and the ground-state to ground-state amplitude of the 3-point function. Our fit returns excited

FIG. 7: Results for the vector form factor at $q^{2}=0$ for $J / \psi \rightarrow$ $\eta_{c}$ decay plotted as a function of lattice spacing. The filled blue circles are from our preferred jpsigamma0 method; the open blue circles are from the etacgamma 0 method. For the $x$-axis we use $\left(m_{c} a\right)^{2}$ to allow the $a$-dependence of our fit function to be displayed simply (blue dashed line and grey band). The fit is to results from the jpsigamma0 method. The errors shown include statistical errors and errors from the $Z$ factor. The experimental result extracted from the branching fraction for $J / \psi \rightarrow \gamma \eta_{c}$ is plotted as the black point offset slightly from the origin for clarity.
state to ground-state and oscillating to ground state amplitudes also. Most of these do not have a significant signal. Indeed the excited state to ground state amplitudes are very small, as expected since they correspond to a hindered M1 transition. A non-zero result is seen for the transition between the oscillating partner of the $\eta_{c}$ (in the etacgamma0 method) and the $J / \psi$. This corresponds to the E1 $\chi_{c 0}$ to $J / \psi$ decay, but not at the correct kinematics for that decay. Likewise a signal is seen for E1 $h_{c} \rightarrow \eta_{c}$ decay in jpsigamma0 method. We will discuss these transitions further elsewhere.

From eq. 27) we can determine $V(0)$ given a value for $V_{00}^{n n}$ and a renormalisation factor, $Z$. For $Z$ we use the fully nonperturbative vector form factor method described in Appendix B2 which normalises the local charm-charm vector current that we are using here by demanding that its form factor is 1 between identical mesons at $q^{2}=0$. This requires a non-staggered spectator quark and we use NRQCD for this. The determination of $Z_{f f}$ then needs the calculation of the form factor of the temporal component of the vector current between two $B_{c}$-like mesons (the mesons do not have to be real $B_{c}$ mesons) at rest. $Z_{f f}$ can be determined with a statistical uncertainty of $0.1 \%$ this way. Details are given in Appendix B 2.

The values for $Z$ are given in Table IX of Appendix B 2 and the values we use here are reproduced in Table VI along with our results for $V_{00}^{n n}, V(0) / Z$ and the $\eta_{c}$ and $J / \psi$ masses and energies. The table is divided into two
with the upper results from the jpsigamma0 method and the lower results from the etacgamma0 method. The two methods give results for $V(0) / Z$ in good agreement, but the jpsigamma0 results are statistically more accurate. This is then our preferred method and the one that we will use for our final result. The agreement between the two methods to within the $2 \%$ statistical errors is a strong test of the control of discretisation errors in the HISQ formalism.

Table IXalso gives results that allow us to test to what extent $V(0)$ depends on $m_{c}$ and the precise tuning of $q^{2}$ to zero. On set 2 we have deliberately mistuned the $c$ quark mass by $5 \%$ and see that it makes no significant difference to $V(0)$ within our $2 \%$ statistical errors. $q^{2}$ is tuned to zero typically within our statistical errors of $(10 \mathrm{MeV})^{2}$. On set 2 comparison between two different values of $q^{2}$ shows no effect within our $1 \%$ statistical errors. We use the value closest to $q^{2}=0$ in our fits below. These are both good tests of the robustness of our results to the tuning of parameters.

Figure 7 shows our results for $V(0)$ plotted as a function of the lattice spacing. To determine the physical value we use a fit similar to that for the hyperfine splitting and leptonic decay constant given in eq. 3. We simplify the fit slightly in dropping the tuning for the physical $c$ mass since our results in Table VI show negligible dependence on the $c$ quark mass. We take the prior on the physical value to be $2.0(0.5)$ and allow for terms in $\left(m_{c} a\right)^{2 i}$ up to $i=5$. We take the prior on the leading $\left(m_{c} a\right)^{2}$ term to be $0.0(3)$ since tree-level $a^{2}$ errors are removed in the HISQ action. We take linear and quadratic terms in $2 \delta x_{l}+\delta x_{s}$ and allow $a^{2}$ dependence multiplying the linear term.

The physical value for $V(0)$ from the fit is $1.90(7)$ from the jpsigamma0 method. The etacgamma0 method gives a result in good agreement with a very similar error. The error is dominated by that from the extrapolation in the lattice spacing. In fact there is no visible lattice spacing dependence in our results and it could be argued that, in a transition from $J / \psi$ to $\eta_{c}$ that probes relatively low momenta, the relevant scale for discretisation errors is well below $m_{c}$. However, to be conservative, we allow discretisation errors to depend on $\left(m_{c} a\right)^{2}$ and allow for multiple powers to appear.

We have also tested extrapolations of $V(0)$ to the physical point using alternative definitions of the renormalisation of the current. We get the same answer using $Z_{f f}$ values taken from $B_{c} \rightarrow B_{c}$ form factors with a heavier $b$ quark mass, as given in Appendix B 2. We also get a result in good agreement if we use values for $Z$ from $Z_{c c}$ given in Appendix B 1 .

Our physical result for $V(0)$ is for a world that does not include electromagnetism, $c$-in-the-sea or allow for $\eta_{c}$ annihilation. The effect of missing electromagnetism is similar to that for the decay constant and so we allow the same additional systematic error of $0.5 \%$. We expect $c$-in the sea effects to be negligible, as for the decay constant. $\eta_{c}$ annihilation affects the mass difference between

FIG. 8: A comparison of results for the charmonium hyperfine splitting from lattice QCD with experiment. We show only results that include sea quarks and make use of multiple lattice spacings to derive a continuum value. The experimental average [7] is given at the top, followed by the result for HISQ quarks from this paper. The Fermilab clover [29] and twisted mass [10] results follow. Neither of these lower two results include an error for missing $\eta_{c}$ annihilation effects. This error is the dominant error for our calculation. Here we show our error bar excluding this effect as a solid line and the total error including this effect as a dotted line.
the $J / \psi$ and $\eta_{c}$ (as discussed in section III A) and therefore affects the momentum of the $\eta_{c}$ that corresponds to $q^{2}=0$ for this decay. Equivalently it means that the real $q^{2}=0$ point corresponds to a non-zero $q^{2}$ in our calculation. Since we allow an uncertainty in the $\eta_{c}$ mass of 2.4 MeV (Table III) this corresponds to an uncertainty around $q^{2}=0$ of $6 \times 10^{-6} \mathrm{GeV}^{2}$, keeping the spatial momentum fixed. From Table VI we see that this would produce a negligible change in $V(0)$, not visible beneath our statistical errors. In addition we can use information from [8] which used results at different $q^{2}$ values to extrapolate to $q^{2}=0$ albeit in the quenched approximation. The $q^{2}$ dependence gave a change in $V\left(q^{2}\right)$ from $V(0)$ of $20 \%$ when $q^{2}$ was $1 \mathrm{GeV}^{2}$. From this it is clear that effects from a slight mistuning because of $\eta_{c}$ annihilation effects should be completely negligible. We take as our final result then:

$$
\begin{equation*}
V(0)=1.90(7)(1) \tag{28}
\end{equation*}
$$

The complete error budget is given in Table III.

FIG. 9: A comparison of results for the decay constant of the $J / \psi$ from lattice QCD with experiment. We include only results that include sea quarks and make use of multiple lattice spacings to derive a continuum value. The experimental average [7] is given at the top, followed by the result for HISQ quarks from this paper. The twisted mass [10] results follow.

## IV. DISCUSSION

Figure 8 compares our result for the charmonium hyperfine splitting to experiment and to that from other lattice QCD calculations. We only show results that have been obtained including sea quark effects and making use of multiple lattice spacing values to derive a physical continuum result. Values are also given for different forms of the clover action in $30-33$ but either at only one value of the lattice spacing or without giving a value from continuum extrapolation. Some of these latter calculations obtain values well below experiment because of the large discretisation errors, particularly for the hyperfine interaction, in the clover formalism.

Our result agrees well with experiment and is more accurate than earlier values, especially since earlier values do not generally include any error for missing $\eta_{c}$ annihilation effects.

Figure 9 similarly compares our result for $f_{J / \psi}$ to that from twisted mass quarks including only $u$ and $d$ quarks in the sea [10] and to experiment (from eq. (8)). Both lattice results agree well with experiment at the $2 \%$ level of accuracy achieved. Our value for $f_{J / \psi}$ gives a value for $\Gamma\left(J / \psi \rightarrow e^{+} e^{-}\right)$of $5.48(16) \mathrm{keV}$ using eq. (8).

Figure 10 shows the same comparison for the vector form factor at $q^{2}=0, V(0)$, for $J / \psi \rightarrow \eta_{c} \gamma$ decay. Our result here using HISQ quarks and including $u, d$ and $s$ quarks in the sea agrees well, at the $4 \%$ level of accuracy achieved, with the result using twisted mass quarks and including only $u$ and $d$ sea quarks.

FIG. 10: A comparison of results for the vector form factor, $V(0)$ for $J / \psi \rightarrow \eta_{c} \gamma$ from lattice QCD with experiment. We include only results that include sea quarks and make use of multiple lattice spacings to derive a continuum value. The experimental result [26] is given at the top, followed by the result for HISQ quarks from this paper. The twisted mass 10 results follow.

The value of $V(0)$ extracted from the experimental branching fraction [26] is $1.7 \sigma$ lower than the lattice numbers where $\sigma$ is dominated by the $8 \%$ uncertainty from experiment. This situation is an improvement over that before the CLEO measurement [8]. However, it is clear that a more stringent test of QCD would be possible with a smaller experimental error for the $J / \psi \rightarrow \eta_{c} \gamma$ branching fraction and this may become possible with BES III although it is a challenging mode [34, 35].

Our value for $V(0)$ corresponds to a width for $J / \psi \rightarrow$ $\gamma \eta_{c}$ of $2.49(18)(7) \mathrm{keV}$ using eq. (14). The first error is from our result and the second from the experimental error in $|\vec{q}|$. Note that in using eq. (14) we put in the experimental masses for the $J / \psi$ and $\eta_{c}$. This is appropriate because these factors are kinematic ones and therefore should be taken to match the experiment. What we calculate in lattice QCD is $V(0)$. In fact, as discussed above, we have good agreement between our results and experiment for $M_{J / \psi}-M_{\eta_{c}}$ and so the kinematic factors would also be correct from lattice QCD. However, extra uncertainty would be introduced by using the lattice QCD results and that is not necessary or appropriate. Our result for the decay width corresponds to a branching fraction for $J / \psi \rightarrow \eta_{c}$ of $2.68(19)(11) \%$, where the first error is from our calculation and the second from experiment, including the experimental width of the $J / \psi$.

Figures 2,3 and 7, which show our results as a function of lattice spacing, confirm that discretisation errors are small (although visible) for the HISQ formalism and that
the approach to the continuum limit is well-controlled. This is discussed further in Appendix C where we compare the dependence on lattice spacing to that for twisted mass quarks 10.

## V. CONCLUSIONS

We have given results for 3 key quantities associated with the $J / \psi$ meson from lattice QCD, for the first time including the effect of all three $u, d$ and $s$ quarks in the sea. The quantities are the mass difference with its pseudoscalar partner, the $\eta_{c}$ meson, the decay constant and the vector form factor at $q^{2}=0$ for $J / \psi \rightarrow \eta_{c}$ decay.

Our first key result is for the $J / \psi$ decay constant. We obtain:

$$
\begin{equation*}
f_{J / \psi}=405(6) \mathrm{MeV} \tag{29}
\end{equation*}
$$

leading to $\Gamma\left(J / \psi \rightarrow e^{+} e^{-}\right)=5.48(16) \mathrm{keV}$. This is to be compared to the experimental result of $\Gamma\left(J / \psi \rightarrow e^{+} e^{-}\right)$ $=5.55(14) \mathrm{keV}$ [7]. We have therefore achieved a $4 \%$ test of lattice QCD from an electromagnetic decay rate (a $2 \%$ test from the decay constant), that does not suffer from CKM uncertainties. This is itself a stringent test of QCD and one for which lattice QCD is absolutely necessary; $f_{J / \psi}$ could not be calculated this accurately with any other method. At the same time we are able to verify that the time-moments of the $J / \psi$ correlator agree as they should with results for the charm contribution to $\sigma\left(e^{+} e^{-} \rightarrow\right.$ hadrons $)$ extracted from experiment. This is a test of QCD to better than $1.5 \%$.

Our $f_{J / \psi}$ result is a critically important test for our calculations that determine the decay constants of the $D_{s}$ [2, 36] and the $D$ [36, 37] to a similar level of precision. In particular it tests the HISQ formalism for $c$ quarks [11] even more stringently than in the $D$ and $D_{s}$ cases because the $J / \psi$ contains two $c$ quarks and is a smaller meson, more sensitive to discretisation effects on the lattice. Combined with our earlier work on using the HISQ formalism for light quarks in $f_{\pi}$ and $f_{K}$ [13, 36, 38], our result for $f_{J / \psi}$ provides compelling evidence that we have the systematic errors in $f_{D_{s}}$ and $f_{D}$ under control.

We can improve our result for $f_{J / \psi}$ further in future by using the vector form factor method of renormalisation rather than the current-current correlator method. This will only be useful if improved experimental results become available. This is expected from BESIII [35].

A further test of QCD/Lattice QCD comes from the $J / \psi$ mass. We find:

$$
\begin{equation*}
M_{J / \psi}-M_{\eta_{c}}=116.5 \pm 3.2 \mathrm{MeV} \tag{30}
\end{equation*}
$$

giving $M_{J / \psi}=3.0975(32)(11) \mathrm{GeV}$ where the second error comes from the experimental average for $M_{\eta_{c}}$ [7]. Experiment gives $M_{J / \psi}=3.0969 \mathrm{GeV}$. This is another strong test of lattice QCD, and indeed QCD, against experiment to be compared to that of the determination
of $M_{D_{s}}$ [2] and $M_{D}$ [3]. The hyperfine splitting is a relatively small relativistic correction in the broader context of charmonium meson masses and the fact that we can do this well (with no free parameters) is because the HISQ formalism is such a highly improved relativistic formalism. This is underlined by a study of the meson dispersion relation (and associated 'speed of light') in Appendix C. In fact our error on $M_{J / \psi}$ is dominated by uncertainties from the effect of annihilation of the $\eta_{c}$ meson to gluons, and it is important to pin these down more accurately.

Our third result for the $J / \psi$ is that for its M1 radiative decay mode to the $\eta_{c}$. We find:

$$
\begin{equation*}
\Gamma\left(J / \psi \rightarrow \gamma \eta_{c}\right)=2.49 \pm 0.19 \mathrm{keV} \tag{31}
\end{equation*}
$$

to be compared to the current experimental value of $1.84(30) \mathrm{keV}$ [26]. The agreement is reasonably good, but the experimental error is large and the lattice QCD result would allow a much stronger test of QCD if this were reduced. This should be possible at BESIII 34]. Since the error in our lattice QCD result is dominated by the continuum extrapolation it will be improved in calculations on superfine and ultrafine lattices as we have done for the decay constant, and $2 \%$ errors should also be achievable here. Again, this is only possible in lattice QCD.

The $J / \psi \rightarrow \gamma \eta_{c}$ decay rate is another test of QCD , along with our leptonic decay constant, that is free of CKM uncertainties. It provides a validation of semileptonic decay rate calculations for $D$ and $D_{s}$ mesons 39 43, that also use HISQ quarks as well as a test of our techniques for nonperturbative current renormalisation that we are using for a range of semileptonic and radiative decays 41-43].

FIG. 11: Difference in mass in MeV for different meson 'tastes' for the $\eta_{c}$ and $J / \psi$ used here, plotted against the square of the lattice spacing. Red open circles show the mass difference between the local non-Goldstone and goldstone $\eta_{c}$ mesons. For the vector we have the mass difference between the local $J / \psi$ meson and the 1 -link $\gamma_{i} \otimes \gamma_{i} \gamma_{j}$ vector (blue crosses) and the 1 -link $\gamma_{0} \gamma_{i} \otimes \gamma_{0} \gamma_{i} \gamma_{j}$ vector (blue open triangles). The local $J / \psi$ meson is the lighter in both cases. Results are for sets 1, 2 and 4 from Tables II and VI Errors are statistical.

## Appendix A: Taste effects in staggered mesons

Each staggered meson comes in 16 different tastes, most easily seen in terms of naive quark operators made with different point splittings:

$$
\begin{equation*}
J_{n}^{(s)}=\bar{\psi}(x) \gamma_{n} \psi(x+s) \tag{A1}
\end{equation*}
$$

Here $s$ is a 4-dimensional vector with 0 or 1 in each component. The different $J_{n}^{(s)}$ operators are orthogonal to each other. To work out the corresponding staggered quark correlators we need the staggering matrix, $\Omega(x)$. In our convention this is:

$$
\begin{equation*}
\Omega(x)=\prod_{\mu=1}^{4}\left(\gamma_{\mu}\right)^{x_{\mu}} \tag{A2}
\end{equation*}
$$

with $\gamma_{4} \equiv \gamma_{0}$. Then the connection between naive quark propagators, which carry a spin index, and staggered quark propagators, which do not, is:

$$
\begin{equation*}
S_{F}(x, y) \equiv\langle\psi(x) \bar{\psi}(y)\rangle_{\psi}=g(x, y) \Omega(x) \Omega^{\dagger}(y) \tag{A3}
\end{equation*}
$$

To work out the phases that appear in the correlator of a particular taste we then simply have to calculate spin traces over products of $\Omega$ and $\gamma_{n}$ factors, see, for example, 11].

Here we use two different tastes for the $\eta_{c}$ and three for the $J / \psi$ and they all have slightly different masses. The mass differences between the different tastes of a

TABLE VII: The perturbative series 45-49 for the ratio $r_{n+2}^{P} / r_{n}^{V}$ for different moments, $n$, in continuum QCD perturbation theory. $c_{n}^{(i)}$ is the coefficient of $\alpha \frac{i}{M S}(\mu=m) ; c_{n}^{(0)}$ is 1.0 for all cases, by definition. $c_{n}^{(i)}$ for $i>3$ were included in the determination of $Z$, allowing for a coefficient of $0.0 \pm 0.5$.
given meson, however, vanish as $\alpha_{s}^{2} a^{2}$. For the $\eta_{c}$ we use the Goldstone meson (in spin-taste notation this is the $\gamma_{5} \otimes \gamma_{5}$ meson) and the local non-Goldstone meson (the $\gamma_{0} \gamma_{5} \otimes \gamma_{0} \gamma_{5}$ meson), which are the first two mesons on the ladder of pseudoscalar tastes. We show the mass difference between them in Figure 11 for coarse and fine lattices. The mass difference amounts on the coarse lattices to a little less than 10 MeV (for a 3 GeV particle) and clearly falls with $a^{2}$ as expected. For the $J / \psi$ we use the local vector $\left(\gamma_{i} \otimes \gamma_{i}\right)$ and two 1-link operators which have a point-splitting in an orthogonal direction to the polarisation $\left(\gamma_{i} \otimes \gamma_{i} \gamma_{j}\right.$ and $\left.\gamma_{0} \gamma_{i} \otimes \gamma_{i} \gamma_{j}\right)$. Note that these are not taste-singlet vectors. The mass difference between tastes for mesons of other $J^{P C}$ is typically much smaller than for pseudoscalars and that is clear here. Figure 11 shows that the mass difference for the vectors is $1-2 \mathrm{MeV}$ on the coarse lattices and not resolvable on the fine lattices.

In Section III C we showed results for $J / \psi \rightarrow \gamma \eta_{c}$ using different tastes of $J / \psi$ and $\eta_{c}$ at the two ends of the 3point function. No difference was seen in the vector form factor at $q^{2}=0$ in the two cases, either on the coarse or fine lattices (within our statistical errors of $2 \%$ ). This is another demonstration that taste effects are very small with HISQ quarks.

## Appendix B: Determining nonperturbative $Z$ factors for local vector currents

## 1. The current-current renormalization method

Time-moments of lattice QCD correlators for zeromomentum heavyonium mesons can be compared very accurately 50 to continuum QCD perturbation theory [45-49] developed for the analysis of the $e^{+} e^{-}$annihilation cross-section. This has been used with pseudoscalar meson correlators made with HISQ quarks to extract $c$ and $b$ masses and $\alpha_{s}$ to better than $1 \%$ [51. These results used the goldstone pseudoscalar correlator, which is absolutely normalised because of the HISQ PCAC relation. Here we apply the same techniques to vector meson correlators but use it to determine the renormalisation factor, $Z$, required for the lattice vector current to match the continuum current.

The time moments of our lattice QCD correlators are

| Set $m_{c} a$ | $Z(4)=Z_{c c} Z(6)$ | $Z(8)$ |  |  |
| :--- | :--- | :--- | :--- | :--- |
| 1 | 0.622 | $0.979(12)$ | $0.945(14)$ | $0.927(17)$ |
| 2 | 0.63 | $0.979(12)$ | $0.945(14)$ | $0.926(17)$ |
| 2 | 0.66 | $0.974(12)$ | $0.941(14)$ | $0.921(17)$ |
| 4 | 0.413 | $0.983(12)$ | $0.953(14)$ | $0.953(17)$ |
| 5 | 0.273 | $0.986(12)$ | $0.970(14)$ | $0.975(18)$ |
| 6 | 0.193 | $0.990(12)$ | $0.982(14)$ | $0.986(18)$ |

TABLE VIII: Renormalisation constants determined from the current-current correlator method on each configuration set used for the determination of $f_{J / \psi}$. The $Z$ value we use is that from moment 4. The errors include an estimate of effects from a gluon condensate contribution, and unknown fourth order and higher terms in continuum perturbation theory. The errors are highly correlated between configuration sets (to better than $1 \%$ of the error). For set 2 we include both the tuned value of $a m_{c}(0.63)$ and the heavier, detuned, value ( 0.66 ). Very little difference is seen between them.
defined as:

$$
\begin{equation*}
C_{n}^{V}=\sum_{\tilde{t}} \tilde{t}^{n} \bar{C}_{J / \psi}(\tilde{t}) \tag{B1}
\end{equation*}
$$

and

$$
\begin{equation*}
C_{n}^{P}=\sum_{\tilde{t}} \tilde{t}^{n}\left(a m_{c}\right)^{2} \bar{C}_{\eta_{c}}(\tilde{t}) \tag{B2}
\end{equation*}
$$

where $\tilde{t}$ is a symmetrised version of $t$ around the centre of the lattice, i.e. going forward in time, $\tilde{t}$ runs from 0 to $L_{t} / 2$ and then from $-L_{t} / 2+1$ to -1 . The extra factor of $\left(a m_{c}\right)^{2}$ in the pseudoscalar case is to make a correlator moment which is finite as $a \rightarrow 0$. For both correlators we expect the small $n$ moments to behave perturbatively, since they probe small times. Then our match to continuum perturbation theory is:

$$
\begin{equation*}
C_{n}^{P}=\frac{g_{n}^{P}\left(\alpha_{\overline{M S}}(\mu), \mu / m_{c}\right)}{\left(a m_{c}(\mu)\right)^{n-4}}+\mathcal{O}\left(\left(a m_{c}\right)^{m}\right) \tag{B3}
\end{equation*}
$$

where $g_{n}$ is the continuum QCD perturbation theory series in the $\overline{M S}$ scheme [45]49]. For the vector correlator a $Z$ factor is needed to multiply the lattice current and so:

$$
\begin{equation*}
C_{n}^{V}=\frac{1}{Z^{2}} \frac{g_{n}^{V}\left(\alpha_{\overline{M S}}(\mu), \mu / m_{c}\right)}{\left(a m_{c}(\mu)\right)^{n-2}}+\mathcal{O}\left(\left(a m_{c}\right)^{m}\right) \tag{B4}
\end{equation*}
$$

$Z$ is then a function of the bare lattice strong coupling constant at each lattice spacing and so this match must be performed separately on each ensemble. By taking the ratio of pseudoscalar and vector moments we can cancel the factors of the quark mass. In fact we also divide each moment by its tree-level value (calculated with the gluon fields set to 1) to reduce discretisation errors, i.e. instead of $C_{n}$ we use $R_{n}$ where

$$
\begin{equation*}
R_{n}=\frac{C_{n}}{C_{n}^{(0)}} \tag{B5}
\end{equation*}
$$

and also take the same ratio, calling it $r_{n}$, in the continuum perturbation theory. Finally $Z$ is given by:

$$
\begin{equation*}
Z(n)=\sqrt{\frac{R_{n+2}^{P} / R_{n}^{V}}{r_{n+2}^{P} / r_{n}^{V}}} \tag{B6}
\end{equation*}
$$

Table VII gives the perturbative coefficients for the series in $\alpha_{\overline{M S}}(m)$ for $r_{n+2}^{P} / r_{n}^{V}$. This is known to 4loops $\left(\alpha_{s}^{3}\right)$ and we include the possibility of unknown higher order terms (to 20th order) with prior values for the coefficients of $0 \pm 0.5$. We take $\mu=m$ but including the possibility of higher order corrections means that the results are almost completely insensitive to $\mu$. We also allow for gluon condensate contributions taking $\alpha_{s} G^{2} / \pi=0 \pm 0.012 \mathrm{GeV}^{4}$. This increases the errors on the determination of the $Z$ values as $n$ increases.

Table VIII gives the results for $Z$ on each ensemble and for moments 4,6 and 8 . The differences between the $Z$ values on a given ensemble arise from discretisation errors. We take our final result for use in section IIIB from moment 4 (and so these numbers are reproduced in Table II) since, even though discretisation errors fall as the moment number increases, the errors from the gluon condensate rise more steeply. The error in $Z(4)$ is around $1 \%$. It is dominated by the uncertainty in higher orders in perturbation theory and so strongly correlated from one lattice spacing to the next. We have checked that we obtain the same final result for $f_{\psi}$ using $\mathrm{Z}(6)$ (but with an error of $1.6 \%$ rather than $1.4 \%$ ).

## 2. The vector form factor method

Vector currents can be normalised completely nonperturbatively by requiring that the vector form factor at $q^{2}=0$ between two identical mesons be 1 since this would be true for a conserved vector current. We use this to normalise the staggered taste-singlet 1-link vector current between two mesons made of staggered quarks in 41. Here, however, we want to normalise the tastenonsinglet local staggered vector current, and we cannot do this using a 3-point function made entirely of staggered quarks. We have to include a non-staggered (and non-doubling) spectator quark in order to remove the requirement for overall taste-cancellation in the 3-point function 52. The Fermilab Lattice/MILC collaboration use this method [53] with a clover spectator quark to normalise a light staggered vector current for the nonperturbative part of their mixed perturbative/nonperturbative approach to normalising the clover-staggered operators for heavy-light meson decay constants. Here we use an NRQCD spectator quark to normalise the local charm staggered vector current. In fact we can use any NRQCDlike action for the spectator since it does not need to correspond to a physical quark. However, for simplicity we do use the NRQCD action developed for our NRQCDlight spectrum calculations [3].

To combine an NRQCD (or other non-staggered) quark with a staggered quark we convert it to a naive quark 52],

FIG. 12: The ratio of the 3 -point function for the ' $B_{c}$ ' to ' $B_{c}$ ' vector form factor to the ' $B_{c}$ ' 2 -point function against the source-current separation, $t / a$. The top plot shows results for $m_{b} a=2.0$ on fine lattices, set 4 , for various values of $T$. Lines join the points for clarity. The shaded red band gives our fit result for the ground state matrix element. The lower plot shows results, also on set 4 , for two different values of $m_{b} a$. The shaded red and blue bands show the fit results for the ground state matrix elements.
re-instating the spin degree of freedom as in eq. A3). A pseudoscalar meson correlator which, with two idential quarks, would simply be the sum over spins and colors of the squared modulus of the propagator, becomes in this case:

$$
\begin{equation*}
C_{Q q}(t)=\sum_{\vec{x}, \vec{y}} \operatorname{Tr}\left\{G(x, y) \Omega(y) g^{\dagger}(x, y) \Omega^{\dagger}(x)\right\} \tag{B7}
\end{equation*}
$$

The trace is over spin and color but separates since the staggered propagator, $g(x, y)$, has no spin and $\Omega$ no color. Then:

$$
\begin{equation*}
C_{Q q}(t)=\sum_{\vec{x}, \vec{y}} \operatorname{Tr}_{c}\left\{\operatorname{Tr}_{s}\left[\Omega^{\dagger}(x) G(x, y) \Omega(y)\right] g^{\dagger}(x, y)\right\} \tag{B8}
\end{equation*}
$$

This makes clear that we can transfer the $\Omega$ matrices to the non-staggered quark propagator, $G(x, y)$, and this allows us, as shown in [14, to combine staggered and nonstaggered quarks from random wall sources. We simply
make the source of the non-staggered quark the product of $\Omega(y)$ (where $y$ runs over a time slice at the source) with the random number at each $y$ value in the random wall, convoluted with smearing functions if required. At the sink we multiply by $\Omega^{\dagger}$ before tracing over spins to combine with the spinless staggered quark propagator. Here we develop this method further for 3-point functions.

For the matrix element of the temporal charm-charm vector current between identical charmed pseudoscalar mesons, at rest, we have:

$$
\begin{equation*}
\left\langle P_{c}\right| V_{t}\left|P_{c}\right\rangle=2 m_{P_{c}} f_{+}(0) \tag{B9}
\end{equation*}
$$

and we can demand that $f_{+}(0)=1$, i.e. we can multiply the left-hand-side by $Z$ to make this true. The temporal component of the vector current is the easiest to use for this purpose although the spatial component of the vector current is the one that we use for $J / \psi \rightarrow \eta_{c}$ decay. For a relativistic action such as HISQ the renormalisation of the spatial and temporal components will be the same up to discretisation errors.

For the 3 -point function needed to evaluate the matrix element above we use an NRQCD heavy quark propagating from 0 to $T$ and HISQ charm quarks from 0 to $t$ and $T$ to $t$ (see Fig. 5). The local staggered temporal vector current $\left(\gamma_{0} \otimes \gamma_{0}\right.$ in spin-taste notation) is inserted at $t$ and the restriction for staggered 3-point functions of an overall tasteless correlator is avoided by the spin content of the NRQCD propagator.

The 3-point function is given by:

$$
\begin{align*}
& C_{3 p t}(0, t, T)=\sum_{s_{T}, s_{t}}(-1)^{x_{T}+y_{T}+z_{T}+t_{T}}(-1)^{t_{t}}(\mathrm{~B}  \tag{B10}\\
& \times \operatorname{Tr}_{\mathrm{c}}\left\{g(t, T) \operatorname{Tr}_{\mathrm{s}}\left[\gamma_{0} \Omega^{\dagger}(T) G(T, 0) \Omega(0)\right] g^{\dagger}(t, 0)\right\}
\end{align*}
$$

The $g$ are HISQ $c$ propagators and $G$ is an NRQCD heavy quark propagator. The $\gamma_{0}$ factor comes from the local temporal vector current. The 3-point function is therefore calculated in a very similar way to the 2 -point function. $\Omega(x)$ multiplied by the random wall at the source time slice, 0 , is used as the source for the NRQCD propagator. At time T this is multiplied by $\Omega^{\dagger}$ and $\gamma_{0}$, source and sink spins are set equal and summed over. This is then the source for the HISQ propagator from $T$ to $t$ which is finally combined with the HISQ propagator generated from the random wall at time slice 0 .

We calculate the 2 -point and 3 -point functions described above for several different NRQCD masses, $m_{h} a$, and $c$ quark masses, $m_{c} a$, on the configuration sets 1,2 and 4 . We also use several different values of $T$ so that our fit benefits from both $T$ and $t$ dependence to improve the extraction of the ground-state masses, amplitudes and matrix elements. The 3 -point and 2 -point correlators are fit simultaneously to the forms given in eqs (1) and 25 . We use the same priors as in section III C. Note that for the 3 -point fit we can now impose symmetry under interchange of the mesons at 0 and $T$ since they are the same. This means that the amplitudes $V^{n n}$ and $V^{o o}$ are square symmetric matrices and $V^{n o}=V^{o n}$.

The key quantity that we extract from the fit is the ground state matrix element $V_{00}^{n n}$. This is proportional to the vector matrix element on the left-hand-side of eq. (B9). We can work out the constant of proportionality by matching our fit equations, eq (25) and (1) to the form expected by inserting a complete set of states in a continuum 3-point function. In this case factors of the mass of the meson ${ }^{4}$ cancel and we find $V_{00}^{n n}=f_{+}(0)$. Then the renormalisation factor we need is given by:

$$
\begin{equation*}
Z=\frac{1}{V_{00}^{n n}} \tag{B11}
\end{equation*}
$$

The results for $Z$ are taken from fits with 5 normal and 4 oscillating exponentials and given in Table IX. We obtain very precise results for $Z$, with errors of $0.1 \%$, without even using the full statistics available for each ensemble. The values are much more precise, for example, than for the implementation given in 53] (although their values are for light quarks rather than charm).

Figure 12 shows the quality of our results through plots of the ratio of the 3 -point to the 2 -point function. Note that we fit the 3 -point and 2 -point functions simultaneously and not just the ratio. It is convenient to plot the ratio, however, because the ground state contribution to this is simply $V_{00}^{n n}$. Our fit allows us to include the effect of excited states, both normal states and oscillating states. The presence of oscillating states is evident in the plots. The upper plot of Figure 12 compares results at different $T$ values. All are included in the simultaneous fit. The lower plot shows results at different values of $m_{h} a$ for a given $m_{c} a$.

The vector form factor method for determining $Z$ is completely nonperturbative. It will therefore be subject to errors coming from lattice QCD in the form of discretisation errors. These mean, for example, that the $Z$ factor at a particular value of the lattice spacing is not completely independent of the mass of the NRQCD spectator quark. From our results in Table IX we see that changing $m_{h} a$ from 2.8 to 1.5 on coarse set 2 (corresponding to change of almost a factor of two) causes a $2 \%$ change in $Z$. On fine set 4 the sensitivity is reduced to a change of $0.2 \%$, not significant within our statistical errors, when $m_{h} a$ is changed from 2.0 to 1.5 , a change in mass of $30 \%$. Since the change in lattice spacing between the coarse and fine sets is a factor of 1.4 , pairs of $a m_{h}$ values on coarse and fine lattices that correspond to approximately the same physical mass are $(2.8,2.0)$ and $(2.0,1.5)$. We will take our central result for $Z_{f f}$ from the $Z$ values corresponding to using $(2.0,1.5)$ and use $(2.8,2.0)$ to check systematic errors coming from $Z$. We see in section III C that we get the same answer from both sets of $Z$ values.

TABLE IX: The $Z$ factors (column 9) obtained from the vector form factor method on different configurations sets (column 1) and for different NRQCD quark masses, $m_{h} a$ (column 4), and $c$ quark masses, $m_{c} a$ (column 5) with $\epsilon$ factor (column 6). The $m_{c} a$ values are those used in our calculation of $J / \psi \rightarrow \eta_{c} \gamma$ described in section III C; the $m_{h} a$ values are arbitrary since they correspond to the spectator quark. $Z$ is given by the inverse of the fit parameter $V_{00}^{n n}$ given in column 8. Column 2 gives the number of configurations used in the calculation and the number of time sources for the origin, 0 . The $T$ values used are given in column 3. Column 7 gives the energy of the NRQCD-c meson obtained from the fit. This is not equal to the mass because there is an energy offset in NRQCD.

|  |  |  | $0.9873(7)$ |  |  |

TABLE X: Rest masses $\left(a M_{\eta_{c}}\right)$ and energies $\left(a E_{\eta_{c}}\right)$ at nonzero momentum $|a \vec{p}|$ for the Goldstone $\eta_{c}$ meson on sets 2 (coarse) and 4 (fine). The rest masses differ slightly from those in Table II because they come from independent fits; on set 4 we have higher statistics here. The zero and nonzero momentum correlator are fitted simultaneously and the speed of light, $c^{2}$, extracted using eq. (C1).

Table IX also shows results for the deliberately mistuned $c$ quark mass of 0.66 on set 2 with which we test the $c$ quark mass dependence of our $J / \psi \rightarrow \eta_{c}$ form factor. A barely significant change in $Z$ is seen between this value and that for the tuned mass of 0.63 . We also see no significant difference in $Z$ as we change the sea light quark masses between set 1 and set 2 .

Discretisation errors also mean that our results for $Z_{f f}$ here do not have to agree exactly with our earlier results for $Z_{c c}$. $Z_{c c}$ has a much larger error coming from unknown higher order terms in continuum perturbation theory. As a result of this, $Z_{f f}$ and $Z_{c c}$ do agree at the level of $1 \sigma$. They also agree within errors with the lattice QCD perturbation theory for this renormalisation, which has a small negative contribution at $\mathcal{O}\left(\alpha_{s}\right)$ 54.

The $Z$ values calculated here form part of a programme to normalise nonperturbatively a range of staggered currents for a variety of weak semileptonic and electromagnetic radiative decay rates 42].

## Appendix C: Discretisation errors

Finally we discuss discretisation errors. For relativistic formalisms the scale of discretisation errors can be set by the quark mass when this is larger than $\Lambda_{Q C D}$ and

FIG. 13: The 'speed-of-light', $c^{2}$, calculated from zero and finite momentum $\eta_{c}$ correlators using HISQ $c$ quarks. The top figure shows $c^{2}$ as a function of the square of the spatial momentum for coarse lattices, set 2 , where $m_{c} a=0.63$ (grey open circles) and for fine lattices, set 4 , where $m_{c} a=0.413$ (pink crosses). The lower figure shows the resulting values of $c^{2}$ as $\vec{p}^{2} a^{2} \rightarrow 0$ as a function of $\left(m_{c} a\right)^{2}$. The dashed straight line is drawn to guide the eye.

FIG. 14: The rest (static) and kinetic masses for the $\eta_{c}$ meson compared between the HISQ formalism (this paper) and the twisted mass formalism (Figure 3 from [10), and plotted against the square of the lattice spacing. The rest mass is given by open circles and the kinetic mass by open triangles, red for twisted mass and blue for HISQ. Errors include the full lattice spacing error on each point.

FIG. 15: $\quad R_{J / \psi}-1$ plotted against $a^{2}$ in $\mathrm{fm}^{2}$ for three different quark formalisms for the $c$ quark: HISQ (this paper, blue open circles), twisted mass (10], red open squares) and Fermilab clover ([29], green open triangles, showing results on the two finest lattices only). $R_{J / \psi}$ is $M_{J / \psi} / M_{\eta_{c}}$ so $R_{J / \psi}-1=\Delta M_{h y p} / M_{\eta_{c}}$. For the twisted mass and Fermilab clover results the heaviest and lightest sea quark masses are plotted at each value of the lattice spacing. Only statistical errors are shown. Additional errors from (twice) the lattice spacing error amount to $2 \%$ for HISQ and Fermilab clover and $4-7 \%$ for twisted mass. The black cross is the experimental average [7], offset slightly from the origin for clarity.

FIG. 16: $\quad f_{J / \psi}$ in GeV is plotted against $a^{2}$ in $\mathrm{fm}^{2}$ for the HISQ formalism (this paper, blue open circles) and for twisted mass ( 10 , red open squares). For the twisted mass case the heaviest and lightest sea quark masses are plotted at each value of the lattice spacing. Only statistical errors are shown for the twisted mass results. For the HISQ results we show the raw data from Table II with statistical and uncorrelated lattice spacing errors. There is an additional error of $1.3 \%$ from correlated lattice spacing and $Z$ factor uncertainties. The black cross is the experimental result from the average leptonic width [7], offset slightly from the origin for clarity.

FIG. 17: The vector form factor for $J / \psi \rightarrow \eta_{c}$ decay at $q^{2}=0, V(0)$, is plotted against $a^{2}$ in $\mathrm{fm}^{2}$ for the HISQ formalism (this paper, jpsigamma0 method, blue open circles) and for twisted mass ( 10 , red open squares). For the twisted mass case the heaviest and lightest sea quark masses are plotted at each value of the lattice spacing. Errors include statistical errors and uncertainties in the $Z$ factors. The black cross is the experimental result from the rate for $J / \psi \rightarrow \eta_{c} \gamma$ decay [26], offset slightly from the origin for clarity.
so they must be monitored closely when working with $c$ quarks.

One simple way to do this is through study of the energy of mesons at non-zero spatial momentum. Because the HISQ formalism is a relativistic formalism we determine meson masses as the result of fitting zeromomentum meson correlators as described in section II, For heavy quarks discretisation errors mean that this mass, known as the 'rest' or 'static' mass, can differ from the mass that controls the momentum-dependence of the energy at non-zero spatial momentum. This latter mass is known as the 'kinetic mass'. An equivalent statement is that the square of the speed-of-light, $c^{2}$, differs from 1 , where [11]

$$
\begin{equation*}
c^{2}(\vec{p})=\frac{E^{2}(\vec{p})-m^{2}}{\vec{p}^{2}} \tag{C1}
\end{equation*}
$$

For $\eta_{c}$ mesons we are able to determine $c^{2}$ very accurately with HISQ quarks when we have $\mathcal{O}(10,000)$ correlators as here. We fit zero and non-zero momentum simultaneously to the form given in eq. (1) (although the zero momentum correlators have no oscillating component). From the fit we obtain the ground state mass, $M_{0}$, in the zero momentum case and the ground state energy, $E_{0}$, in the non-zero momentum case. The simultaneous fit allows us to take correlations into account to improve the error in $c^{2}$. Results are given in Table X, $c^{2}$ is within $3 \%$ of 1 but we can distinguish it from 1 and we can see that it depends on the spatial momentum. This is shown in the top plot of Figure 13 for the coarse lattices, set 2, and the fine lattices, set 4. All tree-level $a^{2}$ errors are removed in HISQ but $c^{2}$ can depend linearly on $a^{2} \vec{p}^{2}$ through $\mathcal{O}\left(\alpha_{s}\right)$ corrections. We see that the slope of $c^{2}$ with $a^{2} \vec{p}^{2}$ is much smaller on the fine lattices than the coarse, as $m_{c} a$ is reduced. This plot can be compared with earlier results in Figure 9 of [55], although note that those results show a jump as the lattice momentum changes from $(1,1,1)$ to $(2,0,0)$. This results from a rotationally-noninvariant discretisation error not evident in our results because of the use of the phased boundary condition of eq. 16) to fix the momentum direction and simply change its magnitude.

From the top plot of Figure 13 we can determine the value of $c^{2}$ at $a^{2} \vec{p}^{2}=0$. The results from the coarse and fine lattices are then shown in the lower plot to lie on a straight line as a function of $\left(m_{c} a\right)^{2}$. The small slope is compatible with the $\left(m_{c} a\right)^{2}$ dependence also being an $\mathcal{O}\left(\alpha_{s}\right)$ effect. The straight line clearly goes through 1 as $m_{c} a \rightarrow 0$ as it must.

Another way to look at these discretisation errors is to compare the rest and kinetic masses for the $\eta_{c}$. The kinetic mass is given by 56]:

$$
\begin{equation*}
M_{k i n}=\frac{|\vec{p}|^{2}-(\Delta E)^{2}}{2 \Delta E} \tag{C2}
\end{equation*}
$$

where $\Delta E=E(\vec{p})-M_{\text {rest }}$. We also have $c^{2}=$ $M_{\text {rest }} / M_{k i n}$ 11. In the absence of errors, for a relativistic formalism, we should have $M_{\text {rest }}=M_{\text {kin }}$ (i.e. $c^{2}=1$ ).

In Figure 14 we compare the rest and kinetic masses for HISQ $\eta_{c}$ mesons using $M_{\text {kin }}=M_{\text {rest }} /\left(c^{2}\left(\vec{p}^{2}=0\right)\right)$ determined from Figure 13 . The rest and kinetic masses differ by $3 \%$ on the coarse lattices and $1.3 \%$ on the fine lattices.

Figure 14 also compares results from the twisted mass formalism, from [10]. For that formalism there is a significantly larger difference between rest and kinetic masses for the $\eta_{c}$ meson, amounting to $35 \%$ on the coarsest lattice spacing. The twisted mass formalism has tree-level $a^{2}$ errors, so a larger effect would be expected. The rest and kinetic masses agree in the continuum limit, as they must.

Figure 15 compares the hyperfine splitting in charmonium in units of the $\eta_{c}$ mass as a function of the square of the lattice spacing for the HISQ and twisted mass formalisms. The quantity plotted is $R_{J / \psi}-1$ where $R_{J / \psi}$ is defined in [10 as $M_{J / \psi} / M_{\eta_{c}}$ and results are given on each of their ensembles. The HISQ results are taken from Table II. We also show results from the Fermilab clover method [29] on their two finest sets of ensembles which correspond to the coarse and fine lattices used here.

All the results tend to the same continuum value which agrees with experiment. Much larger discretisation effects are visible for the twisted mass formalism than for HISQ. These are compatible with the tree level $a^{2}$ errors expected in that formalism, and with a mass scale of approximately 2 GeV (i.e. $m_{c}$ ). These tree level errors are removed in the HISQ formalism, but $\alpha_{s} a^{2}$ errors remain. These seem to be small for this quantity. The Fermilab clover discretisation errors, although in principle $\alpha_{s} a$, are also relatively small over this range of $a$.

Discretisation effects in the hyperfine splitting can also enter through tuning of the $c$ quark mass, because the hyperfine splitting is very sensitive to this. As discussed earlier in this section, there can be significant differences between rest and kinetic masses for mesons made of heavy quarks, and either can be used to tune the quark mass. Both relativistic formalisms, HISQ and twisted mass, use the rest mass. The Fermilab formalism uses the kinetic mass.

For $f_{J / \psi}$ the difference in discretisation effects between the HISQ and twisted mass formalisms is not as large. This is shown in Figure 16. Again, answers in agreement are obtained in the continuum limit. For the moments of the vector correlator our results for $G_{4}^{V}$ (Fig 4), which show very little dependence on the lattice spacing, can be compared to those for the twisted mass formalism in [57, where somewhat larger discretisation effects are visible.

Finally in Figure 17 we compare results for the vector form factor for $J / \psi \rightarrow \eta_{c}$ decay, $V(0)$. Large discretisation effects are evident in the twisted mass results. Once again discretisation effects in the HISQ results are small. Agreement in the continuum limit is again clear, however.

The HISQ results shown here give a further and more testing demonstration than that of [11, 36] of how small the discretisation errors for the HISQ action are, even for a quark as heavy as charm.

#### Abstract

We determine the strange quark condensate from lattice QCD for the first time and compare its value to that of the light quark and chiral condensates. The results come from a direct calculation of the expectation value of the trace of the quark propagator followed by subtraction of the appropriate perturbative contribution, derived here, to convert the non-normal-ordered $m \bar{\psi} \psi$ to the $\overline{M S}$ scheme at a fixed scale. This is then a well-defined physical 'nonperturbative' condensate that can be used in the Operator Product Expansion of current-current correlators. The perturbative subtraction is calculated through $\mathcal{O}\left(\alpha_{s}\right)$ and estimates of higher order terms are included through fitting results at multiple lattice spacing values. The gluon field configurations used are 'second generation' ensembles from the MILC collaboration that include $2+1+1$ flavors of sea quarks implemented with the Highly Improved Staggered Quark action and including $u / d$ sea quarks down to physical masses. Our results are : $\langle\bar{s} s\rangle^{\overline{M S}}(2 \mathrm{GeV})=-(290(15) \mathrm{MeV})^{3},\langle\bar{l} l\rangle^{\overline{M S}}(2 \mathrm{GeV})=-(283(2) \mathrm{MeV})^{3}$, where $l$ is a light quark with mass equal to the average of the $u$ and $d$ quarks. The strange to light quark condensate ratio is $1.08(16)$. The light quark condensate is significantly larger than the chiral condensate in line with expectations from chiral analyses. We discuss the implications of these results for other calculations.

## I. INTRODUCTION

A critical feature of the nonperturbative dynamics of QCD at zero temperature is the condensation of quarkantiquark pairs in the vacuum, spontaneously breaking the chiral symmetry of the action. The value of the chiral condensate (the quark condensate at zero quark mass) is then an important parameter for low energy QCD [1]. The well-known Gell-Mann, Oakes, Renner (GMOR) relation [2]:

$$
\begin{equation*}
\frac{f_{\pi}^{2} M_{\pi}^{2}}{4}=-\frac{m_{u}+m_{d}}{2} \frac{\langle 0| \bar{u} u+\bar{d} d|0\rangle}{2} \tag{1}
\end{equation*}
$$

connects the $u / d$ quark masses times condensate to the square of the mass times decay constant for the Goldstone boson of the spontaneously broken symmetry. Eq.(11) has normalisation such that $f_{\pi}=130 \mathrm{MeV}$. The GMOR relation holds in the limit of $m_{u}, m_{d} \rightarrow 0$. A value for this chiral condensate can be derived from the chiral extrapolation of lattice QCD results for light meson masses and decay constants. See, for example, the recent result of $-(272(2) \mathrm{MeV})^{3}$ for the chiral condensate in the $\overline{M S}$ scheme at 2 GeV using $\mathrm{SU}(2)$ chiral perturbation theory 3 .

The determination of the quark condensate for nonzero quark masses is more problematic because, depending on the method used, there are various sources of un-

[^305]physical quark mass dependence and a careful definition of the condensate is required. This definition must be phrased in terms of the Operator Product Expansion (OPE) since this is the context in which the condensate appears [1, 4, 5]. The OPE allows us to separate short and long-distance contributions in, for example, a short-distance current-current correlator. The expansion is in terms of a set of matrix elements of local operators multiplied by coefficient functions. The aim is for all the long-distance contributions (with scale $<\mu$ ) to be contained in the matrix elements and the short distance contributions (with scale $>\mu$ ) in the coefficient functions. A key matrix element, since it corresponds to a relatively low-dimensional $(d=3)$ operator, is that of the quark condensate. The clean separation of scales in the OPE only works if the local operators are not normal ordered [6, 7]. Then the coefficient functions are analytic in the quark masses and therefore free of infrared sensitivity. This means, however, that the quark mass dependent mixing of $m \bar{\psi} \psi$ with the unit operator must be taken into account and that the vacuum matrix element of $m \bar{\psi} \psi$ is not cut-off independent. The quantity that appears in the OPE is the vacuum matrix element in, for example, the $\overline{M S}$ scheme at the scale $\mu$. We can derive this matrix element from lattice QCD and we give results here for $\mu=2 \mathrm{GeV}$. The results can easily be run to other scales, as appropriate.

The value of the condensate for quarks of non-zero mass up to that of the strange quark is needed in a number of calculations involving light quark correlators. In lattice QCD it is frequently easier and statistically more precise to use strange quarks than very light quarks in
contexts where the quark mass is not expected to be important. Then the strange quark condensate appears in the calculation, however. Examples include the matching to continuum QCD perturbation theory of lattice QCD calculations of moments of heavy-light meson correlators [8] and of light meson correlators at large space-like $q^{2}$ 9]. Such calculations are used to extract quark masses and the strong coupling constant, $\alpha_{s}$. A continuum example where the strange quark condensate is needed is in the determination of the strange quark mass, $m_{s}$, from hadronic $\tau$ decays [10].

Current estimates of the value of the strange quark condensate vary by almost a factor of two [11, 12]. It is not even clear whether the strange condensate is larger or smaller than the light quark condensate. For very large quark masses, $m_{q}>\Lambda_{Q C D}$, say, so that the quark mass dominates the propagator, it seems clear that the condensate should fall to zero, but this does not help in determining the slope of the condensate with $m_{q}$ for small quark masses.

Here we address the determination of the strange (or other non-zero mass) quark condensate by direct calculation in full lattice QCD. By direct we mean that we determine the vacuum expectation value of the strange quark propagator as well as the light quark propagator on a range of gluon field configurations at different values of the lattice spacing and sea quark masses. To isolate the low-energy nonperturbative value of the condensate from these results requires the subtraction of a perturbative contribution. The perturbative contribution in lattice QCD has two pieces. One diverges as $a \rightarrow 0$ and dominates the vacuum expectation value of the strange quark propagator, particularly on our finer lattices. The second piece contains infrared sensitive logarithms of the quark mass which cancel against similar terms in continuum perturbation theory allowing an infrared safe definition of the condensate for use in the OPE, as discussed above.

The error in the final result then depends on how well this subtraction can be done. Here we use an explicit calculation of the perturbative pieces through $\mathcal{O}\left(\alpha_{s}\right)$ and fit for unknown higher order terms. The known quark mass and $a$ dependence of these unknown terms helps in constraining them along with the very small statistical errors in our lattice results. We also use a particularly good discretisation of the Dirac action known as the Highly Improved Staggered Quark (HISQ) formalism [13] on 'second generation' gluon field configurations so that discretisation errors in the physical nonperturbative results are small.

The paper is laid out as follows. In Section II we describe the theoretical background to direct calculations of the quark condensate in lattice QCD. Section III gives our lattice QCD results on gluon configurations with $2+1+1$ flavors of sea quarks, describing the calculation of the perturbative contribution that is subtracted and then the procedure for fitting the remaining nonperturbative condensates as a function of quark mass and lattice
spacing. We also give results from configurations including $2+1$ flavors of sea quarks over a wider range of lattice spacing values but studying only the strange quark condensate in Appendix D. In Section IV we compare to previous values and discuss the implications of our results for both zero and finite temperature QCD calculations. Section V gives our conclusions.

## II. THEORETICAL BACKGROUND

The direct determination of the chiral condensate in lattice QCD requires the calculation of the expectation value over an ensemble of gluon fields, $U$, of $\operatorname{Tr} M^{-1}$ where $M$ is the lattice discretisation of the Dirac matrix. The quark action for a given quark flavor,

$$
\begin{equation*}
S_{f}=\bar{\psi} M_{f} \psi \tag{2}
\end{equation*}
$$

and

$$
\begin{equation*}
\langle\bar{\psi} \psi\rangle=\langle 0| \bar{\psi}_{f} \psi_{f}|0\rangle=-\frac{1}{V}\left\langle\operatorname{Tr} M_{f}(U)^{-1}\right\rangle_{U} \tag{3}
\end{equation*}
$$

where the trace is over spin, color and space-time point and the gluon fields in the ensemble used for the average include the effect of sea quarks (of all flavors, not just $f$ ) in their probability distribution. $V$ is the lattice volume, $L^{3} \times T$. For a naive discretisation of the Dirac action $M$ takes the form:

$$
\begin{equation*}
M=\gamma_{\mu} \Delta_{\mu}+m \tag{4}
\end{equation*}
$$

where $\Delta_{\mu}$ is a covariant finite difference on the lattice:

$$
\begin{equation*}
\Delta_{\mu} \psi_{x}=\frac{1}{2 a}\left(U_{\mu}(x) \psi(x+\hat{\mu})-U_{\mu}^{\dagger}(x-\hat{\mu}) \psi(x-\hat{\mu})\right) \tag{5}
\end{equation*}
$$

and $m$ is the quark mass for that flavor. Because of fermion doubling this formalism describes 16 'tastes' of quarks in 4-dimensions rather than just 1 and we must divide the right-hand side of Eq. (3) by the number of tastes, $N_{t}=16$. The staggered formalism is derived from this naive formalism by a rotation which allows the spin degree of freedom to be dropped. In that case the quark field becomes a 1-component spinor, which is numerically very efficient, and $N_{t}=4$.

For $m=0$ the eigenvalues of $M$ for either naive or staggered quarks, are purely imaginary and come in $\pm$ pairs. Therefore, in the absence of exact zero modes,

$$
\begin{align*}
-\langle\bar{\psi} \psi\rangle & =\frac{1}{N_{t}} \sum_{\lambda}\left(\frac{1}{m+i \lambda}+\frac{1}{m-i \lambda}\right) \\
& =\frac{1}{N_{t}} \sum_{\lambda} \frac{2 m}{m^{2}+\lambda^{2}} \tag{6}
\end{align*}
$$

A calculation at $m=0$ on a finite volume lattice would then give an answer for the quark condensate of zero. This does not mean that chiral symmetry is unbroken,
however. The problem arises because the broad distribution of non-zero eigenvalues (ignoring topological nearzero modes) drops to zero near the origin in a way that depends strongly on the volume. Once the quark mass is below the minimum of the non-zero eigenvalues the result for $\langle\bar{\psi} \psi\rangle$ will be distorted. A more careful consideration of limits must be made. If $V$ is taken to infinity before $m$ is taken to zero then the sum over eigenvalues can be replaced by an integral and the Banks-Casher relation 14 is obtained. This connects the zero-mass condensate to the spectral density at the origin:

$$
\begin{equation*}
\Sigma=-\langle\bar{\psi} \psi(m=0)\rangle=\frac{\pi \rho(0)}{N_{t}} \tag{7}
\end{equation*}
$$

Thus $\Sigma$ can be obtained from studies of the spectral density and, more recently, has also been obtained from matching the distribution of low eigenmodes to random matrix theory in the $\epsilon$ regime [15-17]. Here we are more concerned with extracting a condensate at nonzero quark mass, for example at the strange quark mass, and so the issue above is not relevant. We will work on large volume lattices (over ten times larger than the study in [18] that looked at staggered eigenvalues in the $\epsilon$ regime) at quark mass values that are well within the distribution of non-zero eigenvalues. Our results for $\left\langle\operatorname{Tr} M^{-1}\right\rangle$ then include both the effects of a non-zero value for $\rho(0)$ and a non-zero quark mass.

A second issue arises, however, in the extraction of a physical nonperturbative value for the condensate at non-zero quark mass. A perturbative contribution appears from mixing between the scalar $\bar{\psi} \psi$ operator and the identity since the identity operator has a vacuum expectation value in the trivial perturbative vacuum. This perturbative contribution vanishes at zero quark mass since chiral symmetry is not broken in perturbation theory (for the same reason as that given on the lattice above in Eq. (6)). At non-zero quark mass it contains odd powers of $m$ starting with a quadratically ultra-violet divergent term linear in $m$. This can be illustrated with a tree-level calculation in the continuum to give:

$$
\begin{align*}
-\langle\bar{\psi} \psi\rangle & =\int_{0}^{\Lambda} \frac{d^{4} k}{(2 \pi)^{4}} \frac{12 m}{k^{2}+m^{2}}  \tag{8}\\
& =\frac{3}{4 \pi^{2}}\left(m \Lambda^{2}+m^{3} \log \frac{m^{2}}{\Lambda^{2}+m^{2}}\right)
\end{align*}
$$

The quadratic ultraviolet divergence depends on the scheme used but the $m^{3} \log (m / \Lambda)$ term is universal since it arises from the infrared part of the integral. The coefficient above agrees with that obtained for the $\overline{M S}$ scheme in [19] and on the lattice for highly improved staggered quarks to be described in section IIIA. We stress that a perturbative contribution of this kind is present for all lattice regularisations of QCD, whatever their chiral symmetry properties, and so must be calculated and subtracted to give a physical result. The quadratic divergence present for Ginsparg-Wilson fermions is demonstrated in the quenched approximation in, for exam-
ple, 20 and the additional divergences for the Wilson formalism with broken chiral symmetry in 21].

This subtraction is somewhat analogous to subtracting perturbative contributions to the mean plaquette to obtain the nonperturbative gluon condensate. That, however, is extremely difficult to do because the nonperturbative condensate contribution to the plaquette is so small. This contribution is given at leading order by:

$$
\begin{equation*}
\delta P_{c o n d}=-\frac{\pi^{2}}{36} a^{4}\left\langle\alpha_{s} G^{2} / \pi\right\rangle \tag{9}
\end{equation*}
$$

If we take the value of the gluon condensate as $\mathcal{O}\left(\Lambda_{Q C D}^{4}\right)$ then $\left\langle\alpha_{s} G^{2} / \pi\right\rangle \approx 0.005 \mathrm{GeV}^{4}$. On very coarse lattices for which $a \approx 1 \mathrm{GeV}^{-1}$, this contributes less than $1 \%$ to the value of the plaquette. On finer lattices the nonperturbative condensate contribution is even smaller because it falls as $a^{4}$ while the perturbative contribution falls only as $\alpha_{s}(d / a)$ for some scale $d$. This means that the plaquette is in fact a very good variable to use for the determination of $\alpha_{s}$ from lattice QCD calculations but not for the determination of the gluon condensate [22]. For larger Wilson loops the gluon condensate contribution is larger, being proportional to the square of the area of the loop, but the coefficients in the perturbative series also become larger.

The determination of the nonperturbative quark condensate from $\left\langle\operatorname{Tr} M^{-1}\right\rangle$ is in much better shape than this for several reasons. The main one is that the nonperturbative condensate contribution to $\left\langle\operatorname{Tr} M^{-1}\right\rangle$ in lattice units is only a factor of $a^{2}$ smaller than the leading perturbative contribution rather than $a^{4}$. In addition the perturbative contribution is suppressed by the quark mass, which is small for the $u / d$ and $s$ quarks we will consider here. The perturbative contribution is a welldefined function of the quark mass at every order in perturbation theory and so results at several values of the quark mass, and the lattice spacing, can be used to constrain unknown higher orders, beyond the $\mathcal{O}\left(\alpha_{s}\right)$ that we have explicitly calculated, and we will make use of that here.

## III. LATTICE QCD CALCULATION ON $n_{f}=2+1+1$ GLUON CONFIGURATIONS

The gluon field configurations used here are listed in Table They were generated by the MILC collaboration [23] using a tadpole-improved Lüscher-Weisz gauge action with coefficients corrected perturbatively through $\mathcal{O}\left(\alpha_{s}\right)$ including pieces proportional to $n_{f}$, the number of quark flavors in the sea [24]. The gauge action is then improved completely through $\mathcal{O}\left(\alpha_{s} a^{2}\right)$. Sea quarks are included with the highly improved staggered quark (HISQ) action [13] which has been designed to have very small discretisation errors. Discretisation errors are formally removed through $\mathcal{O}\left(a^{2}\right)$ but higher order errors, particularly staggered taste-changing errors, are seen to

TABLE I: Details of the MILC gluon field ensembles used in this paper. $\beta=10 / g^{2}$ is the $S U(3)$ gauge coupling and $L / a$ and $T / a$ are the number of lattice spacings in the space and time directions for each lattice. $a m_{l, \text { sea }}, a m_{s, \text { sea }}$ and $a m_{c, \text { sea }}$ are the light (up and down taken to have the same mass), strange and charm sea quark masses in lattice units. $a$ is the lattice spacing in fm determined from the decay constant of the $\eta_{s}$ meson in [25] with values for 3,6 and 8 added here. The ensembles 1,2 and 3 will be referred to in the text as "very coarse", 4,5 and 6 as "coarse" and 7 and 8 as "fine."

| Set | $\beta$ | $a / \mathrm{fm}$ | $a m_{l, \text { sea }}$ | $a m_{s, \text { sea }}$ | $a m_{c, \text { sea }}$ | $L / a \times T / a$ |

be smaller with HISQ than with the earlier asqtad staggered quark action [13, 23]. The HISQ action used here has two smearing steps for the gluon field appearing in the quark action with a $\mathrm{U}(3)$ projection of the smeared links between the two smearing steps. The configurations include a sea charm quark in addition to up, down and strange. These configurations are then said to have $2+1+1$ flavors in the sea, since the $u$ and $d$ quarks are taken to have the same mass (denoted $m_{l}$ here). This is heavier than the average $u / d$ mass in the real world on most of the configuration sets but there are three for which the $u / d$ mass has its physical value ( 3,6 and 8 ). The $s$ and $c$ masses are tuned as closely as possible to their correct values on each set. The tuning of the sea $s$ quark mass is accurately done - typically to better than $5 \%$ - so the $u / d$ quark mass can be accurately calibrated in terms of the $s$ quark mass for chiral extrapolations. The values of the lattice spacing for most ensembles were determined in [25] using the decay constant of the $\eta_{s}$ meson. The values vary from 0.15 fm to 0.09 fm as we go from the very coarse to the fine lattices. The spatial volumes are large, from $(2.5 \mathrm{fm})^{3}$ when $m_{l} / m_{s} \approx 0.2$ to $(3.7 \mathrm{fm})^{3}$ when $m_{l} / m_{s} \approx 0.1$.

On each of these ensembles we determine $\left\langle\operatorname{Tr} M^{-1}\right\rangle$ for HISQ valence quarks for various quark masses. To do this we use an identity that relates the quark propagator for staggered quarks to a product of quark propagators:

$$
\begin{align*}
\frac{1}{a m_{q}} \operatorname{Tr} M_{00}^{-1} & =\sum_{n} \operatorname{Tr}\left[M_{0 n}^{-1} M_{n 0}^{-1}\right](-1)^{n} \\
& =\sum_{n} \operatorname{Tr}\left|M_{0 n}^{-1}\right|^{2} \tag{10}
\end{align*}
$$

Here 0 and $n$ are arbitrary lattice sites and $a m_{q}$ is the quark mass in lattice units used for the quark propagator. The righthand side of Eq. 10 is simply the correlator between 0 and $n$ for the Goldstone pseudoscalar meson

FIG. 1: Autocorrelation function, $C_{\Delta T}$ of Eq. 12 for the strange and light quark condensates on coarse set 6 with physical mass light sea quarks. The $x$-axis, $\Delta T$, is the separation in time units between configurations. The strange condensate results are given as blue crosses and the light condensate with red pluses. Errors in $C_{\Delta T}$ are estimated by dividing the configuration time series into five consecutive sets.
made of a quark and antiquark of mass $a m_{q}$. Summing over $n$ projects on to zero spatial momentum and sums over timeslices. Thus, dividing both sides by 4 , the number of tastes for staggered quarks, we obtain:

$$
\begin{equation*}
-a^{3}\langle\bar{\psi} \psi\rangle_{0}=\left(a m_{q}\right) \sum_{t} C_{\pi}(t) \tag{11}
\end{equation*}
$$

The raw condensate value on the left-hand side of this expression is normalised to the single flavor case and the pion correlator on the right-hand side is the usual zeromomentum Goldstone meson correlator. This allows us to determine $\langle\bar{\psi} \psi\rangle_{0}$ by summing over the Goldstone pseudoscalar correlators calculated in [25]. Eq. (10) is derived in [26] for a single propagator origin, 0 , but the derivation can trivially be extended to hold for the random wall source that we use for our correlators in [25]. The identity holds configuration by configuration for lattice QCD quark formalisms with sufficient chiral symmetry and in the continuum for a specific gauge field background. We give an explicit proof of this in Appendix A. Since our Goldstone pseudoscalar correlators are sums of positive numbers they are particularly precise and this precision then carries over to our condensate results. For the light condensate we use the pion correlators made of light quarks and for the strange condensate we use the $\eta_{s}$ correlators made of strange quarks. We stress that what we calculate using Eq. 10 is the vacuum expectation value of the condensate (and not a specific 'in-meson' value) despite the fact that we determine it for convenience from a meson correlator.

Table $\Pi$ gives the valence quark masses used in our calculation and the raw results for the condensate obtained from Eq. 10). The correlator calculations used 16 'random wall' time sources on approximately one thousand

TABLE II: Raw (unsubtracted) values for the light and strange quark condensates in lattice units calculated for valence masses given in columns 2 and 3. The results use the correlators calculated in 25 (via Eq. (11) , but we also give results for additional strange quark masses on sets 1 and 2 and new results on sets 3,6 and 8 . We have 16,000 correlators per ensemble, except for sets 6 and 8 where we use approximately 10000 .

configurations in each ensemble (somewhat fewer on sets 6 and 8$)$ and so the results have very small statistical errors. The valence light quark masses are equal to those in sea (except for a very small change on set 3 ) but we have shifted the valence strange quark masses slightly to be closer to the physical strange quark mass, following [25]. On sets 1 and 2 we give results for two different values of the strange quark mass, to help in constraining the valence mass dependence of the condensate.

Errors on the condensate values are determined after binning over adjacent sets of at least five configurations, following analysis of the autocorrelation function. An example plot is shown, for coarse set 6, in Fig. 1. The autocorrelation function is defined as:

$$
\begin{equation*}
C_{\Delta T}=\frac{\left\langle x_{i} x_{i+\Delta T}\right\rangle-\left\langle x_{i}\right\rangle\left\langle x_{i+\Delta T}\right\rangle}{\left\langle x_{i}^{2}\right\rangle-\left\langle x_{i}\right\rangle^{2}} . \tag{12}
\end{equation*}
$$

Here $x_{i}$ represents a condensate value on configuration $i$ and $x_{i+\Delta T}$ that on a configuration a further $\Delta T$ time units along in the ordered ensemble. $\Delta T=1$ thus corresponds to adjacent configurations. Fig. 1 shows that nearby configurations in the ensembles are correlated and thus binning is necessary to obtain a reliable statistical error. A similar analysis applies to masses and decay constants as discussed in 25].

In the next section we describe the perturbative calculation of the condensate which we will then subtract from the raw results of Table II to enable the nonperturbative condensate to be determined.

## A. Perturbative calculation of $\left\langle\operatorname{Tr} M^{-1}\right\rangle$

We computed the perturbative contribution $\langle\bar{\psi} \psi\rangle_{\mathrm{PT}}$ to the chiral condensate for the HISQ action through firstorder in $\alpha_{s}$ :

$$
\begin{aligned}
-a^{3}\langle\bar{\psi} \psi\rangle_{\mathrm{PT}, \mathrm{HISQ}}= & a m_{0} \times \\
& {\left[c_{0}\left(a m_{0}\right)+c_{1}\left(a m_{0}\right) \alpha_{s}+O\left(\alpha_{s}^{2}\right)\right] }
\end{aligned}
$$

where $a m_{0}$ is the bare quark mass parameter that appears in the HISQ action. The Feynman diagrams required to this order are shown in Fig. 2. The perturbative quadratic ultraviolet divergence discussed in eq. (9) shows up as finite values for the perturbative coefficients, as defined above, in the limit $a m_{0} \rightarrow 0$.

FIG. 2: Feynman diagrams for the calculation of the perturbative contribution to the quark condensate through $\mathcal{O}\left(\alpha_{s}\right)$.

We computed the coefficients from numerical evaluation of the lattice loop integrals over a range of masses that includes the light and strange quark masses that we have used. A representative sample of our results is given in Table III, and is illustrated in Fig. 3 .

An excellent fit to the perturbative coefficients in this range of small quark masses, $a m_{0} \lesssim 0.1$, can be obtained using the following parameterizations

$$
\begin{equation*}
c_{0}\left(a m_{0}\right)=c_{00}+\left(a m_{0}\right)^{2}\left[c_{01} \log \left(a m_{0}\right)+c_{02}\right] \tag{14}
\end{equation*}
$$

and

$$
\begin{align*}
c_{1}\left(a m_{0}\right)= & c_{10}+\left(a m_{0}\right)^{2}\left[c_{11} \log ^{2}\left(a m_{0}\right)\right. \\
& \left.+c_{12} \log \left(a m_{0}\right)+c_{13}\right] . \tag{15}
\end{align*}
$$

Higher order terms in $a m_{0}$ appear as discretisation errors in the comparison to $\overline{M S}$ to be done below and so can be ignored - they are negligible for the masses we are using in any case. The leading logarithm of $a m_{0}$ at each order originates entirely from the infrared region of the
loop momenta, and the respective coefficients $c_{01}$ and $c_{11}$ can easily be computed analytically. The values of these coefficients must and do agree with the values in the $\overline{M S}$ scheme [19]. At one-loop we also have a constraint on the sub-leading (single) logarithm of $a m_{0}$ since, as discussed in Appendix C, all $\log m$ terms must vanish in the difference between the vacuum expectation values of $m \bar{\psi} \psi$ in perturbation theory in the continuum and on the lattice. Allowing for the renormalisation between the $\overline{M S}$ mass and the HISQ bare mass:

$$
\begin{equation*}
\bar{m}(\mu)=m_{0}\left(1+\alpha_{s}\left[-\frac{2}{\pi} \log a \mu+0.1143(3)\right]+\ldots\right) \tag{16}
\end{equation*}
$$

we find that $c_{12}$ should have the value $0.2307(2)$. With the logarithmic terms fixed to their known values we can obtain the other coefficients in eqs. (14) and 15 from a fit to the values for $c_{0}\left(a m_{0}\right)$ and $c_{1}\left(a m_{0}\right)$ as a function of $a m_{0}$. We find:

$$
\begin{align*}
& c_{00}=0.38366(1) \\
& c_{01}=3 /\left(2 \pi^{2}\right) \\
& c_{02}=-0.153(1) \tag{17}
\end{align*}
$$

and

$$
\begin{align*}
& c_{10}=0.03657(7) \\
& c_{11}=-6 / \pi^{3} \\
& c_{12}=0.2307(2) \\
& c_{13}=0.308(15) \tag{18}
\end{align*}
$$

These fits are illustrated in Fig. 3 and reproduce our results for the coefficients to within their numerical integration errors, which are smaller than about $0.01 \%$ for $c_{0}$, and $1 \%$ for $c_{1}$.

The perturbative determination of the vacuum expectation value of $\bar{\psi} \psi$ has also been done in the $\overline{M S}$ scheme, in [19]. The power divergence is missing in this case but, as discussed above, there are terms proportional to $m^{3} \log m$. 19] finds:

$$
\begin{align*}
- & \langle\bar{\psi} \psi\rangle_{\mathrm{PT}, \mathrm{MS}}^{(\mu)}=\bar{m}^{3}(\mu) \times  \tag{19}\\
& {\left[d_{01} l_{m}+d_{02}+\alpha_{s}\left(d_{11} l_{m}^{2}+d_{12} l_{m}+d_{13}\right)+\ldots\right] }
\end{align*}
$$

where $l_{m}=\log (\bar{m}(\mu) / \mu)$ and

$$
\begin{align*}
d_{01} & =c_{01}=\frac{3}{2 \pi^{2}} \\
d_{02} & =-\frac{3}{4 \pi^{2}} \\
d_{11} & =c_{11}=-\frac{6}{\pi^{3}} \\
d_{12} & =\frac{5}{\pi^{3}} \\
d_{13} & =-\frac{5}{2 \pi^{3}} \tag{20}
\end{align*}
$$

TABLE III: Zeroth- and first-order coefficients, $c_{0}$ and $c_{1}$ respectively, for the perturbative condensate, Eq. 14 , for representative values of the bare quark mass parameter $a m_{0}$ in lattice units. The uncertainties are from a numerical evaluation of the lattice perturbation theory loop integrals.

As discussed in Appendix B we must subtract the difference between the lattice QCD and $\overline{M S}$ perturbative calculations from our lattice QCD results to obtain the nonperturbative condensate in the $\overline{M S}$ scheme at the scale $\mu$. We work with the combination $m \bar{\psi} \psi$ which would be RG-invariant in the absence of this perturbative contribution and it is convenient to derive the subtraction needed in lattice units and as a function of the bare lattice quark mass. Using eq. 166 we obtain

$$
\begin{align*}
\Delta_{\mathrm{PT}} & =-a^{4}\left(\left\langle m_{0} \bar{\psi} \psi\right\rangle_{\mathrm{PT}, \mathrm{HISQ}}-\langle\bar{m}(\mu) \bar{\psi} \psi\rangle_{\mathrm{PT}, \overline{\mathrm{MS}}}\right) \\
& =c_{00}\left(a m_{0}\right)^{2}+\alpha_{s} c_{10}\left(a m_{0}\right)^{2}  \tag{21}\\
& +\left(a m_{0}\right)^{4}\left[c_{01} l_{\mu}-0.077(1)\right] \\
& +\alpha_{s}\left(a m_{0}\right)^{4}\left[c_{11} l_{\mu}^{2}+0.1340(2) l_{\mu}+0.406(15)\right]+\ldots
\end{align*}
$$

where $l_{\mu}=\log (\mu a)$. This difference of perturbative expansions is now free of all logarithms of $m$ and therefore well-defined and infrared safe.

## B. Determining the nonperturbative strange and

 light quark condensates
## 1. A first look at the results

The physical condensate in the $\overline{M S}$ scheme at the scale $\mu$ is then defined by:

$$
\begin{equation*}
\langle m \bar{\psi} \psi\rangle_{N P, \overline{M S}}(\mu)=a^{-4}\left(a^{4}\langle m \bar{\psi} \psi\rangle_{0}-\Delta_{P T}\right) \tag{22}
\end{equation*}
$$

where $\langle m \bar{\psi} \psi\rangle_{0}$ is the numerical result from lattice QCD and $\Delta_{P T}$ is given through $\mathcal{O}\left(\alpha_{s}\right)$ as a function of the quark mass in Eq. 21. $\Delta_{P T}$ will also contain unknown

FIG. 3: Zeroth- and first-order coefficients, $c_{0}$ and $c_{1}$ respectively, for the perturbative condensate, Eq. (14), versus the bare quark mass parameter $a m_{0}$ in lattice units. The uncertainties in $c_{0}$ resulting from numerical evaluations of the lattice loop integral are not visible in that plot. The fits given in the text are plotted as dashed lines.
higher order pieces in $\alpha_{s}$ that we can try to determine from a fit to the lattice QCD results. First we look at the effect of the calculated tree-level and one-loop contributions.
$\Delta_{P T}$ is a strong function of the quark mass in lattice units, dominated by the $(m a)^{2}$ terms that give rise to the quadrative divergence with inverse lattice spacing. This means that the relative size of the subtraction compared to the raw results varies strongly with quark mass and with lattice spacing, and this is reflected in the raw results before the subtraction is made. In Fig. 4 the open squares show the unsubtracted results (i.e. setting $\Delta_{P T}$ to zero in Eq. (22p) as a function of the square of the inverse lattice spacing for quarks at the four different masses that we have results for in Table II. strange quarks and light quarks of masses $m_{s} / 5$ (sets 1,4 and 7 ), $m_{s} / 10$ (sets 2 and 5) and the physical value, $m_{s} / 27$ (sets 3, 6 and 8 ).

Instead of plotting the condensate results directly, the
$y$-axis in Fig. 4 is:

$$
\begin{equation*}
R_{l}=-\frac{4 m_{l}\left\langle\bar{\psi} \psi_{l}\right\rangle}{\left(f_{\pi}^{2} M_{\pi}^{2}\right)} \tag{23}
\end{equation*}
$$

for light quarks and

$$
\begin{equation*}
R_{s}=-\frac{4 m_{s}\left\langle\bar{\psi} \psi_{s}\right\rangle}{\left(f_{\eta_{s}}^{2} M_{\eta_{s}}^{2}\right)} \tag{24}
\end{equation*}
$$

for strange quarks. The values of the raw unsubtracted $R_{q}$ are determined directly from Table II using the $a m$, $a M, a f$ and $\langle\bar{\psi} \psi\rangle_{0}$ values given there.

The ratio $R_{q}$ is a good quantity to plot (and later to use in our fits) for a number of reasons:

- $m\langle\bar{\psi} \psi\rangle$ is a physical renormalisation-group invariant quantity as $m \rightarrow 0$, up to discretisation errors, as is clear from the GMOR relation. The division by the square of the meson decay constant times its mass makes a dimensionless ratio which is convenient but it is also one that (from the GMOR relation) we expect to be close to 1 .
- Using the ratio $R_{q}$ also reduces the effect of any slight mistuning of quark masses since the quark mass multiplied in the numerator cancels against the square of the meson mass in the denominator. The tuning of $m_{s}$ uses the $\eta_{s}$ decay constant, as described in 25]. This means that, by definition, $f_{\eta_{s}}$ does not contain discretisation errors that would mask the identification of the pieces that diverge as $a \rightarrow 0$.
- Finally the ratio has reduced finite-volume effects over that in either the numerator or denominator. This is expected from the fact that chiral loop effects, which are sensitive to the volume, cancel in $R_{q}$ [27, [28]. This is illustrated in Fig. 5 where we show results [29] for pion mass, decay constant and (unsubtracted) light quark condensate as well as the ratio $R_{l}$ of Eq. (23) for ensembles with $a m_{l, \text { sea }}=0.00507$ and $a m_{s, \text { sea }}=0.0507$ and three different spatial volumes. The spatial volumes correspond to a spatial length in lattice units of 24,32 and 40. The set with $L / a=32$ is our set 4 (see Table $\bar{I}$. For each quantity we plot the ratio of the value at $L / a$ to that at $L / a=40$. It is clear from the plot that the finite volume dependence in each of $m_{\pi}, f_{\pi}$ and $\langle\bar{\psi} \psi\rangle_{l}$ is cancelled to a very high level of accuracy ( $0.1(1) \%$ for set 4) in $R_{l}$.

Figure 4 shows clearly the presence of a quadratic divergence with $a^{-2}$ in the raw results. This is very 'clean' in our calculations because the form of the divergence is very constrained. Only a term of the form $m_{q} / a^{2}$ is allowed in $\langle\bar{\psi} \psi\rangle$ for staggered quarks, i.e. no term of the form $m_{q}^{2} / a$ can appear. In the ratio $R_{q}$ this term takes the form $C m_{q}^{2} / a^{2}$ where $C$ depends on the meson mass and decay constant. The HISQ formalism has

FIG. 4: $\quad R_{q}$, defined as the ratio of quark mass times condensate in the $\overline{M S}$ scheme at 2 GeV to the square of the meson mass times decay constant, as a function of the square of the inverse lattice spacing. Left to right and top to bottom shows strange quarks and light quarks with masses $m_{s} / 5, m_{s} / 10$ and the physical value. Squares use the unsubtracted condensate, pluses, the condensate after subtraction of the tree-level perturbative correction and crosses, the condensate after perturbative correction through one-loop. The value for $\alpha_{s}$ used to multiply the one-loop coefficient was $\alpha_{V}^{n_{f}=4}(2 / a)$. Dashed lines illustrate very simple linear fits to the unsubtracted results as described in the text.
very small discretisation errors, as is clear from the decay constant and meson mass results in [25, and so there is little additional $a$-dependence to confuse the analysis of the divergent pieces.

Because the power divergence is so dominant it is tempting to try to fit the unsubtracted results for $R_{s}$ to a very simple form: $A+B / a^{2}$. This is in fact possible (it is important to include the error in the inverse lattice spacing when doing this since this is larger than the error in $R_{q}$ ) and we obtain $1.02(3)+0.725(3) / a^{2}$ which is the dashed line in lefthand plot of Fig. 4. We also obtain $1.015(11)+0.229(5) / a^{2}$ for $R_{l}$ with $m_{l}=m_{s} / 5$ and $1.00(1)+0.130(6) / a^{2}$ for $R_{l}$ with $m_{l}=m_{s} / 10$, shown in the next two plots in Fig. 4. These fits are too naive to be useful, as we shall see below, because they miss out many important terms. Consequently the value and error of the intercept, $A$, is unreliable for extracting a nonperturbative result for $R_{q}$, especially in the $s$ quark case. However, the fits do illustrate that the ratio of
slopes is that expected for a term that behaves as $m_{q}^{2} / a^{2}$ (although the simple fit does not allow for the running of the lattice bare quark mass with scale). The ratio of slopes between that for $s$ and for $l$ with $m_{l}=m_{s} / 5$ is 3.2 which corresponds approximately to 5 (for the ratio of one power of the quark masses when the other power is cancelled by the square of the meson mass) divided by the ratio of the square of the decay constants from Table III

Figure 4 compares results for $R_{q}$ in which the tree-level piece of $\Delta_{P T}$ has been subtracted from the raw values of $m\langle\bar{\psi} \psi\rangle$ following Eq. 22 We take $\mu$ to be 2 GeV . These results are indicated by pluses. Now the slope in $a^{-2}$ is much smaller since the most of the divergence has been removed. This makes the results more sensitive to the form of the remaining pieces of the divergence and the simple linear fits that were made to the unsubtracted data are no longer possible.

The $\mathcal{O}\left(\alpha_{s}\right)$ perturbative contribution is very small for

FIG. 5: Finite volume effects in different quantities are illustrated by plotting the ratio of the quantity on lattices of spatial length, $L / a$, of 24 and 32 to that on lattices of spatial length 40. The lattices have the sea quark mass parameters of coarse set 5 . The quantities shown are the pion mass (red pluses), pion decay constant (green crosses) and unsubtracted light quark condensate (blue bursts). Pink squares give the result for the quantity $R_{l}$ defined in Eq. (23) [29]. Statistical errors (not shown) are approximately $0.1 \%$.

HISQ quarks and makes very little difference to the perturbative subtraction. The crosses show the results taking $\Delta_{P T}$ to be the full calculated perturbative subtraction through $\mathcal{O}\left(\alpha_{s}\right)$ given in Eq. 21. We have used $\alpha_{V}^{n_{f}=4}(2 / a)$ [30] for the $\alpha_{s}$ value multiplying the oneloop coefficient, but the coefficient itself is so small that variations in scale for $\alpha_{s}$ make no difference. The crosses are barely distinguishable from the pluses giving the treelevel subtracted numbers.

It is clear from Fig. 4 that there is still some divergence in $a^{-2}$ left in $R_{q}$ after subtraction of the perturbative contribution through one-loop. This is not surprising since we know that $\Delta_{P T}$ will have higher order terms in $\alpha_{s}$. The challenge now is to fit the one-loop subtracted $R_{q}$ allowing for these higher order terms and thereby obtain the physical, nonperturbative, results for the strange and light quark condensates. We will fit both $R_{s}$ and $R_{l}$ simultaneously and use the known mass dependence of the unknown higher order terms to constrain them. At the same time we will allow for higher-order non-divergent mass-dependent terms from perturbation theory as well as physical, non-perturbative, dependence on the quark mass. Possible dependence on positive powers of $a$, i.e. discretisation errors, must also be included.

## 2. Determining a physical result from fitting

We now describe the full fit to the results that we use to determine the final physical values for $\langle\bar{s} s\rangle\left(\equiv\left\langle\bar{\psi} \psi_{s}\right\rangle\right)$ and $\langle\bar{l}\rangle\rangle\left(\equiv\left\langle\bar{\psi} \psi_{l}\right\rangle\right)$ at the physical strange and light quark masses (where $m_{l}=\left(m_{u}+m_{d}\right) / 2$ ). We take the following
form for the ratio $R_{q}$ :

$$
\begin{equation*}
R_{q, 0}\left(a, a m_{q}\right)=R_{\mathrm{NP}, \mathrm{phys}}^{(q)}+\delta R_{P T}+\delta R_{a^{2}}+\delta R_{\chi}+\delta R_{\mathrm{vol}} \tag{25}
\end{equation*}
$$

$R_{q, 0}$ are the raw results obtained from Table $\Pi$ I $R_{\mathrm{NP}, \text { phys }}$ is the final physical result in the $\overline{M S}$ scheme at 2 GeV . The $\delta R$ terms represent fitted or known dependence on $a$ and $a m_{q}$. We use Bayesian techniques (31 to perform the fits so that we can add many higher order terms as part of each $\delta R$ with constrained coefficients. This makes sure that the final error on $R_{\mathrm{NP}, \text { phys }}$ is not underestimated by ignoring the existence of higher order corrections.
$\delta R_{P T}$ contains the known tree-level and one-loop perturbative results given in section IIIA. In addition we include unknown higher-order terms. For the $a^{-2}$ divergence these take the form:

$$
\begin{equation*}
\delta R_{P T, d i v}=a_{n} \frac{4 \alpha_{s}^{n}\left(a m_{q}\right)^{2}}{\left(a f_{\pi}\right)^{2}\left(a M_{\pi}\right)^{2}} \tag{26}
\end{equation*}
$$

with the analogous term for the strange quark case, with the same $a_{n}$. $a_{n}$ is a coefficient whose prior we take to be $0.0 \pm 4.0$ and we allow for $n=2,3$ and 4 . Note that a prior width of 4.0 is conservative given the size of the corresponding coefficient at tree-level and one-loop. For the non-divergent pieces we take:

$$
\begin{equation*}
\delta R_{P T, \text { non-div }}=c_{n} \frac{4 \alpha_{s}^{n}\left(a m_{q}\right)^{4}}{\left(a f_{\pi}\right)^{2}\left(a M_{\pi}\right)^{2}} \tag{27}
\end{equation*}
$$

again with the analogous term for the strange quark case, with the same coefficient $c_{n}$. We take $n=2,3$ and 4. $c_{n}$ in principle contains a sum of powers of $\log (a \mu)$ up to $\log ^{n+1}(a \mu)$. However, since $\log (a \mu)$ is small for $\mu=2 \mathrm{GeV}$ and our range of lattice spacings, these pieces are negligible and do not affect the fit and we simply take a prior on $c_{n}$ of $0.0(4.0)$. Again this is conservative given the results at tree-level and one-loop. For $\alpha_{s}$ we use $\alpha_{V}^{n_{f}=4}(2 / a)[30$ and discuss below the dependence of the results on changing $2 / a$ to a different scale. $\alpha_{V}^{n_{f}=4}(2 / a)$ takes values from 0.35 on the very coarse lattices to 0.26 on the fine ensembles.
$\delta R_{a^{2}}$ allows for discretisation errors. We take the form

$$
\begin{equation*}
\delta R_{a^{2}}=\sum_{i=1}^{2} d_{i}\left(\frac{\Lambda a}{\pi}\right)^{2 i} \tag{28}
\end{equation*}
$$

Only even powers of $a$ appear in discretisation errors for staggered quarks and we take their scale to be set by $\Lambda \approx$ 1 GeV . Since all tree level errors at $\mathcal{O}\left(a^{2}\right)$ are removed in the HISQ formalism we take the prior for $d_{1}$ to be $\mathcal{O}\left(\alpha_{s}\right)$ i.e. $0.0(0.3)$. Higher order $d_{i}$ are given the prior $0.0(1.0)$. We include $a^{2}$ and $a^{4}$ terms, but have checked that higher order terms have very little effect. In addition we include a mass-dependent discretisation error in the form $e(a m)^{2}$, giving $e$ a prior of $0.0(1.0)$. This allows for a number of effects, one of which could be mixing with a gluon condensate. This has negligible impact.
$\delta R_{\chi}$ includes the valence and sea quark mass dependence that allows us to extrapolate to physical light quark masses and interpolate between the strange quark masses that we have to the physical strange quark mass. The chiral corrections to the GMOR relation were analysed in [27] (see also [28]). The leading corrections are particularly simple because the chiral logarithms cancel to leave a correction proportional to $M_{\pi}^{2}$. We allow for both $M_{\pi}^{2}$ and $M_{\pi}^{4}$ terms in our light quark mass fits by defining a chiral expansion parameter

$$
\begin{equation*}
x_{l}=\frac{M_{\pi}^{2}}{2\left(\Lambda_{\chi}\right)^{2}} \tag{29}
\end{equation*}
$$

with $\Lambda_{\chi}=1.0 \mathrm{GeV}$, and taking

$$
\begin{equation*}
\delta R_{\chi, v a l}=\sum_{i=1}^{2} g_{i}^{(l)} x_{l}^{i} \tag{30}
\end{equation*}
$$

We fit the $m_{q}=m_{s} / 5, m_{s} / 10$ and $m_{l, p h y s}$ results with this form taking the prior on the $g_{i}$ coefficients to be $0.0(2.0)$. This allows for a linear term of approximately the size expected in [28]. Higher order terms than $x_{l}^{2}$ have no effect.

The chiral expansion of Eq. 30) combines with the $R_{\text {NP,phys }}$ parameter in Eq. 25 to define the physical nonperturbative light condensate with its mass dependence. Since the GMOR relation is exact as $m_{q} \rightarrow 0$ we enforce this by taking the prior on $R_{\mathrm{NP} \text {, phys }}^{(l)}$ to be $1.0000(5)$. Differences from 1 because of residual lattice finite volume effects up to $0.5 \%$ are allowed for as described in the paragraph above.

The data for $R_{s}$ is fit simultaneously with that for the light quarks, because they share parameters for the perturbative subtraction. However, we largely decouple the physical parameters because the strange quark is relatively far from the chiral limit and we would need a lot of parameters for a chiral expansion to connect light and strange quarks. Instead we allow a separate parameter for $R_{\mathrm{NP}, \text { phys }}^{(s)}$ with the broad prior of $1.0(5)$. We take the same form for the valence mass dependence as in Eq. (30) where now

$$
\begin{equation*}
x_{s}=\frac{\left(M_{\eta_{s}}^{2}-(0.6893(12))^{2}\right)}{2\left(\Lambda_{\chi}\right)^{2}} \tag{31}
\end{equation*}
$$

but this now simply allows for slight mistuning of the strange quark on some ensembles, and the fact that we have two values for the strange quark mass on sets 1 and 2. 0.6893 is the physical value for the $\eta_{s}$ mass determined in [25]. The priors on $g_{i}^{(s)}$ are the same as those on $g_{i}^{(l)}$. Finite volume effects are expected to be completely negligible for $R_{s}$ because they are negligible for the components of $R_{s}$.

The strange quark results in Fig. 4 show some very small sensitivity to the sea light quark masses if we compare results on sets 1 and 2 and sets 3 and 4 . We therefore
allow an additional linear dependence on the light quark mass in the sea in $\delta R_{\chi}$ of the form

$$
\begin{equation*}
\delta R_{\chi, \text { sea }}=\sum_{i=1}^{2} k_{i}\left(\frac{\delta m_{\text {sea }}}{10 m_{s, p h y s}}\right)^{i} \tag{32}
\end{equation*}
$$

where

$$
\begin{equation*}
\delta m_{\text {sea }}=\left(2 m_{l, \text { sea }}+m_{s, \text { sea }}\right)-\left(2 m_{l, p h y s}+m_{s, p h y s}\right) . \tag{33}
\end{equation*}
$$

We take $m_{l, p h y s}=m_{s} / 27.4$ 32 and $m_{s, p h y s}$ values determined from $M_{\eta_{s}}$ as in [25]. The prior for coefficient $k_{i}$ is taken as $0.0(1.0)$ which is conservative given the small effects observed in the results. We take $\delta R_{\chi, \text { sea }}$ to be common to both $R_{s}$ and $R_{q}$ for the light quarks. We note here also that the absence of chiral loop effects at this order means that staggered quark taste-changing effects are also absent. They can be handled, if necessary, with a sea-quark mass dependent $a^{2}$ term [25]. Including such a term here makes no difference to the physical result.
$\delta R_{\mathrm{vol}}$ allows for remaining finite volume effects. These are small, as demonstrated in Fig. 5. They do produce a small systematic effect, however, because the lattice size in units of the pion mass, $M_{\pi} L$, is somewhat smaller on the lattices with smallest $m_{u / d}$. We take:

$$
\begin{equation*}
\delta R_{\mathrm{vol}}=v e^{-M L} \tag{34}
\end{equation*}
$$

where $M$ is the pseudoscalar meson mass made of that quark ( $M_{\pi}$ for $R_{l}$ and $M_{\eta_{s}}$ for $R_{s}$ ) and $L$ is the linear extent of the lattice from Table I. Coefficient $v$ is taken to have prior $0.0(0.2)$, consistent with Fig. 5 .

Fitting $R_{s}$ and $R_{q}, m_{q}=m_{s} / 5, m_{s} / 10$ and $m_{l, p h y s}$, results simultaneously to the form in Eq. (25) readily produces good fits with $\chi^{2} /$ dof $\approx 0.8$ for 18 degrees of freedom. The final fitted result for $R_{u / d}$ and $R_{s}$ (evaluated from $R_{\mathrm{NP}, \mathrm{phys}}^{(q)}$ and $\delta R_{\chi}$ taken at the appropriate physical masses) is robust to the addition of higher order terms in the various corrections.

We take our final results from using $2 / a$ for the scale of $\alpha_{s}$. The results do not change significantly as this is varied (although the fitted coefficients $a_{n}$ do change). Our fits return a substantial value for the coefficient of the power divergent term at $\mathcal{O}\left(\alpha_{s}^{2}\right), a_{2}$, of around 2.0, for $d / a=2 / a$. This is substantially larger than that seen at one-loop but not a particularly large value for a perturbative coefficient in general. It would simply imply that the small coefficient at one-loop for the HISQ action is not repeated at higher orders. We also find that the chiral correction to the GMOR for light quarks is substantial and negative $\left(g_{1}^{(l)}=-1.7(6)\right)$. This will be discussed further below.

The fit results are shown in Fig. 6. The data points (crosses) correspond to the lattice QCD results after subtraction of the perturbative contribution through $\mathcal{O}\left(\alpha_{s}\right)$ (as in Fig. 4). The filled bands show the fitted curves when the full fitted perturbative contribution $\left(\delta R_{P T}\right)$ is

TABLE IV: Error budget for the quantities $R_{s, p h y s}, R_{l, p h y s}$ and their ratio defined in the text. Errors are given as percentages of the final physical result.

|  | $R_{s, p h y s}$ | $R_{l, p h y s}$ | $\frac{R_{s, p h y s}}{R_{l, p h y s}}$ |
| :--- | :--- | :--- | :--- |
| statistics | 6.1 | 0.2 | 5.1 |
| lattice spacing | 10.0 | 0.3 | 9.7 |
| finite volume | 1.5 | 0.03 | 1.5 |
| $\alpha_{s}$ value | 1.7 | 0.06 | 1.7 |
| fitting power divergence | 7.5 | 0.3 | 7.2 |
| other perturbative subtraction | 1.3 | 0.07 | 1.3 |
| خal extrap./interp. $\left(m_{s}\right)$ | 3.0 | 0.1 | 2.9 |
| خal extrap./interp. $\left(m_{l}\right)$ | 4.5 | 0.2 | 4.3 |

subtracted and masses and decay constants are set to the physical values corresponding to the $s$ quark and the light quark (for this we use $M_{\pi}=M_{\pi^{0}}$ ). These bands include the full error from the fit.

Our final physical results for $R_{q}$ are the key results from this paper.

$$
\begin{align*}
R_{l, p h y s} & =-\frac{4 m_{l}\left\langle\bar{\psi} \psi_{l}\right\rangle_{\overline{M S}}(2 \mathrm{GeV})}{\left(f_{\pi}^{2} M_{\pi}^{2}\right)} \\
R_{s, p h y s} & =-\frac{4 m_{s}\left\langle\bar{\psi} \psi_{s}\right\rangle_{\overline{M S}}(2 \mathrm{GeV})}{\left(f_{\eta_{s}}^{2} M_{\eta_{s}}^{2}\right)} \tag{35}
\end{align*}
$$

We find:

$$
\begin{align*}
R_{s, p h y s} & =0.574(86) \\
R_{l, p h y s} & =0.985(5) \\
\frac{R_{s, p h y s}}{R_{l, p h y s}} & =0.583(84) \tag{36}
\end{align*}
$$

The complete error budgets for $R_{s, p h y s}, R_{l, p h y s}$ and their ratio are given in Table IV. The substantial $15 \%$ error that we have in $R_{s, p h y s}$ reflects the difficulty of extracting a physical result from a power divergent quantity. For $R_{l}$ the error is 17 times better largely because the slope of the divergent piece is 15 times smaller. Errors in $R_{s, p h y s}$ are dominated by errors from the lattice spacing and from fitting the remaining power divergent subtraction terms. There are also substantial errors from statistics and from tuning to the light and strange physical mass points. This is done by tuning the appropriate meson masses through the term $\delta R_{\chi, v a l}$ in Eq. 30. This term depends on the lattice spacing through the definition of $x_{l}$ (Eq. 29) and $x_{s}$ (Eq. 31), because the meson masses appear in GeV units in these terms. The uncertainties in these terms then becomes correlated with the fit to the power divergence, increasing the uncertainty. For $R_{l}$ the power divergence is much less of an issue, but these same terms dominate the final error there as well.

FIG. 6: Results from fitting the ratio $R$ for three different quark masses as described in the text. The crosses show the lattice QCD results after subtracting the perturbative values through $\mathcal{O}\left(\alpha_{s}\right)$. Black is for $s$ quarks, blue for quarks with mass $m_{s} / 5$, red for quarks with mass $m_{s} / 10$ and green for quarks at the physical light quark mass. The dashed lines simply join the points of matching color for clarity. The filled bands show the physical curves for strange (black) and light (green) quarks, once the full subtraction of the fitted perturbative contribution is made and masses are set to their physical values. The bands include the full error from the fit.

The results for $R_{l}$ and $R_{s}$ can be converted to values of the condensate using the lattice result for $f_{\eta_{s}}=0.1819(5)$ GeV and $M_{\eta_{s}}=0.6893(12) \mathrm{GeV}$ [25], and experimental values for $f_{\pi}(0.1304(2) \mathrm{GeV})$ and $M_{\pi}(0.13498 \mathrm{GeV})$. We obtain:

$$
\begin{align*}
m_{s}\langle\bar{\psi} \psi\rangle_{s}^{\overline{M S}}(2 \mathrm{GeV}) & =-2.26(34) \times 10^{-3} \mathrm{GeV}^{4} \\
m_{l}\langle\bar{\psi} \psi\rangle_{l}^{\overline{M S}}(2 \mathrm{GeV}) & =-7.63(4) \times 10^{-5} \mathrm{GeV}^{4} \tag{37}
\end{align*}
$$

The ratio of the two values above is slightly more accurate than a naive combination, giving 29.6(4.3).

Using the precise determinations for light quark masses now available from lattice QCD we can finally obtain condensate values. We take $m_{s}^{\overline{M S}}(2 \mathrm{GeV})=92.2(1.3)$ MeV [30, 33] and $m_{s} / m_{l}=27.41(23)$ [32, 34]. These give:

$$
\begin{align*}
\langle\bar{s} s\rangle^{\overline{M S}}(2 \mathrm{GeV}) & =-0.0245(37)(3) \mathrm{GeV}^{3} \\
& =-(290(15) \mathrm{MeV})^{3} \\
\langle\bar{l} l\rangle^{\overline{M S}}(2 \mathrm{GeV}) & =-0.0227(1)(4) \mathrm{GeV}^{3} \\
& =-(283(2) \mathrm{MeV})^{3}, \tag{38}
\end{align*}
$$

where the second error for each condensate in $\mathrm{GeV}^{3}$ comes from the error in the quark masses.

For the ratio of strange to light condensate we have:

$$
\begin{equation*}
\frac{\langle\bar{s} s\rangle^{\overline{M S}}(2 \mathrm{GeV})}{\langle\bar{l} l\rangle^{\overline{M S}}(2 \mathrm{GeV})}=1.08(16)(1) \tag{39}
\end{equation*}
$$

where the first error comes from $R_{s} / R_{l}$ and has the error budget given in Table $\overline{I V}$ and the second error comes from the strange to light quark mass ratio.

## 3. Approach of $R$ to the chiral limit

The relationship of the light quark condensate to the chiral condensate is also important. $R_{q}$ is defined to have the value 1 from the GMOR relation in the chiral limit but the results of Eq. 36 indicate that it approaches this limit from below as the light quark mass is reduced. Supporting evidence for this is found by studying the quantity $R_{\delta}$ derived from the combination of condensates used by the HOTQCD collaboration in their study of finite temperature QCD [35]. We define $R_{\delta}$ by:

$$
\begin{equation*}
R_{\delta}=\frac{4 m_{l}}{f_{\pi}^{2} M_{\pi}^{2}} \frac{\left\langle\bar{\psi} \psi_{l}\right\rangle-\frac{m_{l}}{m_{s}}\left\langle\bar{\psi} \psi_{s}\right\rangle}{1-\frac{m_{l}}{m_{s}}} \tag{40}
\end{equation*}
$$

The quadratic divergence with lattice spacing cancels between the two condensates because it is linear in the quark mass to all orders in perturbation theory. The non-divergent perturbative contributions proportional to the cube of the quark mass are completely negligible here, from the perturbative analysis in section III A, and so we do not need to include them in making $R_{\delta}$ a physical quantity. $R_{\delta}$ can then simply be calculated from the raw data in Table III

FIG. 7: $R_{\delta}$ as a function of $m_{l} / m_{s}$ at three values of the lattice spacing. Points show the raw lattice results: the crosses are from very coarse lattices (sets 1 and 2 with two values of $m_{s}$ on each and set 3 ), open circles from coarse lattices (sets 4,5 and 6 ) and open triangles from fine sets 7 and 8 . The shaded band gives the results of a simple fit incorporating discretisation and finite volume effects as described in the text.

A plot of $R_{\delta}$ against $m_{l} / m_{s}$ is shown in Fig. 7. In the $m_{l} \rightarrow 0$ limit on an infinite volume $R_{\delta} \rightarrow 1$ as $R_{l}$ does. $R_{\delta}$ can be determined more precisely than $R_{l}$, however, because of the nonperturbative cancellation of the power divergence and it clearly approaches 1 from below. $R_{\delta}$ differs from $R_{l}$ by a term which is proportional to $m_{l} / m_{s}$ and to the difference between $\langle\bar{s} s\rangle$ and $\langle\bar{l} l\rangle$. Both the dependence of $R_{l}$ on $m_{l}$ and the difference between $R_{\delta}$ and $R_{l}$ then contribute to the slope with $m_{l}$ seen in Fig. 7 . We cannot separate them and therefore unambiguously identify the slope of $R_{l}$ with $m_{l}$. We can however use this for a consistency check.

We fit $R_{\delta}$ to the simple form:

$$
\begin{align*}
R_{\delta} & =1.000(1)+c_{1}\left(1+c_{2} a^{2}+c_{3} a^{4}\right) \frac{m_{l}}{m_{s}} \\
& +c_{4}\left(\frac{m_{l}}{m_{s}}\right)^{2}+c_{5} e^{-m_{\pi} L} \tag{41}
\end{align*}
$$

This allows for linear and quadratic terms in $m_{l}$ with discretisation errors. We take priors on $c_{1}, c_{3}$ and $c_{4}$ to be $0.0(1.0)$ and prior on $c_{2}$ to be $0.0(0.3)$ consistent with $\alpha_{s} a^{2}$ behaviours. The final term allows for finite volume effects dependent on the combination $m_{\pi} L$. As for our fit to $R_{l}$, we take the prior on $c_{5}$ to be $0.0(0.2)$ for consistency with Fig. 5

The fit gives $\chi^{2}$ /dof of 0.75 for 10 degrees of freedom and a physical slope, $c_{1}$, of $-0.51(4)$. This value is consistent with the difference between $R_{l}$ and 1 in Eq. 36 , and indeed with the difference between $R_{s}$ and 1. This consistency between the results from $R_{\delta}$ and $R_{l}$ indicates that the difference between $\langle\bar{s} s\rangle$ and $\langle\bar{l} l\rangle$ (which would upset this consistency) cannot be large. This is indeed what we also find in Eq. 39 .

## 4. The chiral susceptibility

A further quantity that is of particular interest in studies of QCD at finite temperature is the chiral susceptibility for a quark of flavor $f$ :

$$
\begin{equation*}
\chi_{f}=\frac{\partial}{\partial m_{f}}\left(-\left\langle\bar{\psi} \psi_{f}\right\rangle\right) . \tag{42}
\end{equation*}
$$

We give results here for the chiral susceptibility for zero temperature QCD to fill out the physical picture of the condensate. From differentiation of the path integral for the condensate it is clear that the chiral susceptibility is given by the flavor-singlet scalar correlator. It is convenient to split this into two contributions which we call $\chi_{q}$ and $\chi_{g}{ }^{1} . \chi_{q}$ comes from two scalar operators connected by quark lines, which is the flavor-nonsinglet scalar meson correlator. $\chi_{g}$ comes from two scalar operators con-

[^306]TABLE V: Contributions to the chiral susceptibility, defined in Eq. (44) for very coarse set 1 and coarse set 4 for light ( $m_{l}=m_{s} / 5$ ) and strange quark masses.

| Set | $m a$ | $a^{2} \chi_{q}$ | $a^{2} \chi_{g}$ |
| :--- | :--- | :--- | :--- |
| 1 | 0.013 | $0.54296(36)$ | $0.045(14)$ |
|  | 0.0688 | $0.45359(6)$ | $0.021(7)$ |
| 3 | 0.01044 | $0.50850(18)$ | $0.032(10)$ |
|  | 0.0522 | $0.46231(3)$ | $0.014(4)$ |

nected only by gluons, in which the disconnected contribution is cancelled.

$$
\begin{align*}
\chi & =\chi_{q}+\chi_{g}  \tag{43}\\
\chi_{q} & =\frac{1}{N_{t}} \sum_{n} \operatorname{Tr}\left[M_{0 n}^{-1} M_{n 0}^{-1}\right] \\
\chi_{g} & =-\frac{1}{N_{t}^{2} V}\left(\left\langle\left(\operatorname{Tr} M^{-1}\right)^{2}\right\rangle-\left\langle\operatorname{Tr} M^{-1}\right\rangle^{2}\right)
\end{align*}
$$

The factors of number of tastes, $N_{t}$, above are specific to naive/staggered quarks.

FIG. 8: Results for the quark-line connected scalar correlator on set 1: $s$ quarks (blue crosses) and light quarks with $m_{l}=$ $m_{s} / 5$ (red bursts). The sum over time of this correlator is $\chi_{q}$. Negative values of the correlator are not plotted on this log scale.
$\chi_{q}$ is readily calculated by generating quark propagators with the same random wall source of noise as that used for the $\pi$ and $\eta_{s}$ mesons, but patterned with phases that are -1 on all odd sites on an even-odd partitioning of the lattice. We then combine one of these propagators with the matching one used in the $\pi / \eta_{s}$ meson, again multiplying the odd sink sites with a phase of -1 . Summing over spatial sites at each time slice gives the flavor-nonsinglet scalar correlator. Examples are shown

FIG. 9: Results for the gluon-connected contribution to the scalar correlator on set 1 for $s$ quarks (blue crosses) and light quarks with $m_{l}=m_{s} / 5$ (red bursts). The sum over time of this correlator is $\chi_{g}$.
in Fig. 8. Summing this correlator over time slices gives $\chi_{q}$. Results for $\chi_{q}$ for light and strange quarks on sets 1 and 4 are given in Table V
$\chi_{g}$ can be estimated from our existing results for the light and strange condensates. Because we have 16 time sources for our propagators we can determine the correlation between $\operatorname{Tr} M^{-1}$ operator that are $n$ time slices apart where $n$ is a multiple of 3 for set 1 and a multiple of 4 for set 4 . This gives a correlation function, for example that shown in Figure $9 . \chi_{g}$ is then the sum over time slices of this correlation function. We can estimate $\chi_{g}$ in several ways. Our central result comes from estimating an effective mass from the early time slices that dominate $\chi_{g}$ and where we have a strong signal. We can then reconstruct an estimated correlation function and sum over it. We can also simply sum over the correlator for the time slices that we have and multiply by 3 or 4 as appropriate. From this range of methods we estimate the error in $\chi_{g}$ as $30 \%$. Values are given in Table V. $\chi_{g}$ is much smaller than $\chi_{q}$.

The quantities that are almost Renormlisation-Group invariant, that we can compare, are $m_{f}^{2} \chi_{f}$ and $m_{f}\left(-\left\langle\bar{\psi} \psi_{f}\right\rangle\right.$. This is done in Figure 10 . Both of these quantities contain the same power divergence (proportional to $m_{f}^{2} a^{-2}$ ) in the lattice spacing. In the susceptibility this divergence largely comes from $\chi_{q}$. The nondivergent perturbative contributions to the two quantities will be different but, as we have seen, they are very small and we ignore them here.

We find that the difference between $m_{f}^{2} \chi_{f}$ and $-m_{f}\left\langle\bar{\psi} \psi_{f}\right\rangle$, also plotted in Figure 10, does not depend on the lattice spacing within errors. We simply average over the results at the two values of the lattice spacing

FIG. 10: Results for $m_{f}^{2} \chi_{f}$ (open circles) compared to $m_{f}\left\langle\bar{\psi} \psi_{f}\right\rangle$ (open triangles) as a function of the square of the inverse lattice spacing, for $s$ quarks (top) and light quarks with $m_{l}=m_{s} / 5$ (lower plot). Results are for sets 1 and 4 . Bursts show the difference of these two quantities.
to obtain physical results for

$$
\begin{equation*}
m_{f}\left(1-m_{f} \frac{\partial}{\partial m_{f}}\right)\left\langle-\bar{\psi} \psi_{f}\right\rangle \tag{44}
\end{equation*}
$$

The values are: $2.18(7) \times 10^{-3} \mathrm{GeV}^{4}$ for $s$ quarks and $3.93(9) \times 10^{-4} \mathrm{GeV}^{4}$ for light quarks with $m_{l}=m_{s} / 5$. Comparison of these numbers with the physical results for $m_{f}\left\langle\bar{\psi} \psi_{f}\right\rangle$ given in Eq. 37$\rangle$ allows us to determine the value and sign of $m_{f}^{2} \chi_{f}$. For $s$ quarks the comparison is straightforward and we find:

$$
\begin{equation*}
m_{s}^{2} \chi_{s}=0.08(35) \times 10^{-3} \mathrm{GeV}^{4} \tag{45}
\end{equation*}
$$

consistent with zero.
To obtain a value for $m_{l}^{2} \chi_{l}$ at $m_{l}=m_{s} / 5$ we need a result for $m_{l}\left\langle\bar{\psi} \psi_{l}\right\rangle$ at this mass. Our fit in Sec. III B 2 gives a result for $R_{l=s / 5}$ of $0.915(26)$. At this value of $m_{l}$ we have $M_{\pi}=315 \mathrm{MeV}$ and can estimate $f_{\pi}=145 \mathrm{MeV}$ from our results in Table II. Then $m_{l=s / 5}\left\langle\bar{\psi} \psi_{l=s / 5}\right\rangle=$ $4.78(20) \times 10^{-4} \mathrm{GeV}^{4}$. In the error we have included an
interpolation error for each of the mass and decay constant of $1 \%$. Then, subtracting the result for the difference of Eq. 44 at $m_{l}=m_{s} / 5$ given above, we have

$$
\begin{equation*}
m_{l=s / 5}^{2} \chi_{l=s / 5}=0.85(22) \times 10^{-4} \mathrm{GeV}^{4} \tag{46}
\end{equation*}
$$

which is a small positive slope.
Our results are then consistent with a slope in $\left\langle\bar{\psi} \psi_{f}\right\rangle$ with $m_{f}$ that is positive at $m_{s} / 5$ but may decrease or even become negative by $m_{s}$. If the slope at $m_{s} / 5$ remained constant for larger $m_{f}$ it would give a total change in $\left\langle\bar{\psi} \psi_{f}\right\rangle$ of $3 \times 10^{-3}$ between $m_{s} / 5$ and $m_{s}$ which is not inconsistent with the change of $1.8(3.8) \times 10^{-3}$ that we find in Eq. 38 .

## IV. DISCUSSION

We have determined a physical value for the strange quark condensate from lattice QCD for the first time. This required both nonperturbative lattice QCD results and a perturbative determination of the power divergent contribution through $\mathcal{O}\left(\alpha_{s}\right)$. The calculation relies on the good chiral properties of staggered quarks to control the form of the power divergence and the numerical speed and small discretisation of the Highly Improved Staggered quark formalism allow very precise results to be obtained at several values of the lattice with light $u / d$ sea quark masses. We proceed by tracking deviations from the GMOR relation, making extensive use of our previous work determining the physical properties of the $\eta_{s}$ meson, to obtain the strange quark condensate. Our best result comes from gluon field configurations that include $u, d, s$ and $c$ quarks in the sea. The condensate is given in the $\overline{M S}$ scheme at a scale of 2 GeV . The evolution equation required to run $m\langle\bar{\psi} \psi\rangle$ to other scales, since it is not RG-invariant, is given in Appendix B. We obtain a very consistent result for the strange quark condensate from independent calculations that include $2+1$ favors of sea quarks, as discussed in Appendix D.

Our value is $-(290(15) \mathrm{MeV})^{3}$ giving a ratio of strange to light condensates of $1.08(16)$. Earlier results come from sum rules of various kinds. These show significant variation and often have no estimate of the error associated with the value. Narison [36] gives a compilation with a final value for the ratio of strange to light condensates in the $\overline{M S}$ scheme at a scale of 2 GeV of $0.75(12)$. A value of $0.74(3)$ is quoted from baryon mass splittings in [11. Finite energy sum rules in the kaon sector give a ratio $0.6(1)$ in [37. More recently Maltman 12 ] uses sum rules for the ratio of decay constants $f_{B_{s}} / f_{B}$ along with the 2007 lattice QCD average for this ratio of $1.21(4)$ [38, 39 to obtain $\langle s \bar{s}\rangle /\langle l \bar{l}\rangle_{\overline{M S}}(2 \mathrm{GeV})=1.2(3)$. This updates an earlier result of $0.8(3)$ from Jamin [28] which used a quenched lattice QCD result for $f_{B_{s}} / f_{B}$ of $1.16(4)$. The current lattice QCD world average for $f_{B_{s}} / f_{B}$ is 1.20(2) 40.

FIG. 11: A comparison of results for the ratio of strange to light condensates in the $\overline{M S}$ scheme at 2 GeV .

Fig. 11 compares our result for the strange to light condensate ratio with the results from sum rules discussed above. Our central value lies between the sum rules results, being in agreement with the larger value of [12] but only in marginal agreement with the lower values of 37]. A value below 0.6 is ruled out by our results at the $3 \sigma$ level. Our value is more accurate than the result derived from $f_{B_{s}} / f_{B}$ and has the advantage over all the sum rules results that it is a direct determination from QCD and has a full error budget (Table IV).

We obtain a very accurate value for the light quark condensate, giving $-(283(2) \mathrm{MeV})^{3}$. We can distinguish the ratio $R_{l}$ at the physical light quark mass from that of 1 in the chiral limit using our results in Eq.( 36 ). Defining $\delta_{\pi}$ from [28]

$$
\begin{equation*}
R_{l}=1-\delta_{\pi} \tag{47}
\end{equation*}
$$

we obtain a value $\delta_{\pi}=0.015(5)$. This is somewhat lower than the value of 0.047 (17) estimated in [28], although in agreement within $2 \sigma$. It is not in agreement with the somewhat larger number of 0.06(1) obtained in 41]. Our result implies a value for the combination $\left(2 L_{8}^{r}-H_{2}^{r}\right)$ of low energy constants from the chiral Lagrangian that is a factor of three lower than that used in [28]. The value is $3 \sigma$ larger than zero, however.

Note that we do not expect the value of the light quark condensate to agree with that of the chiral (zero quark mass) condensate, $\Sigma$. The relationship between them is:

$$
\begin{equation*}
\Sigma(2 \mathrm{GeV})=\frac{-\langle\bar{l} l\rangle(2 \mathrm{GeV})}{R_{l, p h y s}} \frac{f^{2}}{f_{\pi}^{2}} \frac{\left(M^{2} / m\right)_{m=0}}{M_{\pi}^{2} / m_{l, p h y s}} \tag{48}
\end{equation*}
$$

Here $f$ is the decay constant in the zero quark mass limit and $M^{2} / m$ is the ratio of the square of the pion mass to the light quark mass in the same limit. $f_{\pi} / f$ can be
determined from chiral extrapolation of lattice QCD results. For example, a recent accurate calculation [3] gives $f_{\pi} / f=1.0627(28)$ including $2+1$ flavors of sea quarks. A preliminary analysis based on the results given here for $2+1+1$ sea flavors in Table II gives 1.056(1), in acceptable agreement. From the figures in [3] we estimate $\left(M^{2} / m\right)_{m=0} /\left(M_{\pi}^{2} / m_{l, p h y s}\right)$ as 1.02. Combining these factors, along with $R_{l}$, into Eq. 48 makes clear that we expect a $3 \%$ difference between the magnitudes of $\Sigma^{1 / 3}$ and $(\langle\bar{l} l\rangle)^{1 / 3}$, dominated by the effect of $f_{\pi} / f$ (so that $\Sigma$ is smaller). This is entirely consistent, assuming no difference between $2+1$ and $2+1+1$ flavors of sea quarks, with the fact that we obtain $\langle\bar{l} l\rangle(2 \mathrm{GeV})=-(283(2) \mathrm{MeV})^{3}$ and [3] obtain $\Sigma(2 \mathrm{GeV})=(272(2) \mathrm{MeV})^{3}$ from a chiral analysis.

Other methods for determining $\Sigma$ are not as accurate, but in reasonable agreement. We quote here two recent examples. JLQCD/TWQCD give a result of $(234(17) \mathrm{MeV})^{3}$ [42 from the eigenvalue spectrum of overlap quarks with $u, d$ and $s$ quarks in the sea. The ETM collaboration give $(299(38) \mathrm{MeV})^{3}$ [43] from fits to the Landau gauge quark propagator with $u$ and $d$ quarks in the sea. Additional lattice results for $\Sigma$ are collected in 44.

Our analysis has implications for other calculations. For example:

- Finite temperature determinations of the chiral phase transition in QCD use an order parameter based on the light quark condensate. A nonperturbative subtraction is made with the aim of removing the power divergent pieces proportional to $m a$ and with the assumption that the higher order $\left((m a)^{3}\right)$ terms are negligible. For example the HOTQCD collaboration uses an order parameter [35] for visualising the transition (fits to find the transition temperature also include other results) which is the ratio between non-zero and zero temperature of

$$
\begin{equation*}
\langle\bar{\psi} \psi\rangle_{l}-\frac{m_{l}}{m_{s}}\langle\bar{\psi} \psi\rangle_{s} . \tag{49}
\end{equation*}
$$

This quantity becomes

$$
\begin{equation*}
\langle\bar{\psi} \psi\rangle_{l, N P}-\frac{m_{l}}{m_{s}}\langle\bar{\psi} \psi\rangle_{s, N P} \tag{50}
\end{equation*}
$$

if we assume only the presence of a power divergence linear in ma. Our analysis shows that this is a good assumption. For example, the difference between subtracting only terms linear in $m a$ at tree level and including terms cubic in $m a$ is $0.2 \%$ for the strange condensate on the coarsest HOTQCD lattices (i.e. those with largest $m_{s} a$ values). An alternative might be to calculate $(1-m \partial / \partial m)\langle\bar{\psi} \psi\rangle$ as discussed in Sec. IIIB4. The quark-line connected piece of this can be calculated directly by combining the expression for $\chi_{q}$ in Eq. 44 and the expression for $\langle\bar{\psi} \psi\rangle$ in Eq. 10 . The combination
becomes [26]:

$$
\begin{equation*}
\left(1-\frac{\partial}{\partial m}\right)_{\text {conn }}\langle-\bar{\psi} \psi\rangle=2 m \sum_{n \text { even }} \operatorname{Tr}\left|M_{0 n}^{-1}\right|^{2} \tag{51}
\end{equation*}
$$

This can clearly be generalised to a sum over even source sites, implemented with a partial random wall. When combined with the quark-line disconnected piece $\chi_{g}$ this gives a physical quantity without power divergent pieces which is close to the value of the condensate itself.

- The comparison of heavy-light current-current correlators to continuum QCD perturbation theory can be used to normalise heavy-light currents in lattice QCD. The light quark condensate appears in this comparison and the results given here will enable us to improve the analysis in 8. This is underway.
- Some recent papers 45 have speculated that the quark condensate may only be non-zero inside hadrons. A much smaller value outside hadrons would significantly ameliorate the fine tuning problem associated with the cosmological constant. This suggestion appears to be in conflict with direct calculations of quark condensates as vacuum expectation values described here.

## V. CONCLUSIONS

We give the first direct determination of the strange quark condensate from lattice QCD , having demonstrated how to extract a well-defined physical value from lattice results that contain a power divergence as the lattice spacing goes to zero. Our results include a calculation through $\mathcal{O}\left(\alpha_{s}\right)$ in lattice QCD perturbation theory of the perturbative contribution to the condensate, part of which is the power divergence. The calculation relies on the good chiral properties of staggered quarks to control the form of the power divergence and the numerical speed and small discretisation of the Highly Improved Staggered quark formalism to obtain precise results at multiple lattice spacings and light quark masses. Our results include values at physical light quark masses.

We obtain a value for the strange quark condensate in the $\overline{M S}$ scheme at 2 GeV of $-(290(15) \mathrm{MeV})^{3}$. We give a full error budget for this result in Table IV, the main sources of error being those associated with fitting and subtracting the remaining power divergence. The result includes $u, d, s$ and $c$ quarks in the sea but we get good agreement with this value from independent calculations that include $u, d$ and $s$ sea quarks only.

The value we obtain for the corresponding light quark condensate (where $\left.m_{l}=\left(m_{u}+m_{d}\right) / 2\right)$ is $-(283(2) \mathrm{MeV})^{3}$. Note that is significantly different from the value for the condensate in the chiral limit. The ratio of our light quark condensate to a recent lattice QCD
value for the chiral condensate from [3] is $1.13(3)$, consistent with the behaviour of meson masses and decay constants approaching the chiral limit.

We have shown that the ratio of four times the quark mass times condensate divided by the square of the meson mass times decay constant approaches the GMOR value (of 1) from below as $m_{l} \rightarrow 0$. At the physical light quark mass the value is $1.5 \%$ below 1 , and at the strange mass it is $57 \%$ of 1 .

Our result for the ratio of the strange condensate to the light quark condensate is $1.08(16)$. This sits in the middle of the spread of results from QCD sum rules but provides significant additional information because it is a direct determination with a full error budget. The result will have impact on a number of other calculations both in the continuum and in lattice QCD. Some of the numerical techniques used here will be useful for determinations of, for example, the strangeness content of the pion or nucleon.

Acknowledgements We are grateful to Eduardo Follana, Elvira Gamiz, Matthias Jamin, Jack Laiho, Doug Toussaint and Roman Zwicky for useful discussions and to the MILC collaboration for the use of their $2+1+1$ gauge field configurations. The calculations described here were performed on the Darwin supercomputer of the Cambridge High Performance Computing service as part of the DiRAC facility jointly funded by STFC, BIS and the Universities of Cambridge and Glasgow. We are grateful to the Darwin support staff for assistance. Our work is supported by the Royal Society, the Wolfson Foundation, the Science and Technology Facilities Council, the National Science Foundation and the U.S. Department of Energy (under Contract DE-AC02-98CH10886).

## Appendix A: Condensates from correlators

Eq. (11) relates the zero-momentum pseudoscalar propagator to the scalar quark-condensate and is a wellknown relationship [26]. The relationship is true (for the HISQ formalism) even on a single gluon configuration. Here, for completeness, we give a simple derivation, using the equivalent naive quark formalism.

The contribution to the propagator from a single gluon configuration is given by

$$
\begin{equation*}
G_{\mathrm{ps}} \equiv \sum_{x} \operatorname{Tr}\left[\gamma_{5}\left(\frac{1}{D \cdot \gamma+m}\right)_{0 x} \gamma_{5}\left(\frac{1}{D \cdot \gamma+m}\right)_{x 0}\right] \tag{A1}
\end{equation*}
$$

where $D$ is the gauge-covariant derivative, and the trace is over spin and color indices. The contribution to the scalar quark-condensate is given by

$$
\begin{equation*}
S \equiv-\operatorname{Tr}\left(\frac{1}{D \cdot \gamma+m}\right)_{00} \tag{A2}
\end{equation*}
$$

To extract the relationship, we multiply by the unit ma-
trix under the trace in the condensate:

$$
\begin{align*}
S= & -\sum_{x y} \operatorname{Tr}\left[(-D \cdot \gamma+m)_{0 x}\left(\frac{1}{-D \cdot \gamma+m}\right)_{x y} \times\right. \\
& \left.\left(\frac{1}{D \cdot \gamma+m}\right)_{y 0}\right] \\
= & -\sum_{x} \operatorname{Tr}\left[(-D \cdot \gamma+m)_{0 x}\left(\frac{1}{-(D \cdot \gamma)^{2}+m^{2}}\right)_{x 0}\right] \tag{A3}
\end{align*}
$$

Only the $m$ term in the numerator of the last expression survives the spinor trace since the other term results in traces of odd numbers of $\gamma$ matrices (which vanish). Consequently

$$
\begin{align*}
S & =-m \operatorname{Tr}\left(\frac{1}{-(D \cdot \gamma)^{2}+m^{2}}\right)_{00} \\
& =-m \sum_{x} \operatorname{Tr}\left[\left(\frac{1}{-D \cdot \gamma+m}\right)_{0 x}\left(\frac{1}{D \cdot \gamma+m}\right)_{x 0}\right] \\
& =-m \sum_{x} \operatorname{Tr}\left[\gamma_{5}\left(\frac{1}{D \cdot \gamma+m}\right)_{0 x} \gamma_{5} \times\right. \\
& =-m G_{\mathrm{ps}} \\
& \left.\left(\frac{1}{D \cdot \gamma+m}\right)_{x 0}\right] \tag{A4}
\end{align*}
$$

which is Eq. 11). Since this relationship is true configuration-by-configuration, it must be true of the ensemble averages as well.

Note that Eq. A4 leads immediately to the GMOR relation (Eq. (1)). To see this rewrite the pseudoscalar propagator in terms of its mesonic intermediate states. Only the pion contribution survives the $m \rightarrow 0$ limit, since the effective decay constants for excited states all vanish in that limit (by the Ward identity). The pion contribution has an amplitude $a=f_{\pi}^{2} m_{\pi}^{3} /(4 m)$ multiplied by an exponential decay in time, whose integral gives $1 / m_{\pi}$.

The analysis of the propagator above only works for quark actions that have a $\gamma_{\mu}$ piece and a scalar piece (and nothing else), and where those two pieces commute with each other. The commuting is essential if you want

$$
\begin{equation*}
(-D \cdot \gamma+m)(D \cdot \gamma+m)=-(D \cdot \gamma)^{2}+m^{2} \tag{A5}
\end{equation*}
$$

with only terms having an even number of $\gamma_{\mu} \mathrm{s}$ on the right hand side. So this proof does not work for Wilson's lattice discretization of the quark action or similar formulations. On the other hand, it is true of staggered-quark formalisms such as HISQ.

Eq.(11) also follows directly from the (integrated) axial Ward identity:

$$
\begin{array}{r}
\sum_{x}\left\langle\left(m_{a}+m_{b}\right) J_{a b}^{5}(x)\left(m_{a}+m_{b}\right) J_{a b}^{5 \dagger}(0)\right\rangle= \\
-\left\langle\left(m_{a}+m_{b}\right)\left(\overline{\psi_{a}} \psi_{a}+\overline{\psi_{b}} \psi_{b}\right)\right\rangle \tag{A6}
\end{array}
$$

with $J_{a b}^{5} \equiv \overline{\psi_{a}}(x) \gamma_{5} \psi_{b}(x)$. This is exact on the lattice for lattice actions with sufficient chiral symmetry and again shows that is an identity, true configuration by configuration and for any $m_{a}$ and $m_{b}$. See [46] for a derivation using twisted mass quarks.

Here we have used the cases $m_{a}=m_{b}$ and both equal to either $m_{l}$ or $m_{s}$ but we can derive from Eq. (A6) a relationship [26] between correlators for the mixed Goldstone pseudoscalar made of light and strange quarks and the 'diagonal' cases:

$$
\begin{align*}
\left(a m_{l}+a m_{s}\right) \sum_{t} C_{K}(t) & =\left(a m_{l}\right) \sum_{t} C_{\pi}(t) \\
& +\left(a m_{s}\right) \sum_{t} C_{\eta_{s}}(t) \tag{A7}
\end{align*}
$$

The left-hand side is then related to the sum of quark masses multiplied by the sum of quark condensates. This does not add new information so we do not make use of this relationship except as a test of our correlators.

## Appendix B: Condensates and the OPE

Condensates typically arise in the non-leading terms of operator-product expansions (OPE). To illustrate, consider moments of two pseudoscalar densities composed of a heavy quark (mass $M$ ) and a light quark (mass $m \ll$ $M)$ where the heavy quark fields are contracted with each other:

$$
\begin{equation*}
(m+M)^{2} \int d \mathbf{x} d t t^{n} J_{5}(\mathbf{x}, t) J_{5}(0) \rightarrow \mathcal{O}^{(n)} \tag{B1}
\end{equation*}
$$

where

$$
\begin{equation*}
\mathcal{O}^{(n)} \equiv \int d \mathbf{x} d t t^{n} \bar{\psi}(\mathbf{x}, t) \gamma_{5} \frac{(m+M)^{2}}{D \cdot \gamma+M} \gamma_{5} \psi(0) \tag{B2}
\end{equation*}
$$

and $\psi$ is the light-quark field. Lattice simulations of $\langle 0| \mathcal{O}^{(n)}|0\rangle$ can be used to determine the heavy quark's mass 47. The $(m+M)^{2}$ factor makes $\mathcal{O}^{(n)}$ independent of the ultraviolet regulator provided $n \geq 4$; that is, lattice and continuum calculations should agree in the limit of zero lattice spacing.

Operator $\mathcal{O}^{(n)}$ is also short-distance, dominated by length scales of order $1 / M$, provided the heavy-quark is sufficiently heavy and the light quarks have momenta small compared with $M$. Consequently the OPE implies that $\mathcal{O}^{(n)}$ can be expressed in terms of a set of local operators in an effective theory, with cutoff scale $\Lambda<M$, and coefficient functions that depend only upon physics between scales $\Lambda$ and $M$ :

$$
\begin{align*}
\bar{M}^{n-4} \mathcal{O}^{(n)} & =\mathbf{1}^{(\Lambda)} c\left(\Lambda / \bar{M}, \bar{\alpha}_{s}, \bar{m} / \bar{M}\right) \\
& +\frac{(m \bar{\psi} \psi)^{(\Lambda)}}{\bar{m} \bar{M}^{3}} d\left(\Lambda / \bar{M}, \bar{\alpha}_{s}, \bar{m} / \bar{M}\right)  \tag{B3}\\
& +\cdots .
\end{align*}
$$

where $\mathbf{1}^{(\Lambda)}$ is the unit operator and we have replaced $\bar{\psi} \psi$ by $m \bar{\psi} \psi$, to simplify the coefficient function. Somewhat arbitrarily, we have chosen to express the right-hand side in terms of masses and couplings at scale $\mu=M(\mu) \equiv \bar{M}$ :

$$
\begin{equation*}
\bar{M} \equiv M(\bar{M}), \quad \bar{m} \equiv m(\bar{M}), \quad \bar{\alpha}_{s} \equiv \alpha_{s}(\bar{M}) \tag{B4}
\end{equation*}
$$

The effective theory on the right-hand side of Eq. (B3) could be, for example, lattice QCD with a lattice spacing $a=\pi / \Lambda$, or QCD with an $\overline{\mathrm{MS}}$ regulator and $\mu=\Lambda$.

The coefficient functions $c$ and $d$ are perturbative when $M$ is large, and analytic in $\bar{\alpha}_{s}$ and $\bar{m} / \bar{M}^{2}$. They can be computed using perturbative matching. For example, we can examine matrix elements of Eq. (B3) between low-energy, on-shell light-quark states $\langle q|$ and $\left|q^{\prime}\right\rangle$. The unit operator drops out and Eq. (B3) can be rearranged to give

$$
\begin{equation*}
d\left(\Lambda / \bar{M}, \bar{\alpha}_{s}, \bar{m} / \bar{M}\right)=\left(\frac{\bar{m} \bar{M}^{n-1}\langle q| \mathcal{O}^{(n)}\left|q^{\prime}\right\rangle}{\langle q| m \bar{\psi} \psi\left|q^{\prime}\right\rangle^{(\Lambda)}}\right)_{\mathrm{PQCD}} \tag{B5}
\end{equation*}
$$

where the right-hand side is computed order-by-order in perturbation theory. Since $\langle q| M \bar{\psi} \psi\left|q^{\prime}\right\rangle$ is independent of $\Lambda, d$ is actually regulator independent:

$$
\begin{equation*}
d=d\left(\bar{\alpha}_{s}, \bar{m} / \bar{M}\right) \tag{B6}
\end{equation*}
$$

Knowing $d$, one would then compute $c$ using perturbative expansions of the vacuum expectation values:

$$
\begin{align*}
& c\left(\Lambda / \bar{M}, \bar{\alpha}_{s}, \bar{m} / \bar{M}\right)= \\
& \quad\left(\frac{\langle 0| \mathcal{O}^{(n)}|0\rangle}{\bar{M}^{4-n}}-\frac{\langle 0| m \bar{\psi} \psi|0\rangle^{(\Lambda)}}{\bar{m} \bar{M}^{3}} d\left(\bar{\alpha}_{s}, \bar{m} / \bar{M}\right)\right)_{\mathrm{PQCD}} \tag{B7}
\end{align*}
$$

Eq. (B7) underscores the importance of avoiding normal-ordered operators in operator-product expansions. Each term on the right-hand side has infrared sensitive contributions that go like $m^{3} \log (m)$. These cancel between the two terms in Eq. (B7), order-by-order in perturbation theory; but this cancelation would have been ruined had we replaced $\bar{\psi} \psi$ by the normal-ordered product : $\bar{\psi} \psi$ : in Eq. B3 (and $c$ would no longer be perturbative).

It is also important to note that $\langle 0| m \bar{\psi} \psi|0\rangle^{(\Lambda)}$ is not cutoff independent, because of operator mixing with the unit operator $m^{4} \mathbf{1}$, which implies that

$$
\begin{equation*}
\frac{d\langle 0| m \bar{\psi} \psi|0\rangle^{(\Lambda)}}{d \log \Lambda}=\gamma_{\text {mix }}\left(\alpha_{s}(\Lambda), m(\Lambda) / \Lambda\right) m^{4}(\Lambda) \tag{B8}
\end{equation*}
$$

where

$$
\begin{equation*}
\gamma_{\mathrm{mix}}\left(\alpha_{s}\right)=\frac{3}{2 \pi^{2}}+O\left(\alpha_{s}\right) \tag{B9}
\end{equation*}
$$

[^307]depends upon the regulator scheme beyond tree-level. This evolution is typically negligible for light quarks because of the $m^{4}$ factor.

## Appendix C: $\overline{\mathrm{MS}}$ condensates from the lattice

The coefficient functions in operator-product expansions such as Eq. ( B 3 ) are most conveniently computed using the $\overline{\mathrm{MS}}$ regulator to define the operators on the right-hand side. On the other hand, the only technology available for determining the nonperturbative matrix elements needed in such analyses is lattice simulation, using the lattice ultraviolet regulator. To combine these techniques we must be able to convert lattice determinations of $\langle 0| m \bar{\psi} \psi|0\rangle$, for example, into the equivalent $\overline{\mathrm{MS}}$ matrix elements.

The relationship is again given by the operator product expansion:

$$
\begin{align*}
(m \bar{\psi} \psi) \frac{(\mu)}{\mathrm{MS}}= & \mathbf{1}^{(a)} \frac{m^{2}}{a^{2}} f(\mu \leftrightarrow \pi / a) \\
& +(m \bar{\psi} \psi)_{\mathrm{LQCD}}^{(a)} h(\mu \leftrightarrow \pi / a)+\cdots \tag{C1}
\end{align*}
$$

where the coefficient functions $f$ and $h$ can only depend upon physics between $\mu$ and the lattice cutoff $\pi / a$. In fact $h=1$ since the matrix elements in

$$
\begin{equation*}
h=\frac{\langle q| m \bar{\psi} \psi\left|q^{\prime}\right\rangle \frac{(\mu)}{\mathrm{MS}}}{\langle q| m \bar{\psi} \psi\left|q^{\prime}\right\rangle_{\mathrm{LQCD}}^{(a)}}=1 \tag{C2}
\end{equation*}
$$

are $\mu$ and $a$ independent, and therefore $h$ must be a number (and 1 is the correct number, from perturbation theory). The coefficient function $f$ is computed order-byorder in perturbation theory using the expansions of the two condensates (computed with their respective regulators):

$$
\begin{align*}
f \equiv & \frac{a^{2}}{m^{2}}\left(\langle 0| m \bar{\psi} \psi|0\rangle \frac{(\mu)}{\mathrm{MS}}-\langle 0| m \bar{\psi} \psi|0\rangle_{\mathrm{LQCD}}^{(a)}\right)_{\mathrm{PQCD}} \\
= & \sum_{n=0} f_{n}^{(0)}(a \mu) \alpha_{\overline{\mathrm{MS}}}^{n}(\mu) \\
& +(a m)^{2} \sum_{n=0} f_{n}^{(1)}(a \mu) \alpha_{\overline{\mathrm{MS}}}^{n}(\mu) \tag{C3}
\end{align*}
$$

The cancellation of all $\log m$ terms between the two matrix elements in $f$ is something of a miracle; it only works if the $m$ in each case is precisely the $m$ that multiplies $\bar{\psi} \psi$ in the action for that case ${ }^{3} . \Delta_{P T}$ in eq. $(21)$ is $(a m)^{2} f$ calculated through $\mathcal{O}\left(\alpha_{s}\right)$.

Additional terms appear in Eq. C1 from mixing with higher dimension condensates, such as the gluon condensate. These are suppressed by positive powers of $a$. For

[^308]the gluon condensate the multiplier is $(m a)^{2}$ from chirality arguments. These terms then simply look like discretisation errors in $m \bar{\psi} \psi$ and are handed as part of the general treatment of those errors.

## Appendix D: Lattice QCD calculation on $n_{f}=2+1$ gluon configurations

We show here further results for the strange quark condensate from two contrasting calculations, both using HISQ quarks, that include $u, d$ and $s$ quarks in the sea, but no $c$ quarks. The first calculation uses sets of MILC configurations corresponding to 5 values of lattice spacing spanning a large range from 0.15 fm to 0.04 fm [48] and using the asqtad formalism for the sea quarks. The second uses HOTQCD configurations [35] and has more lattice spacing values ( 24 in total) but with only a limited number (9) having accompanying meson masses and decay constants. The sea quarks are included using the HISQ formalism with $u / d$ sea quark masses close to the physical value. The second calculation corresponds to the zero temperature results generated to accompany a finite temperature analysis of the phase structure of QCD. This analysis needs many values of the lattice spacing for a fine-grained temperature scale, and the zero temperature results are needed to fix the QCD parameters. The quark condensate is an important order parameter at finite temperature but is also determined in [35] on the zero temperature ensembles.

For the first calculation we use values of the strange quark condensate listed in Table VI. These are obtained from studies of the $\eta_{s}$ correlator on 9 different ensembles at 5 different values of the lattice spacing and multiple sea quark mass values. The lattice spacing values we use here are defined from the $\eta_{s}$ decay constant and are determined in 48. From the values in Table VI we can construct the ratio $R_{s}$ defined in Eq. (24) and fit it as a function of lattice spacing in exactly the same way as that described in section III B 2. The $\mathcal{O}\left(\alpha_{s}^{0}\right)$ and $\mathcal{O}\left(\alpha_{s}^{1}\right)$ perturbative subtractions defined in section III A apply here also since no effects appear at this order from the differing number of sea quarks or the formalism used for them or the improvement coefficients in the gluon action (the MILC $2+1$ asqtad configurations do not include the $n_{f} \alpha_{s} a^{2}$ improvement coefficients in the gluon action). These effects will cause differences in the perturbation theory at $\mathcal{O}\left(\alpha_{s}^{2}\right)$. The $\alpha_{s}^{2}$ and higher order divergent pieces of the condensate are included in the fit with coefficients that, as before, are given a prior value of $0(4)$. The appropriate $\alpha_{s}$ value in this case is $\alpha_{V}^{n_{f}=3}(2 / a)$ rather than $\alpha_{V}^{n_{f}=4}(2 / a)$. Multiple valence $s$ quark masses are given at each lattice spacing and we allow for linear and quadratic dependence on the mistuning of the $s$ quark mass, again as described in section III B 2. We allow for mistuning of the sea quark masses through use of the parameter $\delta x_{\text {sea }}$ 49].

FIG. 12: Results from fitting the values for $R_{s}$ obtained on MILC configurations including $2+1$ flavors of asqtad sea quarks, as described in the text. The crosses give the calculated values after perturbative subtraction through $\mathcal{O}\left(\alpha_{s}\right)$. The hatched band corresponds to the fitted physical value after removing the remaining power divergence and discretisation and sea quark mass effects. Compare to Fig. 6 which includes $2+1+1$ flavors of HISQ sea quarks.

Figure 12 shows, as a hatched band, the physical result from the fit, which has $\chi^{2} /$ dof $=0.4$ for 20 degrees of freedom. For comparison the data points given are the values after perturbative subtraction through $\mathcal{O}\left(\alpha_{s}\right)$. The physical value obtained is

$$
\begin{equation*}
R_{s, p h y s}=0.555(84) \tag{D1}
\end{equation*}
$$

This is completely consistent with the result from $2+1+1$ flavors of HISQ sea quarks in section IIIB 2, and has a similar error. It is not such a complete calculation, lacking light quark mass results and not having such light sea quark masses, and is therefore not our preferred final result. It provides a strong check of our $2+1+1$ result, however, being a completely independent set of numbers. The fits to the $2+1$ results give very similar behaviour to that seen for the $2+1+1$ case, for example choosing a coefficient of the $\alpha_{s}^{2} / a^{2}$ divergence of around 2 .

For the second calculation we use values of the strange condensate from the HOTQCD collaboration [35]. They generated ensembles with an improved gluon action and $u / d$ and $s$ quarks in the sea using the HISQ formalism. The QCD action differs slightly from that in section III. Apart from missing $c$ quarks in the sea, the gauge field configurations here are improved through $\mathcal{O}\left(a^{2}\right)$ at treelevel and without tadpole-improvement, i.e. the fairly substantial $\mathcal{O}\left(\alpha_{s} a^{2}\right)$ improvement coefficients were not included. The lattice spacing was determined using the $r_{1}$ heavy quark potential parameter, or $r_{0}$ on the coarsest lattices where $r_{1} / a<2$. The $s$ quark mass was tuned by determining the mass of the $\eta_{s}$ meson and the light

TABLE VI: Raw (unsubtracted) values for the strange quark condensate along with $\eta_{s}$ masses and decay constants in lattice units calculated for valence masses given in column 4. The calculations use valence HISQ quarks on MILC configuration sets labelled in column 1 that include $2+1$ flavors of asqtad quarks (see 48 for more details about the ensembles). The results are derived from the correlators calculated in [48] and 49] along with Eq.(11), but we also give results for additional strange quark masses on sets 1 and $2 . \delta x_{\text {sea }}$ is the mismatch between the sea $2 m_{l}+m_{s}$ value and the physical result divided by the physical value of $m_{s}$ 49].

quark mass was taken as $m_{s} / 20$ (with some values available for $m_{s} / 5$ but we have not used those). Results for the zero temperature strange condensate are available at 24 values of the lattice spacing from 0.2 fm to 0.07 fm (Table 14 of 35 ] gives values for two times the condensate). Note that these results were obtained by direct calculation of $\left\langle\operatorname{Tr} M^{-1}\right\rangle$ using stochastic techniques. Corresponding values of the lattice spacing are given in Table 16 of [35]; some missing values can be inferred from the tables of temperature values at the corresponding value of $\beta$.

Figure 13 shows the raw unsubtracted results for $m_{s}\left\langle\bar{\psi} \psi_{s}\right\rangle$ as a function of the square of the inverse lattice spacing, as well as the values after making the complete subtraction through $\mathcal{O}\left(\alpha_{s}\right)$ as given in Eq. 21). As for $R_{s}$ in section III B 1 (Fig. 4), the unsubtracted results show clear evidence of a quadratic term in $a^{-1}$ which is significantly reduced, but not completely absent, after the perturbative subtraction.

For a subset of 9 lattice spacing values meson masses and decay constants are also given in Tables 18 and 19 of 35. In fact we use the 7 finest values only because the $s$ quark mass is not as well-tuned for our purposes on the coarsest two lattices. Note that the decay constant values need to be multiplied by $\sqrt{2}$ to match the convention used here. For these we can construct the ratio $R_{s}$ given in 24 . To obtain a physical result for $R_{s}$ we fit the subtracted

FIG. 13: Bursts give the raw data for $m_{s}\left\langle\bar{\psi} \psi_{s}\right\rangle$ from 35 as a function of the square of the inverse lattice spacing. Open circles give results after subtraction of the $\mathcal{O}\left(\alpha_{s}\right)$ perturbative contribution.
results as a function of lattice spacing in the same way as in section III B 2, apart from the use of $\alpha_{V}^{n_{f}=3}(2 / a)$ rather than $\alpha_{V}^{n_{f}=4}(2 / a)$.

The physical value for $R_{s}$ obtained from the fit is

$$
\begin{equation*}
R_{s}=0.79(34) \tag{D2}
\end{equation*}
$$

This is much less accurate than the result from section III, but agrees both with that and the result from
the MILC $2+1$ asqtad ensembles given earlier in this section. We have not extracted a light quark condensate from the HOTQCD results because finite volume sensitivity obscures the power divergence and leads to larger errors.

We conclude from this that there is no sign of disagreeement between the strange quark condensate extracted with $u, d$ and $s$ quarks in the sea and those including also $c$ quarks in the sea.

[^13]:    ${ }^{1}$ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point. The $z$-axis is along the beam pipe, the $x$-axis points to the centre of the LHC ring and the $y$-axis points upward. Cylindrical coordinates ( $r, \phi$ ) are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity $\eta$ is defined as $\eta=-\ln [\tan (\theta / 2)]$ where $\theta$ is the polar angle.

[^14]:    2 The limits presented in this study for $m_{H}>200 \mathrm{GeV}$ assume cross sections based on on-shell Higgs boson production and decay and use MC generators with an ad hoc Breit-Wigner Higgs line shape. Recently potentially important effects related to off-shell Higgs boson production and interference effects between the Higgs boson signal and backgrounds have been discussed $[17,45]$. The inclusion of such effects may affect limits at high Higgs masses ( $m_{H}>400 \mathrm{GeV}$ ).

[^15]:    4 © CERN for the benefit of the ATLAS Collaboration.

    * E-mail address: atlas.publications@cern.ch.

    1 ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the $z$-axis along the beam pipe. The $x$-axis points from the IP to the centre of the LHC ring, and the $y$-axis points upward. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

[^16]:    2 See footnote 1.

[^42]:    ${ }^{2}$ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the

[^43]:    $z$-axis coinciding with the axis of the beam pipe. The $x$-axis points from the IP to the centre of the LHC ring, and the $y$-axis points upward. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

[^44]:    ${ }^{3}$ When two errors are quoted the first is statistical and the second systematic.

[^45]:    ${ }^{4}$ In this channel the jet $p_{\text {T }}$ threshold is raised from 25 GeV to 30 GeV .

[^46]:    ${ }^{1}$ In the following, charged Higgs bosons are denoted $H^{+}$, with the charge-conjugate $H^{-}$always implied. Hence, $\tau$ denotes a positively charged $\tau$ lepton.

[^47]:    ${ }^{2}$ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the $z$-axis along the beam pipe. The $x$-axis points from the IP to the centre of the LHC ring, and the $y$-axis points upwards. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

[^48]:    ${ }^{3} \Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}$, where $\Delta \eta$ is the difference in pseudorapidity of the two objects in question, and $\Delta \phi$ is the difference between their azimuthal angles.

[^49]:    ${ }^{4}$ The electron trigger threshold was increased from 20 GeV to 22 GeV towards the end of data-taking in 2011.

[^50]:    ${ }^{1}$ Corresponding author.

[^51]:    ${ }^{1}$ Corresponding author.

[^52]:    * Corresponding author. E-mail address: jabramovit@smu.edu.

[^53]:    ${ }^{1} w_{\eta^{2}}$ is defined as $\sqrt{\frac{\sum E_{i} \eta_{i}^{2}}{\sum E_{i}}-\left(\frac{\sum E_{i} \eta_{i}}{\sum E_{i}}\right)^{2}}$, where the sums are computed using all the cells $i$ of the cluster ( $E_{i}$ is the energy released in the cell and $\eta_{i}$ its pseudorapidity).

[^54]:    ${ }^{2}$ This uncertainty is mainly due to uncertainties in the transport of the electromagnetic scale determined in the test-beams to the ATLAS detector. For the electromagnetic calorimeter this uncertainty will be much reduced when a sufficient number of $Z$ bosons decaying to electrons is available.

[^55]:    ${ }^{1}$ The ATLAS Coordinate System is a right-handed system with the $x$-axis pointing to the centre of the LHC ring, the $z$-axis following the beam direction and the $y$-axis pointing upwards. The pseudorapidity $\eta$ is an approximation for rapidity $y$ in the high energy limit, and it is related to the polar angle $\theta$ as $\eta=-\ln \tan \frac{\theta}{2}$.

[^56]:    ${ }^{2}$ This additional calibration has been applied to the electromagnetic barrel, electromagnetic endcap and to the full forward calorimeter.

[^57]:    ${ }^{3}$ The truth isolation cut on the average jet response has a negligible impact on the average jet response.

[^58]:    ${ }^{4}$ Time-dependent noise changes for single cells in data are accounted for using regular measurements.

[^59]:    ${ }^{1}$ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the $z$-axis along the beam pipe. The $x$-axis points from the IP to the centre of the LHC ring, and the $y$ axis points upward. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

[^60]:    ${ }^{1}$ Hereafter the charged Higgs bosons will be denoted $H^{+}$, with the charge-conjugate processes implied.

[^61]:    ${ }^{2} \Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}$, where $\eta$ is the pseudorapidity and $\phi$ the azimuthal angle.

[^62]:    ${ }^{1}$ ATLAS uses a right-handed coordinate system originated at the nominal interaction point. The z -axis is along the beam pipe, the $x$-axis points to the centre of the LHC ring and the $y$-axis points upward. Cylindrical coordinates ( $\mathrm{r}, \phi$ ) are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity $\eta$ is defined as $\eta=-\ln [\tan (\theta / 2)]$ where $\theta$ is the polar angle.

[^63]:    ${ }^{2}$ The limits presented in this search assume cross sections based on on-shell Higgs boson production and decay and use MC generators with an ad-hoc Breit-Wigner Higgs line shape. Recently potentially important effects related to off-shell Higgs boson production and interference effects between the Higgs boson signal and backgrounds have been discussed [17,48]. The inclusion of such effect may affect limits at very high Higgs masses ( $m_{H}>400 \mathrm{GeV}$ ).

[^64]:    ${ }^{1}$ Hereafter the charged Higgs bosons will be denoted $H^{+}$, with the charge-conjugate $H^{-}$always implied.

[^65]:    ${ }^{2} \Delta R=\sqrt{(\Delta \eta)^{2}+(\Delta \phi)^{2}}$, where $\Delta \eta$ is the difference in pseudorapitidy of the two objects in question, and $\Delta \phi$ the difference of their azimuthal angles.

[^66]:    ${ }^{1}$ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the z -axis along the beam pipe. The x -axis points from the IP to the center of the LHC ring, and the y axis points upward. Cylindrical coordinates $(\mathrm{R}, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta=-\ln \tan (\theta / 2)$.

[^67]:    ${ }^{1}$ The kinematic acceptance of this search has not been optimized for low mass Higgs bosons.
    ${ }^{2}$ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point. The $z$-axis is along the beam pipe, the $x$-axis points to the centre of the LHC ring and the $y$-axis points upward. Cylindrical coordinates ( $\mathrm{r}, \phi$ ) are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity $\eta$ is defined as $\eta=-\ln [\tan (\theta / 2)]$ where $\theta$ is the polar angle.

[^68]:    ${ }^{1}$ ATLAS uses a right-handed coordinate system with the $z$-axis along the beam pipe. The $x$-axis points to the center of the LHC ring, and the $y$ axis points upward. [^80]:    ${ }^{1}$ The details of this definition are outlined in Refs. [16,17]. While we focus on $F_{2}$, we can consider other observables such as $\left\{F_{1}, F_{3}, d \sigma\right\}$ in a similar manner.

[^81]:    ${ }^{2}$ Note that the Ucor5 fit improves the average $\chi^{2} / p t$ at the expense of an increased $\chi^{2} / p t$ for particular data sets; this reflects the tension (and the different number of data points) between the $\ell^{ \pm} A$ and $\nu A$ data sets.
    ${ }^{3}$ For $x<0.4, \mathrm{NuTeV}$ is compatible with both CCFR and CDHSW data; for larger $x, \mathrm{NuTeV}$ agrees with CDHSW, and the difference with CCFR has been reconciled.

[^82]:    *Presented by Fred Olness

[^83]:    ${ }^{2}$ While the nuclear PDFs can be finite for $x>1$, the magnitude of the PDFs in this region is negligible for the purposes of the present study (cf., Refs. [6, 7, 8, 9, 10]).

[^84]:    ${ }^{3}$ Cf. the Durham HEP Databases for a complete listing: http://www-spires.dur.ac.uk/hepdata/

[^85]:    ${ }^{4}$ We do retain the deuteron data as this has only a small correction over the central $x$-range [3, 1]. The deuteron correction has been applied in the Base-1 fit. Also, for the Drell-Yan Cu data (E605), the expected nuclear corrections in this kinematic range are small (a few percent) compared to the overall normalization uncertainty ( $15 \%$ ) and systematic error ( $10 \%$ ).
    ${ }^{5}$ These PDFs have been determined from a fit to the same data set as in the CTEQ6 analysis with the addition of the the NuTeV dimuon data. The changes to the strange sea induce only minor changes to the other fit parameters; this has a minimal effect on the particular observables ( $d \sigma$, $F_{2}$ ) we examine in the present study.

[^86]:    ${ }^{6}$ While iron is roughly isoscalar, other nuclear PDFs can exhibit larger differences between the $u$ and $d$ distributions-the extreme case being the free-proton PDF. When comparing PDFs we must keep in mind that it is ultimately the structure functions which are the physical observables.
    ${ }^{7}$ In a recent publication, Eskola et al. [10] perform a global reanalysis of their ESK98 [9] nuclear PDFs. While we do not present a comparison here, the results are compatible with those distributions displayed in Fig. 1; a comparison can be found in Figs. 10 and 11 of Ref. [10].

[^87]:    ${ }^{8}$ The corresponding anti-neutrino process is obtained with a $u \leftrightarrow d$ interchange.
    ${ }^{9}$ Note that our comparison with the Kulagin-Petti model is based on the work in Ref. [28].

[^88]:    ${ }^{10}$ In particular, we will find for large $x(\gtrsim 0.5)$ and $Q$ comparable to the proton mass the target mass corrections for $F_{2}^{\mathrm{Fe}} / F_{2}^{\mathrm{D}}$ are essential for reproducing the features of the data; hence the $Q$ dependence plays a fundamental role.

[^89]:    ${ }^{11}$ In Ref. [39], Brodsky and collaborators posit a nonuniversal nuclear anti-shadowing mechanism which yields different effects for CC and NC scattering.

[^91]:    ${ }^{1}$ Technically, the heavy-target data were scaled to a deuteron target, and then isospin symmetry relations were used to obtain the corresponding proton data. Deuteron corrections were used in certain cases.

[^92]:    ${ }^{2}$ The nuclear analogue of the scaling variable $x$ is defined as $x:=A x_{A}$, where $x_{A}=Q^{2} / 2 P_{A} \cdot q$ is the usual Bjorken variable formed out of the four-momenta of the nucleus $\left(P_{A}\right)$ and the exchanged boson $(q)$, with $Q^{2}=-q^{2}$ [33].

[^93]:    ${ }^{3}$ For example, see the CTEQ (Coordinated TheoreticalExperimental Project on QCD) analysis of Ref. [34] which presents the CTEQ6 PDF sets.

[^94]:    ${ }^{4}$ While Ref. [33] extracted the nuclear PDFs using only the NuTeV neutrino-iron DIS data, Ref. [30] demonstrated that the Chorus neutrino-lead DIS data [52] was consistent with the NuTeV data set.

[^95]:    ${ }^{5}$ While it is straightforward to obtain a "fit" to the combined neutrino and charged-lepton DIS data sets, determining the appropriate weights of the various sets and discerning whether this compromise fit is within the allowable uncertainty range of the data is a more involved task. This work is presently ongoing.

[^96]:    ${ }^{1}$ Presented by F. Olness.

[^97]:    ${ }^{2}$ The nuclear PDFs are available on the web from the nCTEQ page at http://projects.hepforge.org/ncteq/ which is hosted by the HepForge project.

[^98]:    ${ }^{3}$ Cf., ZEUS-prel-09-015

[^99]:    ${ }^{4}$ Specifically, the $\chi$-prescription rescales the partonic momentum fraction via $x \rightarrow x\left(1+\left(2 m_{c} / Q\right)^{2}\right)$ in contrast to the traditional Barnett [29] "slow-rescaling" which is $x \rightarrow x\left(1+\left(m_{c} / Q\right)^{2}\right)$.

[^105]:    ${ }^{1}$ The one exception is the CCFR $F_{2}$ which is mildly sensitive to the strange quark PDF via Eq. (1).

[^106]:    ${ }^{2}$ In Eq. (5), $X$ is the observable, $S_{i}^{ \pm}$are the error PDF sets for eigenvalue $i$, and $N_{p}$ is the number of eigenvalues. For CTEQ6.5 $N_{p}=20$, and for CTEQ6.6 $N_{p}=22$.

[^107]:    ${ }^{3}$ Here, we are more interested in the general span of these different PDFs rather than the specific sets and values. For reference, reading from the top to bottom (at $y=0$ ) in Fig. 9(c) left ( $W^{-}$), the specific curves are ABKM09 [22] (gray), MSTW2008 [20] (magenta), HERAPDF10 [72] (orange), CT10 [70] (purple), CTEQ6.5 [71] (black), NNPDF [69] (blue), MRST2004 [73] (red), CTEQ6.1 [18] (green).

[^108]:    ${ }^{4}$ We follow the methodology and notation of Ref. [27]. See this reference for details.

[^109]:    *Presented by Fred Olness

[^110]:    ${ }^{2}$ While we have given a heuristic description of this result (in which we used some illustrative approximations), we emphasize the proof applies to all cases and does not require any such approximations.

[^111]:    ${ }^{3}$ Specifically, ACOT was used for CTEQ6HQ, and S-ACOT- $\chi$ was used in CTEQ6.5 and CTEQ6.6.

[^112]:    ${ }^{4}$ Here, we define the order of the calculation according to the power of $\alpha_{S}$; thus LO is $\alpha_{s}^{0}$, NLO is $\alpha_{s}^{1}$, etc.

[^113]:    ${ }^{5}$ Note, in Figure 7 and in the discussion the diagrams an processes are schematic and illustrative. For example, at NLO we include both $\gamma Q \rightarrow Q g$ and $\gamma g \rightarrow Q \bar{Q}$ as well as all the corresponding subtractions. For details see Refs. [ $22,24]$.

[^114]:    ${ }^{6}$ Recall $\alpha_{S}(\mu)$ is also an unphysical theoretical construct; this has discontinuities across flavor-thresholds at order $\alpha_{s}^{3}$.

[^115]:    ${ }^{7}$ The matching conditions are determined entirely by the DGLAP evolution kernels up to a constant term which must be computed. At NLO, the constant term is zero such that the PDFs are continuous; at NNLO, this term is non-zero.

[^116]:    ${ }^{1}$ Contributed by: J. Fleischer, T. Riemann, V. Yundin
    ${ }^{2}$ An extended description of notations and of the formalism may be found in [105, 106, 107, 108]. The normalization of PJFry follows that chosen in the scalar library. For QCDLoop, $C(\epsilon)=\Gamma(1-2 \epsilon) /\left[\Gamma(1+\epsilon) \Gamma^{2}(1-\epsilon)\right]$.

[^117]:    ${ }^{3}$ One has to carefully control accuracies; e.g. the on-shell conditions for massless particles have to be fulfilled with a numerical precision expected by the scalar functions library in use; for QCDLoop this means on default at least 10 digits.

[^126]:    ${ }^{12}$ There has been a calculation of neutral current electroproduction of heavy quarks $\mathcal{O}\left(\alpha_{s}^{2}\right)$ in the FFNS [326]. however, extra contributions are still required for a VFNS calculation 327.
    ${ }^{13}$ See Ref. [328] and references therein.
    ${ }^{14}$ Details will be presented in a forthcoming publication.
    ${ }^{15}$ Of course, once the massive higher order Wilson coefficients have been computed, it is straightforward to incorporate these results into our calculations.

[^127]:    ${ }^{16}$ Contributed by: A. Denner, S. Dittmaier, S. Kallweit, S. Pozzorini, M. Schulze

[^128]:    ${ }^{17}$ Recent progress in the theoretical description of top-quark pair production at hadron colliders is reviewed in Refs. [332, 333, 334.
    ${ }^{18}$ We note that in the present study the factor $\Gamma_{\mathrm{t}, \mathrm{NLO}}^{-2}$ in 78 is not expanded as $\left(\Gamma_{\mathrm{t}, \mathrm{LO}}+\Gamma_{\mathrm{t}}^{1}\right)^{-2}=\Gamma_{\mathrm{t}, \mathrm{LO}}^{-2}\left(1-2 \Gamma_{\mathrm{t}}^{1} / \Gamma_{\mathrm{t}, \mathrm{LO}}\right)$, like in Eq. (6) of Ref. [336], since this procedure is not directly applicable to the full WWb̄ calculation.

[^129]:    ${ }^{19}$ To be more precise, in Ref. [25] the scale dependence was assessed using a fixed $\Gamma_{\mathrm{t}}$ input, while here we take into account the $\mu$-dependence of $\Gamma_{\mathrm{t}, \mathrm{NLO}}$, which results into slightly different $\sigma_{\mathrm{WWb} \overline{\mathrm{b}}}$ variations at NLO.

[^130]:    ${ }^{20}$ Note that the $M_{\mathrm{e}+\mathrm{b}}$ distribution in Ref. [25] was defined by selecting (based on the Monte Carlo truth) jets that involve negatively charged b-quarks, such that the $\mathrm{e}^{+}$b pairs are consistent with top-quark decays.

[^131]:    ${ }^{21}$ Contributed by: J. J. Lopez-Villarejo, P. Skands

[^132]:    ${ }^{22}$ We take $\hat{p}_{\perp}$ to be the smallest $p_{\perp}$ scale among all the color-connected partons in the parent configuration, i.e., a global measure of the "current" $p_{\perp}$ scale of that topology. This makes the shower a true Markov chain (i.e., history-independent) which has beneficial consequences for matching to matrix elements [349].

[^133]:    ${ }^{23}$ Contributed by: Iain W. Stewart, Frank J. Tackmann

[^134]:    ${ }^{24}$ We thank Fabian Stöckli for collaboration on this NNLL+NNLO reweighting analysis for $p_{T}^{\text {cut }}$.

    ${ }^{27}$ The validation of MadLoop and MadFKS in the context of hadronic collisions has been presented in Ref. [8].

[^137]:    ${ }^{28}$ Such an excess has so far failed to be confirmed by a very similar D0 analysis [407].

[^138]:    ${ }^{29}$ Contributed by: S. Alioli, J. R. Andersen, C. Oleari, E. Re, J. M. Smillie

[^139]:    ${ }^{30}$ Contributed by: J. R.‘Andersen, J. Huston, D. Maître, S. Sapeta, G. P. Salam, J. M. Smillie, J. Winter

[^140]:    ${ }^{31}$ SpartyJet [434] is a set of software tools for jet finding and analysis, built around the FastJet library of jet algorithms 435]. SpartyJet provides four key extensions to FastJet: a simple Python interface to most FastJet features, a powerful framework for building up modular analyses, extensive input file handling capabilities, and a graphical browser for viewing analysis output and creating new on-the-fly analyses.

[^141]:    ${ }^{32}$ Strictly speaking, the events destined for the $W+n$-jet sample were clustered with the $k_{T}$ algorithm with a very small separation, $R=0.03$, and accepted when at least $n$ small- $R$ jets were above the generation cut. These events were then passed through the standard analysis cuts (with or without LoopSim).

[^142]:    ${ }^{33}$ In this study, the same jet definition (anti- $k_{T}$ with $R=0.4$ ) was used for both establishing the separation of the fixed jet-multiplicity contributions and evaluating the cuts and observables.

[^143]:    ${ }^{34}$ Contributed by: J. R. Andersen, D. Maître, J. M. Smillie, J. Winter

[^144]:    ${ }^{35}$ Given the definition of $H_{T}$, we note $H_{T, 2}=p_{T, j_{1}}+p_{T, j_{2}}+p_{T, e}+p_{T, \nu}$.
    ${ }^{36}$ In this study we used the same jet algorithm for both defining the partitioning in jet multiplicities as well as applying cuts and determining observables.

[^145]:    ${ }^{37}$ Contributed by: S. Alioli, J. R. Andersen, V. Ciulli, F. Cossutti, T. Hapola, H. Hoeth, F. Krauss, P. Lenzi, L. Lönnblad, G. Luisoni, D. Maître, C. Oleari, S. Prestel, E. Re, T. Reiter, M. Schönherr, J. Smillie, F. Tramontano, J. Winter, K. Zapp

[^146]:    ${ }^{38}$ An extra veto may be required at this stage, due to the different definitions of the transverse momentum used in the Powheg Box - either for initial or final state radiation - and in PYthia8.

[^147]:    ${ }^{39}$ Particularly for high jet multiplicities, it could be imagined that phase space integrators have difficulties to fully sample the phase space, especially close to kinematic limits. By full phase space, we mean the region that the phase space generator actually filled.

[^148]:    ${ }^{40}$ For the sake of compactness, merging scale variation plots for Tune A2 could not be included here. We hope the reader is

[^149]:    nevertheless willing to consider the following argument - which is only supported by the omitted results.

[^150]:    ${ }^{41}$ This is the default choice in PYTHIA8. Other choices are available to the user.

[^151]:    ${ }^{42}$ Assuming the lepton and the jet to be back-to-back, $\Delta \phi=\pi$, one still needs $\Delta \eta \approx 4$ to obtain $(\Delta R)^{2}=(\Delta \phi)^{2}+$ $(\Delta \eta)^{2} \approx 5^{2}$.

[^152]:    ${ }^{43}$ Contributed by:N. Chanon, S. Gascon-Shotkin, J. P. Guillet, J. Huston, E. Pilon, M. Schwoerer, M. Stockton, M. Tripiana

[^153]:    ${ }^{44}$ Whether the $E_{T j}^{i s o}$ take fixed values or are functions of the photon's transverse momentum does not matter here.

[^154]:    ${ }^{45}$ The logarithmic behaviour holds in when $M_{F} \gg \Lambda_{Q C D}$. In the non-perturbative regime instead no logarithm is expected to develop and one expects rather a power-suppressed behaviour; see ref. [479] for more details.

[^155]:    ${ }^{46}$ Indeed for $E_{0}=0$ the original Frixione prescription is restored.

[^156]:    ${ }^{47}$ Fragmentation scale options depending only on the $p_{T}$ of the photon from fragmentation are not available because Diphox

[^157]:    ${ }^{48}$ Photon radiation directly by a gluon is of course not physically possible; the representation as such in PYTHIA is a technical shortcut for the actual physical process

[^158]:    ${ }^{49}$ Contributed by: M. Cacciari, G. P. Salam and G. Soyez

[^159]:    ${ }^{50}$ This can be defined for the 4-momentum of the jet but we shall only discuss its transverse momentum for simplicity.
    ${ }^{51}$ For the $k_{t}$ or Cambridge/Aachen algorithms, it is usually negative and can be of the order of a GeV .

[^160]:    ${ }^{52}$ This option will only be considered in the case where jets are used as patches.
    ${ }^{53}$ The same technique should also work for the azimuthal-angle dependence of the underlying-event in heavy-ion collisions.

[^161]:    ${ }^{54}$ One may argue whether or not one should subtract the jets in the hard event. We decided to do so to cover the case where the hard event contains Underlying Event which, as a relatively uniform background, will also be subtracted together with the pileup.
    ${ }^{55}$ Note that we have used the ghost placement of FastJet 3 which differs slightly from the one in v2.4.

[^162]:    ${ }^{56}$ This is a bit optimistic but does not affect in any way our discussion.

[^163]:    ${ }^{57}$ Note that the clustering of the main event still needs to include the computation of jet areas since they are needed in Eq. 20.2.2.

[^164]:    ${ }^{58}$ Contributed by: A. Buckley, G. Hesketh, H. Hoeth, F. Krauss, E. Nurse, S. Plätzer, H. Schulz

[^178]:    ${ }^{1}$ Similar considerations also hold for target mass corrections (TMC) and higher twist terms. We focus here mainly on the kinematic region $x<0.1$ where TMC are small [1]. An inclusion of higher twist terms is beyond the scope of this study.

[^179]:    ${ }^{2} \mathrm{An}$ updated analysis of the H 1 measurements extending down to even lower $Q^{2}$ values has been published in Ref. [3], and a combined analysis with ZEUS is in progress.

[^180]:    ${ }^{3}$ At NLO, there are corresponding quark-initiated terms; for simplicity we do not display them here, but they are fully contained in our calculations [6].

[^181]:    ${ }^{4}$ In this subsection we will distinguish $\mu$ and $Q$; in the following, we will set $\mu=Q$ and display the results as a function of $Q$.
    ${ }^{5}$ If we were to compute this process in the $\overline{\mathrm{MS}}$ scheme, the $\ln \left(m^{2} / Q^{2}\right)$ in the SUB term would simply be replaced by a $1 / \varepsilon$ pole which would cancel the corresponding singularity in the NLO contribution.

[^182]:    ${ }^{6}$ It is possible to define other massive schemes that could include additional matching parameters or extra observabledependent contributions. For example, the calculation of $F_{2}^{c}$ in the original RT scheme [7] included extra higher-order contributions that do not vanish as $Q / m \rightarrow \infty$.

[^183]:    ${ }^{7}$ If the beam has nonzero charm-flavor quantum number, such as a $D$-meson, this argument would be incorrect. Technically, $\chi$ scaling violates factorization as we are presuming the mass of the beam fragments; if we perform a thought experiment with a beam of $D$-mesons, charm quark need not be associated with an anticharm quark.
    ${ }^{8}$ We sketch the relevant kinematics in Appendix A.

[^184]:    ${ }^{9}$ Note that the finite mass terms $\left(m^{2} / Q^{2}\right)^{n}$ in $\hat{\sigma}(m)$ receive contributions from both, masses in the heavy quark propagators and masses in the phase space. Still we refer to them as dynamic mass terms and show that they are numerically less important than the mass terms in the slow-rescaling variable $\chi(n)$ which are of purely kinematic origin.

[^185]:    ${ }^{10}$ In Sec. II A 2 we demonstrated that the ACOT calculation reduces to the ZM-VFNS result in the massless limit. We will address the choice of the $\chi(n)$ rescaling in Sec. III A.

[^186]:    ${ }^{11}$ Fractional decomposition of "initial-state" structure functions is understood as $F_{2, L}^{i}=\sum_{j=1}^{6} F_{2, L}^{i j}$.

[^187]:    ${ }^{12}$ Because we use the fully massive ACOT scheme to LO and NLO, the LO result in Fig. 14(b) contains the ( $\mathrm{m}^{2} / Q^{2}$ ) helicityviolating contributions $\sim \mathcal{O}\left(\alpha_{s}^{0}\right)$; hence, it is nonzero. In the S-ACOT scheme, the LO result for $F_{L}$ vanishes, but the NLO result is comparable to the NLO ACOT result.

[^188]:    ${ }^{13}$ Note that in our decomposition, diagrams with a bottom quark in the initial or final state, contribute to the bottom structure function, even in the presence of a charm quark.

[^189]:    ${ }^{14}$ At present, the full set of matching conditions and DGLAP kernels have not been computed at $\mathrm{N}^{3} \mathrm{LO}$.

[^190]:    ${ }^{15}$ Note, we will focus on the gluon-initiated terms, but the demonstration for the quark-initiated pieces is analogous.

[^191]:    ${ }^{16}$ The explicit form of the ACOT subtraction is defined in Sec. IV C [cf. Eq. (36)] of Ref. [5]. For an example of the cancellation between $\sigma_{\mathrm{LO}}$ and $\sigma_{\mathrm{SUB}}$ in a more general context, see Ref. [42].

[^192]:    ${ }^{1}$ Contributed by: J. Fleischer, T. Riemann, V. Yundin
    ${ }^{2}$ An extended description of notations and of the formalism may be found in [105, 106, 107, 108]. The normalization of PJFry follows that chosen in the scalar library. For QCDLoop, $C(\epsilon)=\Gamma(1-2 \epsilon) /\left[\Gamma(1+\epsilon) \Gamma^{2}(1-\epsilon)\right]$.

[^193]:    ${ }^{3}$ One has to carefully control accuracies; e.g. the on-shell conditions for massless particles have to be fulfilled with a numerical precision expected by the scalar functions library in use; for QCDLoop this means on default at least 10 digits.

[^202]:    ${ }^{12}$ There has been a calculation of neutral current electroproduction of heavy quarks $\mathcal{O}\left(\alpha_{s}^{2}\right)$ in the FFNS [326]. however, extra contributions are still required for a VFNS calculation 327.
    ${ }^{13}$ See Ref. [328] and references therein.
    ${ }^{14}$ Details will be presented in a forthcoming publication.
    ${ }^{15}$ Of course, once the massive higher order Wilson coefficients have been computed, it is straightforward to incorporate these results into our calculations.

[^203]:    ${ }^{16}$ Contributed by: A. Denner, S. Dittmaier, S. Kallweit, S. Pozzorini, M. Schulze

[^204]:    ${ }^{17}$ Recent progress in the theoretical description of top-quark pair production at hadron colliders is reviewed in Refs. [332, 333, 334.
    ${ }^{18}$ We note that in the present study the factor $\Gamma_{\mathrm{t}, \mathrm{NLO}}^{-2}$ in 78 is not expanded as $\left(\Gamma_{\mathrm{t}, \mathrm{LO}}+\Gamma_{\mathrm{t}}^{1}\right)^{-2}=\Gamma_{\mathrm{t}, \mathrm{LO}}^{-2}\left(1-2 \Gamma_{\mathrm{t}}^{1} / \Gamma_{\mathrm{t}, \mathrm{LO}}\right)$, like in Eq. (6) of Ref. [336], since this procedure is not directly applicable to the full WWb̄ calculation.

[^205]:    ${ }^{19}$ To be more precise, in Ref. [25] the scale dependence was assessed using a fixed $\Gamma_{\mathrm{t}}$ input, while here we take into account the $\mu$-dependence of $\Gamma_{\mathrm{t}, \mathrm{NLO}}$, which results into slightly different $\sigma_{\mathrm{WWb} \overline{\mathrm{b}}}$ variations at NLO.

[^206]:    ${ }^{20}$ Note that the $M_{\mathrm{e}+\mathrm{b}}$ distribution in Ref. [25] was defined by selecting (based on the Monte Carlo truth) jets that involve negatively charged b-quarks, such that the $\mathrm{e}^{+}$b pairs are consistent with top-quark decays.

[^207]:    ${ }^{21}$ Contributed by: J. J. Lopez-Villarejo, P. Skands

[^208]:    ${ }^{22}$ We take $\hat{p}_{\perp}$ to be the smallest $p_{\perp}$ scale among all the color-connected partons in the parent configuration, i.e., a global measure of the "current" $p_{\perp}$ scale of that topology. This makes the shower a true Markov chain (i.e., history-independent) which has beneficial consequences for matching to matrix elements [349].

[^216]:    ${ }^{31}$ SpartyJet [434] is a set of software tools for jet finding and analysis, built around the FastJet library of jet algorithms 435]. SpartyJet provides four key extensions to FastJet: a simple Python interface to most FastJet features, a powerful framework for building up modular analyses, extensive input file handling capabilities, and a graphical browser for viewing analysis output and creating new on-the-fly analyses.

[^217]:    ${ }^{32}$ Strictly speaking, the events destined for the $W+n$-jet sample were clustered with the $k_{T}$ algorithm with a very small separation, $R=0.03$, and accepted when at least $n$ small- $R$ jets were above the generation cut. These events were then passed through the standard analysis cuts (with or without LoopSim).

[^218]:    ${ }^{33}$ In this study, the same jet definition (anti- $k_{T}$ with $R=0.4$ ) was used for both establishing the separation of the fixed jet-multiplicity contributions and evaluating the cuts and observables.

[^219]:    ${ }^{34}$ Contributed by: J. R. Andersen, D. Maître, J. M. Smillie, J. Winter

[^220]:    ${ }^{35}$ Given the definition of $H_{T}$, we note $H_{T, 2}=p_{T, j_{1}}+p_{T, j_{2}}+p_{T, e}+p_{T, \nu}$.
    ${ }^{36}$ In this study we used the same jet algorithm for both defining the partitioning in jet multiplicities as well as applying cuts and determining observables.

[^221]:    ${ }^{37}$ Contributed by: S. Alioli, J. R. Andersen, V. Ciulli, F. Cossutti, T. Hapola, H. Hoeth, F. Krauss, P. Lenzi, L. Lönnblad, G. Luisoni, D. Maître, C. Oleari, S. Prestel, E. Re, T. Reiter, M. Schönherr, J. Smillie, F. Tramontano, J. Winter, K. Zapp

[^222]:    ${ }^{38}$ An extra veto may be required at this stage, due to the different definitions of the transverse momentum used in the Powheg Box - either for initial or final state radiation - and in PYthia8.

[^223]:    ${ }^{39}$ Particularly for high jet multiplicities, it could be imagined that phase space integrators have difficulties to fully sample the phase space, especially close to kinematic limits. By full phase space, we mean the region that the phase space generator actually filled.

[^224]:    ${ }^{40}$ For the sake of compactness, merging scale variation plots for Tune A2 could not be included here. We hope the reader is

[^225]:    nevertheless willing to consider the following argument - which is only supported by the omitted results.

[^226]:    ${ }^{41}$ This is the default choice in PYTHIA8. Other choices are available to the user.

[^227]:    ${ }^{42}$ Assuming the lepton and the jet to be back-to-back, $\Delta \phi=\pi$, one still needs $\Delta \eta \approx 4$ to obtain $(\Delta R)^{2}=(\Delta \phi)^{2}+$ $(\Delta \eta)^{2} \approx 5^{2}$.

[^228]:    ${ }^{43}$ Contributed by:N. Chanon, S. Gascon-Shotkin, J. P. Guillet, J. Huston, E. Pilon, M. Schwoerer, M. Stockton, M. Tripiana

[^229]:    ${ }^{44}$ Whether the $E_{T j}^{i s o}$ take fixed values or are functions of the photon's transverse momentum does not matter here.

[^230]:    ${ }^{45}$ The logarithmic behaviour holds in when $M_{F} \gg \Lambda_{Q C D}$. In the non-perturbative regime instead no logarithm is expected to develop and one expects rather a power-suppressed behaviour; see ref. [479] for more details.

[^231]:    ${ }^{46}$ Indeed for $E_{0}=0$ the original Frixione prescription is restored.

[^232]:    ${ }^{47}$ Fragmentation scale options depending only on the $p_{T}$ of the photon from fragmentation are not available because Diphox

[^233]:    ${ }^{48}$ Photon radiation directly by a gluon is of course not physically possible; the representation as such in PYTHIA is a technical shortcut for the actual physical process

[^234]:    ${ }^{49}$ Contributed by: M. Cacciari, G. P. Salam and G. Soyez

[^235]:    ${ }^{50}$ This can be defined for the 4-momentum of the jet but we shall only discuss its transverse momentum for simplicity.
    ${ }^{51}$ For the $k_{t}$ or Cambridge/Aachen algorithms, it is usually negative and can be of the order of a GeV .

[^236]:    ${ }^{52}$ This option will only be considered in the case where jets are used as patches.
    ${ }^{53}$ The same technique should also work for the azimuthal-angle dependence of the underlying-event in heavy-ion collisions.

[^237]:    ${ }^{54}$ One may argue whether or not one should subtract the jets in the hard event. We decided to do so to cover the case where the hard event contains Underlying Event which, as a relatively uniform background, will also be subtracted together with the pileup.
    ${ }^{55}$ Note that we have used the ghost placement of FastJet 3 which differs slightly from the one in v2.4.

[^238]:    ${ }^{56}$ This is a bit optimistic but does not affect in any way our discussion.

[^239]:    ${ }^{57}$ Note that the clustering of the main event still needs to include the computation of jet areas since they are needed in Eq. 20.2.2.

[^240]:    ${ }^{58}$ Contributed by: A. Buckley, G. Hesketh, H. Hoeth, F. Krauss, E. Nurse, S. Plätzer, H. Schulz

[^241]:    ${ }^{59}$ Contributed by: A. Buckley, L. Garren, G. Hesketh, H. Hoeth, L. Lönnblad, E. Nurse, S. Plätzer, G. Salam, G. Soyez

[^242]:    ${ }^{60}$ One could also reconstruct the mass given energy and momentum, but this typically gives large precision problems for small masses.

[^243]:    ${ }^{1}$ Recently, a paper by Paukkunen and Salgado [20] discussed that weak boson production at the LHC might be useful in order to constrain nPDFs.
    ${ }^{2}$ Note that the EPS08/EPS09 $[14,15]$ global analyses include single-inclusive $\pi^{0}$ data from the PHENIX experiment at RHIC.
    ${ }^{3}$ A recent paper by Betemps and Machado [27] has performed a calculation for $\gamma+c$ production using however the target rest frame formalism.

[^244]:    ${ }^{4}$ We do not distinguish between heavy-quark and heavy-anti-quark in the final state, that is the sum of $\gamma+Q$ and $\gamma+\bar{Q}$ is considered; therefore here by $q Q \rightarrow q Q \gamma$ we choose to denote the sum of $q Q \rightarrow q Q \gamma$, $q \bar{Q} \rightarrow q \bar{Q} \gamma, \bar{q} Q \rightarrow \bar{q} Q \gamma$ and $\bar{q} \bar{Q} \rightarrow \bar{q} \bar{Q} \gamma$.
    ${ }^{5}$ In $p p$ and $p A$ collisions, however, the Compton subprocess largely dominates the annihilation process from the dominance of the gluon distribution over that of sea-quarks.

[^245]:    ${ }^{6}$ Note that the nDS 04 PDFs [12] are not considered here since these are obtained in a 3-fixed flavor number scheme (no charm PDF) whereas our calculation is in a variable flavor number scheme.
    ${ }^{7}$ More precisely, EPS09 is linked to the CTEQ6.1M proton PDFs [34], HKN07 to the MRST98 [35] set, and the nCTEQ PDFs to the reference PDFs described in ref. [36] which are very similar to the CTEQ6.1M distribution functions [34]. This reference set excludes most of the nuclear data used in the PDF global fit, and therefore is not biased by any nuclear corrections.

[^246]:    ${ }^{8}$ As discussed earlier, EPS08/EPS09 also include inclusive $\pi^{0}$ data from the PHENIX experiment at RHIC, with a strong weight in order to better determine the nuclear gluon distribution.
    ${ }^{9}$ Note also that at lower scales the uncertainties of the nPDFs are even more pronounced.
    ${ }^{10}$ The corresponding sets of nPDFs are available upon request from the authors.

[^247]:    ${ }^{11}$ Note that in Mellin moment $N$-space the relation $c^{p / A}(N, Q) / c^{p}(N, Q) \simeq g^{p / A}(N, Q) / g^{p}(N, Q)$ holds approximately for $Q \sim Q_{0}$.

[^248]:    ${ }^{12}$ This back-to-back kinematics matches the LO case and constrains the transverse momentum of the third particle to be zero.

[^249]:    ${ }^{13}$ We have verified that similar results and conclusions are obtained when using either ATLAS or CMS acceptances at central rapidities.

[^250]:    ${ }^{1}$ While bottom squarks ( $\tilde{b}$ ) can be relatively light in some models [33], their contribution to DIS and other relevant cross sections can be neglected, cf. Ref. [23].

[^251]:    ${ }^{2} \mathrm{We}$ use $m_{c}=1.3 \mathrm{GeV}$ and $m_{b}=4.5 \mathrm{GeV}$. The up, down, and strange quark masses $\left\{m_{u}, m_{d}, m_{s}\right\}$ do not play a role in the evolution, as they are less than the initial evolution scale $Q_{0}=$ 1.3 GeV .

[^252]:    ${ }^{3}$ This value, compatible with the current world average, is about $1 \sigma$ below $\alpha_{s}\left(M_{Z}\right)=0.123 \pm 0.004$; hence, the SM fit with this $\alpha_{s}\left(M_{Z}\right)$ value has a higher $\chi_{\text {tot }}^{2}$ (in the last line of the upper table) than a fit with a floating $\alpha_{s}\left(M_{Z}\right)$ (in the last line of the lower table).

[^253]:    ${ }^{4}$ The extent of plausible systematic shifts is determined by matrices of correlated systematic errors, provided by both Tevatron collaborations and implemented in the CT09 [44] and CT10 analyses [25].

[^254]:    ${ }^{1}$ The NNLO contributions produce marginal modifications compared to the NNLL-NLO result included in the CT10 analysis. We examined these contributions by redoing the calculation for $A_{\ell}\left(y_{\ell}\right)$ after adding the exact $\alpha_{s}^{2}$ correction for $W$ bosons produced with non-zero transverse momentum, which captures a large part of the full NNLO effect. The changes were found to be small and inconsequential in the current fit.

[^255]:    *olness@smu.edu
    ${ }^{\dagger}$ soper@uoregon.edu

[^256]:    ${ }^{1}$ Specifically, we use the program of Ref. [1], although there are other programs that can give the same results. The code is available at http://zebu.uoregon.edu/~soper/EKSJets/jet.html

[^257]:    ${ }^{2}$ Specifically, in this figure we use the functions $f_{1}\left(P_{T}\right)=0.1$, $f_{2}\left(P_{T}\right)=0.08 \log \left(P_{T} / M\right)$, and $f_{3}\left(P_{T}\right)=0.06\left\{\left[\log \left(P_{T} / M\right)\right]^{2}-\right.$ $0.1\}$ where $M=150 \mathrm{GeV}$. These curves are for illustrative purposes only, and the $f_{J}\left(P_{T}\right)$ functions differ from the set $f_{J}\left(P_{T}, y\right)$ we will use to parametrize the correlated systematic uncertainties.

[^258]:    ${ }^{3}$ We shall use $\mathcal{E}_{\text {scale }}$ to denote the theoretical systematic error due to scale dependence only, and $\mathcal{E}$ (no subscript) to denote the total theoretical systematic error.

[^259]:    ${ }^{4}$ We scale $P_{T}$ by $M(y)$ to make the argument of the logarithms dimensionless. This quantity provides a simple scaling, and roughly corresponds to scaling by the maximum $P_{T}, P_{T}^{\max } \sim$ $\sqrt{s} /(2 \cosh (y))$, for large $y$.

[^260]:    ${ }^{5} \mathrm{We}$ do not present curves for $y=1$ and $y=2$ because these curves show a rise of the correction as $P_{T}$ decreases from 200 GeV , even though decreasing $P_{T}$ puts us farther from the threshold. This rise is more pronounced for large $y$ than we see for $y=0$ in Fig. 6. We suspect that this behavior is an artifact of kinematic choices in the algorithm for summing threshold logarithms, rather than being a real physical effect.

[^261]:    ${ }^{6}$ Cf., Eq. (5.9) of Dasgupta et al. in Ref. [5]

[^262]:    ${ }^{0}$ This work is based on lectures presented a the CTEQ Summer Schools on QCD Analysis and Phenomenology. http://www.cteq.org
    ${ }^{1}$ See Ref. [4] and also the webpage citation for the 1999 Nobel Prize in Physics at: http://nobelprize.org/
    ${ }^{2}$ Note, for chiral symmetries there are some subtle difficulties that must be handled carefully. In particular, the properties of the parity operator are dependent on the dimensionality of spacetime.

[^263]:    ${ }^{3}$ In Sec. V we will use dimensional analysis to demonstrate that we must introduce an auxiliary length scale $L$ in addition to the regulator $\epsilon$. For other interesting applications of scaling and dimensional analysis $c f$. Refs. [7, [8]

[^264]:    ${ }^{4}$ We will use MKS units here so that our results reduce to the usual undergraduate textbook expressions.

[^265]:    ${ }^{5}$ For simplicity, we will calculate the potential at the mid-point of the wire; the general case is more complicated algebraically, but yields the same result in the $L \rightarrow \infty$ limit.

[^266]:    ${ }^{6}$ Since the factor $\lambda /\left(4 \pi \epsilon_{0}\right)$ has units of potential, the integral must be dimensionless. Also note we have changed the integration limits from $[-\infty,+\infty]$ to $[0,+\infty]$, and the compensating factor of 2 cancels the factor of 2 in $d \Omega_{n} / 2$.

[^267]:    ${ }^{7}$ For an excellent pedagogical analysis of the renormalization group equation $c f$. Ref. [g].

[^268]:    ${ }^{8}$ The reader is invited to verify that the computation of the electric field $\vec{E}(x)$ in a consistent renormalization scheme yields the previous results of Eq. (17).
    ${ }^{9}$ Cf., Ref. 10], Eq. (46) and Eq. (47).

[^269]:    10 Note, for the special case $\mathrm{D}=2$ the potential $V(r)$ has a logarithmic form; see Table II for details.

[^270]:    ${ }^{1}$ The proton beams at IP2 are transversely polarized but due to rapid spin flips they can be spin balanced to get unpolarized protons.

[^271]:    ${ }^{1}$ We note that the measurement of $J / \Psi$ photoproduction at HERA [589, 620 strongly favors an exponential $t$ dependence at $|t|$ below $1 \mathrm{GeV}^{2}$, but the behavior of exclusive hard scattering cross sections at larger $t$ is poorly known. For a conservative error estimate, we do not want to rule out a dipole behavior at $|t|>1 \mathrm{GeV}^{2}$.

[^272]:    ${ }^{2}$ VGG refers to a computer code originally written by M. Vanderhaeghen, P. Guichon, and M. Guidal. To our best knowledge, the code for DVCS presently used by experimentalists employs a model that adopts Radyushkin's DD ansatz 574.

[^273]:    ${ }^{3}$ These energies and luminosities correspond to those given as medium-energy collider design prior to the INT 10-3 program, e.g., $\sqrt{s}=31.0 \mathrm{GeV}$.

[^274]:    ${ }^{4}$ The energies have been chosen to correspond to the preliminary values of the medium and high energy collider designs as given prior to the INT 10-3 program.

[^275]:    ${ }^{1}$ There is a additional term, corresponding to the cubic Casimir; which is parametrically suppressed for large nuclei [772]. This term generates Odderon excitations in the JIMWLK/BK evolution [773, 774].

[^276]:    ${ }^{2}$ Exclusive observables may also be expressed in terms of solutions of the same Yang-Mills equations, but with more complicated boundary conditions than for inclusive observables.

[^277]:    ${ }^{3}$ More precisely, in the QCD case, that asymptotic behavior in rapidity is reached from any initial condition compatible with perturbative QCD in the UV.

[^278]:    ${ }^{4}$ The calculation of $b_{0}, b_{-1 / 6}$ and $b_{-1 / 3}$ has been performed recently in 868 .

[^279]:    ${ }^{5}$ Note that the normalization of the $J / \Psi$ wavefunction in 600 is erroneously reported as a factor of 100 smaller than the correct value; one can readily see this by comparing with the normalization condition defined in 600 a a with the results reported in 823. It is surprising that this error was not noted in 823, in which the results found in [823] are explicitly compared to those in 600 .

[^280]:    ${ }^{6}$ fig. 8 in 885 also shows that the incoherent process quickly dominates the coherent one as a function of $t$, although we note that there was an error in the calculation of the figure and that the curves plotted do not correspond to the equations in the text of the paper.

[^281]:    ${ }^{7}$ We shall take $m_{f}=0.14 \mathrm{GeV}$, the value used when extracting the dipole cross section from $F_{2}$ data.
    ${ }^{8}$ To compare with the HERA data, we take $\epsilon=0.98$.

[^282]:    ${ }^{9}$ Small-x partons do not contribute significantly to the momentum sum rule and a precise matching to the parton distributions at large $x$ and low $Q^{2}$ is lacking.

[^283]:    ${ }^{1}$ Reference 1226 focused on a lower integrated luminosity and a larger cross section.
    ${ }^{2}$ Reference 1226 used only the current $\tau \rightarrow e \gamma$ limit.

[^284]:    ${ }^{3}$ The contribution of the vector leptoquarks is less clear, for reasons explored in 1226, so we restrict our discussion to the scalar LQs.

[^285]:    ${ }^{4}$ We limit our discussion here to the scenario of "minimal field content" described in 1236 .

[^286]:    ${ }^{5}$ The Bjorken scattering variable is given by $y=Q^{2} / s_{e p} x=1 / 2(1-\cos \hat{\theta})$ where $\hat{\theta}$ is the decay polar angle of the lepton relative to the incident proton in the center-of-mass frame.

[^287]:    ${ }^{6}$ See section 6.3 .2 for a description of the notation. This leptoquark's interactions are given by the Lagrangian terms $\lambda \bar{d}_{R} \ell_{L} \tilde{S}_{1 / 2}^{L}+$ h.c. Also note that this leptoquark evades limits from $\tau \rightarrow e \gamma$ as explained in section 6.3.2

[^288]:    ${ }^{1}$ There is no accelerator problem with using lower energy electron beams.. According to statements from EIC physicists, using electron energies below 5 GeV would not contribute significantly to the physics goals.

[^289]:    ${ }^{2}$ http://conferences.jlab.org/eic2010

[^290]:    ${ }^{1}$ Specifically, there were 1333 DIS data points used out of the 1925 total. 84

[^291]:    ${ }^{2}$ The CCFR arrangement used two C-shaped sections with a horizontal crack at the center to allow placement of hall probes for field calibration. This crack would be eliminated in NuSOnG and instead small slots could be included for this purpose.

[^292]:    ${ }^{\text {a }}$ This "internally self-consistent analysis technique" ${ }^{2}$ was employed by the NuTeV experiment. For NuTeV, however, the statistics were limited and some external data were also used as input.

[^293]:    ${ }^{\mathrm{b}}$ For a recent review of nuclear shadowing see, e.g. Ref. 23.

[^294]:    ${ }^{\text {c }}$ The proposal for the MINER $\nu \mathrm{A}$ experiment is presented in Ref. 32, and the experiment webpage is located at: http://minerva.fnal.gov/.

[^295]:    ${ }^{\mathrm{d}}$ If we work at NLO, $f_{c}\left(x, \mu=m_{c}\right)$ should be strictly greater than or equal to zero; at NNLO and beyond the boundary conditions yield a negative PDF of order $\sim \alpha_{s}^{2}$.

[^301]:    1 This point has frequently been overlooked in lattice QCD calculations.

[^302]:    ${ }^{2}$ This would now amount to 2.9 MeV given that the average experimental width of the $\eta_{c}$ has increased to 30 MeV [7].

[^303]:    ${ }^{3}$ This method is often called 'nonperturbative' in the lattice QCD literature.

[^304]:    ${ }^{4}$ For a meson containing an NRQCD quark the energy obtained from the 2-point and 3-point fits is not its mass. However that is irrelevant here since it cancels.

[^306]:    ${ }^{1}$ In 35 these are called $\chi_{\text {conn }}$ and $\chi_{d i s c}$.

[^307]:    ${ }^{2}$ We are ignoring nonperturbative short-distance physics (for example, small instantons) which can contribute to coefficient functions but is typically nonleading.

[^308]:    ${ }^{3}$ If this isn't the case, then coefficient function $h$ will not equal one, but rather will be a series in $\alpha_{\overline{\mathrm{MS}}}$.
